The amino acid variability in HVR and NS5B was evaluated from cDNA-derived sequences. The occurrence of HVR quasispecies influences the therapeutic outcome; because no strains isolated from non-responder patients showed close pairing, it is possible that some other factors may be responsible for the persistence of infection. However, the possibility of resistant strains can not be denied. The NS5B sequences of non-responder strains were on the same branch, showing the possibility of resistant strain infection in these patients. However, adaptive mutations in NS5B lead to persistence of infection and a severe course of liver disease in patients. These findings reveal that the occurrence of HVR quasispecies, including the presence of resistant strains, is a major factor influencing the therapeutic outcome and disease severity in chronic hepatitis C patients. Genetic variability was not uniformly distributed throughout the HCV genome.

In conclusion, viral quasispecies heterogeneity can be an important marker to predict the response of combination therapy in patients with chronic hepatitis C. Quasispecies complexity on the basis of SSCP pattern could be helpful in differentiation of SVR and NR patients. Complex quasispecies heterogeneity causes high HCV viremia, which was significantly correlated with the severity of liver disease and prognosis during the course of combination therapy. However, there was no significant alteration in SSCP profile during therapy. The occurrence of resistant strains may be another factor contributing to the persistence of HCV infection. Quasispecies in both HVR and NS5B genes may have a major impact on treatment and be a good predictor of virological response. Complex quasispecies are resistant to combination therapy and influence disease prognosis during therapy. Further evaluation of viral quasispecies complexity in the HVR and NS5B genes, as well as other HCV genes (whole genome), is required for a better understanding of the influence of quasispecies on the persistence of infection and disease prognosis during the course of therapy in HCV-infected patients.

COMMENTS

Background

The hepatitis C virus (HCV) continues to persist unless patients are put on interferon therapy. Treatment with interferon-based therapy and error prone replication of the viral genome *via* RNA-dependent RNA polymerase (RDRP) accelerates the evolution of HCV variants during the course of infection. The highly heterogeneous population in HCV-infected patients, consisting of quasispecies, developed because of interferon therapy, immune pressure and replication strategy. Quasispecies are one of the major virological factors other than genotypes that can influence the response to therapy in chronic hepatitis C patients; their role in this needs to be evaluated.

Research frontiers

HCV quasispecies can be detected by cloning of reverse transcription-polymerase chain reaction products; however, sequencing of 15-20 independent clones is expensive and laborious, and not practical for a large number of clinical samples. For large numbers of clinical samples, faster methodologies like single-strand conformational polymorphism (SSCP), heteroduplex analysis (HDA) and gel shift assay (GSA) have been developed based on the differential migration of amplified DNA in acrylamide gel electrophoresis. In the present study, we used the established and reliable method of SSCP for the detection of quasispecies with variations in the HVR and NS5B genes. The patients were grouped on the basis of the number of bands in the SSCP gel. Patients with > 4 SSCP bands were considered to be infected with complex quasispecies (CQS) of HCV. Patients with 3 or 4 bands were considered to be infected with simple quasispecies (SQS); and those with 2 bands were considered to be infected with no quasispecies (NQS). Our interest was to evaluate whether or not the occurrence of quasispecies at baseline influences the virological response and disease severity in chronic hepatitis C patients.

Innovations and breakthroughs

The significance of disease severity on the occurrence of HVR quasispecies in serum of hepatitis C infected patients was observed as all of the cirrhosis and HCC patients showed evolution of quasispecies in this region. However, a major role of NS5B quasispecies was also observed with regard to disease severity. No difference was observed in the SSCP patterns of patients after 24 wk of therapy, confirming the validity of the PCR reaction and SSCP profiles. These results suggest an effect of complex quasispecies with variations in the HVR gene on virological response, as 90.9% (10/11) of patients infected with complex quasispecies with variations in this region did not respond to combination therapy, whereas only 10.0% (3/30) patients infected with complex quasispecies showed SVR. A continuous decline of mean viral load was observed in the patients without complex quasispecies viral infection, suggestive of an influence of quasispecies on viral kinetics and therapeutic outcome during combination therapy.

Applications

The study suggests that quasispecies complexity in both HVR and NS5B genes had a major impact on treatment and is a good predictor of virological responses. However, the existence of quasispecies based on other HCV genes should be further evaluated for a better understanding of the influence of quasispecies on virological responses and disease severity in patients with chronic hepatitis C.

Terminology

Chronic active hepatitis (CAH): anorexia, weight loss, jaundice, ascites, edema present singly or in combination, persistently or intermittently and biochemical features (SGOT, SGPT more than twice normal and globulin 1.5 times normal) of hepatocellular disease for more than 6 months duration. Liver biopsy is necessary for the assessment of disease severity. A diagnosis of cirrhosis of the liver was considered on the basis of the following criteria: ascites, splenomegaly, shrunken liver, endoscopy showing esophageal varices and biochemical features of hepatocellular failure characterized by low serum albumin level (< 2.5 gm). Hepatocellular Carcinoma (HCC): patients were evaluated on the basis of history, clinical examination, liver function tests and serological tests for hepatitis B & C, serum alpha-feto protein levels and liver imaging [ultrasound sonography (US), computed tomography (CT), magnetic resonance imaging (MRI)], and final diagnosis of HCC was made on FNAC (fine needle aspiration cytology). Quasispecies: The origination of a highly heterogeneous population in hepatitis C-infected patients as a result of interferon therapy, immune pressure and replication strategies.

Peer review

In this study the authors assessed whether the occurrence of HCV quasispecies influence responses to antiviral therapy and the severity of chronic hepatitis C. Quasispecies were assessed on the basis of SSCP patterns. The results are interesting and suggest that complex quasispecies are a major factor in non-response to combination therapy. The SSCP pattern remains unaltered during the course of therapy. The concept of this study is interesting; evaluation of other HCV genes should be performed in future work.

Abstract

AIM: To analyze the prevalence of gastroesophageal reflux disease (GERD) related symptoms in patients with diabetes mellitus (DM) and to find out the relationship between diabetic neuropathy and the prevalence of GERD symptoms.

METHODS: In this prospective questionnaire study, 150 consecutive type 2 diabetic patients attending the endocrine clinic were enrolled. A junior physician helped the patients to understand the questions. Patients were asked about the presence of five most frequent symptoms of GERD that included heartburn (at least 1/wk), regurgitation, chest pain, hoarseness of voice and chronic cough. Patients with past medical history of angina, COPD, asthma, cough due to ACEI or preexisting GERD prior to onset of diabetes and apparent psychiatric disorders were excluded from the survey. We further divided the patients into two groups based on presence or absence of peripheral neuropathy. Out of 150 patients, 46 had neuropathy, whereas 104 patients did not have neuropathy. Data are expressed as mean ± SD, and number of patients in each category and percentage of total patients in that group. Normal distributions between groups were compared with Student *t* test and the prevalence rates between groups were compared with Chi-square tests for significance.

RESULTS: The average duration of diabetes were 12 ± 9.2 years and the average HbA1c level of this group was 7.7% ± 2.0%. The mean weight and BMI were 198 ± 54 lbs. and 32 ± 7.2 kg/m^2. Forty percent (61/150) patients reported having at least one of the symptoms of GERD and thirty percent (45/150) reported having heartburn at least once a week. The prevalence of GERD symptoms is higher in patients with neuropathy than patients without neuropathy (58.7% *vs* 32.7%, $P < 0.01$). The prevalence of heartburn, chest pain and chronic cough are also higher in patients with neuropathy than in patients without neuropathy (43.5% *vs* 24%; 10.9% *vs* 4.8% and 17.8% *vs* 6.7% respectively, $P < 0.05$).

CONCLUSION: The prevalence of GERD symptoms in type 2 DM is higher than in the general population. Our data suggest that DM neuropathy may be an important associated factor for developing GERD symptoms.

INTRODUCTION

The prevalence of gastrointestinal (GI) symptoms is reported to be higher in patients with diabetes mellitus (DM)[1] than the general population. Although not generally considered as important causes of morbidity or mortality in DM patients, these symptoms can influence health related quality of life (HRQOL) and affect productivity and employment status[2,3]. GI symptoms can be encountered in up to 75% of diabetic outpatients evaluated in tertiary care referral centers[4,5]. Many patients with GI disorders remain undiagnosed and untreated. The underlying mechanisms of the high prevalence of gastrointestinal symptoms in type 2 DM are poorly defined and controversy exists at the present time. The association of GI symptoms in DM to glycemic control is debated and controversy exists[6,7]. Many of the gastrointestinal symptoms in diabetics suggest motor dysfunction, and a neuropathic basis to those dysfunctions would be a reasonable explanation. A recent study by Bytzer *et al* suggests that GI symptoms in DM were associated with complications of DM, particularly peripheral neuropathy[6]. Some studies even suggest that gastrointestinal symptoms in

diabetic patients were poorly related to diabetic neuropathy, instead were related with psychiatric illness[8,9]. The duration of DM was also an important factor for GI symptoms in type 2 DM patients since longer duration tends to have more complications[1,10].

In the pathophysiology of gastroesophageal reflux disease (GERD), a major mechanism that promotes reflux of gastric contents into esophagus is delayed gastric emptying, a frequent complication of diabetes with neuropathy. The most common symptoms of GERD are heartburn and regurgitation[11] and GERD may also responsible for other symptoms such as hoarseness, asthma (chronic cough) and chest pain. The aim of this study is to analyze the prevalence of GERD symptoms in patients with diabetes and to find out the relationship between the duration of diabetes, BMI, HbA1c, diabetic neuropathy and the prevalence of GERD symptoms. We especially focus on the role of DM neuropathy in the development of symptoms of GERD in type 2 diabetes.

MATERIALS AND METHODS

In this cross-sectional study, 150 type 2 diabetic patients were enrolled. This was comprised of 150 consecutive type 2 diabetic patients attending the endocrine clinic in a major University diabetic center. This was elicited based on a questionnaire distributed to patients.

A junior physician helped the patients to understand the questions. Patients were asked about the presence of five most frequent symptoms of GERD that included heartburn, regurgitation, chest pain, hoarseness of voice and chronic cough[11]. To maximize the specificity of symptoms of GERD for our analysis, we considered only participants with frequent symptoms and excluded patients with less frequent than weekly. Patients' weight, height, BMI, BP, duration of diabetes, medications, HgbA1c and complications of diabetes including neuropathy were obtained within 6 wk of eliciting the answers to the questionnaire. Patients with past medical history of angina, COPD, asthma, cough due to ACEI or preexisting GERD prior to onset of diabetes and apparent psychiatric disorders were excluded from the survey.

We further divided the patients into two groups based on presence or absence of peripheral neuropathy. Out of 150 patients, 46 had neuropathy, whereas 104 patients did not have neuropathy. Presence of neuropathy was determined by past change in neuropathy and positive sensory symptoms including: limbs numbness, prickling sensation, aching pain, burning pain and at least one of the positive neurological examination findings including: (1) decreased pressure or pain sensation: positive monofilament test; (2) decrease of light touch sensation: positive cottonwool swab test; (3) decreased tendon refluxes.

Data are expressed as mean ± SD, and number of patients in each category and percentage of total patients in that group. Normal distributions between groups were compared with Student *t* test and the prevalence rates between groups were compared with Chi-square tests for significance. $P < 0.05$ is selected as significant level.

Table 1 Prevalence of GERD symptoms in DM patients with and without neuropathy

	DM 150	DM w Neuro 46	DM w/o Neuro 104	*P* value
Age (yr)	54 ± 15	56 ± 13	53 ± 16	> 0.10
DM Duration (yr)	12 ± 9.2	14.8 ± 9.1	10.7 ± 9.0	> 0.10
Weight (lbs)	198 ± 54	207 ± 42	194 ± 58	> 0.10
BMI	32 ± 7.2	33.9 ± 6.9	31.2 ± 7.2	> 0.10
HbA1c (%)	7.7 ± 2.0	7.9 ± 1.8	7.7 ± 1.2	> 0.10
Metformin	87/150 (58%)	26/46 (56.5%)	61/104 (58.6%)	> 0.10
GERD	61/150 (40.7%)	27/46 (58.7%)	34/104 (32.7%)	< 0.01
Heartburn	45/150 (30%)	20/46 (43.5%)	25/104 (24%)	< 0.05
Chest pain	10/150 (6.6%)	5/46 (10.9%)	5/104 (4.8%)	< 0.05
Chronic cough	14/150 (9.4%)	8/46 (17.8%)	7/104 (6.7%)	< 0.05
Regurgitation	19/150 (12.8%)	7/46 (15.6%)	12/104 (11.5%)	> 0.10
Hoarseness	5/150 (3.3%)	2/46 (4.4%)	3/104 (2.9%)	> 0.10

GERD: Presence of one or more of the five symptoms. Prevalence of heartburn in US adults is 14% weekly[11].

RESULTS

The mean age ± SD of the group was 54 ± 15; the mean weight and BMI were 198 ± 54 lbs. and 32 ± 7.2 kg/m^2. Eighty-seven (58%) of the patients were women. Ninety two (61%) patients were Caucasians, twenty-five (16.7%) of the patients were African Americans, seventeen (11.3%) of the patients were Asia Americans and twenty-one (14%) patients were from the other ethnic groups. The average duration of diabetes was 12 ± 9.2 years and the average HbA1c level of this group was 7.7% ± 2.0%. All patients took multiple medications including eighty-seven patients (56.5%) took metformin for their DM control.

Forty percent (61/150) patients reported having at least one of the symptoms of GERD and 30% (45/150) reported having heartburn at least once a week (Table 1).

There is no difference in age, body weight, BMI, duration of DM, and combination therapy with metformin between patients with neuropathy and patients without neuropathy ($P > 0.05$). The prevalence of GERD symptoms is higher in patients with neuropathy than patients without neuropathy ($P < 0.01$). The prevalence of heartburn, chest pain and chronic cough are also higher in patients with neuropathy than patients without neuropathy ($P < 0.05$) (Table 1).

DISCUSSION

Gastrointestinal symptoms are frequently encountered in patients with DM. Although not generally considered important causes of mortality in DM patients, these symptoms can influence Health Related Quality of Life (HRQOL)[2,3] and be encountered in up to 75% of diabetic outpatients[4,5]. Our data showed that the overall prevalence of GERD symptoms in diabetics is 40.7% and is greater than in general population (14%) reported in the literature[12]. In a study by Nebel *et al* they reported 7% had daily heartburn and 14% had weekly symptoms[12]. In those with neuropathy, the presence of heartburn (43.5%) was significantly higher than in the group without neuropathy (24%; $P < 0.05$). The mechanisms of the high

prevalence of gastrointestinal symptoms in type 2 DM are poorly defined and controversy at present time. The proposal mechanisms include: over weight and obesity, blood glucose levels at the time of presentation, DM medications, duration of DM and DM complications.

Over weight and obesity are risk factors for symptoms of GERD[13-15], and recent study by Jacobson *et al* found BMI is associated with symptoms of GERD in both normal-weight and overweight women[16]. Most of our type 2 diabetes patients are over weight or obesity with average BMI of 32, so over weight might be explained part of high frequent symptoms of GERD in type 2 diabetes patients. However, there was no difference in BMI between patient with or without neuropathy, over weight or obesity might not associate with the high frequency of GERD symptoms of type 2 DM patients with neuropathy. Acute hyperglycemia (> 200 mg/dL) is a contributory factor for the GI symptoms that can slow gastric motor function and delay gastric empty. Bytzer and colleagues reported that gastrointestinal symptoms were associated with DM complications but not with current glycemia control measured by blood glucose and glycosylated hemoglobin levels and a later study from the same group suggested that GI symptoms were associated with both poor glycemic control and DM complications[1]. Our data indicate that the symptoms of GERD were not associated with recent HbA1c levels. DM medications, especially metformin induce many gastrointestinal symptoms including nausea, vomiting, diarrhea, flatulence, chest discomfort and abdomen discomfort but not heartburn. Since there was no difference in medications usage between patients with neuropathy and without neuropathy, medications might not associate with the high prevalence of GERD symptoms in type 2 DM patients with neuropathy.

In our study, we focused on the symptoms of GERD and found that the prevalence of GERD symptoms is higher in patients with neuropathy (58.7%) than in those without neuropathy (32.7%). Heartburn is noted in 42% of patients with neuropathy *versus* 24% patients without neuropathy. Since experience of heartburn is likely to be blunted by neuropathy, the actual incidence of GERD may even be higher. Our data thus suggest that neuropathy is an important associate factor of the symptoms of GERD in type 2 DM. Delayed gastric emptying is a well-known mechanism promoting gastric retention and reflux. In type 1 DM, peripheral neuropathy is present in the majority of patients with enteropathy and GI symptoms are associated with DM peripheral neuropathy[1]. Two recent repots suggest that the pacemaker cells in the wall of the upper digestive tract are abnormal in experimental diabetes and in a single DM patient[17,18]. It is generally believed that gastroparesis of some degree complicates diabetes of > 10 years in duration when accompanied by peripheral and autonomic neuropathy. Type 2 diabetics with GI symptoms most commonly presented with gastroesophageal reflux disease whereas type 1 diabetics had bloating fullness and satiety[7].

Ideally all patients above the age of 50 and those with alarm symptoms (dysphagia, weight loss, anemia, history of cigarette smoking and alcoholism) with GERD symptoms should undergo esophago gastro duodenoscopy, and gastric emptying studies. However we did not perform these studies since our goal is not to identify a pathogenic mechanism but first to note whether neuropathy contributed to GERD symptoms. Several studies have been published that the validity and reliability these symptoms in identify cases of GERD [13,14]. Furthermore, to improve our specificity for GERD, we restricted our primary analysis to patients who reported at least weekly symptoms.

In summary, the prevalence of GERD symptoms in type 2 DM is higher than in general population and the prevalence of GERD symptoms is higher in patients with neuropathy than patients without neuropathy. Our data suggest that DM neuropathy is an important associated factor for developing GERD symptoms. Patients with DM and neuropathy should be presumed to have GI abnormalities until proven otherwise. The work up should start with thorough patients' history, physical examination, appropriate laboratory test and possible endoscopy examination. Appropriate therapy including dietary manipulation and pharmacological therapy should be given to patients with GERD symptoms to improve health related quality of life.

COMMENTS

Background

Many investigators have reported that the prevalence of gastrointestinal (GI) symptoms is higher in patients with diabetes mellitus (DM) than the general population. Although not generally considered as important causes of morbidity or mortality in DM patients, these symptoms can influence health related quality of life and affect productivity and employment status. The underlying mechanisms of the high prevalence of gastrointestinal symptoms in type 2 DM are poorly defined. The proposal mechanisms include: over weight and obesity, blood glucose levels at the time of presentation, DM medications, duration of DM and DM complications. The association between diabetes peripheral neuropathy and GERD symptoms is controversy at present time. In the present study, we focus on the association of DM neuropathy and the symptoms of gastroesophageal reflux disease (GERD) in type 2 diabetes.

Research frontiers

To analyze the prevalence of GERD symptoms in patients with diabetes and to find out the relationship between the duration of diabetes, BMI, HbA1c, diabetic neuropathy and the prevalence of GERD symptoms. We especially focus on the association between DM neuropathy and symptoms of GERD in type 2 diabetes.

Innovations and breakthroughs

In our study, we found in first time that the prevalence of GERD symptoms is higher in patients with neuropathy (58.7%) than in those without neuropathy (32.7%). Heartburn is noted in 42% of patients with neuropathy *versus* 24% patients without neuropathy. Since experience of heartburn is likely to be blunted by neuropathy the actual incidence of GERD may even be higher.

Applications

Our data suggest that DM neuropathy is an important associated factor for developing GERD symptoms. Patients with DM and neuropathy should be presumed to have GI abnormalities until proven otherwise. The work up should start and appropriate therapy should be given to patients with GERD symptoms to improve health related quality of life.

Peer review

This is a very good study. Much more solid and valid conclusions could be drawn if more appropriate statistical analysis were done.

Abstract

AIM: To explore the influence of polymorphisms in genes encoding for the chemokines Stromal cell-Derived Factor-1 *(SDF-1)/CXCL12* and Monocyte Chemotactic Protein-1 *(MCP-1)/CCL2*, or for the chemokine receptor *CCR5* on the risks of liver-related death and hepatocellular carcinoma (HCC) occurrence in hepatitis C virus (HCV)-infected patients.

METHODS: *SDF-1 3'A*, *MCP-1 (-2518)* and *CCR5-Δ32* polymorphisms, SDF-1α, Regulated upon Activation Normal T cells Expressed and Secreted (RANTES)/CCL5 and MCP-1 serum levels were determined in 120 HCV-infected patients, included at time of cirrhosis diagnosis and prospectively followed-up.

RESULTS: During follow-up, 23/120 (19.1%) patients died and 47/120 (39.1%) developed HCC. Carriers and noncarriers of each genetic marker had similar baseline characteristics estimating the severity of liver disease. The occurrence of death or HCC during follow-up was similar among carriers and noncarriers of each polymorphism. There was no association between the carriage of mutated alleles and chemokine serum levels and the latter were not associated with the risks of death or HCC.

CONCLUSION: This study suggests the lack of association of *SDF-1 3'A*, *MCP-1 (-2518)*, *CCR5-Δ32* polymorphisms with death and HCC occurrence in cirrhotic HCV-infected patients.

INTRODUCTION

Host factors influencing the course of hepatitis C virus (HCV)-related liver disease are still poorly understood. As HCV infection is a major health issue worldwide leading to life-threatening complications such as hepatocellular carcinoma occurrence (HCC), refining the selection of patients with a poorer prognosis in order to intensify anti-viral therapy or HCC screening is of major interest. Among these factors, genetic polymorphisms that could either influence virological response or hepatocarcinogenesis (or both) could be in the future useful markers to improve the selection of HCV-infected patients at higher risk of developing end-stage liver diseases[1].

Chemokines constitute a large family of small (8-10 kDa) cytokines whose effects are mediated by members of a family of 7-transmembrane domain G-pro-

tein coupled receptors[2]. In the liver, chemokines have become increasingly recognized as important mediators of hepatic inflammation[3]. In particular, stromal cell-derived factor-1 (SDF-1)/CXCL12 plays a role in the recruitment and the retention of immune cells in the liver during chronic HCV and hepatitis B virus infection[4]. Lymphocytes infiltrating HCV-infected liver express high levels of the CC chemokine receptor CCR5[5] and the CCR5 ligand, regulated upon activation, normal T cells expressed and secreted (RANTES)/CCL5 may attract naive and activated T cells to the portal and periportal areas[6]. Hepatic stellate cells (HSCs) have been shown to regulate leukocyte trafficking by secreting the CC-chemokine, Monocyte Chemoattractant Protein-1 (MCP-1)/CCL2 and it has been suggested that MCP-1 may have a direct profibrogenic action via HSC chemotaxis[7].

These three major chemokines involved in the pathogenesis of inflammatory liver disease are subject to various genetic polymorphisms[3]. Several studies suggested that chemokine system polymorphisms could be involved in the clinical outcome of HCV-infected patients, either by modulating virological response or by influencing the severity of liver injury. Indeed, significant associations were found between *CCR5-Δ32*, which is a 32-bp deletion in the *CCR5* gene leading to a nonfunctional protein[8], and reduced portal inflammation or milder fibrosis[9], as well as enhanced viral clearance[10]. Furthermore, Promrat *et al* suggested that expression of CCR5 and one of its ligands, RANTES, may be important in the modulation of hepatic inflammation and response to interferon therapy in chronic hepatitis C[11]. This particular *CCR5-Δ32* polymorphism does not appear to be the only chemokine system genetic variant influencing the course of HCV infection; indeed, *MCP-1 (-2518)* allele carriage was found to be associated with higher MCP-1 secretion by hepatic stellate cells and enhanced inflammation and fibrosis[12].

Chemokines have also been shown to be involved in the development of various cancers, mainly breast carcinoma, their physiopathological action including tumour growth, invasion and metastasis[13,14]. Recently, our team showed that SDF-1 stimulates human hepatoma cell growth, migration and invasion, with data obtained in human liver biopsy specimens confirming *in vitro* findings[15]. The homozygous (G to A) mutation at position 801 of the 3'-untranslated region of the *SDF-1* gene, *SDF-1 3'A* has been linked to delayed progression to AIDS in adults with HIV-1 infection[16], but its influence in the course of HCV infection is still unknown.

When taking in account (1) the previously described influence of chemokine system polymorphisms on virological response, liver inflammation and fibrosis in the course of HCV infection and (2) their possible implication in various cancer development and possibly HCC, we hypothesized that these polymorphisms could influence the progression of HCV-related liver injury towards end-stage liver disease. The aim of this work was to study the influence of the most studied polymorphisms *CCR5-Δ32*, *MCP-1 (-2518)* and *SDF-1 3'A* on the prognosis of prospectively followed-up patients with HCV-related cirrhosis, as assessed by the risks of liver-related death and HCC occurrence. As genetic variation affecting the regulatory regions of chemokine genes may modulate their mRNA and protein levels, RANTES, SDF-1α and MCP-1 chemokine serum levels were also determined in these patients.

MATERIALS AND METHODS

Inclusion of patients

The present work is part of a large prospective study, which is ongoing in the department of hepatology of the Jean Verdier hospital, aiming to prospectively assess risk factors involved in HCC development in chronic liver diseases from various etiologies. Among these factors, various genetic polymorphisms have been studied over the past few years including chemokine and chemokine receptor dimorphisms[17-20].

We compiled all new HCV-infected patients who were consecutively referred to our liver unit for diagnosis and treatment between January 1, 1991 and December 31, 2001, and who fulfilled the following inclusion criteria: (1) transparietal or transjugular biopsy-proven cirrhosis; (2) chronic infection by HCV defined by positive serum HCV-RNA; (3) daily alcohol consumption < 20 g; (4) no other cause of liver disease and no infection by the human immunodeficiency virus or hepatitis B virus; (5) no evidence of HCC at the time of inclusion, as judged by negative ultrasonographic findings and serum α-fetoprotein (AFP) less than 50 ng/mL; (6) residence in France; (7) availability of a blood sample to prepare DNA; and (8) acceptance of a regular follow-up for the detection of HCC.

For each patient, the date of inclusion was the date of the first liver biopsy showing cirrhosis. Gender, age, Child-Pugh score, serum alanine aminotransferase (ALT) and aspartate transaminase (AST) levels, platelet count, HCV genotype were recorded at inclusion. The Ethics Committee of our hospital approved the trial.

Follow-up

Patients were prospectively evaluated every 6 mo by physical examination, ultrasonography and AFP measurements. When these investigations suggested possible HCC, computed tomography and/or magnetic resonance imaging and/or a guided liver biopsy were performed according to Barcelona criteria[21].

The two main end-points of the study were the occurrence of HCC, and the occurrence of liver transplantation or death. Follow-up ended at the date of death or liver transplantation, or at the last recorded visit (or information) within the last 6 mo before August 31, 2006, which was set as the final time limit for upgrading the patients' file. The virological response was evaluated in patients who underwent anti-viral treatment. A sustained virological response was defined as the persistence of a negative serum HCV-RNA 6 mo after the end of treatment.

DNA extraction, amplification, CCR5, SDF-1 and MCP-1 genotyping

Genomic DNA was prepared from blood by standard methods[19]. All samples were recoded and blinded. Patients gave written consent for blood sampling and *CCR5*, *SDF-1*, *MCP-1* genotyping. Polymerase chain

Table 1 Characteristics and outcome of patients with HCV-related cirrhosis classified according to MCP1, CCR5 and SDF-1 genotypes

[1]Parameters recorded at inclusion. [2]mean ± SD. [3]Number (percentage) of patients. ALT: Alanine aminotransferase; AST: Aspartate transaminase; HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma occurrence.

reaction amplification of *CCR5* alleles was performed on genomic DNA as previously described[19]. The *SDF-1 3'A* variant (801G to A in the 3'-untranslated region) was detected by electrophoresis on 2.5% agarose gel after PCR amplification and *Msp*I (New England Biolabs, Saint-Quentin-en-Yvelines, France) digestion as previously described[16]. Genotype analysis for *MCP-1 (-2518)* was performed on genomic DNA with PCR with sequence-specific primers followed by restriction fragment length polymorphism analysis as described[22,23]. Briefly, after PCR amplification, PCR products were digested with *Pvu*Ⅱ (recognizes the *MCP-1 -2518* A/G transition) (New England Biolabs).

ELISA assay

All tests were performed using frozen serum collected at fasting and stored at -80℃. SDF-1α, RANTES, MCP-1 serum levels were determined on blood samples collected at inclusion. ELISA assays were performed in patients without evidence of systemic infection at time of blood sample collection as previously described[19].

Statistical analysis

Qualitative variables were compared using the Fischer exact χ^2 test or χ^2 trend test with 1 degree of freedom, while quantitative variables were compared using the non-parametric Wilcoxon test.

The Kaplan-Meier method was used to estimate death and the occurrence of HCC for each parameter noted at enrolment, and the distribution of death and HCC were compared with the Log-rank test[24]. Statistical analysis used the SAS System Package version 8.02 (SAS Institute, Cary, NC).

All reported P values are two-tailed. Associations were first considered statistically significant at a two-tailed α of 0.05.

RESULTS

Characteristics of patients according to the studied genotypes

One hundred and twenty patients were included in this study. All of them had *CCR5* and *SDF-1* genotype assessment and 98 of them had *MCP-1* genotype assessment. Demographic, biological and clinical characteristics according to the *CCR5*, *SDF-1*, and *MCP-1* genotypes are summarized in Table 1. As a very small number of patients were homozygotes for *CCR5-Δ32* allele (n = 0), *SDF-1 3'A* allele (n = 6), *MCP-1 (-2518)* allele (n = 6), we gathered them with heterozygotes in order to compare patients with at least one mutated allele to wild-type homozygotes.

Baseline characteristics estimating the severity of liver disease (prothrombin time, bilirubin levels, albumin, ascites, encephalopathy, Child-Pugh score) were similar among carriers and noncarriers of each genetic marker (Table 1 and data not shown). Demographic data were not different according to allele distributions. Finally, we did not observe any association between the studied chemokine system polymorphisms and the corresponding baseline chemokine serum levels. Thus, there was no association

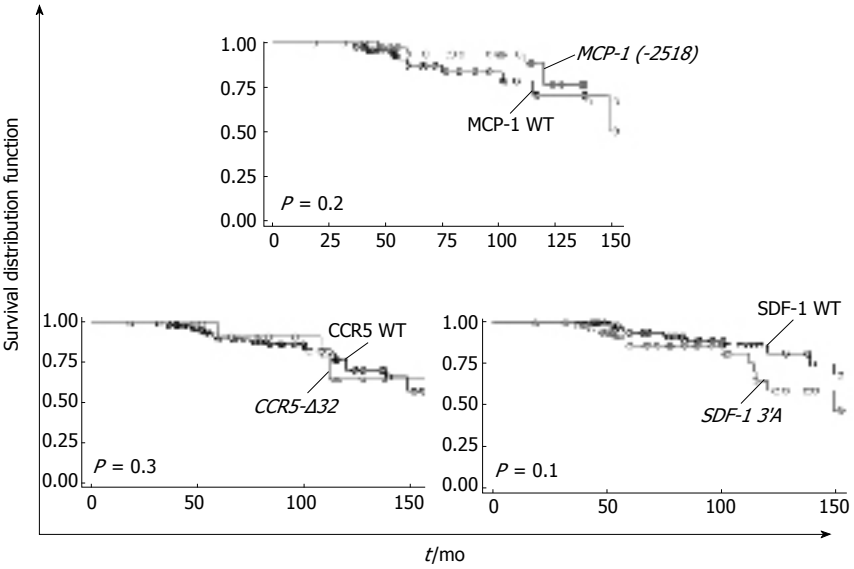

Figure 1 Survival according to *CCR5-Δ32, SDF-1 3'A* and *MCP-1 (-2518)* allele carriage. None of the studied polymorphisms had an influence on survival (at least one mutated allele carriers *vs* wild type homozygotes). *CCR5-Δ32*: Quartile time of survival = 112 mo *vs* 120 mo [RR = 1.02 (95% CI = 0.3-3.4), *P* = 0.3]; *SDF-1 3'A*: Quartile time of survival = 114 mo *vs* 149 mo [RR = 1.9 (95% CI = 0.8-4.4), *P* = 0.1]; *MCP-1 (-2518)*: Quartile time of survival = 139 mo *vs* 115 mo [RR = 0.5 (95% CI = 0.1-1.5), *P* = 0.2].

between the carriage of *CCR5-Δ32* and the serum levels of RANTES, neither between the carriage of *SDF-1 3'A* and SDF-1α serum levels, nor between *MCP-1 (-2518)* allele carriage and MCP-1 serum levels.

Outcome of patients

The incidence of death or transplantation among carriers and noncarriers of each polymorphism is shown in Table 1. Figure 1 displays their prospective influence on these events.

During follow-up, 23/120 (19.1%) patients died or underwent liver transplantation (n = 2). Death was attributable to liver disease in all cases, due to advanced HCC in 19 cases or due to variceal bleeding and/or liver failure in 4 cases. None of the patients included in this study were lost during follow-up. Mean time of follow-up of the cohort was 90.7 ± 43.2 mo.

The incidence of death or transplantation during follow-up was similar among carriers and noncarriers of each genetic marker (Table 1). Using the Kaplan-Meier method, we successively studied the influence of the mutated alleles as risk factors for death/liver transplantation in this cohort. None of the studied polymorphisms had an influence on these events (Figure 1). According to genotypes, quartile time of survival was 112 mo in patients carrying at least one allele *CCR5-Δ32 vs* 120 mo in wild-type homozygotes [RR = 1.0 (95% CI = 0.3-3.4), *P* = 0.3]; 114 mo in patients carrying at least one allele *SDF-1 3'A vs* 149 mo in wild-type homozygotes [RR = 1.9 (95% CI = 0.8-4.4), *P* = 0.1]; 139 mo in patients carrying at least one allele *MCP-1 (-2518) vs* 115 mo in wild-type homozygotes [RR = 0.5 (95% CI = 0.1-1.5), *P* = 0.2].

Seventy-two/120 patients underwent curative antiviral therapy during follow-up. According to genotype distribution, the proportion of treated patients was similar in each group, as well as the infection by HCV genotype 1 which was the most represented in the cohort. None of the studied polymorphisms influenced the sustained virological response (SVR) (Table 1).

Finally, baseline RANTES, SDF-1α or MCP-1 serum levels were not associated with the risk of death/transplantation in our cohort or with the probability of SVR (data not shown).

HCC occurrence

Although inclusion criteria required the absence of detectable HCC at the time of inclusion, 47/120 (39.1%) patients developed HCC during follow-up. Mean time to occurrence of HCC in this cohort was 78.5 ± 40.5 mo.

HCC occurrence during follow-up was not different among carriers and noncarriers of each polymorphism (Table 1). Using the Kaplan-Meier method, we successively studied the influence of the mutated alleles as risk factors for HCC development in this cohort. None of the studied polymorphisms had an influence on this event (Figure 2). According to genotypes, quartile time to HCC occurrence was 72 mo in patients carrying at least one allele *CCR5-Δ32 vs* 68 mo in patients wild-type homozygotes [RR = 0.5 (95% CI = 0.2-1.6), *P* = 0.3]; 72 mo in patients carrying at least one allele *SDF-1 3'A vs* 68 mo in wild-type homozygotes [RR = 1.1 (95% CI = 0.6-2.0), *P* = 0.6]; 67 mo in patients carrying at least one allele *MCP-1 (-2518) vs* 72 mo in patients wild-type homozygotes [RR = 1.1 (95% CI = 0.5-2.1), *P* = 0.8].

Finally, baseline RANTES, SDF-1α or MCP-1 serum levels were not associated with the risk of HCC occurrence in our cohort (data not shown).

DISCUSSION

The results of this study are consistent with a lack of influence of *CCR5-Δ32*, *SDF-1 3'A* and *MCP-1 (-2518)* chemokine system polymorphisms on the prognosis of patients with HCV-related cirrhosis as observed in patients with alcoholic cirrhosis[19]. Our hypothesis, based on the results of several case-control studies displaying an involvement of these genetic variants in the progression of liver injury in HCV-infected patients, was tested on a large cohort of prospectively followed-up patients with a large number of events allowing us to be confident in such a conclusion. The observed discrepancies between the present work and the previously published studies could have several explanations[9,10,12,25].

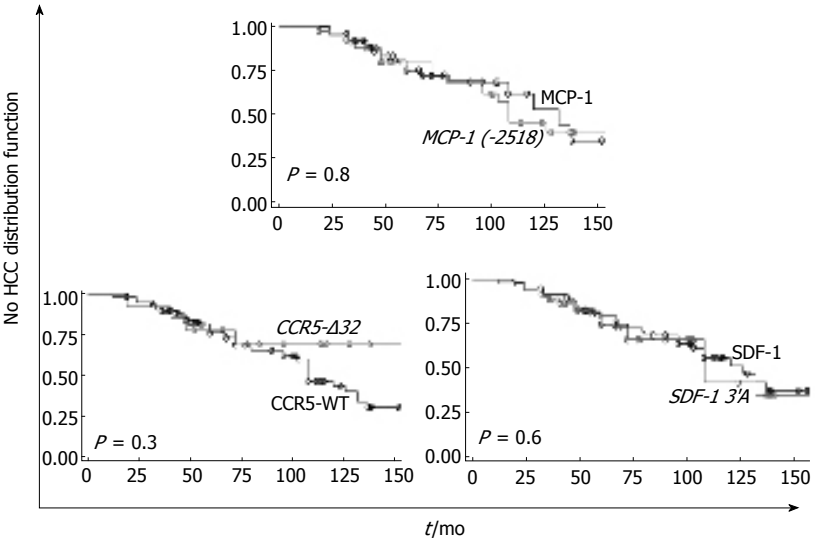

Figure 2 HCC incidence according to *CCR5-Δ32, SDF-1 3'A* and *MCP-1 (-2518)* allele carriage. None of the studied polymorphisms had an influence on the risk of HCC occurrence (at least one mutated allele carriers *vs* wild type homozygotes). *CCR5-Δ32*: Quartile time to HCC occurrence = 72 mo *vs* 68 mo [RR = 0.5 (95% CI = 0.2-1.6), *P* = 0.3]; *SDF-1 3'A*: Quartile time to HCC occurrence = 72 mo *vs* 68 mo, [RR = 1.1 (95% CI = 0.6-2.0), *P* = 0.6]; *MCP-1 (-2518)*: Quartile time to HCC occurrence = 67 mo vs 72 mo [RR = 1.1 (95% CI = 0.5-2.1), *P* = 0.8].

Case-control studies are subject to many methodological biases, including selection bias. Some controversial results have already been reported regarding the involvement of chemokine system polymorphisms in the course of HCV infection. Indeed, Woitas *et al* reported a higher prevalence of the *CCR5-Δ32* allele carriage in HCV-infected patients compared with controls, suggesting that this genetic variant could be associated with a higher risk of developing chronic infection when exposed to the virus[25]. This finding has never been confirmed[9-11,26], raising the issue of selection of specific sub-groups of patients displaying different levels of HCV exposure and the need to confirm such results in independent cohorts. Nevertheless, despite these methodological limitations and controversies[25,27] common to all case-control studies, the influence of chemokine system polymorphisms on HCV-related liver injury relies on solid histological and biological data obtained in human biopsy specimen[9-11].

Our main end-points were the occurrence of liver-related death and HCC in our cohort. These events depend on various and numerous factors, including therapeutic management that can modify the natural course of the disease. As a matter of fact, active preventive procedures aiming to lower life-threatening complications have been carried out in this cohort such as digestive hemorraghe prevention by band ligation or interferon therapy which has been shown to improve survival and lower the risk of HCC incidence in patients with HCV-related cirrhosis[28,29]. As well, as regular HCC screening was carried out in our cohort, patients with small HCC underwent curative treatment, thus modifying their prognosis. Despite the prospective aspect of this study, one could wonder if such therapeutic interventions could induce major changes in the natural course of the disease, thus modifying the importance of chemokine system involvement on the progression of liver injury.

A secondary aim of this work was to assess the influence of the studied polymorphisms on anti-viral therapy. Indeed, several reports showed that CCR5 polymorphisms could be host genetic factors predicting anti-viral treatment success, suggesting that this chemokine receptor could be involved in interferon therapy response[11,30,31]. In the present paper, we did not observe any influence of the studied polymorphisms on anti-viral treatment response.

The functional consequences of the studied polymorphisms are still poorly understood, requiring further *in vitro* and *in vivo* studies aiming to assess if chemokines may be fair serum host factors to explain the inter-individuals differences of evolutions in HCV-infected patients. No association was found between the polymorphisms under study and the baseline serum levels of the corresponding chemokines. Furthermore, these serum levels did not influence the outcome of patients. Nevertheless, the selection of cirrhotic patients is unlikely to be a good choice for the study of the association of polymorphisms with serum levels of a given compound as liver function might affect circulating levels. The assessment of the correlation between chemokine system genetic variants and the corresponding circulating chemokines as well as their possible influence on hepatic injury should be conducted in patients without liver function impairment.

However, these data do not exclude that the chemokine levels in the liver may vary during the course of HCV-related liver disease, as demonstrated by others[32]. Indeed, a statistically significant association between the intrahepatic RANTES expression and the inflammatory activity of chronic hepatitis C was found[32].

It seems reasonable to consider that the progression of liver injury in the course of HCV infection is a continuous pathological process from primo-infection to the development of end-stage liver disease. Nevertheless, mechanisms involved in this progression may not have the same implication before and after the onset of cirrhosis. Thus, the influence of chemokine system could be therefore more critical during the first steps of the infection during which liver inflammation and fibrogenesis are the main physiopathological events. Conversely, their involvement in hepatocarcinogenesis or the progression of liver injury towards liver failure and portal hypertension may not be significant enough (or such events the consequences of too many pathological pathways) to observe an influence of their genetic variants.

In conclusion, the results of this study display a lack of influence of major chemokine system polymorphisms towards liver-related death and HCC occurrence that were previously described as possible host factors influencing the course of HCV infection. This finding highlights the need to assess the prognostic value of such polymorphisms in prospectively followed-up cohorts of patients. If confirmed by other independent cohort studies as previously reported[27], these results suggest that *CCR5-Δ32*, *SDF-1 3'A* and *MCP-1 (-2518)* polymorphisms are not fair candidate genetic variants to select HCV-infected patients at higher risk of developing end-stage liver disease.

COMMENTS

Background

Hepatitis C virus (HCV)-related cirrhosis is a life threatening disease with annual incidences of hepatocellular carcinoma (HCC) and death reaching around 4% and 3% respectively. However, there is wide variability in susceptibility to HCV-related cirrhosis and its outcome such as HCC or death. As epidemiologic factors leading to these complications are well established, the genetic background underlying these differences is still poorly understood and relies on the associations of genetic polymorphisms with such events.

Research frontiers

Polymorphisms in genes encoding for chemokines or chemokine receptors have been associated with the progression of HCV-related liver injury and with various cancer development. However, most of published works are conducted in small-size populations and are case-control studies, thus limiting the reliability of the results observed and the conclusions drawn. Furthermore, their influence on the risks of liver-related death and HCC occurrence in HCV-infected patients is still unknown.

Innovations and breakthroughs

The results of this study are consistent with a lack of influence of chemokine system polymorphisms on the prognosis of patients with HCV-related cirrhosis. This study was carried out in a large cohort of prospectively followed-up patients with a large number of events allowing us to be confident in such a conclusion.

Applications

Exploring new gene variants associated with HCV cirrhosis outcome could be in the future useful markers to improve the selection of HCV-infected patients at higher risk of developing end-stage liver disease.

Terminology

HCC is the most frequent primary liver cancer and the first cause of death in patients with HCV-cirrhosis.

Peer review

This paper shows clearly the lack of any relationship between several genetic markers, the serum level of cytokines and the prognosis of HCV related HCC. Despite their negative results, the study is very well done and described.

Abstract

AIM: To perform a single-center analysis of all double balloon endoscopy (DBE) related cases of pancreatitis identified prospectively from a recorded DBE-complication database.

METHODS: From November 2003 until January 2007, 603 DBE procedures were performed on 412 patients, with data on complications recorded in a database. The setting was a tertiary care center offering DBE. DBE was performed from the antegrade or retrograde route. Outcome measurements included age, gender, medication, indication, DBE-endoscope type, insertion depth, procedure duration, findings, interventions, post-procedural abdominal pain, and post-procedural hospitalization.

RESULTS: This is the largest single-center study reporting on post-DBE pancreatitis prospectively. Six patients (1.0%) developed post-DBE pancreatitis, all after antegrade DBE. There was no association with gender, duration of the procedure or type of endoscope. The mean age was 51.9 years (range 25-78). Four patients had severe pancreatitis. Of these, two had inflammatory signs in the body-tail region, one had pancreatitis in the tail region, and the total pancreas was involved in one.

CONCLUSION: The incidence of post-DBE pancreatitis in our series is higher than previously reported. We found no relation with DBE-endoscope type. The inflammatory changes occurred in the body-tail region of the pancreas, suggesting that post-DBE pancreatitis is caused by repetitive mechanical strain on the pancreas.

INTRODUCTION

Since its introduction in 2001 by Yamamoto[1], double balloon endoscopy (DBE) has revolutionized both diagnostic and therapeutic small bowel endoscopy[2]. This technique allows (intervention) endoscopy of the complete small bowel (often in two sessions) with the possibility of carrying out interventions; e.g. mucosal biopsy, argon plasma coagulation, snare polypectomy, injection therapy, tattooing, foreign body extraction and balloon dilatation. DBE plays an important role in the diagnosis and treatment of obscure gastrointestinal bleeding[3-6], Crohn's disease[7-10], celiac disease[11,12], polyposis syndromes[13] and small bowel tumors. In the series published to date, complications solely related to the diagnostic procedure are rare[14-18]. A recent retrospective multicenter survey indicates a complication rate of 0.8% in diagnostic procedures[16]. In that study, pancreatitis occurred in six of 2362 (0.3%) procedures and contributed to 46% of all complications after diagnostic DBE. Another recent study showed that an asymptomatic rise of serum amylase and lipase levels after antegrade DBE is frequently encountered[19]. Nevertheless, only a few patients develop the clinical picture of post-DBE pancreatitis. The reason for this remains unknown.

This article presents an analysis of all DBE-related cases of pancreatitis identified prospectively from a recorded DBE-complication database of 603 procedures in a single center.

MATERIALS AND METHODS

From November 2003 to January 2007, 603 DBE

Table 1 Patient characteristics

	Gender	Age (yr)	Indication	Scope type	Midazolam (mg)	Fentanyl (mg)	Duration (cm)	Insertion length (cm)	Interventions	Admission (d)	CT inflammation	Peak amylase U/L	Peak lipase U/L

Reference values: amylase 0-100 U/L, lipase 0-70 U/L.

procedures were performed in an outpatient setting in the Department of Gastroenterology at the VU University Medical Center in Amsterdam, The Netherlands. In our procedures, we used the Fujinon EN-450P5- and the thicker Fujinon EN-450T5 endoscopes. Of the total number of procedures, 311 were performed in men (51.6%) and 292 in women (48.4%) with a mean and median age of 59 and 60 years respectively (range 12-94). Informed consent was obtained from all patients in accordance with the institutional review board guidelines. Data recorded in the complication database included age, gender, co-morbidity, surgical history, medication, indication for DBE, depth of insertion as described by May[20], procedure duration, findings, interventions performed, post-procedural abdominal pain, and post-procedural hospitalization. The patients received a combination of midazolam and fentanyl intended for conscious sedation.

The complication database was reviewed. All patients with post-DBE pancreatitis were identified and their charts were reviewed for additional clinical information including severity of pancreatitis, length of hospitalization, peak serum CRP, peak serum amylase, peak serum lipase, abdominal imaging performed, surgery performed and mortality.

According to the literature on post-endoscopic retrograde cholangiopancreatography pancreatitis (ERCP; American Society of Gastrointestinal Endoscopy (ASGE) guidelines), post-DBE pancreatitis was defined as newly developed abdominal pain after a DBE-procedure, requiring at least 2 d of unplanned hospitalization, with a serum amylase $\geqslant$ 3 as the upper limit 24 h after the procedure[21]. According to these guidelines, the severity of the disease was classified as follows: mild pancreatitis requiring 2-3 d of hospitalization; moderate pancreatitis requiring 4-10 d of hospitalization; severe pancreatitis requiring 10 or more days of hospitalization, and/or the occurrence of pseudocysts and/or the need for surgery.

Statistical analysis

The different parameters were compared with t-tests. Results were considered significant if P values were < 0.05.

RESULTS

In a total of 603 DBE procedures, six patients (1%) developed post-DBE pancreatitis. Case summaries are presented in Table 1. Fifty percent of the patients ($n = 3$) was male. The mean age was 47.3 years (range 23-66). DBE was performed for the following indications: iron deficiency anemia ($n = 3$), Crohn's disease ($n = 1$), malabsorption ($n = 1$) and small bowel stenosis after bowel surgery ($n = 1$). The route of the procedure was oral in all 6 patients. In 67% ($n = 4$) the P-type endoscope (Fujinon EN-450P5) was used. The mean duration of the procedures was 108 min (80-148), the mean depth of insertion was 337 cm (250-420). In one patient, a polypectomy was performed.

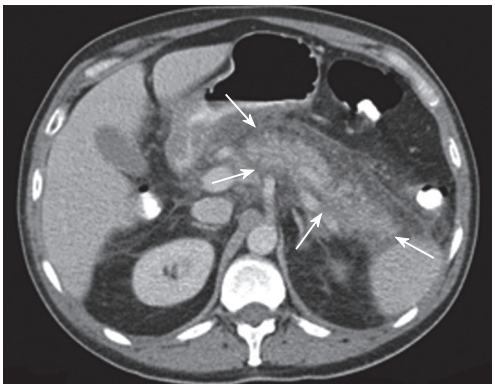

Figure 1 A CT image of a 23-year old female, who developed post-DBE pancreatitis (case 5), showing an inflamed body-tail region, with edema and fatty infiltration (arrows).

All six patients developed clinical signs of pancreatitis within 6 h after the procedure. A scoring system to record the intensity of the pain in the patients was not maintained. The mean duration of admission was 11.2 d (2-22). The mean peak amylase and lipase levels were respectively 692 U/L (321-1395) and 1180 U/L (120-3660). Two patients developed moderately severe pancreatitis (case 1 and 6), and four had severe pancreatitis (case 2-5). In four patients, CT-scan was performed. Two of these patients showed inflammatory signs of the body-tail region of the pancreas with edema and fatty infiltration. One patient had pancreatitis in the tail of the pancreas and developed a pseudocyst during admission (case 3). In one patient, the whole pancreas was involved (Figures 1 and 2). Two patients had moderate clinical and laboratory signs of disease and could be discharged within a few days of admission. Therefore, CT imaging was not performed. One patient underwent laparotomy because postprocedural abdominal pain was suspected to be caused by perforation.

Table 2 Procedural characteristics

	Pancreatitis (n = 6)		No Pancreatitis (n = 597)		
Age (yr)	47.3	(23-66)	59.3	(12-94)	
Gender					
Male	3	(50%)	301	51.60%	
Female	3	(50%)	292	48.40%	
Route					
Oral	6	100%	435	73%	
Anal	0		162	26%	
Endoscope					
P-type	4	67%			
T-type	2	33%			
Duration (min)	108	(80-148)	105	(30-240)	
Insertion depth (cm)	337	(250-420)	270	(25-640)	P = 0.09
Midazolam (mg)	13.3	(10-15)	10	(2.5-25)	
Fentanyl (mg)	0.1	(0.05-0.15)	0.075	(0.025-0.2)	

However, during surgery, pancreatitis was diagnosed and no perforation was present. The other five patients were treated conservatively. There was no mortality in our series.

Table 2 shows clinical and procedural characteristics of the patients that developed acute pancreatitis in comparison with the patients that did not develop pancreatitis. All patients who developed post-DBE pancreatitis had undergone antegrade DBE. Depth of insertion was higher in the patients developing pancreatitis than in those who did not, although this difference did not reach statistical significance.

DISCUSSION

In our series, post-DBE pancreatitis developed after six of 603 procedures (1%). This rate is higher than previously reported in the literature. A study by Heine *et al*, in which our center participated, identified 3 cases of post-DBE pancreatitis in a total of 275 procedures[22]. Two of those patients are also described in the present study. In a prospective multicenter study by Ell and colleagues, 100 patients were included and no pancreatitis occurred[23]. In a retrospective analysis of 378 DBE procedures by Zhong *et al* 2 patients suffered an unspecified rise of serum amylase in conjunction with abdominal pain, which resolved after conservative measures[24]. Whether these patients required hospitalization is not stated. The multicenter questionnaire survey by Mensink *et al* identified 6 cases of pancreatitis in 1728 diagnostic procedures (0.3%) and 1 case of pancreatitis after DBE-assisted ERCP in a patient with a Roux-en-Y reconstruction[16]. Several possibilities should be considered when trying to explain the difference between post-DBE pancreatitis rates in the present study and the previously published studies. First of all, the method of insertion and withdrawal might be a factor in the origin of post-DBE pancreatitis. However, we are not aware of any differences in technique between our center and other centers, while there is close contact and exchange of knowledge with many DBE-performing centers inside and outside The Netherlands. The fact that trained fellows under close supervision regularly perform DBE in our center, and that pancreatitis could be a consequence of relatively inexperienced endoscopists, is also an unlikely explanation since this would most certainly have been reflected in total procedure time, which was almost the same in patients developing pancreatitis and those who did not. Additionally, post-DBE pancreatitis did not occur more frequently after procedures performed by fellows. A third possible explanation could be an underestimation of post-DBE pancreatitis in previously published studies, as is evident in the study by Zhong, which reports two patients with abdominal pain and increased serum amylases without labeling these cases as pancreatitis[24]. Especially, retrospective questionnaire based surveys might be at risk from report or inclusion bias. Differences in definitions of post-procedural complications offer a likely explanation for the difference in reported post-DBE pancreatitis. Since we conducted a review of a recorded database prospectively, using predefined definitions of pancreatitis and its severity, the chance of report or inclusion bias seems lessened.

Figure 2 A transversal CT-image of a 54-year old male, who developed post-DBE pancreatitis (case 4), showing edema and fatty infiltration around the pancreas.

The pathogenesis of post-DBE pancreatitis is not known. Honda *et al* found asymptomatic hyperamylasemia in 5 of 13 patients after antegrade DBE. One of 13 patients developed pancreatitis[25]. Several mechanisms could be responsible for the development of hyperamylasemia or pancreatitis. First, the repetitive mechanical strain on the pancreas, by inserting the endoscope/overtube, by inflated balloons or by stretching movements, could induce pancreatitis, especially by traction at the ligament of Treitz. This hypothesis is supported by the finding that in most cases in which an early CT scan was performed, pancreatitis was located in the tail or body/tail region of the pancreas. As in the study by Mensink *et al*, no significant association between the use of the T-endoscope and the occurrence of pancreatitis was present. This strain-hypothesis is also suggested by our finding that insertion depth (and therefore the number of advancing and stretching movements of both endoscope and overtube) seems higher in the pancreatitis group (P = 0.9, Table 2). A second explanation could be duodenal hypertension due to air trapping between the overtube balloon and the pylorus, which in theory could interfere with pancreatic drainage. In fact, a closed duodenal loop is an established animal model for acute pancreatitis[26-29]. As far as we know, data that could prove this theory do not exist and our finding that procedure time (and therefore the time the supposed duodenal hypertension would have existed) was not different between the groups is not supportive of this theory. Impaired pancreatic drainage

due to temporary obstruction of the papilla could not have resulted in pancreatitis in our series, since we inflate the balloons after Treitz's ligament has been passed.

To our knowledge no cases of pancreatitis have been reported after retrograde DBE-procedures, therefore it is highly unlikely that medications used for sedation could have played an important role. We also noted that all the females that developed post-DBE pancreatitis were premenopausal. However, this series is too small to identify patient-related risk factors. It is therefore unknown whether patient characteristics associated with post-ERCP pancreatitis (like sphincter of Oddi dysfunction, young age or female gender) are also associated with the occurrence of post-DBE pancreatitis[30]. Larger, prospective multicenter studies are needed to investigate operator-dependent factors and to identify additional patient-related risk factors that could explain why some patients develop only transient hyperamylasemia and others severe pancreatitis. Such studies should include early pancreatic imaging. Anatomical and imaging studies on the effect of DBE on the position of the pancreas and proximal duodenum are necessary to investigate the validity of the pancreatic strain and the duodenal hypertension hypotheses.

Although post-DBE pancreatitis is relatively uncommon, it is the most important complication of antegrade, diagnostic DBE. It is of major importance to consider pancreatitis as a cause of post procedural abdominal pain, to avoid unnecessary surgical exploration as has been the case in one of our patients. Abdominal pain after DBE warrants additional investigation. Since hyperamylasemia is quite common after DBE and not discriminative for DBE pancreatitis, the diagnosis should be based on clinical findings and or radiological imaging techniques.

COMMENTS

Background

Double balloon endoscopy (DBE) was introduced by Yamamoto in 2001. This endoscopic technique allows (intervention) endoscopy of the small bowel. Post DBE pancreatitis is a well known complication after antegrade DBE.

Research frontiers

This article describes the cases of post DBE pancreatitis in the largest single center series of DBE procedures to date.

Related publications

Honda *et al* showed that an asymptomatic rise of serum amylase and lipase levels after antegrade DBE occurs frequently. Nevertheless, previous studies indicate that post DBE pancreatitis occurs seldom.

Innovations and breakthroughs

The pathophysiology behind the occurrence of post DBE pancreatitis largely remains unknown. Only a few reports on this subject have been published. Studies to determine the pathogenesis are currently performed in our center.

Applications

The investigation post DBE pancreatitis will help us to determine the pathogenesis of this complication, to define high risk groups, and thus to prevent post DBE pancreatitis.

Terminology

DBE is a endoscopic technique that allows access to the complete small intestine for diagnostic and therapeutics procedures.

Peer review

It is a good manuscript reporting six cases of DBE-associated pancreatitis.

Abstract

AIM: To assess the outcome of patients with acute necrotizing pancreatitis treated by percutaneous drainage with special focus on the influence of drainage size and number.

METHODS: We performed a retrospective analysis of 80 patients with acute pancreatitis requiring percutaneous drainage therapy for infected necroses. Endpoints were mortality and length of hospital stay. The influence of drainage characteristics such as the median drainage size, the largest drainage size per patient and the total drainage plane per patient on patient outcome was evaluated.

RESULTS: Total hospital survival was 66%. Thirty-four patients out of all 80 patients (43%) survived acute necrotizing pancreatitis with percutaneous drainage therapy only. Eighteen patients out of all 80 patients needed additional percutaneous necrosectomy (23%). Ten out of these patients required surgical necrosectomy in addition, 6 patients received open necrosectomy without prior percutaneous necrosectomy. Elective surgery was performed in 3 patients receiving cholecystectomy and one patient receiving resection of the parathyroid gland. The number of drainages ranged from one to fourteen per patient. The drainage diameter ranged from 8 French catheters to 24 French catheters. The median drainage size as well as the largest drainage size used per patient and the total drainage area used per patient did not show statistically significant influence on mortality.

CONCLUSION: Percutaneous drainage therapy is an effective tool for treatment of necrotizing pancreatitis. Large bore drainages did not prove to be more effective in controlling the septic focus.

INTRODUCTION

The course of acute pancreatitis ranges from a mild transitory edematous to a severe necrotizing form. Necrotizing pancreatitis occurs in about 20% of all patients suffering from acute pancreatitis[1]. If infection of the necrotic tissue occurs mortality rates of up to 50% are reported with sepsis and multiorgan failure as most frequent causes[2-5]. It is generally accepted that in infected necrotizing pancreatitis the infected non-vital solid tissue has to be removed in order to control the sepsis. The standard treatment has traditionally been surgery[5,6]. By using modern surgical techniques like open packing, repeated laparatomies, closed packing or closed continuous lavage mortality rates could be decreased to 20%-40%[7-12]. However, these techniques are associated with a considerable surgical trauma which often causes escalation of multiorgan failure and sepsis[7,13]. Moreover, total anaesthesia is mandatory. Thus, in the last decade minimal invasive treatment regimes and in particular percutaneous drainage therapy were included in the management of infected necrotizing pancreatitis.

Ultrasound (US) or computed tomography (CT) guided placement of drainages is reported to be effective in up to 90% for drainage of fluid collections or abscesses with purely liquid content[14]. However, the success rates

for drainage of contained fluid collections in necrotizing pancreatitis are less convincing ranging between 26% and 50%[15,16], with a subsequent frequent need for further surgery. The presumed reason is that infected fluid collections/abscesses in necrotizing pancreatitis are often not completely liquid but contain solid debris. The value of drainage therapy for removal of solid debris is equivocal. Usage of large bore catheters and placement of several drainages is generally considered to be more effective. This hypothesis, however, has not yet been evaluated systematically.

The aim of this retrospective study was to evaluate if patient outcome in infected necrotizing pancreatitis correlates with the number and size of percutaneously placed drainages.

MATERIALS AND METHODS

Patient recruitment and review of data

This is a retrospective study performed at a university hospital. By searching the radiological, surgical and internal medicine databases all patients with the diagnosis acute pancreatitis treated with drainages between 1992 and 2004 were identified. Demographic (age, sex), clinical (length of primary hospital stay, eventual second hospital stay, admittance to intensive care unit, etiology of pancreatitis, diagnostic and conservative therapeutic approaches), laboratory data and characteristics of surgical procedures were collected by reviewing patient charts and surgical reports.

Number of CTs performed per patient and characteristics of percutaneous interventional therapy were collected by reviewing all radiological reports. In particular, number of drainages per patient, date of drainage placement, size of each drainage in French, largest drainage per patient according to French number, estimate of draining lumen of each drainage (by calculating the axial plane of each drainage), and length of drainage placement in days were determined. Moreover, the cumulative draining area (by adding the draining lumina of all drainages per patient), the average draining area (by calculating the average of the draining lumina of all drainages per patient), the cumulative diameter (by adding the diameter according to French number of all drainages per patient), and the average diameter (by calculating the average of the diameter according to French number of all drainages per patient) were calculated.

All drainages had been placed under CT guidance using Seldinger technique. The number and the size of catheters were determined individually for each patient by the intensive care unit (ICU) team and the interventional radiologist. Clinical considerations and the size and location of necroses as well as the suspected amount of fluid and debris (based on CT findings) guided this decision.

For patients with ongoing sepsis and solid tissue within the fluid collections, active necrosectomy was performed. This technique has been described in detail elsewhere[16-18]. Briefly, under local anaesthesia the drainage was replaced by a 24F-30F peel away sheath. Under fluoroscopic and/or endoscopic guidance the solid tissue was fragmented and extracted through the sheath. For this, snare catheters, dormia baskets, forceps and brisk flushing/aspiration were applied.

For patients receiving intensive care treatment, the APACHE Ⅱ score, SAPS Ⅱ, and Ranson score were determined by reviewing the laboratory data and the ICU flow charts.

The Balthazar score and computed tomography severity index (CTSI) were determined by retrospectively reviewing the CT examination at the time of first drainage placement[19]. Radiological analysis was done by a board certified radiologist with 6 years of experience.

Endpoints for patient outcome during hospital stay were defined as patient death and length of hospital and/or ICU stay. All patients were observed until d 250 or censored at the last day of observation.

A telephone interview was performed to investigate long term outcome parameters. The questionnaire included life quality parameters such as ongoing symptoms of pancreatitis after hospital discharge (abdominal pain, diarrhea, intolerance of fat, weight loss), development of exocrine or endocrine dysfunctions, repeated hospital stays and need for further surgery.

Statistical analysis

Parameters assessing drainage characteristics and clinical scores (for ICU patients) were correlated with mortality using logistic regression. Drainage characteristics and clinical scores (for ICU patients) were correlated with length of hospital stay and ICU stay using a Cox proportional hazard model in a univariate model. Variables with a significant influence on the hazard ratio were then included in a multivariate model. The statistical analysis was made with the SPSS 12.0 statistical software (SPSS inc., Chicago, IL). Values are given as total numbers, median with range or as percentages where necessary. A P-value $\leqslant 0.05$ was considered statistically significant.

RESULTS

Patient population

Eighty patients fulfilled the inclusion criteria and were included in the study. The demographic, clinical, laboratory and interventional/surgical data are shown in Table 1.

Clinical and laboratory data

All 80 patients received antibiotic treatment over a median of 44 d with a range from 2 d to 205 d. Antimycotic treatment was established in 43 patients (54%). The diagnosis of infection of the necrotic tissue was based on the examination of aspirated material with Gram´s stain, culture or both. Fine needle aspiration was not routinely performed. Thus, the material which was obtained during the placement of the first drainage was evaluated. Fifty-two patients (65%) showed positive microbiological results. The other 35% might have shown false negative results due to prior initiation of antibiotic therapy.

Intensive care treatment was necessary in 65 out of 80 patients (81%); nine patients required a second ICU

stay later on. Mechanical ventilation was necessary in 50 patients (63%), renal failure with the need of renal replacement therapy occurred in 23 patients (29%).

Radiological data

Each patient received a median of six CTs ranging from 1 to 23, which were all contrast enhanced. The CTSI of all 80 patients was in median 6 ranging from 4 to 10, the Balthazar score was in median 4, ranging from 3 to 4.

Necrosis of the pancreas was diagnosed in 73 patients (91%) on the basis of contrast enhanced CT findings. The location of necrosis was only in the head of the pancreas in 13 patients, in the head and the body in five patients, in the head and the tail in four patients, in the body in three patients, in the body and tail in 10 patients, only in the tail in six patients and involving the whole pancreas in 32 patients. Seven patients did not show necrosis of the pancreas itself, however, extensive peripancreatic fluid collections with presumed necrosis of the peripancreatic fat was present.

Characteristics of drainage therapy

Different catheter types were used (Thal-Quick, Cook, Europe; van Sonnenberg, Peter Pflugbeil, Zorneding, Germany; APD and Flexima, Boston Scientific, Natick, USA). Up to 14 catheters per patient were placed, in median two catheters per patient. Percutaneous catheter drainage was performed on median d 3.5 after admission (range 1 d to 40 d), but with 71 patients being transferred from peripheral hospitals and median hospitalisation of 7 d before (complete data of prior hospital stays was available in 54 out of 71 patients). Drainages remained in situ for a median of 36.5 d (range 1 d to 260 d). The drainage size ranged from 8 French to 24 French catheters. The median drainage plane was 16.9 mm^2, the median cumulative drainage plane was 37.0 mm^2 per patient. The median diameter was 14.0 mm, the median cumulative diameter was 30.0 mm per patient.

No acute complication (like bleeding, bowel perforation, accidental puncture of liver, spleen or kidney) related to catheter placement occurred. However, in 23 patients (29%) the development of fistulas in the pathway was observed later on.

Catheters were exchanged in median two times per placed catheter (range from 1 to 9). Catheter exchange was either done because of drainage blockage or to insert a larger drainage for presumed better drainage of necrotic tissue.

In 18 of 80 patients (23%) an active percutaneous necrosectomy was performed. Ten patients out of these required surgical necrosectomy later on. Six patients underwent surgical necrosectomy without prior percutaneous necrosectomy. Elective surgery was performed in 4 patients (cholecystectomy in three patients and adenomectomy of the parathyroid gland for primary hyperparathyreoidism in 1 patient) during the same hospital stay (Figure 1).

Endpoints

Length of hospital stay was in median 51 d with a range from 3 d to 241 d. A second hospital stay was necessary in 5 patients (6%). The length of stay in the ICU ranged from 2 d to 104 d, in median 22 d. The overall mortality was 34% (27 of 80 patients).

The correlations of the radiological and clinical scores (CTSI, APACHE Ⅱ, SAPS Ⅱ), clinical treatment modalities (invasive ventilation and renal replacement therapy) as well as interventional treatment modalities (number of drainages, median drainage size, largest drainage size and total drainage lumen) with mortality

Repeated development of pancreatitis	3	10.3
Further hospitalisations	8	27.6
Surgery after discharge	7	24.1
Death after discharge	4	13.8

are given in a cox proportional hazard model for overall mortality using uni- and multivariate analysis (Table 2). Significant risk factors for mortality in univariate analysis were the need for mechanical ventilation, renal replacement therapy, the APACHE Ⅱ score and the SAPS Ⅱ score. The total drainage plane showed borderline significance with a *P*-value of 0.052. The median drainage size, the largest drainage size used per patient and the CTSI were not significantly correlated with mortality. In the multivariate model the CTSI was as the only not significant variable included adjusting for the extent of necrosis. Renal replacement therapy and the need for ventilation support were the only parameters which remained significant in the multivariate model.

Long-term outcome

In 29 out of the 53 surviving patients (55%) long-term outcome parameters could be collected. Data are presented in Table 3. Hereby endocrine pancreatic dysfunction is the most frequent factor affecting life quality (35%), followed by diarrhea, weight loss and exocrine pancreatic dysfunction with the need of enzyme-substitution in 24%; 10% reported on repeated pancreatitis episodes; 28% on further hospital stays for related symptoms.

DISCUSSION

Percutaneous drainage is the therapy of choice for treating fluid collections. The success rates for drainage of fluid collections, pseudocysts or simple abscesses in variable sites are reported to be around 90%[20-24]. In contrast, reports on percutaneous drainage in patients with acute necrotizing pancreatitis were overall disappointing showing drainage therapy to be often inefficient with subsequent need for open surgery[15,25]. The presumed reason for this discrepancy is that pancreatic/peripancreatic necroses and pancreatic abscesses contain solid, avital debris. However, some studies reported significantly better success rates treating necrotizing pancreatitis by drainage therapy only[15,26,27]. A common feature of these studies was that large bore catheters (up to 28F) were used. The rationale for this strategy was the hypothesis that large bore catheters might be more effective for mobilizing solid tissue. However, the drawback of using large catheters is the more traumatic approach with the risk of bleeding and organ injury. In the present study, we evaluated the effect of drainage characteristics on the outcome of patients with necrotizing pancreatitis.

The 80 patients included in this study all suffered from acute, necrotizing pancreatitis. The diagnosis was based on the results of contrast-enhanced CT as well as clinical and laboratory findings. Seventy-three patients presented with necrosis of the pancreatic parenchyma itself, 7 patients demonstrated presumed necrosis of peripancreatic tissue. No patients with pseudocysts were included. Fifty-two patients (65%) had microbiologically proven infection of the necrotic tissue. Although for 28 patients (35%) culture was negative, interventional therapy was initiated because the clinical, laboratory and radiological findings strongly suggested infection.

The gold standard for the treatment of infected, necrotizing pancreatitis still is open surgery[28]. However, minimal-invasive interventional approaches continue to gain importance. In the present study, 43% of patients were cured by percutaneous drainage and conservative treatment only. When including those patients who additionally were treated with active, percutaneous necrosectomy without the need for open surgery the cure rate increased to 53%. Six surviving patients (8%) required surgical necrosectomy because percutaneous therapy failed in controlling sepsis. The mortality rate in this study was 34% which is within the expected range of 20%-40%[10-12] reported in the literature. Considering that the study population represented a seriously ill subset of patients as evidenced by high clinical and radiological scores, a mortality rate of 34% is an acceptable outcome.

The time of placement of the first drainage after hospital admission with a median of 3.5 d seems quite short because infection of necroses occur usually within 7 d to 10 d after the onset of symptoms[2,28]. However, it has to be considered, that 71 out of 80 patients (89%) were transferred from other hospitals with median hospitals stays of 7 d before the transfer to the university hospital. Due to the retrospective nature of this study we were able to assess the time of hospital admission, which naturally was not always identical with the time of symptom onset.

As opposed to the APACHE Ⅱ and SAPS Ⅱ scores the CTSI score did not show a good correlation with patient outcome in our study. This is discrepant to results published by Balthazar *et al* who found the mortality and morbidity to be closely correlated to the CTSI[19]. However, Balthazar *et al* studied a patient population covering the whole range of possible CTSI values whereas our population was seriously ill with CTSI values of at least 4. Presumably, the CTSI is not a good parameter to predict outcome in this subset of patients.

No significant correlation between drainage size/number and outcome parameters was found in this study. Rather than abolishing the concept of using large bore drainages we think that our results reflect the fact that the outcome of patients suffering from infected, necrotizing pancreatitis is influenced by a multitude of factors. 81% of the patients in this study required ICU admission with the need for mechanical ventilation and renal replacement therapy in many cases. It seems to be difficult to isolate one single parameter which might modify overall prognosis in such a complex study group. An aggravating factor was the retrospective nature of this study. Different lavage schemes and various types of drainages were used over the years and the size of drainages used is influenced by a multitude of factors. Especially the latter fact is important since the inner diameter of the adapter and of the drainage itself is different for different companies despite the identical outer diameter given in French. Moreover, the length of the drainage is inversely correlated with the flow. A prospective study seems to be necessary to evaluate the impact of drainage characteristics. However, it is questionable if such a study is feasible because large study groups are necessary to provide adequate power.

In conclusion, percutaneous drainage and minimal invasive necrosectomy are efficient tools for treatment of necrotizing pancreatitis. Large bore drainages did not prove to be more effective in controlling the septic focus. However, it seems to be difficult to determine a single prognostic parameter in these multimorbid patients.

COMMENTS

Background

Percutaneous, interventional treatment modalities are safe and efficient tools in the therapy of patients with necrotizing pancreatitis. Special therapy details, like the optimal drainage size, have not yet been evaluated.

Research frontiers

Whereas surgical debridement is often associated with a considerable trauma and may cause escalation of multiorgan failure and sepsis, minimal invasive methods are a safe and effective tool to bridge time to surgery or avoid it at all.

Innovations and breakthroughs

In this article we analyze if drainage size affects outcome in 80 patients with necrotizing pancreatitis.

Applications

Large bore drainages (≥ 16F) did not prove to be more effective in controlling the septic focus than smaller ones (< 16F).

Terminology

Interventional methods in our article include percutaneous, radiologically assisted drainage therapy.

Peer review

This is a well written manuscript. Publication is recommended.

Abstract

AIM: To investigate whether peripheral corticotropin releasing hormone (CRH), which is up-regulated in intestinal inflammation, mediates the post-inflammatory visceral hypersensitivity in a rat model of colitis.

METHODS: We measured mucosal myeloperoxidase (MPO) activity as a marker of inflammation, plasma CRH level, and abdominal withdrawal reflex (AWR) to colorectal distension as a visceral nociceptive response at 2, 7 and 14 d after the induction of colitis with 4% acetic acid.

RESULTS: Colonic inflammation, quantified by MPO activity, significantly increased on d 2 and subsided thereafter, which indicated a resolution of inflammation within 7 d. On the contrary, plasma CRH level and AWR score were increased on d 2, remained high on d 7, and returned to control level on d 14. Intraperitoneal injection of a CRH antagonist, astressin (30 μg/kg), significantly attenuated the post-inflammatory visceral hypersensitivity on d 7. Furthermore, intraperitoneal administration of CRH (3 and 10 μg/kg) mimicked the post-inflammatory visceral hypersensitivity in naive rats.

CONCLUSION: These results suggest that increased peripheral CRH mediates the enhanced visceral nociception in rats recovered from experimental colitis.

INTRODUCTION

Visceral hypersensitivity, which refers to a lowered threshold for visceral pain/discomfort elicited by intraluminal mechanical/chemical stimuli, is a hallmark symptom of irritable bowel syndrome (IBS)[1,2]. IBS is a common functional gastrointestinal disorder that has a great impact on quality of life. It is thought that previous episodes of intestinal inflammation predispose to IBS as intestinal inflammation induces profound changes that persist even after the inflammation subsides[3]. Indeed, patients with ulcerative colitis in remission often express IBS-like symptoms[4], and animals that have recovered from experimental enteritis show visceral hypersensitivity to luminal distension[5,6]. Nevertheless, it has still not been completely elucidated what causes this IBS-like, post-inflammatory visceral hypersensitivity.

Increasing evidence suggests that peripheral corticotropin releasing hormone (CRH) plays an important role in intestinal inflammation. Kawahito *et al*[7] have reported a significant increase in the number of CRH immunoreactive macrophages and enterochromaffin cells in the colonic mucosa of patients with inflammatory bowel disease. In a rat model of chronic granulomatous enterocolitis, both mRNA and protein expression of CRH was found to be increased in cecal inflammatory cells, mesenchymal cells, and myenteric plexi[8]. More recently, an increase in CRH and its receptors was reported in a mouse ileitis model injected with *Clostridium difficile* toxin A[9]. In this model, peripheral injection of CRH receptor antagonists was able to significantly reduce intestinal secretion and inflammation. In accordance with this, genetically CRH-deficient mice showed diminished intestinal responses to *C. difficile* toxin A[10], and RNA interference to silence

CRH expression in the ileum ablated the toxin A-induced inflammatory responses, such as epithelial damage, mucosal edema, and neutrophil infiltration[11]. Collectively, these results indicate that peripheral CRH acts as a pro-inflammatory mediator in intestinal inflammation.

Considering the involvement of peripheral CRH in intestinal inflammation, together with the putative role of intestinal inflammation in the development of visceral hypersensitivity, we hypothesized that increased peripheral CRH might be involved in post-inflammatory visceral hypersensitivity. We tested this hypothesis using a rat model that shows elevated nociceptive responses to luminal distension 7 d after acetic acid-induced colitis without histological and biochemical signs of overt gut inflammation[12]. In this rat model, we found that high levels of peripheral CRH were related to post-inflammatory visceral hypersensitivity.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats, weighing 270-310 g, were housed in a colony room maintained under a 12-h light/dark cycle with a room temperature of 22 ± 1℃ and humidity of 65%-70%. Water and food were available *ad libitum*. Before the intracolonic instillation of chemicals, rats were fasted for 18 h. Colitis was induced by instillation of 1 mL 4% acetic acid into the colon. After 30 s, saline (1 mL) was instilled to flush the lumen. Control animals received saline only (1 + 1 mL). All experimental protocols in this study were reviewed and approved by the Animal Care and Use Committee of Seoul National University.

Myeloperoxidase (MPO) activity

A segment of distal colon (for MPO activity assay) and trunk blood (for plasma CRH level assay) were collected from rats sacrificed by cervical dislocation, following anesthesia with tiletamine/zolazepam (50 mg/kg) between 2:00 and 4:00 pm. The animals had not undergone any treatment (e.g. colorectal distension) other than intracolonic saline or acetic acid instillation. The mucosal layer of the distal colon was stripped off from the segment and minced in 1 mL 50 mmol/L potassium phosphate buffer (pH 6.0) that contained 14 mmol/L hexadecyltrim ethylammonium bromide (Sigma-Aldrich, St. Louis, MO, USA). After homogenization and sonication, the lysates were frozen and thawed three times, then centrifuged for 2 min under 4℃ at 15000 × *g*. Aliquots of the supernatants were mixed with o-dianisidine-HCl (Sigma-Aldrich) and 0.0005% H_2O_2. MPO activity was calculated from the rate of absorbance change, during 1 min, at 460 nm using the extinction coefficient for oxidized o-dianisidine (1.13×10^4/mol/L/cm) and expressed as units/mg of tissue protein quantified by the Bradford method. The enzyme unit was defined as the conversion of 1 μmol of H_2O_2 per min at 25℃.

Plasma CRH level

Blood samples collected in ice-cold EDTA-coated tubes were centrifuged at 1600 × *g* for 15 min at 4℃. Plasma obtained after centrifugation was transferred into sterile microcentrifuge tubes and stored at -70℃ until analyzed. As it is known that the CRH-binding protein interferes with plasma CRH level estimation, we extracted CRH from plasma using ice-cold methanol[13]. Specifically, plasma samples were mixed and incubated with methanol for 15 min at 4℃, and then centrifuged at 2000 × *g* for 20 min at 4℃. The supernatants were transferred to another set of tubes. The pellets were washed with 0.2 mL ice-cold methanol and centrifuged at 2000 × *g* for 15 min at 4℃. The supernatants were pooled and dried by blowing heated air. The extracts were then reconstituted with assay buffer (one-third of original plasma volume) included in the CRH enzyme immunoassay kit (Phoenix Pharmaceuticals, Belmont, CA, USA). Each sample was processed in duplicate and the final data were expressed as pg CRH/mL plasma.

Visceral nociceptive behavior to colorectal distension

Eighteen hour-fasted rats were lightly anesthetized with ether, and a disposable silicon balloon urethral catheter was carefully inserted intra-anally until the tip of the balloon was 4 cm proximal to the anus. While animals were fully awake, ascending-limits phasic distensions (0.2, 0.4, 0.6, 0.8 and 1 mL) were applied for 30 s every 4 min, and the distension-induced abdominal withdrawal reflex (AWR) was scored by an experimenter who was blind to the treatments (0, no behavioral response to distension; 1, brief head movements followed by immobility; 2, contraction of abdominal muscle without lifting of abdomen; 3, lifting of abdomen; and 4, body arching and lifting of pelvic structure)[14]. The overall difference in the visceral nociceptive responses between groups was determined by taking the area under the curve (AUC) calculated as the sum of the responses plotted against the distension volume using the trapezoidal rule.

Chemicals

Astressin (Bachem, Budendorf, Switzerland) and rat/human CRH (American Peptide, Sunnyvale, CA, USA) were dissolved in sterilized saline. Stock aliquots of these peptides were kept at -70℃, and diluted to a final concentration before use.

Statistical analysis

Data are presented as mean ± SE, with n the number of animals. The difference between two groups was statistically analyzed using the Mann-Whitney *U* test (MWU test) at the $P < 0.05$ significance level. Comparisons between three or more groups were performed with Kruskal-Wallis test (KW test), followed by Dunnett's procedure.

RESULTS

To quantify the extent of inflammation, we measured the MPO activity from colonic mucosa. As shown in Figure 1A, MPO activity was dramatically increased in rats at 2 d after induction of colitis (21.0 ± 3.4 *vs* 146.0 ± 45.5 U/mg, $n = 10$ in each group, $P < 0.01$). After 7 d, MPO activity returned to normal (22.0 ± 1.2 U/mg, $n = 10$), indicating a substantial resolution of inflammation. Plasma CRH level was also elevated about twofold in rats at 2 d (333.5 ± 19.7

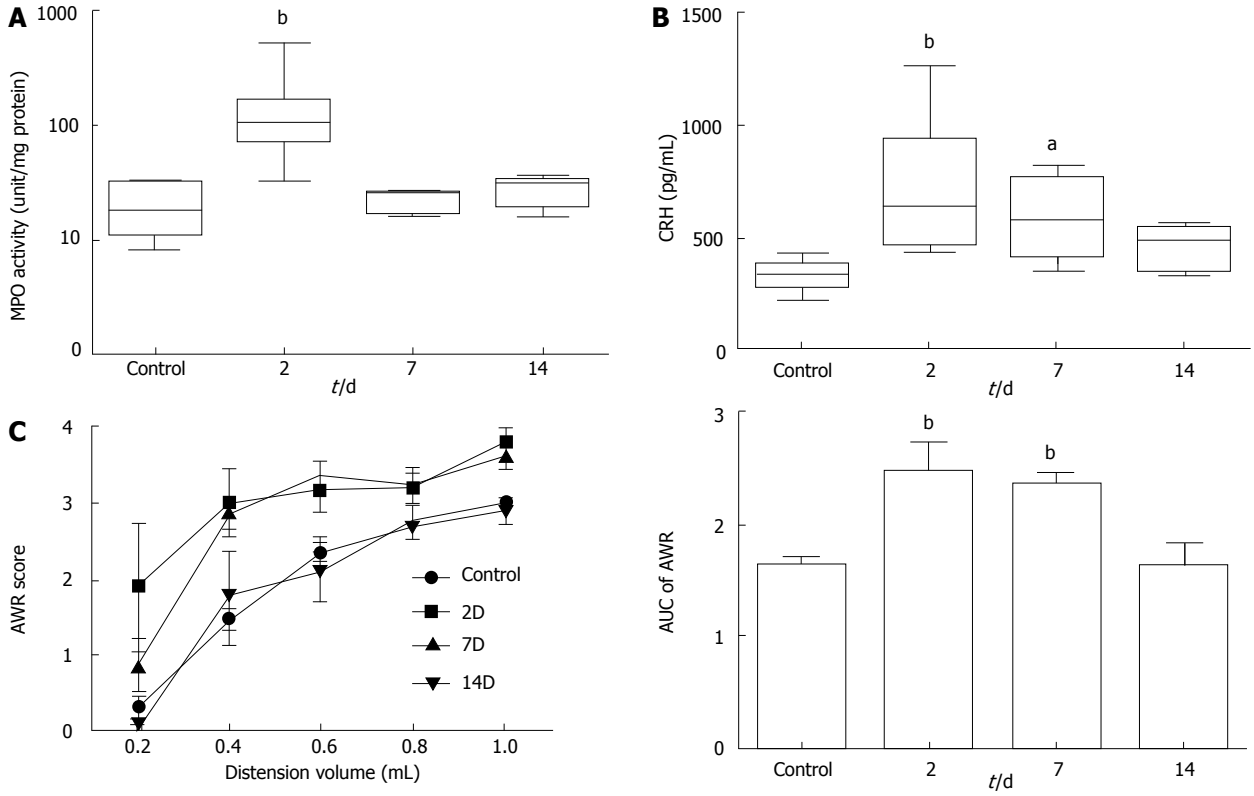

Figure 1 Colitis-induced changes in colonic mucosal MPO activity (**A**), plasma level of CRH (**B**), and visceral nociceptive AWR (**C**). In panel **A** and **B**, the upper and lower whiskers indicate the maximum and minimum values, respectively. Box lines represent the 25th (bottom), 50th (middle) and 75th (top) percentile value; (**C**) The area under the curve (AUC) calculated from the stimulus-response plot is illustrated as a bar graph on the right side. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control by MWU test after KW test ($P < 0.01$).

vs 740.1 ± 88.8 pg/mL, $n = 10$ in each group, $P < 0.01$). Unlike MPO activity, however, the increase in plasma CRH level was maintained in rats at 7 d (587.6 ± 61.1 pg/mL, $n = 8$, $P < 0.05$ from control). It was decreased down to the control level 14 d after induction of colitis (Figure 1B).

Figure 1C demonstrates the response pattern of each experimental group to colorectal distension. We could not detect any difference between the day-matched control rats, thus we pooled the data obtained from control animals. At 2 d after induction of colitis, the animals showed enhanced AWR response, which resulted in a significant increase in the AUC of the stimulus-response plots (1.6 ± 0.1, $n = 15$ *vs* 2.5 ± 0.3, $n = 5$, $P < 0.01$). Rats at 7 d also clearly showed visceral hypersensitivity (2.4 ± 0.1, $n = 8$, $P < 0.01$ from control). Fourteen days after colitis induction, the animals were found to have recovered from the post-inflammatory visceral hypersensitivity.

A similar time course for increased plasma CRH level and enhanced visceral nociceptive behavior, i.e., AWR to colorectal distension, raised the possibility that the sustained increase in peripheral CRH might account for the post-inflammatory visceral hypersensitivity. We further tested this possibility by intraperitoneal administration of CRH receptor antagonist astressin (30 μg/kg), 30 min before colorectal distension. The dose of astressin was chosen based on its ability to prevent defecation and c-Fos expression, which was induced by peripherally administered CRH in other studies[15,16]. Astressin did not change the AWR behavior in control rats (1.7 ± 0.1 *vs* 1.7 ± 0.1, $n = 7$ in each group). However, it significantly decreased the AUC of AWR score in rats at 7 d (2.3 ± 0.2, $n = 7$ *vs* 1.8 ± 0.1, $n = 6$, $P < 0.05$), which indicated that endogenous peripheral CRH mediated the post-inflammatory visceral hypersensitivity (Figure 2A).

We further tested this idea by peripherally injecting exogenous CRH to naïve rats (1, 3 and 10 μg/kg, i.p., $n = 5$ in each group) 30 min before colorectal distension. As shown in Figure 2B, rats that received 3 or 10 μg/kg CRH developed visceral hypersensitivity to colorectal distension. Astressin, administered 15 min before the injection of CRH, showed a tendency to inhibit CRH-induced visceral hypersensitivity in naïve rats (2.3 ± 0.2 *vs* 1.8 ± 0.1, $n = 5$ in each group, $P = 0.07$).

DISCUSSION

The present study provides evidence that suggests increased peripheral CRH underlies the post-inflammatory visceral hypersensitivity. First, visceral hypersensitivity could be observed in rats only at the experimental time points when plasma CRH level was higher than the control level. We found a significant increase in plasma CRH in rats at 2 and 7 d after colitis induction. The level of plasma CRH was back to normal after 14 d. Interestingly, rats at 2 d and 7 d, but not 14 d, showed enhanced AWR behavior in response to colorectal distension. This correlation between sustained CRH increase and visceral hypersensitivity has also been implicated in another rat colitis model. Two different studies have revealed that rats that have recovered from trinitrobenzene sulphonic acid-induced colitis show visceral hypersensitivity to colorectal distension at 28 d after colitis induction[17], and a sustained increase in CRH

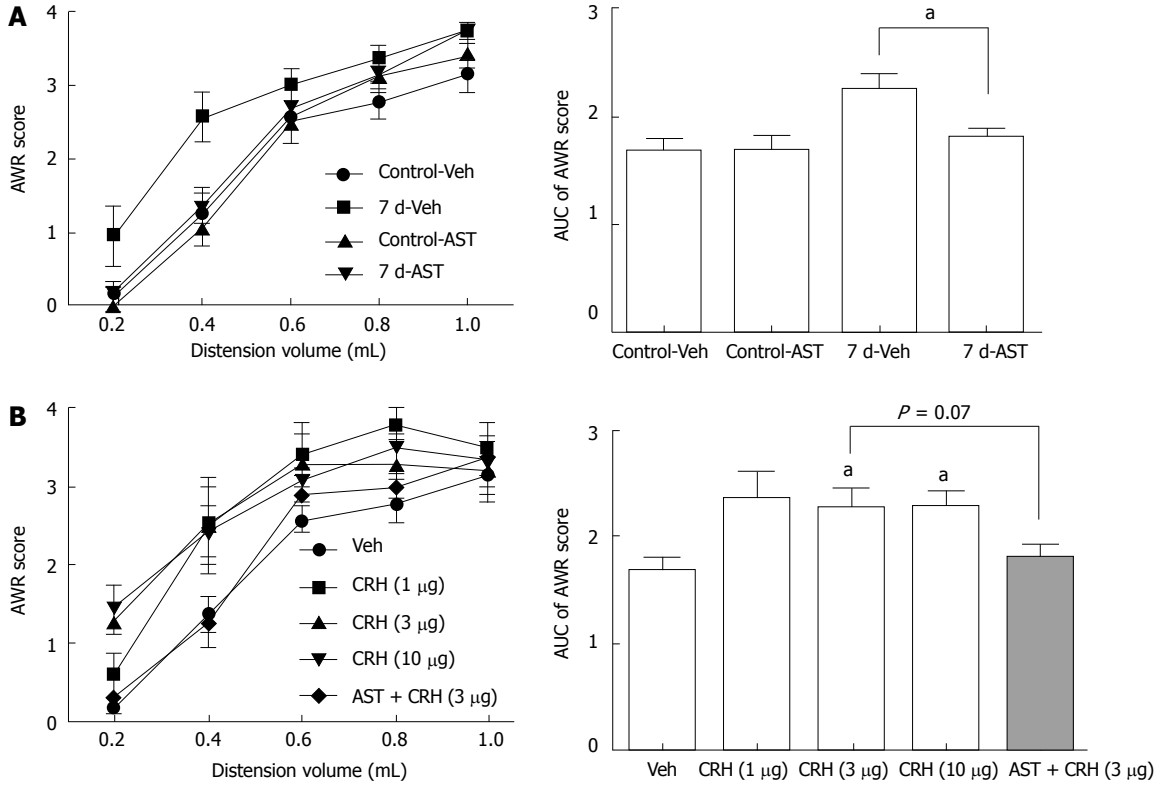

Figure 2 Effect of CRH receptor antagonist astressin (**A**) and CRH (**B**) on the colorectal distension-induced AWR behavior. In each panel, the bar graphs on the right side represent the AUC of the stimulus-response plot. Astressin (AST, 30 μg/kg) and CRH (1, 3 and 10 μg/kg) were administered intraperitoneally. The same amount of saline was given as a vehicle (Veh). $^{a}P < 0.05$ *vs* the paired group in (**A**) or the Veh group in (**B**) by MWU test after KW test ($P < 0.05$).

mRNA expression in hypothalamic paraventricular nucleus at d 30[18]. These two independent reports collectively suggest a role of central CRH in the post-inflammatory visceral hypersensitivity. Considering that the continuous CRH increase in plasma during sustained stress is derived mainly from the hypothalamus[19], it is also likely that the sustained increase in hypothalamic CRH heightens the level of plasma CRH acting peripherally after the resolution of colitis. It will be necessary in future studies to examine the source of increased plasma CRH in our model of post-inflammatory visceral hypersensitivity. Along with the paraventricular nucleus neurons in the hypothalamus, local immune cells resident in the gut may be the sources of the increased CRH in the post-colitis condition.

The second piece of evidence is that astressin, a CRH receptor antagonist that cannot cross the blood-brain barrier, alleviated the visceral hypersensitivity in rats at 7 d when administered intraperitoneally, whereas it had no effect on the AWR behavior in control rats. These results show that endogenous peripheral CRH plays a crucial role only in the hypersensitive visceral nociception in post-colitis condition, but not in normal visceral nociception upon colorectal distension. It is interesting that transgenic mice deficient in CRH1 receptor are less sensitive to colorectal distension than wild-type mice, which indicates that activation of CRH1 receptor is crucial, even in normal visceral nociception in mice[20]. The discrepancy between the results of this study and our current results might be explained by the species difference (mice *vs* rats) and/or the difference in the level of CRH receptor blockade, because knocking out the CRH1 receptor gene eliminates both central and peripheral targets of CRH.

Our third piece of evidence is that peripheral administration of CRH mimicked the post-inflammatory visceral hypersensitivity in naïve rats. How can peripheral CRH render animals more sensitive to colorectal distension? Inflammatory substances are known to sensitize visceral afferents, which results in a decrease in the response threshold, as well as an increase in response magnitude[21]. The sensitization of visceral afferents is regarded as a fundamental mechanism of visceral hypersensitivity[22]. Peripheral CRH has been shown to stimulate mast cells that secrete numerous inflammatory substances including histamine, cytokines, proteases and eicosanoids[23,24]. Interestingly, mast cells have long been implicated to be involved in IBS and visceral hypersensitivity. An increased number of mast cells have been noted in the mucosa of IBS patients[25-28], and the correlation between mast cells and visceral hypersensitivity has been shown in experimental animals. Gue *et al*[29] have reported that the mast-cell stabilizer doxantrazole effectively reduces restraint stress-induced visceral hypersensitivity in rats. McLean *et al*[30] have also reported that, in *Nippostrongylus brasiliensis*-infected rats, an increase in mucosal mast cells was observed at 30 d but not at 90 d post-infection, and that the hypersensitive depressor response to jejunal distension was observed only at 30 d post-infection. In our previous study using the same animal model used in the present study, we found that the number of degranulated mucosal mast cells was higher in rats at 7 d after colitis induction, and that doxantrazole inhibited the post-inflammatory visceral hypersensitivity

in these rats[31]. Therefore, it can be speculated that mast cell activation by peripheral CRH accounts for its ability to induce visceral hypersensitivity. It would be of interest to examine if doxantrazole can prevent the development of visceral hypersensitivity caused by exogenously administered CRH.

Our present findings support the idea that peripheral CRH receptor can be a target for treating IBS symptoms. Recent studies have demonstrated that administration of alpha-helical CRH (9-41), a CRH receptor antagonist, significantly improves gastrointestinal motility, and reduces abdominal pain and anxiety evoked by rectal electrical stimulation in IBS patients[32]. The same antagonist has also been reported to blunt changes in the electroencephalogram (EEG) power spectra upon colonic distention, and almost normalize EEG activity in IBS patients[33]. The effectiveness of CRH receptor antagonist on the IBS-like symptoms, especially visceral hypersensitivity, has also been reported in animal studies. Antalarmin, a CRH1 receptor antagonist, prevents visceral hypersensitivity induced by repeated colorectal distension in female rats[34]. Peripherally administered CRH1 receptor antagonist CP-154 526, which can act centrally by freely crossing the blood-brain barrier, inhibits acute stress-induced visceral hypersensitivity in maternally separated rats[35].

In summary, we found that rats with visceral hypersensitivity after resolution of colitis showed sustained increase in plasma CRH level and that a CRH receptor antagonist inhibited the symptom, which suggests that the increased peripheral CRH mediates the post-inflammatory visceral hypersensitivity, and that CRH receptor can be a target for alleviating this symptom.

COMMENTS

Background

Intestinal inflammation is thought to induce persistent changes in gut function, and indeed, visceral hypersensitivity often develops after intestinal inflammation. However, it is still not well understood what mediates the heightened sensitivity of the gut after resolution of the inflammation.

Research frontiers

IBS is a disorder whose hallmark symptom is visceral hypersensitivity, which is believed to be caused or exacerbated by stress, and corticotropin releasing hormone (CRH) is a pivotal central mediator of the stress response. Therefore, the role of CRH in this bowel disorder is gaining interest. It is also becoming clear that peripheral CRH expression is increased in intestinal inflammation, which raises the possibility that peripheral CRH might be involved in visceral hypersensitivity developed after intestinal inflammation.

Innovations and breakthroughs

Using a rat model of acute colitis as a model of post-inflammatory visceral hypersensitivity, the present study showed the correlation between the level of peripheral CRH and the development of visceral hypersensitivity after experimental colitis. Here, it was also shown that peripheral administration of CRH receptor antagonist and CRH itself could inhibit and mimic the post-inflammatory visceral hypersensitivity, respectively.

Applications

The findings from this study support the idea that peripheral CRH receptor can be a therapeutic target for treating visceral hypersensitivity in IBS.

Terminology

Visceral hypersensitivity refers to increased sensation of stimuli in the gut, which is defined by lowered threshold for visceral pain/discomfort elicited by intraluminal mechanical/chemical stimuli.

Peer review

The design of the controls was rational and reliable. The statistical methods used were appropriate. The results provided sufficient evidence to arrive at the conclusions. The discussion was well organized, and valuable conclusions are provided.

Abstract

AIM: To evaluate the role and our experience of injection sclerotherapy with cow milk in the treatment of rectal prolapse in children.

METHODS: In the last 30 years (1976-2006) we made 100 injections of sclerotherapy with cow milk in 86 children. In this study we included children who failed to respond to conservative treatment and we perform operative treatment.

RESULTS: In our study we included 86 children and in all of the patients we perform cow milk injection sclerotherapy. In 95.3% (82 children) of patients sclerotherapy was successful. In 4 (4.7%) patients we had recurrent rectal prolapse where we performed operative treatment. Below 4 years we had 62 children (72%) and 24 older children (28%). In children who needed operative treatment we performed Thiersch operation and without any complications.

CONCLUSION: Injection sclerotherapy with cow milk for treatment rectal prolapse in children is a simple and effective treatment for rectal prolapse with minimal complications.

INTRODUCTION

Prolapse of the rectum is a herniation of the rectum through the anus[1]. The herniation may be mucosal and may involve only a small ring of mucosa or involve all layers of the rectum (procidentia). These conditions are most common from 3-5 years of age and usually first detected by the childs' parents and usually spontaneously reduce. Parents often provide history of a dark red mass protruding from the childs' anus and the child appears to be pain free[2]. Prolapse of the rectum, which involve only the mucosa, is the least serious form and is most common in the pediatric population[3].

The most common form of rectal prolapse is idiopathic. At this age a child's muscle mass is not well developed and the rectum is loosely adherent to the underlying muscles. These children also spend long periods straining to evacuate their rectum with hips and knees flexed while sitting on a children's "potty"[4]. Children with conditions such as rectal polyps, diarrhea, malnutrition, worms, proctitis, ulcerative colitis congenital megacolon, Ehlers-Danlos syndrome and cystic fibrosis also may have rectal prolapse. Rectal prolapse is common in children with exstrophy of bladder and myelomeningocoele or in similar conditions associated with weakness pelvic musculature or its innervation[5].

Rectal prolapse often occurs with defecation or crying and reduces spontaneously. Failure to reduce may lead to venous stasis, edema and possibly ulcerations. When prolapse is present it is not possible to insert fingers in the space between the prolapsed bowel and anus. The prolapsed bowel may be grasped with lubricated fingers and pushed back in by the parents. If rectal prolapse persists for a long time the bowel becomes edematous and firm steady pressure for several minutes may be necessary to reduce the swelling and allow for reduction[6]. After reduction digital rectal examination is necessary to verify complete reduction. If prolapse immediately recurs, reduction is again necessary and the buttocks strapped together with a single band of adhesive tape for several hours[7].

Most patients with children's rectal prolapse do not require any specific form of treatment; however, it is necessary to prevent excessive straining. Treatment should be directed at dietary correction of constipation, proper toilet training, and at elimination of any underlying disturbance such as parasitic infection, polyps or diarrhea. Oral administration of stool softeners and having the child defecate with feet off the floor may be helpful[8]. Prolonged sessions on the toilet should be discouraged[9]. When parents observe rectal prolapse, reduction of protrusion is aided by pressure with warm compresses and gently push it into the rectum. An immediate replacement of rectal prolapse is necessary to avoid swelling and possible later difficulty in reduction[10]. If edema of the rectum persists, firm steady pressure of the fingertips for several minutes may be necessary to reduce swelling and permit reduction of the prolapse[11]. Surgical procedures may be required for recurrent rectal prolapse refractory to conservative measures[12]. If repetitive attempts at medical therapy have failed and conservative treatments also failed, and the prolapse persists, submucosal injection of sclerosans into the rectal ampula should be done. Children with recurrence after injection of sclerosans require surgical treatment[13].

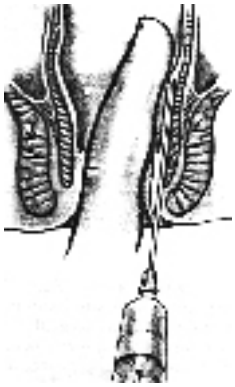

Figure 1 Cow milk is injected along the rectal submucosa.

Sclerotherapy	86
One injection	76
Two injections	6
Three injections	4
Operative	4

MATERIALS AND METHODS

Clinical features

In children with rectal prolapse, before any treatment, we performed sweat chloride test to rule out cystic fibrosis since the incidence of rectal prolapse in patients with cystic fibrosis ranges from 11%-23%[14]. We also obtained patients' stool for ova and parasites. Rectal prolapse has been associated with *Escherichia coli*, antibiotic-associated colitis, *Entamoeba histolytica, Giardia, Salmonella, Shigella,* and *Trichuris species*. Children with recurrent rectal prolapse, with no found underlying causes, should undergo proctosigmoidoscopy to rule out rectal polyps or other rectal lesions[14]. If found, the underlying cause of the prolapse should be treated. Most patients with children's rectal prolapse do not require any specific form of treatment, however, it is necessary to prevent excessive straining. Prolonged sessions on the toilet should be discouraged[15].

In the last 30 years (1976-2006) we had 483 patients with rectal prolapse. Three hundred and ninety seven patients with children's rectal prolapse did not require any specific form of treatment, it is necessary to prevent excessive straining. In this study we included children who failed to respond to conservative treatment and we performed sclerotherapy. In 86 patients repetative attemps at medical therapy failed and conservative treatment also failed and the prolapse persisted; here submucosal injection of sclerosans into the rectal ampula should be done.

Methods

We made 100 injections of sclerotherapy with cow milk in 86 patients. In this study we used conservative treatments and also performed operative treatments. We included 86 children and in all of patients we performed operative treatment. In all children we excluded allergic reactions to cow milk. In 95.3% (82 children) of patients the sclerotherapy was successful and in 4 (4.7%) children we performed operative treatment. Below 4 years we had 62 children (72%) and 24 older children (28%). The youngest boy was 8 mo. old and oldest was 8 years old. The mean age of the patients treated with sclerotherapy was 3.6 years. In 4 children, who needed operative treatment for recurrent rectal prolapse after three cow milk injections of sclerotherapy, we performed the Thiersch operation without complications. The youngest patient with Thiersch operation was 4 years old and oldest girl was 8 years old, the mean age of the patients was 6.2 years.

The technique of sclerotherapy is not difficult, but the surgeon should have experience with this method. The rectum is emptied with suppository and not with an enema. The patient is in the lithotomy position. A long needle is attached to an injection syringe inserted through the skin just outside the mucocutaneos junction and guided to the proper position using a finger in the rectum[16]. Two or three milliliters of cow milk are injected along the rectal submucosa at the depth of 4-5 cm at four different quadrants (Figure 1). In 76 patients, we perform one cow milk injection, in 6 patients two cow milk injections, and in 4 patients three cow milk injections. In these 4 patients with three cow milk injections we performed operative surgical treatment (Table 1). This technique, submucosal injection of sclerosans into the rectal ampula, is designed to produce a perirectal inflammatory reaction to induce scarring and prevent prolapse[17]. Before application of cow milk, the milk was boiled for 10 min. Afterwards, the milk was cooled and application was possible.

In children with recurrent rectal prolapse, after three cow milk injection sclerotherapies, we performed the Thiersch procedure for rectal prolapse. The Thiersch

technique consists of a small incision in the perianal skin at 6 and 12 o'clock[18]. We performed the Thiersch operation with wire in two patients and two patients with a nonabsorbable suture. Through anterior and posterior skin incisions a wire is passed around the anal canal just proximal to the external anal sphincter and tied at an appropriate tension (tie wire/nonabsorbable suture just tight enough to prevent rectum prolapsing and just loose enough to let pass stool)[19]. This wire is tied over a 12 (infant) to 20 (adolescent) Hegar dilator or surgeon's finger placed into the rectum. The therapy is effective to mechanically prevent rectum prolapsing, but it does not treat the underlying disorder. The purpose of this procedure is to keep the rectum from prolapsing by restricting the size of the anal lumen[20].

RESULTS

In the last 30 years (1976-2006) we made 100 injection sclerotherapies with cow milk in 86 children. In this study, we included children who failed to respond to conservative treatment and then we performed operative treatment.

In our study we included 86 children and in all patients we performed cow milk injection sclerotherapy. In 95.3% (82 children) of patients the sclerotherapy was successful and in 4 children with recurrent rectal prolapse we performed operative treatment. We had 62 children (72%) younger than 4 years and 24 older children (28%). The mean age for children with sclerotherapy was 3.6 years. In children who needed operative treatment we performed the Thiersch operation and no children had complications. The mean age of the children with the Thiersch operation was 6.2 years.

When we performed cow milk sclerotherapy every patient had a fever for 2 d and no antibiotics were administrated. We had only one patient who had inflammation in the place where milk was performed and incision was performed. After the Thiersch operation, fortunately, the wire was not rejected by the body and patients did not have enough scar tissue formed to improve control of the anus and to delay the return to the prolapse for months or years after removal of the wire or nonabsorbable suture. The wire was removed 6 mo after the Thiersch operation.

DISCUSSION

There is no optimal or standard procedure for treatment of rectal prolapse[21]. Although in excess of many different operations which have been described so far, some more popular than the others, we performed two procedures in our children's hospital[22].

Most patients with children's rectal prolapse do not require any specific form of treatment; however, it is necessary to prevent excessive straining. Treatment should be directed to dietary correction of constipation, to proper toilet training, and to the elimination of any underlying disturbance such as parasitic infection, polyps or diarrhea. Oral administration of stool softeners and having the child defecate with feet off the floor may be helpful. Prolonged sessions on the toilet should be discouraged.

If conservative treatment was not effective, cow milk injection sclerotherapy is simple and should be considered as the first line treatment of recurrent prolapse. We did not use a sclerosant agent such as 30% saline or phenol in almond oil because cow milk as sclerosing agent is inexpensive, easy for application, and the procedure is safe with no side effects[23]. We had only one complication involving inflammation of the perianal tissue. This procedure involves a 2 d stay in hospital after sclerotherapy.

In children with recurrent rectal prolapse following three cow milk injection sclerotherapies, we performed the Thiersch procedure for rectal prolapse[24]. In 4 children we performed operative treatment, the Thiersch operation. This procedure involves a 2 d stay in hospital after the operation. We did not have any complications after the procedure and the wire was removed 6 mo after the operation[25]. All patients, after the operation, did not have recurrent rectal prolapse.

Rectal prolapse is an intussusception of the rectum, which may be categorized as mucosal or complete. Mucosal prolapse involves protrusion of the mucosa only with the muscular layers of the rectum remaining in place[26]. Complete rectal prolapse or rectal procidentia involves full-thickness protrusion of the rectum through the anus.

Most patients with children's rectal prolapse do not require any specific form of treatment, but it is necessary to prevent excessive straining. Treatment should be directed at dietary correction of constipation, to proper toilet training, and to the elimination of any underlying disturbance such as parasitic infection, polyps or diarrhea. Oral administration of stool softeners and having the child defecate with feet off the floor may be helpful. Prolonged sessions on the toilet should be discouraged.

Surgical procedure may be required for recurrent rectal prolapse refractory to conservative measures. If repetitive attempts at medical therapy have failed and conservative treatment has also failed, and the prolapse persists, submucosal injection of sclerosans into the rectal ampula should be done[27]. Cow milk as a sclerosing agent did not cause any complications. Injection sclerotherapy is simple and effective way to treatment for rectal prolapse in children[28]. Children with recurrence after three injections of sclerosing agent require operative surgical treatment[29].

In the last 30 years (1976-2006) we have performed 100 injection sclerotherapies with cow milk in 86 children. In 95.3% (82 children) of patients the sclerotherapy was successful and in 4 children we performed operative treatment. In children who needed operative treatment we performed the Thiersch operation and no children developed complications[30].

Both surgical treatments (cow milk sclerotherapy and the Thiersch operation) which we performed in our hospital in the last 30 years were very effective, inexpensive, easily available with only 2 d stay in hospital. The results were very good after cow milk sclerotherapy (95.3% patients without recurrence), and 4 patients after the Thiersch procedure were without recurrent rectal prolapse.

COMMENTS

Background

Prolapse of the rectum is a herniation of the rectum through the anus. The herniation may be mucosal and may involve only a small ring of mucosa or involve all layers of the rectum (procidentia).

Research frontiers

Most patients with children's rectal prolapse do not require any specific form of treatment; however, it is necessary to prevent excessive straining. Treatment should be directed at dietary correction of constipation, to proper toilet training, and to the elimination of any underlying disturbance such as parasitic infection, polyps or diarrhea.

Innovations and breakthroughs

Cow milk as a sclerosing agent is inexpensive, easy for application, the procedure is safe with no side effects. Injection sclerotherapy is a simple and effective way to treat rectal prolapse in children. Submucosal injection of sclerosans into the rectal ampula is designed to produce perirectal inflammatory reaction to induce scarring and prevent prolapse. Before cow milk application, the milk was boiled for 10 minutes. After that, the milk was cooled and application was possible.

Applications

In 76 patients (88.3%) we perform one cow milk injection and 95.3% patients were without recurrence. Cow milk is inexpensive, easy for application and without contraindications, except cow milk allergy.

Terminology

Rectal prolapse: Herniation of the rectum through the anus. Sclerotherapy: Submucosal injection of sclerosans into the rectal ampula, is designed to produce perirectal inflammatory reaction to induce scarring and prevent prolapse.

Peer review

The authors reported their long term experience with the treatment of rectal prolapse in children. In relapsing cases they reported a high success rate with cow milk sclerotherapy. This is an interesting manuscript.

Abstract

AIM: To define the parameters that positively predict diagnosis of Crohn's disease (CD) and differentiate it from gastrointestinal tuberculosis (GITB).

METHODS: This prospective study over 3 years was carried out in the consecutive Indian patients with definite diagnosis of CD and equal numbers of patients with definite diagnosis of GITB. Demographic, clinical, laboratory, morphological and histological features were noted in all the patients. Serological tests such as p-ANCA, c-ANCA, IgA ASCA and IgG ASCA, were performed. Endoscopic biopsy and/or surgical tissue specimens were subjected to smear and culture for acid-fast bacilli (AFB) and tissue polymerase chain reaction for tuberculosis (TB PCR). Diagnosis of CD and GITB was based on the standard criteria. Data were analyzed using univariate Chi-square test and multiple logistic regression (MLR).

RESULTS: The study is comprised of 26 patients with CD (age 36.6 ± 8.6 year, male:female, 16:10) and 26 patients with GITB (age 37.2 ± 9.6 year, male:female, 15:11). The following clinical variables between the two groups (CD *vs* TB) were significant in univariate analysis: duration of symptoms (58.1 ± 9.8 *vs* 7.2 ± 3.4 mo), diarrhoea (69.2% *vs* 34.6%), bleeding per rectum (30.7% *vs* 3.8%), fever (23.1% *vs* 69.2%), ascites (7.7% *vs* 34.6%) and extra-intestinal manifestations of inflammatory bowel disease (61.5% *vs* 23.1%). Of these, all except ascites and extra-colonic manifestations were found statistically significant by MLR. Accuracy of predicting CD was 84.62% based on the fever, bleeding P/R, diarrhoea and duration of symptoms while it was 63.4% when histology was reported as inflammatory bowel disease and 42.3% when there was recurrence of disease after surgery. Accuracy of predicting GITB was 73.1% when there was co-existing pulmonary lesions and/or abdominal lymphadenopathy; 75% when tuberculosis was reported in histology; 63.4% when granuloma was found in histology; 82.6% when TB PCR was positive; and 61.5% when smear and/ or culture was positive for AFB. Serological test was not useful in differentiation of CD from GITB. Positivity rates for CD and GITB were: p-ANCA- 3.8% and 3.8%, c-ANCA- 3.8% and 0%, IgA ASCA- 38.4% and 23.1%, and IgG ASCA- 38.4% and 42.3%, respectively.

CONCLUSION: Simple clinical parameters like fever, bleeding P/R, diarrhoea and duration of symptoms have the highest accuracy in differentiating CD from GITB.

INTRODUCTION

In Western countries, the incidence of inflammatory bowel disease (IBD) has progressively increased since 1935[1]. Ulcerative colitis (UC) has peaked earlier than Crohn's disease (CD)[1,2]. Although CD has been increasing worldwide[3], it is generally believed to be rare in developing countries like India[4]. Indian migrants in Western countries have shown increased incidence of IBD, more so in the second generation of immigrants[1,5]. In India, the incidence of UC has significantly increased over the last three decades, whereas the incidence of CD increased progressively in the last decade[4,6-15]. Tuberculosis (TB) remains widely prevalent in developing countries such as India. Also, it is being increasingly encountered in industrialized nations due to

pandemic of human immunodeficiency virus infection and trans-global migration[16-19].

There is a close resemblance in clinical, radiological, endoscopic, surgical and histological features of CD and gastrointestinal tuberculosis (GITB), thus differential diagnosis of these two conditions remains a major challenge to clinicians[7-9,12,19-23]. In India, as more and more cases of CD are being recognized, the definite diagnosis of CD or GITB becomes increasingly important[8,10]. In case of misdiagnosis of GITB, unnecessary anti-tuberculosis therapy (ATT) poses a risk of toxicity and treatment of the primary disease, i.e. CD is delayed. In contrast, treatment with steroids alone (for CD) can be disastrous, if diagnosis of GITB is missed. As response to empirical ATT is considered to be a favouring point for final diagnosis of TB, emergence of multi-drug resistant TB can further complicate the issue by decreasing the therapeutic response even in presence of TB. All these situations highlight the need to establish the diagnosis of either CD or GITB, before starting any form of empirical treatment.

In a recently published study with an exhaustive search for histological and microbiological proof for GITB, definite diagnosis could be established only in 66.5% of cases[10]. In other previous series, attempts are made to differentiate CD and GITB on histopathology of endoscopic or surgical specimens[7,12,22-24]; but no single feature can definitely exclude TB. Recent advances in armamentarium of diagnosis of CD and TB are serology tests, such as anti-neutrophil cytoplasmic antibody (ANCA) and anti-*Saccharomyces Cerevisiae* antibody (ASCA), and tissue polymerase chain reaction (PCR) for *Mycobacterium Tuberculosis* (TB PCR)[25-27]. In one study by our centre, TB PCR was found highly specific for diagnosis of GITB, but lacked sensitivity[11]. In another study at our centre, ASCA was not found useful in differentiating CD from GITB[28].

Thus, it is very difficult to differentiate CD from GITB based on index evaluation of a patient. No single diagnostic criterion can define CD. Follow-up evaluations and treatment response are also important to reach the diagnosis. We have designed a study to define the accuracy of various parameters which can predict diagnosis of either CD or GITB at index evaluation.

MATERIALS AND METHODS

Study design

A prospective data analysis was performed in patients with definite diagnosis of CD and GITB. These data were collected prospectively during the study period.

Patient evaluation

During the study period from January 2002 to December 2004, all the patients with suspected diagnosis of CD and GITB were prospectively evaluated for the following parameters (details wide infra): demographic, clinical, laboratory, morphology, histology, microbiology, serology and treatment response at follow-up evaluation for next one year.

Demographic (age, sex and ethnicity), clinical (chronic diarrhoea, hematochezia, features of intestinal obstruction, fever, perianal involvement, extra-intestinal manifestations, abdominal pain, ascites, weight loss, growth retardation, abdominal lump and duration of symptoms, long duration: > 1 year) and laboratory features (anaemia, hypoproteinemia and erythrocyte sedimentation rate) were noted in all the patients.

Morphological findings of intestine during endoscopy (endoscopic evaluation was done in all by the first author): skip lesions, deep ulcers, aphthous ulcers, fissures, fistula, cobble-stone appearance, stricture and site of involvement.

Histological findings were evaluated using paraffin-embedded tissue specimens after staining with hematoxylin and eosin. Histology of all the specimen was reported by an experienced gastrointestinal pathologist, who was completely unaware of clinical, morphological, microbiological and serological findings. The histological features were as follows: presence of granuloma, characteristics of granuloma (caseation or confluence), ulceration of surface epithelium, appearance of crypts, presence of lymphoid aggregates and site and type of inflammatory infiltrate. Presence of large, dense and confluent mucosal or submucosal caseating granuloma, > four sites of granulomatous inflammation, caseation, band of epitheloid histiocytes in ulcer base and granulomatous inflammation in cecum favoured histopathological diagnosis of TB; whereas presence of small, discrete and loose mucosal non-caseating granuloma, mucosal changes distant to sites with granuloma, focal crypt-related inflammation and granuloma in sigmoid or rectum favoured histopathological diagnosis of CD.

Biopsy specimens (endoscopic, at least 6 biopsy samples, or surgical) were subjected to Ziehl-Neelsen and fluorescence smear for AFB, Bactec culture for AFB and TB PCR. Paraffin-embedded biopsy specimens were tested for detection of *Mycobacterium Tuberculosis* complex by the Gen-Probe (USA) amplified *Mycobacterium Tuberculosis* direct test by PCR assay[11]. The following serological tests were done in all the patients: IgG perinuclear-ANCA (p-ANCA), *in vitro* detection of IgG class of antibodies to myeloperoxidase using quantitative ELISA (MPO antibodies ELISA kit, Genesis diagnostics, UK); IgG cytoplasmic-ANCA (c-ANCA), *in vitro* detection of IgG class antibodies to serine protease-3 (PR3 antibodies ELISA kit, Genesis diagnostics, UK); IgA ASCA, detection of IgA anti-Saccharomyces Cerevisiae antibodies using quantitative ELISA (IgA ASCA ELISA kits, Genesis diagnostics, UK); IgG ASCA, detection of IgG anti-Saccharomyces Cerevisiae antibodies using quantitative ELISA (IgG ASCA ELISA kits, Genesis diagnostics, UK). Titres were considered positive if they were above the upper limit of normal range, i.e. for p-ANCA 0-4 μ/mL, for c-ANCA 0-4 μ/mL, IgA ASCA 0-10 μ/mL and for IgG ASCA 0-10 μ/mL.

All the surgical histological specimens of the patients who underwent intestinal surgeries in the past were re-examined using the above mentioned methods.

During the 1-year follow-up, all the patients were evaluated at regular interval with clinical, laboratory and imaging parameters. Endoscopic evaluations with histological and microbiological studies were performed at least twice (at 6 mo and at 1 year) during the follow-up.

Diagnostic criteria

In presence of demonstrable lesion in gastrointestinal tract,

diagnosis of GITB was established based on the following criteria: (1) presence of caseating granuloma on histology of diseased tissue (intestine, peritoneum or lymph nodes); (2) demonstration of acid-fast bacilli (AFB) on smear or on histological section; (3) positive culture for AFB; (4) histological or microbiological confirmed TB at extra-intestinal site; and (5) positive TB PCR. For the definite diagnosis of GITB, one or more of these criteria had to be fulfilled, except for complete response to treatment. Complete resolution of symptoms and morphological (endoscopic and histological/microbiological) features after completion of standard ATT-$(HERZ)_2(HR)_{10}$ (with or without surgery) was taken as criteria for successful treatment.

Diagnosis of CD was based on morphological (radiological, endoscopic or surgical findings) and pathological criteria suggesting focal, asymmetrical, transmural or granulomatous features: (1) morphological: (a) discontinuous/segmental and asymmetrical mucosal involvement, (b) deep mucosal longitudinal fissures/ulcers, (c) transmural inflammation, (d) rigid and strictured intestinal wall, (e) presence of entero-cutaneous/entero-enteric fistula and/or chronic perianal disease; (2) pathological: (a) normal mucus content in the goblet cells of the inflamed region, (b) lymphocyte aggregation in the mucosa and submucosa, (c) non-caseating granuloma, (d) longitudinal ulcers/fissures, (e) transmural inflammation or inflammation beyond mucosa. For definite diagnosis of CD, the following criteria were used: presence of at least 3 different criteria or presence of non-caseating granuloma on histology with at least 1 other criterion; exclusion of TB (by histology, microbiological and PCR studies) and complete resolution of symptoms and morphological (endoscopic and histological/microbiological) features after 1-year treatment of corticosteroid and 5-ASA preparations (with or without surgery).

Study population

During the study period, definite diagnosis of CD was achieved in 26 patients. In analysing data retrospectively, all these patients with CD and an equal number of consecutive age- and sex-matched patients with definite diagnosis of GITB were included.

Statistical analysis

Data were analyzed using SPSS (PC+version-6 statistical package) by medical statistician. Univariate Chi-square test (UCST) was applied to find out statistically significant variables which may be important in differentiating CD from GITB. $P < 0.05$ was considered statistically significant. These variables were taken for multiple logistic regression (MLR) statistical analysis to find out independent predictive variables for diagnosis of CD. Each significant parameter (clinical, morphological, histological, microbiological and treatment-related) individually or in combination, was further analyzed for sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy in diagnosis of CD or GITB.

RESULTS

Demographic, clinical and laboratory features of both the groups are demonstrated in Table 1. In CD and GITB groups, the following extra-intestinal features (%) were noted: (1) eye-related: episcleritis (3.8% and 0%), uveitis (0% and 0%); (2) skin and mucosa-related: erythema nodosum (7.7% and 3.8%), pyoderma gangrenosum (3.8% and 0%), vasculitis (7.7% and 0%), mouth ulcers (23.1% and 11.5%); (3) musculo-skeletal system related: ankylosing spondylitis (3.8% and 0%), arthritis (38.4% and 15.4%), osteopenia (15.4% and 0%); (4) hepatobiliary system-related: fatty liver (11.3% and 34.6%), autoimmune hepatitis (3.8% and 0%), primary sclerosing cholangitis (0% and 0%), gall stones (11.3% and 3.8%); (5) other system-related: thromboembolism (3.8% and 0%), renal stone (3.8% and 0%), amyloidosis (0% and 0%).

Table 1 Demographic, clinical and laboratory features

Characteristics	CD (n = 26)	GITB (n = 26)	P value

Abdominal lymphadenopathy, *n* (%)	3 (11.5)	11 (42.3)	S
Generalized lymphadenopathy, *n* (%)	0 (0)	2 (7.7)	NS

Morphological features including site and type of lesions, histological and microbiological features as well as serological features are described in Table 2.

Among 26 patients with CD, 7 patients had at least one surgical intervention for intestinal complications before index presentation to our centre. They were not diagnosed as having Crohn's disease at that time, were not on therapy, presented at our centre with recurrence of symptoms, and were included for index evaluation and review of previous surgical histological specimens. Two patients had surgical intervention for intestinal stricture while on therapy for recurrent intestinal obstruction. All patients with CD showed complete response to therapy during the 1-year follow-up.

In GITB group, none of the patients had received ATT before the index evaluation. During the follow-up, 4 patients required surgical interventions for intestinal stricture while on therapy for recurrent intestinal obstructions. All the patients with GITB showed complete response to therapy during follow-up.

On UCST analysis, significant clinical variables were: (a) duration of symptoms, (b) diarrhoea, (c) hematochezia,

(d) fever, (e) ascites, (f) extra-intestinal manifestations. Variables found to be significant for differentiating CD and GITB based on MLR were duration of symptoms, diarrhoea, hematochezia and fever.

In Table 3, sensitivity, specificity, PPV, NPV and accuracy are tabulated for various parameters, which were significant on UCST, either individually or in combination. Clinical score (absence of fever, presence of diarrhoea and hematochezia and long duration of symptoms) had an accuracy of 84.62% to predict CD, with high (> 80%) sensitivity, specificity, PPV and NPV. Parameters like recurrence of disease after surgery, pathological diagnosis of TB, positive TB PCR and positive AFB smear/culture had 100% specificity and PPV, but had low sensitivity and NPV. The accuracy of various parameters in descending order were: clinical score (84.62%); positive TB PCR (82.6%); pathologic diagnosis of TB (75%); extra-intestinal focus of disease (pulmonary lesions and abdominal lymphadenopathy) (73.1%); morphology features (deep linear/serpiginous ulcers and cobble-stone appearance) (67.3%); pathologic diagnosis of IBD and granuloma (63.4%); positive AFB smear/culture (61.5%); and recurrence of disease after surgery (42.3%). Presence of caseating and/or confluent granuloma on histology, positive AFB smear and/or culture, positive TB PCR, histologic interpretation as TB, lack of response to ATT and recurrent disease after surgery were the only features which did not show any overlap between the two groups.

DISCUSSION

In spite of recent technical advances and better understating of pathophysiology, there is still no simple test for differentiating GITB from CD. There are many factors that lead to misdiagnosis. Both the diseases have marked overlap in demographic, clinical, radiological, endoscopic and surgical findings[10,22,23]. They can involve any part of gastrointestinal tract. Both are granulomatous diseases, so inability to find caseating or confluent granuloma on histology can lead to erroneous or non-confident diagnosis by a pathologist. Routine tests for diagnosis of TB such as AFB smear examination, using conventional Ziehl-Neelsen stain, traditional AFB culture using egg-based or agar-based media or Guinea pig inoculation, lack sensitivity and/or are time-consuming[29]. Smear examination using fluorescence technique and culture with Bactec technique are more rapid and more sensitive[29]. As GITB is a paucibacillary disease, sensitivity for detecting mycobacterium in clinical specimens by any of the above methods remains poor. Although many serological tests for TB are commercially available, they are far from satisfactory in diagnostic dilemma[29].

As we previously reported, features, which should alert a clinician for CD at presentation or on subsequent follow-up, were: (1) internal or cutaneous GI fistula; (2) perianal disease; (3) extra-intestinal manifestations, such as pyoderma gangrenosum, uveitis, primary sclerosing cholangitis, aphthous ulcers, arthralgia/arthritis or ankylosing spondylitis; (4) no caseating granuloma on histology and negative AFB smear or culture; (5) no involvement of the peritoneum, abdominal lymph node or site of extra-intestinal tuberculosis, such as extra-abdominal lymph node, lungs, pleura, mediastinum, liver, or kidney; and (6) no response to ATT[10].

In the present study, prolonged duration of illness, diarrhoea, hematochezia and extra-intestinal manifestations were more common in CD as compared to GITB; while fever and ascites were common i GITB. About an 85% accuracy in predicting CD could be reached based on the history of hematochezia, diarrhoea and protracted duration of symptoms, and absence of fever. Endoscopic features or surgical finding of deep linear/serpiginous ulcers/fissures and cobble-stone appearance was more common in CD. None of the clinical or morphological features was exclusive for either of the diagnoses.

Recently, Pulimood *et al* have reported that on mucosal biopsy, in addition to AFB detection, large granuloma, > four sites of granulomatous inflammation, caseation, band of epitheloid histiocytes in ulcer base and granulomatous inflammation in cecum in favour of diagnosis of TB; whereas non-caseating granuloma, mucosal changes distant

Table 3 Sensitivity, specificity and accuracy in diagnosis of CD or GITB

Parameters	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Accuracy (%)
Factors predicting CD					
Clinical score (fever, hematochezia, diarrhoea and duration of symptoms)	80.7	88.4	87.5	82.1	84.62
Co-existing deep linear/ serpiginous ulcers and/or Cobble-stone appearance	69.2	65.3	66.6	72	67.3
Pathologist reporting as IBD	38.4	88.4	76.9	58.9	63.4
Recurrence of disease after surgery	77.7	100	100	66.6	42.3

TB PCR positive	65.3	100	100	74.2	82.6
Smear and/or culture positive for AFB	23	100	100	56.5	61.5
Complete response to ATT	100	100	100	100	100

to sites with granuloma, focal crypt-related inflammation and granuloma in sigmoid or rectum in favour of diagnosis of CD[24]. In other studies, presence of small, discrete, loose mucosal granuloma without caseation are characteristics of CD, whereas large, dense, confluent granuloma with caseation with or without AFB positivity in mucosal or submucosal location favour TB[8,23,24,30]. In the present study, pathological diagnosis of TB had higher sensitivity, specificity and accuracy in predicting GITB than pathological diagnosis of IBD in predicting CD. Histological feature of caseation and/or confluence in granuloma and pathological diagnosis of TB were present in GITB group exclusively and there was no overlap in these findings.

Serological test for IBD is being investigated as diagnostic markers for IBD. Sensitivity of positive ASCA for diagnosis of CD reaches up to 76%, whereas it is 98% in various trials[27]. IgA ASCA and IgG ASCA are considered to be 95% specific for diagnosis of CD when individually tested, but 100% when tested in combination[26,27]. These data come from countries where tuberculosis is uncommon and control population in these studies did not include patients with GITB. In the previous study, we found that (1) serological markers were not significantly different between CD and GITB; and (2) prevalence of positive ASCA was much lower in patients with CD than the reported incidence from Western countries[28]. A recent study by another centre in India showed that ASCA was not helpful in differentiating CD from GITB[31]. The present study confirms these results.

TB PCR was found to be highly specific for GITB, but had poor sensitivity; these results were in accordance with our previous study[11]. TB PCR had accuracy of more than 80% in diagnosis of GITB. There was no false positive result in CD.

Since the sample size was small, patient groups were heterogenic (patients with involvement of both upper and/or lower GI tract were included) and conclusions are made based on prospective data analysis, a prospective study on all the patients with suspected CD or GITB with a larger sample size is needed to validate the clinical score.

In conclusion, simple clinical parameters like absence of fever, presence of hematochezia, presence of diarrhoea and long duration of symptoms have a highest pre-treatment accuracy in diagnosing Crohn's disease and differentiating it from intestinal tuberculosis. Microbiology and histology are useful adjuncts, whereas serology is not useful in differentiating intestinal tuberculosis from Crohn's disease.

COMMENTS

Background

Differentiating Crohn's disease (CD) from gastrointestinal tuberculosis (GITB) is a major problem in the tropical countries, as there is a marked overlap in clinical, radiological, endoscopic and surgical findings. In case of misdiagnosis as GITB, unnecessary anti-tuberculosis therapy (ATT) is given and treatment of CD is delayed. In contrast, in case of misdiagnosis as CD, treatment with steroids alone can lead to fatal dissemination of tuberculosis.

Research frontiers

This study prospectively evaluates various parameters for accuracy in diagnosis of CD or GITB.

Innovations and breakthroughs

Simple clinical parameters (duration of symptoms, fever, diarrhoea and hematochezia) turn out to have maximum accuracy in diagnosis of CD as compared with various laboratory, imaging, pathological, microbiological or serological features.

Applications

A prospective multi-center study involving a large sample size should be planned to validate results of this study.

Peer review

The authors present a nicely conceived and analyzed study with very good clinical data. This study investigates the distinguishing features of intestinal TB and CD. Obviously this is of great importance because of the divergence of management. While of immediate importance in India, it is also of interest because of the increase in CD with affluence in India and because this problem is occasionally seen in Western countries.

Received: August 24, 2007 Revised: November 30, 2007

Abstract

AIM: To evaluate the role and outcome of conventional surgery in the treatment of pyogenic liver abscess in the modern era of minimally invasive therapy.

METHODS: The medical records of thirteen patients with pyogenic liver abscess who underwent surgical treatment between January 1995 and December 2002 were retrospectively reviewed to determine the clinical presentation, indication and nature of surgery, and outcome of surgery.

RESULTS: The patients were predominantly women (10/13) with a mean age of 65 ± 17 years. Their main presenting symptoms were abdominal pain (100%) and fever (77%). The aetiologies included biliary (*n* = 6), cryptogenic (*n* = 3), portal (*n* = 2), and trauma (*n* = 2). Seven patients underwent percutaneous drainage as the initial treatment. Of these, three patients developed peritonitis secondary to peritoneal spillage. Another four patients failed to respond because of multiloculation. Salvage surgery was required in these patients. Six patients proceeded to straight laparotomy: two had marked sepsis and multiloculated abscess that precluded percutaneous drainage, and four presented with peritonitis of uncertain pathology. Surgical procedures included deroofment and drainage (*n* = 9), liver resection (*n* = 3), peritoneal lavage (*n* = 2), cholecystectomy (*n* = 4), and exploration of common bile duct (*n* = 2). One patient required reoperation because of bleeding. Three patients required further percutaneous drainage after surgery. The overall mortality was 46%. Four patients died of multiorgan failure and two patients died of pulmonary embolism.

CONCLUSION: Surgical treatment of pyogenic liver abscess is occasionally needed when percutaneous drainage has failed due to various reasons. Mortality rate in this group of patients has remained high.

Role and outcome of conventional surgery in the treatment of pyogenic liver abscess in the modern era of minimally invasive therapy. *World J Gastroenterol* 2008; 14(5): 747-751 Available from: URL: http://www.wjgnet.com/1007-9327/14/747.asp DOI: http://dx.doi.org/10.3748/wjg.14.747

INTRODUCTION

When not diagnosed early and treated promptly, pyogenic liver abscess can be fatal, with reported mortality rates as high as 80%-100%[1]. Historically, the treatment of choice for pyogenic liver abscess had been open surgical drainage[2]. However, with the advent of minimally invasive therapy such as image-guided percutaneous needle aspiration or catheter drainage and the availability of broad-spectrum antibiotics, patients with pyogenic liver abscess nowadays seldom require open surgery for treatment[3,4]. We aim to evaluate the role and outcome of conventional surgery in the treatment of pyogenic liver abscess in the modern era of minimally invasive therapy.

MATERIALS AND METHODS

Between January 1995 and December 2002, one hundred patients with pyogenic liver abscess were treated at our institution. Among them, thirteen patients required open surgical treatment. The medical records of these thirteen patients were retrospectively reviewed to determine the demographic data, clinical presentation, indications and nature of surgery, and outcome of surgery.

The diagnosis of pyogenic liver abscess was established by a combination of clinical, radiological, operative, and/or microbiological findings. All patients with suspected

Table 1 Clinical features, imaging results, preoperative diagnoses, and aetiologies of pyogenic liver abscess

No.	Sex/age	Coexisting diseases	Clinical features	US/CT findings	Preoperative diagnosis	Aetiology
1	F/74	History of jaundice	Peritonitis, hepatomegaly	18 cm left lobe cyst	Ruptured liver cyst	Biliary (GS)
2	F/83	HT, history of cholecystectomy	Pain, fever	2 cm left lobe abscess	Liver abscess	Biliary (CBDS)
3	M/66	DM	Pain, hepatomegaly	12 cm right lobe abscess	Liver abscess	Cryptogenic
4	F/83	HT, history of cholecystectomy and partial gastrectomy	Peritonitis, abdominal distension	(Dilated small bowel loops on abdominal X-ray)	Ischaemic bowel	Biliary (CBDS)
5	M/39	Recent blunt liver trauma with partial hepatectomy	Pain, fever	Haematoma and abscess along liver resection margin	Liver abscess	Trauma
6	M/34	Gunshot injury to liver with partial hepatectomy 4 months ago	Pain, fever, abscess pointing out	5.5 cm abscess communicating with anterior abdominal wound	Liver abscess	Trauma
7	F/86	HT, DM	Peritonitis, fever, hepatomegaly	Multiple liver cysts, largest one 18 cm in the right lobe	Ruptured liver cyst	Biliary (cystadenoma)
8	F/60	RPC, history of cholecystectomy and HJ	Pain, septic shock	5 cm left lobe abscess	Liver abscess	Biliary (RPC)
9	F/71	Diverticular disease	Pain, fever	13 cm right lobe abscess	Liver abscess	Portal (diverticulitis)
10	F/77	HT, history of thyroidectomy for cancer	Pain, fever	9 cm right lobe abscess	Liver abscess	Cryptogenic
11	F/60	No	Peritonitis, septic shock	Suspected acute cholecystitis	Acute cholecystitis	Biliary (GS)
12	F/64	No	Pain, septic shock	4.5 cm left lobe abscess	Liver abscess	Cryptogenic
13	F/47	DM	Pain, fever	9 cm left lobe and 3.5 cm right lobe abscesses	Liver abscess	Portal (diverticulitis)

HT: Hypertension; DM: Diabetes mellitus; RPC: Recurrent pyogenic cholangitis; HJ: Hepaticojejunostomy; GS: Gallstones; CBDS: Common bile duct stones.

liver abscess were initially investigated by ultrasonography (US) and/or computed tomography (CT) to confirm the diagnosis. Additional radiological studies including endoscopic or magnetic resonance cholangiography, and barium enema were subsequently performed in selected patients to look for the underlying aetiology. Pyogenic liver abscess was considered of cryptogenic origin when no obvious extra-hepatic source of infection could be identified after appropriate investigations. After the cultures of blood and/or liver pus aspirates (either by image-guided percutaneous aspiration or open surgery) were obtained, empirical intravenous antibiotics with ampicillin 500 mg six-hourly, cefuroxime 750 mg eight-hourly, and metronidazole 500 mg eight-hourly were administered. The antibiotics therapy was adjusted according to the results of culture and sensitivity test of pus aspirates. All patients received a six-week course of antibiotics.

The exact approach of initial intervention (percutaneous or surgical treatment) was determined by the patients' clinical condition, the certainty of diagnosis, the radiological findings, and the surgeons' preference. Percutaneous needle aspiration or catheter drainage was done under US-guidance, the technique of which had been reported previously[5]. Patients who failed percutaneous treatment (defined as deterioration of patients' clinical condition and/or persistence or progression of abscess on follow-up imaging studies) or developed procedure-related complications were subjected to surgery. For patients who underwent open surgical drainage, the abscess was located with the help of intraoperative US. Abscess wall was deroofed, and loculations were broken down. Large-bore catheters were placed within the abscess cavity for drainage. For patients with concurrent biliary pathologies, additional biliary tract procedures including cholecystectomy and exploration of common bile duct were performed. Liver resection was done for abscess with total destruction of a segment or section of liver parenchyma. Patients' outcomes, including length of hospital stay, recurrence of liver abscess on follow-up imaging, complications, need for re-intervention, and operative mortality were recorded.

RESULTS

Patients' demographic data and clinical presentation

The patients were predominantly women (ten out of thirteen) with a mean age of 65 ± 17 years. The main presenting symptoms were abdominal pain (100%) and fever (77%). Four patients presented with peritonitis of uncertain pathology despite radiological investigations. Three patients presented with septic shock requiring admission to the intensive care unit. Eleven patients (84.6%) had co-existing diseases (Table 1).

The aetiologies of the liver abscess included biliary (n = 6), cryptogenic (n = 3), portal (n = 2), and trauma (n = 2). The median abscess size was 9 cm (range, 2-18 cm). Eleven patients had a positive pus culture (with Klebsiella in eight patients), while a positive blood culture was only present in the three patients with septic shock (all grew Klebsiella).

Indications and nature of surgery

Seven patients underwent US-guided percutaneous drainage (PD) as the initial treatment. Of these, three patients (No. 2, 3, and 9) developed peritonitis secondary to peritoneal spillage of infected material. Another four patients (No. 5, 10, 12, and 13) failed to respond to PD because of multiloculation of the abscess. They all had persistent fever or progression of the abscess on follow-up US. Salvage surgical therapies, including deroofment and drainage, liver resection, peritoneal lavage, and additional biliary tract procedures, were required in these patients (Table 2). The median time interval between PD and salvage surgery was 3 d (range, 1-22 d).

Six patients proceeded to straight laparotomy. One

Table 2 Indications, nature, and outcome of surgery

	Initial intervention	Indications of surgery	No.	Details	Nature of surgery	Outcome
Pyogenic liver abscess (*n* = 13)	Ultrasonography-guided drainage attempted (*n* = 7)	Complications arising from percutaneous drainage (*n* = 3)	2	Peritoneal spillage	D&D	Survive
			3	Peritoneal spillage	Lavage	Survive
			9	Peritoneal spillage	Lavage	Survive
		Failed percutaneous drainage (*n* = 4)	5	Multiloculated abscess	D&D, debridement	Die of MOFS

			12	Multiloculated abscess	L lat sec, chole	Die of MOFS
			13	Multiloculated abscess	L lat sec, D&D	Survive
	Straight laparotomy (*n* = 6)	Peritonitis of uncertain diagnosis (*n* = 4)	1	Ruptured liver cyst?	D&D, chole	Die of MOFS
			4	Ischaemic bowel?	D&D, ECBD	Die of MOFS
			7	Ruptured liver cyst?	D&D	Survive
			11	Acute cholecystitis?	D&D, chole	Die of PE
		Percutaneous drainage not suitable (*n* = 2)	6	Multiloculated abscess pointing out	D&D, debridement	Survive
			8	Multiloculated abscess in a septic patient	L lat sec	Survive

D&D: Deroofment and drainage; chole : cholecystectomy; ECBD: Exploration of common bile duct; L lat sec: Left lateral sectionectomy; MOFS: Multiorgan failure syndrome; PE: Pulmonary embolism.

Figure 1 Computed tomography of the abdomen showing liver disease. **A**: A liver abscess communicating with the anterior abdominal wound in a patient who had undergone partial hepatectomy for gunshot injury; **B**: A 5-cm liver abscess in the left lateral section with suspicious adjacent satellite abscesses in a patient who presented with septic shock; **C**: Multiple liver cysts in a patient who was subsequently proven to have an infected biliary cystadenoma that had ruptured.

patient (No. 6) had undergone partial hepatectomy for gunshot injury in China four months ago. He presented with a multiloculated liver abscess that was pointing out to the anterior abdominal surface (Figure 1A). Open drainage and debridement of necrotic liver tissues was performed. Another patient (No. 8) with underlying recurrent pyogenic cholangitis and previous history of hepaticojejunostomy presented with marked sepsis from a liver abscess in the left lateral section that precluded PD (Figure 1B). She underwent left lateral sectionectomy. The remaining four patients (No. 1, 4, 7, and 11) presented with peritonitis of uncertain pathology despite radiological investigations (Figure 1C). The preoperative diagnoses were ruptured liver cysts, ischaemic bowel, and acute cholecystitis. All four patients were proven to have ruptured liver abscess on laparotomy (Table 2).

Outcome of surgery

One patient (No. 1) required re-operation on day one because of the surgical complication of massive reactionary haemorrhage. Three patients required further PD after surgery because of intra-abdominal collection (No. 3 and 10) and the complication of biloma (No. 6). The overall mortality rate in this series was 46%. Four patients died of multiorgan failure and two patients died of pulmonary embolism (Table 2). For the seven patients who survived the surgery, the median hospital stay was 18 d (range, 14-27 d). None developed recurrence of liver abscess at a median follow-up of 63 mo (range, 10-108 mo).

DISCUSSION

Pyogenic liver abscess remains a rare but life-threatening disease with mortality rate as high as 80%-100% if untreated[1]. Historically, in the preantibiotic and reimaging era, the cornerstone of therapy for pyogenic liver abscess was open surgical drainage based on the classic work of Ochsner *et al* in 1938[2]. In 1953, McFadzean *et al* from Hong Kong first described the successful treatment of pyogenic liver abscess with closed aspiration and antibiotics[6]. With the introduction of high-resolution imaging modalities including US and CT in the recent two to three decades, image-guided PD has largely replaced surgical drainage as the mainstay of treatment[3,4]. This shift of practice has been guided by a drive for minimally invasive therapy whenever possible. PD has the advantages of avoiding general anaesthesia and an operative procedure, involves a shorter hospitalization, fewer complications, and better

patient acceptance[1]. Selected series of PD report success rates of more than 90%[5,7]. Surgical treatment has been reserved for patients who fail to respond to PD or who have concurrent intraabdominal pathology which requires surgical management[5,8].

In the present retrospective study, the surgical indications of the thirteen patients with pyogenic liver abscess include failure of PD, complications arising from PD, unsuitability of PD, and uncertain diagnosis. The reason for failure of PD in our patients is due to multiloculation of the abscess. Barakate *et al* have identified several predictors for failure of the percutaneous approach, including abscess multiloculation, presentation with abscess rupture, biliary communication, elevated serum urea, creatinine, and total bilirubin[8]. Multiloculation contributes to poorer drainage by compartmentalization of the abscess, which reduces the effectiveness of PD. Two septic patients in our study with multiloculated abscess and concurrent intraabdominal pathology (gunshot injury of the liver and recurrent pyogenic cholangitis) who were considered to be unsuitable for PD were subjected to straight surgery. Surgical drainage allows for breakdown of loculations and more complete drainage of large multiloculated abscess. In fact, some authors have advocated surgical drainage as the first-line treatment for septic patients with multiloculated abscess, as the perceived risk of failure of PD in this group of patients is high, and any delay in adequate drainage can lead to high mortality rate[9]. Another indication for primary surgical treatment, as shown in our study, is the presentation of peritonitis of uncertain diagnosis. All four patients were proven to have ruptured liver abscess on laparotomy. According to Barakate *et al*, abscess rupture is the single independent risk factor predicting failure of PD, and primary surgical treatment is strongly recommended for patients with abscess rupture on presentation[8].

Biliary tract diseases have become the most common aetiology of pyogenic liver abscess in the recent decades[3,4,7,8]. Although endoscopic retrograde cholangiopancreatography can easily deal with biliary obstruction due to common duct stones[10], other diseases like gallstones and recurrent pyogenic cholangitis with liver atrophy and intrahepatic duct stones will still require surgical treatment. Four patients in our study had undergone cholecystectomy for concurrent gallstone disease, while two patients had undergone exploration of common bile duct for clearance of common duct stones. Left lateral sectionectomy was performed in three patients with multiloculated abscess affecting segments Ⅱ and Ⅲ of the liver (one of them had underlying recurrent pyogenic cholangitis and intrahepatic duct stones and the other two had failed PD). Liver resection is particularly useful in patients with multiple abscesses or multiloculated abscess confined to a single lobe which cannot be drained even with open surgery[11].

With advancements in minimally invasive surgical techniques, laparoscopic management of pyogenic liver abscess has been shown by some authors to be feasible and safe[12-14]. The laparoscopic approach is a low-risk alternative to open surgery for patients who have failed PD[12]. As most patients requiring surgical intervention for pyogenic liver abscess are severely ill with sepsis, they may tolerate laparoscopic surgery better than open surgery. Comparing with open surgery, laparoscopic surgery has the advantages of faster recovery, less immunosuppression, shorter hospitalization, and better cosmesis[13]. Laparoscopy allows effective drainage of multiloculated abscess and thorough peritoneal lavage in case of ruptured abscess[14]. Laparoscopic US can also be done to localize concomitant abscesses and detect associated biliary pathology. In the hands of a skilled hepatobiliary and laparoscopic surgeon who is equipped with the proper tools, laparoscopic liver resection for liver abscess is also feasible[15].

The mortality rate for pyogenic liver abscess had been up to 40% until the 1980s[8]. Since then, more effective antibiotic therapy, improvement in imaging techniques, and development of image-guided PD, have resulted in published overall mortality rates between 6%-14%[5]. However, most reported series have included a heterogeneous group of patients who have undergone different treatment methods, including medical treatment alone, PD, and surgery. For the subgroup of patients undergoing surgical treatment, the mortality rate still averages 20%[16-19]. The overall mortality rate in the present surgical series is 46%. Four patients died of multiorgan failure and two patients died of pulmonary embolism. In a multivariate analysis of forty-six patients with pyogenic liver abscess, Mischinger *et al* found that a high Acute Physiology and Chronic Health Evaluation (APACHE) Ⅱ score and the underlying disease (malignancy) but not the mode of therapy was independent predictors of mortality[18]. Chou *et al* also found that the systemic effects of liver abscess with sepsis and multiple organ failure were significant factors in predicting mortality[19]. In the present study, no statistical analysis of prognostic factors is performed because of the small sample size. However, we believe that the high mortality rate may be attributed to the large size of the liver abscess (median size 9 cm), a higher proportion of patients with abscess multiloculation and abscess rupture on presentation, and the associated comorbidities of the patients. Moreover, the highest mortality is observed in the subgroup of patients who failed PD and underwent salvage surgery (three out of four died). The median time interval between PD and salvage surgery was 3 d. According to Herman *et al*, in a septic patient with pyogenic liver abscess, aggressive therapy should be instituted as soon as possible, as any delay or failure of adequate drainage would increase morbidity and mortality[9]. For this reason, they recommended surgical drainage instead of PD as first-line treatment in septic patients, and they were able to show a low mortality of 8.5% in their series. Recently, a low mortality rate of 4.5% was also reported by Tan *et al*, who subjected patients with pyogenic liver abscess larger than 5 cm in size to surgical drainage as first-line treatment[20].

In conclusion, because of its minimally invasive nature, PD is still regarded as the first-line treatment for most patients with pyogenic liver abscess. Surgical treatment is occasionally required when PD has failed, when the patients have concurrent intraabdominal pathology, or when the diagnosis is uncertain. In selected group of septic patients with large and multiloculated abscess, surgical drainage may be used as the first-line treatment. However, the overall mortality rate in patients undergoing surgical treatment has remained high.

COMMENTS

Background

Pyogenic liver abscess remains a rare but life-threatening disease with mortality rate as high as 80%-100% if untreated. Historically, the treatment of choice for pyogenic liver abscess had been open surgical drainage. However, with the advent of minimally invasive therapy such as image-guided percutaneous needle aspiration or catheter drainage and the availability of broad-spectrum antibiotics, patients with pyogenic liver abscess nowadays seldom require open surgery for treatment. The aim of this study was to evaluate the role and outcome of conventional surgery in the treatment of pyogenic liver abscess in the modern era of minimally invasive therapy.

Research frontiers

It is still uncertain whether first-line treatment with surgical or percutaneous drainage of large pyogenic liver abscess (size > 5 cm) results in better clinical outcome. This controversial issue can only be properly addressed by a randomised controlled trial. With advancements in minimally invasive surgical techniques, laparoscopic management of pyogenic liver abscess has been shown by some authors to be feasible and safe. Further studies to compare the efficacy and safety of laparoscopic versus open drainage of pyogenic liver abscess should be conducted.

Innovations and breakthroughs

This study does not intend to bring about any major innovations or breakthroughs in the management of pyogenic liver abscess. It mainly serves as a reminder to readers of the modern era treatment planning for pyogenic liver abscess, with a special emphasis on the role and outcome of conventional surgery in the treatment of this old but deadly pathology.

Applications

This study serves as a reminder to readers of the management algorithm of pyogenic liver abscess in the modern era of minimally invasive therapy. Because of its minimally invasive nature, percutaneous drainage is still regarded as the first-line treatment for most patients with pyogenic liver abscess. Surgical treatment is occasionally required when percutaneous drainage has failed, when the patients have concurrent intraabdominal pathology, or when the diagnosis is uncertain. In selected group of septic patients with large and multiloculated abscess, surgical drainage may be used as the first-line treatment.

Terminology

'Pyogenic liver abscess' is a pus-filled lesion within the liver caused by bacterial infection. 'Percutaneous drainage' is a minimally invasive treatment option for pyogenic liver abscess, which can be done under local anaesthesia. Under X-ray or ultrasonography guidance, a fine catheter is inserted through the skin (*via* a tiny skin incision) into the liver abscess cavity for pus drainage.

Peer review

This study serves as a reminder to readers of the modern era treatment planning for an old deadly pathology. Patients with pyogenic liver abscess are at very high risk of decompensation with rapid progression to multi-system failure and they need to be sent to appropriate centres for expedited appropriate stepwise treatment.

Abstract

AIM: To present our trial using a combination of the human acellular dermal matrix (HADM) implant and an interpositional omentum flap to repair giant abdominal wall defects after extensive tumor resection.

METHODS: Between February and October of 2007, three patients with giant defects of the abdominal wall after extensive tumor resection underwent reconstruction with a combination of HADM and omentum flap. Postoperative morbidities and signs of herniation were monitored.

RESULTS: The abdominal wall reconstruction was successful in these three patients, there was no severe morbidity and no signs of herniation in the follow-up period.

CONCLUSION: The combination of HADM and omentum flap offers a new, safe and effective alternative to traditional forms in the repair of giant abdominal wall defects. Further analysis of the long-term outcome and more cases are needed to assess the reliability of this technique.

INTRODUCTION

The treatment of abdominal wall neoplasms, whether primary or secondary, continues to present a challenging problem to general surgeons. Extensive tumor resection of those neoplasms can result in giant abdominal wall defects. Reconstruction of the abdominal wall is still not easy to an average general surgeon, even to a plastic surgeon. Most reports described reconstructing giant abdominal wall defects by using synthetic mesh implants, autologous tissue graft, or a combination of the two methods mentioned above.

Synthetic mesh such as polypropylene (PP) and expanded polytetrafluoroethylene (ePTFE) are the mainstays of ventral hernia repair and commonly used to repair other trunk defects today. For PP, as a result of its macroporous structure, the mesh induces intense fibrovascular infiltration and incorporates into the surrounding musculofascial tissue to provide a strong repair. However, it is also associated with adhesions to intraabdominal viscera and enterocutaneous fistula formation[1-3]. ePTFE has been used in an attempt to reduce these complications and has been reported to cause fewer adhesions to the bowel because of its microporous surface structure. However, incorporation into the surrounding tissue is limited[4-6]. Furthermore, both of them contain permanent prosthetic material and are largely intolerant of infection[7-10], particularly if used in contaminated fields or in the event of exposure owing to dehiscence or breakdown of the overlying skin.

However, abdominal wall tumors, particularly secondary ones, are frequently accompanied by contamination or infection. Such situations are a contradiction for implanting PP or ePTFE. Absorbable mesh, such as Vicryl can be used as a temporary support in contamination or infection situation[11,12]. But the patient needs a second-stage operation for implanting an inabsorbable mesh to complete a definite repair. Additionally, some secondary tumors invade the complete abdominal wall including skin. Therefore, a single mesh is not enough without skin coverage.

The use of autologous tissue flaps, in most time musculocutaneous flaps such as tensor fasciae latae, rectus femoris, rectus abdominis and latissimus dorsi, combined with or without incorporation of synthetic meshes, has been described in the successful repair of abdominal wall defects[13-16]. It eliminates the complications associated with synthetic implant intolerance and is a good replacement of the full-thickness abdominal wall. Despite the advantages of autologous tissue, the creation of a donor site, the potential for donor site morbidity and limited size decrease this technique's application[17,18]. The preparation of a musculocutaneous flap, whatever pedicled or free, greatly increases operation time, complexity, and are generally outside the scope of practice of many general surgeons[13,19].

Recently, some biologic materials were introduced to hernia repair and abdominal wall reconstruction. Human acellular dermal matrix (HADM) is a biologic material derived from human cadaveric dermis. In 1992 it was first used as a dermal replacement in burn surgery[20]. Since then it has been used successfully in the repair of oral defects and replacement of soft tissues in plastic and pelvic procedures[21-25]. The advantages of HADM is its resistance to infection, the absence of a permanent foreign body at the repair site and its excellent mechanical properties (strength to failure, plasticity and flexibility)[23,26-28]. These properties make it an attractive alternative to prosthetic mesh in abdominal wall replacement. Animal models and some case reports using HADM have shown successful hernia repair, abdominal wall reconstruction and resistance to infection in contaminated cases[1,29-39]. Therefore, HADM is an ideal alternative to synthetic mesh for abdominal wall restoration after tumor resection, especially in the situation of infection or contamination.

The omentum serves a multipurpose in the medical field. The pedicled omentum flap is a special autologous tissue flap, but its preparation is much easier than musculocutaneous flaps. It has been reported to reconstruct abdominal wall defects successfully[40-43]. The omentum consists of abundant blood vessels, fat, and lymphatic tissue and is known for its unique immunologic and angiogenic properties[44]. We suppose, in the reconstruction of abdominal wall after tumor resection, it is a good alternative to the musculocutaneous flap and favorable for HADM remodeling after its implantation.

The purpose of this article is to present our approach of using a combination of the HADM implant and an interpositional omentum flap to repair giant abdominal wall defects after extensive tumor resection.

MATERIALS AND METHODS

Patients

Between February and October of 2007, three patients (two men and one woman) with giant defects of the abdominal wall after extensive secondary tumor resection underwent reconstruction with HADM (8 mm thickness, Renov, China) and omentum flap. The first patient was a 51-year-old woman with secondary gallbladder carcinoma, the second one was a 66-year-old man with secondary renal carcinosarcoma, and the third was a 62-year-old man with secondary sigmoid carcinoma. Defect size ranged from 10 cm × 8 cm to 22 cm × 16 cm. The first patient had an overlying skin defect that was covered with a free thigh skin graft and the later two had enough skin and subcutaneous tissues coverage.

Surgical technique

Operations are performed by a team consisting of general and plastic surgeons. Initially, the tumor was widely resected at least 3-5 cm beyond the margin of the tumor and completeness of clearance was ascertained by frozen sections. The abdominal cavity was entered and any bowel that was adherent to the parietal peritoneum along the fascial margin was freed to create space for the underlying portion of the HADM patch.

Then, the greater omentum was evaluated with regard to its size, vascular pattern, and reach for a given defect. The omentum was mobilized fully and pedicalized on either the right or left gastroepiploic arteries. The exit point was a 3-4 cm slit, located on the side ipsilateral to the defect. The right subcostal site is preferred because the liver protects against herniation of bowel.

Next, the HADM patch was applied using an underlay technique. The number of HADM sheets used depended on the size of the defect. After rehydration, several sheets of HADM were sewn together and inserted as an underlay patch with interrupted horizontal mattress sutures. An allowance of 2-3 cm circumferentially was given for the underlaid portion. The patch should be taut but not excessively tight to achieve a tension-free repair. The omentum flap was then gently spread over the HADM and loosely interrupted sutured to the muscle and fascia margin with 0 Prolene. Closed suction drains were placed above and below the omentum flap.

Finally the subcutaneous tissues and skin or graft skin was closed above the omentum. All patients were given abdominal binders postoperatively for additional support for at least 6 mo while the repair matured.

RESULTS

Case 1

A 51-year-old woman presented with secondary gallbladder carcinoma over her upper abdominal wall. She had a history of radical operation of gallbladder carcinoma three years before and was diagnosed with abdominal wall metastasis two years postoperation. Radiotherapy and systemic chemotherapy proved not to be effective and an ulcer with infection developed one year later (Figure 1A).

Figure 1 Case 1. **A**: The view of the abdominal wall before operation; **B**: The defect after extensive tumor resection; **C**: Reconstruction with HADM which was placed in an underlay fashion. The pedicled omentum flap was brought into the subcutaneous plane by means of a 4-cm slit at the left subcostal site; **D**: The HADM patch was completely covered by the omentum flap; **E**: A left free thigh skin graft was raised to cover the skin defect; **F**: The view of abdominal wall 1 mo postoperatively.

Intraoperatively, the tumor was noted to involve the entire thickness of the abdominal wall and adhered to the left lobe of the liver and pylorus. Wide excision resulted in a full-thickness upper abdominal wall defect measuring 22 cm ×16 cm (Figure 1B). The greater omentum was mobilized fully and pedicalized on the left gastroepiploic artery. The exit point was a 4 cm slit, located on the left subcostal site. Reconstruction was performed using the HADM patch described above. Five sheets of HADM (four 10 cm × 8 cm and one 10 cm × 5.5 cm) were sewn together and inserted as an underlay patch with 0 Prolene interrupted horizontal mattress sutures (Figure 1C and D). The overlying skin defect was covered with a free thigh skin graft (Figure 1E). She recovered uneventfully (Figure 1F). At 7-mo follow-up, the repair was noted to be intact and there was no sign of herniation. Several metastatic lesions were found in her left lung at the sixth month post-operation, but the patient is still alive.

Case 2

A 66-year-old man presented with recurrent renal carcinosarcoma over his right upper lateral abdominal wall (Figure 2A). He had a history of renal carcinosarcoma excised half a year previously. Intraoperatively, the tumor was found between the peritoneal membrane and muscle. There was no invasion of the subcutaneous tissue. Wide excision resulted in a right lateral abdominal wall defect measuring 15 cm × 11 cm (Figure 2B), but the excision was not complete in the original renal zone because some tumor tissue was located beside the spinal column and circled around the inferior caval vein which was only leaving for radiotherapy and chemotherapy. Reconstruction was performed as similar as in case 1. One sheet of 10 cm × 8 cm and one of 10 cm × 5.5 cm HADM were sewn together and inserted as an underlay patch. The upper part was fixed on the diaphragm. The omentum was transposed extraperitoneally through a 4-cm opening on the right subcostal site (Figure 2C and D). The subcutaneous tissue and skin were closed above the omentum flap (Figure 2E). He recovered uneventfully (Figure 2F). At 4-mo follow-up, the reconstruction remains stable and he is able to perform normal daily activities.

Case 3

A 62-year-old man presented with an advanced sigmoid colon carcinoma, which perforated chronically into the lower part of the left musculus rectus abdominis and infiltrated to the bladder. Computed tomography demonstrated infiltration through the peritoneum to the abdominal wall muscles. Excision of the abdominal lesion was performed with a 2 cm lateral margin, removing the parietal peritoneum and the full thickness of the muscle. Intraoperative frozen section revealed clear resection margins. This resulted in a defect measuring 10 cm × 8 cm. Reconstruction was performed similar to case 2. The omentum was mobilized and pedicled on the left gastroepiploic artery. The exit point was located on the inner side of the defect. The patient's post-operative recovery was uneventful and there was no infection of his abdominal wall. The patient was followed up for only 1 mo and there is no herniation up to now.

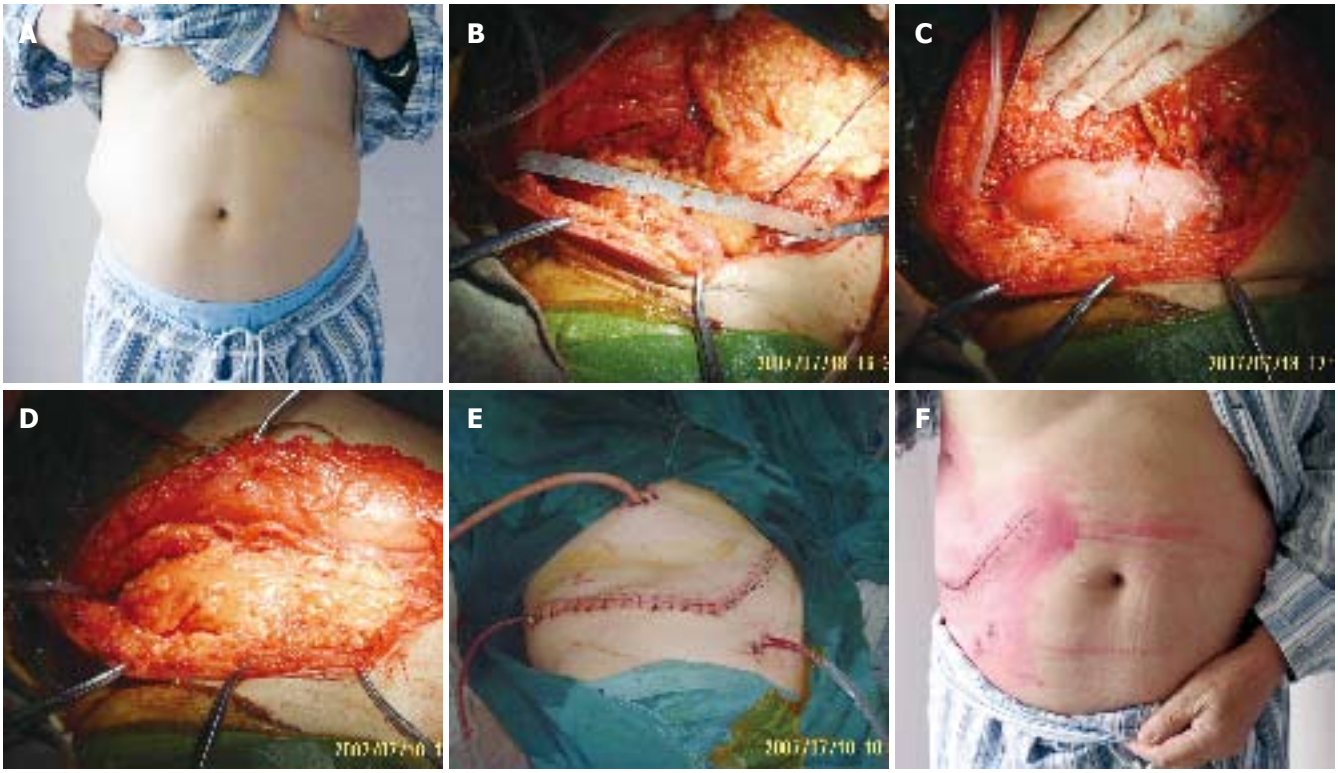

Figure 2 Case 2. **A**: The view of the abdominal wall before operation; **B**: The defect after extensive tumor resection; **C**: Reconstruction with HADM which was placed in an underlay fashion. The pedicled omentum flap was brought into the subcutaneous plane by means of a 4-cm slit at the right subcostal site; **D**: The HADM patch was completely covered by the omentum flap; **E**: The subcutaneous tissue and skin were closed above the omentum flap; **F**: The view of the abdominal wall 2 wk after operation.

DISCUSSION

Extensive resection of abdominal wall tumors frequently leads to a giant defect. Additionally accompanying with infection or contamination, repairing such a giant defect is still a challenging task to general surgeons. The current techniques of abdominal wall reconstruction all have their disadvantages: the transferring of a musculocutaneous flap creates a donor site where it can create potential donor site morbidities and is time-consuming. Inabsorbable synthetic mesh is intolerant to infection and sometimes results in an excessive foreign body reaction, absorbable mesh is sometimes used only as a temporary support of abdominal wall in a two stage operation. Therefore, new alternatives are called on to replace the old techniques. Here, we report our trial in three secondary abdominal wall tumor patients by combining HADM with an interpositional omentum flap as a technique to successfully repair giant abdominal wall defects after extensive tumor resection.

HADM is a biologic material derived from human cadaveric dermis. Chemical and physical processing removes all cellular components of the dermis while preserving the extracellular matrix and basement membrane components. This results in a sheet consisting of extracellular material that acts as a signal for fibroblast incorporation, collagen deposition, and collagen maturation. These changes occur when the material is implanted into the human body[26-28]. The extracellular matrix stays intact and is gradually revascularized and remodeled into autologous tissue while maintaining its structural integrity. Animal models proved that early revascularization of the graft is thought to enhance resistance to infection and contamination[29]. So its biggest benefit is its tolerance of overlying infection without breakdown or loss of strength. Additionally, the advantages of HADM also include the absence of a permanent foreign body at the repair site and excellent mechanical properties, such as strength to failure, plasticity and flexibility[23,26-28]. Based on these facts, we believed that HADM is an ideal alternative of synthetic mesh for abdominal wall restoration after tumor resection, especially in the infected or contaminated situation.

A pedicled omentum flap is easy to prepare, and in most times it can reach defects over all quadrants of the abdominal wall. The omentum, consisting of abundant blood vessels, fat, and lymphatic tissue, is known for its unique immunologic and angiogenic properties. Therefore, it can be used in infected or contaminated situations. By using it as an interpositional flap, we harness such properties to facilitate wound healing[44-45] and promote remodeling of HADM after implantation. We have demonstrated that the omentum, with its size, vascularity and bulk, can be used successfully as a local flap in combination with the HADM in abdominal wall restoration. Although an omentum flap is not stronger than a musculocutaneous flap, the HADM sheet plays a role of resisting pressure from the abdominal cavity, and an additional free skin graft could easily be taken for the patient who has a full-thickness abdominal wall defect. An omentum flap is somewhat easier to prepare compared to a musculocutaneous flap which avoids a donor site and its associated morbidities and additionally shortens the operation time. Sometimes it also avoids microsurgery that is needed for a free musculocutaneous flap, which

represents an advantage in patients with significant comorbidities such as diabetes. In our cases, an omentum flap combined with HADM allowed us to repair a giant abdominal wall defect after an extensive tumor resection in a relatively short operation with no severe morbidity. To our knowledge, this technique has never been described before.

Up to now, no herniation was observed in these three patients. But we know that the number of our cases is too small and the follow-up period is too short. Because of the theorized structural remodeling of HADM, the long-term integrity of the abdominal wall after reconstruction remains in question. But this technique may potentially be used in the restoration of abdominal wall after extensive tumor resection, especially in patients presenting with a secondary tumor with infection or contamination.

In conclusion, the combination of HADM and omentum flap offers a safe and effective alternative to traditional forms in the repair of giant abdominal wall defects. The HADM appears to have the ability to survive in contaminated or infected surgical fields, the omentum flap is easy to prepare and avoids a donor site defects and morbidities that may result from a free or pedicled musculocutaneous flap transferring. The combination offers the opportunity for a single-staged reconstruction after extensive tumor resection. That also means it provides an option when neither synthetic prosthetic mesh nor musculocutaneous flap can be used to achieve closure. Further analysis of the long-term outcome and more cases also are needed to assess the reliability of this technique; nonetheless favorable short-term results are a welcome change for the surgeon called on to deal with such challenging dilemma.

COMMENTS

Background

Extensive resection of abdominal wall tumor frequently leads to a giant defect, which is difficult to repair for general surgeons. The current techniques of abdominal wall reconstruction, such as transferring a musculocutaneous flap and implanting a synthetic mesh have their disadvantages. Here, we report our trial in three secondary abdominal wall tumor patients by combining human acellular dermal matrix (HADM) with an interpositional omentum flap as a technique to successfully repair giant abdominal wall defects after extensive tumor resection.

Innovations and breakthroughs

The technique of combining the HADM implant and an interpositional omentum flap is to be used for the first time to repair giant abdominal wall defects after extensive tumor resection.

Applications

The combination of HADM and omentum flap offers a safe and effective alternative to traditional forms in the repair of giant abdominal wall defects after extensive tumor resection, especially in secondary tumor patients with infection or contamination.

Terminology

HADM: a biologic material derived from human cadaveric dermis, which has been used successfully in the repair of oral, abdominal and other tissue defects. Pedicled omentum flap: a special autologous pedicled flap which serves multipurpose in medical field.

Peer review

This manuscript presents a new way to reconstruct giant abdominal wall defects using the combination of a HADM implant and an interpositional omentum flap which appears to provide a safe and reliable alternative in this area.

Abstract

AIM: To analyze the expression profiles of a human gastric-cancer-related gene, *GCRG123*, in human gastric signet-ring cell carcinoma tissues, and to perform bioinformatics analysis on *GCRG123*.

METHODS: *In situ* hybridization was used to explore the *GCRG123* expression pattern in paraffin-embedded gastric tissues, including 15 cases of signet-ring cell carcinoma, 15 of intestinal-type adenocarcinoma, and 15 of normal gastric mucosa. Northern blotting was used to analyze the differences in *GCRG123* expression between stomach signet-ring cell carcinoma and intestinal-type adenocarcinoma tissues. Online software, including BLAST, Multalin and BLAT, were applied for bioinformatics analysis. National Center for Biotechnology Information (NCBI) and the University of California Santa Cruz (UCSC) databases were used for the analyses.

RESULTS: The *in situ* hybridization signal appeared as blue precipitates restricted to the cytoplasm. Ten out of 15 cases of gastric signet ring cell carcinoma, normal gastric mucosal epithelium and pyloric glands showed high *GCRG123* expression. Low *GCRG123* expression was observed in gastric intestinal-type adenocarcinoma and normal gastric glands. Northern blotting revealed that *GCRG123* was up-regulated in signet-ring cell carcinoma tissue but down-regulated in intestinal-type adenocarcinoma tissue. BLAST and Multalin analyses revealed that the *GCRG123* sequence had 92% similarity with the ORF2 sequence of human long interspersed nuclear element retrotransposons (LINE-1, L1). BLAT analysis indicated that *GCRG123* mapped to all chromosomes. *GCRG123* was found to integrate in the intron-17 and -23 of Rb, 5′ flanking region of IL-2 and clotting factor IX genes.

CONCLUSION: *GCRG123*, an active member of the L1 family, was up-regulated in human gastric signet-ring cell carcinoma.

INTRODUCTION

Gastric cancer remains one of the most common forms of cancer worldwide with approximately 870 000 new cases and 650 000 deaths per year[1-4], which accounts for about 9.9% of new cancers[5]. Worldwide, there has been a decline in the incidence of the intestinal type gastric cancer in the last few decades, following the overall decline in the incidence of gastric cancer. By contrast, the decline in the diffuse type gastric cancer has been more gradual. Some studies have reported an increase in the diffuse type of gastric carcinoma, especially the signet-ring cell type[6]. As a result, the diffuse type now accounts for about 30% of gastric carcinomas in some reported series[7]. Intestinal-type and diffuse-type gastric cancer differ in their epidemiology, pathogenesis, genetic profile, and clinical outcome[8].

In 1999, we cloned a gene segment *GCRG123*, which was down-regulated in gastric adenocarcinoma. BLASTX analysis revealed that the predicted *GCRG123* product was a lamin-like protein[9]. Recently, we have used the updated GeneBank database for further analysis on the *GCRG123* sequence. We found that *GCRG123* appeared to be a long interspersed nucleotide element-1 (LINE-1, L1) family member. Additionally, we revealed that *GCRG123* was ultimately up-regulated in stomach signet-ring cell carcinoma, as well as in normal pyloric glands and epithelia, which shows an opposite expression pattern

compared with its down-regulation in stomach intestinal-type adenocarcinoma.

MATERIALS AND METHODS

Patients and tissue acquisition

All samples were obtained from the Department of Pathology, General Hospital of Chinese PLA. Specimens of paraffin-embedded gastric tissues, including 15 cases of gastric signet-ring cell carcinoma, 15 of advanced gastric intestinal-type adenocarcinoma and 15 of normal gastric mucosal tissues, were collected for *in situ* hybridization analysis. One set of fresh gastric signet-ring cell carcinomas and paired non-cancerous gastric tissues, and one set of fresh gastric intestinal-type adenocarcinomas and paired non-cancerous gastric tissues were used for Northern blot analysis. The diagnosis of cancer was confirmed through histology.

In situ hybridization

cRNA probe labeling: Digoxigenin-labeled anti-sense and sense cRNA probes were prepared by *in vitro* transcription (DIG RNA Labeling Kit (SP6/T7); Roche Diagnostics, Mannheim, Germany). Briefly, the following labeling procedure was employed: purified *GCRG123* cDNA 100 ng/10 μL, 5 × NTP labeling mixture 4 μL, 5 × transcription buffer 4 μL, and RNA polymerase SP6/T7 2 μL were mixed gently, centrifuged, and then incubated for 1 h at 42℃. Two microliters of RNase-free DNase I was added to remove template DNA, by incubating for 15 min at 37℃, and the reaction was finally stopped by adding 2 μL 0.2 mol/L EDTA (pH 8.0). Labeling efficiency was directly detected by a spot test as described in the protocol of the kit.

Hybridization: All specimens were fixed in 10% neutral-buffered formalin and embedded in paraffin. A series of 5-μm thick sections were cut for analysis. *In situ* hybridization was performed as previously described[10,11] with some amendments, using digoxigenin-labeled anti-sense cRNA probes. Briefly, the slides were dried at 40℃ overnight, dewaxed, rehydrated and pretreated with DEPC-treated PBS containing 100 mmol/L glycine and 0.3% Triton X-100, respectively. The sections were then permeabilized with 20 μg/mL RNase-free proteinase K (Merck, Darmstadt, Germany) for 20 min, incubated at 37℃ for at least 20 min with prehybridization buffer. Each section was overlaid with 30 μL hybridization buffer containing 10 ng digoxigenin-labeled cRNA probe and incubated at 42℃ overnight. After hybridization, the section was incubated with digoxigenin antibody (75 mU/mL) for 2 h. The positive signal for *GCRG123* mRNA was detected by using NBT/BCIP (Promega, WI, USA) as a substrate. Sense cRNA probes were used as a negative control. The presentation of blue staining in the cytoplasm was considered positive. The positive staining of cytoplasm was scored manually as described below: -, barely detectable light blue; 1+, diffuse light blue; 2+, blue; 3+, dark blue. More than 100 non-tumor or tumor cells were quantified in each measurement, and more than one measurement was required to confirm the diagnosis. Consequent slides with H&E staining were then reviewed to compare the histological patterns to the staining patterns in the *in situ* hybridization preparations.

Northern blot analysis

Dig Northern Starter Kit (Roche Diagnostic, Indianapolis, IN, USA) was used. The procedure of hybridization was performed according to the manufacturer's protocol. Digoxigenin-labeled cRNA probe was generated as described above. Digoxigenin-labeled sense cRNA probe was used as a negative control. The hybridization signals were visualized with chemiluminescence, which was recorded on X-ray films. The exposure time was 10 min.

Bioinformatic analysis

BLAST (http://www.ncbi.nlm.nih.gov/BLAST/)[12] was used for sequence similarity search. MultAlin (http://bioinfo.genopole-toulouse.prd.fr/multalin/multalin.html)[13] was used for multiple sequence alignment analysis. BLAT (http://genome.ucsc.edu/cgi-bin/hgBlat) was applied to find the genomic coordinates of mRNA, and to search for gene family members[14]. Alignment parameters were set as default. NCBI and UCSC databases were used for the analyses.

Informed consent

The study protocol was approved by the Institutional Review Board of the hospital under the guidelines of the 1975 Declaration of Helsinki. Written informed consent was obtained from all patients.

RESULTS

In situ hybridization

GCRG123 expression was analyzed at the mRNA level using *in situ* hybridization. The hybridization signal appeared as blue staining in the cytoplasm. Fourteen gastric intestinal-type adenocarcinoma cases showed - to ± staining (Figure 1A). Interestingly, 10 out of 15 gastric signet-ring cell carcinoma tissues were stained 2+ to 3+ (Figure 1B), while the other signet-ring cell tissues were stained ± to +. In the normal gastric mucosa, all gastric epithelia and pyloric glands were heavily stained (grade 2+ to 3+) (Figure 1C and D), however, the normal gastric glands were stained lightly (Figure 1C).

Northern blotting

Both normal gastric tissue and signet-ring cell carcinoma tissue showed strong hybridization signals, while the gastric intestinal-type carcinoma tissue showed a weak signal. These results seem to indicate that *GCRG123* expression was higher in gastric signet-ring cell carcinoma than in intestinal-type adenocarcinoma (Figure 2).

Bioinformatic analysis

The sequence of *GCRG123* was enrolled for a sequence-similarity search in the GenBank database. *GCRG123* shared 92% similarity with the human transposon L1 (M80343) sequence, as well as the highly active L1 sequence reported

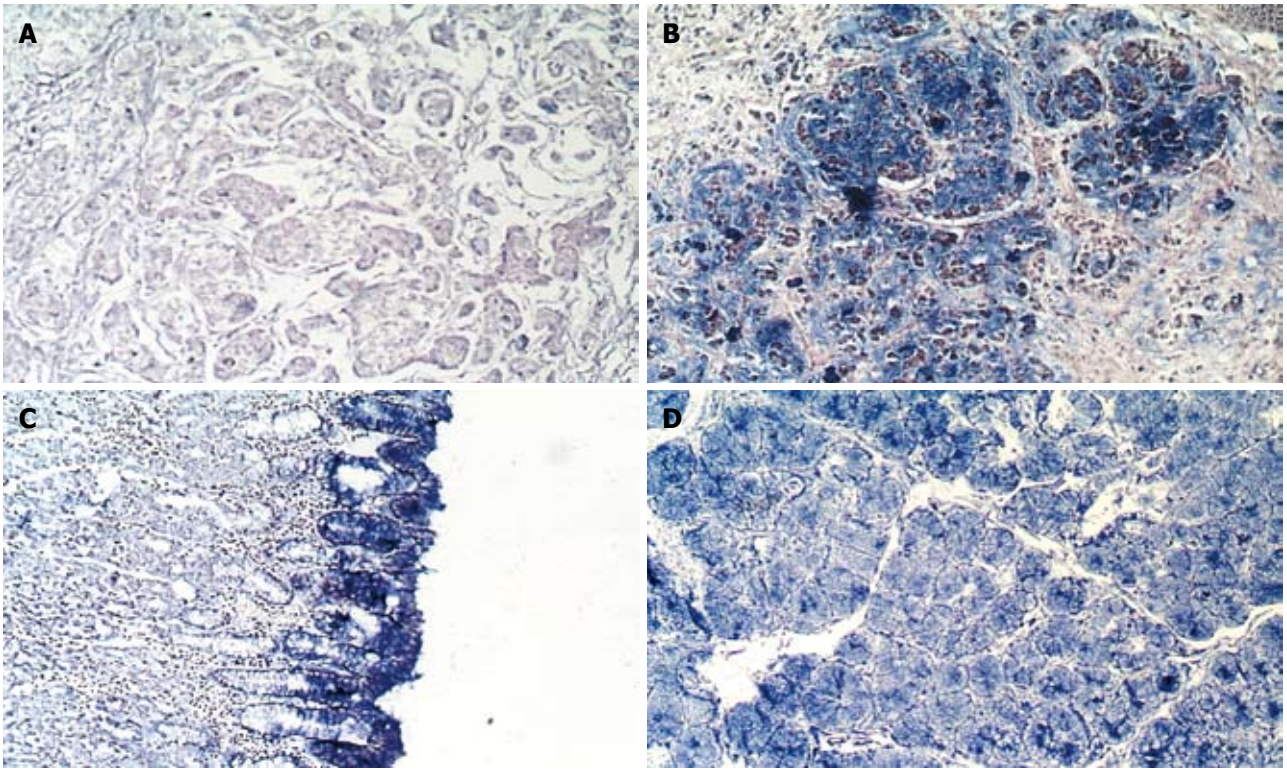

Figure 1 *In situ* hybridization analysis of *GCRG123* in gastric mucosa. *GCRG123* showed low expression (blue precipitates restricted to the cytoplasm) in intestinal-type adenocarcinoma (**A**) and normal gastric glands (**C**, left region); high expression in signet-ring cell carcinoma (**B**); normal epithelia (**C**); and normal pyloric glands (**D**). NBT/BCIP was used as an alkaline phosphatase substrate (magnification was 10 × 10).

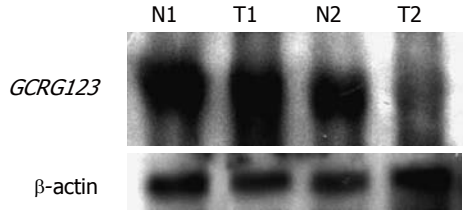

Figure 2 Northern blotting of *GCRG123* in gastric tissues. The expression of β-actin served as an internal control. Total RNA, 1 μg per lane, was separated on a 1% agarose/formaldehyde gel. After blotting onto a nylon membrane, the membrane was probed with digoxigenin-labeled anti-sense *GCRG123* cRNA. N, normal gastric tissue; T, tumor; 1, signet-ring cell carcinoma; 2, intestinal-type adenocarcinoma.

in the literature[15]. Multalin analysis revealed that *GCRG123* was located at nucleotides 2767-3215 of L1, at which the L1 ORF2 dwells (Figure 3). *GCRG123* was found to integrate in intron-17 and -23 of Rb (L11910), the 5' flanking region of IL-2 (X67285), and the 5' flanking region of clotting factor IX (X75349) genes (GenBank accession numbers in parentheses). BLAT analysis showed that *GCRG123* mapped to all the human chromosomes.

DISCUSSION

Our previous bioinformatic analysis of *GCRG123* showed that the predicted peptide sequence of *GCRG123* has 80% homology with a human lamin-like protein (GenBank accession number, AAA36178)[9], therefore, we predicted that *GCRG123* might be a gene that encoded a lamin-like protein. However, the results of the present study indicate that *GCRG123* tends to be an active LINE-1 family member.

Retrotransposable elements, such as L1, Alu and endogenous retroviruses, make up some 45% of human DNA[16]. L1 is one of the most successful retrotransposons and occupies 17% of DNA[17]. In the early stages, because of the lack of any obvious correlation with cellular functions, retrotransposable elements were considered to be mere remnants of our genetic evolution and given the name "junk DNA"[18]. However, recent data have revealed that some L1s do remain retrotransposition-competent. It has been shown that L1 is a functionally capable gene. For example, human embryonic stem cells can express endogenous L1 elements[19]. L1 can retrotranspose in neuronal precursors, and can consequently alter the expression of neuronal genes, which in turn, can influence neuronal cell fate *in vitro*[20]. L1 retrotransposition can also occur in non-dividing somatic cells[21].

A retrotransposition-competent, functional L1 element covers about 6.1 kb and contains a 5' untranslated region, a 1-kb ORF1 that encodes a protein (p40) with RNA-binding ability, followed by a 3.8-kb ORF2 that codes for a protein (p150) with endonuclease and reverse transcriptase (RT) activities, and a cysteine-histidine-rich domain. The 3' end of L1 is terminated by a short 3' untranslated region and a poly(A) tail[22-26]. L1 likely integrates into the genomic DNA by a process called target primed reverse transcription and shapes mammalian genomes through many different ways, such as retrotransposition, transduction and gene expression alteration[27]. Although the overwhelming majority of L1s (about 99.8%) are inactive because of 5' truncations, internal

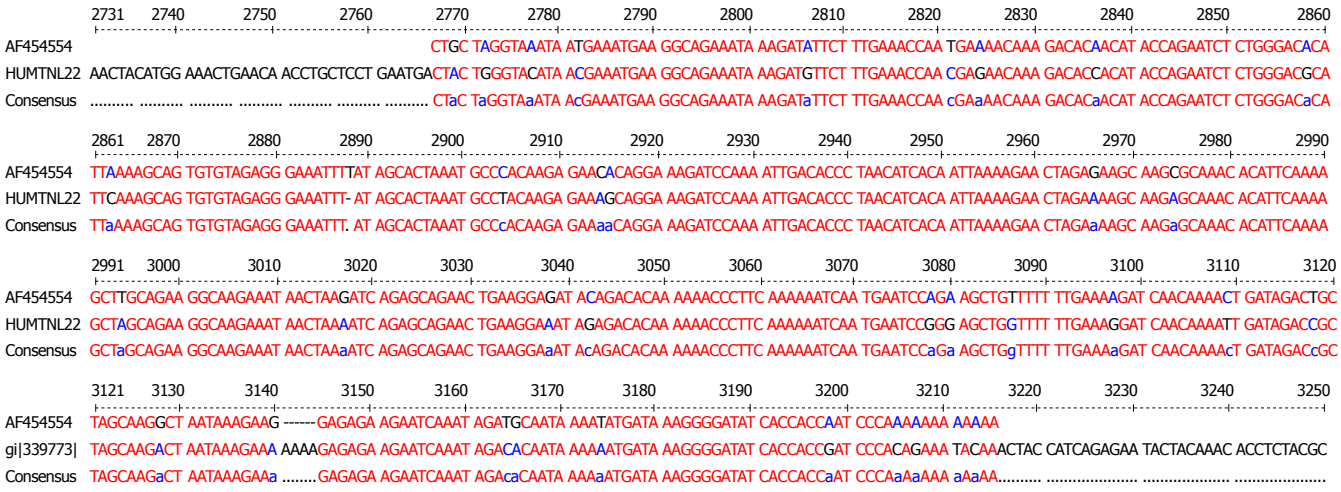

Figure 3 Multalin analysis of *GCRG123* (AF454554) and L1 (HUMTNL22). Red font represents high consensus, blue or black font represents low consensus.

rearrangements and mutations, 80-100 retrotransposition-competent L1s have been predicted in humans. Remarkably, 84% of the retrotransposition capability of these elements has been shown to be present in six highly active L1s[15].

It has been proposed that retrotransposons modulate the expression of specific genes through a transcriptional interference-based mechanism. To exert such effect on neighboring genes, retrotransposons need not necessarily be full-length, nor retrotransposition-competent, but simply endowed with functional promoter elements[28]. Previous studies have shown that some non-full length L1 elements (even shorter than 500 bp) may yield L1 products such as L1 RNA or active RT[29-31]. L1 RNAs are also involved in extensive RNA splicing that can radically alter the diversity of expressed RNA forms from these elements, as well as influence their impact on gene expression upon genomic insertion[32].

The state-of-the-art understanding of L1 described above prompted us to propose that *GCRG123* may be an active L1 family member, as supported by our findings. First, the *GCRG123* sequence shared 92% homology with the conserved sequence of the highly active L1s (hot L1s). Second, *GCRG123* can map to all chromosomes, which is similar to L1s. Third, *GCRG123* can integrate in the intron or 5' flanking region of some known genes, which suggests that it has the potential to adjust the function of these genes. Finally, *in situ* hybridization and Northern blot analysis at the mRNA level showed a distinct *GCRG123* expression pattern in different kinds of gastric mucosa cells.

A lot of evidence has indicated that L1 is involved in a wide spectrum of diseases, including cancer[28,33,34]. In colon cancer, the *APC* gene can be disrupted by somatic insertion of an L1 sequence into the last exon of the gene[35]. Takai *et al* have found that hypomethylation of L1 is detected in human hepatocellular carcinoma, but never in the surrounding liver tissues, whether or not liver cirrhosis is present[36]. Hypomethylation of L1 has also been revealed in urothelial carcinoma and prostate adenocarcinoma[37-39]. In malignant cells, there is a direct correlation between the hypomethylation of 5' L1 sequences and the presence of L1 proteins, which suggests that elements with hypomethylated 5' ends are transcriptionally active[40]. The hypomethylation of repetitive elements in cancer is directly linked to the neoplastic process and not a simple consequence of loss of growth control[41]. Previous studies have shown that L1 is essential for the proliferation of tumor cells. The functional knock-out of LINE-1 expression by RNAi reduces the proliferation and promotes the differentiation of tumorigenic human cells[29,42]. Up till now, no data about the relationship between L1 and stomach cancer have been reported. The present study on the distinct expression pattern of *GCRG123* in gastric signet-ring cell carcinoma may be the first to link an L1 family member to stomach oncogenesis.

During previous decades, several histological classification systems, such as those of Lauren, Nakamura and Ming, have been widely used for gastric adenocarcinoma. These systems agree that the intestinal/differentiated/expending type and diffuse/undifferentiated/infiltrative type differ greatly in terms of epidemiology, pathogenesis, genetic profile, and clinical outcome[8,43-46]. Signet-ring cell carcinoma belongs to the diffuse/undifferentiated/infiltrative type group. Nakamura has indicated that the morphological findings of undifferentiated type carcinoma under light and electron microscopy are similar to both the mucous cells of pyloric crypts and pyloric gland cells[44]. Interestingly, our study found that *GCRG123* was over-expressed in pyloric gland cells, epithelia (surface mucous cells) and signet-ring cells, which correlated with Nakagawa's description of undifferentiated carcinoma. The distinct *GCRG123* expression patterns in intestinal-type adenocarcinoma and signet-ring cell carcinoma also support the concept that these two types of carcinoma have different genetic profiles. *GCRG123* is over-expressed simultaneously in gastric epithelia, pyloric glands and signet-ring cell carcinoma, therefore, we believe that *GCRG123* might be closely associated with gastric mucous secretion. Further studies are required to confirm this speculation.

COMMENTS

Background

Evidence indicates that a retrotransposition-competent, functional L1 element is involved in a wide spectrum of diseases, including cancer. A previous study

has shown that a gene segment *GCRG123* is down-regulated in human gastric intestinal-type adenocarcinoma. Intestinal- and diffuse-type gastric cancers differ in their epidemiology, pathogenesis, genetic profile and clinical outcome.

Research frontiers

To modulate the expression of specific genes, retrotransposons, such as L1, need not necessarily be full-length, nor retrotransposition-competent, but simply endowed with functional promoter elements. Some non-full length L1 elements could yield L1 products such as L1 RNA or active RT. L1 is essential for the proliferation of tumor cells. The functional knock-out of L1 expression reduces cell proliferation and promotes cell differentiation.

Innovations and breakthroughs

GCRG123 may be an active L1 family member, because of its sequence homology with the conserved sequence of the highly active L1s and its integration in the intron or 5' flanking region of some known genes. *In situ* hybridization and Northern blot analysis showed that *GCRG123* was up-regulated in signet-ring cell carcinoma. Besides, *GCRG123* was also over-expressed in normal gastric epithelia and pyloric glands. The present study possibly represents the first to link an L1 family member to stomach oncogenesis.

Applications

Updated knowledge about L1 shifts the focus from protein-coding genes to repeated retroelements as mediators of abnormal biological processes. Functional L1 family members may be regarded as promising targets in the development of novel, differentiation-inducing approaches to cancer therapy. The distinct expression pattern of *GCRG123* in gastric signet-ring cell carcinoma may provide a new area to further understand the genetic characteristics of gastric signet-ring cell carcinoma.

Terminology

LINE-1: highly repeated sequences, 6-8 K base pairs in length, which contain RNA polymerase II promoters. They also have an ORF that is related to the RT of retroviruses, but they do not contain long terminal repeats. Copies of the LINE 1 (L1) family form about 17% of the human genome.

Peer review

This is an interesting article. The title reflects the major contents of the article. The abstract gives a clear delineation of the research background, objectives, materials and methods, results and conclusions. The methods are innovative and systematic. A detailed description has been provided. The results provide sufficient experimental evidence or data from which scientific conclusions can be drawn. The discussion is well organized and an overall theoretical analysis is given. The most current literature is cited. Overall, a it is well-written and well-researched article.

Abstract

AIM: To determine the platelet-activating factor (PAF) synthesis and its receptor expression in Kupffer cells in rat carbon tetrachloride-induced cirrhosis.

METHODS: Kupffer cells, isolated from the livers of control and CCl_4-induced cirrhotic rats, were placed in serum-free medium overnight. PAF saturation binding, ET-1 saturation and competition binding were assayed. ET-1 induced PAF synthesis, mRNA expression of PAF, preproendothelin-1, endothelin A (ETA) and endothelin B (ETB) receptors were also determined.

RESULTS: A two-fold increase of PAF synthesis (1.42 ± 0.14 *vs* 0.66 ± 0.04 pg/μg DNA) and a 1.48-fold increase of membrane-bound PAF (1.02 ± 0.06 *vs* 0.69 ± 0.07 pg/μg DNA) were observed in activated Kupffer cells of cirrhotic rats. The application of ET-1 to Kupffer cells induced PAF synthesis in a concentration-dependent manner in both cirrhotic and normal rats *via* ETB receptor, but PAF synthesis in the activated Kupffer cells was more effective than that in the normal Kupffer cells. In activated Kupffer cells, PAF receptor expression and PAF binding capacity were markedly enhanced. Activated Kupffer cells raised the [^{125}I]-ET-1 binding capacity, but changed neither the affinity of the receptors, nor the expression of ETA receptor.

CONCLUSION: Kupffer cells in the course of CCl_4-induced cirrhosis are the main source of increased PAF. ET-1 is involved endogenously in stimulating the PAF synthesis in activated Kupffer cells *via* ETB receptor by paracrine. ETA receptor did not appear in activated Kupffer cells, which may exacerbate the hepatic and extrahepatic complications of cirrhosis.

INTRODUCTION

Kupffer cells[1], resident macrophages in the liver, constitute the largest population of macrophages in the body and are critical effector cells for the defense against invading micro-organisms and foreign molecules. On the other hand, Kupffer cells in the pathogenesis of different types of liver injury[2-4] have been demonstrated to be involved in several models of liver damage induced by chemicals including carbon tetrachloride, alcohol and allyl alcohol[5,6]. The pathologic role of Kupffer cells has been confirmed by the attenuation of hepatotoxicity in terms of steatosis, inflammation, and necrosis in animals. It is hypothesized that Kupffer cells are activated in response to chemical administration and promote tissue damage by releasing biologically active mediators such as prostaglandins, TNFα, oxygen free radicals, and other proinflammatory mediators[7-9]. Platelet-activating factor (PAF) is the trivial name for a phospholipid called 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine that has unique phospholipid autacoid exhibiting diverse biological activities in various tissues and organs such as isolated lung, liver and brain, and different types of cells (platelet, neutrophils, endothelial cells, neural cells)[10-15]. These activities include platelet secretion and aggregation, broncho-constriction, increased vascular permeability, and systemic hypotension[16-18]. Previous studies demonstrate that PAF could raise portal vein pressure and stimulate glycogenolysis[19,20], the infusion of low doses of synthetic

PAF into the systemic circulation of normal rats caused hyperdynamic status, and PAF production may be dangerous in patients with portal hypertension[20,21]. PAF acts as both a multifunctional soluble proinflammatory agent and a specific membrance-bound adhesion molecule[22-24]. Since the biological effects of PAF are mediated by its specific receptor[25,26], almost all actions of PAF can be prevented by blocking its receptor with antagonists. PAF binding to its receptor induces release of arachidonic acid and produces cycloxygenase-derived eicosanoids[27], glycogenolysis, *etc.* which may mediate vasoconstriction and affect portal vein pressure and hemodynamics. Recent studies have shown that Kupffer cells possess a large number of high affinity PAF receptors which, when stimulated, synthesize and release several active lipid mediators such as eicosanoides and PAF[28]. Houssert *et al* showed that Kupffer cells contain mRNA for the endothelin B (ETB) receptor. However, they did not measure ET binding in Kupffer cells. PAF synthesis/release and its receptor expression in activated Kupffer cells are far from clear in carbon tetrachloride induced cirrhosis. The aim of this study was to elucidate the characteristics of PAF synthesis/release and its receptor expression of the Kupffer cells in rat carbon tetrachloride-induced cirrhosis.

MATERIALS AND METHODS

Establishment of animal model of liver cirrhosis

The experimental protocols were approved by the Animal Care and Use Committee of the Institute of Infectious Diseases of PLA. Cirrhosis was induced in male Sprague-Dawley rats (230-250 g) by intraperitoneal injection of CCl_4 (0.15 mL/kg twice a week for 8 wk). Control rats received injection of the carrier (peanut oil). Rats were allowed access to water containing phenobarbital (0.4 g/L) as the only drink source throughout the induction four days before the CCl_4 treatment. This treatment caused complete distortion of the hepatic architecture due to excessive deposition of the extracellular materia (ECM), portal hypertension, hyperdynamic state and ascites in more than 70% of rats.

Preparation of Kupffer cells

Kupffer cells were prepared from carbon tetrachloride induced male Sprague-Dawley rats . Briefly, after the collagenase (type Ⅳ from clostridium histoticum, 0.025%)/protease (type XIV, from streptomyces griseus, 0.05%) digestion of liver and removal of the hepatocytes and cells debri by low speed centrifugation, Kupffer cells and endothelial cells were purified from other nonparenchymal cells by density gradient centrifugation using 30%(W/V) metrizamide. Kupffer cells were then isolated with a modified centrifugal elutriation procedure. The viability of the Kupffer cells was greater than 95% as determined by trypan blue exclusion. Finally, Kupffer cells were suspended in Williams' medium E (Sigma) containing 10% heat-inactivated fetal calf serum, 5000 U/mL penicillin and 5000 μg/mL streptomycin and plated onto 12- well culture plates at a density of 0.5×10^6 cells/cm^2, and incubated in an atmosphere of 95% air/5% CO_2 at 37℃. The medium was renewed after incubated for 3 h and the cells were used for experiments after an overnight incubation. Purity of the cells determined was greater than 95% by immunostaining with ED2 (Kupffer cells), desmin (stellate cells) and factor Ⅷ related antigen (endothelial cells).

Determination of PAF level in associated Kupffer cells and medium

Lipid extraction: Lipid in associated Kupffer cells and medium was extracted according to the method of Bligh & Dyer. In brief, 1 mL medium was added with methanol (2.5 mL) and chloroform (1.25 mL) was prepared (methanol: chloroform:medium is 2:1:0.8 v:v:v). The mixture was kept for 1 h at room temperature, and added with chloroform (1.25 mL) and water (1 mL), (methanol: chloroform:water is 1:1:0.9 v:v:v). The new mixture was kept for 1 h at room temperature and centrifuged at 1200 × *g* for 15 min. The chloroform layer was dried under a stream of nitrogen at 35℃. In associated Kupffer cells, methanol (2.5 mL), chloroform (1.25 mL) and water (1 mL) (methanol:chloroform:water is 2:1:0.8 v:v:v) were added into the medium.

Purification of PAF: Amprep silica mini-column was used according to the instructions of its manufacturer. In brief, residue was dissolved in 200 μL chloroform and applied to a Bond Elut SI column. The column was washed with 3 mL chloroform, 2 mL chloroform-methanol (3:2, v:v) and 3 mL chloroform-methanol-28% aqueous ammonia (70:85:7, v:v:v), and eluted with 2 mL chloroform-methanol-28% aqueous ammonia (50:50:7, v:v:v). Eluate was evaporated till dried, and the residue was dissolved in 200 μL saline containing 0.1% Triton X-100.

Determination of PAF: Platelet activating factor [^{3}H] scintillation proximity assay (SPA) system kit (Amersham Pharmacis Biotech, USA) was used according to the instructions of the manufacturer.

Morphometric analysis: The activated Kupffer cells were incubated for a day and stained by the method of immunohistochemistry to recognize membrane-bound PAF within activated Kupffer cells. The primary antibody used was a sheep anti-PAF polyclonal preparation [platelet activating factor [^{3}H] scintillation proximity assay (SPA) system kit, Amersham Pharmacis Biotech, USA] The primary antibody was incubated overnight and followed by 0.5 h with secondary antibody in streptavidin-horseradish peroxidase at 1:2500 dilution (DAKO LSAB+ kit, peroxidase, KO679).

Determination of mRNA expression of PAF receptor in activated Kupffer cells

The levels of the low abundance mRNA transcripts of PAF receptor were determined by semiquantitative reverse transcriptase polymerase chain reaction (RT-PCR) using the following procedure. β-actin mRNA expression was determined using the same amount of cDNA as β-actin mRNA. RNA was isolated from the livers using an

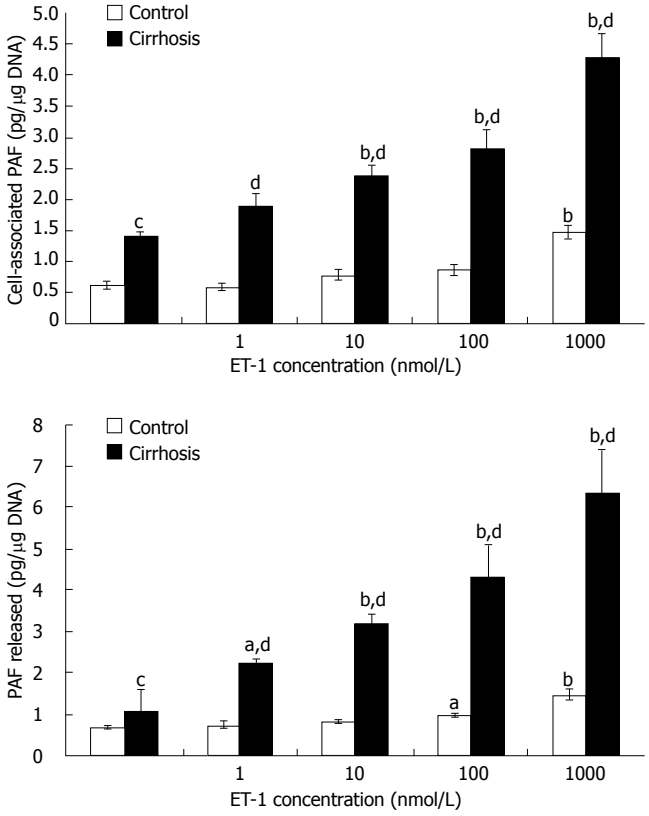

Figure 1 Effect of ET-1 on PAF synthesis in cultured activated Kupffer cells. Kupffer cells from control and cirrhotic rats were cultured and stimulated with increasing concentrations of ET-1 for 15 min in serum-free medium. Cell-associated and released PAF levels were determined as explained in the Methods section. Each point represents an average of triplicate values ± SEM from a representative of two experiments. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* vehicle; $^{c}P < 0.05$ and $^{d}P < 0.01$ *vs* control.

RNA isolation kit (ToTALLY RNA™, Ambion, Austin, TX) as per the instructions of the manufacturer. The concentration of RNA was determined by measuring A260, and the purity was checked by the A260/A280 ratio (greater than 1.8). Two μg total RNA obtained from Kupffer cells was used for the preparation of cDNA by reverse transcriptase-PCR. The PCR primers for PAF cDNA and β-actin cDNA are: 5'-GCCACAACACAGAG GCTTGA-3' (F) and 5'-TCCATTGCTCTGGGCAGGAA -3' (R) (121 bp); 5'-TTCTACAATGAGCTGCGTGTG-3' (F) and 5'-TTCATGGATGCCACAGGATTC-3' (R) (561 bp), respectively. DNA equivalent of 5 ng original RNA was used in PCR. The reaction mixture (50 μL) contained 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 1.5 mmol/L $MgCl_2$, 0.2 mmol/L dNTPs, 20 pmol PCR primer and 2 units of Platinum Taq DNA polymerase (GIBCO-Invitrogen, Carlsbad, CA). The reaction for PAF receptor was run for 35 cycles as follows: denaturation at 94℃ for 1 min, annealing at 60℃ for 30 s, and extension at 72℃ for 30 s. The PCR products were resolved in a 2.5% agarose gel and stained with 1 × SYBR Green I (FMC Biproduct, Rockland, ME). The gels were scanned under blue fluorescence light using a phosphorimager and the band intensity was quantified using ImageQuant software (Molecular Dynamics, Sunnyvale, CA, USA).

Determination of PAF receptor in activated Kupffer cells

After an overnight incubation, Kupffer cells were washed and incubated in 50 mmol/L Tri-HCl , pH 7.2 (5 mmol/L $MgCl_2$, 125 mmol/L choline chloride, 0.25% BSA) containing 0.125-32 nmol/L ^{3}H -PAF (151 Ci/mmol, UK) ± 10 μmol/L unlabelled PAF (C16) (saturation binding) at 22℃ for 3 h. The reaction was terminated with the addition of 5 mL ice-cold assay buffer, the cells were washed in assay buffer and digested with 5% SDS at 60℃ for 30 min. Radioactivity was detected with 5 mL β-scintillation solution. The results were expressed as CPM of ^{3}H -PAF bound per μg protein.

Determination of mRNA expression of preproET-1 and ET-1 receptors in Kupffer cells

Semiquantitative RT-PCR assay was employed to assess the relative levels of preproET-1, ET-1 receptors in Kupffer cells. β-actin mRNA expression was determined using the same amount of cDNA. The PCR primers specific for prproET-1 cDNA are: 5'-CCAACTCTGGGCTCTCCA TGCTGG-3' (F) and 5'-GAATGGCACTGTGTCTCTG CTCTC-3' (R) [241 bp]; for ETA cDNA: 5'-CCCTTCGA ATACAAGGGCGA-3' (F) and 5'-GAAGAGGGAACC AGCACAGTTTCTACTTCTGC-3' (R) [291 bp]; and for ETB cDNA: 5'-GGCTGTTCAGTTTTCTACTTCTGC-3' (F) and 5'-AGAATCCTGCTGAGGTGAAGG-3' (R) [210 bp]. PCR amplification reaction was performed as follows. PCR products were resolved in a 1.2% agarose gel and stained with 1 × SYBR Green I (FMC Biproduct, Rockland, ME, USA). The other procedures were the same for the PAF receptor mentioned above.

Determination of ET-1 receptor in Kupffer cells

After an overnight incubation, activated Kupffer cells were washed with HBSS containing 10 mmol/L HEPES, pH 7.4, and 0.1% bovine serum albumin (HBSS/BSA) and then placed in the medium containing 6.25-800 pmol/L [^{125}I]-ET-1 ± 1 μmol/L unlabelled ET-1 (saturation binding). In the competition binding assay, cells were incubated with 50 pmol/L [^{125}I]-ET-1 ± 1 μmol/L unlabelled ET-1, 5 μmol/L ETA antagonist BQ-123 or 5 μmol/L ET B antagonist BQ-788. After incubation at 22℃ for 3 h, the cells were washed with HBSS/BSA and digested with 0.75N NaOH for determination of radioactivity. Specific binding of [^{125}I]-ET-1 was different in cell-associated radioactivity in the presence and absence of 1 μmol/L unlabelled ET-1.

Statistical analysis

The values are presented as averages of triplicate determinations ± SEM. Each experiment was repeated at least three times using cells from different animals. Student *t* test was employed for statistical comparison of the paired samples. A *P* value of < 0.05 was considered statistically significant.

RESULTS

Effect of ET-1 on PAF synthesis in activated Kupffer cells

Basal release of PAF was increased by about two-fold in cirrhotic rat Kupffer cells as compared with the control

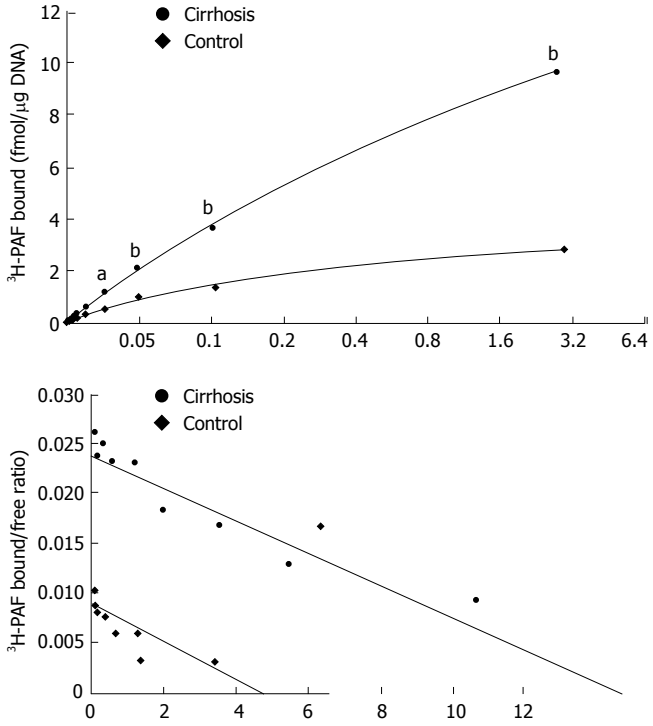

Figure 2 **A**: Saturation curve binding to cirrhotic and normal rat Kupffer cells. Cells were used after overnight culture for receptor binding assay as described in the Method section. ^{3}H-PAF at a concentration between 0.125 and 3.2 nmol/L was incubated with Kupffer cells in presence or absence of 5 μmol/L unlabeled PAF at 22℃ for 3 h. $^aP < 0.05$, $^bP < 0.01$ *vs* control; **B**: Scattered blot analysis of ^{3}H-PAF binding to cirrhotic and normal rat Kupffer cells. The results were analyzed by scatchard plot. Cirrhosis: R = 0.99, Kd = 2.08 nmol/L, Bax = 27.1882 ± 2.0885 fmol/mg. DNA; Control: R = 0.96, Kd = 1.57 nmol/L, Bax = 4.4024 ± 0.3155 fmol/mg. DNA.

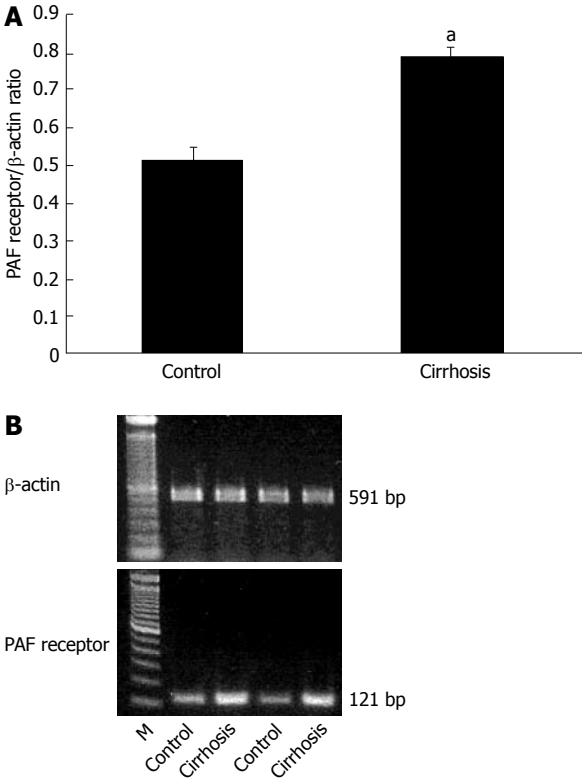

Figure 3 **A**: The mRNA expression of cirrhotic rat Kupffer cell PAF receptor. Expression of β-actin mRNA (β-actin control: 90 311.14 ± 3882.67; cirrhosis: 110 958.2 ± 1484.58). $^aP < 0.05$ *vs* control; **B**: Character of the PAF receptor expression in cirrhotic Kupffer cells. Total RNA was extracted from the cells for determination of PAF receptor mRNA expression by semiquantitative reverse transcriptase polymerase chain reaction assays as described in the Method section.

(1.42 ± 0.14 *vs* 0.66 ± 0.04 pg/μg DNA, $P < 0.01$), while basal release of membrane-bound platelet-activating factor was only increased by about 1.48-fold (1.02 ± 0.06 *vs* 0.69 ± 0.07 pg/μg DNA, $P < 0.01$) (Figure 1). Interestingly, activated Kupffer cells appeared to release more PAF than membrane-bound platelet-activating factors. Application of ET-1 to rat Kupffer cells induced the PAF synthesis in both control and activated Kupffer cells (Figure 1). However, the effect was more pronounced in the latter. Significantly induced PAF synthesis occurred at 100 nmol/L ET-1 in control and cirrhotic Kupffer cells, and therefore, statistical significance was observed at 1-1000 nmol/L ET-1. Immunochemical detection of ET-1 induced PAF synthesis in cirrhotic and normal Kupffer cells showed that cytoplasm PAF was stained, strongly and increased in a concentration-dependent manner (B, D pulsed ET-1 100 nmol/L), and the cytoplasm of PAF staining in activated Kuppffer cells increased more significantly than that in the controls.

PAF receptor expression in cirrhotic Kupffer cells

Scattered blot analysis of the saturation binding data revealed about a six-fold increase in ^{3}H -PAF binding capacity in cirrhotic Kupffer cells as compared with the controls (Bmax of 27.19 ± 2.09 *vs* 4.40 ± 0.32 fmol/μg. DNA). The affinity of the receptors was not altered in the cirrhosis (Kd of 2.08 ± 0.22 nmol/L in the cirrhosis and 1.57 ± 0.17 nmol/L in the control) (Figure 2A and B). In cirrhosis, PAF receptor expression of activated Kupffer cells increased 1.5-fold as agaist the control (0.78 ± 0.03 *vs* 0.52 ± 0.03) (Figure 3A and B), which was consistent with PAF receptor saturation binding data.

Preproendothelin-1 and ET-1 receptor expression in cirrhotic Kupffer cells

Figure 4 illustrates the scattered blot of the results of [^{125}I]-ET-1 saturation binding assays in cirrhotic Kupffer cells. Activated Kupffer cells increased their binding capacity by about two-fold as compared with the control (Bmax of 1639 ± 27.71 *vs* 820.4 ± 28.75 fmol/μg DNA). No change was observed in the affinity of the receptors in the cirrhosis (Kd of 37.72 ± 6.08 pmol/L in cirrhosis and 22.79 ± 3.46 pmol/L in the control). As shown in Figure 5, in 50 pmol/L [^{125}I]-ET-1, the [^{125}I]-ET-1 specific binding capacity increased by about 1.7-fold (Bmax of 0.34 ± 0.02 *vs* 0.20 ± 0.01 fmol/μg DNA). In the cirrhotic Kuppfer cells, the number of ET-1 receptor was larger than that of the control. ETA receptor antagonist BQ-123 did not affect [^{125}I]-ET-1 specific binding (specific binding: 0.34 ± 0.02 fmol/μg DNA; BQ-123: 0.25 ± 0.02 fmol/μg DNA in cirrhosis; specific binding: 0.22 ± 0.01 fmol/μg DNA, BQ-123: 0.18 ± 0.01 fmol/μg DNA in control), but ETB receptor antagonist BQ-788 significantly blocked [^{125}I]-ET-1 specific binding (cirrhosis: 0.08 ± 0.003 fmol/μg DNA; control: 0.09 ± 0.002 fmol/μg DNA). This revealed that activated Kupffer cells only increased the number of ETB

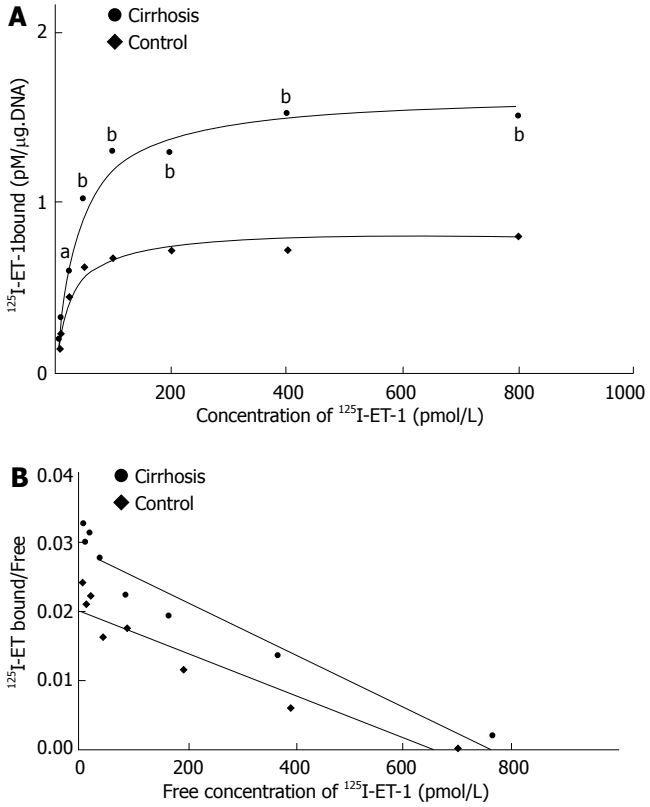

Figure 4 **A**: Saturation curve of ^{125}I-ET-1 binding to cirrhotic and normal rat Kupffer cells. ^{125}I-ET-1 at a concentration between 6.25-800 pmol/L was incubated with Kupffer cells (1×10^6), in presence or absence of 2 μmol/L unlabeled ET-1 at 20℃ for 3 h; **B**: Scattered blot analysis of ^{125}I-ET-1 binding to cirrhotic and normal rat Kupffer cells. The result was analyzed by scatchard plot. Cirrhosis: R = 0.98, Kd = 37.72 pmol/L, Bax = 1639 ± 67.7 fmol/mg. DNA; Control: R = 0.94, Kd = 22.79 pmol/L, Bax = 820.4 ± 28.7 fmol/mg. DNA.

receptor, but never changed the ET-1 receptor expression. Figure 6 shows the characteristics of the expression of preproendothelin-1 and ET-1 receptor subtypes in the Kupffer cells of cirrhotic rats. The activated Kupffer cells neither expressed preproendothelin-1 nor changed the expression of ET-1 receptor subtypes, they only expressed ETB receptor which was increased by 166.07% as compared with the control (0.34 ± 0.01 *vs* 0.21 ± 0.01).

DISCUSSION

Elucidation of the interactions between activated Kupffer cells and ET-1 as a method for detecting hepatic cirrhosis and attendant hemodynamic abnormalities in pathophysiology, has been a topic of intensive investigations in the recent years. Previous studies have demonstrated that ET activates both phosphoinositide metabolism and prostaglandin synthesis in rat Kupffer cells[30] and ET-1 stimulates PAF synthesis in Kupffer cells[29], while the current study has demonstrated that ET results in biosynthesis and release of PAF[31] in cultured rat Kupffer cells. The diversity of ET actions in Kupffer cells might be explained by the existence of more than one receptor subtype or activation of more than one signal transduction pathway after endothelin binding. Houssert[32] found that Kupffer cells contain mRNA for the ETB receptor, however they did not measure ET binding in Kupffer cells. Based on the growing body of evidence regarding hepatic cirrhosis, it is evident that Kupffer cells act as

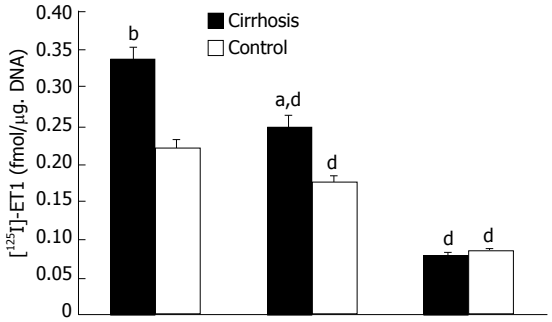

Figure 5 Competition binding assay (50 pmol/L ^{125}I-ET-1 ± 1 μmol/L unlabelled ET-1, 5 μmol/L ETA antagonist BQ-123 or 5 μmol/L ETB antagonist BQ-788). Specific binding of [^{125}I]-ET-1 was different in cell-associated radioactivity in the presence and absence of 1 μmol/L unlabelled ET-1. $^aP < 0.05$, $^bP < 0.01$ *vs* control; $^dP < 0.01$ *vs* [^{125}I]-ET-1.

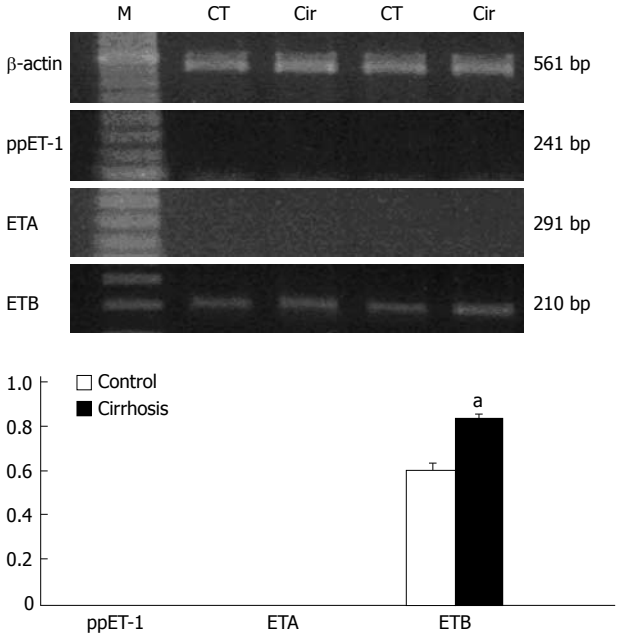

Figure 6 Characteristics of the preproendothelin-1 and ET-1 receptor subtype expression in the cirrhotic rat Kupffer cells. RNA was extracted from the cells for determination of preproET-1 and ET-1 receptor subtypes mRNA expression by semi-quantitative reverse transcriptase polymerase chain reaction assay. Graphical presentation of data as standardized relative to expression of β-actin mRNA (β-actin control: 90 311.14 ± 3882.67; cirrhosis: 11 095.82 ± 1484.58). $^aP < 0.05$ *vs* control.

critical effector cells in the pathogenesis of cirrhosis and hemodynamic abnormalities[33]. Our study has demonstrated that PAF could lower the systemic arterial pressure and raise the portal pressure[34,35], so PAF is a principal mediator of hyperdynamic circulation and portal hypertension. As illustrated in Figure 1, activated Kupffer cells enhanced the synthesis of PAF, and appeared to secrete more PAF than membrane-bound platelet-activating factor. PAF synthesis was increased in a concentration-dependent manner in both cirrhotic and normal rat Kupffer cells. In the present study, enhanced synthesis of PAF by activated Kupffer cells may account for the increased hepatic concentration and PAF level. The increase (Figures 2 and 3) in activated Kupffer cells demonstrated that PAF had an autocrine function on activated Kupffer cells. PAF increase in activated Kupffer

cells has been implicated to be an important mediator of hyperdynamic circulation associated with liver cirrhosis. In agreement with the previous reports in cirrhotic patients, increased blood PAF levels were observed in CCl_4-induced cirrhotic rats[36]. The results of the present study suggest that the enhanced synthesis and release of PAF by activated Kupffer cells may contribute to its elevated circulating concentration in cirrhotic rats. The basal levels of cell-associated and secreted PAF were significantly higher in activated Kupffer cells than in the controls. Because the biological effects of PAF are mediated by its specific receptor, almost all actions of PAF can be prevented by blocking its receptor antagonists. The binding of PAF to its receptor may induce the release of arachidonic acid and PAF, and the vasoconstriction, portal vein pressure and hyperdynamic circulation may be mediated and influenced by eicosanoids.

ET-1 induced PAF synthesis in activated Kupffer cells increased in a concentration-dependent manner, revealing that endogenously produced ET-1 can increase the hepatic concentration and PAF levels in cirrhosis. The activated Kupffer cells did not express preproendothelin-1, either, indicating that ET-1 stimulates PAF synthesis in activated Kupffer cells by paracrine. Clearly, Kupffer cells are major contributors to the increased hepatic concentration and PAF level in cirrhosis.

It has been known that Kupffer cells contain only ETB receptor. The ET-1 saturation and competition binding assay show that ET-1-induced increase in PAF synthesis was mediated *via* ETB receptor. Activated Kupffer cells enhanced the binding capacity, but did not change the affinity of the receptors (Figures 4 and 5), although the number of PAF receptors was increased. Activated Kupffer cells did not express ETA receptor (Figure 6). As a result of hepatic injury, ETA receptor did not appear in activated Kupffer cells. In cirrhosis, activated Kupffer cells did not change the character of ET-1 receptor expression.

In conclusion, activated Kupffer cells in the course of CCl4-induced cirrhosis are the main source of increased PAF; endogenously, ET-1 can stimulate PAF synthesis in activated Kupffer cells via ETB receptor by paracrine; and as a result of hepatic injury, ETA receptor did not appear in activated Kupffer cells. The PAF receptor expression in activated Kupffer cells and PAF binding capacity are markedly increased in cirrhosis, which may exacerbate the hepatic and extrahepatic complications of cirrhosis.

COMMENTS

Background

Kupffer cells in the pathogenesis of different types of liver injury have been demonstrated to be involved in several models of liver damage induced by chemicals including carbon tetrachloride, alcohol and allyl alcohol. The high affinity platelet-activating factor (PAF) receptors, when stimulated, synthesize and release several active lipid mediators including eicosanoides and PAF. Kupffer cells have been shown to contain mRNA for the ETB receptor. However, no ET binding was measured in Kupffer cells. PAF synthesis/release and its receptor expression in activated Kupffer cells is far from clear in the carbon tetrachloride induced cirrhosis. Kupffer cells are activated in response to chemical administration and promote tissue damage by releasing biologically active mediators such as prostaglandins, TNFα, oxygen free radicals, and other proinflammatory mediators. PAF raised portal vein pressure and stimulated glycogenolysis, and PAF production may be dangerous in patients with portal hypertension as reported previously. The biological effects of PAF are mediated by its specific receptor, therefore, almost all actions of PAF can be prevented by blocking its receptor with antagonists. PAF binding its receptor induces release of arachidonic acid and production of cycloxygenase-derived eicosanoids, glycogenolysis, etc. which may mediate vasoconstriction and affect portal vein pressure and hemodynamics.

Research frontiers

Elucidation of the interactions between activated Kupffer cells and ET-1 as the mechanism detecting hepatic cirrhosis and attendant hemodynamic abnormalities in pathophysiology, has been a topic of intensive investigations in the recent years.

Innovations and breakthroughs

This paper has confirmed that expression of PAF receptor in activated Kupffer cells and PAF binding capacity are markedly increased in cirrhosis, which may exacerbate the hepatic and extrahepatic complications of cirrhosis.

Applications

Based on the result of this research, we can decrease the synthesis of PLT in Kupffer cells by suppressing the secretion of ET-1, or blocking its receptor, which may lighten or defer the hepatic and extrahepatic complications of cirrhosis.

Terminology

Kuppfer cells, resident macrophages in the liver, constitute the largest population of macrophages in the body and are critical effector cells for the defense against invading micro-organisms and foreign molecules. Platelet-activating factor (PAF) is the trivial name for a phospholipid called 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine that has unique phospholipid autacoid exhibiting diverse biological activities on various tissues and organs such as isolated lung, liver and brain, and different types of cells (platelet, neutrophils, endothelial cells, neural cells). ET-1 stimulates PAF synthesis in Kuffer cells.

Peer review

The data presented by the authors strongly supports the hypothesis that Kupffer cells in cirrhotic livers are a main source of PAF, which contribute significantly to secondary signs of cirrhotic liver like portal hypertension. The topic is very interesting, and the experiments performed mainly prove the conclusions of the authors.

Abstract

AIM: To study the relationship between anti-β2-glycoprotein Ⅰ (aβ2GP Ⅰ) antibodies and platelet activation state in patients with ulcerative colitis (UC) and its significance.

METHODS: Peripheral blood samples were collected from 56 UC patients (34 males and 22 females, aged 43.5 years, range 21-66 years), including 36 at active stage and 20 at remission stage, and 25 sex-and age-matched controls. The level of aβ2GP Ⅰ was measured by ELISA. The platelet activation markers, platelet activation complex-Ⅰ (PAC-Ⅰ) and P-selectin (CD62P) were detected by flow cytometry.

RESULTS: The A value for IgG aβ2GP Ⅰ in the active UC group was 0.61 ± 0.13, significantly higher than that in the remittent UC and control groups (0.50 ± 0.13 and 0.22 ± 0.14, $P < 0.01$). There was a significant difference between the two groups ($P < 0.01$). The A value for IgM aβ2GP Ⅰ in the active and remittent UC groups was 0.43 ± 0.13 and 0.38 ± 0.12, significantly higher than that in the control group (0.20 ± 0.12, $P < 0.01$). However, there was no significant difference between the two groups ($P > 0.05$). The PAC-Ⅰ positive rate for the active and remittent UC groups was 30.6% ± 7.6% and 19.6% ± 7.8% respectively, significantly higher than that for the control group (6.3% ± 1.7%, $P < 0.01$). There was a significant difference between the two groups ($P < 0.01$). The CD62P positive rate for the active and remittent UC groups was 45.0% ± 8.8% and 31.9% ± 7.8% respectively, significantly higher than that for the control group (9.2% ± 2.7%, $P < 0.01$). There was a significant difference between the two groups ($P < 0.01$). In the active UC group, the more severe the state of illness was, the higher the A value for IgG aβ2GP Ⅰ was, and the positive rate for PAC-I and CD62P was positively correlated with the state of illness (Faβ2GP Ⅰ = 3.679, $P < 0.05$; FPAC-I (%) = 5.346, $P < 0.01$; and FCD62P (%) = 5. 418, $P < 0.01$). Meanwhile, in the same state of illness, the A value for IgG aβ2GP Ⅰ was positively correlated to the positive rates for PAC-I and CD62P.

CONCLUSION: aβ2GP Ⅰ level, platelet activation state and their relationship of them are closely correlated with the pathogenesis and development of UC.

INTRODUCTION

β2-glycoprotein Ⅰ (β2GP Ⅰ) contains 150-200 mg/L glycoprotein in plasma[1] and is synthesized by hepatocytes[2]. It participates in fat transfer and metabolism due to its lipotropy[3], and is also known as apolipoprotein H (apoH)[4]. It was reported that β2GP Ⅰ is an immunogen in antiphospholipid syndrome (APS)[5-10]. Antiphospholipid antibody is the only autoantibody that induces blood into hypercoagulability state, just like one bridge between two physiology systems, immunity and coagulation, which may cause formulation of arterial and venous thrombosis with

unknown reasons[11-15]. β2GP I is known as a target antigen of antiphospholipid antibody[16-19]. Although ulcerative colitis (UC) is an inflammatory bowel disease (IBD) with unknown reasons, it is closely related to immunity, thrombosis formulation and blood hypercoagulability state[20-24]. To research the possible mechanism of blood hypercoagulability state, we measured the aβ2GP I level and detected the platelet activation state in serum of UC patients.

MATERIALS AND METHODS

Materials

Heparin sepharose CL-6B and sephadex G-100 were from Swedish Pharmacia Company. Flow cytometer (FACSort Calibur Type) was from American Becton Dickion Company and MB-Ⅲ enzyme mark instrument was from Beijing New Technology Institute. Fluorescein isothiocyanate labeled against platelet activation GPI1b/Ⅲa (PAC-I FITC) fibrinogen receptor McAb, phycoerythrin labeled anti-P-selectin (CD62P PE) McAb, peridinin chlorophyll protein labeled platelet glycoprotein Ⅲ (CD61 per-cp) McAb, negative control RGDS as a PAC-I blocker, phycoerythrin labeled mouse IgG (Mouseγ1PE), FACS flow TM sheath fluid were all from American Becton Dickion Company. Horseradish peroxidase labeled goat anti-human IgG was a product from Canadian Anogen, and horseradish peroxidase labeled goat anti-human IgM was from Huamei Company. The rest agents used were of national analytical purity.

Patients

Fifty-six patients attending to No. 1 and 2 Hospitals Affiliated to Jilin University from September 2003 to December 2004 were included in the study as UC group. Of the 56 UC patients (34 males and 22 females at the age of 21-66 years with a mean age of 43.5 years), 36 had active UC, 20 had remittent UC. The average disease course was 18 mo. All the cases were diagnosed based on the diagnostic criteria for inflammatory bowel disease (IBD) revised at the National Inflammatory Bowel Disease Conference held in 2000. Of which, 47 patients were diagnosed based on the findings in clinical, endoscopic and pathologic examinations, 9 patients were diagnosed based on the findings in clinical and endoscopic examinations. None of the patients had hypercoagulability state in the heart, liver, kidney, pulmonary and cerebrovascular diseases. The patients did not take any drugs affecting coagulation and fibrinolytic systems 4 wk before their diagnosis. Twenty-five healthy persons (15 males and 10 females at the age of 22-58 years with a mean age of 42.5 years) served as the control group. There was no significant difference in sex and age between the two groups.

Measurement of β_2GP I level

Five microlitre of 700 mL/L perchloric acid was added into 200 mL human plasma, stirred for 15 min at 4℃, centrifuged at 12000 r/min for 20 min at 4℃, dialyzed (0.02 mol/L Tris-HCl, pH 8.0, 0.03 mol/L NaCl) and concentrated by heparin sepharose CL-6B affinity chromatography. Linear gradient elution (0.03-0.35 mol/L NaCl) was performed to collect about 0.25 mol/L elution, which was dialyzed (0.02 mol/L Tris-HCl, pH 8.0, 0.03 mol/L NaCl) and concentrated by heparin sepharose CL-6B affinity chromatography. Linear gradient elution was performed (0.15-0.35 mol/L NaCl), and the elution peak containing β2GP I was collected and concentrated. The sample was dialyzed (0.02 mol/L Tris-HCl, pH8.0, 0.03 mol/L NaCl) and concentrated. Sephadex G-100 was separated, elution peak containing β2GP I was collected, dialyzed (0.02 mol/L Tris-HCl, pH 8.0, 0.03 mol/L NaCl) and concentrated. Protein was determined with the Lowry method and protein purity was assayed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and ultraviolet scanning.

Detection of aβ_2GP I by ELISA

IgG aβ2GP I and IgM aβ2GP I were detected in each serum sample. Multi-wells were set for the two antibodies (n = 3). Enzyme labeled 96-well plates were disposed with ^{60}Co. Their surface was oxygenized and 100 μL coating solution containing 4 μg/mL β2GP I was added and stored at 4℃ overnight. The coating solution was recycled, the plates were washed three times(3 min each time) with phosphate-buffered solution-Tween 20 (PBS-T) and 6 g/L gelatin-PBS-T was added (100 μL per well) and sealed at 37℃ for 1 h. The plates were washed three times (3 min each time). The diluted serum sample was added (100 μL per well) and incubated at 37℃ for 2 h. The plates were washed three times (3 min each time) with PBS-T. The two antibodies were discarded, the plates were washed three times (3 min each time) with PBS-T. Stained liquid o-phenylene diamine was added (100 μL per well) and reacted with shade for 5 min, 2 mol/L H_2SO_4 was added (50 μL per well) and shaken evenly. The reaction was terminated and optical density value at 492 nm was detected with enzyme mark instruments.

Detection of platelet activation state in UC patients by flow cytometry

Three mL venous blood was taken. The first 2 mL mixed with tissue fluid was discarded, and the remained 1 mL was added into anticoagulative tubes, shaken and mixed evenly. PAC-I FITC, CD62P PE, CD61 per-cp (20 μL each) were added into experimental tubes for 10min. PAC-I FITC, IgG1PE, CD61 per-cp (20 μL each) and 10 μL RGDS were added into the control tubes, and 5 μL mixed blood was shaken evenly and added into the tubes separately. After incubated for 20 min at the room temperature, PBS (pH 7.2) was added, shaken evenly for 30 min and stored at a cool dark place.

Statistical analysis

SPSS 11.5 statistical software was used to establish database and analyze the data. Comparison between groups was made by t test and comparison between multi-independent samples was carried out by One-way ANOVA, related analysis was performed by Pearson analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Extraction and purity of β_2GP I

β2GP I was detected as one band by three-step

Table 1 Detection results of aβ2GP I in patients among groups (A_{492}, mean ± SD)

Group	*n*	IgM	IgG
Active UC group	36	0.43 ± 0.13[b]	0.61 ± 0.13[b,d]
Remittent UC group	20	0.38 ± 0.12[b]	0.50 ± 0.13[b]
Control group	25	0.20 ± 0.12	0.22 ± 0.14

[b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* remittent UC group.

Table 2 Positive expression rate for platelet activation marker in different groups of patients (%, mean ± SD)

Group	*n*	PAC-I	CD62P
Active UC group	36	30.6 ± 7.6[b,d]	45.0 ± 8.8[b,d]
Remittent UC group	20	19.6 ± 7.8[b]	31.9 ± 7.8[b]
Control group	25	6.3 ± 1.7	9.2 ± 2.7

[b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* remittent UC group.

chromatography, while molecular weight 50 000 and purity over 90% were determined by SDS-PAGE.

Detection of aβ2GP I in different groups of patients

Comparison of IgM aβ2GP I levels in different groups: there was a statistically significant difference in IgM aβ2GP I level between the active UC and control groups ($t = 7.010$, $P < 0.01$) and between the remittent UC and control groups ($t = 5.000$, $P < 0.01$). No statistically significant difference was found in IgM aβ2GP I level between the active and remittent UC groups ($t = 1.416$, $P > 0.05$).

Comparison of IgG aβ2GP I level in different groups: there was a statistically significant difference in IgG aβ2GP I level between the active UC and control groups ($t = 6.879$, $P < 0.01$) and between the active and remittent UC groups ($t = 3.034$, $P < 0.01$) (Table 1).

Positive expression rate for platelet activation marker in different groups of patients

The positive expression rates of platelet activation markers PAC-I and CD62P were sharply increased in the active UC group. There was a statistically significant difference between the active UC and control groups ($t_{PAC\text{-}I\ (\%)} = 15.679$, $t_{CD62P\ (\%)} = 19.664$, $P < 0.01$) and between the active and remittent UC groups ($t_{PAC\text{-}I\ (\%)} = 5.142$, $t_{CD62P\ (\%)} = 5.551$, $P < 0.01$). The positive expression rate in the remittent UC group was higher than that in the normal control group ($t_{PAC\text{-}I(\%)} = 8.305$, $t_{CD62P\ (\%)} = 13.306$, $P < 0.01$) (Table 2).

Correlation between aβ2GP I platelet activation marker and disease grades in 36 active UC patients

One-way ANOVA showed that there was a statistically significant difference of aβ2GP I level, PAC-I and CD62P in the disease grades (mild, moderate, severe) of patients with active UC [$F_{a\beta2GP\ I} = 3.679$ ($P < 0.05$), $F_{PAC\text{-}I\ (\%)} = 5.346$ ($P < 0.01$); F_{CD62P} (%) = 5.418 ($P < 0.01$, Table 3)]. Pearson correlation analysis displayed that the correlation coefficient of aβ2GP I (IgG) and PAC-I, and aβ2GP I (IgG) and CD62P PE was $r = 0.472$ and $r = 0.523$ ($P < 0.05$) respectively for mild active UC patients. The correlation coefficient of aβ2GP I (IgG) and PAC-I, and aβ2GP I (IgG) and CD62P was $r = 0.659$ ($P < 0.05$) and $r = 0.714$ ($P < 0.01$) respectively for moderate active UC patients. The correlation coefficient of aβ2GP I (IgG) and CD62P, and aβ2GP I (IgG) and PAC-I was $r = 0.714$ ($P < 0.01$) and $r = 0.878$ ($P < 0.01$) respectively for severe active UC patients. The correlation coefficient of aβ2GP I (IgG) and PAC-I, and aβ2GP I (IgG) and CD62P was $r = 0.878$ ($P < 0.01$) and $r = 0.902$ ($P < 0.01$) respectively for severe active UC patients.

Table 3 Correlation between aβ2GP I, platelet activation marker and disease grades in 36 active UC patients

Grade	*n*	aβ2GP I 492 (IgG)	PAC-I positive rate (%)	CD62P positive rate (%)
Mild	19	0.64	31.8	48.7
Moderate	11	0.80	40.6	60.9
Severe	6	0.92	53.7	71.2
F		3.679	5.346	5.418
P		< 0.05	< 0.01	< 0.01

DISCUSSION

β2GP I is a kind of glycoprotein in normal plasma. It has been shown in a recent study[19] that β2GP I plays an important role in the pathophysiological processes of human beings, such as production of APS autoantibody and formation of hypercoagulability state. Its molecule is a single polypeptide chain consisted of 326 amino acids and can be divided into five special functional domains under intermolecular disulfide bond influence, each of which is a circular permutation on the space. There are abundance amino acid sequences with positive charges in the fifth functional domain, the binding sites of which to phospholipids are located on C-terminal end. Cys281- Cys288 is the binding site and can combine with the surfaces of anionic phospholipids and particles with negative charges. One of their important physiological functions is to adjust the distribution of anionic phospholipids expressed on the activated platelets.

It was reported that immune factors play an important role in the pathogenesis of UC[25-27]. Thromboembolic disease is one of three main causes resulting in death of UC patients. Most scholars believe that hypercoagulability state, micro-thrombosis formation and platelet activation may play an important role in the pathogenesis of UC[28,29].

The pathogenesis of APS and UC mainly depends on immune factors, presence of hypercoagulability state and thrombosis formulation. aβ2GP I also plays an important role in the pathogenesis of APS[30].

In the present study, the serum aβ2GP I level in UC patients was measurable. The IgG aβ2GP I level in the active UC group was higher than that in the remittent UC and control groups, indicating that aβ2GP I may have a certain role in the pathogenesis of UC. Antiphospholipid antibody is just like one bridge between the two physiology systems, immunity and coagulation, which may lead to

arterial and venous thrombosis with unknown reason. Moreover, aβ2GP I is one of the most important autoantibodies. Whether aβ2GP I presence plays an important role in hypercoagulability state and thrombosis formation in ulcerative colitis remains unclear. We have proved, in this study, not only the platelet activation state but also the correlation between platelet activation and disease severity in active UC patients.

Flow cytometer and platelet glycoprotein McAb can accurately detect platelet activation. In this study, phycoerythrobilin labeled CD62P McAb was selected as a molecular marker, CD62P also known as GMP140, a protein on resting platelet α granule membrane. Since granules are released onto the platelet surface when platelets are in an active state, CD62P is expressed on the active platelet membrane instead of on the resting platelet membrane, which is a symbol of active platelets.

GPⅡb/Ⅲa is a glycoprotein on platelet membrane, which can be expressed in resting and active platelets, but only in activated platelets. The binding site of GPⅡb/Ⅲa and fibrinogen can be exposed. Moreover, since PAC-I is a McAb inhibiting the binding site, it is an effective means for detecting activated platelets because they can only combine with active platelets.

In the present study, the positive expression rate for platelet activation markers, PAC-I and CD62P, in active UC patients, was obviously higher than that in the control and remittent UC groups, indicating that platelet activation is one of the main reasons for blood hypercoagulability state in UC patients. At the same time, the positive expression rate for platelet activation markers in remittent UC group was higher than that in the control group ($P < 0.01$), indicating that platelet activation is a difficultly-eliminated factor. Anti-platelet activation therapy for patients at the remission stage can delay the disease progression and further improve prognosis and life quality of UC patients.

Not only high aβ2GP I level but also high activation state of platelets in patients with UC was detected in this study and the relationship between aβ2GP I level, platelet activation state and disease severity was further studied.

There was a significant difference in the positive expression rates of aβ2GP I (IgG), PAC-I and CD62P between the active UC patients, which increased when the disease was aggravated. Moreover, the positive expression rates of aβ2GP I (IgG), PAC-I and CD62P were positively correlated with the severity of the disease, suggesting that aβ2GP I and platelet activation play an important role in the development of ulcerative colitis and there is a mutual causality between aβ2GP I and platelet activation. Excessive inflammatory response may lead to loss of tolerance to some autoantigens. When the autoantibody is induced and damage is aggravated, inflammatory factors may cause platelet activation. Activated platelets and phospholipids with negative charges from the inner layer of cytomembrane are exposed on the surface of cytomembrane, which combines with β2GP I easily. After the combination, the concealed antigenic epitopes of β2GP I are exposed, thus producing anti-β2GP I antibody and other autoantibodies. aβ2GP I can not only combine with platelets but also activate platelets and endothelial cells[31], accelerating adhesion of monocytes and promoting the development of UC and complications, such as thrombosis.

In summary, aβ2GP I is one of the possible causes for blood hypercoagulability state in UC patients. The results of this study provide a new theoretical foundation for the pathogenesis of UC.

COMMENTS

Background

Although UC is an inflammatory bowel disease with unknown reasons, it is closely related to immunity and blood hypercoagulability state, just like APS. Anti-β2-glycoprotein antibody plays an important role in the pathogenesis of APS, which is our cut-in point in this study.

Research frontiers

The increased risk of thromboembolic complications in patients with UC is well recognized. It was reported that the incidence of thromboembolic events is 1%-8% in patients with inflammatory bowel disease. In addition, patients with inflammatory bowel disease may experience thromboembolic events at a younger age. Disease activity is a probable risk factor for thromboembolism. The hypercoagulable state in active UC patients is closely related to abnormal platelet function, resulting in a high probability of microvascular thrombosis and microcirculatory dysfunction, but so far, the reasons remain unclear.

Innovations and breakthroughs

Studies on factors such as vWF, XIIa, IX, VIIa, VIIIa, Va, and abnormal platelet function are available. In this study, we explored the cause for hypercoagulable state in UC patients based on the autoimmunity.

Applications

This study provided a new theory for the pathogenesis and development of UC, which is very helpful to estimate illness state and prognosis. Moreover, anti-thrombotic compounds seem to be therapeutically beneficial for UC patients.

Terminology

APS: Anti-phospholipid syndrome, a clinical condition characterized by recurrent thrombotic events and/or pregnancy morbidity associated with the persistence of antiphospholipid antibodies.

Peer review

This paper is very interesting because the authors studied an interesting problem related with the hypercoagulation state in some patients with ulcerative colitis.

Abstract

AIM: To detect *Salmonella enteritidis* (*S. enteritidis*) in paraffin slices and antigen location in infected duck tissues.

METHODS: Rabbits were immunized with purified bacillus to obtain *S. enteritidis*-specific antibody, which were then extracted by the caprylic-ammonium sulphate method, purified through High-Q columns. An indirect immuno-fluorescent staining method (IFA) was established to detect the *S. enteritidis* antigen in paraffin slices. *S. enteritidis* was detected in each organ tissue of ducklings experimentally infected with *S. enteritidis*.

RESULTS: The gland of Garder, heart, kidney, spleen, liver, brain, ileum, jejunum, bursa of Fabricius from *S. enteritidis* experimentally infected ducklings were positive or strongly positive, and the *S. enteritidis* antigen was mainly distributed in the infected cell cytoplasm.

CONCLUSION: IFA is an intuitionist, sensitive and specific method in detecting *S. enteritidis* antigen in paraffin wax slices, and it is a good method in diagnosis and antigen location of *S. enteritidis*. We also conclude that the gland of Garder, heart, kidney, spleen, liver, ileum, jejunum are target organs in *S. enteritidis* infections of duck, and *S. enteritidis* is an intracellular parasitic bacterium.

INTRODUCTION

Salmonella enteritidis (*S. enteritidis*) is the infectious disease causing Zoonoses. *S. enteritidis* is one of the primary causes of human food poisoning throughout the world, and has become a pointed public health problem[1-4]. China is the biggest country in the raising and consumption of duck in the world, but the *S. enteritidis* bacillus infection is a severely important infectious disease in the duck industry[5]. *S. enteritidis* outbreaks have been found to be associated with the consumption of contaminated and undercooked poultry products, such as eggs and egg-containing products, and have become a serious economic and public health problem[6]. Conventional methods for isolation of *S. enteritidis* are too laborious, not sufficiently sensitive or correct[7,8]. To our knowledge, a serum method for detection and antigen location of *S. enteritidis* has not been reported. Thus, to establish a rapid, sensitive and highly specific

method for detection of *S. enteritidis* is necessary. We established the Indirect Immunofluorescent (IFA) method to detect and antigen locate *Salmonella enteritidis* to offer a clinical means of diagnosis and apathogenic mechanism of ecology.

MATERIALS AND METHODS

Bacteria strain

S. enteritidis MY1 strain (obtained from Avain Disease Research Center of Sichuan Agriculture University).

Rabbit anti-serum preparation

Briefly, 5 mL of *S. enteritidis,* an overnight culture grown in LB broth, was harvested by centrifugation after 18 h at 37℃. Then diluted at 4×10^9 cfu and inactivated by formaldehyde and equaled to complete Freund's adjuvant (CFA) made the antigen. Rabbits were immunized with 1 mL antigen to obtain *S. enteritidis*-specific antibody, which was then extracted by the caprylic-ammonium sulphate method[9], purified through High-Q columns.

The establishment of the IFA

According to references[10], the following factors were considered to establish the method: (1) antigen recovery, to partly recover the antigens based on a microwave using 0.01 mol/L pH 6.0 citrate buffer solution for 20 min, 200 μg/mL parenzyme for 20min and no recovery; (2) rinsing water: 0.01 mol/L pH 7.4 PBS, 0.01 mol/L pH 7.4 PBS (containing 0.05% Tween-20) and rinsing water separately; (3) confining liquid: using 10% horse serum and 10% BSA to confine; (4) the diluted content of anti-rabbit-SE IgG: 1:25; 1:50; 1:100 and 1:200, incubate time: 4℃ overnight and 37℃ for 40 min; (5) the diluted content of the FITC labeled goat anti-rabbit IgG: 1:25; 1:50; 1:10 and 1:200; (6) foiled liquid: partly used 0.01% Evans Blue and unfoiled.

Artificial infected cases detection

Experimental infections were performed with a *S. enteritidis* MY1 strain. In brief, a group of 24 (specific antibody of SE negative) Bei Jing duck were inoculated with 0.2 mL (2×10^9 cfu) of *S. enteritidis* at the age of 7 d in the crop. Twenty-four uninoculated 7-d-old ducks were used as control animals.

After 24 h post-inoculation some of the ducks began to die resulting in organ harvesting. The organs were detected by IFA and conventional isolation respectively.

Treatment included first, using a non-selective pre-enrichment medium of buffered Peptone Water, incubated at 37℃ for 18 h. Then, using the selective enrichment media-Selenite Cystine Broth, incubating at 37℃ for 18 h. And then, transferring to SS agar, two differential media, Macconkey agar and Triple sugar iron agar were streaked and incubated at 37℃ for 24 h. Suspected colonies were picked up for biochemical and serological tests. The following tests were used: glucose, maltose, arabopyranose, mannitol, glycitol, hydrogen sulfide, MR, lysine decarboxylase, argininedecarboxylase, ornithinedecarboxylase, *etc.* Serotypes were identified by multivalence serum of $O_{A\text{-}F}$ and $O_{1, 9, 12}$ factor serum. The results were referred to[11,12].

The other organs were submerged in 4% formaldehyde, after 24 h; the organs were then embedded in paraffin. Then the tissue sections were made at 4 μm and stained with an indirect immunofluorescent technique.

Specific detection

The established method was applied to detect the livers from the dead ducks infected by *S. pullorum, S. gallinarum, E. coli Riemerella anatipestifer, P. multocida* and Duck plague virus (obtained from the Avian Disease Research Center of Sichuan Agriculture University).

The standard of judging results

The standard of the results are according to the presence, quantity, the depth and lighting of the coloured cells under the fluorescent microscope. There are no flavoviren cells judged negative, infra 5% weakly positive, 5%-50% positive, super 50% strong positive.

RESULTS

Results of anti-SE antibody

The purified anti-rabbit-SE IgG has an Antigen Jade Enlarge (AGE) potency to 1:32, through the SDS-PAGE, there are duplicate bands, and the molecular weight equals to the l-chain and H-chain of IgG. This suggests the IgG is highly pure.

The optimum conditions of IFA

The optimum conditions of this IFA were as follows: Ten minutes antigen retrieval by microwave with 0.01 mmol/L citrate buffer solution (pH 6.0); 10 min antigen retrieval by pancreatin; incubate in 10% bovine serum albumin at 37℃ for 30 min; dilute the primary antibody (1:25) and incubate for 40 min at 37℃; and then incubated at 37℃ for 30 min with diluted FITC-labeled-secondary antibody (1:100) which contains 0.01% Evans.

Distribution in organs of the infected ducks

We detected the organs by IFA after 24 h, a large part of the organs had positive results, and the results were as follows (Figure 1): Heart: Presented as a strong positive, Cardiac muscle fiber had positive cells, and the positive signal distributing the cytoplasm (Figure 1A). Kidney: Presented positive, the mesenchyme between the tube of the Kidney had positive cells, and the positive signal distributing the cytoplasm (Figure 1B). Liver: Presented positive, the mesenchyme between the hepatic cord had positive cells, and the positive signal distributing the cytoplasm (Figure 1C). Bursa of Fabricius: presented positive, the area of the medulla of the follicle had positive cells, and the positive signal distributing the cytoplasm (Figure 1D). Brain: Presented positive, positive cells presented in capillary vessels, and the positive signal distributing the cytoplasm (Figure 1E). Gland of Garder: Presented as a strong positive, the mesenchyme of the tube of the gland had positive cells, and the positive signal

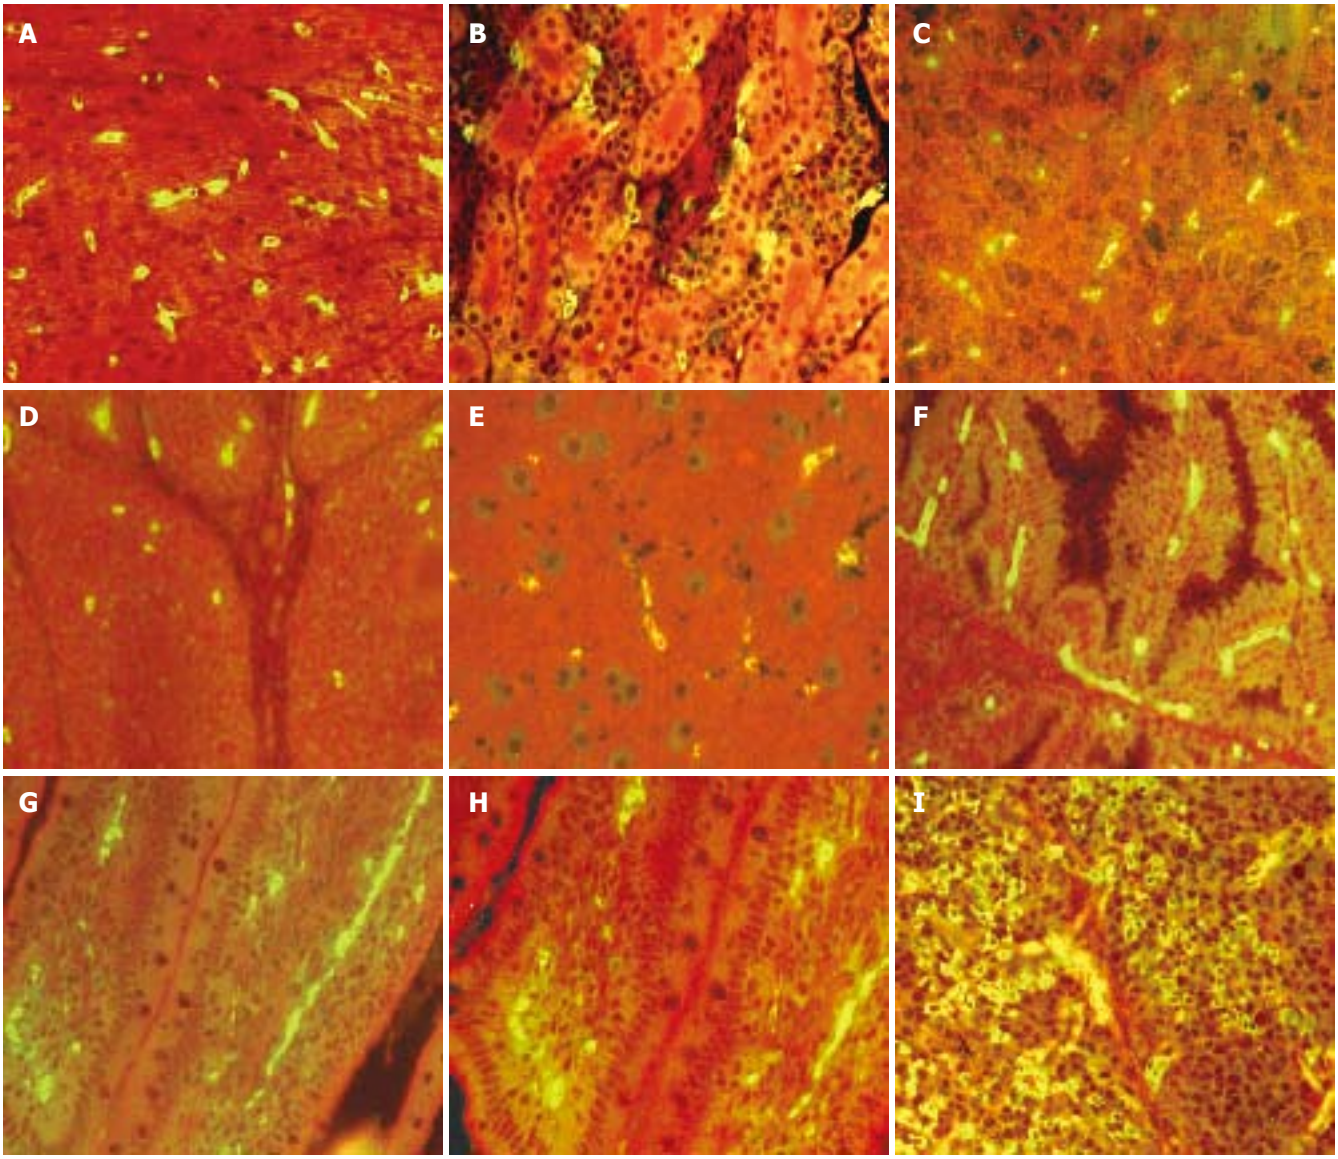

Figure 1 Organ tissues from SE-inoculated ducks immunofluorescent stain for SE. **A**: Positive staining baclli are adhering to the Cardiac muscle fiber (Heart); **B**: Positive staining baclli are adhering to the mesenchyme between the tube of Kidney (Kidney); **C**: Positive staining baclli are adhering to the mesenchyme between the Hepatic cord; **D**: Positive staining baclli are adhering to the area of medulla of the Follicle; **E**: Positive staining baclli are adhering to vascular endothelial cell; **F**: Positive staining baclli are adhering to the mesenchyme of the tube of the gland; **G, H**: Positive staining bacllis are adhering to the interstitial tissue of the lamina propria in villi; **I**: Positive staining baclli are adhering to red medulla. (Images were acquired by using 40 x objective).

Table 1 The results of man-made clinical cases detection using isolation and IFA methods

Detection methods	Results of different organs (faeces) by different methods (positive/total)								
	Heart	Liver	Spleen	Lung	Kidney	Intestine	Brain	Thymus	BF
Isolation	2/24	24/24	24/24	2/24	24/24	24/24	3/24	0/24	8/24
IFA	24/24	24/24	22/24	0/24	24/24	20/24	2/24	0/24	5/24

distributing the cytoplasm (Figure 1F). Small intestine: Numerous *S. enteritidis* organs were observed lying free within the interstitial tissue of the lamina propria in the villi, and the strong positive signals observed in the cytoplasm (Figure 1G, H). Spleen: Presented strong positive, a number of positive cells with particle immunofluorescent antigen distributed in the red medulla of the spleen (Figure 1I).

The results of conventional isolation

All the positive samples detected by the isolation method can be detected by this IFA (Table 1).

The results of specific detection

We detected the livers from the dead ducks infected by *S. pullorum, S. gallinarum, E. coli Riemerella anatipestifer, P.multocida* and Duck plague virus, *S. enteritidis*. The result

Table 2 The results of the specific detection, the positive labeled with (+), negative (-)

Strains	*S. pullorum*	*S. gallinarum*	*E. coli*	*R.A*	*P.multocida*	*DPV*	*SE*
Results	-	-	-	-	-	-	+

showed only the *S. enteritidis* infected, present positive reaction; the others have negative reaction. This suggested good establishment for specificity of the IFA (Table 2).

DISCUSSION

Comparing the differences between IFA and other methods

In the present study, there is little to report about the clinical diagnosis beside conventional methods of isolation for *S. enteritidis*, but there is much about other species. Gast *et al*[6] collected various organs of the infected birds and isolated the bacteria, but it is too laborious, not sufficiently sensitive and correct and can not be used with the rapid diagnoses. Kim *et al*[13] detected the *S. enteritidis* by enzyme immunoassay and had a good result. Desmidt *et al*[14] observed the *S. enteritidis* in the ceca of chickens by immunohistochemistry, which can be used to locate sub-cells of organ tissues of *S. enteritidis* infected chickens. Coope[15] detected the *S. enteritidis* by Dot-Blot and Western-Blot, which is rapid and specific, but could not detect the location in sub-cells of organ tissues. Compared to the above method, the IFA method established has the ability to detect and locate cells and organ tissues of *S. enteritidis* infection, thus offering a clinical means of diagnosis and a pathogenic mechanism of ecology.

The distribution of S. enteritidis in organ tissues

We checked all the ducks when they began to die. At 24 h post-inoculation, the positive signals were observed in the small intestine and spleen; at 36 h, in the heart, kidney, livers, bursa of Fabricius, and Gland of Garder; at 72 h, the positive signals were at the peak; at 6 d post-inoculation, the signals began to reduce. From the result (Figure 1) of the study, we know that the IFA can detect the antigens in almost all organ tissues. The small intestine (ileum, jejunum), heart, liver, kidney, spleen, the Gland of Garder have strong positive signals (Figure 1A-C, I), and presented in the cytoplasm of phagocytic cells of the macrophile system. This may be caused by phagocytic cells after entering the host. Meanwhile, we can detect a positive signal in the brain, a positive signal presented in the vascular endothelial cell, which may be caused by *S. enteritidis* invading the organs and *S. enteritidis* in blood. At the anaphase of infection, the infection appeared bacteremic, the *S. enteritidis* needed to transit the vascular endothelial cells, and uniformly distributed in the cytoplasm of the vascular endothelial cells. We also detected small positive signals in the bursa of Fabricius.

The value of S. enteritidis infections from other viral infectious diseases

Immuno-fluorescent labeled bacilli were associated with the epithelial surface of the intestinal villi at 4 h. At 24 a strong positive signal was detected intracellularly in the small intestine (Figure 1G, H). This resulted in a positive signal which only presented in the lamina propria of the villi. This is a big difference from Duck plague virus (DPV)[16] and Duck Hepatitis Virus (DHV)[17], which was located in the lamina propria. This variation might be related to a different microenvironment[18] in different parts of the gut, dividing into a microcolony at that site. The microenvironment has an important effect in the colonization of the gut, primarly as follows. Gastric acid is the first defense of the intestinal infection, the bacterium can hardly survive (pH < 1.5). The slime layer of the intestinal mucosa has a barrier function to the *S. enteritidis*; moreover pankrin, bile salt and small intestinal juice can depress the bacterium. Some studies suggest that the gene encoding the invasive protein is depressed because of the bile[19,20]. Meanwhile, the involvement of mucosal IgA in the protection against *S. enteritidis* involving the epithelial surface has been reported[21,22]. The cathodolyte antibacterial peptide secreted by pit cells in the small intestine belongs to the Toalexin family, which can increase the permeability of the cytomembrane of the bacterium, and not profit to survive[23].

The intestine is an important barrier for prevention against invasion by bacteria. The lymphoid tissue called Peyer macular under the muscoa[24] consists of T cells, B cells, macrophages and dendritic cells, following the swallowing of the pathogenic bacterium.

The immune reaction also played an important role in preventing *S. enteritidis* lying free in the endothelial cells of the intestine. After swallowing the *S. enteritidis* by macrophage and heterophil granulocyte, both happened to outbreak by breathing, which produced oxygen free radical, for instance, O_2-, H_2O_2, OH-, and O_2- and so on. The oxygen free radical can kill and wound bacteria; the cell factors (IL-1, IL-6, TNF-α[25]) composed and released have a pathopoiesis effect and a bactericidal effect; when the *S. enteritidis* invades the enterocyte, it can induce the secretion of IL-8[26], which can kill and wound bacteria. $CD4^+$ T cells also have an effect on the immune defense[27].

The cooperation between the host cells and S. enteritidis infections

Infection with bacteria is usually started by oral ingestion of the pathogen and is followed by bacterial colonization of the gut and invasion of internal tissues. Intracellular replication is essential for the virulence.

Attachment to host tissues is the first important step to establish a bacterial infection. The attachment is primarily referred to as the inv gene[28]. Once attached to the host cells, the bacterium manifests athletic phenomenon of invasion of the cells, phagocytosis by cell invagination. After fusion of macrophage lysosomes with phagosomes, the *S. enteritidis* appears in the phagocytotic vesicle of the cytoplasm[29], and may destroy the cell invagination. In the present study, there are different reports about the *S. enteritidis* entering the cell, the bulk of the investigations

support the view that *S. enteritidis* enters the cell by a virulence factor. Higashide and McGhie suggest that when *S. enteritidis* enter the cell, firstly SspC excreted by TTSS insert into the plasma membrane, then Sip and SipA bind to the actin of the cytoskeleton and rearrange the frame, which enhances the entrance of the bacterium[30,31]. Scientists report recently that the dendritic cell (DC) residing in the mucosa of the small intestine can use the dendrite to open the tight junction of the cells, and directly ingest the bacteria from the mucosa[32]. From the result (Figure 1), the positive signal distributed in the cytoplasm of infected cells of the organ tissues, we conclude that *S. enteritidis* is an intracellular parasitic bacterium.

COMMENTS

Background

Salmonella enteritidis (*S. enteritidis*) is the infectious disease causing Zoonoses. *S. enteritidis* is one of the primary causes of human food poisoning throughout the world. China is the biggest country in growing and consumption in the world, but the *S. enteritidis* bacillus infection is the severely important infectious disease in raising duck's industry. But the pathogenic mechanism of ecology is unknown.

Research frontiers

The *S. enteritidis* can be isolated from various organs of the infected birds. It is possible that the *S. enteritidis* invades the tissues of these organs; electron microscopic studies of chicks have shown passage of *Salmonella* through ileocecal mucosa. The observation of attachment and invasion of the ceca of infected chicks have been reported. Also, in mammalian animal models, the colonization of *S. enteritidis* has been studied further. However, there are few studies about ducks.

Innovations and breakthroughs

The present study was to establish a serum method for detection and antigen location of *S. enteritidis* which has not been reported.

Applications

The results can offer a clinic means of diagnosis and pathogenic mechanism of ecology.

Peer review

This is a methodology manuscript. The author of this manuscript establishes a method of IFA and detected the organs of the *S. enteritidis* infected ducks. The author conclude that IFA is a sensitive and specific method in detecting *S. enteritidis* antigen in paraffin slice; it's a good method in diagnosis and antigen location of S. enteritidis; the Gland of Garder, heart, kidney, spleen, liver, and small intestine are target organs in *S. enteritidis* infections of duck; *S. enteritidis* is an intracellular parasitic bacterium.

Abstract

AIM: To identify and understand the regular distribution pattern for *Salmonella enteritidis* (*S. enteritidis*) in the internal organs of mice after an oral challenge over a 3 wk period.

METHODS: Assays based on the serovar-specific DNA sequence of *S. enteritidis* from GenBank, and a serovar-specific real-time, fluorescence-based quantitative polymerase chain reaction (FQ-PCR) were developed for the detection of *S. enteritidis*. We used this assay to detect genomic DNA of *S. enteritidis* in the blood and the internal organs, including heart, liver, spleen, kidney, pancreas, and gallbladder, from mice after oral challenge at different time points respectively.

RESULTS: The results showed that the spleen was positive at 12 h post inoculation (PI), and the blood was at 14 h PI. The organism was detected in the liver and heart at 16 h PI, the pancreas was positive at 20 h PI, and the final organs to show positive results were the kidney and gallbladder at 22 h PI. The copy number of *S. enteritidis* DNA in each tissue reached a peak at 24-36 h PI, with the liver and spleen containing high concentrations of *S. enteritidis*, whereas the blood, heart, kidney, pancreas, and gallbladder had low concentrations. *S. enteritidis* populations began to decrease and were not detectable at 3 d PI, but were still present up to 12 d PI in the gallbladder, 2 wk for the liver, and 3 wk for the spleen without causing apparent symptoms.

CONCLUSION: The results provided significant data for understanding the life cycle of *S. enteritidis* in the internal organs, and showed that the liver and spleen may be the primary sites for setting itself up as a commensal over a long time after oral challenge. Interestingly, it may be the first time reported that the gallbladder is a site of carriage for *S. enteritidis* over a 12 d period. This study will help to understand the mechanisms of action of *S. enteritidis* infection *in vivo*.

INTRODUCTION

A significant proportion of human salmonellosis is caused

by consumption of raw or partially cooked eggs[1-3]. *Salmonella enteritidis* (*S. enteritidis*) is one of the main causes of gastrointestinal infection in China. Incidence of infection is highest in children, elderly, and immunosuppressed individuals[4]. *S. enteritidis* is a facultative intracellular pathogen capable of causing disease in a wide range of host species. After oral ingestion, *S. enteritidis* cells rapidly reach the bowel and penetrate the macrophages, spread to the mesenteric lymph nodes, and in severe cases, can reach the circulatory system[5]. The macrophages carry the organism to the liver, pancreas, and spleen, where the bacteria are thought to replicate in both phagocytic and nonphagocytic cells[5]. Also, it was reported that the *S.* typhimurium can be shed into the gallbladder from the liver, where either an active infection (cholecystitis) or a chronic infection can develop[6,7].

Previous studies showed that *S. enteritidis* was usually cleared from internal organs more than 8 wk after inoculation of poultry. How *S. enteritidis* survives within macrophages is unclear. It seems likely that the type Ⅲ secretion system encoded by *Salmonella* pathogenicity island 2 may play a major role. Moreover, extensive studies of mouse have shown the role for T cells, natural killer cells, macrophages, neutrophils and numerous cytokines in *Salmonella* resistance[8,9]. Numerous studies indicate that *S. enteritidis* cells have evolved strategies to resist and overcome innate immune defenses[10,11]. Up to date, the mechanisms by which *S. enteritidis* and other serotypes persist within the host and the reasons for the absence of immune clearance are not known. As a result of the increased prevalence of *S. enteritidis* and its complex life cycle, identifying the regular distribution pattern of *S. enteritidis* in the internal organs over a 3 wk period, which is not described hitherto, will help to understand its mechanism of action.

One of the main advantages of FQ-PCR is the ability to quantitate unknown samples. With this assay, it is possible to carry out a rapid quantitative analysis of DNA over a wide linear range, with an unknown template. The specific DNA fragment (Sdf I) of *S. enteritidis* was reported by Agron *et al*[12], which was screened for using the Supression Subtractive Hybridization method, and appears to only be found in serovar *enteritidis* strains[12,13]. Here, based on the study of Agron *et al*, we developed a standard curve (this methodology is the first time established which based upon the Sdf I DNA fragment), and then applied this to the study of internal organ distribution of *S. enteritidis* in mice.

MATERIALS AND METHODS

Bacterial strains

A total of 19 *Salmonella* strains were included in this study. Most strains were purchased from the National Center for Medical Culture Collection, including *S. enteritidis* (Human, No. 50041), *S. enteritidis* (Human, No. 50040), *S. enteritidis* (Mouse, No. 50338), *S. enteritidis* (Human No. 50100), *S. enteritidis* (Human, No.50128), *S. enteritidis* (Human, No. 50335), *S. enteritidis* (Mouse, No. 50336), *S. enteritidis* (Human, No. 50760), *S. choleraesuis* (No. 50191-1), *S. typhi* (No. 50013), *S. typhimurium* (No. 50115-13), *S. paratyphi* (No. 50001-24), *S. pullorum* (No. 50047-2), *S. anatum* (No. 50083-4), *S. gallinarum* (No. 50770), *S. dublin* (No. 50761). Three strains were isolated and maintained by the Avian Diseases Research Center, Collage of Veterinary Medicine of Sichuan Agricultural University, including *S. enteritidis* (Duck, No. MY_1), *S. enteritidis* (Duck, No. SC1), *S. enteritidis* (Chicken, No. CD1).

Preparation of bacterial samples and generation of standard templates

Briefly, 5 mL of bacterial culture was grown overnight in Luria-Bertani broth and 500 μL of the culture was harvested by centrifugation. The pellet was resuspended in 500 μL TE buffer (pH 8.0) and 2 μL of lysozyme solution (30 g/L) was added, followed by lysis using 10% SDS (80 μL) at 60℃ for 1 h. DNA was purified by extraction with an equal volume of phenol/chloroform/isoamyl alcohol (25:24:1). Then, a 1/10 volume of 3 mol/L sodium acetate and 2 volumes absolute ethanol were added, and the nucleic acid was then pelleted by centrifugation, washed with 70% ethanol, and dried under vacuum. The DNA genomic pellet was resuspended in 30 μL TE buffer (pH 8.0), and stored at -20℃ until use.

A conventional PCR was carried out using a template from *S. enteritidis* (Chicken, No. CD1), with primers F_1 and R_1 (designed with Sdf I, Genbank Accession No. AF370707.1, generated by TakaRa Biotech, DaLian, China). The primer sequences from 5' to 3', were as follows: F_1, TGTGTTTTATCTGATGCAAGAGG; and R_1, CGTTCTTCTGGTACTTACGATGAC. Amplification was carried out in a total volume of 50 μL, containing 1 μL each primer (25 μmol/L), 1 μL dNTPs (10 mmol/L), 2.5 U Taq DNA Polymerase (TaKaRa Taq, TakaRa Biotech), 5 μL 10 × PCR buffer (with Mg^{2+}, 25 mmol/L), and 6 μL templates, then made up to a volume of 50 μL with deionized water. An initial denaturation at 95℃ for 5 min was followed by 32 cycles of denaturation at 94℃ for 30 s, annealing at 52.5℃ for 30 s, and extension at 72℃ for 40 s. Finally, an additional extension was achieved for 10 min at 72℃. The product size was 293 bp.

Finally, the product was gel-excised and quantified with appropriate standards. Its concentration was determined spectrophotometrically using the Bio-Rad-Smartspec-3000 instrument, according to the manufacturer's instructions. The standards were diluted, divided into aliquots, and frozen before used.

Development of FQ-PCR and its products

The FQ-PCR assay, including volume, Mg^{2+} concentration, probe and primer concentrations, and annealing temperature were optimized initially. Subsequently, the sensitivity of the assay, the linear range and standard curve were determined by using known amounts of purified template DNA (generated as described above). The primers (F_2 and R_2) and TaqMan-probe (FP) of FQ-PCR were designed using an internal region of the 293 bp sequences (described above, generated by TakaRa Biotech), and were used as follows, from 5' to 3': F_2, TTGATGTGGTTGGTTCGTCACT; R_2, TCCCTGAA TCTGAGAAAGAAAAACTC; and TaqMan-probe (FP), FAM- TGCAGCGAGCATGTTCTGGAAAGC-TAMRA.

Amplification of FQ-PCR was carried out in a total volume of 25 μL, containing 0.6 μL each primer (10 μmol/L), 0.75 μL dNTPs (10 mmol/L), 1.25 U EX Taq DNA Polymerase (TaKaRa EX Taq Hot Start Version, TakaRa Biotech), 5 μL 5 × PCR buffer (free Mg^{2+}), 0.8 μL TaqMan-probe (5 μmol/L), 0.5 μL Mg^{2+} (250 mmol/L) and 5 μL aliquot of the sample DNA templates (for the standards DNA templates, 1 μL was added), then made up to a volume of 25 μL with deionized water. Each run consisted of a 95℃ 5 min hot start, which activated the conjugated polymerase, followed by 45 cycles with a 94℃ denaturation for 30 s, 55℃ annealing for 30 s, and reading the fluorescent signal at this step.

The primers of FQ-PCR (F_2 and R_2) were used for conventional PCR with *S. enteritidis* (Chicken, No. CD1) DNA templates, in order to verify the specific amplification. Amplification was carried out in volume of 50 μL, containing 1 μL each primer (25 μmol/L), 1 μL dNTPs (10 mmol/L), 2.5 U Taq DNA polymerase (TaKaRa Taq, TakaRa Biotech), 5 μL 10 × PCR buffer (with Mg^{2+}, 25 mmol/L), and 6 μL templates, then made up to a volume of 50 μL with deionized water. An initial denaturation at 95℃ for 5 min was followed by 32 cycles of denaturation at 94℃ for 30 s, annealing at 49℃ for 30 s, and extension at 72℃ for 40 s. Finally, an additional extension was achieved for 10 min at 72℃. A 10 μL aliquot of PCR product was electrophoresed on a 1.5% agarose gel for 40-50 min at 80 V, and visualized and photographed under UV illumination. Simultaneously, DNA sequences of the products were carried out by TakaRa Biotech.

FQ-PCR standard curve

Based on the previous studies to generate the standard curve as follows[14-16]: Standards DNA were used to establish a standard curve and the standards contained amplified target DNA in different quantities which were measured by fluorimetic analysis (iCyclerQ, Bio-Rad, USA). The Primers F_2 and R_2 were used for this amplification, the DNA was 10-fold serially diluted in nuclease-free water and standard curve was generated by using 1.0×10^5 to 1.0×10^{10} gene copies of standards DNA. Concentrations of the standards were measured by fluorimetic analysis, then an analysis of key cycler measurements were performed after each run to verify identical amplification efficiencies and conditions between runs. Finally, based on the data generated, a standard curve for the icycler was obtained and based on the standard curve to obtain the copies number of *S. enteritidis* for the samples.

Specificity,sensitivity and reproducibility of the FQ-PCR

All 19 bacterial strains were used to assess the specificity of the FQ-PCR. The phenol/chloroform/isoamyl alcohol method (described above) was used to prepare the DNA template, 6 μL of this aliquot was used in FQ-PCR.

To determine the detection limit of this FQ-PCR assay, different quantities of standard DNA of *S. enteritidis* was added. We used phenol/chloroform/isoamyl alcohol method to extract DNA of tissue from several control group samples (described below), and added 1.0×10^5-1.0×10^{-1} copies of the standard DNA for each. Finally the results were measured by fluorimetric analysis.

To evaluate the variability between experiments, three different known concentrations of DNA were amplified by performing the assay described above in triplicate. For each experiment, the crossing point, average crossing point, standard deviation, and coefficient of variation for each assay were calculated.

Experimental infection of mice

Our infection model was based on the previous studies, which showed that orally introduced *S. enteritidis* had a rapid transit time through the intestine and established itself within the walls of the gut in more than 3 d[17,18]. 80 mice (age 9 wk, specific-pathogen-free) were purchased from the Animal Center of Sichuan University, China. In brief, a group of 60 mice was oral infected with a virulent *S. enteritidis* strain (Chicken, No. CD1, LD_{50} is 4.0×10^8 cells after oral challenge), at 4.0×10^6 cells per mouse (In our preliminary experiments, the results showed that this dose of challenge can induce clinical signs and pathology in mice, but can not cause death). Another group of 20 mice was treated with an equal volume of water as a control. Blood, heart, liver, spleen, kidney, pancreas, and gallbladder were analyzed by FQ-PCR at different post-inoculation time points, at 30 min, 1 h, 2 h, 4 h, 8 h, 12 h, 14 h, 16 h, 18 h, 20 h, 22 h, 24 h and 36 h and 2 d, 3 d, 6 d,9 d,12 d and 2 wk,3 wk.

Three mice from infected group and one from control group were sacrificed at each time point (There was a potential complication of *S. enteritidis* DNA in the blood for the tissue results, particularly in the spleen and liver where large amounts of blood could be accumulated, so the mice were perfused before the tissue collection) and its organs were aseptically harvested and immediately placed in 1.5 mL labeled snap-cap tubes, and frozen. The blood sample, 200 μL, was obtained from the vena caudalis with syringe aseptically before sacrificed. For the bile sample, 200 μL was obtained from gallbladder with syringe aseptically after sacrificed, and frozen.

DNA extraction from tissue samples was described below: Briefly, 0.5 g of the tissue sample was ground up using a tissue grinder in the 1.5 mL Eppendorf tube. The pellet was resuspended in 500 μL TE buffer (pH 8.0) with 10 μL Proteinase K (30 g/L) and incubated at 37℃ for 2 h. Finally, with a conventional phenol/chloroform/isoamyl alcohol method (described above), to extract the genomic DNA of *S. enteritidis* from tissue, used 5 μL aliquot of DNA template for FQ-PCR detection.

For the bile and blood samples, taking 200 μL to be harvested by centrifugation, then the pellet was resuspended in 500 μL TE buffer (pH 8.0) with 3 μL Proteinase K (30 g/L), and incubated at 37℃ for 1 h. Finally, used the phenol/chloroform/isoamyl alcohol method (described above) to extract DNA template and used 5 μL to be detected.

Comparative the differences between FQ-PCR and the traditional bacterial culture method

All the samples of mice were detected by the traditional bacterial culture method in order to identify the accuracy of this FQ-PCR method. Firstly, taking 0.1 g or 20 μL tissue sample, then used the selective enrichment media-

Selenite Cystine Broth, incubated at 37℃ for 20 h. And then, transferred to *Salmonella* Shigella Agar (SS agar). two differential media, Macconkey agar and Triple sugar iron agar were streaked and incubated at 37℃ for 24 h. Suspected colonies were picked up for biochemical and serological tests. The following tests were used glucose, maltose, arabopyranose, mannitol, glycitol, Hydrogen sulfide, MR, lysine decarboxylase, argininedecarboxylase, orinithinedecarboxylase, *et al.*

Serotypes were identified by multivalence serum of O_{A-F} and $O_{1,9,12}$ factor serum. The results were referred to[19,20] incomplete sentence-authors must complete.

Statistical analysis

All samples were analyzed three times with a mean and standard error. Data were analyzed on an IBM compatible personal computer using SPSS version 11.0. Effects were considered to be significant if $P < 0.05$. Finally, based on the standard curve (described aboved) to obtain the copies number of *S. enteritidis*. The *S. enteritidis* DNA copy concentrations were expressed as the mean $\log_{10}$ copies genome numbers per 0.5 g or 0.2 mL of tested tissue or blood and bile, respectively.

RESULTS

Specific verification of FQ-PCR products

The primers of FQ-PCR were used for conventional PCR with *S. enteritidis* (Chicken, No. CD1) DNA templates, in order to verify the specific amplification. Results showed that the PCR produced an intense band with the expected 130 bp for *S. enteritidis*, which indicated 100% specificity. Also, Sequence analysis was carried out using BLASTn and BLASTn Programs of National Center for Biotechnology Information, and resulted in 100% homology with DNA of *S. enteritidis*, Genbank Accession No.AF370707.1.

FQ-PCR standard curve

By using standards template containing from 1.0×10^5 to 1.0×10^{10} copies, accurate results for a series of samples were obtained, based on the data used to generate the standard curve with the iCycler IQ Detection System (Bio-Rad; USA). The correlation coefficient for the associated standard curve was 1.000 and PCR efficiency was 98.2%, which indicated that the crossing threshold values for the standards fell within accurate range. Through the formula as follows, we could quantitate the DNA copies of *S. enteritidis* for unknown samples, Y= -3.366X + 44.914 (where Y is the threshold cycle, and X is the log of the starting quantity) (Figure 1).

Specificity, sensitivity and reproducibility of the FQ-PCR

All 19 bacterial strains were used to assess the specificity of the FQ-PCR, indicated that only *S. enteritidis* strains genomic showed the positive results, while there was no positive results with none *S. enteritidis* strains.

A range from 1.0×10^5 to 1.0×10^{-1} copies of *S. enteritidis* standards template was used, the limit of detection was 10 copies/μL.

Three different, known concentrations of DNA, 1.0×10^9 to 1.0×10^7 copies/μL, were amplified by performing the assay described above in triplicate. Analysis of these values proved that the assay was reproducible, as the coefficient of variation was statistically low, at < 1.8%, the standard deviation was 1.1%, and the threshold cycle for each concentration was difference between 0.2 cycle and 0.4 cycle, highly reproducible.

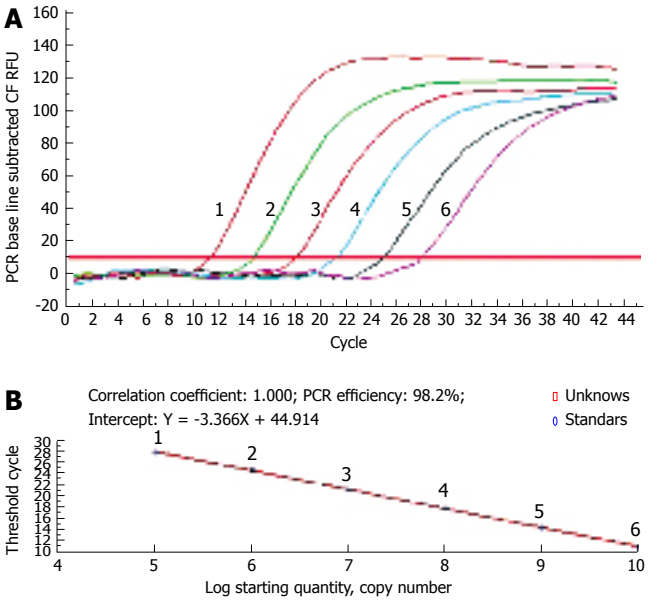

Figure 1 Used the standards DNA template with 10-fold serial dilutions to develop standard curve. **A**: Amplification curve; **B**: Standard curve; 1, 1.0×10^{10} copies/μL; 2, 1.0×10^9 copies/μL; 3, 1.0×10^8 copies/μL; 4, 1.0×10^7 copies/μL; 5, 1.0×10^6 copies/μL; 6, 1.0×10^5 copies/μL.

Clinical signs and gross necropsy

S. enteritidis-inoculated mice appeared to be clinically normal, and there were no sings of depression or diarrhea, and feeding and drinking behavior remained normal at 30 min to 8 h, and 6 d to 3 wk PI. However, mice developed significant clinical signs of *S. enteritidis* infection at 12 h to 3 d PI. At necropsy, gross lesions were observed in all of the mice at this period, such as hyperemia of intestine, swelling of gallbladder[19,20].

Distribution of S. enteritidis in the internal organs

The distribution of *S. enteritidis* within the internal organs after oral challenge was determined by means of FQ-PCR, over a 3 wk period at intervals. Results showed that the spleen was positive at 12 h PI, with about 2.95×10^2 copies/0.5 g. Then, blood had positive results at 14 h PI with about 2.75×10^2 copies/0.2 mL, and the organism was detected in the liver and heart at 16 h PI, pancreas was positive at 20 h PI, and the last organ to show a positive results were the kidney and gallbladder at 22 h PI. The copy numbers of *S. enteritidis* in each tissue reached a peak at 24-36 h PI, with the liver, spleen containing high concentrations of *S. enteritidis*, about 2.00×10^4 to 3.31×10^6 copies/0.5 g, whereas the blood, heart, kidney, pancreas and gallbladder had low concentrations, ranked from 5.13×10^2 to 1.70×10^5 copies/0.5 g (0.2 mL). Numbers of bacteria decreased at 3 d-9 d, the level of *S.*

Table 1 The distribution and quantity of *S. enteritidis* within different internal organs and blood after oral challenge at different times

Time	Blood	Heart	Liver	Spleen	Kidney	Pancreas	Gallbladder
30 min	0.00	0.00	0.00	0.00	0.00	0.00	0.00

$\log_{10}$ copies per 0.2 mL for Blood and bile; $\log_{10}$ copies per 0.5 g for others.

enteritidis clearly decreased, with the blood, heart, kidney, and pancreas not having a positive result. The mice were capable of carrying *S. enteritidis* cells were present up to 12 d PI in the gallbladder, 2 wk for the liver, and 3 wk for the spleen without causing any apparent symptoms. Importantly, the level of *S. enteritidis* cells number compared to the other organs at 2-12 d PI, the gallbladder can contain about 1.25×10^2 to 7.94×10^2 copies/0.2 mL. It may be the first time reported that the gallbladder is a site of carriage for *S. enteritidis*, and *S. enteritidis* can persist over a 12 d period within it. Also, the control group did not have any positive results at any time in any location. The details are shown in Table 1.

The results of the traditional bacterial culture method

All the samples from different time points were detected by traditional bacterial culture method, and the results showed that the traditional bacterial culture method had positive results when the *S. enteritidis* target DNA concentrations were > $10^{4.02}$ copies per 0.5 g or 0.2 mL. Apparently, the FQ-PCR assay provides a more sensitive and accurate method for the this study.

DISCUSSION

Once attached to the host cells, *S. enteritidis* can manifest athletic phenomenon of invasion, such as phagocytized by cell invagination. After fused by macrophage, *S. enteritidis* cells will appear in cytoplasm, survive and multiply there[21]. Humoral immunity contributes to serve as the first line of defense against *S. enteritidis* infection. After the *S. enteritidis* cells are swallowed by macrophage and heterophil granulocyte, both of them happen to outbreak of breathing and produce oxygen free radical, for instance H_2O_2, OH-, O_2^-[22], which can kill and wound the bacterium. The cell factors, such as IL-1, IL-6 *et al*, also have the bactericidal effect for the *S. enteritidis* invasion[23]. In contrast, cellular immune responses have been rarely investigated, although such responses are crucial for protective immunity against *S. enteritidis*. The mechanisms by which *Salmonella*-specific $CD4^+$ T cells contribute to protective immunity are incompletely understood, but T-cell proliferation, the sine qua non of $CD4^+$ T-cell activation, and the production of gamma interferon can be regarded as in vitro indicators of these essential elements of protective immunity[24]. Our data (Table 1) showed that the *S. enteritidis* populations decreased obviously or were not detectable in most detected-samples at 6 d PI, without causing apparent symptoms. Perhaps, the results of this study indicate that the mice have an efficient protective immunity after oral challenge.

Salmonella cells have to attach to or form a close association with the intestinal epithelium in order to establish and persist in the gut and subsequently invade the underlying tissues[25,26]. *S. enteritidis* usually do not cause a disseminated systemic disease in humans, but clinically manifest as gastroenteritis and diarrhea[27]. The probability of establishment of persistent infection may involve a subtle interplay between host susceptibility and the challenge strain and does of *S. enteritidis*[10,28]. It has been reported that *S. enteritidis* can rapid distribution throughout the gastrointestinal tract, translocation to the mesenteric lymph nodes and spread to the liver and spleen of the mice. In the liver, the bacteria are ingested by the Kupffer cells, and then they invade the hepatocytes[29, 30]. In our studies, the spleens were positive at 12 h PI, but not the blood. It may be an indication that *S. enteritidis* cells were drained by the lymphatic system circulation (especially the Peyer's patchs in gut) priority. Also, recent studies have shown that some systemic spread of *salmonella* can occur without drainage through the lymphatic system and blood circulation[31]. Pathogen sampled subepithelial or even luminally by dendritic cells or CD18-expressing phagocytes can be transferred directly to the liver and spleen[32,33].

Previous studies showed that there is a association between *Salmonella* and intracellular survival in macrophages, which can be regarded as safe sites for bacterial multiplication[34,35]. However, how *S. enteritidis* survives within macrophages is unclear. It seems likely that the type Ⅲ secretion system encoded by *Salmonella* pathogenicity island 2 may play a major role[36,37]. One of the functions of *Salmonella* pathogenicity island 2 is to inhibit NADPH oxidase-dependent killing of *Salmonella*[38] . Also, it has been reported that the *S.* typhimurium genome encodes many mechanisms that allow resistance to the stressful environment encountered within the macrophage. Such stress include the production by NADPH oxidase of superoxide anion (O_2^-) and other reactive oxygen species (ROS), and by inducible nitric oxide (NO) synthase (iNOS) of NO and other reactive nitrogen species (RNS)[39,40]. A number of important bacterial pathogens infect, replicate, and persist within nucleated cells of the host, T-cell-mediated immunity has proven to be a critical factor in the effective clearance of many such intracellular bacterial pathogens. However, *Salmonella* can induce suppression of cellular responses[41]. Simultaneously, it has been

reported that chicken macrophages display differences in their responses to *S. enteritidis* and *S.* typhimurium, and contribute to the differential pathogenesis of these *Salmonella* serovars[42]. Also, it has been reported that *S. enteritidis* infection induce less inflammation resulting in a more commensal, while *S.* typhimurium infection can be cleared more rapidly by induction of inflammatory[43,44]. *S. enteritidis* resulted in increased splenic CD3 and reduced B populations, it was difficult to associate this increase with *S. enteritidis* clearance due to lack of any significant changes in $CD4^+$ of $CD8^+$ cells[45].The functions of the spleen and liver in filtration, immune responsiveness and activation of complement have been well documented. Spleen is a container for the lymphocyte-rich white pulp and macrophage-rich red pulp; it is comprised of distinctive B cells and macrophages. So, what we described above may be the reason for why significant number of *S. enteritidis* cells can persist over a long time in liver and spleen without causing apparent symptoms *in vivo* in this study. Up to day, the colonization mechanism of *S. enteritidis* in the gut and the internal organs are not clear and further studies should be carried out.

Interestingly, the gallbladder is a site of carriage in this study, it is also the storage site for bile. Our studies may be the first to report that *S. enteritidis* can persist for as long as 12 d PI in gallbladder in mice. Bile is produced in the liver and consists of many components, including bile salts, cholesterol, and bilirubin. Bile salts are detergents that aid in degradation and dispersion of lipids, and such make bile a good antimicrobial agent[7]. It has been reported that *Salmonella* is resistant to high concentrations of bile and individual bile salts[46]. From the liver, the *S.* typhimurium can be shed into the gallbladder, and this infection is frequently associated with gallbladder abnormalities, such as gallstones, also, this infection is often asymptomatic and can last for many years[5,6]. Biofilms have recently been implicated as the cause of many chronic infection in human[47]. *S. enteritidis* are capable of shielding themselves from environmental stress, host immune response and phagocytosis by the secretion of an apparently amorphous matrix of secreted polysaccharides[47-50]. This matrix provides a very stable environment and results in high levels of resistance to antimicrobial agents[46,50]. Often, it is difficult to clear the infection unless the substrate to which the bacteria are attached is removed[7]. In our studies, *S. enteritidis* cells can persist for 12 d PI with low concentrations, about 1.25×10^2 to 6.61×10^2 copies/0.2 mL. The gallbladder appeared to be gross lesion (such as swelling) at 20 h to 2 d PI. Interestingly, there were not any significant gross lesions over the 3-12 d PI period, although there was nearly the same number of *S. enteritidis* cells over the 12 d period.

FQ-PCR has become a potentially powerful alternative in microbiological diagnostics due to its simplicity, rapidity, reproducibility, and accuracy[51,52]. However, variation results may be due to either the PCR inhibitors, or a large amount of DNA from background organism DNA. In preliminary experiments, we used phenol/chloroform/isoamyl alcohol method to extract DNA of tissue from several control group samples (described above), and added 1.0×10^5 copies of the standard DNA for each. Finally, fluorimetic cycler measurements were performed as described above. The results showed that all the tests can obtain the expected data and the variability was statistically low, at < 4.3%. So, this methodology is very accuracy for studying on the distribution of *S. enteritidis* in the internal organs.

In conclusion, our results provide significant data for helping to clarify the pathogenic mechanism of *S. enteritidis* in the internal organs, and show that the liver and the spleen are the primary sites of invasion in normal mice after oral challenge, interestingly, the gallbladder is a site of carriage over a 12 d period in this study, to our knowledge, this is the first time reported, and future studies should be carried out.

COMMENTS

Background

There are over 2500 serovars in the genus *Salmonella*. It has been a public health concern for over 100 years, and the incidence of *Salmonella* infections has risen dramatically, especially those caused by *S. enteritidis*. Therefore, knowledge about *Salmonella* infection could be an additional means for decreasing the incidence of infection. Infection with *Salmonella* is usually started by oral ingestion of the pathogen, and is followed by bacterial colonization of the gut and invasion of internal tissues. As a matter of course, it is necessary to understand its mechanisms of action in the internal organs.

Research frontiers

To date, the regular distribution pattern for *S. enteritidis* in the internal organs of mice after oral challenge has not been established. FQ-PCR, as a rapid, sensitive technique for precise quantitation of nucleic acid, will be an ideal method to study the distribution of *S. enteritidis* in the internal organs.

Innovations and breakthroughs

These studies have identified the regular distribution pattern of *S. enteritidis* invasion in the internal organs, which is not described hitherto. Moreover, it may be the first time reported that the gallbladder is a site of carriage for *S. enteritidis* over a 12-d period.

Applications

This study will provide significant data for clarifying the pathogenic mechanisms of *S. enteritidis* in the internal organs, and may ultimately lead to new insights in prevention and therapy.

Peer review

The manuscript by Deng and colleagues represents a clear and straight-forward study into the distribution and persistence on *S. enteritidis* in the internal organs of infected mice. The hypothesis and methods are clearly presented, and the results will help future studies.

Abstract

AIM: To measure plasma ghrelin levels in children and adolescents, analyze the associated factors, and investigate the role of ghrelin in obesity, insulin resistance and reproductive physiology.

METHODS: A total of 283 subjects aged 4.8-15.8 year were enrolled. Fasting blood samples were collected and plasma ghrelin levels were measured by radioimmunoassay. Fasting glucose (FG), fasting insulin (FI), baseline testosterone (T), estradiol (E2), prolactin (PRL), luteinizing hormone (LH), follicle-stimulating hormone (FSH), serum total cholesterol (TC), triglyceride (TG), alanine aminotransferase (ALT) and uric acid (UA) were measured. Body mass index (BMI), insulin resistance by homeostasis model (HOMA-IR) and beta cell function by homeostasis model (HOMA-β) were calculated.

RESULTS: The median ghrelin level was 290 ng/L (15.0-1325.0 ng/L). Bivariate correlation analysis showed that ghrelin levels were inversely correlated with BMI, ALT, TG, UA, LH, FI and HOMA-IR (all $P < 0.05$). No other significant correlation was found between ghrelin levels and age, gender, TC, E2, FSH, PRL, FG and HOMA-β. Stepwise multiple regression analysis showed that only BMI and FI were independent determinants of plasma ghrelin levels in these children and adolescents ($P = 0.018$ and $P = 0.046$, respectively), which explained 25.4% of the variance.

CONCLUSION: These data suggest that the lower ghrelin levels in obese subjects may be the result of obesity and hyperinsulinemia, which is very common in obese subjects. Moreover, ghrelin may regulate human reproductive physiology indirectly.

INTRODUCTION

Ghrelin, recently isolated from rat and human stomachs, is an endogenous ligand for growth hormone secretagogue receptor (GHSR) type 1a[1,2]. Recent studies have shown that ghrelin is secreted from hypothalamus, pituitary, endocrine pancreas islets, bowel, kidney, heart and testis[1,2]. Besides stimulating GH secretion, ghrelin has been reported to have other endocrine and non-endocrine actions, including stimulation of lactotroph and corticotroph secretion, effects on the gonadal axis, cardiovascular activity, influence on behavior and sleep, modulation of cell proliferation, repression of apoptosis, and orexigenic effects[3-7]. However, most of these studies used animal models and there were some discrepancies in the results. Thus, the regulation of ghrelin secretion and its specific role in endocrinology in humans, including the gonadal axis, insulin resistance, energy balance and obesity, are not completely understood.

In this study, we measured plasma ghrelin levels in Chinese children and adolescents, analyzed their associated factors, and investigated the role of ghrelin in obesity, insulin resistance and reproductive physiology.

MATERIALS AND METHODS

Materials

A total of 283 subjects aged 4.8-15.8 year (mean ± SD;

9.4 ± 2.4 year) were enrolled in this study. They included 133 males and 150 females. Body mass index (BMI) was 12.15-44.00 kg/m^2 (19.88 ± 6.23 kg/m^2) with a median BMI Z score of 0.52. Ninety-six individuals were prepubescent and 187 were pubescent, including 107 with Tanner Ⅱ stage breasts, 53 with Tanner Ⅲ, 19 with Tanner Ⅳ and eight with Tanner Ⅴ. Subjects with obesity were included and subjects with other endocrine diseases, viral hepatitis, kidney and infectious diseases were excluded. Written informed consent was obtained from the parents and the study was approved by the Ethics Committee of the Children's Hospital of Zhejiang University School of Medicine, China.

Plasma ghrelin measurement

Two-milliliter venous blood samples were obtained by venipuncture after an overnight fast and were placed in a tube with 30 μL 10% EDTA and 20 μL aprotinin. Plasma was isolated and stored at -70℃ until analysis. Plasma total ghrelin levels, including Ser 3-octanoyl and Ser 3-des-octanoyl ghrelin, were measured by radioimmunoassay. The commercially available kits were purchased from Phoenix Pharmaceuticals (Burlingame, CA, USA). The assay sensitivity and CV were 10 ng/L and 5%-10%, respectively.

Biochemistry markers

Fasting glucose (FG) and insulin (FI) levels were measured by glucose oxidase method and radioimmunoassay (Beijing North Biotechnology Invest, China). Insulin resistance by homeostasis model (HOMA-IR) and beta cell function by homeostasis model (HOMA-β) were calculated according to Matthews *et al*[8]: HOMA-IR = FG × FI/22.5 and HOMA-β = 20 × FI/(FG-3.5).

Baseline testosterone (T), estradiol (E2), prolactin (PRL), luteinizing hormone (LH) and follicle-stimulating hormone (FSH) were measured by chemiluminescence (Siemens, Gwynedd, UK). Serum total cholesterol (TC), triglyceride (TG), alanine aminotransferase (ALT) and uric acid (UA) were measured in the clinical laboratories of the Children's Hospital of Zhejiang University School of Medicine.

Body composition measurements

Body composition was measured in the morning after an overnight fast. Body weight was measured to the nearest 0.1 kg on an electronic scale, and body height was measured to the nearest 0.1 cm, with the subjects in underwear and barefoot. BMI was calculated as weight (kg) divided by height (m) squared.

Statistical analysis

Statistical analyses were conducted by using SPSS software (11.5 Version) (SPSS, Chicago, IL, USA). Quantitative data with normal distribution were presented as the mean ± SD, and data with skewness distribution were presented as the median (min-max). The T and E2 levels, which were lower than measured limits (both 20 ng/dL), were treated as the lower limit. The relation between fasting ghrelin levels and other factors was analyzed by bivariate correlation using the Pearson test. Stepwise multiple linear regression models were used to examine the determinants of plasma ghrelin levels. Differences were considered statistically significant at $P < 0.05$.

Table 1 Bivariate correlation analysis between fasting ghrelin levels (ng/L) and other factors

	r value	*P* value
Age (yr)	-0.107	0.073
Gender (male 1, female 0)	0.082	0.167
BMI Z score	-0.259	< 0.001
FI (mIU/L)	0.283	< 0.001
FG (mmol/L)	-0.108	0.085
HOMA-IR	0.266	< 0.001
HOMA-β	-0.049	0.447
ALT (U/L)	-0.192	0.002
TG (mmol/L)	-0.136	0.029
TC (mmol/L)	-0.051	0.258
UA (μmol/L)	-0.210	0.001
T (ng/L)	-0.149	0.016
E2 (ng/L)	-0.075	0.226
LH (IU/L)	-0.120	0.053
FSH (IU/L)	-0.063	0.281
PRL (μg/L)	-0.003	0.963

RESULTS

In 283 subjects, the levels of FG, FI, HOMA-IR and HOMA-β were 4.55 ± 0.64 mmol/L, 7.60 mIU/L (2.0-56.90 mIU/L), 1.57 (0.29-12.39) and 156.80 (-5240 to 10 640), respectively. The levels of ALT, TG, TC and UA were 18.0 U/L (6.0-369.0 U/L), 1.42 mmol/L (0.22-8.64 mmol/L), 4.18 mmol/L (2.12-7.81 mmol/L) and 297.75 ± 82.09 μmol/L, respectively. The levels of T, E2, LH, FSH and PRL were < 200.0 ng/L (< 200.0-2700 ng/L), < 20.0 ng/L (< 20-98.6 ng/L), 0.30 IU/L (0.10-98.60 IU/L), 2.40 IU/L (0.10-100.0 IU/L) and 13.30 μg/L (2.90-69.30 μg/L). The median ghrelin level was 290 ng/L (15.0-1325.0 ng/L).

Bivariate correlation analysis was performed between fasting ghrelin levels and other factors, including age, gender (female as 0, male as 1), BMI Z score, ALT, TG, TC, UA, T, E2, LH, FSH, PRL, FG, FI, HOMA-IR, and HOMA-β (Table 1). The results showed the ghrelin levels were inversely correlated with BMI, ALT, TG, UA, FI and HOMA-IR (all $P < 0.05$). LH, age and FG had a marginal relationship with ghrelin (P ranged from 0.053 to 0.085). No other significant correlation was found between ghrelin levels and gender, TC, E2, FSH, PRL and HOMA-β.

Stepwise multiple regression analysis included all the factors which showed $P < 0.1$ in the bivariate correlation analysis. We found that only FI and BMI were independent determinants of plasma ghrelin levels in these children and adolescents, which explained 22.7% of the variance (Table 2). Plasma ghrelin levels were inversely associated with FI and BMI Z score ($P = 0.026$ and $P = 0.048$, respectively). HOMA-IR, T, LH, ALT, TG, UA and age were excluded in the equations (all $P > 0.05$).

Table 2 Multiple linear regression analysis for determinant of plasma ghrelin levels

Variable	Coefficient (Beta)	*r* value	*P* value
FI (mIU/L)	-1.208	2.244	0.026
BMI Z score	-1.107	1.985	0.048
FG (mmol/L)	-0.203	1.857	0.065
ALT (U/L)	-0.099	1.252	0.212
T (ng/L)	-0.081	1.125	0.262
HOMA-IR	0.099	1.251	0.277
UA (μmol/L)	-0.046	0.574	0.567

LH (IU/L)	-0.017	0.237	0.813
TG (mmol/L)	0.002	0.029	0.977

r^2 for the model = 0.227.

DISCUSSION

Ghrelin has recently been identified as a ligand of GHSR type 1a. It has been reported to have endocrine and nonendocrine actions[3-7], although there have been some contrary results. Also, the regulation of ghrelin secretion and its exact role have not yet been fully elucidated. In this study, we measured the plasma ghrelin levels in 283 Chinese children and adolescents and investigated the associated factors. We found that the median ghrelin level was 290 ng/L (15.0-1325.0 ng/L), which was similar with that reported previously[9,10].

We also found that BMI Z scores were inversely correlated with fasting plasma ghrelin levels, both by bivariate correlation and multiple regression analyses. This confirmed the view that ghrelin is closely associated with obesity. Ghrelin has been considered as a cause of obesity in some studies, on account of the fact that ghrelin has orexigenic effects in both rats and humans[11,12]. However, the results of most studies in humans, similar to our own, have demonstrated that ghrelin levels are negatively correlated with BMI Z score[9,13]. Moreover, Marzullo *et al* have reported that active ghrelin levels in subjects with obesity are lower than those in lean subjects[14]. These findings are contrary to the view that ghrelin is a factor in obesity. We speculate that the lower ghrelin levels in obesity are part of negative feedback to inhibit appetite and body weight, but not the primary cause of obesity[15]. This is also supported by the fact that circulating ghrelin levels increase in anorexia and cachexia[16-18]. However, animals without ghrelin do not have significantly altered body weight or food intake when compared with their wild-type littermates[19,20]. This suggests that it is a part of a reversible feedback mechanism, but not a determinant factor. Further studies are required to investigate the effect and the mechanism of ghrelin deficiency in individuals with obesity.

We also report that FI, HOMA-IR, ALT, UA and TG (but not glucose or HOMA-β) were negatively associated with plasma ghrelin levels. Moreover, FI was an independent factor of ghrelin levels by multiple regression analysis. These findings are supported by several previous studies[21,22] and suggest that insulin suppresses circulating ghrelin, independently of glucose. Hence, we speculate that hyperinsulinemia, which is very common in children and adolescents with obesity[23-25], might partly explain their lower ghrelin levels.

Some previous studies have suggested that ghrelin plays a role in the regulation of reproductive physiology. Expression of ghrelin in rat and human testes has been investigated[26,27], and some studies have reported that ghrelin levels are related to GnRH and androgens[28-31]. However, some animal studies have shown that ghrelin stimulates GnRH and/or androgens *in vitro*[28,29], but inhibits these hormones *in vivo*[30,31]. However, similar studies investigating the relationship between ghrelin and the gonadal axis in humans are rare, and the actual role of ghrelin in reproductive physiology is still unclear. In this study, we found that T and LH (but not E2 and FSH) were negative associated with fasting plasma ghrelin levels, although T and LH were not independent factors for ghrelin levels in stepwise regression analysis. This finding suggests that ghrelin regulates reproductive physiology in humans indirectly.

There are several limitations in this current study. Firstly, the sample may have been too small to find major differences. Secondly, we measured total circulating ghrelin, including Ser 3-octanoyl and Ser 3-des-octanoyl ghrelin, but not the active form of ghrelin. Thirdly, the actual correlation coefficients between serum ghrelin levels and BMI Z scores and FI were low. These imply that some other factors play a role in regulating circulating ghrelin levels.

In summary, our data suggest the lower ghrelin levels in subjects with obesity are the result of obesity and hyperinsulinemia, which is very common in these subjects. Moreover, ghrelin may regulate human reproductive physiology indirectly. Further studies are required to improve our understanding of the ghrelin effect and regulation of ghrelin secretion.

ACKNOWLEDGMENTS

We thank all the children and their parents for participating in this research project. We also thank Jiang You-Jun, Hong Fang, Dong Guan-Ping, Wang Chun-Lin, and Shen-Hong for their exceptional patient care and organization.

COMMENTS

Background

Ghrelin is an endogenous ligand for growth hormone secretagogue receptor type 1a and has some endocrine and non-endocrine actions. However, the regulation of ghrelin secretion and its specific role in endocrinology in humans, including the gonadal axis, insulin resistance, energy balance and obesity, are not completely understood.

Research frontiers

Worldwide, obesity has reached epidemic proportions. Obesity also increases the risk of developing a number of chronic diseases including insulin resistance, type 2 diabetes, hypertension, hypercholesterolemia, stroke, and heart attack. Hence, analysis of the relationship between ghrelin levels, obesity and insulin resistance is necessary.

Related publications

The prevalence of obesity has increased in China, which is closely associated with

metabolic syndrome (*Int J Obes* 2007; 31: 15-22). Some studies have reported the relationship between obesity, adipocytokines and cytokines (*Endocrin J* 2005; 52: 519-524. *Indian Pediatr* 2007; 44: 275-279).

Innovations and breakthroughs

The lower ghrelin levels in subjects with obesity may be the result of obesity and hyperinsulinemia, which is very common in these subjects. Moreover, ghrelin might regulate human reproductive physiology indirectly.

Applications

Regulating ghrelin levels may be beneficial for improving insulin sensitivity, controlling body weight, or even reproductivity.

Terminology

Insulin resistance is a condition in which the cells of the body become resistant to the effects of insulin, that is, the normal response to a given amount of insulin is reduced. As a result, higher levels of insulin are needed in order for insulin to have an effect. Almost all individuals with type 2 diabetes mellitus and many with hypertension, cardiovascular disease, and obesity are insulin resistant.

Peer review

This study is of particular importance to childhood health and obesity, and correlates many factors with plasma ghrelin in the fasting state. It suggests an interesting hypothesis linking hyperinsulinemia and obesity to lower ghrelin levels.

Abstract

AIM: To evaluate portalsystemic hemodynamic changes in chronic severe hepatitis B.

METHODS: Hemodynamic parameters included portal vein diameter (PVD), portal vein peak velocity (PVPV), portal vein volume (PVV), spleen length (SPL), spleen vein diameter (SPVD), spleen vein volume (SPVV) and umbilical vein recanalization. They were measured by Color Doppler ultrasonography in 36 patients with chronic severe hepatitis B, compared with 51 normal controls, 61 patients with chronic hepatitis B, 46 patients with compensable cirrhosis, and 36 patients with decompensable cirrhosis.

RESULTS: In the group of chronic severe hepatitis B, PVD (12.38 ± 1.23 mm) was significantly different from the normal control, compensable cirrhosis and decompensable cirrhosis groups (P = 0.000-0.026), but not significantly different from the chronic hepatitis group. PVPV (16.15 ± 3.82 cm/s) dropped more significantly in the chronic severe hepatitis B group than the normal control, chronic hepatitis B and compensable cirrhosis groups (P = 0.000-0.011). PVV (667.53 ± 192.83 mL/min) dropped significantly as compared with the four comparison groups (P = 0.000-0.004). SPL (120.42 ± 18.36 mm) and SPVD (7.52 ± 1.52 mm) were longer in the normal control and chronic hepatitis B groups (P = 0.000-0.009), yet they were significantly shorter than those in the decompensable cirrhosis group (P = 0.000). SPVV (242.51 ± 137.70 mL/min) was also lower than the decompensable cirrhosis group (P = 0.000). The umbilical vein recanalization rate (75%) was higher than the chronic hepatitis B and compensable cirrhosis groups. In the course of progression from chronic hepatitis to decompensable cirrhosis, PVD, SPL and SPVD gradually increased and showed significant differences between every two groups (P = 0.000-0.002).

CONCLUSION: Patients with chronic severe hepatitis B have a tendency to develop acute portal hypertension, resulting in significantly reduced portal vein perfusion. Observation of the portalsystemic hemodynamic changes may be contributed to the disease progression of chronic liver disease.

INTRODUCTION

Chronic severe hepatitis carries a very high mortality rate (60%-80%), and causes about 22 600 deaths in China annually. It is widely known that progression of liver diseases is accompanied by histological changes of the hepatic parenchyma, such as inflammation, necrosis and fibrosis, as well as hemodynamic changes. Because hepatic circulation closely correlates to chronic liver disease, confirmation of the changes in the hepatic circulation is important for clarifying the disease progression. Liver biopsy is the gold standard for the grading and staging of the viral hepatitis. However, this procedure causes discomfort, and is invasive for the patients, especially those with prolonged prothrombin time[1-3]. Ultrasonography has the advantages of low cost, easy operation and high acceptability by the patients. It can provide not only valuable information on the morphological changes of the liver but also liver hemodynamics by color Doppler flow imaging[4-7]. The introduction of color Doppler

ultrasonography has been an important breakthrough in the noninvasive evaluation of splanchnic hemodynamics. Both qualitative and quantitative evaluations of the portalsystemic circulation are being widely used in patients with chronic hepatitis and cirrhosis[8-10]. However, until the present, there have been only a few reports on portalsystemic hemodynamic changes in chronic severe hepatitis B in the literature. Furthermore, there is no consensus on the role of Doppler parameters in grading the severity of chronic liver disease[11-16]. The purpose of this study is to evaluate portalsystemic hemodynamic changes in chronic severe hepatitis B non-invasively, and to delineate more definitively the role of Doppler parameters in patients with chronic hepatitis B and cirrhosis, as compared with normal subjects, chronic hepatitis B, compensable cirrhosis and decompensable cirrhosis patients.

MATERIALS AND METHODS

Subjects and diagnostic criteria

Between April 2005 and August 2007, 230 subjects were recruited in this study. Among them, 191 were males and 39 were females, with an average age of 34.7 ± 13.5 years (ranging from 10 to 77 years). According to the program of prevention and cure for viral hepatitis amended by the Chinese Society of Infectious Disease and Parasitology and the Chinese Society of Hepatology of Chinese Medical Association in the Xian meeting held in September 2000[17], the subjects were divided into five groups: 36 patients with chronic severe hepatitis; 51 normal controls; 61 patients with chronic hepatitis B; 46 patients with compensable cirrhosis; and 36 patients with decompensable cirrhosis. There were no significant differences in the gender and age among these five groups. Diagnoses of patients in the control groups except the normal group were made on the basis of pathological examination of liver biopsy specimens and laboratory findings. Ethical approvals of the liver biopsy were obtained before the operations. Subjects in the normal control group had normal hepatic functions, and no histories of chronic liver disease. Compensable cirrhosis belonged to Child-Pugh A, the diagnostic criteria included A $\geqslant$ 35 g/L, Bil <35 μmol/L, PTA > 60%, and portal hypertension but no ascites, hepatic encephalopathy and upper gastrointestinal bleeding. Decompensable cirrhosis belonged to Child-Pugh B, C, the diagnostic criteria included serious hepatic function abnormalities, such as A < 35 g/L, A/G < 1.0, Bil > 35 μmol/L, PTA < 60%, and ascites, hepatic encephalopathy, upper gastrointestinal varices or bleeding. Diagnostic criteria of chronic severe hepatitis B[18] included the basic conditions, i.e. the course of hepatitis B surface antigen-positive exceeded six months and the level of serum bilirubin in liver failure index exceeded ten times compared by normal level (17.1 μmol/L), which was above 171 μmol/L. Two additional conditions included (at least one liver failure index or more than one indexes below): (1) Prothrombin activity < 40%; (2) Hepatic encephalopathy; (3) Ascites; (4) Progressive reduction in liver size; (5) Hepatorenal syndrome. Exclusion criteria for patients in this study were autoimmunity hepatitis, alcoholic hepatitis, and the abnormality of cardiac and renal function accompanied by systemic hemodynamic changes.

Doppler measurements

All subjects were tested in the morning after an overnight fast and informed consents were obtained. All Doppler studies were performed with a color and pulsed Doppler unit (BIOSOUND AU4) armed with a 3.5-5.0 MHz convex probe. According to our previous study with the aim to select valuable ultrasonographic predictors for the evaluation of hepatic inflammation and fibrosis degree in chronic hepatitis[10], we selected the following Doppler parameters for this study: portal vein diameter (PVD), portal vein peak velocity (PVPV), portal vein volume (PVV), spleen length (SPL), spleen vein diameter (SPVD), spleen vein volume (SPVV), and umbilical vein recanalization.

The conditions of Doppler measurement: the sampling size was nearly equal to the vessel diameter, the angle between the Doppler beam and the longitudinal axis of the vessel was kept at less than 60°. Portalsystemic Doppler parameters were automatically determined for all samples of the Doppler signal that lasted for more than two cardiac cycles. Doppler ultrasound parameters were measured in triplicate, and the results were averaged.

In order to reduce inter-observer variability to a non-significant level, all examinations were performed by one of the author's that was blind to the patients' clinical details. Feasibility of a satisfactory Doppler US examination was required for each patient recruited in this study. All patients were not affected by cardiopulmonary, circulatory, renal, or abdominal diseases and were not taking medications. The formula of blood volume was $(V) = 1/4\pi \times a \times b \times 0.57\ V_{peak} \times 60$ (mL/min) a: antero-posterior diameter of vessel, b: transverse diameter of vessel, Unit: cm, V_{peak}: peak velocity.

Statistical analysis

Results were described as mean ± SD and analyzed on the computer with SPSS 11.0 software (SPSS Inc, Chicago, IL, USA). Differences in means among the groups were evaluated by one-way ANOVA and LSD. Proportions were evaluated by χ^2-test. P values < 0.05 were considered statistically significant.

RESULTS

Means of the portalsystemic hemodynamic parameters in different groups are shown in Table 1.

Differences of the portalsystemic hemodynamic parameters in different groups are shown in Table 2.

PVD in the chronic severe hepatitis group was significantly different from the normal control, compensable cirrhosis and decompensable cirrhosis groups, but not significantly different from chronic hepatitis B group. Among the four comparison groups, PVD gradually increased and was significantly different between every two groups with disease progression; PVPV in the chronic severe hepatitis group evidently decreased in comparison to the normal control, chronic hepatitis B

Table 4 Differences of umbilical vein recanalization rates in different groups

Group and group	χ^2 values	*P*
RCG and ICG	9.954	0.002
RCG and SCHG	23.135	0.000
ICG and SCHG	3.003	0.083

NCG: Normal control group; CHG: Chronic hepatitis B group; RCG: Compensable cirrhosis group; ICG: Decompensable cirrhosis group; SCHG: Chronic severe hepatitis B group.

Differences of the umbilical vein recanalization rates in different groups are shown in Table 4.

The umbilical vein recanalization rate in the chronic severe hepatitis group significantly increased in comparison to the compensable cirrhosis group and there was no significant difference from decompensable cirrhosis group. There were no umbilical vein recanalizations in the normal control and chronic hepatitis B groups.

DISCUSSION

Chronic severe hepatitis B refers to patients with evidence of chronic liver disease that then develops acute decompensation of liver function. Usually, the acute decompensation of liver function is caused by one or more potentially reversible precipitating events, such as superimposed acute hepatic necrosis due to other hepatotropic virus infections drugs, alcohol, or ischemia sepsis, worsening renal function, and gastrointestinal bleeding. Chronic severe hepatitis often includes both acute-on-chronic liver failure and chronic liver failure[19]. In China,

the majority of fulminant hepatitis is chronic liver failure caused by hepatitis virus B. Because of the underlying pathological changes of chronic hepatitis or liver cirrhosis, when liver failure leads to massive necrosis of the liver, treatments become more difficult[20]. Obviously, chronic severe hepatitis B threatens the health of hepatitis patients because of its poor prognosis and high mortality.

Our results showed that there were no significant differences in PVV among the four control groups (P = 0.178-0.580), but PVV in the chronic severe hepatitis B group obviously decreased and was significantly different from the four comparison groups (P = 0.000-0.004). This reason may be, in our opinion, predominantly due to mechanical factors. As the liver disease progresses from chronic hepatitis to decompensable cirrhosis, hepatocellular inflammation, necrosis, development of regenerative nodules and collagen deposition, lobule reconstruction occur. These pathological changes may be resulted in gradual increase of portal vein circumfluence resistance, gradual decrease of portal vein velocity, and gradual dilation of portal vein diameter. In this process, dilation of the portal vein diameter may counteract the decrease in portal velocity, thus PVV was able to retain stability in a certain extent, so that hepatic perfusion could be maintained. However, in chronic severe hepatitis B, because of patchy areas of confluent massive hepatocellular necrosis, condensation of the reticulin framework of the lobule occurs in a short time, hepatic sinus interval becomes narrow, and even obstructed, and blood vessel bed decreases. Rapid increase of portal vein circumfluence resistance may be the result of these pathological changes, and may result in an obvious decrease in PVPV and acute portal hypertension formation. It was reported that patients with acute hepatitis and fulminant hepatitis developed portal hypertension with the aggravation of hepatic inflammation degrees[21,22]. Additionally, PVD was difficult to dilate to compensate for PVPV decrease in time, so PVV significantly dropped in comparison to the control groups. Because PVV in chronic severe hepatitis significantly decreased (only 76% of the normal group), hepatic perfusion derived from the portal vein was insufficient, and hepatocellular ischemia and hypoxia deteriorated tissue injury. Meanwhile, chronic severe hepatitis B could occur as a result of hepatic ischemia and hypoxia, and finally formed a vicious circle severely affecting the prognosis. This hypothesis may provide a theoretical base for clinical experience of dilating hepatic vessel, relieving portal vein resistance, increasing PVV and perfusion, and improving hepatic microcirculation[23].

There was no significant difference in PVPV between the chronic severe hepatitis B and decompensable cirrhosis groups (P = 0.413). The reason might be that PVPV in the two groups partly overlapped. It was well known that chronic severe hepatitis B included patients who had decompensable cirrhosis with < 40% prothrombin activity and total bilirubin > 171 μmol/L.

In the progression from chronic hepatitis to decompensable cirrhosis, PVD, SPL and SPVD gradually increased and showed significant difference between every two groups (P = 0.000-0.002). Our results revealed that PVD, SPL and SPVD were useful predictors of the disease progression from chronic hepatitis to decompensable cirrhosis. This was identical with O'Donohue[24].

Normally, after interruption of the placental circulation at birth, the umbilical vein collapses and forms the ligamentum teres in the adult. However, when portal hypertension occurs, the umbilical vein may recanalize and serve as a collateral route[25,26]. It was recognized in 10%-29% of patients with portal hypertension[27]. In our results, in the progression from chronic hepatitis to decompensable cirrhosis, the rate of umbilical vein recanalization gradually increased, but it was 75% (27/36) in the chronic severe hepatitis B group, which was obviously higher than that in the control groups. We considered that from chronic hepatitis to decompensable cirrhosis, portal pressure slowly rose and chronic portal hypertension formed, extensive collateral channels opening, portal vein dilation and spleen enlargement occurred. These factors could decompress portal system. However, in chronic severe hepatitis B, PVD and SPL could not compensate in time due to acute portal hypertension formation. Decompression of the portal system had to rely on collateral circulation formation such as umbilical vein recanalization. This was likely to be the reason for the higher rate of umbilical vein recanalization in chronic severe hepatitis.

In addition, there were other factors responsible for portalsystemic hemodynamic changes. Liver circulation included portal vein and hepatic artery perfusion[28,29]. It was the limitation in this study that portal vein perfusion was measured alone. In recent years, some new techniques and methods have been introduced to the hemodynamic study in liver. For example, hepatic vein transit time was measured by spectral Doppler or pulse-inversion imaging[30,31].

In conclusion, patients with chronic severe hepatitis B have a tendency to develop acute portal hypertension, resulting in an obvious decrease in portal vein perfusion. Observation of portalsystemic hemodynamic changes may contribute to the disease progression of chronic liver disease.

COMMENTS

Background

The introduction of color Doppler ultrasonography has been an important breakthrough in the noninvasive evaluation of splanchnic hemodynamics. The purpose of this study is to evaluate portalsystemic hemodynamic changes in chronic severe hepatitis B non-invasively, as compared with normal subjects, chronic hepatitis B, compensable cirrhosis and decompensable cirrhosis patients.

Research frontiers

Both qualitative and quantitative evaluations of the portalsystemic circulation are being widely used in patients with chronic hepatitis and cirrhosis. However, up to the present, there have been only a few reports on portalsystemic hemodynamic changes in chronic severe hepatitis B in the literature. Furthermore, there is no consensus on the role of Doppler parameters in grading the severity of chronic liver disease.

Innovations and breakthroughs

The article found that portal vein perfusion obviously decreased in chronic severe hepatitis B; portal vein diameter (PVD), spleen length (SPL), spleen vein diameter (SPVD) gradually increased and showed significant difference between every two groups in the progression from chronic hepatitis to decompensable cirrhosis.

Applications

This study was of important clinical values of evaluation portalsystemic hemodynamic changes in chronic severe hepatitis B and proved that Doppler

parameters could play an important role in grading the severity of chronic liver disease.

Terminology

Chronic severe hepatitis B refers to patients with evidence of chronic liver disease that then develops acute decompensation of liver function.

Peer review

This study was of important clinical values, which could comprehensively clarify portalsystemic hemodynamic changes in chronic severe hepatitis B, and grade the severity of chronic liver disease from chronic hepatitis to decompensable cirrhosis.

Abstract

Approximately 10% of patients with gastrointestinal stromal tumors (GIST) develop other neoplasms, either synchronously or metachronously. In this report we describe coexistence of a gastrointestinal stromal tumor and a hepatic perivascular epithelioid cell tumor (PEComa) in a 51-year-old woman with no evidence of tuberous sclerosis. A subcapsular hepatic nodule (0.8 cm in diameter) was found during surgery for symptomatic gastric neoplasm (15 cm in diameter) arising from the lesser curvature. Both tumors revealed histomorphological and immunohistochemical features confirming a diagnosis of a small incidental hepatic PEComa and a high risky extramural gastric GIST, respectively. The patient remained disease-free 25 mo after surgery with no evidence of tumor recurrence or new neoplasms. To our knowledge, this is the first report of PEComa in a patient with GIST. Hepatic lesions detected synchronously or metachronously in patients with GISTs may represent histogenetically distinct lesions and should be sampled to confirm or exclude metastatic GISTs.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) represent the most common mesenchymal neoplasms of the gastrointestinal (GI) tract with an estimated incidence of 14.5 cases/million inhabitants[1]. Histologically, GISTs may show pure spindle cells, epithelioid, mixed and rarely pleomorphic morphology and are characteristically strongly immunoreactive for c-kit (CD117). GISTs occur more frequently in the stomach (60%-70%), small intestine (20%-30%), colorectum and esophagus (together ≤ 10%). Metastases predominantly occur in the peritoneum and liver[2].

Perivascular epithelioid cell tumors (PEComas) belong to a family of mesenchymal neoplasms including angiomyolipoma, clear-cell "sugar" tumors of the lung and other organs, lymphangiomyomatosis (LAM) and a rare group of morphologically and immunophenotypically similar lesions that may affect soft tissues, viscera and bones[3-5]. The term PEC (perivascular epithelioid cell) was coined by Bonetti *et al*[6] to describe the epithelioid cells found in these neoplasms. Primary hepatic PEComas are extremely rare[7], the majority of them were reported as monotypic or epithelioid angiomyolipoma.

Synchronous or metachronous malignant neoplasms are detected in almost 10% of GIST patients. In this regard, the majority of GISTs associated with other neoplasms are incidentally detected during surgery for intra-abdominal cancers. Hepatic neoplasm during GIST surgery is exceptionally rare. In this report, we describe the first case of GIST with a synchronously diagnosed hepatic PEComa, both of them were completely surgically resected.

CASE REPORT

A 51-year-old woman sought medical care in November 2004 due to pain in the left hypochondrium for 2 mo. She reported a weight loss of 7 kg during that period. Physical examination revealed no signs of the tuberous sclerosis complex (TSC). A computerized tomography (CT) of the

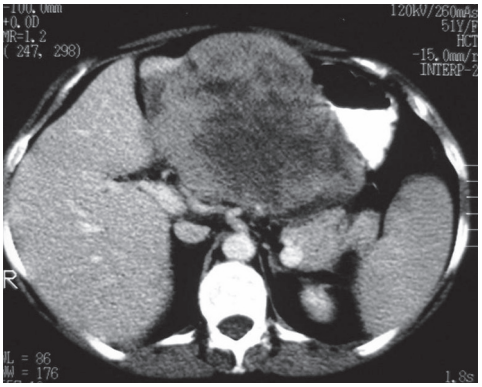

Figure 1 Computed tomography of the abdomen showing a 15-cm heterogeneous, solid expansile, regularly-shaped lesion located in the epigastrium and in contact with the left hepatic lobe and gastric wall.

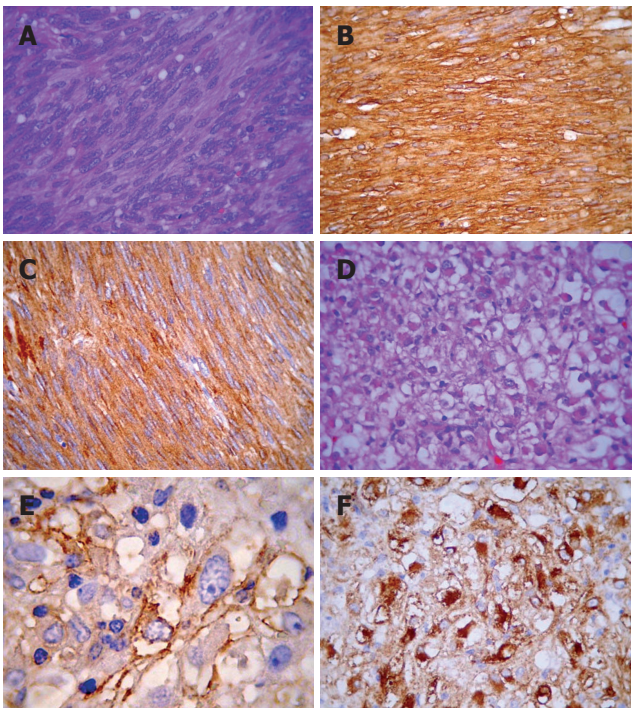

Figure 2 Morphological and immunohistochemical features of gastric GIST (**A-C**) and hepatic PEComa (**D-F**). **A**: GIST with characteristic spindled bipolar cells with occasional paranuclear cytoplasmic vacuoles; **B** and **C**: Strong staining for CD117 and CD34, respectively; **D**: Hepatic PEComa with a monotonous epithelioid morphology with cytoplasmic clearing that is hardly distinguishable from epithelioid GIST (note scattered cells with rhabdoid cytoplasm); **E**: A coarsely granular HMB45 reactivity; **F**: HH35 showing a strong paranuclear cytoplasmic reactivity.

abdomen showed a 15 cm well circumscribed solid expansile epigastric mass in contact with the left hepatic lobe and the gastric wall (Figure 1). CT of the thorax and pelvis did not show metastasis. At surgery, the mass was found to be attached to and infiltrating the gastric wall near the small curvature and could be successfully resected together with the large omentum and adjacent gastric wall involving the tumor. During surgery, a small subcapsular nodule located in the left hepatic lobe near the large gastric tumor was detected and resected. No tumor was found in the kidneys. The patient had a total abdominal hysterectomy for uterine leiomyomatosis in December 2006. At present, 25 mo after the surgery, she is under regular clinical follow-up with no evidence of tumor recurrence or metastasis.

Table 1 Summary of immunohistochemical features of the two tumors surgically excised

Antigen (Antibody clone)[1]	Dilution	PEComa	GIST
CD117	1:600	-	+
CD34	1:50	-	+
Vimentin	1:350	+	+
Cytokeratins (AE1/AE3)	1:250	-	-

HMB-45	1:40	+	-
S100 protein	1:200	-	+

[1]DakoCytomation, Carpinteria, California, USA.

The resected gastric tumor measured 15.5 cm × 13.0 cm × 11.5 cm and was highly cellular, consisting of fascicles of spindled cells with elongated nuclei and finely granulated chromatin. Mitotic activity was brisk (3 mitoses/10 high-power fields). Cellular atypia was minimal and necrosis was absent (Figure 2A). Immunohistochemistry showed a strong expression of CD117 and CD34 (Figure 2B and C). The hepatic nodule measured 0.8 cm × 0.6 cm and was located near the hepatic surface, partly covered by its capsule. Histology showed sheets of large epithelioid cells with abundant eosinophilic, sometimes clear cytoplasm and mildly pleomorphic nuclei with evident nucleoli. A prominent feature was the presence of numerous dilated vascular spaces with a hemangiopericytic pattern. Necrosis or mitotic figures were not observed (Figure 2D). Immunohistochemistry showed a strong expression of HMB-45 and muscle specific actin (HHF-35), establishing a diagnosis of hepatic PEComa (Figure 2E and F). Table 1 summarizes the immunohistochemical data for both lesions.

DISCUSSION

The diagnosis of synchronous or metachronous neoplasias is not uncommon in clinical practice. Genetic predisposition and exposure to specific etiological or risk factors may be responsible for the association of histogenetically distinct tumors[8]. In such a circumstance, a second neoplasm developing in a patient with a known history of cancer is at a special risk of being misinterpreted as a metastatic disease, in particular, if this metachronous neoplasm presented at a site typically involving metastasis from the previously treated cancer, underscoring the need for sampling and a more careful interpretation of clinical, radiological and histopathological findings.

It was reported that the occurrence of synchronous and metachronous neoplasms is approximately 10% in patients diagnosed with GISTs and half of the cases can be diagnosed synchronously[9]. Gastrointestinal tract carcinomas are most frequently associated with GIST[9,10].

The presence of hepatic nodules in patients with a GIST must be carefully evaluated using appropriate immunohistochemical marker panel in order to distinguish metastatic GIST from other histogenetically distinct lesions (PEComa in the current case). Synchronous or metachronous primary hepatic neoplasms found incidentally in GIST patients are exceptionally rare with ⩽ 5 cases reported so far, including four hepatocellular

carcinomas and one inflammatory pseudotumor[9,11,12].

GISTs may enter the differential diagnosis of PEComas, since both can affect intra-abdominal structures. Due to their heterogeneous morphologic spectrum, GIST and PEComa may show largely overlapping features, thus representing a great differential diagnostic challenge for histopathologists. PEComas can be erroneously mistaken for GIST due to the monotonous epithelioid morphology and cytoplasmic clearing seen in a subset of both, combined with positive CD117 observed in some PEComas[5,7,13] and lacking or weak CD117 expression observed in a subset of epithelioid GISTs harboring mutations in platelet-derived growth factor receptor A (*PDGFRA*)[14]. Evert *et al*[13] reported a case of a malignant PEComa of the rectovaginal space mimicking a GIST and advocated the use of melanocytic markers in cases of suspected GIST with less than 50% of tumor cells expressing CD117. However, the characteristic morphology of PEComas may facilitate diagnosis in most of the cases. In difficult cases, immunohistochemistry would confirm the diagnosis of PEComa, as PEComas commonly show a characteristic myomelanocytic marker profile, occasionally with a characteristic perivascular distribution of HMB45 positive cells. PEComas commonly consist of epithelioid to elongated cells with abundant clear to granular eosinophilic cytoplasm with a perivascular organization of PECs in some of the cases[15]. While expression of HMB45 is a regular feature in most PEComas, smooth muscle markers and S100 show a rather heterogeneous and inconsistent reactivity pattern. CD117 expression in PEComas shows variable results, however, this finding is probably rare (5%) when appropriate immunohistochemical techniques are applied[5,16]. CD34 expression is generally lacking in PEComas.

Renal angiomyolipomas are frequently associated with TSC and even the sporadic cases present loss of heterozigosity (LOH) in chromosome 16p (harboring the *TSC2* locus)[3]. The pathogenesis of PEComas other than angiomyolipoma and LAM is not well understood. GISTs have not been reported to be associated with the TSC. *TSC2* LOH, as detected in some PEComas, have not been analysed in GISTs. Based on this and the finding that lesions of the PEComa family are KIT-negative in the majority of cases[5], it is likely that the coexistence of these two lesions in the current case represents a coincidence.

Hepatic PEComas, previously referred to as epithelioid or monotypic angiomyolipoma, are extremely rare[7,17-20]. To our knowledge, this is the first case reported in a patient with GIST.

In summary, we documented the first case of a GIST coexisting with a PEComa. Careful histopathological evaluation is mandatory for correct interpretation of the findings and, consequently, for appropriate patient treatment. A wide immunohistochemical panel is necessary to approach this differential diagnostic dilemma.

Abstract

A young man with a previous history of episodes of mild solid food dysphagia was admitted with a total dysphagia. The esophagogastroduodenoscopy (EGDS) showed an extensive disruption of mucosal layer with a cul-de-sac in the lower part of the esophagus. Soon after the procedure, the patient suffered from an acute chest pain and subsequent CT scan demonstrated an intramural circumferential dissection of thoracic esophagus, and a mediastinal emphysema. An emergency right thoracotomy was performed, followed by a total esophagectomy with esophagogastroplasty and jejunostomy. The histopathology confirmed that mucosal and submucosal layers were circumferentially detached from muscular wall and showed an eosinophilic infiltration of the whole organ with necrosis and erosions of mucosal, submucosal and muscular layers. The diagnosis was esophageal perforation in eosinophilic esophagitis.

INTRODUCTION

Idiopathic eosinophilic esophagitis is an underdiagnosed disease with typical endoscopic findings. The clinical presentation includes solid food dysphagia in young adults who have an atopic predisposition. Food impaction necessitating endoscopic intervention is common. Mucosal rents and rarely perforations occur with simple passage of the endoscope[1]. We report a case of circumferential mucosal dissection in a young man with eosinophilic esophagitis.

CASE REPORT

A 32-year-old man was admitted into a local hospital service of gastroenterology with a diagnosis of food impaction. The patient had no previous history of upper gastrointestinal disease and had suffered from mild solid food dysphagia over the last years. All previous dysphagic episodes underwent spontaneous resolution and some of them were occasionally associated with various atopic symptoms. Upon admission, the patient was in good general conditions although presented mild distress due to tachypnea (RR 35/min); other vital signs were within normal limits. Since the patient complained of a total dysphagia in swallowing any liquids, it was impossible to perform a gastrografin esophagography. Therefore, the patient underwent EGDS that showed no food impaction, but an extensive disruption of mucosal layer with a cul-de-sac in the lower part of the esophagus. Soon after the endoscopy, the patient suffered from an acute chest pain and a severe discomfort with development of an extensive neck and anterior thoracic emphysema. A CT scan was performed.

The CT scan identified an intramural circumferential dissection of thoracic esophagus, a pneumomediastinum and a subcutaneous emphysema of the neck and of the anterior thoracic wall (Figure 1). Following the diagnosis of esophageal perforation, a right thoracotomy was performed. During the operation a 1.5 cm esophageal perforation at T1 level was detected. A peroperative EGDS was executed, and the mucosal and submucosal layers were circumferentially dissected from the muscular part of the esophageal wall. The dissection extended from 19 cm below the upper dental arcade up to the lower portion of the thoracic esophagus, ending at a cul-de-sac that stopped the endoscope progression. The mucosal and submucosal layers, circumferentially detached from muscular wall, looked like a whitish flap distally-fixed and floating inside the esophageal lumen (Figure 2). The endoscopy allowed to explore both the false and true visceral lumens. Due to the severe alteration of almost the whole thoracic esophagus wall, a simple suture of the perforation

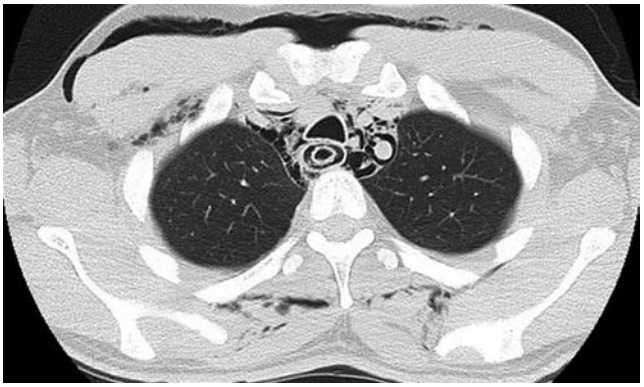

Figure 1 CT scan shows oesophageal double lumen associated with pmeumomediastinum and subcutaneous emphysema.

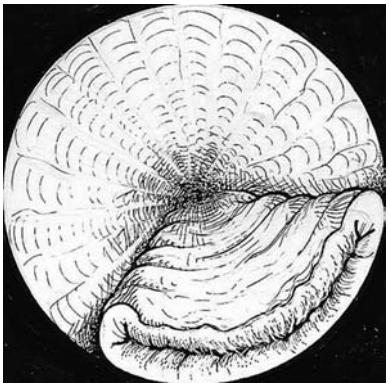

Figure 2 The drawing shows the endoscopic view of the esophagus: mucosal and submucosal layers are totally dissected from muscular wall. The false lumen ends in a cul de sac.

appeared hazardous, thus a total esophagectomy with esophagogastroplasty and jejunostomy was performed.

The histopathology confirmed an eosinophilic infiltration of the whole organ with necrosis and erosions of all mucosa, submucosa and in some areas of the muscular layer. The diagnosis was eosinophilic esophagitis.

The patient received 2 d of ICU. Gastrografin esophagogram on the 10th post- operative day showed normal pattern and motility of the neoesophagus. Three months after surgery, the patient had a good quality of life, ate a normal diet and did not experience any weight loss.

DISCUSSION

Eosinophilic esophagitis (EE) is an isolated, eosinophilic inflammation of the esophagus. The symptoms of EE used to be confused with gastroesophageal reflux (GERD).

Recent reports suggest a multi-step allergy process starting with an atopic skin response that primes the esophagus for further allergen exposure. A population of eosinophils different from gut and blood that specifically reaches the esophagus in EE was demonstrated[2]. The allergic reaction involved in EE is non-IgE mediated. The most commonly involved food includes milk, eggs, nuts, beef, wheat, fish, shellfish, corn and soy. However, almost all the food is implicated[3].

The diagnosis of EE is suggested by an unexplained dysphagia or by a food impaction in a young adult with a personal and family allergic history.

Clinical features include dysphagia (93%), food impaction (62%), heartburn (23.6%) and history of atopia (51.6%)[4]. Endoscopic findings are mucosal fragility/oedema, rings, strictures, whitish pinpoint exudates and small-calibre esophagus in various cases whereas 8.8% of patients have a normal endoscopy[4]. The presence of more than 15 eosinophils per high power field on esophageal biopsies is required to establish the diagnosis[4]. Therapeutic options include restriction of diets, various medicaments (systemic and topical corticosteroids, leukotriene receptor antagonists and, most recently, an anti-interleukin-5 monoclonal antibody) and endoscopic dilatation[5]. The administration of corticosteroids resulted in symptomatic improvement in more than 95% of cases. A trial with corticosteroids before bougienage may reduce the active inflammation and the complication rate[2]. Esophageal perforation is described as a complication[4] and one case was treated with subtotal esophagectomy[6]. Although a spontaneous circumferential mucosal dissection was already described[7], we are not aware of any other cases associated with eosinophilic esophagitis.

We believe that in our patient the dissection is most likely spontaneous, since no impacted food has been found in either the endoscopic examination or the resected esophagus. However, we can not exclude that the dissection may be caused or enlarged by the esophagoscopy, therefore this risk must be always born in mind while deciding to perform an endoscopy for young patients with sudden total dysphagia and with a personal and familial history of atopic symptoms. With regard to esophageal perforation, it is certainly iatrogenic, since the symptoms correlated with this complication (acute chest pain, severe discomfort, extensive neck and anterior thoracic emphysema) appeared at the end of the endoscopic examination.

Abstract

The differential diagnosis between intracystic hemorrhage and cystadenocarcinoma of the liver is often difficult even with the use of various imaging modalities. A 73-year-old woman was admitted to our hospital with the complaint of right upper quadrant pain. Ultrasonography (US) demonstrated a heterogeneous echogenic cyst measuring 11 cm × 8 cm in size in S2 of the liver, indicated intracystic hemorrhage of simple liver cyst or cystadenocarcinoma, but the differential diagnosis was considerably difficult. Levovist (Schering, Berlin, Germany) US revealed no enhancement of the intracystic structures, suggesting a clot in the case of intracystic hemorrhage. An operation was performed and the resected lesion showed a solitary benign liver cyst, measuring 5.5 cm × 4.7 cm × 8.5 cm containing a large blood clot. The patient had an uneventful recovery after the surgery. Levovist US may play an important role in discrimination between intracystic hemorrhage of simple hepatic cysts and cystadenocarcinoma of the liver.

INTRODUCTION

Hemorrhage into a simple liver cyst is rather uncommon. The differential diagnosis between intracystic hemorrhage and cystadenocarcinoma of the liver is difficult with the various imaging studies currently available[1,2]. Consequently, hepatectomy has been performed unnecessarily, even in cases with benign liver cysts with intracystic bleeding, based on a wrong preoperative diagnosis of cystadenocarcinoma. We report on a patient with intracystic hemorrhage complicating a simple liver cyst in whom the diagnosis was made accurately by Levovist (Schering, Berlin, Germany) Ultrasonography (US) Imaging.

CASE REPORT

A 73-year-old woman with chronic hepatitis C had been under follow-up for two years. She had been followed up by laboratory examination every month and imaging studies such as US and Computed Tomography (CT) every six months as screening procedures for hepatocellular carcinoma. The previous US and CT had only shown a simple cyst measuring 1.3 cm in diameter in segment 4 (S4) of the left lobe. The patient did not complain of any abdominal discomfort during this period, nor was there any history of abdominal injury.

The patient was admitted to hospital with the complaint of right upper quadrant pain. Her blood pressure was 110/62 mmHg, pulse was 84/min, and physical examination revealed spontaneous pain, tenderness, and no muscular defense in the abdomen. The liver was not palpable under the right rib cage. The laboratory examination findings were almost normal

Figure 1 US image showing a heterogeneous echogenic cyst in S2, measuring 11.0 cm × 8.0 cm and showing intracystic septations and structures.

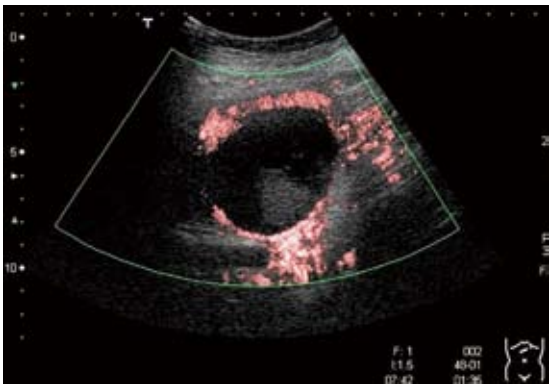

Figure 2 CEU images demonstrating absence of enhancement of the intracystic septations and structures and smooth of the enhanced cyst wall.

except as follows: anemia (red blood cell count, 399 × 10^4/mm^3; hematocrit, 30%; hemoglobin, 12.6 g/dL) and elevated serum CRP (3.5 mg/dL). The serum was negative for antibody against Echinococcus antigens by enzyme-linked immunosorbent assay.

US demonstrated a heterogeneous echogenic cyst measuring 11 cm × 8 cm in size with intracystic structures in S2 of the liver (Figure 1), indicating a intracystic hemorrhage of simple liver cyst or cystadenocarcinoma, but the differential diagnosis was considerably difficult on the US imaging. Levovist (Schering, Berlin, Germany) US revealed no enhancement of the intracystic septations and structures, suggested a clot in case of intracystic hemorrhage. Moreover the enhanced cyst wall was smooth in contour, suggested a simple cyst (Figure 2). Hence, the hemorrhage into a simple cyst including intracystic blood clot was indicated by Levovist US. On plain CT, the intracyst showed heterogeneous low-density, and intracystic septations were not detected. On magnetic resonance imaging (MRI), T1-weighted images revealed the clot as a low-intensity and the fluid as a high-intensity, whereas T2-weighted image shows the clot as low-intensity and the fluid as high-intensity. Although a high-intensity lesion on T1-weighted images is not specific for hemorrhage and can be observed in other conditions (mucinous fluid, melanin component, and fat content), the visualization of a high-intensity lesion on T2-weighted images may suggest

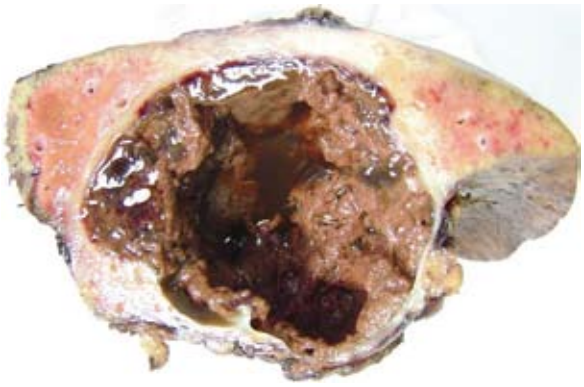

Figure 3 Histological examination showed that the intracystic structures were clots caused by the intracystic hemorrhage.

the diagnosis of intracystic hemorrhage. No contrast agent could be used both in CT and MRI studies, because of the patient's history of asthma. Based on the imaging findings, we diagnosed the case as one of hemorrhage into a simple cyst. Because of the risk of the enlargement and rupture of the cystic lesion, operation was considered to be indicated. Lateral sectionectomy, cholecystectomy, and intraoperative cholangio-graphy (IOC) were performed. Exploratory laparotomy revealed a large cystic lesion which occupied the left lobe of the liver with adhesion of the omentum minor to its wall. IOC revealed no communication between the intrahepatic bile duct and the cystic lesion. The resected lesion showed a solitary benign liver cyst, measuring 5.5 cm × 4.7 cm × 8.5 cm containing a large blood clot (Figure 3). The blood clot in the cyst was apparently visualized as the intracystic structures on the US and MRI and CT. The cystic wall consisted of fibrous tissue with capillary proliferation and hemorrhage, and was lined by one row of cuboidal epithelial cells. The patient had an uneventful recovery and was discharged 17 d after the surgery.

DISCUSSION

Cystic lesions in the liver are currently classified into acquired and congenital cysts, or parasitic and nonparasitic cysts. Acquired cysts include traumatic, inflammatory, and proliferative cysts[3]. Simple cysts or nonparasitic liver cysts are considered to be congenital and most simple cysts encountered in clinical practice are congenital. The etiology of simple cysts is unclear, and they presumably arise from developmental defects during the formation of bile ducts. The lining epithelium of these cysts is identical to that of the biliary tract[4], although an open communication with the biliary system is unusual.

Hepatic simple cysts are predominantly asymptomatic. However, symptoms may be caused by rapid growth or occurrence of complications. The complication rate has been reported to be about 10%, and complications include intracystic hemorrhage, infection, intraperitoneal rupture, torsion, inflammation, and obstructive jaundice, with hemorrhage and infection as the most commonly encountered complications[5].

In our case, the differential diagnosis would have

been even more difficult if a cystadenocarcinoma was complicated by intracystic hemorrhage. One of the characteristic findings of cystadenocarcinoma on sonography has been reported to be highly echogenic internal septations[6].

In many countries, microbubble contrast agents are now available for improved US imaging. Levovist is one of such microbubble agents, consisting of an admixture of galactose granules with a small (0.1%) amount of palmitic acid that produces multiple small (approximately 3 μm) stabilized air bubbles when suspended in water. Levovist produces Doppler enhancement of the blood pool for 2-5 min[7], followed by a late hepatosplenic phase that lasts for more than 30 min[8]. In our patient, the intracystic structures mimicking malignancy that was visualized on US was demonstrated to be an avascular lesion on CEU, suggested a clot of intracystic hemorrhage. In addition, the enhanced cyst wall was shown to have a smooth contour, suggested the diagnosis of a simple cyst. Hence, we diagnosed the hemorrhage into a simple cyst.

The treatment of a simple liver cyst complicated by intracystic hemorrhage can be either surgical or nonsurgical. In recent years, there has been a trend away from surgical treatment, as injection of absolute alcohol into the cyst has been shown to yield better results with fewer complications. However, in our patient, surgery was chosen because the cyst began to grow rapidly in size, with the attendant risk of rupture. Therefore, we could examine the resected tissue specimens which showed that the lesion was an encapsulated unilobular cyst filled with morphologically irregular blood clots. The histological findings in resected tissue specimens in relation to the MR images of intracystic hemorrhage in simple liver cysts has previously been reported by one group[9]. In our reported case, we could compare the histological findings in the resected tissue specimens with the CEU findings. Moreover, some groups have even reported detection of the active bleeding point in such cases by CEU[10,11]. In our case, the active bleeding point was not detected, perhaps because the bleeding had already stopped. However, CEU may be useful for diagnosing active intracystic hemorrhage.

In conclusion, CEU may play an important role in the correct diagnosis of a simple hemorrhagic cyst by demonstrating the avascularity of the visualized intracystic structures. We followed up the patient of a simple liver cyst complicated by intracystic hemorrhage in whom CEU was very useful for diagnosis.

Abstract

Chronic diarrhea is one of the most frequent gastrointestinal manifestations in acquired immunodeficiency syndrome (AIDS). Protozoa and nontuberculous mycobacteria (NTM) are opportunistic pathogens that can easily infect these patients. Among the NTM, *Mycobacterium avium* complex (MAC) is the most frequently observed pathogen in HIV-infected patients. However, NTMs other than MAC have not been reported as a gastrointestinal pathogen as yet. We present a case of chronic diarrhea in an AIDS patient in whom *Mycobacterium ulcerans* and *cryptosporidium* co-infection is evidenced from colonic tissue.

INTRODUCTION

HIV infection, which frequently involves the gastrointestinal tract, may be associated with diarrhea, abdominal pain, esophageal symptoms, malabsorption, and weight loss[1,2]. The gastrointestinal tract is the major target for pathogens in HIV-infected patients and as many as a third of patients with AIDS are initially seen by a gastroenterologist[3]. In those instances, diarrhea is the most frequent manifestation in AIDS and HIV-positive patients. Diarrhea has been reported to be present at the same time during their illness in as many as 80% of North American patients with AIDS, and the prevalence may approach to 100% in developing countries, causing a significant morbidity and mortality[4-6]. Those suffering from chronic diarrhea tend to have a low quality of life and seem to have higher annual health costs. Typical infectious diseases affecting the intestinal tract in HIV-infected patients are caused by protozoa (*Microsporidium, Cryptosporidium*), bacteria (*Clostridium difficile, Salmonella, Shigella, Campylobacter*, and MAC), viruses (Cytomegalovirus, Herpes simplex) and fungi (*Candida species*). Before the HIV epidemic, NTM was an unusual cause of disease in humans. Nowadays, however, NTM especially MAC, is one of the most common causes of intestinal bacterial infection in AIDS patients[2,7]. But non-MAC NTMs, including *Mycobacterium ulcerans*, have not been reported as a pathogen in the gastrointestinal tract.

We report herein a case of colonic infection with an unusual NTM, *Mycobacterium ulcerans*, which caused chronic diarrhea in a patient with AIDS.

CASE REPORT

A 40-year-old man complained of persistent diarrhea associated with a 9 kg weight loss during the last 3 mo. He described his diarrhea as watery stools that occurred five to six times per day, especially at night. There was no previous history of travel, food, medication, or any medical or familial disease. He denied melena or hematochezia. On physical examination, the patient had a chronic ill-looking appearance but there were no remarkable findings except for a slightly dehydrated tongue. His blood pressure was 110/70 mmHg, pulse was 70 beats per minute, respiratory rate was 20 breaths per minute, and temperature was 36.2℃. His height was 167 cm and weight was 54 kg. The abdomen was soft and nontender

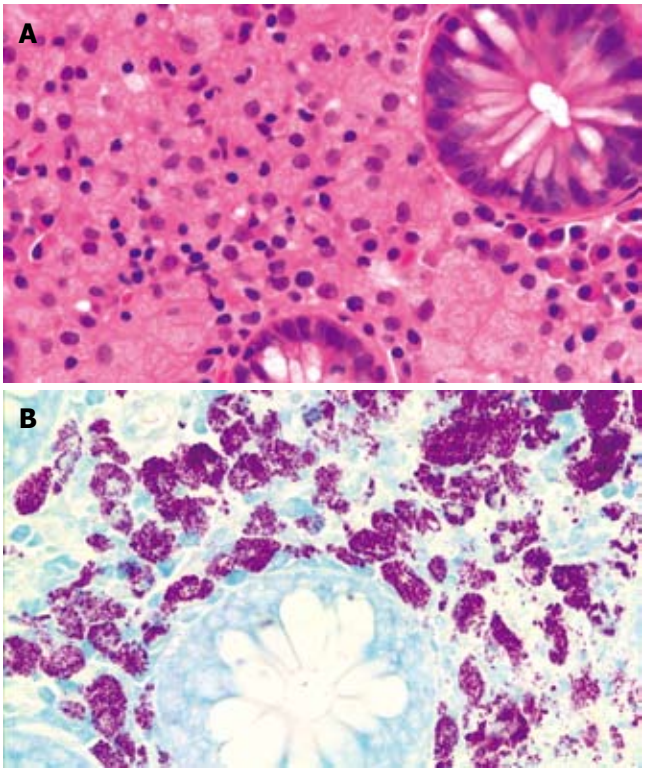

Figure 1 Pathologic examination of biopsy specimen from sigmoid colon revealing foamy histiocytic collections in lamina propria by hematoxylin and eosion stain (**A** × 400) and innumerable acid-fast bacilli collections by Ziehl-Neelsen stain (**B** × 400).

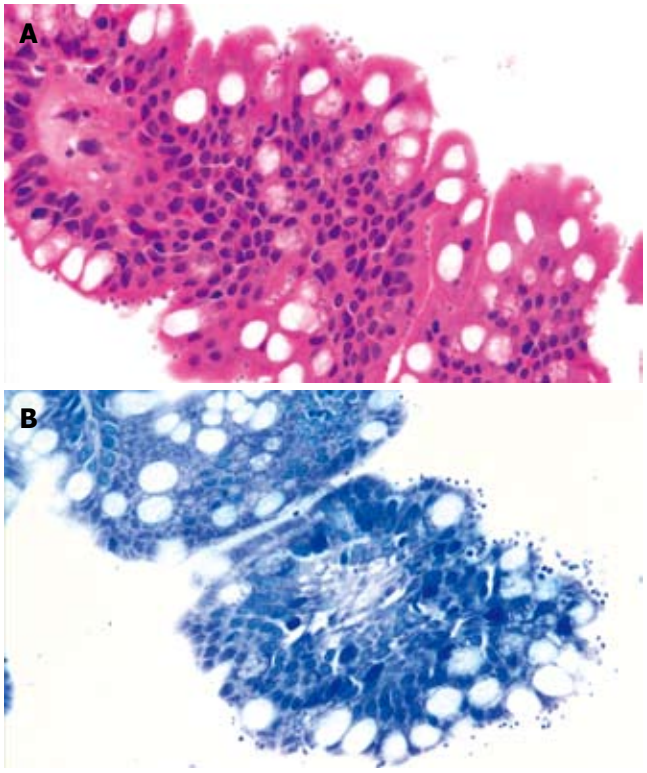

Figure 2 Pathologic examination of biopsy specimen from terminal ileum showing many tiny organisms of the *Cryptosporidium* species with mild chronic inflammation on the surface of the luminal border of the crypt epithelial cells by hematoxylin and eosion stain (**A** × 400) and Giemsa stain (**B** × 400).

without hepatosplenomegaly. The bowel sound was slightly increased. Rectal examination revealed no palpable masses or blood clots. The hemoglobin level was 14.4 g/dL, white blood cell count was 4200/mm^3, and platelet count was 159 000/mm^3. The serum electrolyte levels, urinalysis, and tests of renal, liver, and thyroid function were normal. The C-reactive protein level was 0.1 mg/dL. Stool examinations for ova, parasites, bacterial pathogens, and *Clostridium difficile* toxin were negative. Colonoscopy showed normal findings but a blind mucosal biopsy was done at the terminal ileum and sigmoid colon to evaluate the chronic diarrhea. Also, anti-HIV antibody was checked to rule out AIDS, which is an important cause of chronic diarrhea. The result of anti-HIV antibody was positive. CD4 T cell count was 168/mm^3. We asked the patient about his medical history again and he admitted to an HIV positive history to us. He was diagnosed with AIDS at another hospital in 2002 and treated with highly active antiretroviral therapy (HAART). However, he voluntarily discontinued his treatment in 2004. The biopsy specimen from the sigmoid colon demonstrated foamy histiocytic collections in lamina propria by hematoxylin and eosin stain and revealed innumerable acid-fast bacilli collections by Ziehl-Neelsen stain (Figure 1). The possibility of NTM on colonic biopsy would have to be considered instead of *Mycobacterium tuberculosis* because of innumerable acid-fast bacilli collections. The biopsy specimen from the terminal ileum demonstrated mild chronic inflammation with protozoa infection consistent with cryptosporidiosis (Figure 2). To further evaluate the small bowel, a capsule endoscopy was performed. The whole small bowel showed mild edematous and hyperemic mucosal change (Figure 3).

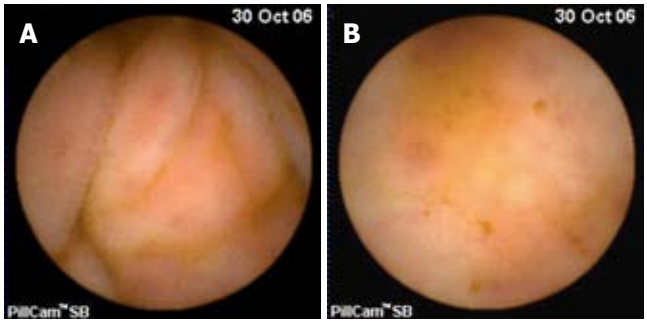

Figure 3 Capsule endoscopic findings of small bowel showing mild edematous (**A**) and hyperemic (**B**) mucosal change.

PCR-restriction fragment length polymorphism analysis (PRA)

To identify the species of NTM, we used PCR-restriction fragment length polymorphism of the rpoB gene. PRA offers an easy, rapid, and inexpensive way to identify *Mycobacterium* species in a single experiment. Recently, Lee *et al*[8] chose the rpoB gene as a target and the restriction analysis of a 360-bp fragment within the rpoB gene after single Msp I digestion showed that it was highly effective for differentiating most *Mycobacterium*. They suggested that PRA using the novel region of the rpoB gene is more simple, rapid, and accurate versus other

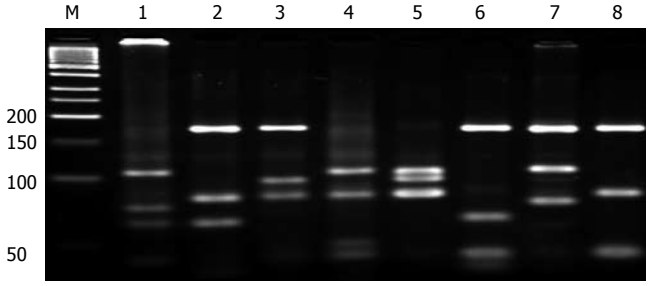

Figure 4 Identification of the species of NTM by PCR-restriction fragment length polymorphism of the rpoB gene. Lane: M, DNA size marker; lane1, M. ulcerans; lane 2, *M. tuberculosis*; lane 3, *M. intracellulare*; lane 4, *M. avium*; lane 5, *M. abscessus*; lame 6, *M. kansasii*; lane 7, *M. fortuitum*; lane 8, *M. gordonae*.

conventional methods such as chromatography or DNA sequence analysis. Briefly, we got the genomic DNA from paraffin-embedded colonic specimen. PCR was carried out with 10 ng genomic DNA, 10 pmol of each primer, 5'-TCAAGGAGAAGCGCTACGA-3' (RPO5') and 5'-GGATGTTGATCAGGGTCTGC-3' (RPO3') and DyNAzyme Ⅱ DNA polymerase (FINNZYMESY, Espoo, Finland) resulted in a 360-bp PCR product. After successful amplification, the PCR products were subjected to restriction enzyme digestion with 5U of Msp I (Boehringer Mannheim Biochemicals, Mannheim, Germany). For interpreting the PRA profile generated by each species, a 50-bp ladder DNA size marker (Boehringer Mannheim) was used. From the PRA, we discovered that the NTM species was *Mycobacterium ulcerans* (Figure 4).

The patient was diagnosed with *Mycobacterium ulcerans* and *cryptosporidium* co-infection. He was treated with clarithromycin and ethambutol to target the NTM and with HAART for underlying AIDS. After three months of treatment for NTM, the patient said that his diarrhea was much improved.

DISCUSSION

Since the discovery of AIDS in 1981, HIV infection has spread quickly and become a very serious health problem for humans, not only in Western world, but also in Asian area. Since the first case of HIV infection was reported in Korea at 1985, the number of those infected with HIV has steadily increased. Despite the introduction of HAART, diarrhea remains a common disease manifestation related to HIV infection and is a diagnostic problem. The incidence of chronic diarrhea in AIDS patients does not change after HAART[9]. In other words, the incidence of opportunistic infections is still too high to ignore them. Opportunistic infections are responsible for 68%-85% of diarrhea in HIV-infected patients[7,10].

Initially, we did not know the exact medical history of the patient. However, HIV-related diarrhea must be included in evaluating chronic diarrhea, especially when it is associated with weight loss. Therefore, we performed a routine serologic test for HIV infection. Patients with chronic diarrhea in HIV-infected persons often cause a difficult diagnostic problem. There are proved pathogens or causes of drugs including protease inhibitors, but no causes of diarrhea are commonly encountered. The usefulness of endoscope in evaluating diarrhea in HIV-infected patients has been well investigated[11-13]. Because of the common involvement of the small bowel, colonoscopy is preferred to flexible sigmoidoscopy in HIV-infected patients with chronic, unexplained diarrhea[13]. Although colonoscopy is frequently performed in these patients, the usefulness of biopsy of normal mucosa is uncertain. Shah *et al*[14] suggested that colonoscopy with biopsy is a useful tool in the investigation of patients with chronic diarrhea, which yields a histological diagnosis in 31% of patients. In our case, we performed a blind biopsy from normal mucosa, because the serology for HIV was positive, and we thought that the histological evaluation would give us good information for the proper diagnosis. With the histological diagnosis, we had a clue as to how to properly treat the patient. This is in accordance with the suggestion of Shah *et al*[14] that colonoscopy with biopsy is a useful tool in the investigation of patients with chronic diarrhea, not only from the abnormal mucosal lesion but also from the normal one.

NTMs are ubiquitous organisms that are different from tuberculosis and represented by more than 65 different species[15]. The most frequent forms of NTM include *Mycobacterium avium* complex (MAC, 61%), *Mycobacterium fortuitum* (19%) and *Mycobacterium kansasii* (10%), with smaller percentages of *Mycobacterium gordonae* and *Mycobacterium chelonae*[15,16]. Mycobacterial involvement of the bowel either by tuberculosis or MAC may lead to diarrhea. Antony *et al*[17] reported that MAC is the most commonly identified organism in patients with chronic diarrhea and low CD4 lymphocyte counts. Although tuberculosis appears to be symptomatic in all cases, a large number of patients with MAC have an asymptomatic infection of the gut. Endoscopic findings of MAC infection may be nonspecific. Sun *et al*[18] reviewed 55 reported cases of MAC infection with an endoscopic description which involved the gastrointestinal tract in AIDS patients, and found that the most common endoscopic finding is multiple raised nodules (38%) in the involved sites. The other endoscopic findings of MAC infection include normal findings (36%), erythemas (13%), ulcerations (11%), edemas (11%), friabilities (11%), reduced mucosal vascular patterns (9%), erosions (4%), confluent nodules (4%), strictures (2%), and aphthous erosions (2%). Therefore, for a definitive diagnosis in symptomatic patients, especially those without typical endoscopic findings, it is essential to obtain tissue specimens for histopathologic examination and microbiologic culture. Isolates of *Mycobacterium* from tissue biopsies or blood are almost always indicative of the disease[19]. The organism is readily seen on biopsy specimens with acid-fast staining, and the number of organisms is often striking. Rarely, a NTM other than a MAC has been isolated upon a colonic biopsy in a HIV patient[19]. In our case, a very rare NTM, *Mycobacterium ulcerans*, was isolated in colonic mucosa, and it is presumed to be the cause for the patient's chronic diarrhea. Many clinical syndromes are similar to those seen with MAC and only can be differentiated by identification of the organism, like PRA or DNA sequence analysis[20].

Mycobacterium ulcerans is known to cause skin diseases, such as Buruli ulcer, an important health problem in

several West African countries. Although the disease is known to be associated with contaminated water, the mode of transmission has not yet been understood[21,22]. *Mycobacterium ulcerans* produces the toxin mycolactone, which induces necrosis and ulceration by its own cytotoxic and immunosuppressive properties. HIV infection has not been reported as a risk factor for Buruli ulcer[23]. However, severe clinical forms of the disease have been described in HIV-positive patients[24]. To our knowledge, this is the first case of colonic infection with *Mycobacterium ulcerans*, which caused chronic diarrhea in a patient with AIDS.

In conclusion, *Mycobacterium ulcerans* and *crypto-sporidium* co-infection is the cause of chronic diarrhea in AIDS patients. Serologic test of HIV must be performed when evaluating chronic diarrhea, especially when it is associated with significant weight loss. We think that colonoscopy with routine biopsy is a useful tool for accurate diagnosis of chronic diarrhea.

Abstract

Tuberous sclerosis complex (TSC) is a dominantly inherited disorder which characterized by the growth of hamartomatous in multiple organs. Unlike the common development of renal angiomyolipoma, hepatic angiomyolipoma rarely occur in patients with TSC. We report here a patient with hepatic angiomyolipomas and concurrent hepatocellular carcinoma in TSC. This represents the first reported case in English literature. In this patient, multiple hepatic angiomyolipomas were diagnosed with recognition of their fat components and typical clinical settings. Hepatocellular carcinoma in the left liver lobe was definitely diagnosed by US guided biopsy. In such clinical settings, fat containing lesions in liver can be reasonably treated as angiomyolipomas, but non fat containing lesions must be differentiated from hepatocellular carcinoma, imaging guided biopsy can be adopted to confirm the diagnosis.

INTRODUCTION

Tuberous sclerosis complex (TSC) is a dominantly inherited disorder with a prevalence of 1/6000 to 1/9000 in general population[1,2]. In patients with TSC, the incidence of renal angiomyolipoma has been reported in up to 80%, but hepatic angiomyolipoma has been less reported[3,4]. We recently encountered a patient with pathologic proved coincident hepatocellular carcinoma and hepatic angiomyolipomas in TSC. To our knowledge, there is no reported case of hepatic angiomyolipomas with concomitant hepatocellular carcinoma in TSC in English literature. We present here the imaging findings of this case, and discuss the diagnosis and it's practical significance.

CASE REPORT

A 51 years old woman was admitted in our hospital because of intrahepatic nodules found incidentally by abdominal ultrasonography (US) on general health examination. Her past medical history showed a right nephrectomy for renal angiomyolipomas 16 years prior to this admission. Physical examination revealed multiple miliary russet papilla on her face and several periungual fibroma. A palpable mass was touched with mild knock pain in the left flank. Laboratory analysis showed normal liver function, hepatitis B surface antigen (HBsAg) was positive. Concentration of serum alpha fetoprotein (αFP) was 7694 μg/mL (normal, < 20 μg/mL). Urine routine test and renal function were normal.

Abdominal US revealed multiple well-circumscribed nodules of various size with homogeneous hyperechoic nodules in the liver, and a hypoechoic nodule in the left liver lobe was noted. Plain helical CT scan showed multiple round well-defined nodules with variable fatty density in the liver (Figure 1A). After administration of intravenous contrast material, the non-fat components of these lesions were enhanced heterogeneously (Figure 1B). Apart from those fat containing lesions, the precontrast CT scan demonstrated a poor defined hypodensity mass with no fat component situated in the left liver lobe (Figure 1C). On dynamic contrast enhanced CT, it presented as nearly homogeneous isodensity in the arterial phase, hypodensity with dotted vessel in the portal venous phase in comparison with the surrounding liver (Figure 1D and E). On coronal reconstruction images, it was adjacent to the left portal vein. Left giant renal heterogeneous mass with fatty density and hemorrhage was found meanwhile (Figure 1F).

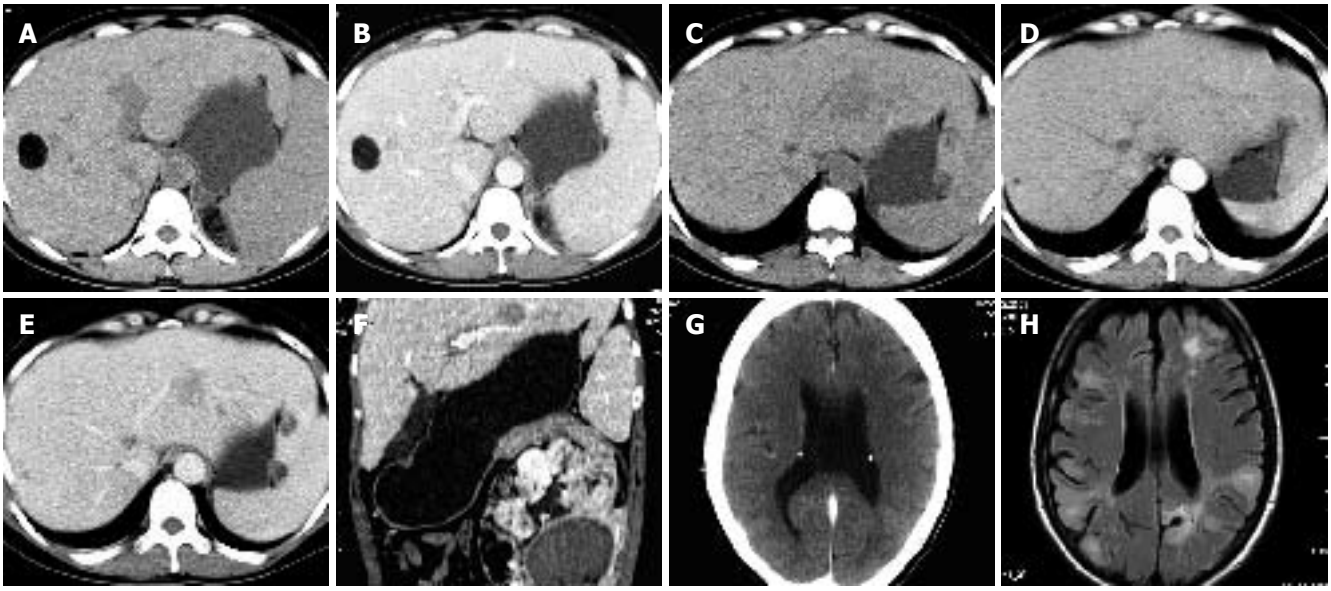

Figure 1 Photocopy detect of the patient. **A**: Plain helical CT scan demonstrats a round well defined nodule with fat component in the liver; **B**: Enhanced CT scan shows that the non-fat component of the lesion is mildly enhanced; **C**: Plain CT scan shows an entire solid mass with no fat component in the left liver lobe and multiple distributed nodules with variable fat components in the liver; **D**: Enhanced CT shows the solid mass with no fat component in the left liver lobe as nearly homogeneous isodensity in the arterial phase; **E**: Enhanced CT scan shows the solid mass in the left liver lobe as hypodensity with dotted vessel in the portal venous phase; **F**: Coronal reconstruction images shows that the mass is adjacent to the left portal vein, and a left giant renal heterogeneous mass with fatty density and hemorrhage is noted; **G**: Cerebral CT scan demonstrats symmetrical subependymal calcified tuber; **H**: FLAIR MR imaging shows multiple cortical tubers with high signal intensity in the bilateral hemisphere, linear and irregular spherical high signal areas from periventricular to subcortical regions in the left occipital and frontal lobes.

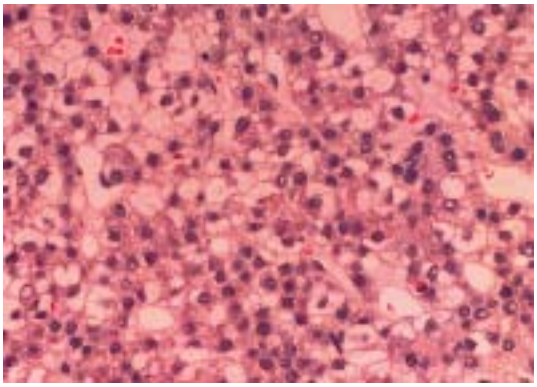

Figure 2 High-power photomicrograph shows tumor cells with eosinophilic cytoplasm arranged in solid pattern and inconspicuous sinusoid-like or slit-like blood vessels (HE, original magnification × 100).

Based on the abdominal imaging findings and the history of right nephrectomy for renal angiomyolipoma, TSC with multiple organs involved was suggested. Then cerebral CT scan was applied immediately after enhanced abdominal CT scan. Cerebral CT scan demonstrated symmetrical subependymal calcified tuber (Figure 1G). MRI showed multiple cortical tubers with high signal intensity in the bilateral hemisphere, linear and irregular spherical high signal areas from periventricular to subcortical regions in the left occipital and frontal lobes on T2WI and FLAIR sequence (Figure 1H). According to the typical clinical information and imaging findings, TSC with multiple organs involved, multiple angiomyolipomas in liver and left kidney was first considered. But the possibility of concurrent hepatocellular carcinoma can't be excluded in this patient because of the remarkable increasing concentration of serum alpha fetoprotein (7694 μg/mL).

Ultrasound-guided biopsy of the mass with no fat component in the left liver lobe with 18-gauge needle was performed. Histopathological examination of the specimen showed heptocellular carcinoma. Neoplastic cells with eosinophilic cytoplasm were arranged in solid pattern, and inconspicuous sinusoid-like or slit-like blood vessels were noted (Figure 2). Immunohistochemical study showed AFP+, CD34+, HbsAg and HMB45 were negative.

The patient refused to undergo liver resection; ultrasound-guided radiofrequency ablation was performed. CT scan showed complete ablation of the heptocellular carcinoma, and she was uneventful during one year follow up.

DISCUSSION

TSC is an autosomal dominant disorder involving multiple organs[1,2]. The mutation of two tumor suppressor genes (TSC1 and TSC2) could account for the pathogenesis of hamartomatous in tuberous sclerosis[5]. In recent literature, hepatic angiomyolipoma has been reported in up to 13%-21% of patients with TSC, especially in female patients with bilateral diffuse renal angiomyolipomas[6]. However, coexistence of hepatocellular carcinoma and hepatic angiomyolipoma is extremely rare [7]. To our knowledge, no report of coincident hepatocellular carcinoma and hepatic angiomyolipomas in TSC exist in English literature.

Angiomyolipoma is a rare benign, non-encapsulated mesenchymal tumor consisting of vessels, smooth muscle and adipose tissue[3]. Hepatic angiomyolipoma is

often asymptomatic and found incidentally on imaging studies[6]. In the setting of tuberous sclerosis, hepatic angimyolipomas are often accompanied by bilateral renal angiomyolipomas. Imaging studies play a key role in the diagnosis of hepatic angimyolipoma. On ultrasonography, hepatic angiomyolipomas often presented as multiple well defined, round hyperechoic nodules. Plain CT scan showed them as multiple hypodensity nodules with variable amounts of fatty density. After administration of intravenous contrast material, the non-fat components of these lesions were enhanced heterogeneously. The imaging findings of hepatic angiomyolipoma are similar to those of renal angiomyolipoma. The diagnosis of hepatic angiomyolipoma is often made on recognition of its fat component[6-9].

However, nearly 50% hepatic angiomyolipomas may present as solid mass with least or no fat-component[10]. Plain CT scan usually shows it as well circumscribed, hypodensity nodules. On dynamic contrast CT, it is often heterogeneous hyperdense in the arterial phase, hypodense with prominent central vessel in the portal venous phase. The enhancement pattern of hepatic angiomyolipoma is similar to that of hepatocellular carcinoma, so it's difficult to be differentiated from hepatocellular carcinoma[9-11]. However, no case of concurrent hepatocellular carcinoma and hepatic angiomyolipoma in TSC has been previously reported in the literature. It has even been reported that non-fatty hepatic lesions in TSC can be regarded as hepatic angimyolipomas[6,11]. In our patient, the imaging findings of multiple hepatic angiomyolpomas with fat component were in accordance with previously reported. The diagnosis of TSC with multiple organs involved was definitely based on the revised clinical diagnostic criteria[1]. But hepatocellular carcinoma can not be excluded in this patient, because the solid mass in the left liver lobe was presented as poor defined and hypovascular, and no fatty density can be found in it on the dynamic contrast enhanced CT. The imaging findings of the solid mass were not in accordance with those of hepatic angiomyolipomas without fat components. In addition, the markedly increasing concentration of serum alpha-fetoprotein strongly suggested the existence of hepatocellular carcinoma. This was confirmed with ultrasound guided biopsy of the solid mass with no fat component in the left liver lobe. Our case suggests that non-fatty hepatic lesions in TSC can't be regarded as angiomyolipomas arbitrarily, they must be differentiated from hepatocellular carcinoma, because the natural history of hepatic angiomyolipoma is benign, and it needn't surgery, except for suffer of complications[12], but hepatocellular carcinoma should be removed surgically.

In conclusion, awareness of coincident hepatocellular carcinoma and hepatic angiomyolipomas in TSC is important. When intrahepatic mass with no fat component be found in such clinical setting, the possibility of concomitant hepatocellular carcinoma and hepatic angiomyolipoma should be considered. Imaging studies and laboratory tests can help in the differentiated diagnosis. Imaging guided biopsy can be adopted to confirm the diagnosis.

Abstract

It is one of the most important problems for general surgeons to decide which operation should be undertaken on patients with intra-abdominal infection, especially those with concomitant abdominal hypertension. Recentlly, closure techniques using prosthetic meshes in order to retain abdominal tension and to control sepsis have become very popular for patients with abdominal sepsis and hypertension. We used chorioamniotic membrane instead of plastic material to cover the open abdomen. We conclude that human chorioamniotic membrane prepared under sterile conditions may be an alternative to conventional plastic bags in daily practice, for preventing serosal erosion and fistulas in patients undergoing open abdominal surgery.

TO THE EDITOR

There are some important indications for open abdominal surgery, such as abdominal compartment syndrome, damage control surgery, severe peritonitis and infected pancreatic necrosis. A Bogota bag, which is sutured to the abdominal wall or to the fascia, is used to cover the open abdomen. It needs to be changed frequently until the underlying problem in the abdomen is solved. If there is no need of early abdominal closure, a skin graft is placed over the granulation tissue that covers the viscus. After that, the deliberately created ventral hernia is repaired 6-12 mo later. The above situation has been changed considerably with the introduction of vacuum application and biological prosthetic material[1-5]. Until recently, the practice was to discharge patients with an open fascia and partially closed skin.

An open abdomen is a heavy burden for the body. Electrolyte-fluid losses and protein-energy requirements are high in the open abdomen. The need for intensive care also increases costs, and the condition becomes more serious if there are coexisting fistulae or an open stoma in the gut.

We consider the use of chorioamniotic membrane as a biological material when vacuum application is not possible or plastic cover might be harmful. To the best of our knowledge, this is the first instance in which chorioamniotic membrane has been used for this purpose.

The chorioamniotic membrane was obtained from elective cesarean section, after patient consent was obtained. The membrane was prepared under sterile conditions by removing the cotyledons from the placenta (Figure 1). The membrane was then kept in 1 L normal saline containing 1 g streptomycin and 1 MU penicillin at 4℃ for 24 h. After each irrigation of the abdomen, chorioamniotic membrane was applied as a cover, with maternal surface facing the viscera (Figure 2). This procedure was repeated every 2 d. Immediately following the second application, it was clearly observed that serosal erosion showed signs of healing and the adhesions between the loops became clearer. The application decreased edema of the gut and abdominal wall, and the bowel was attached to the abdominal wall (Figure 3). Patients were discharged for definitive treatment planned after 6 mo. There were no problems in early follow-up. Six months postoperatively, ventral hernias were successfully repaired using omental or online mesh hernioplasty.

Open abdomen is a life saving procedure when indicated. Its mortality and morbidity increase when combined with that of the primary underlying illness[5]. Currently, patients with open abdomen are discharged with a ventral hernia, which is covered with a graft that needs further repair.

It is reported that by using vacuum methods, fascial defects are reduced sufficiently to be closed[1-4]. It is also

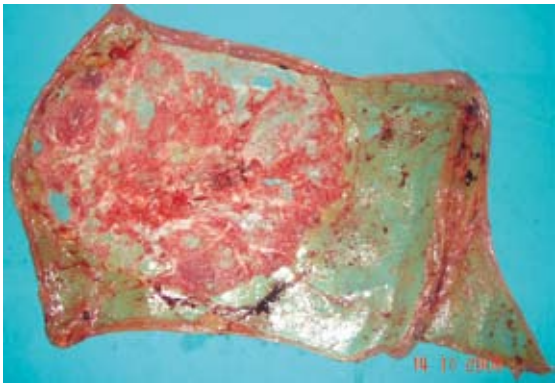

Figure 1 Preparation of chorioamniotic membrane from the placenta by removing the cotyledons under sterile conditions.

Figure 2 Suture of human chorioamniotic membrane to abdominal skin.

Figure 3 Appearance of the abdomen after membrane application.

reported that in cases where closure is inadequate, by using acellular dermis, patients can be sent home without a fascial defect[5]. However, there is no long-term follow-up of wide series on outcomes with this biological material.

In our patients, human chorioamniotic membrane obtained from elective cesarean sections was used instead of the plastic Bogota bag. It is a natural biological material, therefore, it is a more appropriate cover for erosion of the intestinal serosa. Moreover, chorioamniotic membrane accelerated adhesions among the loops and helped to stabilize the abdomen.

There are different indications for the use of placental amniotic membrane. It is used successfully to cover tendon defects, to prevent adhesions[6]. The membrane is also used for eye and skin diseases[7]. Previously, in order to prevent fistula of damaged bowel segments, fibrin glue, together with acellular dermal matrix, was used for covering the open abdomen. We have used human chorioamniotic membrane for the same purpose[8,9].

We use the chorioamniotic membrane because the amniotic membrane is very thin. The maternal surface is placed over the viscera. Another possibility is to place the membrane between the viscus and the peritoneum. Similar outcomes may be expected with this method and vacuum techniques. In the latter, the deepest part of the vacuum system which is plastic cover is placed between the peritoneum and the viscus to prevent the parietal peritoneum from adhering to the visceral peritoneum. In our method, because the fetal surface is not sticky and smooth, it might prevent the viscus from adhering to the peritoneum. In the present case, because it was impossible to keep the viscus in the abdomen, we deliberately aimed for adhesion between the parietal and visceral peritoneum.

We conclude that human chorioamniotic membrane prepared under sterile conditions may be an alternative to conventional plastics bags in daily practice, for preventing serosal erosion and fistulas in patients with an open abdomen. The biological membrane is cheap, practical and is well suiting over viscera. It is sutured easily and does not make plies like the plastic material in use.

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327/ CN 14-1219/R) is a weekly journal of with a circulation of more than 15707, published on the 7th, 14th, 21st and 28th of every month. *WJG* is a peer-reviewed journal. The number of overseas users with an independent IP address was 15600, representing 123 countries worldwide. Original research, reviews, comments, and case reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted elsewhere simultaneously.

Publication model

WJG is a journal with a so-called public beneficial publication model, which consists of an Open Access and the commercialized publication model (i.e. payment by the third party). This publication model has been proven very effective and produced fruitful outcome. By 21st December 2007, the number of visit hits to the *WJG* website has reached 21350084. *WJG* advocates the tenet that the research funding granted to scientists be used to serve scientists, by which high quality scientific articles can be published.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from the organization in which the author(s) works should be provided with the contributed article to warrant not give away any secret and if the contributed article is completed in cooperation by authors from different organizations, a letter of recommendation from each of the organizations should be provided to ensure not given away any secret.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained in the mailing process.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381901-600. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. font with ample margins. The preferred font is Book Antiqua. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, author contributions; disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analysed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend. Otherwise, article is rejected. Reviewers are acknowledged in the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou Univerisity, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, that reflect the content of the study.

Text
For articles of these sections, original articles, rapid communicatin and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. As require, figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. The examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is nessesary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to make out the high resolution-figures of E-version or the printed one.

Tables
Three-line tables should be numbered 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate that already contained in the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "Fom references [19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement
PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement
DOI roots in the serial number indexed by CrossRef (http://www.crossref.org/guestquery/). DOIs are required for journal articles, conference papers and book titles but are optional for journal titles, volumes and issues and book chapters/entries and components. CrossRef is currently working on expanding the types of content it registers DOIs for to include theses and dissertations and database records. The author should supply the DOI for journal citation.

The accuracy of the information of the journal citations is very important. We will interlink all references with DOI in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter and responses, to reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a CAF from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After the manuscript goes online, links to PDF edition of submitted manuscript, peer-reviewers' report and revised manuscript will be created. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors could benefit from the feedbacks and revise the manuscript according to the comments in real time.

Science news releases

Authors of accepted manuscripts are suggested to write science news to their articles as both following guidelines and samples, and the news will be released soon at EurekAlert/AAAS --http://www.eurekalert.org. The title for news is less than 90 characters. The summary for news is less than 75 words, and main body less than 500 words. The science news should be lawful, ethical, and tightly based on your original contents with attractive title and amusing pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

The incidence of obesity is steadily rising, and it has been estimated that 40% of the US population will be obese by the year 2025 if the current trend continues. In recent years there has been renewed interest in the surgical treatment of morbid obesity in concomitance with the epidemic of obesity. Bariatric surgery proved effective in providing weight loss of large magnitude, correction of comorbidities and excellent short-term and long-term outcomes, decreasing overall mortality and providing a marked survival advantage. The Laparoscopic Sleeve Gastrectomy (LSG) has increased in popularity and is currently very "trendy" among laparoscopic surgeons involved in bariatric surgery. As LSG proved to be effective in achieving considerable weight loss in the short-term, it has been proposed by some as a sole bariatric procedure. This editorial focuses on the particular advantages of LSG in the treatment of morbid obesity.

INTRODUCTION

The incidence of obesity is steadily rising, and it has been estimated that 40% of the US population will be obese by the year 2025 if the current trend continues[1]. An alarming indicator of the health crisis related to the epidemic of obesity is that 15% of children and adolescents are obese (body mass index BMI > 95th percentile on the Centers for Disease Controls and Prevention standard charts), and over 20% are at risk (BMI > 85 percentile)[2]. In recent years there has been renewed interest in the surgical treatment of morbid obesity in concomitance with the epidemic of obesity, and application of the laparoscopic techniques to the field of bariatric surgery as well. Bariatric surgery proved effective in providing weight loss of large magnitude, correction of comorbidities and excellent short-term and long-term outcomes[3-5], decreasing overall mortality and providing a marked survival advantage[6,7]. The number of laparoscopic Roux-en-Y Gastric ByPass (LRYGBP) procedures have continued to increase in the last few years. This has contributed to the profound enthusiasm of the surgical community for bariatric surgery. In this context, new bariatric procedures can be rapidly accepted by the surgical community, as has already happened in the case of laparoscopic adjustable gastric banding (LAGB). The latter is a paradigm of the "surgical enthusiasm" for a bariatric procedure. LAGB has rapidly reached wide diffusion, giving the label of bariatric surgeon to any laparoscopic surgeon able to place a band around the stomach of an obese patient. However, with time this procedure proved not to be the panacea that one would have thought it to be after its introduction. Due to a high rate of long-term failure, the literature indicates fewer LAGB procedures and more Roux-en-Y gastric bypass (RYGBP) procedures are being performed, and surgeons are choosing laparoscopic RYGBP[8-10] The Laparoscopic Sleeve Gastrectomy (LSG) is being performed more frequently and is currently very "trendy" among laparoscopic surgeons involved in bariatric surgery. LSG is not a new operation as it is the restrictive part of a more complex malabsorpitive bariatric procedure; i.e., the biliopancreatic diversion with duodenal switch (BPD-DS)[11,12]. Gagner and coworkers adapted the BDP-DS to the laparoscopic approach[13], and then introduced the concept of the staged approach to very obese patients

with the LSG being the first step[14]. As LSG proved to be effective in the short-term in achieving considerable weight loss, it has been proposed by some to be used solely as a bariatric procedure.

SURGICAL TECHNIQUE

LSG involves a longitudinal resection of the stomach on the greater curvature from the antrum starting opposite of the nerve of Latarjet up to the angle of His. The first step of the procedure is the division of the vascular supply of the greater curvature of the stomach, which is achieved with the section of the gastro-colic and gastro-splenic ligaments close to the stomach. The greater curvature must be completely freed up to the left crus of the diaphragm to completely resect the gastric fundus that harbours the ghrelin secreting cells of the stomach. The second step of the procedure is the longitudinal gastrectomy that "sleeves" the stomach to reduce it to a narrow tube. A naso-gastric tube is used to obtain a precise calibration and to avoid stenosis of the gastric plasty. There is no consensus as to where to start the gastrectomy, and which calibre of the naso-gastric tube to use. Gagner recommended starting the gastrectomy 10 cm proximal to the pylorus[14]. Baltazar recommended starting 4 cm from the pylorus in the case of DS, and only 2 cm from it if the LSG is intended as the sole bariatric procedure[15]. Different calibres of naso-gastric tubes have been reported by different authors from 32 Fr[15] to 60 Fr[14] The rational for starting closer to the pylorus and using a small calibre bougie to fashion the gastric tube is to increase the restrictive character of the procedure. The final volume of the gastric tube has been reported to be as small as 60 mL[15] and as large as 200 mL[13,14]. The staple line can then be reinforced with sutures or Seamguard to reduce the rate of staple line leak or bleeding[16] (Figure 1).

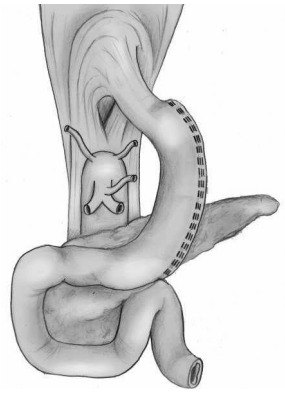

Figure 1 Laparoscopic sleeve gastrectomy.

PHYSIOLOGY OF LSG

One of the mechanisms involved in weight loss observed after the LSG is the dramatic reduction of the capacity of the stomach. The concept of restriction has been widely used in bariatric surgery in vertical banded gastroplasty (VBG) and LAGB. The distension of the small gastric pouch in the LAGB procedure or VBG is supposed to account for the feeling of early fullness, enhanced satiety and decreased hunger experienced by a patient after the ingestion of small quantities of food. The fact that the use of small calibre nasal-gastric tubes, as small as 30 Fr for LSG as proposed by Baltazar, provides faster and increased weight loss is in favour of the role of mechanical restriction as an important determinant in terms of weight loss that can be obtained with LSG[15].

The hormonal modifications induced by LSG differ from those found after a purely restrictive procedure as LASGB. Ghrelin, a peptide hormone mainly produced in the fundus of the stomach, is supposed to be involved in the mechanisms regulating hunger and has been a focus of interest in a growing number of recently published papers[17]. Ghrelin is secreted by the endocrine cells of the stomach (X/A-like cells), which reside in the oxyntic glands of the gastric fundus[18-20]. Gastric ghrelin producing cells are in contact with the basolateral membrane adjacent to the blood-stream and most of them do not come in contact with gastric content[18-21]. The gastric fundus contains 10 to 20 times more ghrelin per 1 × *g* of tissue than the duodenum[18-22] with diminishing concentrations being found in the jejunum and ileum[18,19,23]. Ghrelin has been also found in different additional tissues in very low concentrations such as the lungs, kidney, pancreatic islets, gonads, adrenal cortex, placenta and others[24]. Ghrelin regulates the secretion of growth hormone release and is a potent orexigenic (appetite-stimulating) peptide. This last effect of ghrelin is mediated by the activation of ghrelin receptors in the hypothalamus/pituitary area[25].

There is some evidence that body weight is the major determinant in the long-term regulation of the plasma concentration of ghrelin[26,27]. Accordingly, it has been shown that plasma concentration of ghrelin is increased in the case of negative energy balance situations such as low-calorie diets[26,28], chronic exercise[28,29], cancer anorexia[28], and anorexia nervosa[29], and are decreased in positive balance situations such as weight regain after overfeeding, or during the weight recovery phase of anorexia nervosa[30] or in obese patients[31]. However as no putative mechanisms have been elucidated so far to explicate the changes in the plasma levels of ghrelin in the long term, further studies are necessary to define this issue.

On the other hand, plasma concentration of ghrelin is acutely regulated by the intake of food with a meal to meal variation[31,32]. Plasma ghrelin concentration rises just before the onset of meal and declines thereafter suggesting that ghrelin could play a role in the signal of meal initiation[18,23,33,34], acting as the counterpart of the several meal-related satiation factors such as cholecystokinin, peptide -YY, glucagons-like peptide 1. Although the mechanisms responsible for the postprandial suppression of ghrelin are not known there is evidence that neither gastric nutrients nor gastric distension affect the plasma level of ghrelin[35]. Different studies investigated the plasma levels of ghrelin after different bariatric procedures, such as LASGB, LRYGBP and BPD[17]. Unfortunately, the results of these studies are difficult to compare because the patients studied were in different states of energy balance, the techniques of sampling were different, and either the fasting or postprandial ghrelin levels were reported[17]. Nevertheless, there is overall evidence that LASGB is

associated with significantly increased total plasma levels of ghrelin as opposed to LRYGBP, which is followed by a decrease of ghrelin[36-41].

As LASGB preserves the whole stomach, the gastric fundus, which is the major ghrelin producing tissue, is not excluded form contact with food. Ghrelin levels are increased with diet induced weight loss. Interestingly RYGBP has been shown to be associated with low levels of circulating ghrelin that persist at 1 and 3 years follow-up[42,43]. On the contrary, LASGB, VBG[44], and antireflux surgical procedures[37,45-48] are not associated with a decline of the circulating levels of ghrelin[42]. The most important difference between these procedures and LRYGBP is the contact of food with the gastric fundus of the stomach. The mechanism hypothesized to explain why ghrelin is down-regulated after LRYGBP is the override stimulation theory as described by Cummings. The empty stomach that is acutely associated with increased levels of circulating ghrelin would result in a continuous stimulatory signal that ultimately suppresses ghrelin production[23-26]. However, whether weight loss after LRYGBP is directly related to the changes in plasma levels of ghrelin is still a matter of debate[49].

Holdstock *et al*[50] found increased levels of ghrelin 12 mo after GBP and argued that weight loss is not directly related to plasma concentration of ghrelin. Faraj *et al*[51] proposed that the plasma levels of ghrelin are related to the state of energy balance. During the period of weight loss after GBP, ghrelin is secreted by sources other than the stomach because of the negative energy balance resulting in plasma levels higher than controls. Once patients have completed their weight loss phase and have reached a state of energy balance, plasma levels of ghrelin are comparable to those of controls despite massive weight loss The disparate results reported in the literature on the mechanism involved in weight loss after LRYGBP imply that the relationship between the mechanical effects of surgery and neuroendocrine response is complex and far from being clearly elucidated.

Lager *et al*[52] reported significantly reduced levels of ghrelin in 10 obese patients undergoing LSG at 1 and 6 mo after surgery. Interestingly, these patients were prospectively compared with 10 patients undergoing a LASGB procedure that resulted in significantly increased levels of ghrelin at 1 and 6 mo. This was paralleled by a superior weight loss in the group of patients undergoing LSG, which might be related to the low levels of circulating ghrelin with no compensatory hunger. In the case of BPD, the circulating levels of ghrelin are differently affected, depending on the type of gastrectomy that is associated with the BPD. In the case of BDP, according to Scopinaro, the gastric fundus is preserved and ghrelin levels are not reduced as reported by Adami *et al*[47]. On the contrary, when the BPD is associated with the pylorus preserving sleeve gastrectomy and duodenal switch (BPD-DS), the circulating levels of ghrelin are markedly suppressed[53].

Ghrelin seems to play a key role in the complex energy balance loop and it is logical to hypothesize that its changes are involved in the neurophysiologic mechanisms responsible for the changes in appetite observed after bariatric surgery. At the moment, the short term results of LSG are more similar to those observed after LRGBP than other purely restrictive procedures. Whether the observed change in circulating ghrelin level is a predictor of the long-term success of a given bariatric procedure, such as LSG, is not yet clear.

PRO AND CONS OF LSG

The seducing potential of LSG relies in the fact that this operation is a straightforward procedure that can be generally completed laparoscopically, even in the case of an extremely obese patient. It does not involve any digestive anastomosis, no mesenteric defects are created eliminating the risk of internal hernia[54], no foreign material is used as in the case of gastric banding, the whole digestive tract remains accessible to endoscopy, it is not associated with Dumping syndrome, the risk of peptic ulcer is low and the absorption of nutrients, vitamins, minerals and drugs is not altered.

However, some points need to be underlined at least for those who are too enthusiastic about LSG. First, although LSG is generally an easy procedure, it may become a true nightmare in the very obese patient, especially in men with a huge left liver lobe, and the long staple line may leak postoperatively. Secondly, in face of the eventual regain of lost weight or insufficient weight loss, the surgeon must be ready to do a second procedure that must be part of his technical armamentarium. The last problem is represented by the choice of the second procedure, which is traditionally the BPD-DS in the case of patients with a BMI > 50. Other teams propose the LRYGBP but it is still not clear whether the latter can provide further weight loss in the case of patients with an initial BMI > 50. The Scopinaro procedure or the VVLRYGBP are other alternatives, and the stomach might be re-sleeved in case of gastric tube dilation.

RESULTS OF LSG

Only a few studies on sleeve gastrectomy for morbid obesity have been published so far. By performing a search in PubMed MEDLINE (National Library of Medicine) for English-language articles published until March 2007 using the key words *laparoscopic, sleeve gastrectomy*, and considering only series reporting at least 30 patients, a total of 6 papers reporting a total of 328 cases was obtained[15,55-59]. Table 1 summarizes relevant data collected from these articles.

Mean initial BMI ranged from 37.2 kg/m^2[57,58] to 65.4 kg/m^2[56] with a case of a patient with an extreme BMI at 91 kg/m^2[56]. These data suggest that very high and even extreme BMI does not represent a contraindication to LSG. In fact, the two staged approach is becoming the rule in the case of super-super obese patients (BMI > 60 kg/m^2) in which more complex procedures such as RYGBP or biliopancreatic diversion are very difficult to perform. The rational of the staged approach to super and super-super obese patients is to achieve a substantial weight loss with the consequent amelioration of obesity-related comorbidities with a simple procedure such as LSG, thus allowing the second procedure in patients with lower operative risks. Of the 328 cases, data on gender

Table 1 Studies of Sleeve Laparoscopic Sleeve Gastrectomy including at least 30 patients

Study type	Sample size	Sex	Age(yr)	Mean follow up (mo)	Death (%)	Complications	Mean operative time (min)	Initial BMI	EWL (%)	Reference

NA: Non Applicable; M: Men; EWL: Excess Weight Loss; min: Minutes; pts: Patients; ref: Reference.

were available for 297 cases, for a total of 96 males (32%) and 201 females (68%) undergoing the procedure. In fact, beside high BMI, male gender is another important risk factor for postoperative morbidity and mortality and is associated with technical difficulties at the time of surgery. Men, in fact, often have an android body habitus whereby excess body fat is localized in the peritoneal cavity and the left lobe of the liver is often enlarged rendering the access to the stomach and hiatal region difficult[55]. Thus, the relatively high percentage of male patients undergoing SG in the literature reflects the choice of the bariatric surgeon in favour of SG, which is less challenging than other procedures requiring larger dissections and intestinal anastomoses.

In 3 of the 6 studies analyzed (total of 130 patients)[57-59], LSG was performed as the sole procedure; i.e. not followed by other types of bariatric operations. However, one of these patients[57] underwent a laparoscopic gastric bypass one year after LSG because he failed to achieve a satisfactory weight loss. In the last 3 studies, enrolling a total of 198 patients[15,55,56], LSG was intended as the first step of a combined approach to achieve an initial weight loss in "difficult" patients with the second step being a LRYGBP or DS. Among the 198 patients undergoing the LSG as the first step of the combined approach strategy, 51 patients finally underwent the second procedure: 36 had a LRYGBP and 15 a DS. Interestingly, in the 3 studies in which LSG was performed as a first step procedure, only a part of the initially programmed second procedures were finally performed. It can be speculated that at least in some of the cases the weight loss achieved after LSG alone was satisfying[55,56,59].

Mean operative time was clearly reported in 4 of the 6 studies[55-57,59], ranging from 70 min[57] to 143 min[56]. As expected, the operative time is longer in patients with high BMI.

Unfortunately complete data about excess weight loss are reported in 3 of the 6 studies[57-59]. This is a main concern as the primary outcome of bariatric surgery is excess weight loss, and a given procedure cannot be evaluated correctly if the functional results are not reported. Mean excess weight loss ranged from 52.8% (follow up 6 mo)[59] to 83.3% (follow up 12 mo).

Three postoperative deaths were recorded for 328 patients (death rate of 0.9%) and a total of 34 major and minor complications were reported (morbidity 10.3%). Fifteen of these were considered minor complications: 5 transient renal failures not requiring dialysis, 5 patients requiring ventilatory support for > 24 h, 1 pulmonary atelectasis, 1 case of prolonged postoperative vomiting treated conservatively and spontaneously resolved, 3 dehydrations. By excluding minor complications, a total of 19 major complications occurred (major complication rate 5.8%). Major complications managed conservatively included 4 cases of staple-line leaks, 5 strictures of the gastric plasty, 2 cases of bleeding and 2 cases of pulmonary embolus[55-57]. Six patients with major postoperative complications required re-operation. Re-operations were performed by laparoscopy in 4 cases of intraperitoneal bleeding[12,49,51,52]. One case of staple-line leak[59] and a case of gastric ischemia required re-operation by laparotomy[58].

Bariatric surgery is associated with a mortality rate of 0.1-2.0 in large studies[60-64]. In a recent meta-analysis by Buchwald *et al*[65], postoperative mortality was 0.5% for RYGBP, 0.1% for gastric banding, and 1.1% for malabsorpitive procedures. In one of the largest prospective studies[66], the SOS trial, postoperative complications occurred in 13% of patients, including

bleeding in 0.5%, embolism or thrombosis in 0.8%, wound complications 1.8%, and pulmonary complications in 6.1%. In a recent review of the literature, Baker *et al*[67] reported an average rate of leak after LRYGBP of 2.77% (range 0.3% to 8.3%).

The evolution of obesity related comorbidities after SG has not been clearly reported. However, SG should be effective in improving comorbidities, such as non alcoholic fatty liver disease/nonalcoholic steatohepatitis (NAFLD/NASH)[68], as with any other procedure that induces weight loss because the improvement of comorbidities is directly dependent on weight loss. Overall these results suggest that LSG is safe and effective in the short term to achieve a substantial weight loss. There is no evidence so far that weight loss obtained with LSG can be maintained in the long term.

WEIGHT REGAIN AFTER LSG INDUCED INITIAL WEIGHT LOSS

In other words, can LSG be proposed as a sole bariatric procedure? When the LSG is done as the first step of a staged approach in very obese patients, the second procedure is generally done when the weight loss reaches a plateau, in the case of weigh regain or simply when the patient can undergo more safely the second step regardless of weight loss stabilization or regain. The possible mechanisms that account for the limited weight loss or weight regain include a technical problem, such as an incomplete resection of the fundus of the stomach where the ghrelin producing cells are located. This may occur in patients with hiatal hernia, which is often associated with excessive body weight[69]. Gastric dilatation has been evocated as being responsible for poor weight loss after LSG with or without DS[70]. An excessive large pouch may be the result of an excessively large pouch created at the initial operation due to a too large calibration tube, or because of inappropriate surgical technique such as missed posterior gastric folds. Excessive pressure against the pouch wall by large meals, repeated vomiting or distal obstruction may also account for pouch dilation[71]. Other factors may be claimed as responsible for poor weight loss or weight regain after LSG, such as the spontaneous dilation of the gastric tube over time, the switch to a high caloric, soft, liquid diet, and, last but not least, LSG may have a limited potential for weight loss as do most restrictive procedures.

The question whether the LSG may work as a sole bariatric procedure in the long term cannot be answered yet. For this reason LSG should be proposed as the first step of a staged approach in patients for whom a BPD-DS or LRYGBP seems too hazardous because of very high BMI (super obesity-BMI > 50 or super-super obesity-BMI > 60), and/or associated diseases whether related or not to obesity. The decision to do a LSG may also be made during surgery in the case of intraoperative findings, such as liver cirrhosis, adhesions, too thick mesenterica contraindicating a more complex procedure. Then, the second step may be deferred until deemed necessary because of insufficient weight loss or weight regain. On the other hand, the LSG should not be proposed to patients with a BMI < 50 until evidence is provided for its effectiveness in achieving weight loss in the long term compared to the results obtained with RYGBP, which remains the gold standard of bariatric procedures at the moment. Exceptions might warrant a pure restrictive procedure, such as for patients with inflammatory bowel disease for whom the intestinal bypass is not advised, and transplanted patients for whom the intestinal bypass may interfere with the absorption of immunosuppressive drugs.

Abstract

Celiac disease is a gluten-dependent small intestinal mucosal disorder that causes malabsorption, often with diarrhea and weight loss. Diagnosis is based on detection of typical biopsy changes in the proximal small bowel, followed by evidence for an unequivocal response to a gluten-free diet. Refractoriness in celiac disease may be due to poor diet compliance, sometimes intentional, or consumption of ubiquitous sources of gluten. Alternatively, the original diagnosis may not be correct (eg., duodenal Crohn's disease), or a second cause for symptoms may be present (eg., collagenous colitis, functional bowel disorder). In some with recurrent symptoms, a complication may be present (eg., collagenous sprue, small bowel carcinoma, lymphoma). In some, a response to a gluten-free diet can not be unequivocally defined, and more precise historical terms have been used including "sprue-like intestinal disease" or "unclassified sprue". Although a "wastebasket diagnosis", these likely represent a heterogeneous group, and some, but not all, may develop lymphoma. Precise definition will be critical in the future as an array of new treatments, including biological agents, may emerge.

INTRODUCTION

Celiac disease is a gluten-dependent malabsorption disorder that involves the small bowel and can cause diarrhea and weight loss. Diagnosis is based on two criteria: first, proximal small intestinal mucosal biopsies that show typical biopsy abnormalities; and second, evidence for an unequivocal response to a gluten-free diet. Severe ("flat") or variably severe small bowel mucosal architectural abnormalities are present with crypt epithelial cell hyperplasia and villous atrophy. Lymphoid cell changes also occur, including intraepithelial lymphocytosis. Alterations are most severe in duodenum and proximal jejunum, and less severe, or absent, in ileum. Although characteristic, these findings are not specific or diagnostic alone as several disorders can produce similar, but not necessarily, identical histopathological changes (Table 1). Some serological assays (eg., tissue transglutaminase antibodies, or tTG) are useful screening tools in adults, but these alone do not permit a definitive diagnosis. The most critical step in the diagnosis of celiac disease is definition of a gluten-free diet response. Usually, with a gluten-free diet, diarrhea resolves and weight gain occurs. Histopathologic changes in the small bowel normalize, initially in distal intestinal sites of involvement, and later, sometimes only after prolonged periods (even months to years), in the proximal duodenum[1,2]. Recent studies have also shown that normalization of duodenal biopsies may take even longer in the elderly[3].

REFRACTORINESS IN CELIAC DISEASE

Recurrent symptoms may occur in established celiac disease (Table 2). Most often, this appears to be due to poor compliance with a strict gluten-free diet, although compliance is sometimes very difficult to define or fully ascertain. Intentional dietary indiscretion may be obvious, or, alternatively, there may be limited awareness of gluten-containing food sources. Gluten is so ubiquitous, known to be present in pill capsules and communion wafers, as well as in a host of processed food products. Gluten-free foods may be quite expensive, limited in their palatability, and, especially in some developing countries, difficult to obtain. Moreover, professionals, including physicians and dietitians, support groups and the internet, all represent potential sources of inaccurate information. Motivation to follow a strict diet may be limited if symptoms are minimal or absent when "cheating" occurs. Finally, social or peer pressure, especially during adolescence or early adulthood may also hinder efforts to maintain compliance.

In some with recurrent symptoms, however, other causes may be responsible. It is possible that the original

Table 1 Some causes of biopsy changes similar to celiac disease

Causes	Diseases
Sprue syndromes	Collagenous sprue
	Mesenteric lymph node cavitation syndrome
	Oats-induced villous atrophy
	Other protein injury (soy, milk)
	Unclassified or refractory sprue
Infectious causes	Infectious gastroenteritis
	Specific infections (eg., parasite: strongyloidiasis, Protozoan: giardia, mycobacteria)
	Tropical sprue
	Stasis syndrome (contaminated small bowel syndrome)
	Whipple's disease
Deficiency causes	Nutrients (zinc, vitamin B12, folic acid)
	Kwashiorkor
	Immunodeficiency syndromes
Others	Intestinal lymphangiectasia
	Crohn's disease (duodenum)
	Graft-versus-host disease
	Immunoproliferative disease (lymphoma)
	Macroglobulinemia
	Zollinger-Ellison syndrome
	Drug-induced small bowel injury (eg. NSAIDs)

diagnosis was incorrect, especially if there was only limited attention to defining the response to a gluten-free diet. And, there are many conditions that may cause a virtually identical histopathological small bowel lesion[4]. In addition, a second cause for symptoms may have developed. These may include other associated or linked disorders, like collagenous colitis[5] or even a functional bowel disorder. Alternatively, in those that appear to have "refractory" symptoms, a complication may have developed (eg., collagenous sprue, small intestinal carcinoma, lymphoma)[6]. In some with persistent symptoms and architecturally abnormal biopsies, clonal expansion of an aberrant intra-epithelial lymphocyte population has been reported (so-called type 2 disease versus type 1 disease with apparently normal intraepithelial lymphocyte phenotype). This condition has been labeled "cryptic T-cell lymphoma" as there appears to be a higher risk of overt T-cell lymphoma[2,7].

UNCLASSIFIED SPRUE OR "SPRUE-LIKE INTESTINAL DISEASE"

Sometimes, the small bowel biopsy changes do not appear to improve despite apparently good compliance on a gluten-free diet. Persistent symptoms and changes in the small bowel biopsies are present. Although a relatively treatment-resistant form of celiac disease could be present, possibly with a distal small bowel diet response, it is more likely that celiac disease is not present at all. Rather than labeling these patients with refractory celiac disease, more precise terms have been historically used including "sprue-like intestinal disease" or "unclassified sprue"[8].

In these, persistent symptoms and ongoing pathological changes are present despite a strict gluten-free diet. In some reports, persistent pathological abnormalities refer to results of repeated endoscopic biopsies from the proximal small bowel during an arbitrary time period of 6 mo to up to one year. Rarely, there is a rapidly progressing disease course that makes it difficult to show a convincing response to a gluten-free diet. While clinical and pathological changes are reminiscent of celiac disease in some of these patients, there is usually no convincing evidence that a gluten-free diet response ever occurred. "Sprue-like intestinal disease" or unclassified sprue is a "wastebasket" disease diagnosis that appears to represent a heterogeneous group of different disorders. Some eventually develop lymphoma, but some do not. A few are reported to have epithelial cell antibodies, specificially anti-enterocyte and anti-goblet cell antibodies. These have been reported in both children or adults with persistent diarrhea and severe biopsy changes, similar to untreated celiac disease. In these, no response to a gluten-free diet or any dietary exclusion occurs. Some believe that these represent a distinct autoimmune enteropathic disorder[10].

Table 2 Recurrent or refractory symptoms in celiac disease

Dietary non-compliance
Ubiquitous gluten source (eg., pill capsules)
Wrong initial diagnosis
Associated or second cause (eg., collagenous colitis)
Superimposed complication (eg., collagenous sprue, lymphoma)

FUTURE DEVELOPMENTS

Refractory disease represents a complex array of difficult clinical problems, in part, because definitions are evolving and there is no clear consensus for treatment, unless a lymphoma has already been detected. In case reports of refractory disease with clonally expanded T-cell populations, use of infliximab[11] and cladribine[12] were described, but progression to overt lymphoma occurred. In addition, use of autologous hematopoietic stem-cell transplantation has also been done, but with mixed results, especially if overt T-cell lymphoma is present[13-15]. Better refinements in the definition of refractory diseases are needed, possibly using genetic markers to identify risk[16]. These may eventually aid in treatment, especially with emergence of an array of new biological agents for treatment of immune-mediated and malignant disorders.

Abstract

Nonalcoholic fatty liver disease (NAFLD) is a group of diseases with excess fat in liver in the absence of a poorly defined limit of alcohol consumption. Most common variety, a universal public health problem, is associated with insulin resistance caused by a host of genetic and epigenetic defects modulated by life style and environmental factors. In fact the term NAFLD is loose to incorporate so many etiologies except alcoholism and few other etiologies, presenting as fat in liver. However as a sign fatty liver is very important in predicting the risk of diabetes, cardiovascular disease, stroke, cirrhosis and cancer. Abnormal fat accumulation can result from several defects in nuclear receptors associated with lipid sensing, synthesis and oxidation like LXR, FXR, SREBP, ChREBP and PPAR; defects in the lipid influx-efflux channels, insulin signaling, proteins involved in fatty acid catabolism, defects in adipose tissue development and function, inappropriate nutrition and finally defects in neural regulatory mechanisms. The progress of the disease is determined by the basic defects which results in fat accumulation, an individual's immunological response to the accumulated fat and its derivatives and the oxidant stress response. Congregation of unrelated genetic defects under same diagnosis 'NAFLD' can result in inefficient patient management. Further studies are required to understand the molecular basis of fatty liver to enable a personalized management of diseases presenting as fatty liver in the absence of alcohol abuse.

INTRODUCTION

"It was six men of Hindustan, To learning much inclined, Who went to see the Elephant, (Though all of them were blind), That each by observation, Might satisfy his mind. "God bless me! but the Elephant: Is very like a wall! Is very like a spear! Is very like a snake! Is very like a tree! Is very like a fan! Is very like a rope!" And so these men of Indostan, Disputed loud and long, Each in his own opinion, Exceeding stiff and strong, Though each was partly in the right, And all were in the wrong!"

-John Godfrey Saxe (1816-1887).

Although alcohol-induced liver steatosis was already described by Thomas Addison in 1845, it is appreciated only since 1962 that steatosis can also occur without the use of alcohol, so-called non-alcoholic steatosis[1]. The term nonalcoholic steatohepatitis (NASH) was coined in 1980 to describe "the pathological and clinical features of non-alcoholic disease of the liver associated with the pathological features most commonly seen in alcoholic liver disease itself"[2]. In fact, the finding that some obese individuals had a liver disease histologically indistinguishable from alcoholic liver disease itself had long been recognized.

The etiopathogenesis of nonalcoholic fatty liver disease (NAFLD) has been disputed loud and long (Figure 1). NAFLD is a vague term for a spectrum of diseases which differ not only in the presentation but also in the etiologies which warrants a personalized approach in the diagnosis and treatment of this condition. All possible etiologies and pathogenesis models have been assigned to it from mitochondrial, oxidant stress, hormonocentric to adipocentric models[3,4]. On the other hand the term NAFLD is loose to incorporate so many etiologies except alcoholism and few other etiologies, presenting as fat in liver. Interestingly despite the diversity in root cause and irrespective of the fact they fall inside or out side the conventional inclusion or exclusion criteria many of them share common pathways of disease progression evolution and termination. Here in this review, we once again review the 'elephant' and attempt to classify and generalize the disorder based on the etiology.

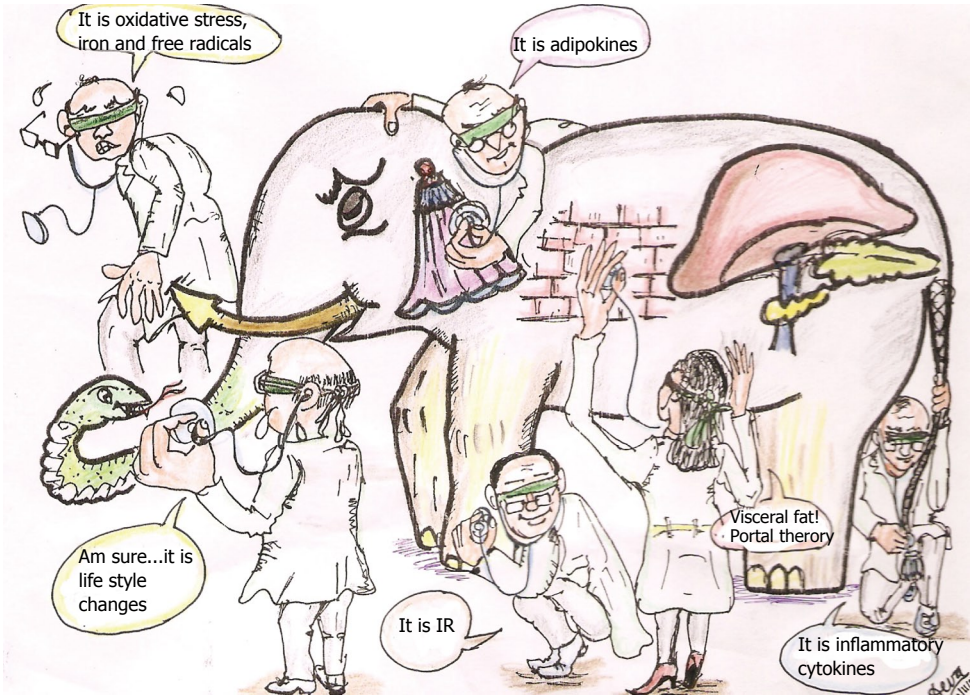

Figure 1 The pathogenesis of NAFLD has been disputed by many loud and long. The term "nonalcoholic fatty liver disease" is imprecisely defined; there is uncertainty regarding its pathogenesis. The elephant (NAFLD) has been interpreted by many and several possible etiologies and pathogenesis models have been assigned to it like 'insulin resistance', mitochondrial defects, adipokine imbalance, visceral fat, inflammatory cytokines and oxidant stress.

NAFLD: A nonspecific diagnosis and a misnomer?

A variety of genetic defects and pathogenic pathways can result in NAFLD. Fatty liver is a sign rather than a proper diagnosis. As a sign it is very important in predicting the possibility of diabetes, cardiovascular risk, stroke, cirrhosis and cancer. Symptoms, severity and prognosis for same amount of fat in liver differ very much from person to person and fat may be totally absent in late stages of the disease. In addition, there is no genetic or clinical marker specific for NAFLD. Opinion regarding the histopathological diagnosis and staging differ even among experts and there is a lack of reproducibility[5,6]. Furthermore, authors have differed on the level of alcohol consumption that can reliably distinguish between alcoholic steatohepatitis and NASH.

"Nothing makes sense in biology without the concept of evolution"

'Nothing in Biology Makes Sense Except in the Light of Evolution' is a 1973 essay by the evolutionary biologist Theodosius Dobzhansky, criticizing Young Earth creationism and espousing evolutionary creationism makes sense with 'NAFLD' as well.

The ability to obtain food and manage periods of starvation and the ability to fight infectious diseases were most critical in survival of primates and indeed their survival was threatened by starvation and infectious diseases than obesity and autoimmunity or cancer. So, primate evolution always favored "thrifty genotypes"[7] which were efficient in fat storage and burning. Similarly 'infection resistant' genotypes were favored by evolution. The cultural evolution was faster so that the 'genetic-evolution' lagged behind or became static. As we 'evolved' from hunter-gatherer life style to computer savvy-chair bound, calorie rich-fast food friendly and 'hygienic' life style our past started haunting and our 'vestigial genes' started their manifestation in the form of the pandemic called Metabolic Syndrome with associated insulin resistance (IR), NAFLD, chronic inflammatory disorders and cancer.

Evolutionary history of adipose tissue, liver and immunocytes adds more sense to this picture. It is interesting to note that all the above has same ancestor-the "fat body" which is the mammalian homologue of all the three tissues in insects[8,9]! Over expressing peroxisome proliferator-activated receptor gamma (PPAR-γ) a gene that is vital for differentiation and maturation of adipocyte genes in hepatocytes can induce adipocyte like features in hepatocytes. Similarly gene expression profile of macrophage is very similar to adipocyte[10-13]. Hence all the three systems are simultaneously affected in disorders like NAFLD (Figure 2). Indeed in fatty liver disease, hepatocytes become lipid-loaded and resemble adipocytes with the formation of large lipid droplets, expression of adipogenic and lipogenic genes such as adipose differentiation-related protein (ADRP), PPAR-γ and sterol regulatory element binding protein (SREBP)[3,9-13]. The interactions and involvement of the trio in development of fatty liver is discussed further in this article.

NAFLD AS THE LIVER MANIFESTATION OF A GENERALISED FAT STORAGE DISORDER

Logically if fat has to get accumulated there are four ways (Figure 3): (1) increased inflow (increased availability of lipids and lipid precursors); (2) decreased outflow/secretion; (3) increased synthesis; and (4) decreased oxidation.

Increased inflow

It has been observed that nearly 80% of people who undergo liver transplantation following cirrhosis from NASH get back the disease in few years[14]. This point

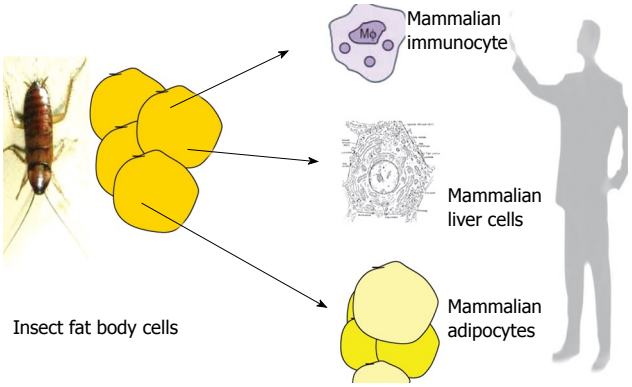

Figure 2 It is interesting to note that adipose tissue, liver and immunocytes has same ancestor-the "fat body" which is the mammalian homologue of all the three tissues in insects. Over expressing PPAR-γ in hepatocytes can induce adipocyte like features in hepatocytes. Similarly gene expression profile of macrophage is very similar to adipocytes. All the three cell systems are affected in disorders like NAFLD and obesity.

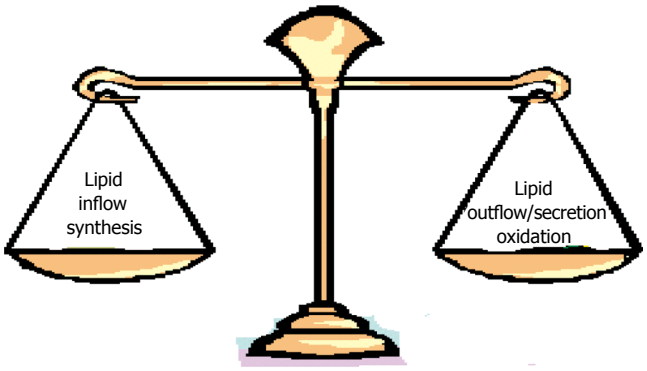

Figure 3 Fat gets accumulated in liver when there an imbalance between inflow (increased availability of lipids and lipid precursors) and outflow/secretion, synthesis and oxidation.

to the fact that at least in majority of the patients the cause lays outside the liver. Adipose tissue functions as an energy reserve; where energy can be stored in the most concentrated form viz. lipids safely unlike other tissues where it could cause 'lipid toxicity'[15]. This way it also acts as an energy sink in times of plenty. Soon after feeding the blood would be over loaded with energy rich compounds and the adipose tissue has an important role in clearing these compounds, especially lipids which are potentially harmful. However in chronic over nutrition adipocytes may become overloaded and may no longer be able to take up circulating lipids and glucose. Insulin is a stimulator of lipoprotein lipase the enzyme which mediates extraction of fatty acids from circulating lipoproteins which are the carriers of lipids as triglycerides (TG). Through the tissue-specific action of lipoprotein lipase, the TG-derived free fatty acids (FFA) are taken-up by peripheral tissues. Similarly the type-4 glucose transporters on adipocyte surface are also insulin dependent[16]. Probably the over loaded adipocytes may adopt insulin resistance (IR) as a strategy to save them selves from further overloading, damage and cell death (apoptosis?). As soon as the energy sinking capacity of the adipose tissue is exceeded the energy rich substrates starts 'over flowing' to other tissues like liver and muscle. This could be only one but the commonest mechanism of fatty liver. Nearly 60% of TGs deposited in liver in NAFLD comes from circulating nonesterified fatty acids[17]. The TGs contained within adipose tissue are continuously being hydrolyzed into fatty acids and glycerol by the enzyme hormone-sensitive lipase (HSL). Insulin resistance impairs uptake of glucose from blood into skeletal muscle and adipose tissue; serum non-esterified fatty acid (NEFA) levels may also be elevated due to the failure of insulin to suppress HSL mediated lipolysis[16].

However (1) other mechanisms which induces IR in adipose tissue or defects in the transporters of lipids into adipose tissue which limits influx of lipids, (2) defects in the control mechanisms involved in the release of lipids from adipocytes, (3) defects in normal growth and proliferation of adipose tissue, could result in plasma lipid pooling and ectopic fat deposition such as fatty liver. As in the case of adipocytes hepatic fat over load may lead to hepatic insulin resistance (HIR)[18]. Therefore it should be possible to reverse fatty liver by 'unloading' the extra fat. This is indeed true. For example surgical obesity management techniques like gastric banding based on restriction of the gastric reservoir produces early satiety and reducing oral intake induces significant weight loss by unloading of fat reserves reverses fatty liver. Exercise and diet restriction and consequent fat reduction still remains the mainstream therapy in NAFLD[19,20]. Interestingly removal of excess fat by liposuction doesnot improve insulin sensitivity[21]. This is possibly because as adipocytes are removed the buffering action provided by them on circulating energy rich substrates is decreased.

A small part of the fatty acids released by HSL as described before are re-esterified within adipocytes while most overflow into the blood which exceeds the normal oxidative needs of the body. Liver is another immediate buffer that has been shown to have a high capacity for accumulating fat and redirecting or oxidizing it later depending on the energy homeostatic signals. Within the liver, these fatty acids are either oxidized or re-esterified into TGs and secreted into the blood bound to VLDL[16,18]. The fatty acids re-esterified by the liver into TG are almost exclusively from adipose tissue lypolysis[22].

Gluconeogenesis in liver needs supply of fatty acids and glycerol released from adipocytes. Glycerol contributes 90% of the substrate for hepatic gluconeogenesis in prolonged fasting mice. In man about 20% of hepatic gluconeogenesis is mediated by glycerol. Gluconeogenesis needs a coordinated efflux of glycerol from adipocytes and influx into hepatocytes through adipocyte specific glycerol channel, designated aquaporin adipose (AQPap/7) and a liver-specific aquaglyceroporin was also identified and named AQP9[23]. Discord between efflux and influx channels possibly play an important role in the pathogenesis of NAFLD and diabetes mellitus.

Over flow of fat to liver could be due to increased dietary intake. Even after a short term fat feeding liver fat increases three fold without increase in visceral or skeletal muscle fat[18]. Indeed the adipose tissue fat is an indicator of liver fat. The intrahepatic lipids increase by 22% for

any 1% increase in total adipose tissue, by 21% for any 1% increase in subcutaneous adipose tissue and by 104% for 1% increase in intra-abdominal adipose tissue[24]. Thus liver bears the brunt as soon as adipose tissue buffering reaches its limit.

Zucker rats (*fa/fa*) have inactivating mutation in the leptin receptor and hence obese and develops fatty liver. Liver specific correction of leptin receptor deficiency results in reduced TG accumulation in the liver but not in other non-adipose tissues. This could be an example of adipokine mediated communication between adipose tissue and liver. Leptin in conditions of 'calorie excess' signals liver to increase lipid oxidation and to down regulate lipid synthesis and thus protect it and other organs from steatosis[25]. Ob/ob mice with mutations in Scd1 had histologically normal livers with significantly reduced triglyceride storage and VLDL production. Down regulation of SCD1 is an important component of leptin's metabolic actions[26].

As the buffering capacity of liver also exceeds its limit lipid starts getting accumulated in cardiovascular system and other organs. The macrophages associated with blood vessels, the evolutionary kin of adipocytes and hepatocytes, will try to "buffer" the excess lipids by phagocytosis and later oxidize them partly to form toxic free radicals and immunogenic compounds. They become 'foamy cells' as their capacity to accumulate fat reaches the limit[27]. This eventually leads to "fibrosis" of vessel wall (atherosclerosis is homologous to cirrhosis of liver) and an increase in CVS related mortality. Indeed some studies published recently find the seeds of CVS mortality in NAFLD[28-30] (Figure 4).

Defects in fatty acid transporters in adipocytes also could result in hypertriglyceridemia and subsequent increased inflow of FA to liver. For example

CD36-/-mice lacking the fatty acid transporter that is normally present in muscle and adipose tissue showed increased hepatic TG content and a decreased sensitivity of hepatic glucose production to insulin[31].

There are multiple genetic defects which culminate in adipose tissue deficiency and adipose tissue deficiency invariably results in fatty liver. Lean transgenic mice that express ZIP/F-1 protein in adipose tissue, which blocks the function of several classes of transcription factors, are insulin resistant and developed fatty liver. Interestingly in these mice upon transplantation of fat tissue insulin resistance as well as the fatty liver disappeared[32]. PPAR-γ mutant mice develop IR and fatty liver in conjunction with the terminal atrophy of adipose tissue[33]. Sterol regulatory element-binding proteins (SREBPs) are a family of transcription factors that activate the entire program of cholesterol and fatty acid synthesis. The transgenic mice that overexpress nuclear SREBP-1c (aP2-SREBP-1c) exclusively in adipose tissue have very little adipose tissue, apparently as a result of disturbed adipocyte differentiation. They develop severe hyperglycemia, hyperinsulinemia, and lipid accumulation in liver[34,35]. The fatty liver dystrophy (*fld*) mutant (lipin-deficient) mice are characterized by neonatal fatty liver and hypertriglyceridemia that resolve at weaning, glucose intolerance and increased susceptibility to atherosclerosis and neuropathy. Adult *fld/fld* mice exhibits 80% reduction in mass both white and brown fat pads compared with wild-type controls, and consist of immature adipocytes[36]. Human examples of adipose tissue deficiency and consequent fatty liver is described else where in this paper.

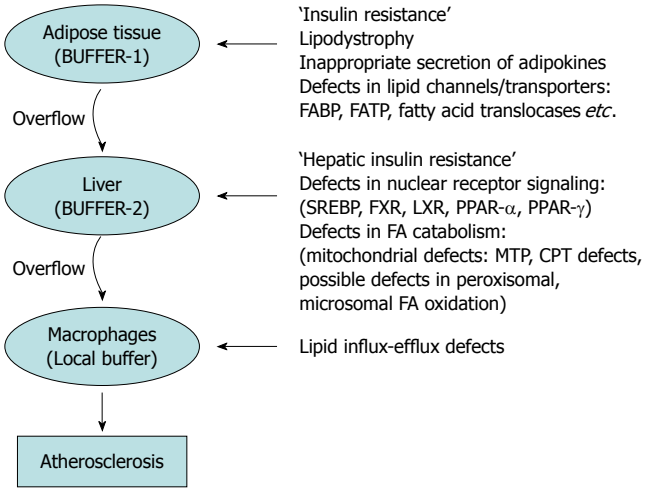

Figure 4 Adipose tissue functions as an energy reserve; where energy can be stored in the most concentrated form viz. lipids safely. In other tissues lipid accumulation could cause 'lipid toxicity'. Adipose tissue 'buffers' the lipids and energy rich compounds which are pumped into the blood stream soon after meals. However when excess calories overload adipose tissue the buffering action ceases, resulting in overflow of lipids to liver which is the next buffer. But as soon as liver also is overloaded, lipids overflow and gets accumulated in various other organs. In blood vessel walls macrophages takes up the excess lipids to form foam cells initiating a cascade which results in fibrosis of vessel walls.

Increased intake

The lipid intake is determined by lipoproteins which are carriers of lipids to liver predominantly from adipose tissue and digestive tract through the circulatory system. The lipids are further transported into hepatocytes by various 'lipid transporters' which are membrane bound channels and cellular lipid binding proteins like fatty acid transport proteins (FATP), fatty acid translocase (FAT/CD36), fatty acid binding proteins (FABP), caveolin-1 *etc*. Tissue accumulation of FA requires intracellular trapping involving association between many membrane' intracellular FA binding proteins.

FATP is highly expressed in hepatocytes and adipocytes that reveal high-level FA uptake for both metabolism and storage. FATP1 is found in adipose tissue and in the heart. FATP2 and FATP5 are expressed in the liver, while FATP4 is expressed in the intestine[37]. Overexpression of FATP5 in cultured cells has been shown to increase FFA uptake while knock out of FATP-5, results in decreased accumulation of fat in liver and decreased production of conjugated bile acids[38-40]. A recent study found an upregulation of FABP4 and FABP5 in NAFLD independent of obesity[13]. Thus FATP5 is an important membrane protein involved in fatty acid accumulation by the liver. In mice, which are FAT/CD36-deficient, the flux of fatty acids toward the liver is increased, precipitating steatosis, but there without any evidence of an increase in hepatic VLDL production[41].

The fatty acid taken up by liver is oxidized and excess is esterified and accumulated or secreted. Esterification is most

efficient with mono-unsaturated lipids as monounsaturated fatty acyl-CoAs are the preferred substrates for the synthesis of triacylglycerol (TAG) in the endoplasmic reticulum (ER)[42]. This is possibly one reason why loss of members of desaturation enzyme family, stearoyl-CoA desaturase which catalyses the rate-limiting step in the synthesis of monounsaturated fatty acids, particularly oleate (18:1) and palmitoleate (16:1), protects mice against fatty liver in mice[43].

The decreased outflow

The increased hepatic uptake and biosynthesis of FAs are compensated through increased removal of lipids from the liver. In this process, VLDL plays a central role. The principal apoprotein for this particle is apoB100, but apoE and apoC-Ⅰ, C-Ⅱ, and C-Ⅲ are incorporated as well[44]. Lipid homeostasis in mammalian cells is regulated by a family of membrane-bound transcription factors designated sterol regulatory element-binding proteins (SREBPs). In the liver, three SREBPs regulate the production of lipids for export into the plasma as lipoproteins and into the bile as micelles. nSREBP-1a transgenic mice develop a massive fatty liver engorged with both cholesterol and triglycerides[45].

The bile acid receptor farnesoid X receptor (FXR; NR1H4) is a central regulator of bile acid and lipid metabolism. FXR protects the liver from the deleterious effect of bile acid overloading by inhibiting their biosynthesis and stimulating their excretion. FXR regulates the expression of several apolipoproteins involved in the transport and metabolism of lipids[46,47] (Figure 5).

Bile acid reduces the secretion of VLDL by repressing microsomal triglyceride transfer protein (MTTP) which mediates lipidation of apoB100 to form VLDL[48]. This effect is possibly mediated through FXR. Pharmacologic agents that induce hepatic steatosis like amiodarone, tetracycline, pirprofen, tianepine inhibited MTTP activity[49]. However it is still unclear whether FXR mediated decrease in triglyceride rich VLDL secretion and consequent decrease in lipid out flow from liver is important in the pathogenesis of fatty liver.

Abetalipoproteinemia, a genetic disease which is associated with fatty liver is caused by mutations in the MTTP gene resulting in blockage of VLDL assembly and secretion[48]. MTTP-493 G/T polymorphism may influence NASH by modulating postprandial lipemia and lipoprotein metabolism; homozygous GG carriers have a more atherogenic postprandial lipid profile than the other genotypes, independently of adipokines and insulin resistance[50]. Fatty acid level is sensed in liver by PPAR-α and genes which promote lipid secretion like FABP, MTTP and apoB100 are upregulated[51-53]. Indeed this could be one mechanism by which fibrates which are PPAR-α agonists used in the treatment of NAFLD exerts its effect. Since lipid synthesis should go hand in hand with lipid secretion; as lipogenesis is increased by activation of the liver X receptor, hepatic VLDL production is also increased. Selective modulators of nuclear receptors involved in lipid homeostasis could thus revolutionize the treatment of NAFLD, Gall Stone disease, obesity and type 2 diabetes mellitus.

HDL particles participate in reverse cholesterol transport, the mechanism by which cholesterol from extrahepatic tissues returns to the liver for excretion as biliary cholesterol[44]. Low HDL-cholesterol is associated with metabolic syndrome and NAFLD[28]. ABCA1 is a lipid binding protein which increases reverse cholesterol transport to pre-beta HDL. Patients with low HDL-cholesterol and abnormal cellular lipid efflux due to ABCA1 gene defects (Tangier disease) also have elevated plasma triglycerides[44,54] and fatty liver.

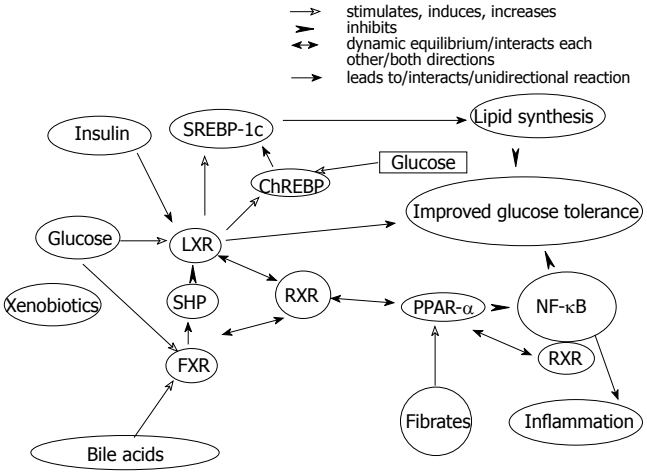

Figure 5 The complex interactions between various nuclear receptors involved in lipid-carbohydrate-bile acid homeostasis determines fat accumulation in liver. SREBP-Sterol regulatory element-binding proteins LXR-liver xenobiotic receptor, FXR-farnesoid xenobiotic receptor, SHP-short heterodimer partner, RXR-retinoid xenobiotic receptor, PPAR-peroxisome proliferator-activated receptor, ChREBP-carbohydrate responsive element binding protein. NF-κB-nuclear factor κB.

The increased synthesis

The synthesis of lipid and lipoproteins is important to metabolic disorders. In NAFLD nearly a quarter of the accumulated fat comes from *de novo* lipid (DNL) synthesis[17] and hepatic lipid synthesis is markedly increased in NAFLD[55]. Acetyl coenzyme A (acetyl CoA) is a crucial metabolic intermediate in carbohydrate and protein catabolism towards lipid synthesis. Acetyl CoA carboxylase (ACC) and Fatty Acid synthetase are two major enzymes that drive DNL in the liver[3]. Inhibitors of ACC decreases lipid accumulation by hepatocytes and might prove useful in the development of novel therapeutic agents to combat fatty liver[56].

Synthetic pathways for triacylglycerol (TAG), cholesterol and its esters, and phospholipids are separate, but transcriptionally co-regulated[57]. In insulin sensitive tissues and particularly in the liver, the transcription factor SREBP-1c transduces the insulin signaling regulating lipid synthesis. Overexpression of nSREBP-1c in the liver of transgenic mice bypasses insulin requirement and activates the same genes stimulated by insulin and produces a triglyceride-enriched fatty liver with no increase in cholesterol. The mRNAs for fatty acid synthetic enzymes and rates of fatty acid synthesis are elevated fourfold in liver[57,58]. Alcohol induces fatty liver partly by impairing PPAR-α and PPAR-γ activity and activation of SREBP-1[59]. Overexpression of nSREBP-2 in liver increases the mRNAs encoding all cholesterol biosynthetic enzymes[57,60].

Under physiological conditions, SREBP-1c is transiently

induced in the liver by insulin through activation of IRS-2; this causes a switch from glycogen synthesis to lipid synthesis. To complete a feedback loop, SREBP-1c then suppresses IRS-2 transcription. Under certain pathogenic conditions, expression of SREBP-1c in the liver remains elevated, and this increases lipid synthesis with resultant accumulation of fat[61].

Hepatitis B virus (HBV) infection is associated with fatty liver in a significant proportion of patients. HBV encoded protein HBx causes lipid accumulation in hepatic cells which is mediated through SREBP1 and PPAR-γ[62].

Obesity and insulin resistance is a pro-inflammatory state characterized by increased levels of pro-inflammatory cytokines[27,63]. Cytokines like IL-6 and TNF-α further promotes insulin resistance by increasing hepatic suppressors of cytokine signaling (SOCS) expression[3,63,64]. Over expression of SOCS-1 and SOCS-3 in liver causes insulin resistance and an increase in the key regulator of fatty acid synthesis in liver, SREBP-1c. In obesity, increased SOCS proteins enhance SREBP-1c expression by antagonizing STAT3-mediated inhibition of SREBP-1c promoter activity[64]. Interestingly n-3 PUFAs downregulate SREBP 1-c, which increases transcription of genes responsible for fatty acid synthesis such as fatty acid synthase and stearoyl Co-A desaturase[65].

The liver has a central role in glucose homeostasis. On feeding, glucose influx triggers gene expression changes in hepatocytes to suppress endogenous glucose production and convert excess glucose into glycogen or fatty acids to be stored in adipose tissue. This process is controlled by insulin, although debate exists as to whether insulin acts directly or indirectly on the liver. Transcriptional activation of glycolytic and lipogenic genes requires the presence of both insulin and glucose, neither of which is active alone. Recently, carbohydrate responsive element binding protein (ChREBP) emerged as a pivotal transcription factor implicated in the regulation of lipogenic genes by glucose[66].

Liver xenobiotic receptor (LXR) is another glucose sensor which is activated by glucose and switches on several genes involved in fatty acid synthesis[67]. An LXR-binding site in the *SREBP-1c* promoter activates SREBP-1c transcription in the presence of LXR agonists. When lipogenesis is increased by pharmacological activation of the liver X receptor, hepatic VLDL production is increased 2.5-fold, and the liver produces large TG-rich VLDL particles[68]. Interestingly, glucose induces expression of LXR target genes involved in cholesterol homeostasis like ABCA1 which is defective in Tangier disease[67].

A common feature of many metabolic pathways is their control by retinoid xenobiotic receptor (RXR) heterodimers. It is interesting to note that LXR heterodimerizes with RXR. Promiscuous RXR also heterodimerizes with PPAR members. PPAR-α plays a pivotal role in fatty acid catabolism in liver by upregulating the expression of numerous genes involved in mitochondrial fatty acid oxidation. Thus RXR is a common partner of two nuclear receptors acting in opposite directions with regard to fatty acid metabolism. So both LXR and PPAR-α compete for the limited pool of RXR and this dynamic equilibrium determines the direction of lipid metabolism[69].

FXR also plays a key regulatory role in glucose homeostasis. FXR-null mice developed severe fatty liver and elevated circulating FFAs, which was associated with elevated serum glucose and impaired glucose and insulin tolerance[70]. Activation of FXR lowers plasma glucose levels in fasted, fed, diabetic mice. Bile acids, by activating FXR, induce the expression of short heterodimer partner (SHP)[71]. SHP then interferes with SREBP-1c expression by inhibiting the activity of LXR and eventually other transcription factors that stimulate SREBP-1c expression[47].

An increase in serum triglyceride concentrations and fatty liver have been observed in patients with malabsorption of bile acid as found in chronic inflammatory bowel disease[72], ileal resection and cholestyramine treatment. This could be due to loss of bile salt mediated inhibitory effect on fatty acid synthesis mediated through FXR and further research is required in this area.

It may be noted that NAFLD is classically associated with gall stone disease and hypertriglyceridemia[30,73]. The increased incidence of gall stones at least partly is due to decreased secretion of bile salts, which are potent emulsifiers, and the consequent instability of bile pigments resulting in precipitation and stone formation. It would be logical to hypothesize that defective FXR expression or signaling and consequent deficiency in bile inhibition of fatty acid synthesis might play a role in certain cases of hepatic steatosis associated with biliary stones.

Hepatocyte nuclear factor-4α (HNF-4α) is a transcription factor which is mutated in monogenic autosomal dominant non-insulin-dependent diabetes mellitus type 1 (MODY-1), controls the expression of several genes, including hepatocyte nuclear factor 1α (HNF-1α), a transcription factor which regulates the expression of several hepatic genes and the human CYP7A1 gene in bile acid synthesis and phosphoenolpyruvate carboxykinase (PEPCK) gene in gluconeogenesis[74]. Long-chain fatty acids, including palmitic acid, have been identified as endogenous HNF-4α ligands and this allows the transcriptional control of gluconeogenesis during active lipid synthesis. It is interesting to note that glucose and fructose induces lipogenesis reduces hepatic HNF-4α levels, which in turn attenuates the expression of sex hormone binding globulin (*SHBG)*, a biomarker of metabolic syndrome[75]. Thus HNF-4α is another major protein at the cross roads of sex hormones, diabetes, fatty liver, dyslipidemia and gall stone disease.

Nuclear receptors are notoriously promiscuous. They are known to be activated, inhibited or otherwise modulated by numerous xenobiotic compounds which include alcohol, drugs, insecticides, dietary contaminants and numerous other chemicals acquired from environment[76]. This could explain the association of certain drugs as well as environmental toxins with fatty liver[77,78]. It may be noted that many of the *de novo* lipid synthesis pathways described above are shared by both alcoholic and nonalcoholic fatty liver disease.

The decreased oxidation

Fatty acid oxidation is compartmentalized in eukaryotic organisms into three subcellular organelles, with beta-oxidation confined to mitochondria and peroxisomes

and CYP4A-catalyzed omega oxidation occurring in the endoplasmic reticulum. Beta oxidation is primarily involved in the oxidation of fatty acids with carbon chains not longer than twenty while peroxisomal oxidization predominantly deals relatively complex and toxic fatty acids containing twenty or more carbon atoms and C27-bile acid intermediates[79]. Microsomal omega oxidation system hydroxylates saturated and unsaturated fatty acids which will eventually be oxidized by the other two oxidation systems[79]. Some of the key enzymes of these three fatty acid oxidation systems in liver are regulated by PPAR-α. When mice fed on a methionine-choline deficient (MCD) diet-a dietary model of fibrosing steatohepatitis-were treated with the PPAR-α agonist, Wy-14643, developed significantly less steatohepatitis, markedly lower ALT levels and less lipid peroxidation compared to controls. This occurred despite a marked increase of the liver P-450 enzymes which are oxidant stress inducers[80]. Mice lacking PPAR-α (PPARα-/-) fail to respond to the inductive effects of peroxisome proliferators, whereas those lacking fatty acyl-CoA oxidase (AOX-/-), the first enzyme of the peroxisomal beta-oxidation system, exhibit extensive microvesicular steatohepatitis, leading to hepatocellular regeneration and massive peroxisome proliferation, implying sustained activation of PPAR-α by natural ligands[79]. Ethanol a common cause of fatty liver interferes with DNA binding and transcription-activating properties of PPAR-α, as demonstrated with cultured cells and in ethanol-fed mice. Treatment of ethanol-fed mice with a PPAR-α agonist can reverse fatty liver even in the face of continued ethanol consumption[81].

Mitochondrial beta oxidation results in shortening of fatty acids and FA are oxidized carbon by carbon into acetyl-CoA subunits, which either condenses into ketone bodies that serve as oxidizable energy substrates for extrahepatic tissues, especially during starvation, or enter into the tricarboxylic acid cycle. Mitochondrial beta oxidation is regulated by carnitine palmitoyl transferase-1 (CPT-1), the carnitine concentration and malonyl-CoA, which inhibits CPT1. Fatty acids, fatty acyl-CoAs and several structurally different chemicals known as peroxisome proliferators, which activate PPAR-α, regulate CPT1 levels in the liver[82]. Inhibition of fatty acid oxidation in the liver is a intrahepatic cause of the development of liver steatosis. For instance, etomoxir, a CPT-1inhibitor, inhibits fatty acid oxidation and induces steatosis[83].

Thioredoxin (TRX) is an important redox regulator protein that has a redox-active dithiol/disulfide in its active site[84]. TRX binding protein-2 (TBP-2) was identified as a TRX binding protein from a yeast two-hybrid system study, and as a negative regulator of TRX through direct interaction. TBP-2 null mice are viable and fertile, but under fasting conditions, their survival rate was sharply reduced, concomitant with fatty liver, hypoglycemia, dyslipidemia, severe bleeding and hepatic and renal dysfunction. This mouse has been proposed as an animal model for Reye's syndrome an acute illness which is encountered exclusively in children below 15 years of age characterized clinically by vomiting and signs of progressive central nervous system damage, hypoglycemia and extensive fatty liver and liver damage[84]. TBP-2 is also reported to be a causative gene for familial combined hyperlipidemia (FCHL) in mice. Individuals with genetic deficiencies in fatty acid transport and mitochondrial oxidation show a similar pathology to Reye syndrome, which is defined as a Reye-like syndrome, such as CPT-I deficiency[85]. Defects in different enzymes involved in fatty acid utilization give rise to different disorders. A defect in long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) is associated with acute fatty liver of pregnancy (AFLP) while medium-chain acyl-CoA dehydrogenase (MCAD) defect is involved in sudden infant death syndrome (SIDS)[86].

Less is understood about the role of mitochondrial beta oxidation in development of NAFLD. Mitochondrial trifunctional protein (MTP) catalyzes long-chain fatty acid oxidation. Chronic alcoholism is known to cause mitochondrial damage[87]. Megamitochondrion with crystalline inclusions is a feature of NAFLD underscoring its importance in pathogenesis[88]. A mouse model for MTP deficiency reported that homozygous (*MTPa*-/-) mice suffer neonatal death. Heterozygosity for fatty acid oxidation defects predisposes to NAFLD and insulin resistance in aging mice. Thus impaired mitochondrial oxidation may play an important role in pathogenesis of NAFLD[89]. Primary or age-related defects in mitochondrial beta oxidation could play a role in development of NAFLD[90]. MTP defects in man are recessively inherited and children with defects of any of the three enzymatic functions exhibit mostly microvesicular hepatic steatosis[91].

A diet that provides 2%-5% of energy from (n-3) and (n-6) PUFA leads to a coordinate suppression of glycolytic and lipogenic genes and to an induction of genes involved in fatty acid oxidation. This metabolic balance in liver leads to a 'partitioning' of fatty acids away from triglyceride synthesis toward fatty acid oxidation[92]. Long-chain n-3 PUFAs upregulate PPAR-α, increases transcription of genes responsible for fatty acid oxidation, such as mitochondrial CPT 1 and peroxisomal acyl-CoA oxidase[65]. Thus PUFA intake could be beneficial in treatment of NAFLD.

Epigenetic factors

The thrifty phenotype hypothesis (Barker's hypothesis) postulates epigenetic memory of the fetal/neonatal environment[93]. Feeding rats a high-carbohydrate diet during suckling rapidly leads to hyperinsulinism. Moreover, when these female rats become pregnant, hyperinsulinism also rapidly appears in their offspring even though they are fed a normal diet, suckling milk from their mothers[94]. Epigenetic regulation of gene expression involves chemical modification of chromatin by enzymes such as sirtuins (SIR2-related proteins), whose activities are linked to cellular energy stores and in lower organisms, sirtuin signaling interface with insulin signaling pathways[95,96] and SIR2 orthologues could possibly be involved in the pathogenesis of fatty liver disease.

Timers of fatty liver disease

Many biological processes are timed and there is a biological clock which keeps the time at the molecular level. Recent

studies have revealed that endogenous rhythms are generated at the cellular level by circadian core oscillators, which are composed of transcriptional/translational feedback loops involving a set of *CLOCK* genes. Obese diabetes attenuated this rhythmic expression in most of the clock and adipocytokine genes in adipose tissue. There was impairment in the rhythmic expression of the *CLOCK* genes in the liver as well. Interestingly, pioglitazone treatment improved the attenuated rhythmicity in the liver but not the adipose tissue[97]. A recent human study suggests a potential role of the *CLOCK* gene variants and their related haplotypes increased susceptibility to NAFLD and disease progression[98].

FATTY LIVER: THE MANY FACES IN CLINICS

The classic 'metabolic syndrome associated NAFLD'

The 'classical NAFLD' which is the 'fatty liver of affluence' is the commonest form and is associated with metabolic syndrome and can be viewed as a special class of adipose tissue malfunction and disordered lipid homeostasis. MS can be consider MS as inappropriate expression of 'thrifty genes' resulting in obesity, abnormal fat deposition, dyslipidemia, diabetes, pro-inflammatory (and pro-neoplastic?) states[99]. NAFLD, which is characterized by abnormal fat deposition in liver and chronic pro-inflammatory state, has been considered as a liver manifestation of MS[100]. This is substantiated by the epidemiological data where 50%-80% of the NAFLD has associated MS depending on the area studied and methods adopted. The association of NAFLD with MS and IR has been extensively reviewed by Marchesini *et al* and Cortez-Pinto *et al*[4,100].

Metabolic Syndrome is a tool for identifying individuals who are at the cardiovascular risk rather than a single disease. NAFLD is gaining importance in this context. Recent studies have reported the association of NAFLD with multiple classical and non-classical risk factors for cardiovascular disease (CVD). Moreover, there is a strong association between the severity of liver histopathology in NAFLD patients and greater carotid artery intima-media thickness and plaque, and lower endothelial flow-mediated vasodilation (as markers of subclinical atherosclerosis) independent of obesity and other MS components[28-30,101,102].

Identification of MS is very useful not only as a tool to identify people with cardiovascular and diabetic risk but also NAFLD but much confusion exists in the criteria of MS[103]. Criteria for MS should be convenient but flexible to the regional and ethnic differences is important in establishing its association with NAFLD, a disease which progress asymptomatically to cirrhosis[104]. There exists significant genetic environmental and life style diversity in population across different continents and cultures. For example Asian Indians are prone to central obesity and for same degree of weight gain are more insulin resistant[105-107].

In case of other well known syndromes, a single or a few well defined genetic defects results in the clustering of a host of strongly associated phenotypic features. But in MS, a host of poorly defined genetic defects results in loosely associated clustering of phenotypic features. The primary underlying causes of the metabolic syndrome are thought to be insulin resistance. Central obesity almost certainly is a major cause of insulin resistance[103]. There is considerable doubt whether all patients with the metabolic syndrome are indeed insulin resistant[103]. Many nondiabetic adults with a wide range of age and body mass are hyperinsulinemic and insulin resistant (about 50%), approximate 25% are insulin resistant but without hyperinsulinemia and the same proportion are hyperinsulinemic but without insulin resistance[103,107]. Thus the lack of consensus regarding MS criteria, insulin resistance cut off value together with the complex pathogenesis of hepatic steatosis makes it difficult to evaluate their association.

The lean nonalcoholic fatty liver disease

It became clear that Non-alcoholic steato hepatitis (NASH) has an equal sex distribution and that many, perhaps even the majority of patients according to some reports are neither obese nor diabetic[108].

We already described the importance of adipose tissue in fatty acid buffering. Several congenital forms of lipodystrophy are associated with fatty liver. Berardinelli-Seip syndrome caused by mutation of *BSCL2* gene is characterized by a near-total lack of body fat from birth. Interestingly *BSCL2* gene is highly expressed in the brain but only modestly in adipocytes, suggesting a role for the central nervous system in the pathogenesis[109]. MRI studies also reveal a near-complete absence of metabolically active adipose tissue from most subcutaneous areas, intraabdominal and intrathoracic regions and bone marrow. Fatty liver has been noted during infancy and can lead to cirrhosis and its complications. They show extreme insulin resistance[110].

Dunnigan variety of familial partial lipodystrophy and Mandibuloacral dysplasia (type-A lipodystrophy) are associated with laminin gene mutation, causes fatty liver and IR. PPAR-γ mutations result in a dominant form of lipodystrophy and fatty liver. Similarly in acquired lipodystrophies like Lawrence syndrome; hepatomegaly due to fat infiltration is a consistent finding[110].

In patients who undergo liposuction or other forms of obesity reduction surgery, fatty liver is a common finding. Highly active antiretroviral therapy (HAART) therapy for HIV, a combination that includes HIV-1 protease inhibitors, is associated with the development of lipodystrophy in the majority of patients after 18 mo to 2 years of treatment. It is characterized by fatty liver following marked reduction in subcutaneous fat from the face, trunk and limbs, resulting in an appearance of "increased muscularity". These patients are prone to develop insulin resistance, hypertriglyceridemia and fatty liver[111]. In animal models of lipodystrophy IR and fatty liver are corrected by infusion of adipokines[112]. This underscores the role of adipokines in modulating the response of adipose tissue and as messengers to other organs in response to changing energy environment and adaptive mechanisms like IR. Removal of adipose tissue causes IR and fatty liver in hamsters[113]. It is well known that patients who undergo liposuction as a treatment for

obesity do not show metabolic benefits[21]. It won't be surprising if liposuction worsens insulin resistance and fatty liver as this procedure removes active adipocytes from subcutaneous spaces. Thus, any defect that prevents adipose tissue from acting as an 'energy rich substrate sink' would result in fatty liver.

The fatty liver associated with infectious and immunological disorders

Fatty liver is associated with many chronic inflammatory conditions. Hepatitis C especially type 3 genotype is associated with fatty liver in nearly 50% of the patients. In patients with chronic liver disease due to hepatitis C virus, the major adipokine adiponectin was positively correlated with hepatic inflammation and adiponectin receptors were differentially regulated in the setting of hepatic insulin resistance[114]. It has been shown, that HCV internalization is facilitated *via* LDL (low density lipoprotein) receptors and the virus enters into the cell via endocytosis. More recently, a broadly expressed lipoprotein binding receptor, the human scavenger receptor class B type 1 was shown to serve as a receptor for HCV[115]. According to Younossi the HCV genotype 3 core protein inhibits very low-density lipoprotein (VLDL) secretion, leading to hepatic steatosis. Several studies demonstrate that steatosis disappears after patients with hepatitis C genotype 3 achieve a sustained response. The resolution of steatosis after treatment strongly supports the association between hepatic steatosis and HCV genotype 3[116].

Though less frequently, Hepatitis B is also associated with fatty liver. The hepatitis B virus encoded protein, HBx causes lipid accumulation in hepatic cells which mediated is by SREBP1 and PPARγ[117].

Fatty liver has been reported with certain bacterial infections like Q fever[118].

Autoimmune diseases like systemic lupus erythematosis (SLE) and rheumatoid arthritis *etc* are also associated with fatty liver[119].

There are reports that NAFLD is characterized by a low-grade systemic inflammation[120]. This could be partly because of the association of NAFLD with obesity which is a pro-inflammatory state. Conditions that induce inflammatory state in liver might in long term stimulate adipocytes and macrophages because they have a common ancestry and hence they share many cytokines, growth factors and signaling pathways[8-11,13]. There are many ways by which fat is deposited in liver but it is the body's response to fat and its derivatives which determines the progress of the disease from simple fatty liver to steatohepatitis and cirrhosis.

The xenobiotic fatty liver

NASH features are also encountered as an adverse reaction to a few drugs-for example, amiodarone and perhexiline. Drug like methotrexate, aspirin, vitamin A, glucocorticoids, amiodarone and synthetic estrogen causes macrovescicular steatosis while microvesicular is caused by valproic acid, tetracycline, nucleoside analogues etc. Chronic alcoholism causes predominantly macrovescicular steatosis[121,122]. However some hepatocytes in these livers with microvesicular steatosis may also reveal a macrovesicular fatty change, implying that with the progression of disease some of these small lipid vacuoles may fuse to become a large droplet.

The metabolism of ethanol enhances the level of NADH in the liver which, in turn, stimulates the synthesis of fatty acids and their incorporation into triglycerides. Ethanol mediated impairment or inhibition of PPAR-α and PPAR-γ and stimulation of SREBP, the receptor molecules that control the enzymes responsible for the oxidation and synthesis of fatty acids, respectively, appear to contribute to the overall lipid load in the alcoholic liver[59].

These xenobiotics cause steatosis by a host of mechanisms. Drugs like tetracycline, aspirin etc do so predominantly by inhibiting hepatic fatty acid oxidation[49]. Jamaican vomiting syndrome which is caused by hypoglycin-A present in unripened ackee fruit[121,123] is an example for natural toxins inducing fatty liver. Estrogen, various pesticides etc probably induces various nuclear receptors like FXR, PXR, CXR, LXR, PPARs *etc.* involved in lipid homeostasis as these nuclear receptors are promiscuous[76,77]. There is a paucity of literature and much research has to be done in this field.

Reye's syndrome and Reye like syndrome associated fatty liver

This acute illness is encountered exclusively in children below 15 years of age classically following a viral infection and the use of aspirin. It is characterized clinically by vomiting and signs of progressive central nervous system damage, signs of hepatic injury and hypoglycemia. Morphologically, there is extensive fatty vacuolization of the liver and renal tubules. There is mitochondrial dysfunction with decreased activity of hepatic mitochondrial enzymes. There are reports linking Thioredoxin Binding Protein-2, a protein that interacts with thiredoxin which is an important redox regulator protein and Rye's syndrome. Individuals with genetic deficiencies in fatty acid transport and mitochondrial oxidation show a similar pathology to Reye syndrome, which is defined as a Reye-like syndrome, such as CPT deficiency[84,85].

The fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a syndrome that occurs late in pregnancy and is often associated with jaundice and hepatic failure. AFLP has an incidence of 1 per 13000 deliveries. It affects women of all ages and races. The liver is typically small. AFLP is more common when the mother is carrying a male fetus and associated with a deficiency of long-chain-3-hydroxy acyl COA dehydrogenase (LCHAD). Preeclampsia or the HELLP syndrome, which may complicate eclampsia, presents in a similar fashion and progresses to severe liver dysfunction, though typically with a normal size liver. Aminotransferase elevations are typically modest in all of these conditions[124].

An association between recurrent maternal acute fatty liver of pregnancy with a fetal fatty acid oxidation disorder was reported first in two siblings who both died at 6 mo of age[125]. In another study involving 11 pregnancies in 5 mothers where 6 babies had confirmed deficiency of LCHAD, by enzymatic analysis of cultured skin fibroblasts. The mothers had either AFLP or HELLP

Table 1 Fatty liver: the many faces in clinics

Classification of fatty liver	
Classic metabolic syndrome associated fatty liver	'Fatty liver of the affluent': commonest form of fatty liver; associated with metabolic syndrome
The lean nonalcoholic fatty liver	Includes lipodystrophies, known and unknown adipose tissue defects of various origin resulting in lean phenotypes, liposuction (?)
Fatty liver of infection/ chronic inflammatory diseases	HCV, HBV, Q fever (?) autoimmune diseases
Xenobiotic fatty liver	Drugs like tetracycline, amiodarone, alcohol, environmental industrial toxins
Fatty liver of defective fatty acid catabolism	Reyes syndrome, reye like syndrome, sudden infant death syndrome, fatty liver of pregnancy
Malnourishment associated fatty liver	'Fatty liver of the deprived' : kwashiorkor
Transient fatty liver	Fatty liver which develops transiently following short excess calorie intake

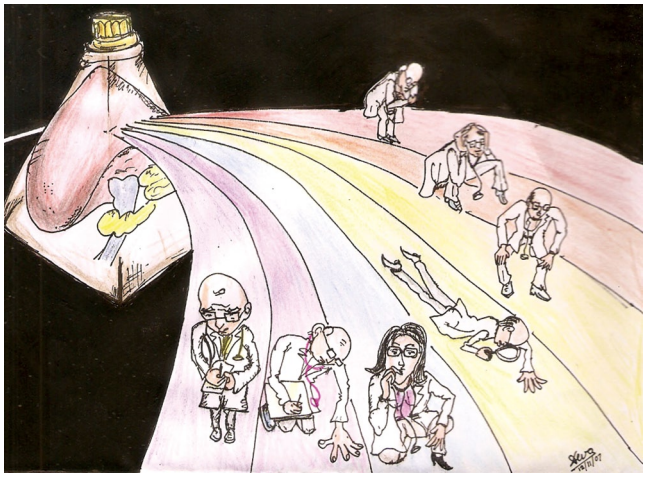

Figure 6 With the progress of medicine at molecular level diseases like type 2 diabetes and 'NAFLD' which results from a spectrum of genetic defects would split into hundreds if not thousands of diseases with 'individual' identity providing patients' accurate diagnosis of the disease and accurate treatment with minimum 'side effects' which is unavoidable in today's 'blind clinical practice'.

syndrome in all six pregnancies with the LCHAD deficient fetuses[126]. However how fetal defects induce acute fatty liver in mothers is still not clear.

Fatty liver in malnutrition

Protein malnutrition, especially in infancy and early childhood, accounts for most cases of severe fatty liver in the tropical zones of Africa, South America, and Asia. The hepatic changes may be associated with other clinical and pathologic features of Kwashiorkor. High plasma levels of free fatty acids are generally regarded as a key biochemical feature of the condition. Glucose intolerance is another characteristic feature. Interestingly in marasmus, a form of protein-calorie malnutrition, fatty liver is not part of the clinical picture[127].

The benign fatty liver-the non-progressive fatty liver

Kagansky *et al* evaluated 91 octogenarians (mean age, 85.56 ± 3.76 years) to determine the prevalence and the clinical presentation of NAFLD in the elderly. Among these patients, who had been admitted to a geriatric hospital, about 50% were diagnosed with NAFLD. An association of NAFLD with the metabolic syndrome or advanced liver disease was not observed in this older patient population. These data indicate that NAFLD is a common and relatively benign finding in the elderly[128]. Another study, examined sequential liver biopsies obtained from 103 NAFLD patients. The mean interval between biopsies was about 3 years and found that the stage of fibrosis slowly progressed in 37% of patients but remained stable in 34%[129]. The observation that NAFLD patients without NASH have a benign prognosis confirmed in several other studies as well[130].

Transient fatty liver

It is possible that fatty liver is physiological than pathological under certain circumstances for example after a fat carbohydrate rich diet for a short period. Increase in hepatic TG content can occur within 10 d after starting the high-fat diet in mice[131]. Overnight fasting increases plasma FFA to such an extent that liver TG content increases in dogs[132]. It is logical to assume that as in laboratory animals transient fatty liver follows a short term calorie rich diet in man as well. Unfortunately there is no diet related guide line for ultrasonological determination for fatty liver in the diagnosis of NAFLD. Ideally the subject should be on 'normal' and balanced diet at least for a week prior to ultrasonological evaluation for NAFLD. In a large population based study involving 4401 subjects it was observed that fatty liver regressed in a significant number of participants; fatty liver regressed in 14% of men and 25% of women[133]. In another follow up study involving sequential liver biopsies from 103 NAFLD patients it was observed that disease regressed in 29% of the cases[129]. In another recent study fatty liver regressed in nearly 1 of every 2 cases and had a substantially benign course[134]. A carbohydrate rich but fat deficient diet may predispose to fatty liver as surplus carbohydrate induce adipogenic genes[135]. This could well explain the fatty liver, which follows total parenteral nutrition[136].

The classification of fatty liver is summarized in Table 1.

NEED FOR PERSONALIZED MANAGEMENT OF NAFLD: NO TWO PEOPLE ARE THE SAME!

The advances in science would soon empower us to understand subtle differences between two individual patients at genotypic and phenotypic levels. It seems likely that a major focus of medicine over the next two decades will be within the arenas of 'pathogenomics', molecular diagnostics and 'pharmacogenomics' as a prelude to personalized molecular medicine. All polygenic

diseases like type 2 diabetes and 'NAFLD' would split into hundreds if not thousands of diseases with 'individual' identity providing patient' accurate diagnosis and accurate and effective treatment with minimum 'side effects' which is unavoidable in today's 'blind clinical practice' (Figure 6).

The difference in genotype and environment could explain the differences in the results observed even between drug well controlled drug trials and why certain drug therapies are effective only in certain individuals.

Above all, molecular level diagnosis and personalized treatment is more important because of difference in life style and environmental factors which are detrimental in the disease progress and treatment options. As mentioned before interactions between the genotype, phenotype and environment determines the disease process.

CONCLUSION

Currently the term NAFLD is loose to incorporate a host of diseases presenting with fatty liver in the absence alcohol abuse. 'Insulin resistance associated fatty liver' is the commonest type which could result from a variety of genetic, epigenetic defects and environmental factors. Clinically fatty liver is an important sign in predicting the risk of diabetes, cardiovascular accidents, stroke, cirrhosis and cancer. Individual variability in evaluating alcoholism and histopathological specimens, the variety of genetic defects presenting as fatty liver, together with the absence of reliable disease markers makes the accurate diagnosis of NAFLD difficult. Fat accumulation results from imbalance between feeding and physical activity, inflow and out flow, synthesis and oxidation. At molecular level defects in nuclear receptor signaling involving lipid sensing, synthesis and oxidation, defects in the lipid influx-efflux channels, proteins involved in insulin signaling, fatty acid catabolism, molecular defects in adipose tissue development, maturation and function and neural signaling can cause steatosis.

Bundling of several genetic defects under same diagnosis can result in inefficient patient management. With the advances in molecular medicine and diagnostics, diseases like NAFLD and Diabetes Mellitus Type-2 which are currently considered and managed as single entities would split into several distinct entities which might differ in management. Thus exploration of the molecular and genetic basis of NAFLD will allow us to segregate and manage them appropriately.

Abstract

Many advances have been made in the understanding of Crohn's disease (CD) pathogenesis during the last decade. CD is currently seen as a predominantly T-lymphocyte-driven disease characterized by the presence of a complex cocktail of interacting cytokines, chemokines and other mediators produced by a variety of cell types. Prevailing theories of CD pathogenesis suggest that patients' T-lymphocytes are inappropriately activated in the setting of an immune imbalance, which is itself caused by an unfortunate confluence of genetic and environmental factors. The T-cell response then leads to the chronic inflammation characteristic for the disease. Various environmental factors may play a role in the development of CD, but microbes are most consistently implied. This theory is based on epidemiological, clinicopathological, genetic and experimental evidence. Despite the abundance of arguments for the implication of bacteria in the etiopathogenesis of CD, the precise role of bacteria in this disease still remains elusive. Three not necessarily mutually exclusive theories have been proposed: (1) an unidentified persistent pathogen; (2) an abnormally permeable mucosal barrier leading to excessive bacterial translocation; and (3) a breakdown in the balance between putative "protective" versus "harmful" intestinal bacteria ("dysbiosis"). At present, one cannot exclude with certainty any of these three proposed hypotheses; they may all apply to CD to a certain extent.

INTRODUCTION

Many advances have been made in the understanding of Crohn's disease (CD) pathogenesis during the last decade. CD is currently seen as a predominantly T-lymphocyte-driven disease characterized by the presence of a complex cocktail of interacting cytokines, chemokines and other mediators produced by a variety of cell types. Prevailing theories of CD pathogenesis suggest that patients' T-lymphocytes are inappropriately activated in the setting of an immune imbalance, which is itself caused by an unfortunate confluence of genetic and environmental factors. The T-cell response then leads to the chronic inflammation characteristic for the disease.

MICROBES, AN ENVIRONMENTAL FACTOR IMPLIED IN CD PATHOGENESIS

Various environmental factors such as smoking, appendectomy and the composition of the diet may play a role in the development of CD[1-6]. Microbes are however the most consistently implied factor in CD pathogenesis. This theory is based on epidemiological, clinicopathological, genetic and experimental evidence.

Epidemiological evidence

Evolutions in the epidemiology of CD during the second half of the 20th century may be explained in part by changes in the exposure of the human intestine to microbes over the same period. Some investigators propose that increased hygiene and the concomitant delayed exposure to enteric pathogens have contributed to the surging incidence of CD[7]. Not only the timing but also the type of microbes to which the gut is exposed may be important[8]. Changing dietary practices such as decreased consumption of oats, rye and bran, increased consumption of uncooked pork, unpasteurized milk and cheeses, and drinking well water instead of tap water may all favour a shift from a "protective" to a "harmful" gastrointestinal (GI) flora[9]. The "cold chain hypothesis" postulates that

CD results from an increased and chronic exposure to microbes which are able to survive at low temperatures (so-called psychrotropic bacteria, such as *Listeria monocytogenes*, *Yersinia enterocolitica*, *Clostridium botulinum* and *Bacillus cereus*). The chronic ingestion of these bacteria, new in the 20th century, would result from the increasingly common use of refrigeration in food preparation and storage, with the domestic refrigerator as the final step in the cold chain[10]. Another possible cause of sustained alterations in the gut microbiota is the increased use of antibiotics in human and veterinary medicine. Insufficient doses of antibiotics can induce a capacity for toxin production in bacteria or can make them invasive. It has been documented that prior antibiotic therapy can promote the outbreak of CD, and antibiotic use 2-5 years pre-diagnosis has an odds ratio of 1.32 in CD incident cases after adjusting for age, sex, smoking and the use of other drugs[11,12].

Clinicopathological evidence

The clinicopathological features of incident and recurrent CD, including its extra-intestinal manifestations, can be mimicked to a certain degree by specific enteric infectious diseases. Most notable in this regard are *Campylobacter*, *Salmonella*, *Shigella* and *Yersinia* infections. These can all present with an endoscopic picture of focal/segmental enterocolitis. *Yersinia* species (spp) may persist for a long time in the bowel wall and sustain chronic inflammation with its attendant consequences for tissue architecture. Differential diagnosis is by stool or blood culture or serology, as biopsies can show focal active colitis reminiscent of CD[13-22]. Other infectious microorganisms, which can cause diagnostic confusion, are *Escherichia coli (E. coli)* serotype O157:H7[23], *Chlamydia trachomatis*[24], *Mycobacterium tuberculosis*[25], *Actinomyces* spp[26], *Entamoeba histolytica*[27], *Giardia lamblia*[28], *Blastocystis hominis*, *Cryptococcus neoformans* and *Histoplasma capsulatum*.

Diarrhoea is a major symptom of CD, but also of infectious gastro-enteritis. This may occasionally cause differential-diagnostic problems. Infection with enteric viruses such as rotavirus, Norwalk-agent or adenovirus may provoke an exacerbation of pre-existing CD and thus enters in the differential diagnosis of CD relapse[29]. Acute bacterial enteritis can be confused with a first attack of CD, especially if stool cultures remain negative. Fulminant CD colitis with toxic dilatation, while being rare, is commonly treated surgically. These cases may be confused with infection by *Entamoeba histolytica*, *Salmonella* spp, *Campylobacter jejuni* and *Clostridium difficile*, which can sometimes be treated medically[30,31]. Chronic diarrhoea in immunocompetent patients is generally caused by non-infectious diseases like CD. The three most common infectious causes are *Giardia lamblia*, *Entamoeba histolytica* and *Clostridium difficile* (the latter can be provided with a niche by previous use of antibiotics). The clinicopathological manifestations in all three can be confused with CD. Clinical activity of CD may diminish with CD4 T-cell depletion in AIDS. On the other hand, very low CD4-counts may allow the development of AIDS-related GI infections[32]. Microscopic examination of a colonoscopic biopsy set may be helpful in the differential diagnosis between infectious gastro-enteritis and a first attack or relapse of CD. Infectious disease usually shows a picture of acute self-limited colitis, although this may evolve over time in focal active colitis. In such cases, differential diagnosis from CD becomes more difficult[33]. It should be noted that the typical histological features of chronic inflammatory bowel diseases (basal plasmocytosis, crypt distortion, villous colonic mucosa, crypt atrophy) increase in frequency with longer disease duration[34].

Infections may also arise as side-effects of CD therapy. Induction and maintenance of remission in active disease are usually obtained by suppressing the adaptive immune system. The attending risk is a re-activation of suppressed infectious agents or the creation of new opportunities for opportunistic pathogens. Examples of such infectious agents are *Clostridium difficile*, *Mycobacterium tuberculosis*, *Aspergillus spp*, cytomegalovirus, varicella-zoster virus and Epstein-Barr virus. The surgical treatment of CD can be complicated by abdominal wound sepsis (e.g. by *E. coli*, *Proteus spp* and *Staphylococcus aureus*), unless antibiotic prophylaxis was applied. The increased risk of surgical infections may be related to the high degree of bacterial translocation in CD[35].

It has been observed that CD recurrence in the neoterminal ileum after curative ileal resection depends on the presence of the faecal stream[36]. Histopathological and electron microscopic studies have shown that intestinal contents trigger postoperative recurrence proximal to the ileocolonic anastomosis already in the first days after surgery[37]. Metronidazole therapy for 3 mo decreases the severity of this early endoscopic recurrence and seems to delay symptomatic recurrence as well[38]. Likewise, ornidazole treatment for up to 1 year significantly reduces the endoscopic and clinical recurrence rate of CD after surgery[39]. The construction of a nipple valve may delay and perhaps prevent symptomatic recurrence[40]. A possible explanation is that the anastomotic configuration may influence colonization rates in the neoterminal ileum. When compared with controls, the neoterminal ileum in CD patients is more heavily colonized by *E. coli*, enterococci, bacteroidetes and fusobacteria[41].

Genetic evidence

In 2001, two independent groups identified the CARD15 gene on chromosome 16q as a susceptibility gene in CD. Three common single-nucleotide polymorphisms (SNPs) of this gene were found to be associated with development of CD: two missense mutations, Arg702Trp (SNP8) and Gly908Arg (SNP12), and a frameshift mutation, Leu1007fsinsC (SNP13)[42,43]. The CARD15 protein functions as an intracellular receptor for muramyl dipeptide (MDP), the minimal structural motif of peptidoglycan, a common component of gram-positive and gram-negative bacterial cell walls. MDP may enter the cytosol via the transporter protein hPepT1 and then binds to the C-terminal leucine-rich repeat (LRR) domain of the CARD15 protein[44]. Upon recognition of MDP, CARD15 activates the nuclear factor kappa B (NF-κB) pathway via a Rick/Rip2 interaction[45]. Because NF-κB is a key factor in the inflammatory response, CARD15 is considered as a pro-inflammatory molecule. The CD-associated mutations of the CARD15 gene affect the LRR domain of the protein and thus may impair its pro-inflammatory function. This

has potentially serious consequences given the normal expression of CARD15 in cells of the monocyte lineage and in Paneth cells, which are both involved in antibacterial defense[46-48]. The increased odds ratio for CD in double-dose CARD15 mutation carriers, the impaired defensin production by Paneth cells in ileal CD[49,50], data from *in vitro* models of transiently transfected cell lines[51-53] and a loss of response to MDP observed in *ex vivo* analyses of circulating monocytes from CD patients[54] all suggest a loss-of-function model for CARD15 in CD. It seems paradoxical that loss of function in a pro-inflammatory molecule such as CARD15 can cause an inflammatory condition such as CD. Most authors propose that defective recognition of bacterial components allows an increased bacterial proliferation in the gut, which in turn would be a powerful stimulus for the adaptive immune system. The end result might seem a T-lymphocyte-driven disease. Attractive as this theory is, it remains however at present wholly speculative. It should be noted that other explanations for the paradox have been offered as well[55-58].

Experimental evidence

There are currently more than 20 animal models of chronic inflammatory bowel disease. These models can be divided into 4 groups: (1) genetically induced as a result of deletion (e.g. $IL10^{-/-}$, T-cell receptor mutant mice) or overexpression of genes (e.g. IL7 transgenic mice, HLA-B27 transgenic rats); (2) adoptive transfer models (e.g. the CD45RB transfer model, the heat shock protein 60 CD8 T-cell transfer model); (3) inducible colitis models (e.g. TNBS- or DSS-induced colitis); and (4) spontaneous colitis models (e.g. C3H/HejBir mice, SAMP1/Yit mice)[59]. All the genetically engineered mouse models require commensal enteric bacteria for the development of intestinal inflammation. Various organisms including *Helicobacter* spp and *E. coli* have been implicated[60,61]. The role of the flora in the initiation of inflammation may be host-dependent. Development of inflammation in these animal models further requires a particular genetic background and the presence of T-helper cells[62].

THE PRECISE ROLE OF BACTERIA IN THE PATHOGENESIS OF CD

Despite the abundance of arguments for the implication of bacteria in the etiopathogenesis of CD, the precise role of bacteria in this disease still remains elusive. Three not necessarily mutually exclusive theories have been proposed: (1) an unidentified persistent pathogen; (2) an abnormally permeable mucosal barrier leading to excessive bacterial translocation; and (3) a breakdown in the balance between putative "protective" versus "harmful" intestinal bacteria ("dysbiosis").

The unidentified persistent pathogen theory

The similarities between CD and some forms of infectious enterocolitis are sufficiently evident that numerous specific microbial aetiologies for CD have been proposed over the years. One of the first descriptions of what later became known as "Crohn's disease"[63] was made by Dalziel in 1913[64]. He noted similarities between his cases of "chronic interstitial enteritis" in humans, and Johne's disease in cattle, which is caused by *Mycobacterium avium subsp paratuberculosis (MAP)*. He therefore suggested that *MAP* may have been the cause of the disease which he described. This hypothesis has since been tested extensively by numerous investigators, and evidence has accumulated both in favour and against the theory. *MAP* has been cultured from CD tissues[65] and peripheral blood of CD patients[66], although not uniformly[67]. The variability in the results may be partly due to the fastidious culture requirements of the cell wall-deficient forms ("L-forms") of *MAP*, which are reportedly present in CD. Detection rates for *MAP* DNA in CD tissues using a specific PCR range everywhere from 0% to 100%[68-70]. This large variation may be due to differences in DNA extraction techniques or to geographical variations in the prevalence and modes of transmission of *MAP*[71]. Investigation of the presence of an immune response to *MAP* antigens in CD patients has also yielded both positive and negative results[72,73]. Enthusiasm for *MAP* as the causative agent of CD has further diminished after the recent publication of the results of a large, prospective, placebo-controlled, double-blind, randomized trial of 2 years clarithromycin, rifabutin and clofazimine in active CD, with a further year of follow-up included in the study design[74]. Although after 16 wk treatment significantly more subjects were in remission in the antibiotic arm than in the placebo arm, this benefit could not be sustained later on. After two years, the relapse rate was similar in the antibiotic and the placebo group. The good result in the first 16 wk may have been due to concomitant administration of a tapering course of prednisolone, which can have non-specific bacterial effects. Numerous other specific bacteria have been proposed as candidate causative agents of CD, including *Pseudomonas maltophilia*[75], *Mycobacterium kansasii*[76], *Chlamydia trachomatis*[77], *Bacteroides fragilis*[78] and *Listeria monocytogenes*[79]. Like *MAP*, *P maltophilia* and *M kansasii* were first isolated from CD tissues as L-forms. This is by no means a rare phenomenon as a variety of other bacteria such as *Enterobacteriaceae*, *Staphylococcaceae* and *Streptococcaceae* have been cultured from tissues of IBD patients (but not from control subjects) as L-forms as well. Recovery rates of these L-forms are apparently not influenced by previous medical treatment. This suggests either that L-forms may be involved in disease causation, or that their presence in mucosal biopsies is a result of the disease process itself[80]. Adherent-invasive *E. coli* (AIEC) is a specific pathovar which has been isolated from the intestinal mucosa of CD patients. The reference strain LF82 is able to adhere to intestinal epithelial cells, to invade these cells via a mechanism involving actin polymerization and microtubules organization, and to survive and replicate within macrophages[81-83]. Recently, it was shown that pathogenic B2+D *E. coli* strains are significantly more abundant in IBD patients than in controls. The B2+D phylogenetic groups are associated with the presence of serine protease autotransporter proteins and adherence factors and may have a significant role in disease aetiology[84].

The excesssive bacterial translocation theory

Bacterial translocation can be defined as the passage of

viable endogenous bacteria from the GI tract to mesenteric lymph nodes and other internal organs. The proportion of surgically treated CD patients with bacterial translocation prior to antibiotics administration varies between 30% and 50%, which is much higher than in controls (5%-15%). This suggests that bacteria leak from the bowel lumen in a high proportion of CD patients. The translocating bacteria may be involved in the pathogenesis of fistulas and abscesses, and translocation may predispose patients undergoing laparotomy to the systemic inflammatory response syndrome. Bacterial strains involved in translocation include *E. coli*, *Enterococcus* spp, *Clostridium perfringens*, *Proteus* spp and *Bacteroides fragilis*. Distension of the intestine proximal to a stricture may predispose to bacterial translocation[85,86].

The dysbiosis theory

The human gut contains a large number of microorganisms, most of which belong to the domain Bacteria. The intestine of an adult human individual may contain more than 500 different bacterial species at any moment, with 30-40 species comprising up to 99% of the total population[87]. The concentration of bacteria increases along the small bowel from approximately 10^4 in the jejunum to 10^7 colony-forming units (CFUs) per g of luminal content at the ileal end, with predominance of gram-negative aerobes and some obligate anaerobes. The colon is heavily populated by strictly anaerobic bacteria at concentrations of approximately 10^{12} CFUs per *g* of luminal content[88]. The traditional method to investigate the composition of the gut flora is culture-based: bacteria are isolated on selective growth media and identified by phenotypic characteristics. However, over 50% of the bacterial cells observed by microscopic examination of a faecal specimen cannot be grown in culture. Molecular biologic techniques have recently been developed to characterize these bacteria. These new techniques are largely based on the sequence diversity of the 16S rRNA gene. This gene is essential for the survival of all bacteria, since it encodes a part of the ribosomal RNA. Its sequence contains well-preserved and more variable parts. The variability between the 16S rRNA gene sequences of two bacterial species can be used as a measure for their phylogenetic distance. Alternatively, the 16S rRNA gene sequence can be used to identify or characterize the bacteria present in a biological specimen, even if they are not cultivable. A large number of 16S rRNA gene sequences (> 79 000) are currently available in public databases[89].

Several studies using different methods have repeatedly shown that the faecal microflora differs between CD patients and healthy controls, although the reported changes are not always consistent[90]. Bowel contents in quiescent CD are characterized by high total viable counts, high biodiversity and temporal stability. There is an increased number of obligate anaerobic Gram-negative rods, e.g. *Bacteroides fragilis* and *B vulgatus*. Many unusual species are also present in low numbers. On the other hand, counts of butyrate-producing Firmicutes (especially those of the *Clostridium leptum* group) are typically diminished. This may lead to an increased frailty of the intestinal epithelium[91-97]. The observed changes are independent of disease location, the presence of anatomical abnormalities secondary to inflammation or scarring, treatment with sulphasalazine or corticosteroids and even surgery. It has therefore been suggested that the faecal flora abnormalities in CD may be due to constitutional factors[98-102]. CD relapse causes huge disturbances in faecal flora composition. With diarrhea, total viable counts diminish due to a decrease in the number of strictly anaerobic bacteria (e.g., bifidobacteria). There is also a shift towards facultative anaerobes (particularly *E. coli*)[103,104].

The alterations in the luminal or faecal flora in CD patients are however not necessarily relevant for what happens at the mucosal level. Most studies of the mucosal flora report an increased likelihood to obtain positive culture results and higher total viable counts in CD patients' biopsies than in controls, especially in the ileum. Mucosa-associated bacteria in CD typically form a thick, densely populated biofilm associated with the mucus which covers the intestinal epithelium. Bacterial concentrations are higher in normal-looking CD mucosa than in biopsies obtained from visibly inflamed areas[105-111]. Not only the abundance but also the composition of the mucosa-associated flora is abnormal in CD. In general, the prevalence of the phyla Proteobacteria and Bacteroidetes is increased at the expense of the phylum Firmicutes[112]. Facultatively anaerobic bacteria (enterobacteria and enterococci) are found more frequently in ileum biopsies from CD patients than in normal subjects[113]. Taken together, the literature data suggest that the mucosal flora in CD patients is abnormal even before the onset of inflammation[114].

CLINICAL IMPLICATIONS

Given the abundant evidence for a role of bacteria in the pathogenesis of Crohn's disease, it has been suggested that the intestinal bacterial flora can be manipulated for therapeutic purposes. Several investigators have reported on the use of antibiotics and probiotics in CD patients. From these data, it appears that treatments must be individualized, depending on disease location and activity[115].

Antibiotics

Antibiotic therapy in Crohn's disease may decrease the number of mucosa-associated bacteria, kill or suppress bacterial variants which induce early histological lesions, and reduce the rate of bacterial translocation. Broad-spectrum antibiotics are frequently and successfully used in the treatment of mild to moderate CD, although no large controlled trials have yet been performed[116].

Metronidazole has been most extensively investigated. This antibiotic is active against strictly anaerobic bacteria. It has been used in monotherapy, especially with colonic and ileocolonic CD, but not for ileitis[117-120]. It has however many side-effects such as nausea, anorexia, dysgeusia, dyspepsia and peripheral neuropathy, which may limit its use.

Other antibiotics have also been tested. Ciprofloxacin therapy is one of the potential treatments of active CD, and is also effective when used in combination with standard treatment in patients with resistant disease[121,122]. Combined ciprofloxacin plus metronidazole treatment has

been shown to be a potential alternative to steroid therapy in the acute phase of CD, although it is more effective in colonic than in isolated small bowel disease[123,124]. The combination of ciprofloxacin and metronidazole is also used in the treatment of perianal CD[125]. Other antibiotics which have been tested are rifaximin[126] and clarithromycin[127].

Probiotics

Probiotic therapy is one possible approach to the prevention of relapse in CD patients. Several microorganisms such as *E. coli* Nissle, *Lactobacillus GG* and *Saccharomyces boulardii* have been tested. At present however, there is no evidence that these probiotic preparations perform better than placebo or aminosalicylates in this setting. The use of probiotics as a maintenance therapy for medically or surgically induced remission in CD is therefore currently not recommended[128].

CONCLUSION

At present, one cannot exclude with certainty any of the three proposed hypotheses on the role of bacteria in CD etiopathogenesis. Uninflamed bowel mucosa in CD may be heavily colonized by facultative anaerobe and/or aerotolerant bacteria, possibly due to a genetically determined defect in the capacity of the mucosa to "hold back" such bacteria. The ecological conditions prevailing in this mucosa-associated biofilm may then enable some bacteria to acquire particular virulence traits by horizontal gene transfer. Eventually, pathovars may arise which have an increased capacity for adherence to and invasion of the mucosa. Aphtoid ulcerations may develop in this setting. Once the mucosal integrity is broken down, bacterial translocation through the bowel wall is greatly enhanced and may lead to the development of complications such as fistula and abscesses. The human body may then react with a basically appropriate but uncontrollable inflammatory response which leads to further tissue damage. While this disease causation theory stresses global disturbances in the composition of the bowel flora and increased bacterial translocation, it cannot be excluded that specific bacteria may be particularly damaging to people who are genetically susceptible to the development of CD. The adherent-invasive *E. coli* pathovar is perhaps the most likely candidate in this regard.

Abstract

Colorectal cancer (CRC) remains a leading cancer killer worldwide. But the disease is both curable and preventable at an early stage. Regular CRC cancer screening has been shown to reduce the risk of dying from CRC. However, the importance of large-scale screening is only now starting to be appreciated. This article reviews a variety of imaging procedures available for detecting ulcerative colitis (UC) and Crohn's disease (CD), polyps and CRC in their early stage and also presents details on various screening options. Detecting, staging and re-staging of patients with CRC also require multimodality, multistep imaging approaches. Staging and re-staging with conventional colonoscopy (CC), computer tomography colonography (CTC), magnetic resonance colonography (MRC) and positron emission tomography/computer tomography colonography (PET/CTC) are of paramount importance in determining the most appropriate therapeutic method and in predicting the risk of tumor recurrence and overall prognosis. The advantages and limitations of these modalities are also discussed.

INTRODUCTION

Over 55 000 Americans are expected to die of Colorectal cancer (CRC) in 2006[1]. It is estimated that there is over a 5% chance that an American will develop CRC in their lifetime and over a 2% chance that an American will die from CRC. In some Asian countries, the incidence of colorectal cancer rises rapidly[2]. Compared to Westerners, Chinese patients have a slightly lower prevalence of colon neoplasia, more distal distribution of neoplasia, and higher likelihood of concomitant proximal advanced neoplasia and distal neoplasia[3].

When used appropriately, screening for CRC can reduce disease-related morbidity and mortality[4]. Current methods include fecal occult blood testing (FOBT), flexible sigmoidoscopy, double contrast barium enema (DCBE), and conventional colonoscopy (CC); all are cost-effective techniques. Unfortunately, offering an array of options has not increased screening utilization, which continues to lag behind that of other common cancers[5]. Newer techniques, particularly virtual colonoscopy (VC), including CTC, MRC and PET/CTC may offer attractive alternatives for healthcare provider recommendation and patient use[6].

COLORECTAL CANCER RISK FACTORS

The exact causes of CRC are not known. However, studies show that the following risk factors increase a person's chances of developing CRC: over the age of 50, high fat and calories and low fiber diets, family history of colorectal cancer, previous history of CRC or adenomas, a cholecystectomy was performed ten years or more ago, severe ulcerative colitis (UC) and Crohn's disease (CD) for over ten years, *etc*[7-9].

There is substantial evidence that most CRC arise from preexisting adenomas. A large body of clinical evidence

Table 1 Characteristics of medical images in detecting CRC

Modalities	Characteristics
DCBE	Cost-effective, efficient, safe, could be performed and interpreted by GI radiographers to reduce waiting
Colonoscopy	Cost-effective, endoscopic resection of polyps, endomicroscopy opening the way of in vivo molecular imaging
CTC	Less uncomfortable, minimally invasive, with radiation exposure, 3D virtual dissection of colon,
MRC	Limited bowel preparation, unpleasant rectal tube, filling colon with saline and contrast, no radiation
PET/CTC	Accurate whole-body tumor staging, with integrated morphological and functional images, more irradiation

supports the belief that over 95% of CRC arise from benign adenomatous polyps that develop and grow very slowly over many years[10]. Consequently, polypectomy of colorectal adenomas was shown to reduce the incidence of CRC by nearly 80%. Progression of an adenoma into cancer can be predicted by its size, villous histology, degree of dysplasia, and inherited or environmental factors. Advanced adenomas are the primary target in colorectal screening. Advanced adenomas were generally large (> or = 10 mm in size); only a small percentage were medium sized (6-9 mm). There was a very low prevalence of high-grade dysplasia and invasive carcinoma in the medium-sized group of lesions[11]. So, there is a firm consensus that larger (> or = 10 mm) colonic polyps should be removed; however, the importance of removing smaller polyps (< 10 mm) is more controversial.

ULCERATIVE COLITIS OR CROHN'S DISEASE AND COLORECTAL CANCER

People with UC or CD have a high risk of developing CRC, even if the disease is in remission[12]. Regular screenings and early detection are critical. In people with UC or CD, CRC may be preceded by polyps or may arise from flat mucus membranes, thus requiring more intensive and more frequent colonoscopies[13]. CRC is more often multiple and uniformly distributed throughout the colon and often occurs in younger people with UC or CD[14]. CRC is one of the most serious potential results of IBD and explains up to one sixth of all deaths in UC patients and one twelfth of all deaths in CD[15]. Longer duration of the disease, extensive colitis, primary sclerosing cholangitis and family history of CRC are the main risk factors. Relative risk of CRC is 2.5 and small bowel cancer risk is 31.2 in CD[16]. A recent meta-analysis estimated that one in five patients with UC will develop CRC over 30 years, with the risk of CRC being greatest in patients with extensive UC of long duration. Patients with CD also have an increased risk of CRC[17]. Given this fact, it is necessary to early examine UC or CD by current and future approaches to CRC prevention in IBD patients[18].

COLORECTAL CANCER PROACTIVE SCREENING

CRC is generally more treatable when it is found early. CRC screening is used to detect cancer, precancerous polyps, or other abnormal conditions. If screening detects an abnormality, diagnosis and treatment can occur promptly. In addition, finding and treating polyps may be one of the most effective ways to prevent the development of cancer altogether. Because often there are no symptoms and symptoms do occur depend on the location of the cancer in the gastrointestinal tract, regular screening and early detection are important for people who are at average risk and have a higher risk, such as those with UC or CD. If CRC is detected at an early stage, the 5-year survival rate is 90%. Unfortunately, less than 40% of CRC are detected at an early stage[19]. Once the cancer has spread regionally and involves adjacent organs or lymph nodes, this rate drops to 40%-65%; 5-year survival is less than 10% for patients with distant metastases[20].

Many existing screening tools, invasive or not, are often debated such as FOBT, sigmoidoscopy and complete colonoscopy. New tools are in development and have to be evaluated in current practice: VC, new endoscopic technologies, DNA on faeces or proteomics with markers in serum. When used appropriately, screening for CRC can reduce disease-related morbidity and mortality[21]. Recent studies stress the fact that finding and resecting advanced adenomatous polyps, and thereby preventing cancer, is becoming a primary objective of screening programs. Several papers also show the potential of emerging new methods of screening by imaging the colon with VC[22]. The sensitivity of VC for large adenomas and CRC appears to be high, although results vary by center and there is a steep learning curve. (Table 1).

BACKGROUND OF VIRTUAL CONLONOSCOPY

VC is a new method for studying the colon. It consists in acquisition of CT, MR and PET/CT images and could elaborate them with a workstation, creating endoluminal vision as likely as traditional colonoscopy does, permitting the complete exploration of colonic lumen, and of tumoral stenosis[23]. The analysis of the differences between CT, MR and PET/CT colonography shows that these techniques present both advantages and disadvantages, such as the impossibility to perform MR in patients with pace-maker or in claustrophobic patients and the impossibility to perform CT with iodated agents in patients with renal failure or with a story of adverse reactions. The increased use of these techniques is due to the high sensitivity of last-generation CT, MR and PET/CT machine, to the increased spatial resolution, to specific softwares for digital cleaning of colon, to the introduction of high-end workstations and to the possibility of computer assisted diagnosis (CAD)[24]. So, it is desirable that the increasing spread of multidetector CT devices

Table 2 Comparison of medical image modalities' values in colonography

Modalities	Specificity	Sensitivity	Accuracy
DCBE	+	+	-
Colonoscopy	+++	++	+++
CTC	+	++	_
MRC	++	+	+
PET/CTC	++	++	+++

Legend: _- poor; + fair; +++ good; ++++ excellent.

and the future technical innovations should have the effect to increase culture and experience in various diagnostic centers about VC, making possible the spreading of VC as a screening tool (Table 2)[25].

CT COLONOGRAPHY

Current CT techniques require meticulous bowel preparation and gas insufflations prior to the examination. The procedure requires a scan time of about 25 to 30 s with new multidetector CT scanners, and sedation is not used. The advantages of CTC over CC include its safety, its ability to demonstrate the entire large bowel in almost all patients, even following incomplete endoscopy, to accurately localize lesions, and to examine the entire colon in patients with obstructing tumors. Additionally, CTC allows simultaneous preoperative tumor staging. There are few reported complications from CTC[26,27].

People with ulcerative colitis or Crohn's disease

Over the past several years, significant advances have been made in the diagnostic techniques used in the management of UC and CD. Improved radiographic imaging techniques based on CT imaging allow noninvasive means of evaluating the small bowel in patients with known or suspected CD[28]. CTC may help to distinguish between patients with acute and chronic inflammatory bowel disease (IBD). Especially extraintestinal complications, tumorous as well as pseudo-tumorous lesions can be detected with high sensitivity and specificity. CTC is clinically useful for the evaluation of CD, especially those with stenotic lesions[29,30]. Current findings also suggest that although the widespread use of VC in CD is currently not indicated because of possible false-negative findings, this technique may represent an alternative to CD in noncompliant postsurgical patients with a rigid stenosis not allowing passage of the endoscope[31].

People with polyps

Screening for colorectal polyps is a controversially discussed indication for CTC. Sensitivity and specificity range widely and decrease with decreasing polyp size. However, better results can be achieved using multidetector technology. Most frequently, the examination is well tolerated and assessed by patients to be more acceptable than CC[32]. A meta-analysis of 2610 patients, 206 of whom had large polyps, showed high per-patient average sensitivity (93%) and specificity (97%) for colonography; sensitivity and specificity decreased to 86% and 86%, respectively, when the threshold was lowered to include medium polyps. When polyps of all sizes were included, studies were too heterogeneous in sensitivity (range, 45%-97%) and specificity (range, 26%-97%) to allow meaningful meta-analysis. CTC seems sufficiently sensitive and specific in the detection of large and medium polyps[33,34].

The sensitivity of CTC was heterogeneous but improved as polyp size increased (48% for detection of polyps < 6 mm, 70% for polyps between 6 and 9 mm, and 85% for polyps > 9 mm). Characteristics of the CTC scanner, including width of collimation, type of detector, and mode of imaging, explained some of this heterogeneity. In contrast, specificity was homogenous (92% for detection of polyps < 6 mm, 93% for polyps from 6 to 9 mm, and 97% for polyps > 9 mm). CTC is highly specific, but the range of reported sensitivities is wide[35]. Patient or scanner characteristics do not fully account for this variability, but collimation, type of scanner, and mode of imaging explain some of the discrepancy. This heterogeneity raises concerns about consistency of performance and about technical variability. These issues must be resolved before CTC can be advocated for generalized screening for CRC[36].

Diagnosis and staging of colorectal cancer

Because CRC has widely varying appearances in both endoscopy and CTC, familiarity with the gamut of morphologic appearances can help improve interpretation of the results[37,38]. The addition of intravenous contrast material to CTC can aid differentiation of true colonic masses from pseudolesions such as residual stool and improves the depiction of enhancing masses that might otherwise be obscured by residual colonic fluid[39]. In contrast to staging of most other tumors, staging of CRC depends more on the depth of tumor invasion than on the size of the primary mass. The diverse appearances of colorectal cancers at two- and three-dimensional CTC include sessile, annular, ulcerated, necrotic, mucinous, invasive, and noninvasive lesions[40]. Imaging pitfalls that can simulate or obscure neoplasms are retained fecal material or fluid, incomplete distention, and advanced diverticulosis[41].

Contrast-enhanced CTC can simultaneously evaluate metastatic disease, local recurrence, and metachronous neoplasia in CRC, in recurrent CRC. Contrast-enhanced CTC has the potential to detect local recurrence, metachronous disease, and distant metastases in patients with a history of invasive CRC. Suboptimal sigmoid distention can be seen on contrast-enhanced CTC, predominantly in patients with right hemicolectomies[42]. Contrast-enhanced CTC is a promising method for detecting local recurrence, metachronous disease, and distant metastases in patients with prior invasive CRC. The technique can also serve as a useful adjunct to colonoscopy by detecting local recurrences or metachronous disease that are endoscopically obscure or by serving as a full structural colonic examination when endoscopy is incomplete[43].

MR COLONOGRAPHY

MRC has gained access into clinical routine as a means

for the assessment of the large bowel. There are widely accepted indications for MRC, especially in patients with incomplete CC. Furthermore, virtual MRC is more and more propagated as a screening tool, with advantages especially inherent to the non-invasive character of this procedure and the lack of ionizing radiation exposition. Beyond a sufficiently high diagnostic accuracy, outstanding patient acceptance is a major advantage of MRC as a diagnostic modality[44]. Precondition for establishment of MRC as a diagnostic tool in secondary prevention of CRC is not only high diagnostic accuracy but also a good acceptance amongst patients[45].

People with ulcerative colitis or Crohn's disease

The degree of the contrast enhancement of the bowel wall may be a criterion for the degree of inflammation in CD[46]. This study provides strong evidence that the combination of MRI enteroclysis and MRC is practicable and supplies additional results regarding the regions which are not seen with ileo-colonoscopy in the work-up of patients with CD[47]. The presented data indicate that 'fecal tagging MRC' is not suitable for an adequate quantification of inflammatory diseases of the large bowel. Furthermore, overall acceptance of endoscopic colonoscopy was superior to MRC[45,48]. MRC represents a promising alternative to CC for the assessment of colonic anastomoses in patients with previous colonic resection[49]. In summary, whether or not the survival of endoscopy is under debate, MRI could mark a historic turning point in gastroenterology. So, MRI hardware might interdisciplinarily be used by, e.g., radiologists and gastroen terologists[50].

People with polyps

Dark-lumen MRC has failed to detect all polyps smaller than 5 mm in diameter which are generally not clinically relevant at the moment of their detection and thus can be kept under surveillance. However, MRC as a non-invasive imaging modality is a promising alternative to CC in the detection of clinically relevant polyps larger than 5 mm in diameter[51]. The diagnostic performance of MRC was prospectively evaluated by using limited bowel preparation in patients with polyps of 10 mm or larger in diameter in a population at increased risk for CRC, with CC as the reference standard. Two hundred patients (mean age, 58 years; 128 male patients) were included; 41 patients had coexistent symptoms. At colonoscopy, 12 patients had 22 polyps of 10 mm or larger. Per-patient sensitivity was 58% (seven of 12) for observer 1, 67% (8 of 12) for observer 2, and 75% (9 of 12) for both observers combined for polyps of 10 mm or larger. Per-patient specificity was 95% (178 of 188) for observer 1, 97% (183 of 188) for observer 2, and 93% (175 of 188) for both observers combined. Per-polyp sensitivity was 55% (12 of 22) for observer 1, 50% (11 of 22) for observer 2, and 77% (17 of 22) for both observers combined. Interobserver agreement was 93% for identification of patients with lesions of 10 mm or larger. In patients at increased risk for CRC, specificity of MRC by using limited bowel preparation was high, but sensitivity was modest[52-54].

Diagnosis and staging of colorectal cancer

MRC is useful for detection of colonic pathology and assessment of proximal colon in patients with colonic cancer after incomplete colonoscopy[55-56] Wong *et al* reported 51 patients with incomplete colonoscopy who were recruited to have MRC performed. Forty-four patients had incomplete colonoscopy because of an obstructing tumor. The other seven patients had incomplete colonoscopy because of excessive bowel looping. Apart from one patient suffering from chronic obstructive airway disease with resulting nondiagnostic MRC, all other patients had MRC successfully performed. Each colon was divided into six bowel segments for analysis. All 300 segments were of diagnostic quality and were assessed by the MRC. MRC correctly identified all 44 obstructing tumors demonstrated by initial CC. Synchronous tumors in proximal colonic segments were identified in two patients by MRC. In addition, MRC identified two colonic tumors located in bowel segments inaccessible by CC because of excessive looping[57]. A meta-analysis had MRC versus colonoscopy as a diagnostic investigation for CRC. This study suggests that MRC is an imaging technique with high discrimination for cases presenting with CRC. The exact diagnostic role of MRC needs to be clarified (e.g. suitable for an elderly person with suspected CRC. Further evaluation is necessary to refine its applicability and diagnostic accuracy in comparison with other imaging methods such as CTC[58]. MRC could be useful in screening programs of patients at high risk for colon cancer. Patients with MRC-detected endoluminal lesions must undergo CC for histologic diagnosis[59].

PET/CT COLONOGRAPHY

Endoscopic and radiologic studies are frequently required in IBD to determine disease activity, extent of disease, and delineating disease type. PET and PET/CT using fluorine-18-fluoro-deoxyglucose to identify metabolically active tissues may offer a simple noninvasive alternative to conventional studies in identification and localization of active intestinal inflammation[60]. Today, PET imaging has been shown to be superior to conventional CT staging when assessing patients with CRC for local and distant metastases. PET/CT scanners provide accurately fused morphological and functional imaging within a single examination. Thus a combined whole body PET/CTC approach may serve as an attractive alternative to a multistep multimodality workup comprising CT, PET/CT, and CC[61-63].

Detection of ulcerative colitis or Crohn's disease

Over the past several years, significant advances have been made in the diagnostic techniques used in the management of UC and CD. Detection of disease activity in IBD is of crucial importance for diagnosis and management of the disease[64]. ^{18}F-fluorodeoxyglucose (18F-FDG) accumulates in malignant tissues but also at the sites of infection and inflammation and in autoimmune and granulomatous diseases by the overexpression of distinct facultative glucose transporter (GLUT) isotypes (mainly GLUT-1 and GLUT-3) and by an overproduction of glycolytic

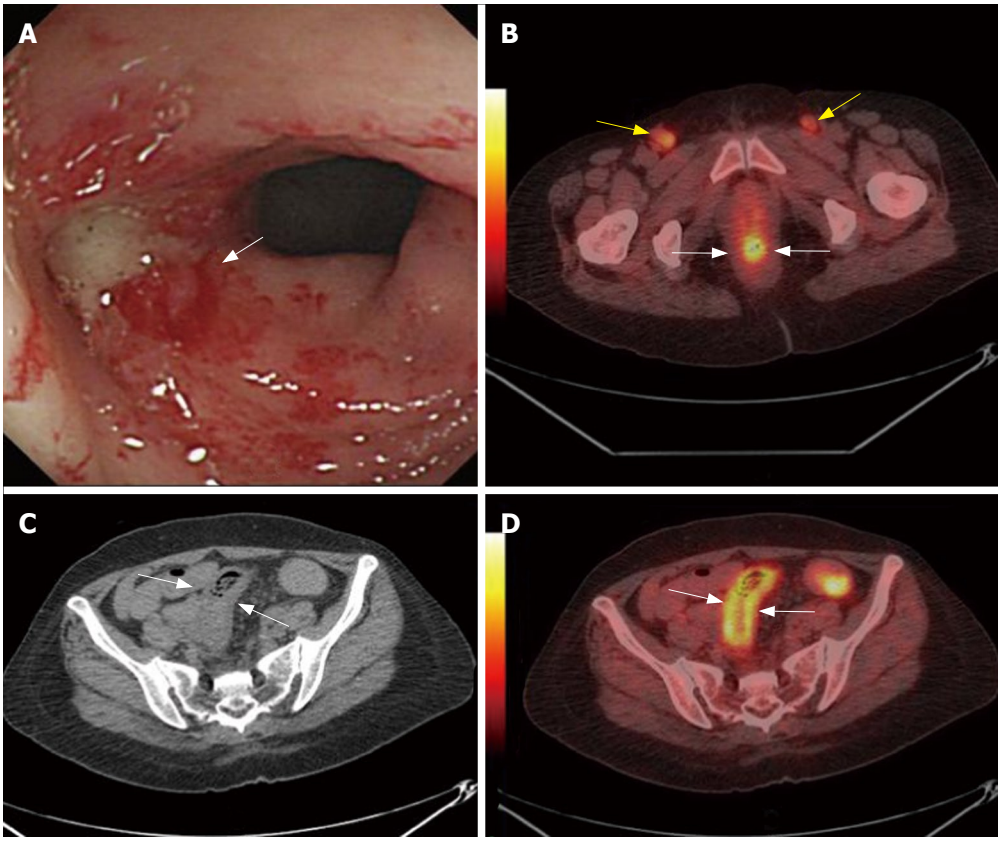

Figure 1 A 56-year-old woman was suffered from uterine cervix cancer and accepted local radiation and chemotherapy 2-mo ago. CC found enterocolitis of sigmoid colon (white arrow, **A**). PET/CT detected high metabolism metastasis lymphoid nodes at both sides of the inguina (yellow arrows, **B**) and rectum wall was high metabolism (white arrows, **B**). CT showed thickening of sigmoid colon wall (white arrows, **C**). PET/CT illustrated sigmoid colon wall was high metabolism (white arrows, **D**). Biopsy followed by PET/CT revealed metastasis lymphoid nodes at both sides of the inguina. The case illustrated the potential value of PET/CTC in radiation enterocolitis.

enzymes in cancer cells and inflammatory cells[65]. It is confirmed that PET activity correlated well with active inflammation in both UC and CD, suggesting that this may be a noninvasive method of identifying disease activity in patients with IBD[66]. Neurath *et al* suggested that FDG-PET appear to be a reliable noninvasive tool for simultaneous detection of inflamed areas in the small and large bowel of patients with CD and can be used to detect disease activity in the terminal ileum and colon of CD patients with high sensitivity and specificity[67].

PET or PET/CT in pediatric inflammatory bowel disease

Diagnosis of chronic IBD in children requires noninvasive, atraumatic diagnostic tools that depict localization and acuity of inflammation and yield only a low radiation dose. Loffler *et al* reported a retrospective analysis with histology as the standard of reference, FDG-PET showed a sensitivity/specificity/accuracy of 98%/68%/83% as compared to CC (90%/75%/82%) and US (56%/92%/75%). For the small bowel, FDG-PET was even more reliable (100%/86%/90%). Because of its high sensitivity and accuracy, FDG-PET is an excellent, noninvasive diagnostic tool for IBD. Depicting inflammation in the whole bowel, while being not traumatic, it is attractive for use especially in children. FDG-PET is especially reliable for the small bowel and can inform application of topical therapy[68,69]. However, curtailed anatomical information provided by FDG-PET often renders accurate localization of lesions difficult. PET/CT offers a better noninvasive tool for identifying and localizing active intestinal inflammation in patients with IBD. PET and PET/CT may not be able to replace conventional studies; however, it may be useful when conventional studies cannot be performed or fail to be completed[70].

PET or PET/CT in radiation enterocolitis

Radiation enteritis is a functional disorder of the large and small bowel that occurs during or after a course of radiation therapy to the abdomen, pelvis, or rectum. The large and small bowels are very sensitive to ionizing radiation. Almost all patients undergoing radiation to the abdomen, pelvis, or rectum will show signs of acute enteritis. Injuries clinically evident during the first course of radiation and up to 8 wk later are considered acute[71]. Chronic radiation enteritis may present months to years after the completion of therapy, or it may begin as acute enteritis and persist after the cessation of treatment. Only 5% to 15% of persons treated with radiation to the abdomen will develop chronic problems[72]. According to our initial experiences, FDG-PET/CT also has a potential value in management of radiation enterocolitis and other radiation complications (Figure 1).

Whole body staging and restaging of colorectal cancer by PET/CT

Staging of patients with CRC often requires multimodality, multistep imaging approach. PET/CTC is the latest technique used in CRC screening and staging, which could complete the TNM staging in one-stop examination. Kuehle et al performed a rodent polyp model to assess the feasibility of PET/CTC for the detection of colorectal masses in a rodent polyp model in an intraindividual comparison with dark-lumen MRC. Detection of small

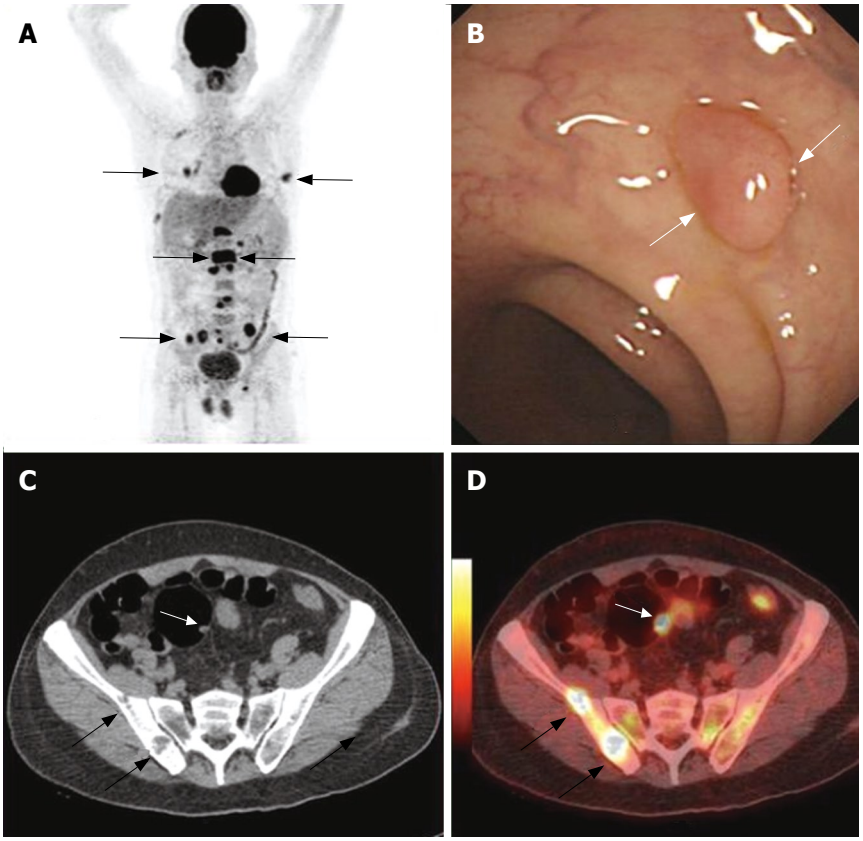

Figure 2 A 63-year-old man was detected multi metastases in whole body PET/CT scan with unknown original tumor (black arrows, **A**). CC showed a polyp at the sigmoid colon (white arrows, panel **B**). CT detected bone destruction at the right ilium (black arrow, **C**) and a polyp at the sigmoid colon (white arrow, **C**). PET/CTC localizes the high metabolism bone destruction lesions (black arrows, **D**) and high metabolism polyps at sigmoid colon (white arrow, **D**). Histopathology follow by CC revealed a inflame polyp. The case illustrated the potential value of PET/CTC in screening colorectal polyps.

tumors with PET/CTC and MRC is possible in a rodent model[73]. PET/CTC is equivalent to CT + PET for tumor staging in patients with CRC. PET/CTC in conjunction with optical colonoscopy may be a suitable concept of tumor staging for patients with CRC[74]. Kinner *et al* developed and evaluated a combined whole-body PET/CTC protocol for dedicated CRC staging in routine clinical use. The results showed that staging patients with whole-body PET/CTC is technically feasible and accurate and patients with incomplete colonoscopy or potential synchronous bowel lesions might benefit from this approach (Figure 2)[75].

Whole body PET/CT with integrated colonography is technically feasible for whole body staging in patients with CRC. PET/CT has altered management plan in 24% of patients with primary CRC in correct direction. PET/CT should be considered a part of standard workup for preoperative evaluation in a subset of patients with CRC[76]. CT and superparamagnetic iron oxide-enhanced MR imaging are more sensitive but less specific than PET in the detection of liver metastases. PET/CT can detect more patients with extrahepatic tumor than CT alone[77]. The sensitivity, specificity and overall accuracy of PET in detecting intra-abdominal extrahepatic CRC were 82%, 88% and 86%, respectively, compared with 88%, 94% and 92%, respectively, of PET/CT. For detection of extra-abdominal and/or hepatic CRC, these were 74%, 88% and 85% of PET and 95%, 100% and 99% of PET/CT. The sensitivity, specificity and overall accuracy of PET in detecting primary tumors were 80%, 69% and 75%, respectively, compared with 89%, 92% and 90%, respectively, of PET/CT. PET/CT appears to be a very promising method for distinguishing a viable tumor from fibrous changes, thereby avoiding unnecessary laparotomy[78]. This integrated protocol may be of substantial benefit in staging and restaging patients with CRC (Figure 3)[79].

CT COLONOGRAPHY *VS* MR COLONOGRAPHY

A meta-regression technique was performed to compare the diagnostic accuracy of CTC and MRC, compared with CC for patients presenting with CRC. Overall sensitivity and specificity of CTC (95%, 95% respectively) and MRC 95%, 95% respectively) in detection of CRC was similar. Meta-regression analysis showed no significant difference in the diagnostic accuracy of both modalities. Both tests showed large area under the summary receiver operating characteristic curve, with high diagnostic odds ratios. Factors that enhanced the overall accuracy of MRC were the use of intravenous contrast, faecal tagging and exclusion of low-quality studies. This meta-analysis suggested that CTC and MRC have similar diagnostic accuracy in detecting CRC. Study quality, size and intravenous/intra-luminal contrast agents affect diagnostic accuracies. For an exact comparison to be made, studies evaluating CTC, MRC and CC in the same patient cohort would be necessary[80-82].

VIRTUAL COLONOSCOPY *VS* COVENTIONAL COLONOSCOPY

CTC is reliable for detecting lesions 6 mm or larger in size. It permits evaluation of the region proximal to an occlusive

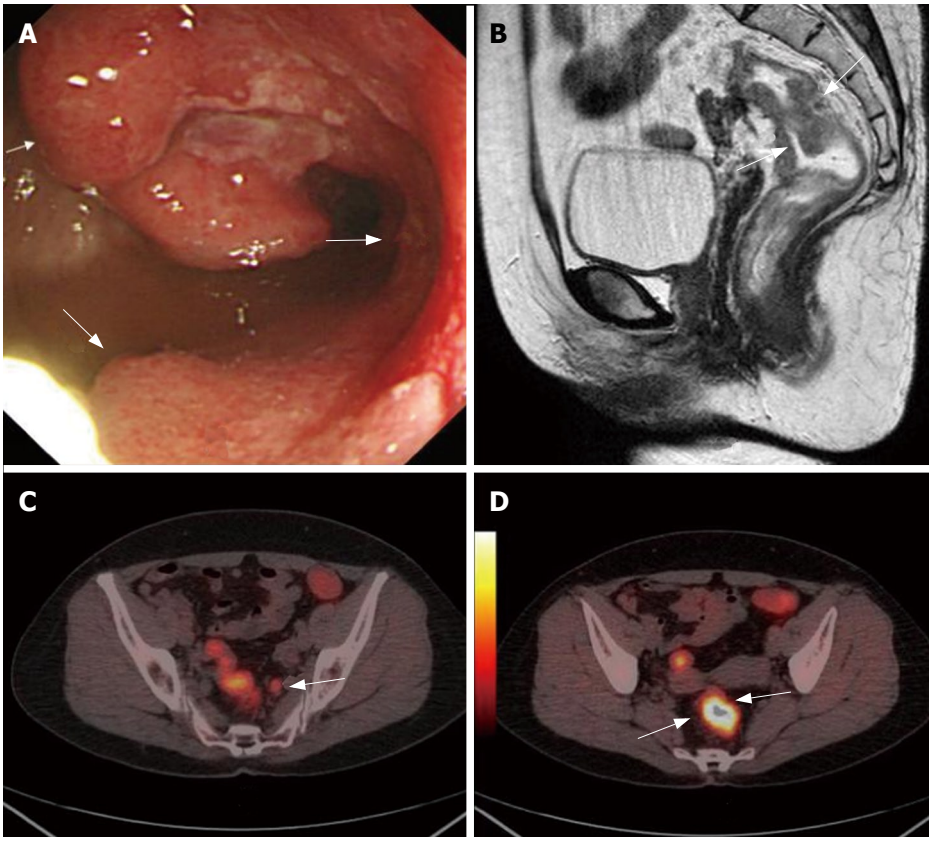

Figure 3 A 56-year-old women complained about blood stool for about 1 year. CC showed one stenotic tumoral site in the rectum (white arrows, **A**). Sagittal MRC showed thickened rectum with suspected infiltration of the surrounding tissue (white arrows, **B**). Axial PET/CTC showed a high metabolism metastasis lymphoid node (white arrow, **C**). Axial PET/CTC revealed tumor sites with elevated glucose metabolism and clear circumscription (two white arrows, **D**). PET/CT also indicated no tumorous infiltration of the adjacent tissue and no distant metastases. This was later verified by histopathology. The case illustrated the value of VC in CRC TNM staging.

growth, which is often impossible with CC[83]. CTC is a good imaging tool for the exclusion of CRC in a population unfit for or unable to complete colonoscopy or barium enema, with reasonable sensitivity and specificity for detection of CRC[84]. MRC is a promising modality with high accuracy for detecting colorectal polyps larger than 5 mm in diameter. In IBD, MRC can be used to assess disease activity, including spreading[85-86]. In detecting colon lesions, MRC achieved a diagnostic accuracy similar to CC. However, MRC is minimally invasive, with no need for sedation or analgesics during investigation. There is a lower percentage of perforation risk, and all colon segments can be evaluated due to multi-sectional imaging availability; intramural, extra-intestinal components of colonic lesions, metastasis and any additional lesions can be evaluated easily[87]. MRC is a feasible and useful method of evaluating the entire colon in patients with incomplete CC. The majority of the patients found MRC less unpleasant than CC and a majority would prefer MRC over CC as a future colon examination. MRC also appears to be less time consuming to the patients and medical personnel than CC with post-procedural monitoring[88,89]. MRC proved reliable in evaluating the majority of colonic segments inaccessible with CC. The identification of additional disease at MRC underscores the need for a second diagnostic step in the setting of incomplete CC[90].

COMPLICATIONS AND LIMITATIONS

Perforation of the colon and rectum is a rare complication of VC. Older age and underlying concomitant colonic disease were present in patients with perforation[91]. The cancer risks associated with the radiation exposure from VC are unlikely to be zero, but they are small. A best estimate for the absolute lifetime cancer risk associated with the radiation exposure using typical current scanner techniques is about 0.14% for paired VC scans for a 50-year-old, and about half that for a 70-year-old. These values probably could be reduced by factors of 5 or 10 with optimized VC protocols. In terms of the radiation exposure, the benefit-risk ratio is potentially large for VC[92].

Many differences between the studies with high sensitivity (94%)[93]. Additional obstacles for implementation in prevention of CRC may be controversial results concerning patient acceptance, the large-scale use of ionizing radiation, difficulties in detecting flat adenomas, and extracolonic findings[94]. Flat lesions and small polyps are the other two main causes for missed lesions at 8 multi-detector rows CTC[95,96]. Currently, CTC is less cost-effective than conventional endoscopy[97]. CTC and MRC present both advantages and disadvantages, such as the impossibility to perform MR in patients with pace-maker or in claustrophobic patients and the impossibility to perform CT with iodated agents in patients with renal failure or with a story of adverse reactions[98,99]. Although application of PET and PET/CT in CRC diagnosis, staging and re-staging has been widely accepted by oncologists, there are no data of PET/CTC in CRC screening. But in the high risk patients and follow up of CRC patients after treatment, the examination is still cost-effective. Radiation dose exposures to the patient who accepts this examination is another main problem which should be further studied in the near future[100,101].

COST-EFFECTIVE ISSUES

CTC is an effective screening test for colorectal neoplasia.

However, it is more expensive and generally less effective than CC. CTC can be reasonably cost-effective when its diagnostic accuracy is high, as with primary 3-dimensional technology, as if costs are about 60% of those of CC. Overall, CTC technology will need to improve its accuracy and reliability to be a cost-effective screening option[102]. CRC screening is cost-saving in Italy, irrespective of the technique applied. CTC appeared to be more cost-effective than flexible sigmoidoscopy, and it may also become a valid alternative to CC[103]. VC involves a helical CT or MR scan of the abdomen and pelvis to detect colorectal polyps and cancer. Both modalities have shown promising sensitivity in revealing larger polyps, in comparison with CC. Caution should be exercised in its clinical implementation due to significant interobserver variation and individual learning curves. A Danish study indicates that CTC can be performed cost-effectively compared to CC. CTC is recommended in preference to DCBE after incomplete CC[104].

DERIVATIVE TECHNIQUE FOR CRC SCREENING

Stool DNA testing

Stool DNA testing provides an acceptable noninvasive alternative for CRC screening that can identify early-stage CRC and adenomatous polyps in routine clinical practice[105]. Abbaszadegan[106] *et al* reported that this test could detect CRC related genetic alterations by analyzing stool DNA with a sensitivity of 64% and 20% and a specificity of 95% and 100% for long DNA and p16 respectively. An abnormal stool DNA test correlated with a colonoscopically demonstrable abnormality in 49% of cases (34 of 69). Abnormal findings, including CRC in 4% of cases (3 patients), single or multiple adenomatous polyps in 23 patients (33%), hyperplastic polyps in 3 patients (4%), and colitis in 5 patients (7%). Colonoscopy was reported as negative in 51% of patients (35 of 69), including 2 cases (3%). A non-invasive molecular stool-based DNA testing can provide a screening strategy in high-risk individuals[107].

Computer-aided detection

The latest CAD systems indicate a clinically acceptable high sensitivity and a low false-positive rate, and observer studies have demonstrated the benefits of these systems in improving radiologists' detection performance[108]. Polyps were classified as small ($\leqslant$ 5 mm), medium (6-9 mm), and large ($\geqslant$ 10 mm). A total of 118 polyps (small, 85; medium, 19; large, 14) were found in 56 patients. CAD detected 72 polyps (61%) with an average of 2.2 false-positives. Sensitivity was 51% (43/85) for small, 90% (17/19) for medium, and 86% (12/14) for large polyps. For all polyps, per-patient sensitivity was 89% (50/56) for the radiologist and 73% (41/56) for CAD. For large and medium polyps, per-patient sensitivity was 100% for the radiologist, and 96% for CAD. CAD shows high sensitivity in the detection of clinically significant polyps with acceptable false-positive rates[109] and CAD for CTC significantly increases per-patient and per-polyp detection and significantly reduces interpretation times but cannot substitute adequate training[100].

PET/MRI colonography

Predicting the future is difficult, and any attempt to do so is fundamentally flawed. But the fusion of PET with MRI could compensate for their disadvantages and therefore offers several advantages in comparison to PET or MRI alone. The combination of these two excellent diagnostic imaging modalities into a single scanner improves the diagnostic accuracy by facilitating the accurate registration of molecular aspects and metabolic alterations of the diseases with exact correlation to anatomical findings and morphological information. PET/MR imaging is to become a multimodality platform for molecular imaging and PET/MRI colonography might be a promising diagnostic modality for use in CRC screening in the decades to come due to the considerably lower radiation exposure in contrast to PET/CTC and the high soft tissue resolution of MRI in contrast to CT in the future[110-101].

CONCLUSION

With the exponential development in computer processing power, CT, MR and PET/CT colonography offer numerous advantages over more traditional methods of radiologic diagnosis, and provide essential information not only for initial diagnosis, but also for management, follow-up and detection of potential complications. Will CT, MR and PET/CT colonography replace conventional colonoscopy in the future? We do not believe so at present. However, combined with several derivative techniques on the horizon involving stool DNA testing, computer-aided detection and PET/MRI colonography, these techniques may further improve the specificity and sensitivity of imaging modalities in CRC screening and save the colonoscopy resource for the patients who need treatment.

Abstract

Stem cells from extra- or intrahepatic sources have been recently characterized and their usefulness for the generation of hepatocyte-like lineages has been demonstrated. Therefore, they are being increasingly considered for future applications in liver cell therapy. In that field, liver cell transplantation is currently regarded as a possible alternative to whole organ transplantation, while stem cells possess theoretical advantages on hepatocytes as they display higher *in vitro* culture performances and could be used in autologous transplant procedures. However, the current research on the hepatic fate of stem cells is still facing difficulties to demonstrate the acquisition of a full mature hepatocyte phenotype, both *in vitro* and *in vivo*. Furthermore, the lack of obvious demonstration of *in vivo* hepatocyte-like cell functionality remains associated to low repopulation rates obtained after current transplantation procedures. The present review focuses on the current knowledge of the stem cell potential for liver therapy. We discuss the characteristics of the principal cell candidates and the methods to demonstrate their hepatic potential *in vitro* and *in vivo*. We finally address the question of the future clinical applications of stem cells for liver tissue repair and the technical aspects that remain to be investigated.

INTRODUCTION

Orthotopic liver transplantation (OLT) is the gold standard treatment for end-stage liver failure and for numerous liver based inborn errors of metabolism. However, organ shortage remains a major limiting factor and alternative solutions are being examined in the liver therapy field. Liver cell transplantation (LCT) is emerging with heartening success[1,2], but is still limited by cell viability, modest engraftment and limited tissue availability. Increasing interest is carried to stem cells regarding the recent demonstration of their plasticity[3]. Theoretical advantages of stem cells for tissue regenerative medicine are multiple: ease of harvest, proliferation capacity, efficiency of *in vitro* transfection and potential use of autologous cells. Different types of stem cells are eligible for liver cell therapy according to their hepatic potential, for instance mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs) and adult liver stem/progenitor cells. Despite encouraging results, key pitfalls remain while using stem cells-derived hepatocyte-like cells: lack of tissue-specific functionality and, up to now, no evidence of strong liver repopulation level in animal models. Moreover, the demonstration of the acquired hepatocyte-like phenotype is impaired by technical restraints. To reach clinical application, stem cell therapy requires further development to become competitive regarding LCT. Here, we present the current knowledge on the use of stem cells for hepatic tissue engineering and describe the future orientations in the field.

IDENTIFICATION OF THE STEM CELL CANDIDATES

Mesenchymal stem cells

Firstly described in 1970 from bone marrow (BM) isolates[4], these cells can currently be obtained from various tissue sources as BM, cord blood (CB), adipose tissue, umbilical cord blood (UCB). Their *in vivo* function

and behavior remain largely unknown[5]. MSCs have the characteristics to be highly proliferative *in vitro*, easily transfectable, resistant to cryopreservation[6] and to display a large *in vitro* and *in vivo* differentiation potential[7]. The first description of their hepatic potential was provided by Lee *et al*[8] and confirmed by other studies[9-26] (Table 1). While some studies evidenced the *in vivo* potential of MSCs[10,21], this was recently questioned by other authors who did not detect engrafting cells after syngeneic transplantation[20]. However, experimental protocols were quite different rendering comparison hazardous. A key advantage of MSCs is their immunological properties making them lesser immunogenic and possibly able to induce tolerance as highlighted by promising *in vitro* studies and clinical trials[27-32].

Hematopoietic stem cells

These cells constitute the paradigm of stem cells: cells capable of self-renewing, proliferation and production of a progeny of committed cell lineages, permitting the regeneration of the tissue, even after transplantation. These can be isolated from BM, UCB and peripheral blood[33] making them highly available while they are still difficult to expand *in vitro*[34,35]. In this cell population, cell identity and phenotype are mainly determined by a selection procedure whose criteria remain debated[36]. HSCs have recently aroused much enthusiasm in the hepatology field after the demonstration of their hepatic differentiation potential as described in Table 2. A majority of studies used mononuclear cell preparations[37-63], which hamper the identification of the cells involved in the differentiation process. For that reason, we included in Table 2 only studies using defined subpopulations[64-80]. However, HSCs' liver potential is increasingly debated[40,65,81-84] and the possibility of cell fusion as an explanation of 'plasticity' make these cells less considerable for a clinical use[85].

Adult liver stem cells

As organ shortage is limiting the availability of this cell population, the conditions for their use in cell therapy are

governed by two main characteristics, a high proliferation rate and/or a robust cell banking capacity. Regarding their promising hepatocyte-like functionality, some cell compartments could be promptly considered for toxicological assays. Even if identity and *in vivo* function of this cell population are currently under controversy, four main types of hepatic progenitors are described: oval cells, small hepatocytes, liver epithelial cells and mesenchymal-like cells. Oval cells are generated from the biliary tree in response to hepatic injury. They display a bipotent differentiation potential (hepatic and biliary cells) and can be expanded *in vitro*. There is no consensus on whether these cells are originating in BM or not[48,86]. However, similar cell types were recently isolated from healthy liver[87]. The first description of small hepatocytes isolation was made by Mitaka *et al*[88] from a non-parenchymal fraction after centrifugation of isolated liver cells. These cells are smaller than hepatocytes, possess an *in vitro* proliferation capacity[89] and can differentiate into mature hepatocytes *in vitro*[90]. Liver epithelial cells is a population firstly described by Tsao *et al*[91] and more recently in healthy adult human liver[92]. Although different from oval cells, these cells are bipotential and able to differentiate into hepatocyte-like cells *in vivo*[92]. A mesenchymal-like cell population has also been isolated from adult human liver[93,94]. This population depicts high

level of proliferation and, as MSCs, possesses a broad differentiation potential. How these cells share MSCs' immunological properties has to be determined. Other cell types were also isolated from manipulated livers[95], but the possibility of culture artefacts[96,97] should always be considered before describing new 'liver progenitor cells'.

Other cell types

Embryonic stem cells constitute, at present, the best *in vitro* model for hepatocyte differentiation. However, ethical restrictions[98] and the possibility of malignancies development[99] mainly limit their use in the clinical setting[100,101]. Other more committed cell lineages as monocytes[102,103] or fibroblasts[104] were evaluated for hepatic differentiation. In this context, recent data about nuclear reprogramming[105] provided possible explanation of the differentiation potential of cells thought to be restricted to a cell lineage.

IN VITRO STUDY AS ARGUMENT FOR HEPATOCYTE COMMITMENT

Up to now, studies illustrating *in vitro* hepatic features of stem cells-derived hepatocyte-like cells were essentially confined at the phenotypic rather than the functional level. Acquisition of specific markers is a tool for evidencing a cell commitment while hepatocyte-like functionality is required to consider a cell for therapy.

Hepatocyte-like phenotype

While a morphological change is common after *in vitro* cell conditioning, the morphology is rarely similar to mature hepatocytes and authors should rather talk about a 'hepatocyte-like morphology' in differentiating cells, more especially as ultrastructural data are mostly not provided. How the morphological changes are evocative of the acquisition of an epithelial phenotype is questionable as similar morphological changes can be obtained when incubating hBM-MSCs with a classical differentiation medium or with a control medium[106]. Using specific protein and mRNA marker expression for the description of a hepatocyte-like phenotype could also be questioned as many studies were based on restricted panel of markers and as some authors described the presence of hepatocyte-specific markers in undifferentiated cells[8,14,16,22,82,107,108]. The broadest amount of markers for phenotypic characterization should be used. In this manner, we observed an incomplete and erratic acquisition of hepatocyte-specific features in hBM-MSCs[106], cf Table 1. Moreover, these cells partially maintained the expression of native mesenchymal markers, suggesting a chimerical phenotype. This phenotype could be the result of the artificial *in vitro* differentiation process.

Hepatocyte-like functionality

The functional characterization of stem cells-derived hepatocyte-like cells is, up to now, principally achieved by commercially available assays (ELISA, colorimetric tests, PROD or EROD assays) whose handling are often poorly reproducible and quite difficult to interpret, or by other tests (as lipoprotein uptake) with low specificity. As clearly stated by Hengstler *et al*[109] in a recent report, there is a crucial need for standardized and normalized techniques for characterizing hepatocyte-like functionality in differentiating cells. Regarding clinical application, one should provide the evidence of a specific functional activity after differentiation before considering stem cells for cell therapy.

IN VIVO STUDY AS PROOF OF HEPATOCYTE DIFFERENTIATION POTENTIAL

Direct detection of differentiated donor cells in situ

Most studies about stem cells *in vivo* hepatic repopulation and differentiation are performed in a xenogeneic setting (e.g. human cells transplanted into immunocompromised rodents). The impact of cell-to-cell interactions in an interspecies microenvironment on cell adhesion and differentiation[110] is poorly documented. Moreover, this model does not reflect clearly the clinical reality and data must be carefully interpreted. In the same way, a drawback of allogeneic cell transplantation in rodents is that stem cell behavior was described to be quite different between species making extrapolation to human perilous[111]. Besides a huge diversity in the studies design, almost all *in vivo* models are based on the analysis of a repopulation potential after cell infusion in a diseased liver. Putative mechanisms of hepatic repopulation and tools designed to enhance it are described in Figure 1. It arises from the literature that hepatocyte differentiation from extrahepatic stem cells does not occur (or at very low level) in a non-injury model, and that the injury has to be strong enough and give advantage to the donor cells to seed and proliferate into the liver parenchyma. This was elegantly suggested by Stadtfeld *et al*[83] who demonstrated in a transgenic mouse model the minor role of the hematopoietic compartment in the adult liver ontogenetic development. Drug-induced liver injury has to be considered only as a tool for studying *in vivo* hepatocyte differentiation potential and no consensual protocol exists to date. Many questions are still opened: type of liver injury, time dependency of liver stimulus (acute *vs* chronic liver failure), use of drugs blocking host cell regeneration, relevance of injury after cell transplantation (compatibility with donor cell viability), *etc*. Globally, liver repopulation after stem cell transplantation remains limited. It is noteworthy that these data were obtained after single cell injection while for clinical purpose one would consider serial injections. Engraftment level has to be determined in this situation. By comparison, LCT can potentially reach higher repopulation levels[112] and, for that reason, is currently more valuable for clinical purpose. Conversely, some authors reported amazing repopulation levels with HSCs[73] or with UCB stem cells[16], but in both cases animal models were highly permissive and not representative of common cell transplant procedures. Methods for evaluation of cell engraftment are multiple and deal each with proper pitfalls[113]. For example, fluorescent in situ hybridization for detecting Y chromosome in a sex-mismatched transplantation

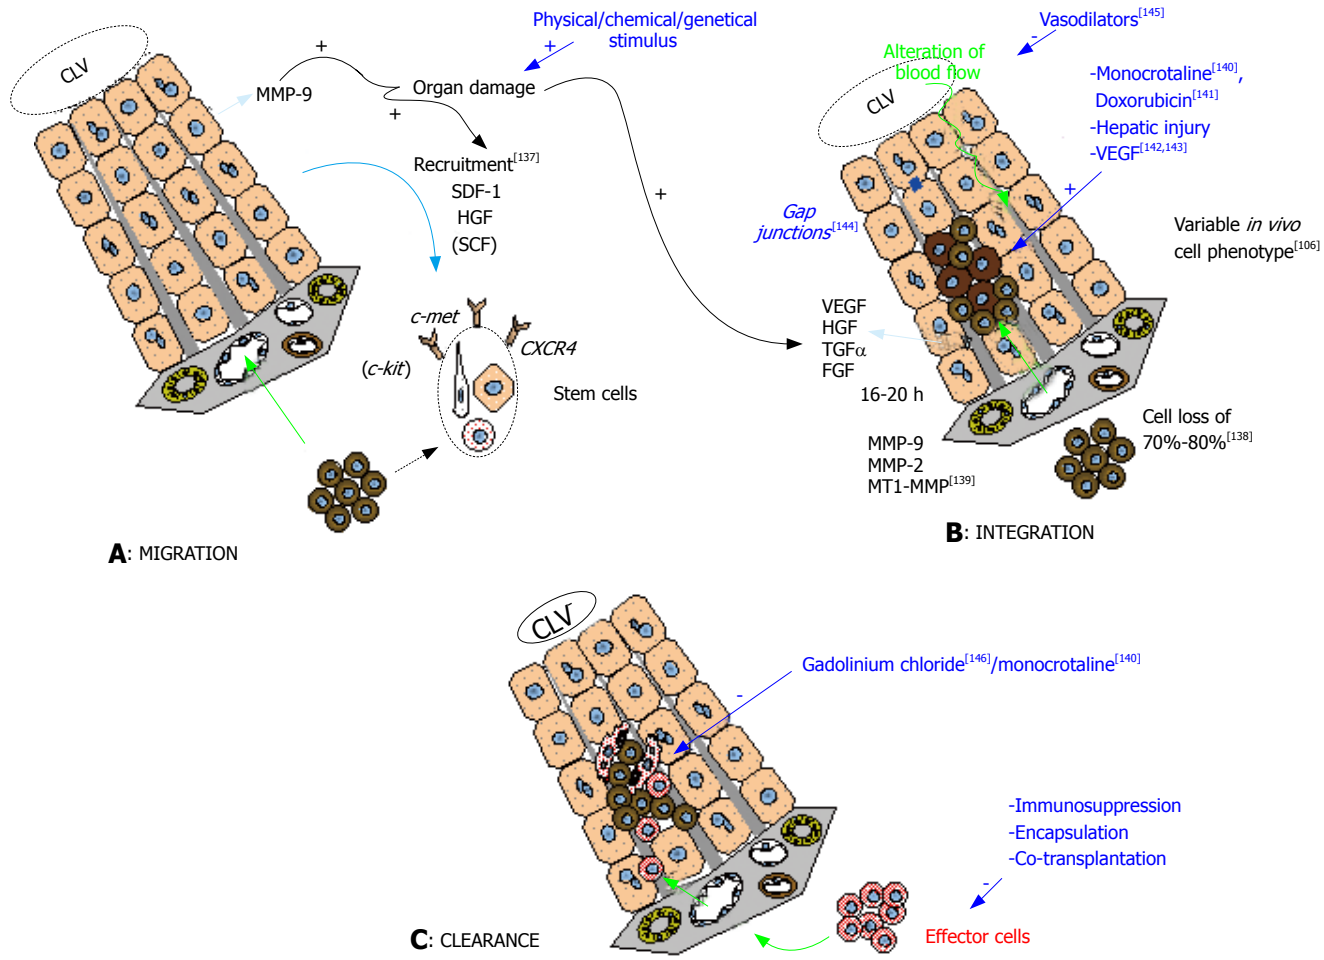

Figure 1 Mechanisms of liver repopulation after stem cell transplantation. **A**: Stem cell migration into the liver parenchyma after spleen infusion is guided mainly by the splenic and the portal vein flow. Homing of the cells is tightly regulated by chemoattractive agents (as SDF-1, HGF and SCF) secreted by liver cells under liver damage conditions[136], and acting respectively through the interaction with CXCR4, c-met and c-kit receptors of stem cells. MMP-9, expressed by host hepatocytes after injury, is implicated in the homing process through its action on the extracellular matrix. This process can be triggered by various types of liver injury; **B**: While reaching the portal vein, 70% to 80% of the infused cells are lost and phagocytosis by macrophages/phagocytes can be observed in the portal areas[137]. After 16-20 h post-infusion, the remaining cells enter the liver sinusoid after having crossed over the endothelial barrier rendered permeable by a local secretion of VEGF[137], and by the combined action of various MMPs[138]. The permeabilization of the endothelium by specific drugs owning toxicity against endothelial cells (as monocrotaline[139] or doxorubicin[140]) or acting on the permeation (VEGF[141,142]) was described to enhance the repopulation rate of the infused cells. The penetration of the parenchyma is facilitated by the action of MMPs and the disruption of gap junctions[143]. The cell implantation creates an alteration of venous blood flow which can hamper the progression of the cells inside the parenchyma but can be alleviated by the use of vasodilators[144]. Globally, inducing liver injury facilitates cell integration by remodeling the liver architecture and by creating a local microenvironment favorable for the proliferation of the transplanted cells. This is mediated by the local secretion of cytokines/growth factors (HGF, FGF, TGFα). Cell implantation implicates the reformation of gap junctions that can be observed 3 to 7 d after transplantation. The implanted cells display variable cell phenotype parallel to the level of their hepatocyte differentiation; **C**: After integration, some cells will be cleared from the hepatic parenchyma. Dead cells lacking implantation stimulus or cell-to-cell interactions will be phagocytes by Kupffer cells. This can be inhibited by the use of gadolinium chloride[145] or by monocrotaline[139] which was demonstrated in animal models to improve the kinetics of cell implantation. Other cells will be rejected by the host immunological system (effector cells) and tools to alleviate this rejection are multiple (immunosuppression protocols, encapsulation of the infused cells, co-transplantation with cells owning immunosuppressive properties). FGF: Fibroblastic growth factor; HGF: Hepatocyte growth factor; MMP: Matrix metalloproteinase; SCF: Stem cell factor; SDF: Stromal derived factor; TGF: Transforming growth factor; VEGF: Vascular endothelial growth factor.

can be difficult to interpret and, at low positivity levels, could be hampered by female microchimerism occurring after several litters[114]. The evaluation of *in vivo* cell differentiation is prominently performed by objectifying protein markers expression whereas immunoassays are often technically limited by antibodies affinity or specificity. For instance, the demonstration of *in vivo* expression of HepPar-1 (OCHE15 clone) should be questioned because of the antibody's cross-reactivity between species. For that reason, the use of combined techniques is recommended for the identification of *in vivo* differentiating cells, as staining assays performed on serial sections and association of various techniques (ex: *in situ* hybridization, immunostaining, cell tracking with fluorescent molecules, flow cytometry, RT-PCR, cellular magnetic resonance) (Figure 2).

Demonstration of donor cell functionality through their metabolic activity

The gold-standard for evaluating *in vivo* differentiation is the detection of cell functionality. To this end, some authors reported albumin secretion in transplanted mice serum. Other reports on '*in vivo* functionality' are argued on basis of the reduction of mortality rate, improvement of liver regeneration or of liver fibrosis[26,59,81,115-118]. It has to be determined how these findings are the fact of indirect

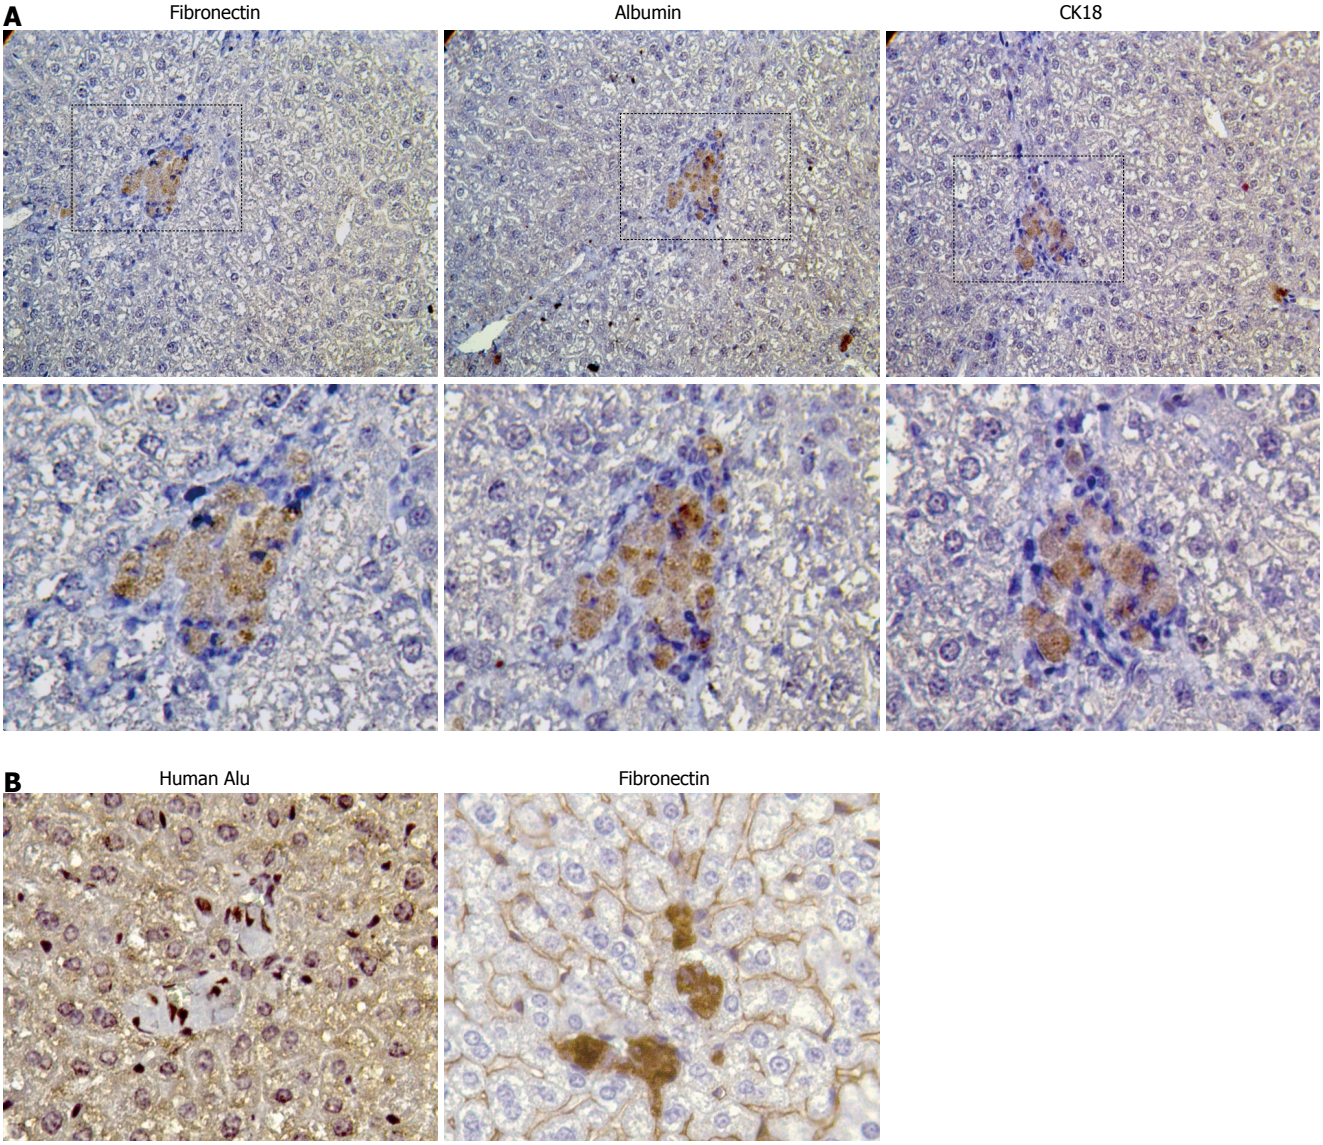

Figure 2 Analysis of liver engraftment of transplanted stem cells. Human BM-MSCs were transplanted into the liver of partially hepatectomized SCID mice and livers were screened after one month for analysis. **A**: Staining on serial sections for fibronectin, albumin and CK18 by immunohistochemistry revealed a co-expression of mesodermal and hepatocyte markers and confirmed the chimerical phenotype of hepatocyte differentiating MSCs (400 ×); **B**: The use of combined techniques for revealing the expression of human alu probe by *in situ* hybridization and of fibronectin by immunohistochemistry in a cell cluster (800 ×).

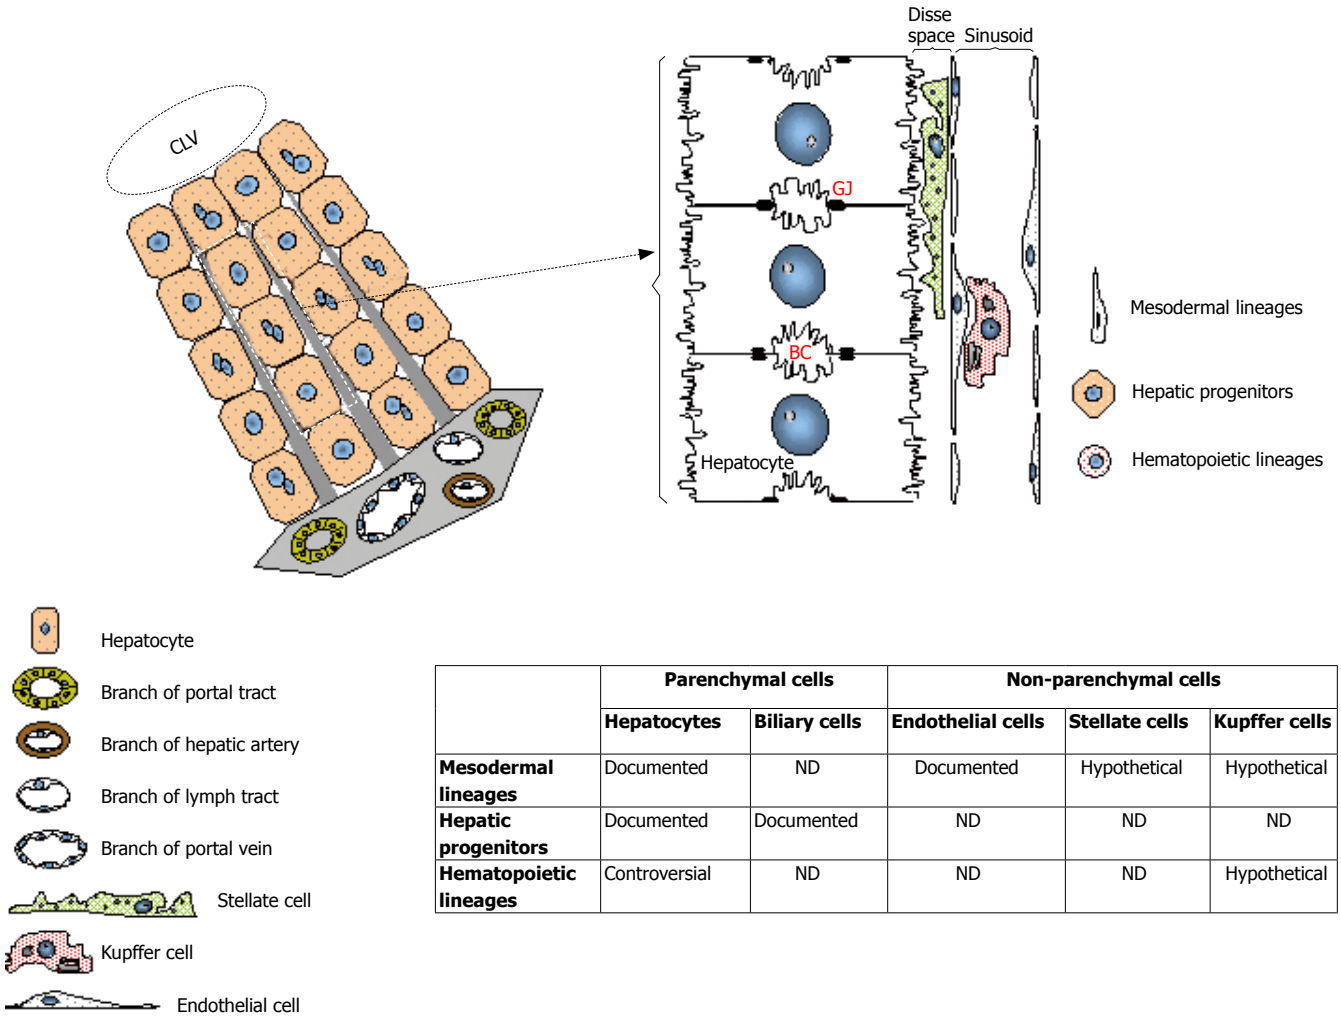

cell-to-cell interactions or of direct cell functionality. However, Lagasse *et al*[73] historically demonstrated the improvement of tyrosinemia disease in mouse after cell infusion whereas the selective pressure in this model is high and elicits fusion events.

Implication of cell fusion in the differentiation process

The fusion process implies that a cell inserts its genetic content into another cell to form a resulting unit that acquire the 'host' phenotype. The resultant product creates a heterokaryon in which the nuclei do not always fuse. The concept of fusion has emerged after experiments on co-culture of BM cells with ESCs[119,120]. Fusion between hematopoietic cells and hepatocytes has been demonstrated[43,121-125] and invalidated[69,126,127]. This is explained by the conceptual diversity of these studies and perhaps the complexity of the process itself. For example, fusion events can be acted by HSCs[128] or require homing of these cells and implication of progeny, as highlighted by studies showing fusion between myelomonocytic lineages and hepatocytes[122,125]. Interestingly, studies providing strong data about fusion used the $FAH^{-/-}$ model which produces mitotic and chromosomal abnormalities[129] that could strengthen the fusion process. It appears that selective pressure is necessary to induce relevant fusion processes which happen rarely in a non-injury model. How the cell fusion and plasticity phenomenon are parts of the same process or vary in importance according to the population used (stem cells versus committed cells[130]), has to be explored by tracing the donor cells in their route and studying signalling pathways. Interestingly, fusion events have, to date, never been described with MSCs[10,21].

FROM BENCH TO CLINICAL SIDE

Literature concerning the use of stem cells for clinical

	Parenchymal cells		Non-parenchymal cells		
	Hepatocytes	**Biliary cells**	**Endothelial cells**	**Stellate cells**	**Kupffer cells**
Mesodermal lineages	Documented	ND	Documented	Hypothetical	Hypothetical
Hepatic progenitors	Documented	Documented	ND	ND	ND
Hematopoietic lineages	Controversial	ND	ND	ND	Hypothetical

Figure 3 Involvement of stem cells in the regeneration of the liver parenchymal and non-parenchymal cell lineages. Schema shows the liver architecture and details the topography of the cell populations. In the table are resumed the cell fractions that could potentially be the targets of differentiation after transplantation of stem cells. Some of these differentiation potentials were documented with stem cells while other were contradicted and were thus exposed as controversial. Other differentiation pathways are purely hypothetical based on the embryonic origin of the stem cells. BC: Bile canalicule; CLV: Centrolobular vein; GJ: Gap junctions.

therapy is unceasingly growing in many fields (including hematology, cardiology, neurology and orthopedics)[131]. However, to date, there is no clear documentation about long-term safety of such procedure[132,133]. Multi-center consensual state-of-the-art about several clinical aspects is mandatory. First is the election of the appropriate clinical indication. In the hepatology field, liver-based inborn errors of metabolism are the most attractive candidate because of the possibility for elective treatment and, in some cases, the absence of global liver function impairment making technical procedures more feasible. The lack of liver injury may limit stem cells engraftment and differentiation. However, stem cells therapy remains relevant since small increases of the deficient enzyme activity can improve patients' quality of life. In that case, the acquisition of a specific enzyme activity has to be demonstrated *in vitro* before cell transplantation. Liver cirrhosis/fibrosis has been considered: besides encouraging results, there is, to date, no evidence about a direct or a mediated cell involvement, nor about how the fibrosis could hamper cell implantation[116]. Before considering acute liver failure for stem cell therapy, it would be necessary to achieve a performing banking of functional hepatocyte-like cells. Globally, the possibility of repeated cell infusions could render cell therapy advantageous over OLT in patients whose disorder is not life-threatening (ex: Criggler-Najar patients). In this condition, whether stem cells could have an advantage on liver cells according to their proliferative capacity needs further assessment. Other points requiring consensus is the technique and route of cell delivery (surgically placed catheter *vs* transcutaneous injection), the amount of delivered cells and timing of infusions, and the protocol of immunosuppression.

CONCLUSION

The first challenge for considering stem cells for therapy is the proof of their safety at long term by *in vitro* and *in vivo* assays. The other major goal is the determination of their *in vivo* functionality in small animal models combining a metabolic disorder allowing objective screening of cell function and a permissive immunological context (SCID or knock-out mice, immunosuppression therapy in allotransplantation). Large animal models would provide

definitive arguments about safety and functionality and allow an ideal setting for designing immunosuppression protocol and cell injection program. These models will be useful to attest the place of stem cells in liver cell therapy by comparison with LCT. Further research is also mandatory to examine the involvement of stem cells in the reconstitution of the non-parenchymal cell compartment after transplantation. Indeed, some cell populations have the potential to differentiate into endothelial cells[93,134,135] or could differentiate into mesodermal lineages similar to their phenotype (as hepatic stellate cells or fibroblasts) and as such interfere with the liver tissue architecture (Figure 3). Regarding the promising results obtained using MSCs as third-party for HSCs transplantation[29,31] or in immunological pathologies[30], the immunomodulatory role of these cells as adjuvant in LCT or in OLT should be determined.

Abstract

AIM: To investigate the effects and molecular mechanisms of berberine on improving insulin resistance induced by free fatty acids (FFAs) in 3T3-L1 adipocytes.

METHODS: The model of insulin resistance in 3T3-L1 adipocytes was established by adding palmic acid (0.5 mmol/L) to the culture medium. Berberine treatment was performed at the same time. Glucose uptake rate was determined by the 2-deoxy-[^{3}H]-D-glucose method. The levels of IkB kinase beta (IKKβ) Ser^{181} phosphorylation, insulin receptor substrate-1(IRS-1) Ser^{307} phosphorylation, expression of IKKβ, IRS-1, nuclear transcription factor kappaB p65 (NF-κB p65), phosphatidylinositol-3-kinase p85 (PI-3K p85) and glucose transporter 4 (GLUT4) proteins were detected by Western blotting. The distribution of NF-κB p65 proteins inside the adipocytes was observed through confocal laser scanning microscopy (CLSM).

RESULTS: After the intervention of palmic acid for 24 h, the insulin-stimulated glucose transport in 3T3-L1 adipocytes was inhibited by 67%. Meanwhile, the expression of IRS-1 and PI-3K p85 protein was reduced, while the levels of IKKβ Ser^{181} and IRS-1 Ser^{307} phosphorylation, and nuclear translocation of NF-κB p65 protein were increased. However, the above indexes, which indicated the existence of insulin resistance, were reversed by berberine although the expression of GLUT4, IKKβ and total NF-κB p65 protein were not changed during this study.

CONCLUSION: Insulin resistance induced by FFAs in 3T3-L1 adipocytes can be improved by berberine. Berberine reversed free-fatty-acid-induced insulin resistance in 3T3-L1 adipocytes through targeting IKKβ.

Berberine reverses free-fatty-acid-induced insulin resistance in 3T3-L1 adipocytes through targeting IKKβ. *World J Gastroenterol* 2008; 14(6): 876-883 Available from: URL: http://www.wjgnet.com/1007-9327/14/876.asp DOI: http://dx.doi.org/10.3748/wjg.14.876

INTRODUCTION

Berberine is an isoquinoline alkaloid extracted from *Rhizoma Coptidis*. It was initially used as a heat-clearing and detoxicating agent and an anti-inflammatory drug in clinical practice. Recently, it has been reported that activating the AMP-activated protein kinase (AMPK) pathway is the underlying mechanism for berberine improving insulin resistance, lowering blood sugar, and correcting lipid metabolism disorders[1-4]. A question will be asked if the anti-inflammatory effect of berberine is related to the effect of insulin-resistance improvement. It has been reported that salicylic acid, a traditional anti-inflammatory agent, reverses obesity- and diet-induced insulin resistance by inhibiting IkB kinase β (IKKβ)[5,6]. This has provided us with a new approach of studying the effect of berberine: is IKKβ a potential target for berberine for improving insulin resistance and relieving inflammation? This study established a model of insulin resistance induced by free fatty acids (FFAs) in 3T3-L1 adipocytes in order to observe the effects of berberine on the expression of inflammation molecules such as IKKβ, nuclear transcription factor kappaB p65 (NF-κB p65)

and insulin-signal-transduction related molecules such as insulin receptor substrate-1 (IRS-1), phosphatidylinositol-3-kinase (PI-3K) and glucose transporter 4(GLUT4), with an attempt to confirm that IKKβ is the target for berberine on relieving inflammation and improving insulin resistance.

MATERIALS AND METHODS

Drugs and reagents

Berberine (B3251), palmitic acid (PA, P0500), sodium acetylsalicylic acid (As, A5376) and fatty-acid-free bovine serum albumin (FAF BSA, A8806) were all purchased from Sigma (St Louis, MO, USA).

Cell culture and differentiation

3T3-L1 preadipocytes (obtained from Cell Center of the Institute of Basic Medicines, Chinese Academy of Medical Sciences, China) were grown to confluence in Dulbecco's minimal essential medium (DMEM; obtained from Gibco Invitrogen, USA) containing 25 mmol/L glucose and 10% fetal bovine serum (FBS; obtained from Gibco Invitrogen) at 37℃ in a humidified atmosphere containing 5% CO_2. Two days after confluence, cells were placed in DMEM containing 25 mmol/L glucose, 0.5 mmol/L isobutylmethylxanthine (15879), 1 μmol/L dexamethasone (D4902), 10 μg/mL insulin (I-6634) (all purchased from Sigma), and 10% FBS for 2 d, and then for 2 d in DMEM that contained 25 mmol/L glucose, 10 μg/mL insulin, and 10% FBS. Thereafter, cells were maintained in and re-fed every 2 d with DMEM, 25 mmol/L glucose, and 10% FBS until used in experiments 8-12 d after the start , when between 90 and 95% of the cells exhibited an adipocyte phenotype[7].

Establishment of insulin-resistance model and grouping

Fully differentiated 3T3-L1 adipocytes were cultured for 12 h in serum-free DMEM with 0.2% BSA. Then they were cultured for 24 h in DMEM containing 0.5 mmol/L PA and 1% BSA (model group), or for 24 and 48 h in DMEM containing 0.5 mmol/L PA, 10 μmol/L berberine, 1% BSA (high-dose berberine group, BH24, BH48 group), or in DMEM containing 0.5 mmol/L PA, 1 μmol/L berberine, 1% BSA for 24 h and 48 h（low-dose berberine group, or BL24, BL48 groups), or cultured in DMEM containing 0.5 mmol/L PA, 5 mmol/L As, 1% BSA for 24 h and 48 h (As group, or As24, As48 group); or in DMEM containing 1% BSA for 24 h (normal group).

Determination of glucose uptake rate

3T3-L1 preadipocytes (5×10^5/well) were differentiated to adipocytes in a 24-well plate. After serum-starvation in 0.2% BSA DMEM overnight, the cells were incubated in 0.2% BSA DMEM containing 0.5 mmol/L PA or (and) 1 μmol/L, 10 μmol/ L Ber or 5 mmol/L aspirin for 24 or 48 h. Then, the cells were incubated in 1 mL Krebs/Ringer phosphate (KRP)/HEPES (131.2 mmol/L NaCl, 4.71 mmol/L KCl, 2.47 mmol/L $CaCl_2$, 1.24 mmol/L $MgSO_4$, 2.48 mmol/L Na_3PO_4, 10 mmol/L HEPES, pH 7.4) with or without 100 nmol/L insulin for 30 min at 37℃, after being washed three times in KRP/HEPES buffer. Next, the cells were incubated in 1 mL KRP/HEPES containing 0.5 μCi/mL 2-deoxy-D-[^{3}H] glucose (purchased from Beijing Yuanzi Hi-Tech, China) for 10 min at 37℃. Finally, the cells were washed three times in ice-cold PBS and solubilized in 1 mL 0.1 mol/L NaOH for 2 h. Radioactivity was determined by liquid scintillation spectrometry. Non-specific deoxyglucose uptake was measured in the presence of 20 μmol/L cytochalasin B (Sigma), and specific glucose uptake was detected from the subtracted total uptake. Three replicate wells were set up and each experiment was repeated three times[8]. Additionally, a Cell Counting Kit-8 (CCK-8) was employed for the monitoring of the number and viability of the cells[9].

Western blot analysis

3T3-L1 preadipocytes were grown and differentiated into adipocytes in 35-mm culture dishes. After serum-starvation in 0.2% BSA DMEM overnight, the cells were incubated in 0.2% BSA DMEM containing 0.5 mmol/L PA or (and) 1 μmol/L, 10 μmol/L Ber or mmol/L Aspirin for 24 or 48 h. Then, whole-cell lysate was made in lysis buffer (1% Triton X-100, 50 mmol/L KCl, 25 mmol/L HEPES, pH 7.8, 10 μg/mL leupeptin, 20 μg/mL aprotinin, 125 μmol/L dithiothreitol (DTT), 1 mmol/L phenylmethylsulfonyl fluoride (PMSF), 1 mmol/L sodium orthovanadate) by sonication. For NF-κB p65 detection, cytosolic and nuclear fractions were separated (first buffer: 10 mmol/L HEPES pH 7.9, 10 mmol/L KCl, 0.1 mmol/L EDTA, 1.5 mmol/L $MgCl_2$, 0.1% NP4O, 1 mmol/L DTT; second buffer: 20 mmol/L HEPES pH 7.9, 420 mmol/L NaCl, 0.1 mmol/L EDTA, 1.5 mmol/L $MgCl_2$, 25% glycerol, 1 mmol/L DTT, 0.5 mmol/L PMSF. Protein concentrations were measured by BCA Protein Assay kit (Pierce, USA).The protein (50 μg) in 50 μL reducing sample buffer was boiled for 5 min, and resolved by SDS-PAGE for 2 h at 110 V. Then, the protein was transferred onto a polyvinylidene difluoride (PVDF) membrane. After transfer, the PVDF membrane was washed with 25 mL Tris-buffered saline (TBS) for 5 min at room temperature. The membrane was incubated in 25 mL blocking buffer (1 × TBS, 0.1% Tween-20 with 5% non-fat dry milk) for 2 h at room temperature, and then washed three times for 5 min each with 15 mL TBS/0.1% Tween-20 (TBS/T). The membrane was incubated with primary antibody including IKKβ antibodies, phosphorylated IKKβ Ser^{181} antibodies, phosphorylated IRS-1 Ser^{307} antibodies (Cell Signaling, USA), IRS-1 antibodies, PI-3K p85 antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA), GLUT4 antibodies (R&D Systems, USA) NF-κB p65 antibodies (Neomarkers, USA), β-actin antibodies (Lab Vision, USA) (at the appropriate dilution) in 10 mL primary antibody dilution buffer with gentle agitation overnight at 4℃, and then washed three times for 5 min each with 15 mL 10 × TBS/0.1% TBS/T. The membrane was incubated with HRP-conjugated secondary antibody (1:3000; Pierce) in 10 mL blocking buffer with gentle agitation for 2 h at room temperature, and washed three times for 5 min each

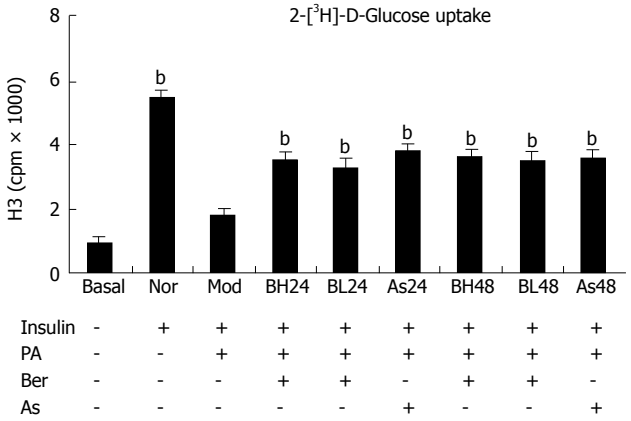

Figure 1 Insulin-induced 2-deoxy-[^{3}H]-D-Glucose uptake in 3T3-L1 adipocytes . 3T3-L1 preadipocytes (5×10^5/well) were differentiated to adipocytes in a 24-well plate. After serum-starvation in 0.2% BSA DMEM overnight, the cells were incubated in 0.2% BSA DMEM containing 0.5 mmol/L PA or (and) 1 μmol/L, 10 μmol/L Ber or 5 mmol/L Aspirin for 24 h or 48 h. Then, the cells were incubated in 1 mL KRP-HEPES without or with 100 nmol/L insulin for 30 min at 37℃ after washed three times in KRP-HEPES buffer. Next, the cells were incubated in 1 mL KRP-HEPES containing 0.5 μCi/mL 2-deoxy-D-[^{3}H] glucose for 10 min at 37℃. Finally, the cells were washed three times in ice-cold PBS and solubilized in 1ml of 0.1 mol/L NaOH for 2 h. Radioactivity was determined by liquid scintillation spectrometry. Nonspecific deoxyglucose uptake was measured in the presence of 20 μmol/L cytochalasin B and specific glucose uptake was detected from the subtracted total uptake. Three replicate wells were set up and each experiment was repeated three times. $^bP < 0.01$, *vs* Mod group.

with 15 mL TBS/T. Immunoreactive bands were detected with the ECL kit (Pierce) and immunoreactive bands on autoradiography films were scanned (Bio-Rad). Intensity of the immunoblot signal was analyzed quantitatively using Quantity One software (Bio-Rad).

Detection of NF-κB p65 proteins by laser scanning confocal microscopy (LSCM)

3T3-L1 preadipocytes were differentiated into adipocytes in a six-well plate. After serum-starvation in 0.2% BSA DMEM overnight, the cells were incubated in 0.2% BSA DMEM containing 0.5 mmol/L PA or (and) 10 μmol/L Ber or 5 mmol/L aspirin for 24 or 48 h. Cells were harvested and coverslips were fixed with fixed liquid (dehydrated alcohol: acetone; 1:1 v/v) for 10 min and 1% Triton X-100 for 5 min. After completely rinsing with water and washing with PBS, rabbit-anti-human NF-κB p65 antibody (1:100, 50 μL) was added drop wise and stored at 4℃ overnight. The following day, after washing with PBS, Cy-3-labeled sheep-anti-rabbit IgG was added drop wise, and the samples were incubated in a wet box in the dark at 37℃ for 30 min. After washing with PBS in the dark, diamidino phenylindole (DAPI) solution was added drop wise to counterstain the nucleus for 30 s (in the dark at room temperature, about 37℃). After washing with PBS and distilled water, 50% buffered glycerol was used for coverslip sealing. Image acquisition was achieved using an Olympus FV500 fluorescent microscope. An immersion objective lens was used to observe the samples. The excitation wavelengths of CY-3 and DAPI were 552 and 358 nm, respectively. The emission wavelengths were 565 and 460 nm, respectively. Ten randomly selected areas were taken from each coverslip to account for variations in the expression levels of NF-κB p65. Images were analyzed quantitatively by the HMIAS-2000 Imaging System, China.

RESULTS

Berberine increases insulin-induced glucose uptake in 3T3-L1 adipocytes with insulin resistance

We used 3T3-L1 adipocytes as a cellular model to analyze the insulin signaling pathway. 3T3-L1 adipocytes were treated with PA (0.5 mmol/L, 24 h) to induce insulin resistance. Insulin-induced glucose uptake was measured to determine insulin sensitivity. The results showed insulin-induced glucose uptake was 5.6 times higher than that in the normal group, but was inhibited by as much as 67% after incubation with PA for 24 h. This is consistent with reports FFA induces insulin resistance in cell culture[10,11]. However, intervention with berberine or aspirin reversed the condition completely. Insulin-induced glucose uptake was increased by 82% and 93% after intervention with 1 and 10 μmol/L berberine for 24 h, and increased by 93% and 101% after intervention with berberine for 48 h, respectively. The data was performed in a dose- and time-dependent manner. In addition, the insulin-induced glucose uptake was increased by 109% and 97%, respectively, in the aspirin groups (Figure 1). The viability and number of cells might have decreased because of the toxic effects of 48-h aspirin treatment (Table 1).

Berberine increases the expression of IRS-1 and PI-3K p85 protein in 3T3-L1 adipocytes with insulin resistance

To understand the role of insulin signal transduction proteins in the mechanism by which berberine acts on FFA-induced insulin resistance, IRS-1, PI-3K p85 and GLUT4 protein abundance were detected with IRS-1, PI-3K p85 and GLUT4 antibodies by immunoblotting in 3T3-L1 adipocytes. The results showed that expression of IRS-1 and PI-3K p85 protein was reduced after incubation with FFA (0.5 mmol/L PA, 24 h) ($P < 0.01$) and this reduction was inhibited by berberine (1 or 10 μmol/L) or aspirin (5 mmol/L). The data was still performed in a

dose- and time-dependent manner ($P < 0.01$) (Figure 2A and B). However, there was no change in the expression of GLUT4 protein after the intervention of FFA, berberine and aspirin (Figure 2C).

Berberine inhibits FFA-induced IRS-1 Ser^{307} phosphorylation in 3T3-L1 adipocytes

Serine phosphorylation precedes IRS-1 degradation[12-14] and Ser^{307} phosphorylation of IRS-1 has become a molecular indicator of insulin resistance[15-18], therefore, we investigated the effect of berberine on IRS-1 Ser^{307} phosphorylation with phosphorylation-specific IRS-1 Ser^{307} antibody by immunoblotting. In 3T3-L1 adipocytes, PA (0.5 mmol/L, 24 h) may have induced IRS-1 Ser^{307} phosphorylation and berberine (1 or 10 μmol/L) or aspirin (5 mmol/L) were found to reduce IRS-1 Ser^{307} phosphorylation, and this reduction by berberine was dose- and time-dependent. These results suggest that Ser^{307} phosphorylation contributes to IRS-1 degradation and berberine inhibits FFA-induced IRS-1 Ser^{307} phosphorylation in 3T3-L1 adipocytes (Figure 3).

Berberine inhibits FFA-induced IKKβ Ser^{181} phosphorylation in 3T3-L1 adipocytes

It was reported that Ser^{307} of IRS-1 can be phosphorylated by either IKK or JNK[15,19], and IKK is more sensitive

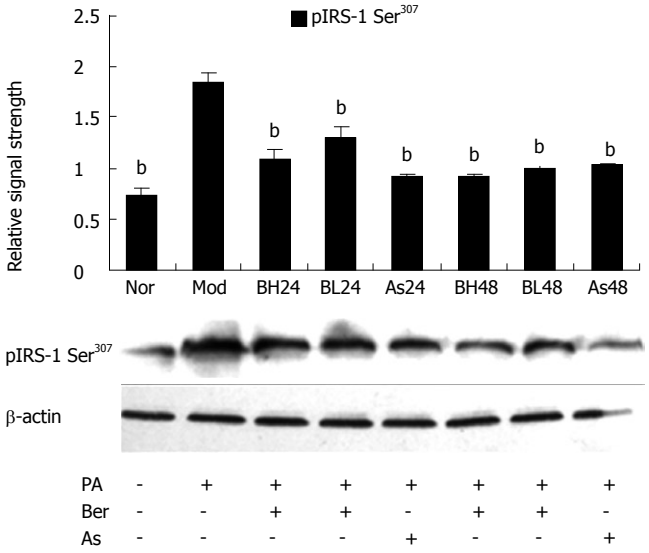

Figure 3 Effect of Ber on the IRS-1 Ser^{307} Phosphorylation in 3T3-L1 Adipocytes. Fully differentiated cells were cultured for 12 h in serum-free DMEM with 0.2% BSA and then they were, respectively, cultured for 24 h in DMEM containing 0.5 mmol/L PA and 1% BSA (Mod); or cultured for 24 and 48 h in DMEM containing 0.5 mmol/L PA, 10 μmol/ L Ber, (1% BSA, BH24) BH48; or in DMEM containing 0.5 mmol/L PA, 1 μmol/ L Ber, 1% BSA for 24 h and 48 h (BL24, BL48); or cultured in DMEM containing 0.5 mmol/L PA, 5 mmol/L aspirin, 1% BSA for 24 h and 48 h (As24, As48); or in DMEM containing 1% BSA for 24 h (Nor). IRS-1 phosphorylation was determined in the whole cell lysate by immunoblotting with the phosopho-spcific IRS-1(Ser^{307}) antibody. Each experiment was repeated three times. $^{b}P < 0.01$, *vs* Mod group.

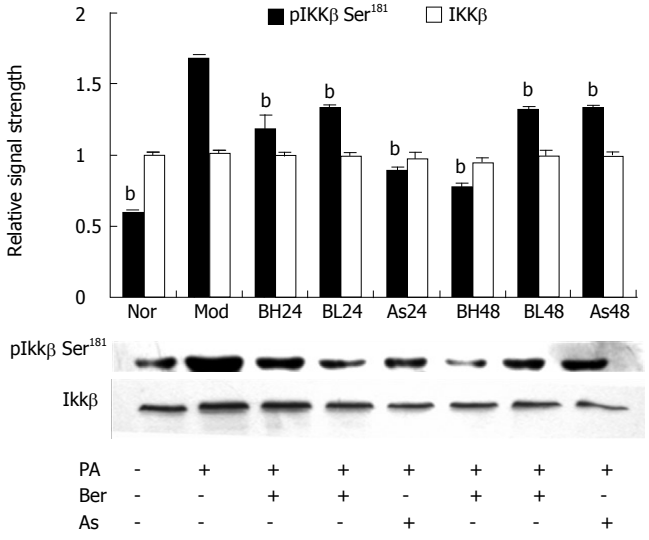

Figure 4 Effect of Ber on the IKKβ Ser^{181} Phosphorylation and IKKβ protein expression in 3T3-L1 Adipocytes. IKKβ phosphorylation and IKKβ protein expression were determined in the whole cell lysate by immunoblotting with the phosopho-spcific IKKβ (Ser^{181}) antibody and IKKβ antibody respectively. Each experiment was repeated three times. $^{b}P < 0.01$, as compared with Mod group.

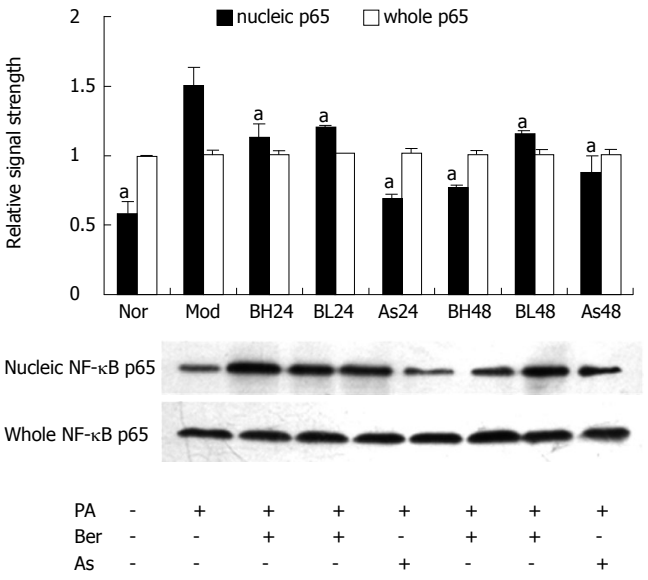

Figure 5 Effect of Ber on the whole NF-κB p65 and nucleic NF-κB p65 protein expression in 3T3-L1 Adipocytes. Fully differentiated cells were cultured for 12 h in serum-free DMEM with 0.2% BSA and then they were, respectively, cultured for 24 h in DMEM containing 0.5 mmol/L PA and 1% BSA (Mod); or cultured for 24 and 48 h in DMEM containing 0.5 mmol/L PA, 10 μmol/L Ber,1% BSA (BH24, BH48); or in DMEM containing 0.5 mmol/L PA, 1 μmol/L Ber, 1% BSA for 24 h and 48 h (BL24, BL48); or cultured in DMEM containing 0.5 mmol/L PA, 5 mmol/L aspirin, 1% BSA for 24 h and 48 h (As24, As48); or in DMEM containing 1% BSA for 24 h (Nor). whole NF-κB p65 and nucleic NF-κB p65 protein expression were determined in the whole cell lysate and nucleic cell lysate by immunoblotting respectively. Each experiment was repeated three times. $^{a}P < 0.05$ *vs* Mod group.

to FFAs. In mammalian cells, phosphorylation of Ser^{181} at the activation loop is essential for activation of the catalytic activity of IKK[20,21]. In this study, we investigated an effect of berberine on IKKβ serine^{181} phosphorylation and protein abundance of IKKβ with the phosphorylation-specific IKKβ Ser^{181} antibody and IKKβ antibody by immunoblotting. In 3T3-L1 adipocytes, PA (0.5 mmol/L, 24 h) may induce IKKβ Ser^{181} phosphorylation; berberine (1 μmol/L, 10 μmol/L) or aspirin (5 mmol/L) were found to reduce IKKβ Ser^{181} phosphorylation, with the the reduction by berberine in a dose- and time-dependent manner ($P < 0.01$). However, IKKβ protein abundance was unchanged during this study. These results suggest Ser^{307} phosphorylation of IRS-1 is associated with activation of IKKβ, and that berberine inhibits FFA-induced IKKβ Ser^{181} phosphorylation in 3T3-L1 adipocytes (Figure 4).

Berberine inhibits expression of FFA-induced nuclear NF-κB p65 protein in 3T3-L1 adipocytes

The NF-κB/Rel transcription factors are present in the cytosol in an inactive state, combined with the inhibitory IkB proteins. The key step in NF-κB nuclear translocation is mediated by IKKβ. In this study, we examined the effect of berberine on NF-κB p65 protein abundance obtained from whole-cell extracts and nuclear extracts with NF-κB p65 antibody, by immunoblotting. The results showed that, in 3T3-L1 adipocytes, PA (0.5 mmol/L, 24 h) may have induced nuclear NF-κB p65 protein, and berberine (1 or 10 μmol/L) or aspirin (5 mmol/L) were found to reduce expression of NF-κB p65 protein, and this reduction by berberine was dose- and time-dependent ($P < 0.05$). However, whole NF-κB p65 protein abundance was unchanged during this study (Figure 5).

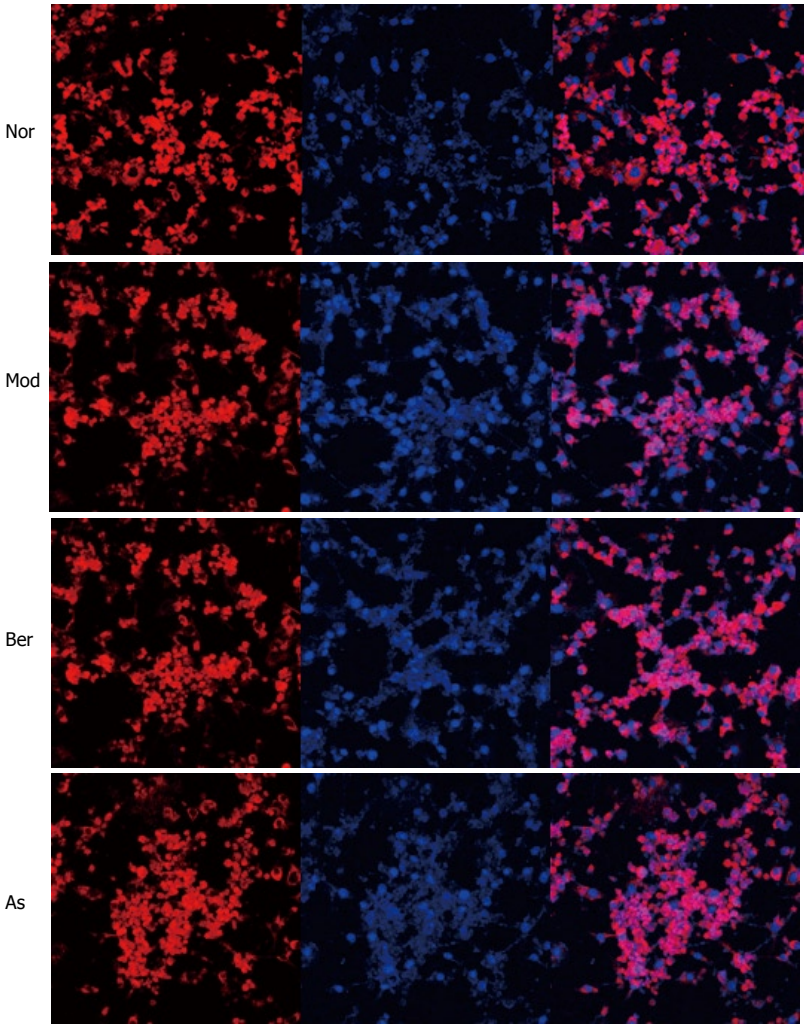

Figure 6 Fully differentiated cells were cultured for 12 h in serum-free DMEM with 0.2% BSA and then they were, respectively, cultured for 24 h in DMEM containing 1% BSA for 24 h (Nor); or cultured for 24 h in DMEM containing 0.5 mmol/L PA and 1% BSA (Mod); or cultured for 48 h in DMEM containing 10 μmol/L Ber, 0.5 mmol/L PA, 1% BSA (Berberine); or cultured for 24h in DMEM containing 5 mmol/L aspirin, 0.5 mmol/L PA, 1% BSA (Aspirin). Without FFA stimulation NF-κB p65 is predominately found in the cytoplasm, imparting red color (Nor). While FFA stimulation, NF-κB p65 is translocated into the nucleus, showing pink color (Mod). The addition of 10 μmol/L Ber or 5 mmol/L aspirin clearly inhibits the FFAs induced NF-κB p65 translocation, as there is hardly any nuclear p65 staining found and in the figure, both red and pink colors can be observed (Berberine and Aspirin).

Berberine inhibits nuclear translocation of NF-κB p65 protein in 3T3-L1 adipocytes

To test the hypothesis that berberine inhibits expression of FFA-induced NF-κB p65 protein in 3T3-L1 adipocytes, immunofluorescence by LSCM was used to investigate the distribution of NF-κB p65. Nuclei were stained with DAPI (blue) and NF-κB p65 was stained with CY-3 (red). The confocal superimposition of the two fluorescence stains yielded a pink color, which indicated that NF-κB p65 was translocated into the nuclei. The results showed that, without FFA stimulation, NF-κB p65 was predominately found in the cytoplasm, and imparted a red color (normal group), while with FFA stimulation, NF-κB p65 was translocated to the nucleus, and showed a pink color (model group). The addition of 10 μmol/L berberine or 5 mmol/L aspirin clearly inhibited the FFA-induced NF-κB p65 translocation; there was hardly any nuclear p65 staining found, and in the figure, both red and pink colors can be observed (indicating berberine and aspirin), which is consistent with the Western blot analysis results (Figure 6).

DISCUSSION

Berberine is an isoquinoline alkaloid extracted from *Rhizoma Coptidis*, and it was initially used as a heat-clearing and detoxicating agent and as an anti-inflammatory drug in clinical practice. Further pharmacological studies have found that the effects of berberine include improving insulin resistance, lowering blood sugar, and correcting disorders of lipid metabolism[1-4]. Based on the effects of berberine on diabetes and the new notion that type 2 diabetes is essentially a disease of chronic inflammation, we make hypothesis if the anti-inflammation effect of Ber is related to the effect of insulin-resistance improvement.

Recently, it has been reported that salicylic acid, a traditional anti-inflammatory agent, reverses obesity- and diet-induced insulin resistance by inhibiting IKKβ[5,6]. Many studies have shown insulin signal transduction proteins are regulated, not only by tyrosine phosphorylation, but also by Ser/Thr phosphorylation. IKKβ, a Ser/Thr protein kinase, is closely related to the development of insulin resistance and is known to be a new target for the improvement of insulin resistance[5]. Is IKKβ a potential molecular target for berberine for improving insulin resistance and relieving inflammation?

In our previous studies, we have established a murine model of insulin resistance by injection of small doses of streptozotocin via the tail vein plus oral administration of high-fat and high-caloric diet. After treatment with berberine for 10 wk, the levels of fasting blood glucose and insulin were substantially lowered; the oral glucose tolerance test was conspicuously improved; serum inflammatory factors IL-1β, IL-6, TNF-α, acute-phase

reactive protein (CRP), and adhesion molecules (ICAM-1, VCAM-1) were obviously lowered; and at the same time, tyrosine phosphorylation of insulin receptor β subunit, tyrosine phosphorylation of IRS-1, expression of IRS-1, GLUT4, PI-3K protein, and translocation of GLUT4 protein were significantly elevated in adipose and muscular tissues, compared with those in the model group. This suggests berberine reduces inflammation, lowers blood glucose and improves insulin resistance[22-24].

In the present study, we investigated the underlying mechanisms of the effects of berberine on insulin resistance and inflammation *in vitro*. Insulin resistance in 3T3-L1 adipocytes was induced by incubation with PA (0.5 mmol/L, 24 h), as judged by a 67% decrease in insulin-stimulated glucose uptake. This was reversed by prior incubation of cells with berberine or aspirin. The expression of IRS-1 and PI-3K p85 proteins was reduced after PA incubation and this reduction was inhibited by intervention with berberine (1 or 10 μmol/L) or aspirin (5 mmol/L). However, there was no change in GLUT4 abundance after incubation with FFAs, berberine and aspirin. The results suggest inhibition of insulin-induced glucose uptake is caused by reduction of IRS-1 and PI-3K, not GLUT4. Thus, IRS-1 and PI-3K p85 protein, but not GLUT4, might be involved in the effects of berberine on insulin resistance in 3T3-L1 adipocytes.

It has been shown Ser^{307} phosphorylation contributes to IRS-1 degradation in hepatocytes in response to insulin[25]. In our study, PA may have increased IRS-1 Ser^{307} phosphorylation, while berberine or aspirin were found to reduce IRS-1 Ser^{307} phosphorylation. It can be inferred that the same mechanism contributes to FFA-induced degradation of IRS-1 in adipocytes, and Ser^{307} phosphorylation of IRS-1 was inhibited by berberine. Since Ser^{307} of IRS-1 can be phosphorylated by IKK[15,19] and phosphorylation of Ser^{181} at the activation loop is essential for activation of the catalytic activity of IKK[20,21], we observed the expression of IKKβ Ser^{181} phosphorylation in 3T3-L1 adipocytes. PA may have increased IKKβ Ser^{181} phosphorylation, and this was reversed by prior incubation of cells with berberine or aspirin. It was demonstrated that IKKβ Ser^{181} phosphorylation may contribute to IRS-1 Ser^{307} phosphorylation in response to FFAs, and berberine inhibited FFA-induced IKKβ Ser^{181} phosphorylation in 3T3-L1 adipocytes.

It is known the NF-κB/Rel transcription factors are present in the cytosol in an inactive state, complexed with the inhibitory IkB proteins, and that NF-κB nuclear translocation is mediated by IKKβ[26,27]. In our study, we detected NF-κB p65 protein in whole-cell and nuclear extracts, and investigated the distribution of NF-κB p65. It has been shown that in 3T3-L1 adipocytes, PA may increase the expression of NF-κB p65 protein, while berberine or aspirin reduce the expression of NF-κB p65 protein. However, NF-κB p65 protein abundance was not changed during this study. LSCM demonstrated significant translocation of NF-κB p65 into the nucleus after stimulation with PA. The translocation was inhibited by berberine or aspirin, which is consistent with the results of Western blot analysis. Taken together, the data suggest that berberine inhibits translocation of NF-κB p65 into the nucleus in 3T3-L1 adipocytes.

In summary, our study demonstrated potential links between chronic inflammation and insulin resistance. IKKβ may be an important target for this link. Increased IKKβ activity promotes insulin resistance, while reduction in IKKβ activity significantly improves insulin sensitivity. In the signaling pathway, FFAs activate IKKβ, which leads to Ser^{307} phosphorylation in IRS-1 and translocation of NF-κB p65 into the nucleus[28,29]. On the one hand, serine phosphorylation is responsible for a reduction in tyrosine phosphorylation of IRS-1, which leads to a reduction in IRS-1 protein and insulin resistance. On the other hand, translocation of NF-κB p65 into the nucleus may enhance the production of inflammatory molecules such as TNFα. The positive feedback loop may perpetuate a cycle of low-level inflammatory signaling that leads to insulin resistance. Our findings were consistent with those reported by Gao *et al*[30]. Thus, inhibitors of IKKβ, such as aspirin and berberine, through the same signaling pathway, have significant effects on insulin resistance. Therefore, we conclude berberine might achieve its anti-inflammatory and insulin-resistance-improving effects by inhibiting phosphorylation of IKKβ Ser^{181}.

COMMENTS

Background

Berberine was initially used as a heat-clearing and detoxifying agent and an anti-inflammatory drug in clinical practice. Further pharmacological studies have found the effects of berberine include improving insulin resistance, lowering blood sugar and correcting disorders of lipid metabolism *in vitro* and *in vivo*. It has been shown that type 2 diabetes is essentially a disease of chronic inflammation. The question remains if the anti-inflammatory effect of berberin is related to the effect of insulin resistance improvement.

Research frontiers

Recently, it has been reported that salicylic acid, a traditional anti-inflammatory agent, may reverse obesity- and diet-induced insulin resistance by inhibiting IKKβ. Many studies have shown insulin signal transduction proteins are regulated, not only by tyrosine phosphorylation, but also by Ser/Thr phosphorylation. IKKβ, a Ser/Thr protein kinase, is closely related to the development of insulin resistance and is known as a new target for the improvement of insulin resistance. Is IKKβ a potential molecular target for berberine for improving insulin resistance and relieving inflammation?

Innovations and breakthroughs

Our research has established a model of insulin resistance induced by FFA in 3T3-L1 adipocytes, and we have observed the effects of berberine on the expression of inflammatory molecules such as IKKβ, NF-κB and insulin-signal-transduction-related molecules such as IRS-1, PI-3K and GLUT4. These results showed IKKβ may be an important target for potential links between chronic inflammation and insulin resistance. Berberine might achieve its anti-inflammatory and insulin-resistance-improving effects by inhibiting phosphorylation of IKKβ Ser^{181}.

Applications

Our study showed IKKβ may be a potential molecular target for berberine when improving insulin resistance and relieving inflammation. The use of berberine as

an inhibitor of IKKβ provides us with a new approach for the treatment of non-infectious chronic diseases, such as type 2 diabetes, obesity, hypertension, atherosclerosis and ischemic cerebrovascular disease.

Terminology

IKKβ: IKK is a multi-subunit protein kinase. There is strong biochemical and genetic evidence that the IKK complex consists of two catalytic subunits, IKKα and IKKβ, and a regulatory subunit, IKKγ. However, of the two catalytic subunits, only IKKβ is essential for NF-κB activation in response to pro-inflammatory stimuli. Many studies have shown that IKKβ, a Ser/Thr protein kinase, is closely related to the development of insulin resistance, and is known as a new target for the improvement of insulin resistance.

Peer review

This study investigated the influence of berberine on FFA-treated 3T3-L1 cells. Similar data have not been published so far and the figures are clearly presented.

Abstract

AIM: To investigate the interrelationship between *H pylori* and Epstein-Barr virus (EBV) infection in the gastric carcinogenesis having in focus the *p53* mutation and the c-Myc, Bcl-2 and Bax expression.

METHODS: seventy-one gastric carcinoma tissues were assessed by polymerase chain reaction (PCR) for *H pylori* and *in situ* hybridization for EBV. c-Myc, Bcl-2 and Bax expression were detected by immunohistochemistry and single-stranded conformational polymorphism (SSCP) for *p53* mutation.

RESULTS: The positivity rates for *H pylori* and EBV were 94.4% and 8.45%, respectively. The majority of the cases displayed only the *H pylori* presence. All EBV positive cases were also *H pylori* positive. None infectious agent was observed in 5.55% of the cases. The intestinal type tumor was more frequent in the co-infected and non-infected groups. The female predominated in the non-infected group showing statistical significance (70.4% *vs* 29.6%, $P = 0.039$). The Bcl-2 was only detected in the group exclusively infected by *H pylori*. However, c-Myc and Bax were detected in the three groups but with a low frequency in the co-infected group. Mutation of *p53* was present in all groups, with the highest frequencies in the *H pylori* positive groups.

CONCLUSION: The frequency of *H pylori* infection in gastric carcinomas was high. The presented data indicated that gastric carcinogenesis has different pathways depending of the presence of the two investigated infectious agents, suggesting a possible involvement of *H pylori* with apoptotic process. The low expression of c-Myc and Bax in the EBV-positive groups suggests that EBV may inhibit the expression of these proteins. Nevertheless, *p53* mutation shows to be a relevant alteration, independent of both infectious agents.

INTRODUCTION

Gastric cancer is the fourth most common cancer and the second cause of cancer-related death worldwide[1]. There is substantial international variation in the gastric cancer incidence with the highest rates reported from Korea, Japan and Eastern Asia. Other high incidence areas include Eastern Europe and parts of Latin America, while Western Europe and the United States of America generally have low incidence rates. The global burden of gastric cancer is shifting rapidly from the developed world to the developing world[2].

Over 95% of stomach tumors are adenocarcinomas which are subdivided into two main histological types: intestinal type and diffuse type. The intestinal type is

related to corpus-dominant gastritis with gastric atrophy and intestinal metaplasia, whereas the diffuse type usually originates in pangastritis without atrophy[1,2].

The two main anatomic sites of gastric adenocarcinoma are proximal (cardia) and distal (noncardia). The frequency of the theses tumor sites varies in populations from different geographic locations, racial and socio economic groups. They may differ in genetic susceptibility, pathologic profile, clinical presentation and prognosis. The observed differences between gastric cancers by anatomic sites suggest that they are distinct diseases with different etiologies. Although the distal cancer is usually more frequent, a decreased incidence has been observed in this site while the incidence of the proximal site tumors have increased since the 1970's especially among males in the Western countries[1,3,4].

There are several etiologic factors involved in gastric cancer such as low socioeconomic status, diet, hereditary factors and *H pylori* infection, as the most cited in studies about this issue. Besides the *H pylori*, Epstein-Barr virus (EBV) infection is also associated with development of gastric cancer[1,2,6].

The discovery of *H pylori* infection in the early eighties proved a turning point in the understanding of the gastric cancer pathogenesis. While the link between *H pylori* and peptic ulcer was established soon after the successful culture of the bacteria, the association with gastric cancer remained doubtful for almost a decade before credible evidence could be presented. The major reason for this delay was the inability to demonstrate the presence of active infection in gastric cancer tissue[1,2]. Despite the recognition of the association between *H pylori* and gastric cancer the pathogenic mechanism involved in this process is still not understood.

In spite of the wide bibliography regarding to the other tumors, the first report about the association of the EBV with gastric carcinomas was in a case of lymphoepithelial-like gastric carcinoma[7]. Soon after, it was identified in common gastric carcinomas[8]. EBV infection is found in approximately 10% of ordinary gastric adenocarcinoma cases; however most of the mechanisms used by the virus to control this process are still unknown. Recent studies have shown that the expression pattern of EBV-encoded genes in gastric carcinoma is different from that in Burkitt's lymphoma and nasopharyngeal carcinoma (NPC), suggesting that the oncogenic mechanism of the EBV in gastric carcinoma may be unique[6,9,10].

In attempt to understand the carcinogenic process triggered by these two infectious agents, some works have looked for alteration in genes/proteins that these agents can target, and therefore, pointing possible pathogenic pathways. In this sense, proteins involved with cell cycle or apoptosis process emerge as a candidate for having a crucial role in the development of the neoplasms. Some of these, like c-Myc, *p53* and the apoptotic family members such as Bcl-2 and Bax, deserve attention for playing a key function in the cell proliferation and cell fate, besides they already have shown involvement in the tumorigenesis process in a variety of tumors, including gastric cancer[11-13].

Although the proteins mentioned above have different levels of alteration in gastric carcinoma, the association with *H pylori* or EBV is controversial[14-16]. Additionally, there is just one paper related *H pylori* and EBV infection with concomitant analysis, in gastric carcinomas, in which, proteins involved in cell cycle and apoptosis process were also evaluated[10]. So, the aim of the present study was to investigate the interrelationship between *H pylori* and EBV infection in the gastric carcinogenesis having in focus the *p53* mutation, and the expression of c-Myc, Bcl-2 and Bax.

MATERIALS AND METHODS

Clinical specimens

The present study was approved by the ethic committee from Federal University of Ceará and all subjects signed informed consent prior to inclusion. Samples from eighty-two patients with gastric carcinoma were collected from two hospitals of the Ceará State, Brazil: Walter Cantídeo Hospital at Federal University of Ceará and Saint House of Mercy in Fortaleza, both located in Fortaleza, the capital of the State. A representative formalin-fixed tumor specimens embedded in paraffin blocks was selected and histological sections (5 μm) were subjected to immunohistochemistry and *in situ* hybridization (ISH). Clinico-epidemiological data were collected from the medical reports. Upon gastrectomy, fragments of tumor were collected and subjected to DNA extraction and Polymerase Chain Reaction (PCR) to detect *urease C* gene of *H pylori* and *p53* mutation.

DNA extraction

DNA was extracted from frozen tumor tissue just when the fragment presented more than 80% of tumor cells. The genomic DNA was extracted using cetyltrimethyl ammonium bromide (CTAB) adapted from the method of Gary[17]. Although we have collected samples from 82 patients, DNA extraction was done in 71 samples because the others did not reach the established percentage of tumor cells.

Detection of H pylori and the presence of cagA gene

The PCR was done to detected *H pylori* infection because this technique is sensitive and specific and it was used by many studies[6,18,38].

The *H pylori* infection was detected by amplification of *urease C* gene using primers for PCR, described by Lage *et al*[18]. For the *H pylori*-positive samples, the presence of the *cag*A gene was identified using the primers described by Domingo *et al*[19]. PCR mixtures for amplification of both genes were prepared in a volume of 25 μL containing 0.4 μmol/L of each primer; 1.5 μmol/L $MgCl_2$; 0.8% Tween 20 and 1 μL of DNA sample. PCR products were analyzed by 1% agarose gel electrophoresis with ethidium bromide staining. Sample was considered *H pylori* positive when an *ure*C fragment of 294bp was amplified while *cag*A gene was positive when a fragment of 297bp was detected. As positive control we used DNA known *H pylori* positive and as negative control we used distillated water.

RNA in situ hybridization

The presence of the EBV was identified by the expression of EBV-encode small RNA-1 (EBER1), the most

abundant viral product in latently infected cells. RNA *in situ* hybridization was performed using a 30bp biotinylated probe complementary to the RNA EBER1 described by Shibata and Weiss[8]. Briefly, after the deparaffinization and rehydration, endogenous peroxidase was blocked with 3% H_2O_2 solution. Enzymatic digestion was performed with proteinase K (0.02 μg/μL final concentration) for 13 min. Prehybridization was done with pre-hybridization solution (Denhardt's solution [3.5X]; SSC [4.5X]; EDTA [0.0075 mol/L]; SDS [0.35%]; NaH2PO4 [0.75 mol/L]; dextran sulfate [10%]) for 60 min at 37℃. Soon after, the slides were incubated overnight at 37℃ with hybridization solution containing 0.3 ng/μL of the probe. After washing with 2X SSC buffer, the signal was amplified using anti-biotin antibody (clone BK, mouse, dilution 1:20) and biotinylated anti-immunoglobulin antibody (polyclonal, rabbit, dilution 1:100). Detection was accomplished using streptavidin-biotin-peroxidase method and the reaction was developed with 3, 3'-diaminobenzidine chromogen. All antibodies were purchased from DakoCytomation®. The slides were counterstained with Harris hematoxylin. A case of nasopharyngeal carcinoma was used as positive control in each reaction, as well as a negative control by omitting the probe. Nuclei with a brown or black staining were considered positive.

Immunohistochemistry

The expression of the proteins Bcl-2, Bax and c-Myc was detected according to the method described by Hsu *et al*[20]. After the deparaffinization and rehydration, antigen retrieval was carried out by microwave-treatment of the slides for 15 min in 10 mmol/L citrate buffer solution (pH 6.0). Endogenous peroxidase activity was blocked with 3% H_2O_2 solution. Primary antibodies were incubated for 16 h at 4℃-8℃ in a humid chamber. All antibodies were purchased from DakoCytomation®. The reaction was detected with LSAB + system (DakoCytomation®) according to the manufacturer's recommendation.

Histopathological and staining analysis

The histological classification (Laurén) was obtained from the medical reporters and was confirmed by a professional pathologist of the team. The slides were evaluated by three experienced technicians independently using light microscopy at a magnification of 400X. In the *in situ* hybridization and immunohistochemistry techniques, the results were expressed as percentage of positive cases. In the immunohistochemistry analysis, only the cases with $\geqslant$ 5% of stained tumor cells were considered as positive while in the *in situ* hybridization, any nuclear staining in tumor cells were considered. For all analyses, at least 1000 tumor cells were counted in high power fields.

Analysis of p53 mutation

To detection of mutation in the *p53* gene was used Single-Stranded Conformational Polymorphism (SSCP) test. Exons 5-9 of *p53* gene were amplified by PCR using four pairs of the primes described by Murakami *et al*[21]. Each PCR reaction for a total of 25 μL final volume consisted of 0.2 mmol/L of the four deoxynucleotide triphosphate, 1.5 mmol/L $MgCl_2$, 0.4 μmol/L of each primer and 0.5 U of Taq DNA polymerase (Invitrogen®). The cycling temperature included an initial temperature at 95℃ for 5 min, followed by 35 cycles of 95℃ for 1 min, 1 min for annealing temperature (55℃ for exons 5 and 8/9; 63℃ for exons 6 and 7), and extension at 72℃ for 1 min. For SSCP analysis, five or six microliters of each PCR products were mixed with a equal volume of stop solution (95% of formamide, 20 mmol/L EDTA, 0.05% of xylene cyanol and 0.05% of bromophenol blue), heated at 95℃ for 5 min and immediately placed on ice and loaded onto a gel containing 12.5% acrylamide (GenePhor™, Amersham Pharmacia Biotech). Electrophoresis was performed using Electrophoresis Unit GenePhor (GE-Healthcare), at 4℃ for 3 h. The patterns of the bands were then visualized by a DNA Silver Staining Kit (Amersham Pharmacia Biotech).

Statistical analysis

The analyses were carried out using the statistical programs EPINFO® 6.04 d version and SPSS® 12.0. Statistically significant differences were evaluated by Chi square test (χ^2). The results were considered as statistically significant when *P*-values were less than 0.05.

RESULTS

Among the analyzed cases, 57 were males and 25 were females. The mean age was 56.5 years (range, 23 to 90 years). Among 71 selected patients, males were a majority [70.4% (50/71)] and 49.3% (35/71) were more than 65 years old. Regard to the Lauren's classification, the intestinal type tumors demonstrated a slightly higher frequency (59.2%).

Detection of H pylori, EBV and markers

The *H pylori* infection was detected by PCR in 67 out of 71 (94.4%) gastric carcinomas. The correlation with sex showed a statistically significant difference $P = 0.041$ (Mantel-Haenszel), in this analysis, since almost all males were *H pylori* positive [98% (49/50)] while the females had a slightly lower prevalence [85.7% (18/21)]. Concerning the gastric regions, the rate of *H pylori* infection in the antrum was higher [55.22% (37/67)] than that of the cardia [28.35 (19/67)] and body [14.92% (10/67)]. The pathogenic genotype of *H pylori* (*cag*A +) was found in 62.7% (42/67) of the cases. Among these cases the intestinal type tumors was predominant [61.9% (26/42)].

The frequency of EBV infection was 8.45% (6/71). All EBV-positive cases were males and half of them were located in the gastric antrum [50% (3/6)]. Concerning the markers, the frequency of Bcl-2, Bax, c-Myc and of the *p53* mutation was 5.63% (4/71), 54.92% (39/71), 42.25% (30/71) and 73.23% (52/71), respectively. An EBV positive case is shown in Figure 1A, while the Figure 1B-D show the Bcl-2, Bax and c-Myc immunodetection, respectively. The Figure 2 is a SSCP gel showing the migration pattern of exons 5 and 7 of *p53* gene.

Relationship between H pylori, markers and p53 mutation

The *cagA* gene was detected in 62.7% (42/67) of the cases with *H pylori* infection. The relationship between

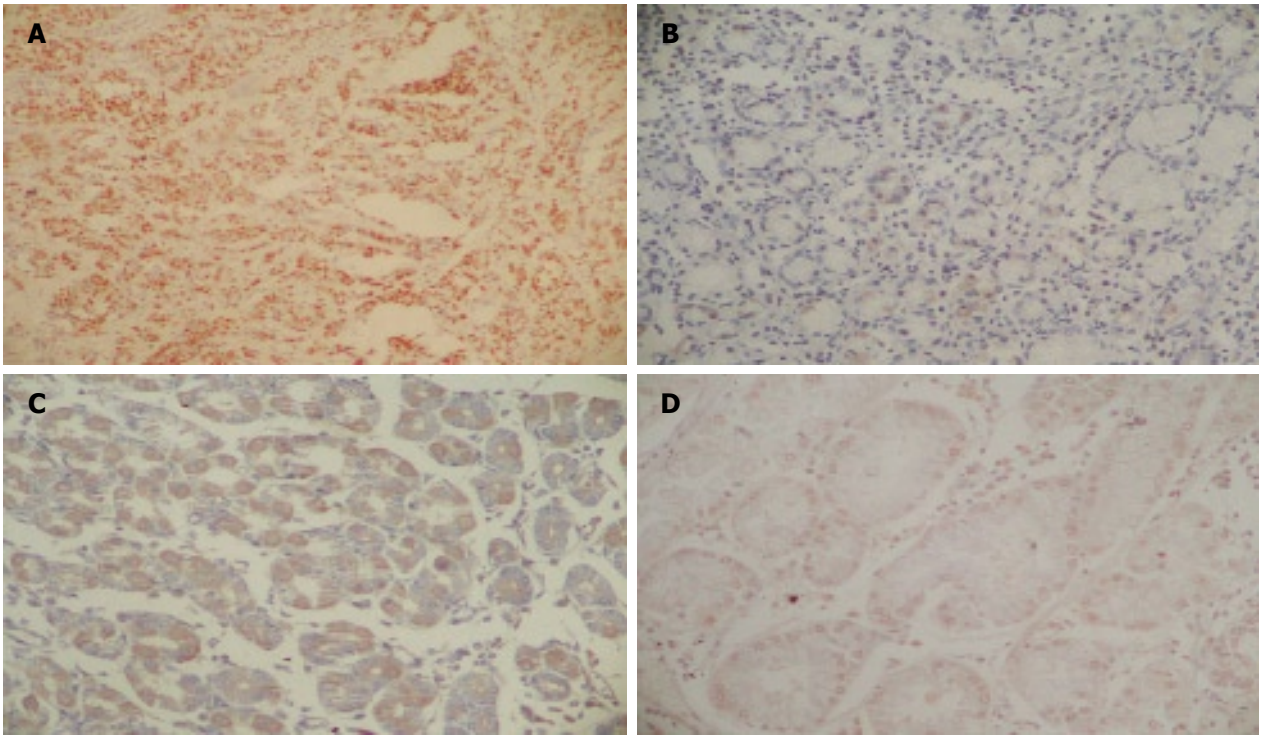

Figure 1 **A**: *In situ* hybridization detection of EBV RNA in gastric cancer (X400); **B**: Bcl-2 expression in gastric carcinoma (× 400); **C**: Bax expression in gastric carcinoma (×400); **D**: c-Myc expression in gastric carcinoma (× 400).

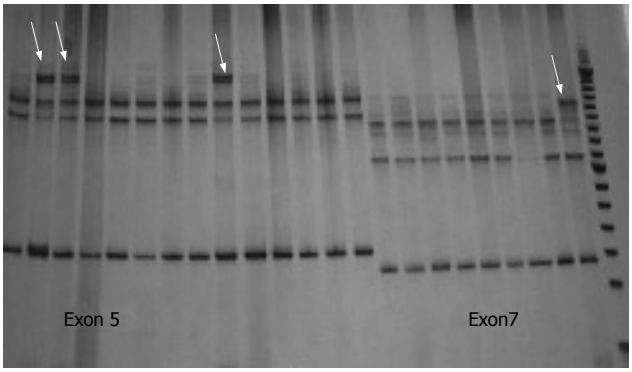

Figure 2 SSCP gel of *p53* gene. The arrows show the different migration patterns of exon 5 (lines 1 to 14) and 7 (lines 15 to 23).

Bcl-2, Bax and c-Myc was statistically not significant. The relationship of the *cag*A(+) with the *p53* mutation reached statistical significance ($P = 0.035$).

Relationship between EBV and H pylori

To investigate a possible relation between *H pylori* and EBV infection in the gastric tumorigenesis, the cases were divided in three groups: Hp(+)/EBV(+); Hp(+)/EBV(-) and Hp(-)/EBV(-). These groups accounted for 8.45% (6/71), 86% (61/71) and 5.55% (4/71) of the total, respectively. No EBV-positive case was found without *H pylori* infection.

The Table 1 summarizes the clinico-pathological data of the groups. The difference in gender distribution was statistically significant ($P = 0.039$), and, although overall the males predominated, in the Hp(-)/EBV(-) group the females were more frequent (75%). Furthermore, this group was represented by the most advanced ages. The intestinal type was more frequent in the Hp(+)/EBV(+) and Hp(-)/EBV(-) groups, although the distribution failed to reach statistical significance ($P = 0.339$), while in the group with only *H pylori* infection both histological types, intestinal and diffuse, occurred at the same rate.

In the two groups in which the *H pylori* were present, the *cag*A genotype predominated in tumors of the intestinal type. In the Hp(+)/EBV(+) group, 2 out of 3 tumors of Ⅳ stage were *cag*A(-), on the other hand, in the group with only *H pylori* infection, most of the tumors (6/9) in the same stage were *cag*A(+).

The diffuse type tumors, notably in the Hp(+)/EBV(+) and Hp(-)/EBV(-) groups, were in advanced stages (ⅢB and Ⅳ), while this was not the case in the intestinal type tumors. However, the correlation of the Lauren's classification with tumor stage was never significant. The diffuse type tumors of the Hp(+)/EBV(-) group had similar prevalence of *cag*A (+) and *cag*A (-) strains of *H pylori*. There was not any significant association between diffuse type and the tumor sites.

The Figure 3 shows the tumor stage distribution among the groups. Despite the small size of the groups with both or no infectious agents, it was possible to observe that the Ⅳ stage was the most represented stage in all groups. Even so, the earlier stage was present in the three groups. Not statistical significance was obtained in this analysis ($P = 0.179$).

The distribution of the studied markers according to the groups is presented in Figure 4**.** Although the expression of Bcl-2 was low, it was only observed in tumors with *H pylori* infection alone. Nevertheless, high expression of Bax and c-Myc was observed in the groups

Table 1 Correlation between clinico-pathological data, detection of EBV and *H pylori* and the pathogenic genotype (*cagA*) of *H pylori* *n* (%)

Clinico-pathological data	Total	Groups			*P*-value
		Hp(+)/EBV(+) (*n* = 6)	Hp(+)/EBV(-) (*n* = 61)	Hp(-)/EBV(-) (*n* = 4)

Hp(+)/EBV(-) and Hp(-)/EBV(-), when compared with the coinfected tumors. A high frequency of the *p53* mutation was observed in all groups, especially Hp(+)/EBV(+) and Hp(+)/EBV(-). None of the markers significantly correlated with any of the groups.

DISCUSSION

H pylori is known to be a carcinogen agent of gastric cancer. The major advance in this field came with the recognition that chronic *H pylori* infection induces physiological and morphological changes within the gastric environment increasing the risk for neoplastic transformation. Now, it is widely accepted that chronic *H pylori* infection induces hypochlorhydria and gastric atrophy, which are precursors of gastric cancer[1,2]. Recently, it was found that EBV is also linked to the development of a portion of gastric carcinomas. Since then, several studies have been carried out about EBV carcinogenic role in these tumors. The relationship between EBV infection and gastric cancer has been demonstrated by strong pieces of evidence such as the monoclonality of the viral genome and its presence in almost all tumor cells, indicating that the infection had occurred before malignant transformation and that the tumor cells had been originated from an infected primary cell[6,8,9].

In this study, we assessed the status of EBV by ISH and *H pylori* infection by PCR in 71 cases of gastric carcinomas. The frequency of *H pylori* infection (94.4%) was higher than previous studies, where it ranged from 34.1% to 92%. These differences can be due to: (a) the sensitivity of the screening technique, since most previous studies used serology, rapid urease test and/or histological evaluation; (b) and the fact that these studies were performed in different world regions and it is known that the *H pylori* infection is more frequent in developing countries[8,16,22-24]. On the other hand, EBV was detected in 8.45% of our cases. Although low, this prevalence is in agreement with reported results from various world regions, which vary from 2% to 23.6%[6,9,14,24,25]. The epidemiological data are also in accordance with previous studies. The male-female ratio was 2:1 and the majority of the patients were older than fifty five[1,2]. Like in other studies, the intestinal type was more frequent than the diffuse type[1,8].

Despite the known importance of *H pylori* and EBV in the gastric cancer etiology, few studies have focused on the interrelationship of these two agents in gastric cancer cases. Thus, we investigated the presence of both *H pylori* and EBV, in parallel with the histopathological features, the status of the tumor suppressor p53, the expression of the c-Myc oncogene and the apoptotic proteins Bcl-2 and Bax, which have a key role in the tumor development. To do so, patients were divided in three groups based on the presence or absence of the infectious agents.

In our analysis, we observed a skewed gender distribution among groups, which reached statistical significance ($P = 0.039$). The groups with both infectious agents were composed only by males, while in the group without any agent females were predominant (3:1). The association between sex and infection observed in other studies showed that males were more susceptible than females to EBV and *H pylori* infection[26,27]. Although the gastric antrum was the prevalent site of gastric cancer,

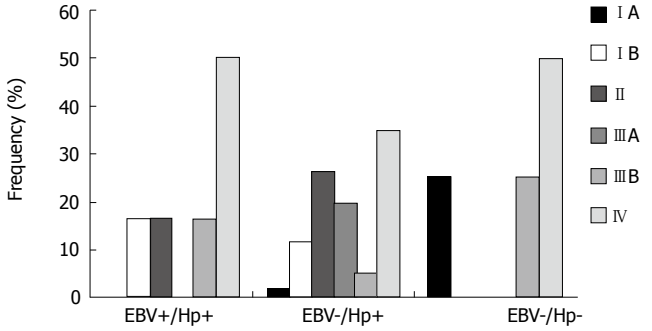

Figure 3 Distribution of the cases by tumor stage in the three defined groups: Hp(+)/EBV(+); Hp(+)/EBV(-); and Hp(-)/EBV(-). $P = 0.179$.

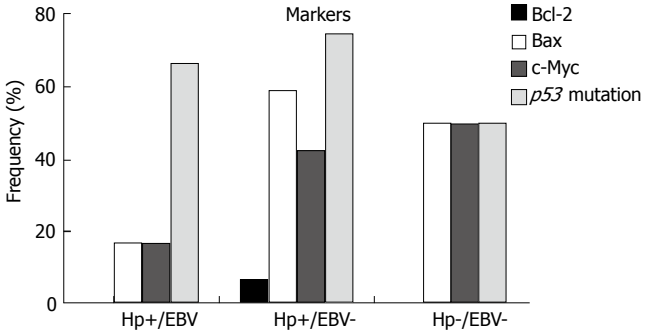

Figure 4 Frequencies of positive cases for the oncoproteins in the three defined groups: Hp(+)/EBV(+); Hp(+)/EBV(-); and Hp(-)/EBV(-). Bcl-2, $P = 0.706$; Bax $P = 0.135$; c-Myc, $P = 0.433$; *p53*, $P = 0.501$.

some studies have shown that EBV is related to the gastric carcinoma in cardia, middle stomach and gastric stump[8]. In our study, we found a slight increase of incidence of tumors located in the cardia in the group with EBV infection compared with patients with *H pylori* infection alone. However, due to the absence of tumors with only EBV infection, we could not evaluate the real relevance of this finding. In spite of the fact that previous studies failed to show a significant association between cardia tumors and *H pylori* infection[6,28], our data point to a possible association between cardia tumors and the presence of either infectious agents, since only the Hp(-)/EBV(-) group did not present tumors located in the cardia[8,29].

The intestinal type was prevalent in all groups, however in the group with *H pylori* infection alone the prevalence of the diffuse and intestinal type were similar, indicating that *H pylori* can be involved with the diffuse type. Reports concerning the association of *H pylori* with histological types of gastric cancers are controversial. Some studies have shown an association between *H pylori* and intestinal type[2,30], while others have observed a balanced distribution between the two histological types, like in the present work[31,32].

Some works have shown an association between Bcl-2 expression and EBV-positive gastric carcinomas[9]. However, the present study did not detect Bcl-2 in the group with EBV infection. On the other hand, Bax was detected in all groups with the highest expression in the group with *H pylori* infection alone, which also presented Bcl-2 expression as mentioned above. Although some authors have shown an increased Bcl-2 expression in *H pylori*-positive cases, in the group (Hp+/EBV-) the Bcl-2 expression was very low[33-37]. Although it was not statistically significant, our findings suggest a possible correlation between *H pylori* and Bcl-2 expression, unlike with EBV.

A few *in vitro* studies have shown that EBV facilitates the tumor development by inducing the expression of the c-Myc protein[39,40]. In present study, the expression of c-Myc was higher in the groups without EBV infection indicating a relationship of c-Myc with gastric carcinogenesis but not with EBV infection[41]. Additionally, some studies point to the involvement of *H pylori* with c-Myc[38,41]. The biological significance between *H pylori* and c-Myc is still not understood. A study from Zang *et al*[38] has linked the c-Myc expression with cell proliferation while a study from Yang *et al*[40] on a gastric carcinoma cell line has pointed to a relationship with apoptosis. On the other hand, Kim *et al*[42] have shown a decrease of c-Myc expression after *H pylori* eradication, but not in its mRNA level, showing the complexity of this process. The data presented here show a high frequency of c-Myc expression in the group with only *H pylori,* but this was similar to the noninfected group. Therefore, the c-Myc expression may be influenced by the presence of *H pylori*, but it is also triggered in a *H pylori* independent way. Nevertheless, it seems that the presence of the EBV may also play a role since the frequency of c-Myc protein was the lowest among the groups, and this may be a disturbing factor when its biologic significance is considered.

The mutation of the *p53* gene is among the major alterations of the multi-step process of gastric carcinogenesis, while it has also been reported in pre-malignant lesions of the stomach, such as chronic gastritis, intestinal metaplasia and dyspepsia. Kodama *et al*[43] have suggested an accumulation of wild-type *p53*, especially in the *H pylori* infected mucosa probably due to the *H pylori*-induced DNA damage. The present study shows the highest frequency of *p53* mutation in the groups with *H pylori* infection, especially among the cagA+ cases, corroborating previous studies[16,3,4]. The high percentage of *p53* mutation in EBV-associated and EBV-negative gastric carcinomas was observed in our study which was also demonstrated in other studies, demonstrating that the *p53* mutation is a relevant alteration in gastric carcinogenesis independent of the infection[15,16,43].

Finally, this study shows the high prevalence of *H pylori* infection in gastric carcinomas in Ceará State. The groups indicate that there are different pathways according to the presence of infectious agents, with female being predominant in the group without infection. *H pylori* seems to influence the expression of Bcl-2, since this protein was observed only in the group infected exclusively by this microorganism. The Bax and c-Myc expression was present in all groups. However, the highest expression in the EBV-negative groups suggests that EBV may inhibit their expression. The mutation of the *p53* gene was present in all groups possibly indicating that it was not only a consequence of the infectious agent.

COMMENTS

Background

Helicobacter pylori and Epstein-Barr virus are important agents on gastric carcinogenesis. Proteins involved with cell cycle or apoptosis process emerge as a candidate for having a crucial role in the development of the neoplasms. Some these, like c-Myc, *p53* and the apoptotic family members such as Bcl-2 and Bax, deserves attention for having a key function in the cell proliferation and cell fate, besides they already have shown involvement in the tumorigenesis process in a variety of tumors, including gastric cancer. So this article tries to associate *H pylori* and EBV infection, at the same time, with gastric carcinoma and some proteins of the cell cycle.

Research frontiers

Helicobacter pylori and Epstein-Barr virus infection related with gastric carcinogenesis.

Innovations and breakthroughs

Although *H pylori* and Epstein-Barr virus were well established as gastric cancer etiological agents, works on gastric cancer never associated an analysis of both agents at the same time, so this article did it.

Applications

Although this work had a small number of cases, it may justify further studies on the issue.

Peer review

This paper demonstrates that *H pylori* infection is very high (94.4%) in Brazil, associated with EBV infection and c-Myc, Bcl-2, Bax and *p53* overexpression in some cases. These results have significant implications on the clinical management and on the research on the pathogenesis of this cancer.

Abstract

AIM: To evaluate and characterize the patterns of disease progression of metastatic or unresectable gastrointestinal stromal tumor (GIST) treated with imatinib mesylate, and to determine the prognostic significance associated with disease progression.

METHODS: Clinical data and computed tomography (CT) images were retrospectively reviewed in 17 GIST patients who were treated with imatinib mesylate from October 2002 to October 2006. Apart from using size measurement for evaluation of tumor response [Response Evaluation Criteria in Solid Tumors (RECIST) criteria], patterns of CT changes during treatment were evaluated and correlated with clinical data.

RESULTS: There were eight non-responders and nine responders. Five patterns of CT change during treatment were found: focal progression (FP), generalized progression (GP), generalized cystic change (GC), new cystic lesion (NC) and new solid lesion (NS). At the end of study, all non-responders showed GP, whereas responders showed cystic change (GC and NC) and response according to RECIST criteria. Overall survival was significantly better in patients with cystic change or response within the RECIST criteria compared with GP patients (P = 0.0271).

CONCLUSION: Various patterns of CT change in patients with GIST who responded to imatinib mesylate were demonstrated, and might determine the prognosis of the disease. A combination of RECIST criteria and pattern of CT change are proposed for response evaluation in GIST.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are uncommon neoplasms that arise from mesenchymal cells in the walls of the gastrointestinal tract and account for 0.1%-3.0% of all gastrointestinal neoplasms and 5.7% of sarcomas[1,2]. GISTs arise most often from the stomach (60%-70%), followed by small intestine (20%-25%), but rarely from the rectum (5%), esophagus, colon or appendix[3]. GISTs differ from the other mesenchymal neoplasms histopathologically by immunohistochemical expression of CD 117 (c-kit proto-oncogene)[4].

Surgical resection is the standard initial treatment for non-resectable GISTs. However, locally advanced and metastatic tumors of the peritoneum or liver can effectively be treated with imatinib mesylate (known as Gleevec in the United States, Glivec in the rest of the world, and previously referred to as STI 571; Novartis Pharmaceuticals, Basel, Switzerland), a selective-tyrosine kinase inhibitor[5,6]. The drug acts as a c-kit blocker and is highly effective in patients with advanced disease[7], with nearly half of the patients responding to treatment[8].

For optimal clinical outcome, the accurate assessment

of tumor response to imatinib mesylate has become important. Computed tomography (CT), magnetic resonance imaging (MRI), and fluorodeoxyglucose positron emission tomography (FDG-PET) are acceptable imaging techniques to assess response to imatinib mesylate, with FDG-PET being superior[5,9]. CT is commonly used to assess therapeutic response in patients with GISTs. CT enables characterization of primary and recurrent tumors. In the past, the treatment response has been classically quantified using only a decrease in size as the main criterion for tumor response[10]. Recent studies have shown a cyst-like appearance with no further decrease in size is inconsistent with therapeutic response[11-13].

The purpose of this study was to evaluate and characterize the patterns of disease progression of metastatic or unresectable GIST treated with imatinib mesylate. In addition, the study sought to determine the prognostic significance associated with disease progression.

MATERIALS AND METHODS

The study was conducted under the approval of the Institutional Review Board and Ethics Committee of Ramathibodi Hospital Faculty of Medicine, Bangkok, Thailand. Seventeen consecutive patients with metastatic and unresectable GISTs diagnosed histopathologically as positive for CD117 were included in this retrospective review. All patients had a period of imatinib treatment during October 2002 to October 2006. Patients received a starting dose of 400 mg/d imatinib mesylate orally. In the event of disease progression, an increase in daily dosage to 800 mg was allowed. In cases of side effects, the dose was decreased to 300 mg/d. In cases of clinical non-response or death, the treatment was terminated. Our patients included 13 men and four women, aged 36-69 (mean 53) years. The primary tumor sites were the stomach (eight patients), small bowel (six), rectum (two) and retroperitoneum (one patient). At enrollment, 10 patients had initial metastatic disease, three had recurrent disease, three had no free surgical margin, and one had unresectable advanced disease.

Sixty-two lesions (38 in the liver, nine in the mesentery, six in the pararectal region, three in the stomach, two in the peritoneum, two in the lymph nodes, one in the retroperitoneum, and one in bone) were evaluated on the basis of the Response Evaluation Criteria in Solid Tumors (RECIST) criteria for each organ and body compartment invaded by the tumor. Inclusion criteria were as follows: (1) all lesions > 1.0 cm in the longest diameter; and (2) lesions ranging from 0.5 to 1.0 cm in the longest diameter, with no more than five lesions. Exclusion criteria were: (1) lesions < 0.5 cm in the longest diameter; and (2) lesions which were difficult to follow up due to changing location (small bowel and mesentery), or having partial volume.

We retrospectively reviewed the medical records and radiological features of each patient.

Imaging techniques

Each patient underwent baseline CT before treatment (with the exception of patients who underwent scans at another hospital before treatment). Follow-up studies consisted of CT at 1-mo intervals for up to 6 mo after imatinib mesylate treatment. The routine CT at our institution was performed on a spiral CT unit (LightSpeed Plus; General Electric Medical Systems, Milwaukee, WI, USA; Somatom Sensation Cardiac 64; Siemens, USA). CT scans of the upper, lower or whole abdomen were performed (5- or 3-mm slice thickness, 1- or 1.5-pitch, and 5.0- or 7.5-mm collimination) from the level of the diaphragm to the end of the kidney, from the top of the kidney to the pubic symphysis, and from the level of the diaphragm to the pubic symphysis, in the upper, lower and whole abdomen, respectively. Oral contrast, 1000-1500 mL 2% diatrizoate meglumine was given about 2 h prior to scanning, and an intravenous bolus of 100-120 mL 60% non-ionic contrast agent (Omnipaque 300 (GE Healthcare, USA), Ultravist 300 (Schering AG, Germany) or Xentrix 300 (Guerbet, France)) was administered at the rate of 3 mL/s.

A triphasic scanning technique was used after intravenous injection of the contrast agent, with scanning pre-contrast, and delays of 20-30 s and 70-80 s for the arterial and porto-venous phase, respectively.

Image analysis

Images were viewed using the eFilm Workstation software. The CT findings at presentation and during therapy were viewed by one experienced radiologist, who determined the change in size, CT attenuation coefficients, characteristics of tumor images, and overall tumor response. Using eFilm Workstation, tumor size at the longest cross-sectional dimension of each lesion was measured by the same techniques as for baseline measurement. The sum of the longest diameters of lesions in each patient was calculated. The percentage change in the sum of the longest dimensions from the pretreatment evaluation to that at each visit was computed for each patient. The percentage change graded was determined using the RECIST criteria[14].

The CT attenuation co-efficient (density) of the tumor in Hounsfield units (HU) was measured by drawing a region of interest (ROI) that circumscribed the margin of the tumor. The portovenous phase images were used for the tumor-density measurement compared with the pre-contrast phase. The average tumor density was then computed for each patient.

The follow up encompassed all available clinical data, including physical examinations, performance status, laboratory tests, histopathological examinations, and radiology imaging procedures (CT, MRI). For definition of the standard of reference, all patients were rated as responders or non-responders by a medical oncologist at the end of the follow-up. Responders were defined as: (1) improvement or disease-free status that was confirmed by a medical oncologist; and (2) tumor response according to the RECIST criteria (CR, PR and SD). Non-responders were defined as: (1) progression, recurrence, or death from GIST that was confirmed by a medical oncologist; and (2) PD according to the RECIST criteria.

Patterns of CT change after treatment

In addition to distinguishing changes in size using the RECIST criteria, the patterns of changes in CT findings were categorized into five groups. (1) Focal progression

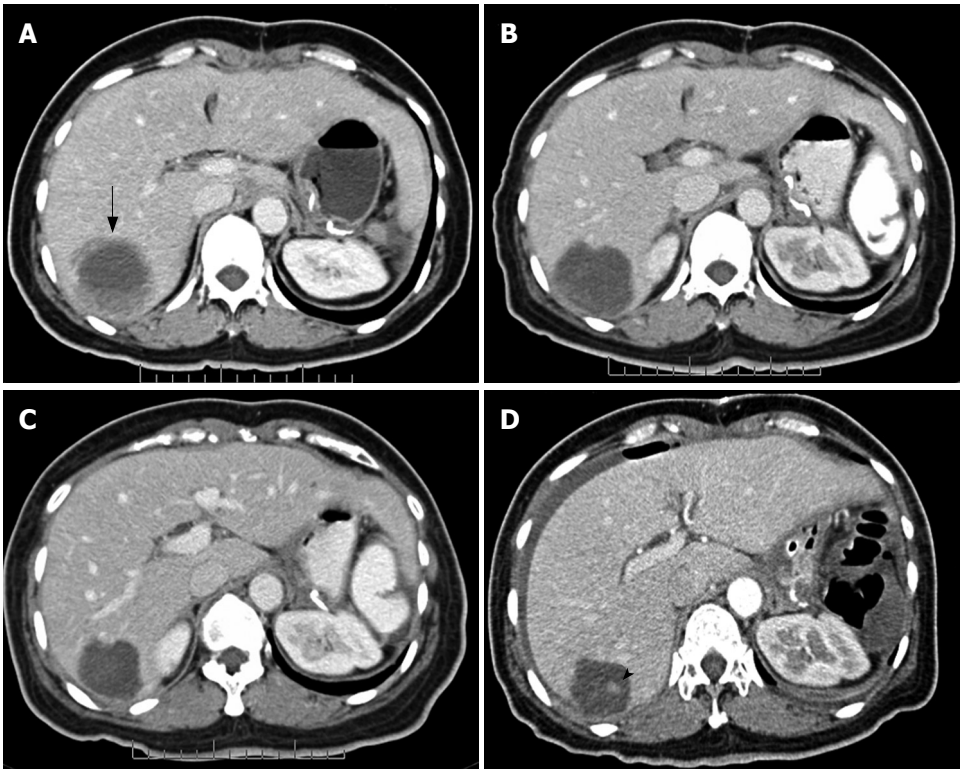

Figure 1 FP pattern. Contrast-enhanced CT of the abdomen obtained from a 39-year-old woman with metastatic GIST in the right lobe of liver. **A**: Before imatinib therapy, the lesion showed ill-defined thickened rim enhancement (arrow); **B**: After 2 mo therapy, a nearly complete cystic change and a thin lesion boundary were observed; **C**: After 5 mo therapy, a further decrease in size (partial response by RECIST) was seen; **D**: After 10 mo therapy, a small enhancing nodule was seen. Nodule within a mass or FP (arrow head).

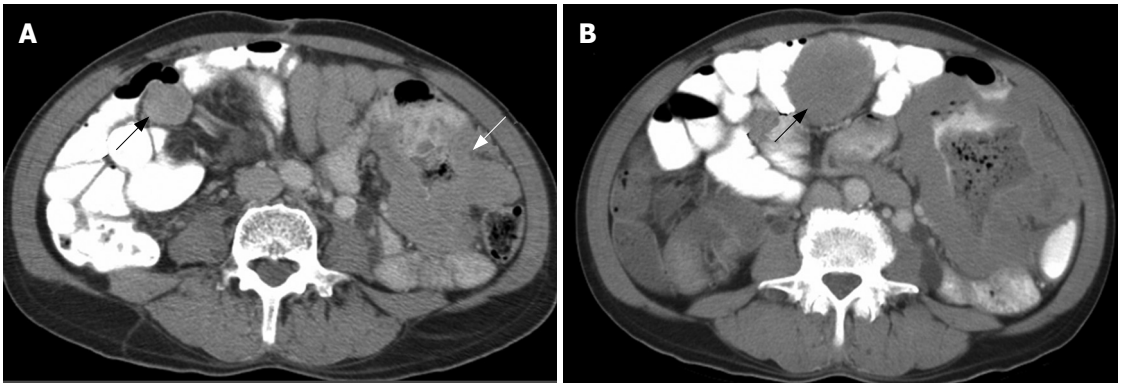

Figure 2 GP pattern. Contrast-enhanced CT of abdomen obtained from a 55-year-old man with metastatic GIST in the mesentery. **A**: Before imatinib treatment, there were mesenteric masses (arrows); **B**: After 2 mo therapy, there was interval progression in both mesenteric masses, as demonstrated by increased tumor size and thickness of the enhancing wall (arrows).

(FP) was defined as single-site progression, which was either an increase in size (PD in the RECIST criteria), an increase in the solid part of the tumor, or development of a new enhancing focus within the pre-existing tumor mass (or described as a nodule within the mass) (Figure 1). (2) Generalized progression (GP) was defined as an increase in tumor size (PD in RECIST criteria), with an enhancing pattern in two or more tumor masses (Figure 2). (3) New solid lesion (NS), with or without a cystic component, was defined as the appearance of one or more new lesions that had an enhancing lesion with or without a cystic component (Figure 3). (4) Generalized cystic change (GC) was defined as the appearance of cystic change in two or more tumor masses (Figure 4). (5) New cystic lesion (NC) was defined as the appearance of one or more new lesions that had relatively low density, without any enhancing component (Figure 5).

Statistical analysis

Statistic analysis was performed with STATA software (StataCorp LP, College Station, TX, USA). Patient age, tumor location, overall response, and pattern of tumor changes were analyzed. Survival was calculated from the day of imatinib treatment until death or the final day of the patient's visit to the outpatient clinic. Kaplan–Meier analysis with a log rank test was used to compare patterns of CT changes and survival distribution. $P < 0.05$ was considered to indicate a significant difference between groups.

RESULTS

Patient characteristics

There were 17 patients included in this study (13 men and four women) with a median age of 52 years (range 36-69 years). Primary tumor sites were in the stomach in eight

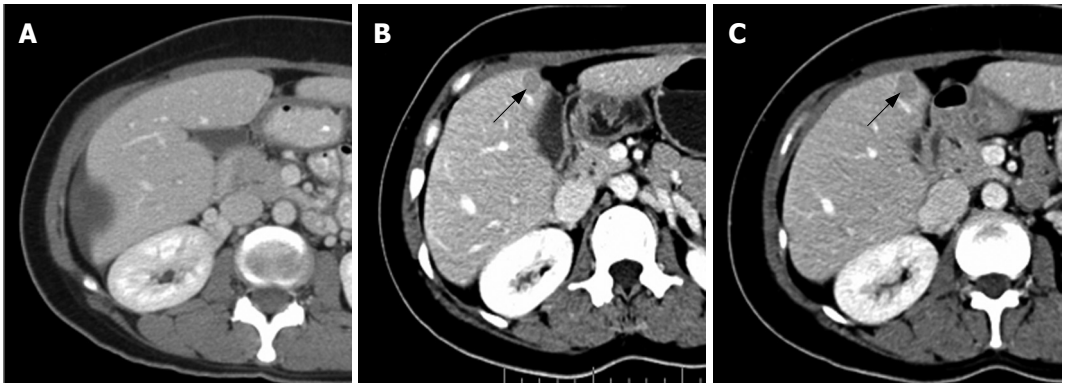

Figure 3 NS pattern. Contrast-enhanced CT scan of abdomen obtained in a 39-year-old woman with metastatic GIST in the liver. **A**: Before imatinib treatment, a large subcapsular cystic lesion in the right hepatic lobe and a small amount of free fluid were noted; **B**: After 10 mo therapy, there were new, well-defined, homogeneous enhancing nodules adjacent to the gallbladder (arrow); **C**: After 13 mo therapy, there was a slight increase in size of the mentioned nodule (arrow).

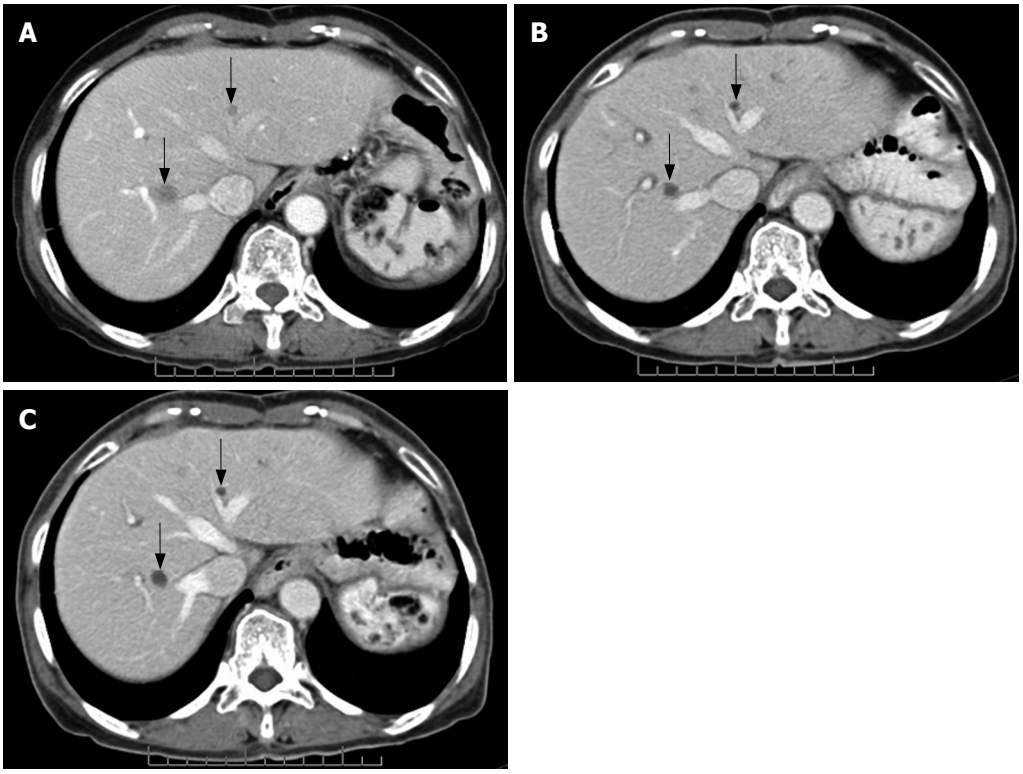

Figure 4 GC pattern. Contrast-enhanced CT scan of the abdomen obtained in a 64-year-old man with metastatic GIST in both lobes of the liver (arrows). **A**: Before imatinib treatment, there were a few rather ill-defined, small homogeneous enhancing lesions in the liver (arrows); **B**: After 4 mo therapy, they showed better-defined, non-enhancing, low-density lesions; **C**: After 8 mo therapy, well-defined small cystic lesions with no interval change in size are noted.

patients (47%), small bowel in six (35%), rectum in two (12%), and retroperitoneum in one (6%). The sites of active disease were in the liver in 10 patients, mesentery in three, pararectal region in three, stomach in three, and one each in the peritoneum, lymph nodes, retroperitoneum and bone. Ten patients (59%) had initial metastatic disease, three (17.5%) had recurrent disease, three (17.5%) had no free surgical margin, and one (6%) had unresectable advanced disease.

Overall response correlating with patterns of CT change

At the end of study, there were eight non-responders and nine responders. Non-responders consisted of two live and six dead patients. The median time of follow up was 11 mo (range 3-29 mo). The majority of active disease was found to be located in the liver, with a minority in the mesentery, retroperitoneum and bone. All patients developed the GP pattern at the end of follow up. Two patients developed FP, whereas one developed NS. One of the FP patients showed initial GC and NC. For one patient who had active sites in the liver and mesentery, GP was observed in the mesentery, while the liver lesions showed a GC pattern. The remainder of GP and NS had the same pattern throughout till the end. The median time to GP was 5.5 mo (range 2-23 mo). However, one patient showed GP after a prolonged 23 mo of SD and had early initial NC.

There were nine responders. They showed GC, NC, and response according to RECIST criteria in five, one and three patients at the end of study, respectively. The active sites of GC were in the liver (one patient), pararectum (two), and one each in the stomach and peritoneum/intra-abdominal nodes. One patient showed NC in the liver. The median time to GC and NC was 3.5 mo (range 2-8 mo). Of the three patients with no change in pattern, two

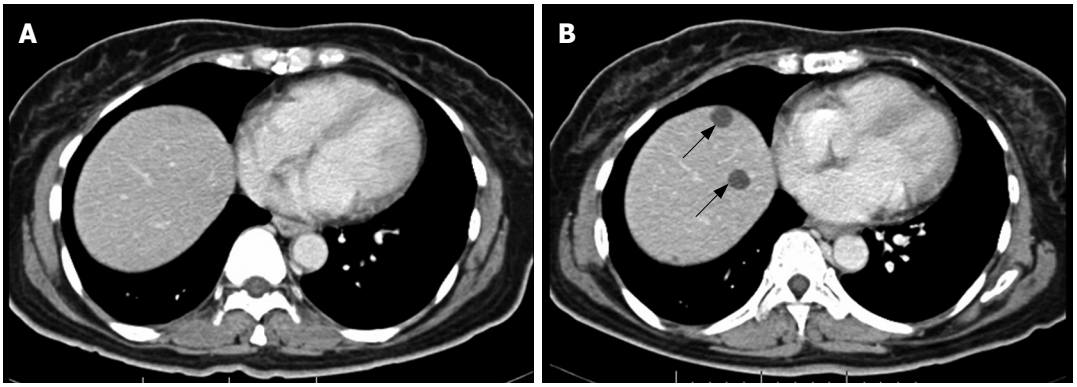

Figure 5 NC pattern. Contrast-enhanced CT scan of abdomen in 50-year-old woman with metastatic GIST in the liver. **A**: Before imatinib treatment, no liver metastases were visible at this level; **B**: Contrast-enhanced CT after 2 mo treatment with imatinib. At least two non-enhancing low-density lesions were newly seen at the dome of the liver (arrows).

Table 1 Median survival time according to pattern of CT change

Patterns of CT change	No. of patients (%)	No. of deaths	Median survival time (mo)	*P* value
GC + NC	6 (35)	0	-	0.00271
CR + PR + SD	3 (18)	0	-	0.00271
GP	8 (47)	6	11	0.00271

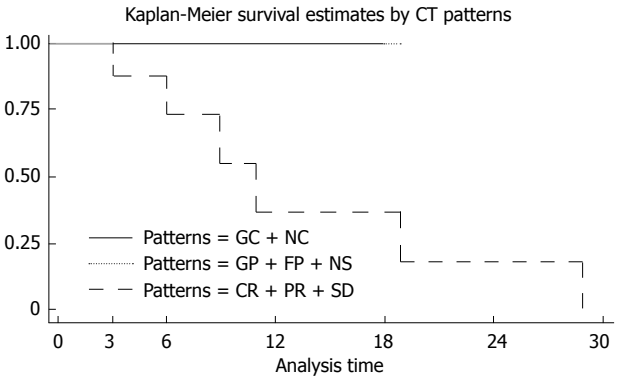

Figure 6 Overall survival after imatinib therapy, according to the patterns of CT change.

patients had a change in size only (PR and CR within the RECIST criteria), while the third patient showed a slight decrease in size (SD). The patient with CR had an active site in the stomach (no free margin in surgery) without metastasis, and the time to CR was 4 mo. The SD patient had an active site in the mesentery. Half of the responders showed PR in the initial follow up.

Survival data analysis according to patterns of CT change

Complete information on the patients' clinical course of imatinib treatment was obtained in 17 cases. Median follow-up time was 15 mo (range 3-29 mo). Survival status was alive in 11 (64.7%) and dead due to disease in six (35.3%). Median overall survival time of the patients after imatinib treatment was 19 mo (95% CI, 9.3-80.5). Overall survival was better in GC/NC and CR/PR/SD (response according to RECIST) compared with GP patients, and *P* was 0.0271 (Table 1, Figure 6).

DISCUSSION

GIST is an uncommon tumor with no effective therapy in advanced disease. This has been the case for inoperable tumors until the advent of imatinib mesylate, which is a molecular targeted therapy. Imatinib mesylate is the first effective systemic treatment for advanced GISTs, and yields a benefit of 50%-80%[15]. Although, the efficacy and safety of imatinib mesylate have been examined in large studies, few have focused on the pattern of tumor changes after treatment. Knowledge on these patterns of response to treatment are important to adequately manage patients and to interpret clinical trials employing new tyrosine kinase inhibitors known as sunitinib[16].

The percentage overall response with imatinib treatment in this study was nearly equal to that in a previous study, which showed an overall response rate of about 50%, with 5% of those with a CR demonstrating a clinical response by CT scan[8].

This study demonstrated different patterns of CT changes in responders and non-responders during treatment with imatinib mesylate. Apart from the RECIST criteria, cystic change (GC, NC) was used to evaluate the response to treatment. If the lesions showed cystic change, even though it was a new lesion or a cystic change in a previous lesion, it was considered to be disease improvement. Several studies have supported the finding that cystic change is a feature of tumors which have responded to treatment, due to tumor necrosis and cystic or myxoid degeneration[10,17-19]. Many authors have suggested new cystic lesions are characteristic of a response in small solid hepatic lesions, which cannot be seen in the initial image due to iso-density compared to liver parenchyma[20-22]. FDG-PET in these patients has confirmed no glucose radiotracer uptake in the cystic lesions, whereas the tumor size remains unaltered[8,23,24]. This suggested there were no metabolically active tumor cells.

The non-responder lesions showed three patterns of disease progression during treatment: GP, FP and NS. These patterns represented an increased solid component in terms of generalized or focal change. The FP pattern manifested as an increase in the solid component, such as increased wall thickness or a nodule within a mass[25,26]. Several studies have demonstrated that a solid nodule appearing inside a residual cystic mass indicating early retrogression after partial response to imatinib mesylate that corresponded to depicting new foci of increased FDG

uptake in PET scan[11,23]. Few non-responders showed early FP or NS before developing GP, and finally, death. This may urge further treatment, such as surgery of the focal mass, or the new tyrosine kinase inhibitor sunitinib[16,27-30]. Additionally, one of non-responders showed relapse of FP after cystic change of hepatic lesions. The authors speculated this event may have been a regrowth from a residual tumor cell. However, the patient had prolonged stable disease before developing GP.

Interestingly, there was one non-responder, who had two active sites of disease and showed a mixed response. The patient had GC in hepatic lesions but GP in mesenteric lesions. Thus, evaluation of the tumor response should be analyzed on a lesion by lesion basis.

The present study had several limitations. First, a small number of patients were enrolled. Second, the follow-up duration after imatinib treatment was uneven (range 1-6 mo), due to lack of certain protocol criteria for imaging follow up. Third, there was no gold standard reference (such as surgical pathology after imatinib treatment or FDG-PET scan) for evaluation of tumor response.

In conclusion, various patterns of CT changes for evaluation the tumor response were presented which might determine disease prognosis. A combination of RECIST criteria and patterns of CT change have been proposed for better response evaluation in GISTs. The early detection of focal solid or new solid lesions after maximal dose of imatinib mesylate suggests disease progression and might be helpful in early intervention such as surgery or new tyrosine kinase inhibitors.

COMMENTS

Background

For optimal clinical outcome, the accurate assessment of tumor response to any treatments is important. RECIST criteria have commonly been used to assess response in solid tumors for decades. The criteria are based solely on changes in size of mass on cross-sectional imaging studies. However, there are circumstances in which the response according to RECIST criteria does not correspond to clinical outcome. This means other imaging criteria may be needed to improve assessment. There are observations that show changes in pattern enhancement can be different in tumors after treatment. Among solid tumors, metastatic GISTs are a good example to show how pattern of enhancement in CT can predict clinical outcome.

Research frontiers

Many new anticancer drugs are being developed, particularly those which affect tumor blood vessels, so-called antiangiogenic drugs. Imatinib mesylate (also known as Gleevec, a selective-tyrosine kinase inhibitor) is one of these, and is highly effective in patients with metastatic GISTs. Due to its effect on tumor angiogenesis, the change may be able to be observed during dynamic contrast enhancement acquisition by using CT or MRI techniques.

Innovations and breakthroughs

This study showed evaluating response of metastatic GISTs to imatinib by size alone is not enough. Combined changes in density or pattern enhancement on CT are more reliable.

Applications

The combined use RECIST criteria and changes in the pattern of enhancement are useful in evaluating tumor response, particularly in patients treated with antiangiogenic drugs or other means that have an effect on tumor blood vessels.

Peer review

This is an interesting study on the follow-up of non-resectable GIST treated with imatinib. Tumor response was assessed by the RECIST criteria complemented by other criteria on CT. Overall, the results show beautiful iconography.

Abstract

AIM: To investigate the effects of vitamins (A, C and E) on liver injury induced by ethanol administration during liver regeneration in rats.

METHODS: Male Wistar rats subjected to 70% partial hepatectomy were divided into five groups (groups 1-5). During the experiment, animals of Group 1 drank only water. The other four groups (2-5) drank 30 mL of ethanol/L of water. Group 3 additionally received vitamin A, those of group 4 vitamin C and those of group 5 received vitamin E. Subsequently serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), albumin and bilirubin were measured colorimetrically. Lipid peroxidation (thiobarbituric-acid reactive substances, TBARS) both in plasma and liver was measured, as well as liver mass gain assessment and total DNA.

RESULTS: Compared with sham group, serum AST and ALT increased significantly under ethanol treatment (43% and 93%, respectively, with $P < 0.05$). Vitamin C and vitamin E treatment attenuated the ethanol-induced increases in ALT and AST activity. Ethanol treatment also decreased serum albumin concentration compared to sham group (3.1 ± 0.4 g/dL *vs* 4.5 ± 0.2 g/dL; $P < 0.05$). During liver regeneration vitamins C and E significantly ameliorated liver injury for ethanol administration in hepatic lipid peroxidation (4.92 nmol/mg and 4.25 nmol/mg *vs* 14.78 nmol/mg, respectively, with $P < 0.05$). In association with hepatic injury, ethanol administration caused a significant increase in both hepatic and plasma lipid peroxidation. Vitamins (C and E) treatment attenuated hepatic and plasma lipid peroxidation.

CONCLUSION: Vitamins C and E protect against liver injury and dysfunction, attenuate lipid peroxidation, and thus appear to be significantly more effective than vitamin A against ethanol-mediated toxic effects during liver regeneration.

INTRODUCTION

Alcohol liver disease is a world-wide medical complication of alcohol abuse[1]. Although important progress has been made in understanding its pathogenesis, the mechanisms involved in its development are as yet not fully understood.

Oxidative stress is a key step in the pathogenesis of ethanol-associated liver injury. The deleterious effects of alcohol, at least partly involve oxidative injury that has been documented by measurement of oxidant radicals, alterations in oxidant/antioxidant balance and oxidant induced changes in cellular proteins and lipids[2].

After ethanol is absorbed, it is distributed to all tissue, and body fluids in direct proportion to blood levels[3]. Ethanol affects the liver more than any other organ[4], since its metabolism implies generation of free radicals that can damage cell structure and function, particularly when antioxidant mechanisms are not able to neutralize them[5,6]. Animal models show the mechanisms by which both acute alcohol administration and chronic alcohol consumption affect the liver. Chronic ethanol administration induces an increase in lipid peroxidation either by enhancing the production of oxygen reactive species, or by decreasing the level of endogenous antioxidants[7]. Short-term ethanol administration has been reported to decrease vitamins and increase superoxide generation in the liver[8]. The enhanced superoxide generation increases lipid peroxidation and induces liver dysfunction in rats that have been subjected to acute ethanol exposure[9].

One of the most prominent antioxidant defense systems are vitamins (A, C and E) acting as co-factors for many enzymes, protecting cells against free radical-mediated damage[10], as free radical scavengers. Besides, large ethanol intakes have deleterious effects on nutritional status[7,8].

Recently, it has become clear that antioxidant nutrients, including vitamins, are important for neurological function[11-13]. High intake of vitamins E and C have been found to be associated with lower risk of Alzheimer's disease[14]. In addition, evidence for alcohol-induced oxidant injury comes from studies in which pretreatment with antioxidants such as vitamin E, vitamin C, and agents that enhance antioxidant capacity attenuate alcohol induced effects[15].

Nutrient intermediary metabolism is a vital function of the healthy adult liver. Fortunately, the liver appears to have a tremendous reserve capacity in this regard, since general nutritional status is well-preserved until severe hepatic parenchymal loss occurs. Indeed, several clinical and biochemical markers of nutritional status are often used to gauge the severity of liver dysfunction, with evidence of severe malnutrition implying end-stage liver disease. Hepatocyte proliferation occurs rarely in healthy adults, but it is necessary to replace liver cells lost by hepatic necrosis or resection. These facts have prompted speculation on whether decreased hepatic mass and metabolism are involved in the initiation and progression of hepatic regeneration following liver injury[16]. Restoration of normal hepatic structure and function is the goal of therapy for acute and chronic liver injury of varying etiologies. Consequently, strategies to optimize compensatory hepatic regenerative growth have tremendous therapeutic relevance. Better understanding of the mechanism regulating cellular proliferation, and organ regeneration will play a critical role in designing treatments to enhance liver regeneration[16]. Current knowledge suggests several approaches. Thus, novel agents that correct the fundamental cellular disturbances resulting from excessive ethanol consumption represent attractive therapeutic strategies.

In the present study, we investigated the effects of vitamins A, C and E in rats with liver injury induced by ethanol administration during liver regeneration. Specifically, we planed to evaluate: (a) whether the effect of the vitamin supplementation protects against ethanol-induced lipid peroxidation; (b) whether vitamin supplementation can attenuate ethanol-induced hepatic injury and dysfunction during liver regeneration.

MATERIALS AND METHODS

Animal and chemicals

Male Wistar rats (230-270 g, body weight) were obtained from Centro Médico Nacional "20 de Noviembre" ISSSTE-MEXICO. The rats were housed in animal quarters at the Escuela de Dietética y Nutrición ISSSTE-MEXICO. They were maintained at 22℃ with a 12-h light/dark cycle and allowed to consume standard rat pellet chow (Purina de México SA) and water *ad libitum* before treatments. After 10 d of adaptation the procedure was begun. All procedures involving experimental animals were done according to our Federal Regulations for Animal Experimentation and Care (Ministry of Agriculture; SAGAR, Mexico).

Vitamins A, C and E and thiobarbituric acid were from Sigma (Sigma Chemical St. Louis MO). All other chemicals were from the best quality available.

Surgical procedures

Two-thirds partial hepatectomy (PH) was performed according to the technique of Higgins and Anderson[17]. The operations were carried out between 08:00 and 10:00 hours under light diethyl ether anesthesia and consisted of removal of the median and left lateral lobes of the liver. As controls, sham-operated rats were subjected to the same surgical procedure, without remission of the liver mass.

Experimental designs

After surgery, rats were housed individually and fed with rat pellet chow. They were grouped (n = 30 for each experimental group) as follows: (1) control rats (sham operated and PH-only treated rats) who received water *ad libitum*; (2) PH rats who received a 30 mL/L ethanol solution in their drink container (PH-ethanol group) in a voluntary way, the intake being registered daily. Ethanol consumption was calculated in terms of g/kg per day. Ethanol consumption usually averaged 1.5 ± 0.5 g/kg per day and blood alcohol levels have been reported to vary between 75 mg/dL and 150 mg/dL[18-20]. On the other hand, PH-ethanol treated rats were divided into the following treatment groups: (a) PH-ethanol treated rats with intraperitoneal doses of vitamin A (PH-ethanol-Vitamin A group), 4000 UI per day[21]; (b) PH-ethanol treated rats with intragastric doses of vitamin C (PH-ethanol-Vitamin C group), 250 mg/kg per day[22]; and (c) PH-ethanol treated rats with intraperitoneal doses of vitamin E (PH-ethanol-Vitamin E

group), 250 mg/kg per day[22]. All the treatments (ethanol solution and vitamins) were given daily during seven days; the animals' weights were recorded daily.

Serum and liver samples

On the eighth day of treatment, animals were killed by decapitation previously anesthetized with sodium pentobarbital (40 mg/kg of b.w.). Blood samples were obtained and serum isolated. Serum was kept frozen at -70℃ until use. The liver was isolated and weighed and it was placed quickly in an ice-cold PBS (phosphate saline buffer solution, pH 7.5) and washed until it was bloodless. The liver was placed in 9 volumes of ice-cold solution Tris-HCL buffer (50 mmol/L Tris-HCl, 180 mmol/L KCL, 10 mmol/L EDTA, and 0.02% butylated hydroxytoluene; pH 7.4) and homogenized using four to five strokes of a Teflon homogenizer spinning at 1000 r/min. Homogenate was divided into samples and frozen at -70℃ until its subsequent use. Total protein concentration was determined by the Lowry method[23], using bovine serum albumin (BSA) as a standard.

Enzymes and metabolites assay from serum

Serum enzymes, alanine aminotransferase (ALT; EC 2.6.1.2) and aspartate aminotransferase (AST; EC 2.6.1.1) activities as indicators of the extent of liver injury were measured colorimetrically using a diagnostic kit (Sigma Chemical Co., St. Louis, MO) following the instructions provided by the manufacturers.

Serum albumin and total bilirubin concentrations, documenting the extent of liver dysfunction, were determined colorimetrically using a Sigma Diagnostic kit (Sigma Chemical Co., St. Louis, MO) following the instructions provided by the manufacturer.

Thiobarbituric acid reactive substances assay

To determine the thiobarbituric acid reactive substances (TBARS) in liver, homogenate was used according to method of Song[24]. Briefly, to 0.2 mL of the tissue homogenate, 0.2 mL of 8.1% sodium dodecyl sulfate, 1.5 mL of 20% acetic acid, 1.5 mL of 0.9% thiobarbituric acid, and 0.6 mL of distilled water were added and vortexed. The reaction mixture was placed in a water bath at 95℃ for 1 h. After cooling on ice, 1.0 mL of distilled water and 5.0 mL of butanol/pyridine mixture (15:1, v/v), were added and vortexed. After centrifugation at 10000 r/min for 10 min, the resulting upper phase was determined at 532 nm. The concentration of TBARS was calculated using 1, 1, 5, 3-tetraethoxypropane as a standard[24]. In the serum, the determination of TBARS concentration was made as described above with 200 μL serum.

Restitution of liver weight and total DNA measured

Hepatic regeneration was determined by the calculation of liver weight restitution and total DNA concentration. The extent to which the liver mass had been reconstituted was also evaluated. Resected livers were weighed at the time of PH. This weight was divided by 0.7 to derive the initial (pre-PH) weight of each liver. Each post-PH liver remnant was also weighed at the time of death. For each rat, the weight of the remnant liver was normalized to the weight of that rat's entire liver at the time of PH and expressed as the percentage of the rat's initial liver weight according to the following formula: (wt of liver remnant/initial liver wt) × 100[25]. Data from all PH rats per treatment group were used to calculate the mean ± SE at the end of the experimental time. DNA concentrations were determined fluorometrically according to Labarca and Paigen[26].

Table 1 Mortality and body weight parameters in each experimental group after seven days of treatment partial hepatectomy (PH), ethanol (EtOH) and some vitamins

Group	Mortality (%)	Initial body weight[1] (g)	Final body weight[1] (g)	Differential between final and initial weight (g)
Sham	0/30 (0)	259 ± 10	274 ± 1	15
PH	0/30 (0)	250 ± 11	267 ± 10	17
PH-EtOH	22/30 (73.3)[a]	255 ± 10	276 ± 15	21
PH-EtOH-VA	16/30 (53.3)[e]	255 ± 12	270 ± 12	15
PH-EtOH-VC	10/30 (33.3)[e]	260 ± 12	275 ± 10	15
PH-EtOH-VE	8/30 (26.6)[e]	242 ± 10	258 ± 11	16

[1]Values are the mean ± SE of survivors for each experimental group (n = 8-22) as it corresponds. VA: Vitamin A; VC: Vitamin C; VE: Vitamin E. [a]$P < 0.05$ *vs* the sham group; [e]$P < 0.05$ *vs* hepatectomized + ethanol group.

Statistical analysis

All data are expressed as mean ± SE. Statistical analysis was performed using Student's t-test and ANOVA where appropriate. Differences between groups were considered to be statistically significant at $P < 0.05$.

RESULTS

Mortality and body weight

The effect of the combination of ethanol and vitamins on the mortality and the body weight of the rats is shown in Table 1. It is observed that the ethanol group (PH-EtOH), presented a significant mortality (73.3%; $P < 0.05$) in comparison with the sham group and the group the PH-only group. On the contrary, the administration of the vitamins A, E and C in the ethanol group, decreased mortality, increasing significantly ($P < 0.05$) survival capacity as compared with the PH-EtOH group; 73.4% for the vitamin E group (PH-EtOH-VE), 66.7% for the vitamin C group (PH-EtOH-VC) and 46.7% for the vitamin A group (PH-EtOH-VA). As for the body weight, there were differences observed in the initial weight (after the hepatectomy) and the final weight (seven days after treatment) in the animals of all the experimental groups, which confirms that this parameter is not altered by the surgery or other used substances.

Ethanol and vitamins effect over the liver regeneration

Table 2 shows the results of the indicators (restitution of the liver mass, liver/body ratio and mgDNA/g liver ratio) associated with the process of hepatic regeneration. The PH-EtOH group had a significant decrease in the hepatic indicators compared to the PH-only group. Except for the PH-EtOH group, all the experimental groups treated with

Table 2 Evaluation of liver regeneration parameters in each experimental group after seven days of treatment with partial hepatectomy (PH), ethanol (EtOH) and vitamins. Experimental designs are described in material and methods section

Group	Restitution liver mass[1] (%)	Resected liver mass[1] (g)	Final liver weight[1] (g)	Liver/body ratio[1] (%)	mgDNA/g liver[1]
Sham	None	None	9.41 ± 0.3	3.41 ± 0.2	2.1 ± 0.2
PH	83.95 ± 3.0	6.9 ± 0.3	8.27 ± 0.3	3.09 ± 0.3[a]	4.1 ± 0.4[a]
PH-EtOH	54.89 ± 2.0[c]	6.8 ± 0.4	5.33 ± 0.2[c]	1.93 ± 0.1[a,c]	2.9 ± 0.1[a,c]
PH-EtOH VA	62.90 ± 3.9[c,e]	7.1 ± 0.3	6.38 ± 0.4[c]	2.36 ± 0.3[a,c,e]	3.4 ± 0.2[a,c,e]
PH-EtOH-VC	79.00 ± 2.0[c]	7.0 ± 0.5	7.90 ± 0.2[e]	2.87 ± 0.2[a,e]	4.0 ± 0.3[a,e]
PH-EtOH-VE	81.00 ± 3.0[c]	6.8 ± 0.2	7.86 ± 0.3[e]	3.03 ± 0.3[a,e]	3.9 ± 0.4[a,e]

PH-EtOH-VE	4.6 ± 0.3[e]	0.29 ± 0.03[a,c,e]

[1]Values are the mean ± SE of survivors for each experimental group (n = 8-22) as it corresponds. vitamin A (VA); Vitamin C (VC); vitamin E (VE). [a]$P < 0.05$ *vs* the sham group; [c]$P < 0.05$ *vs* the hepatectomized group; [e]$P < 0.05$ *vs* hepatectomized + ethanol group.

ethanol in combination with the vitamins showed a recovery in the hepatic regeneration process; but the group that obtained the major protection was the one treated with vitamin E (PH-EtOH-VE) and vitamin C (PH-EtOH-VC), obtaining values comparable to the PH-only group.

The difference with the PH-only group with the vitamin E group (PH-ETOH-VE) and the vitamin C group (PH-EtOH-VC) was 2.95% and 4.95% for the restitution of the liver mass, 0.06% and 0.22% for the liver/body ratio, and 0.2 and 0.1 of mgDNA/g of liver, respectively. On the other hand, the group treated with ethanol and vitamin A (PH-EtOH-VA) only had a recuperation of 62.9% for the restitution of the liver mass, being significantly different from the PH-only group (83.9%, $P < 0.05$), and 2.36% (*vs* 3.09%, $P < 0.05$) and 3.4% (*vs* 4.1%, $P < 0.05$) for the other parameters, liver/body ratio and mgDNA/g of liver, respectively.

Effects of vitamin treatment on serum metabolite levels

The results of the liver metabolic integrity are presented in Table 3. There are similar concentrations of serum (bilirubin and albumin) both in animals with hepatectomy as well as the sham group animals. When ethanol was administered as in the (PH-EtOH) group, there was a significant decrease in serum albumin (31 g/L *vs* 47 g/L, $P < 0.05$) and an increase in bilirubin (17.2 mg/L *vs* 4.0 mg/L, $P < 0.05$) compared to the PH-only group. This serum alteration is normalized when ethanol and one of the vitamins is administered in combination, giving a better recuperation of both metabolites with vitamin C or E, since albumin increases its concentration to 42 g/L in the PH-EtOH-VC group and 46 g/L in the PH-EtOH-VE group, while in bilirubin their values are reduced to 4.5 mg/L and 2.9 mg/L respectively. The group treated with vitamin A did not reach values comparable to the PH-only group because its behavior was similar to the PH-EtOH group.

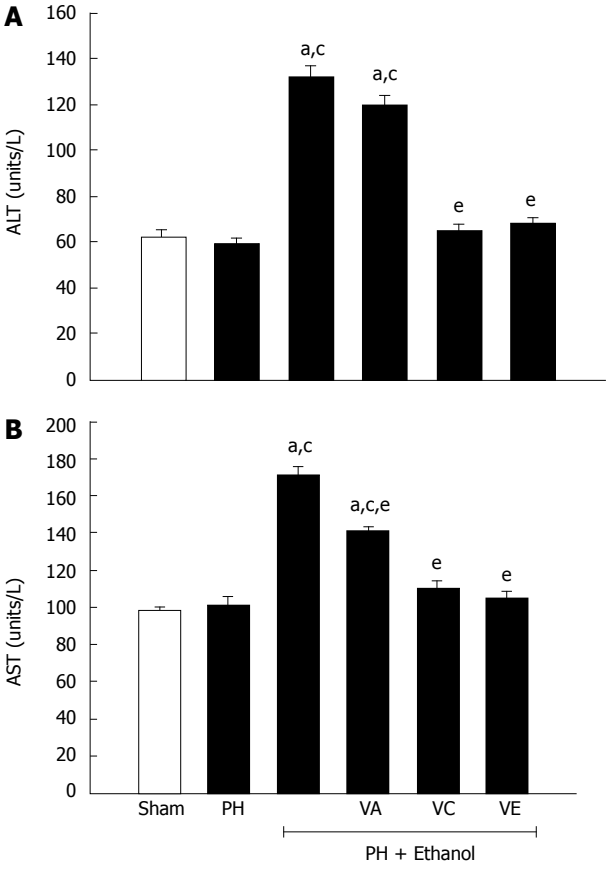

Figure 1 Effect of vitamins on specific activities of serum alanine and aspartate aminotransferase (**A** and **B**) during liver regeneration and ethanol intoxication. Values are means ± SE (n = 8-10); [a]$P < 0.05$ *vs* the sham group (sham); [c]$P < 0.05$ vs the hepatectomized group (PH); [e]$P < 0.05$ *vs* hepatectomized + ethanol group (PH + Ethanol). VA: Vitamin A; VC: Vitamin C; VE: Vitamin E.

Effects of vitamin treatment on serum enzymes activities

The protective effect of the vitamins was evaluated with the enzymatic activity of the alanine aminotransferase (ALT) and the aspartate aminotransferase (AST) because they reflect the liver function. As is shown in Figure 1, the ethanol increased significantly the serum concentration of both enzymes, observing an activity of 2-times for ALT (A)

and 1.7-time for AST (B) compared to PH-only and sham groups. A similar effect is observed in the animals treated with ethanol plus the vitamin A, giving evidence of the low potential of this vitamin to promote hepatic regeneration. On the contrary, the partial hepatectomized rats treated with combinations of ethanol and vitamins C or E showed a significant decrease in the serum concentration of ALT and AST levels, reaching values comparable to the control group (sham group).

Effect of vitamins on TBARS-induced by ethanol treatment in PH rats

To evaluate the damage produced by the reactive oxygen species (ROS), the TBARS concentration was determined in liver and serum in the animals treated with ethanol and the diverse vitamins (Figure 2). An increase of almost double is observed in the hepatic concentrations of TBARS (panel A) in the rats with PH in comparison with the sham group. This increase becomes more evident, when the animals are treated for seven days with ethanol, with 14.78 nmol/mg, which is 3.3 times and 1.4 times greater than the sham group (4.48 nmol/mg) and the PH-only group (10.55 nmol/mg), respectively.

Contrary, the three groups with ethanol and a vitamin showed a decrease in the hepatic concentration of TBARS, although the most relevant protection was observed in the PH-EtOH-VC (4.92 nmol/mg) and PH-EtOH-VE group (4.25 nmol/mg), since these values were similar to the sham group (4.48 nmol/mg). It is important to mention, that the PH-EtOH-VA group (10.74 nmol/mg) only presented a reduction comparable to the PH-only group (10.55 nmol/mg).

In the case of the corresponding concentrations in serum (Figure 2, panel B), the rats of the PH-EtOH group presented a significant increase of 80% in relation to the sham group. On the contrary, when vitamin C or E was administrated to the rats intoxicated with ethanol, there were no differences observed in the serum concentrations of TBARS in comparison with the rats of the PH-only group. Contrary, when vitamin A was administered, the serum TBARS group was similar to the PH-EtOH group, observing an increment of 20% and 22% with respect to the PH-EtOH-VC and the PH-EtOH-VE groups respectively.

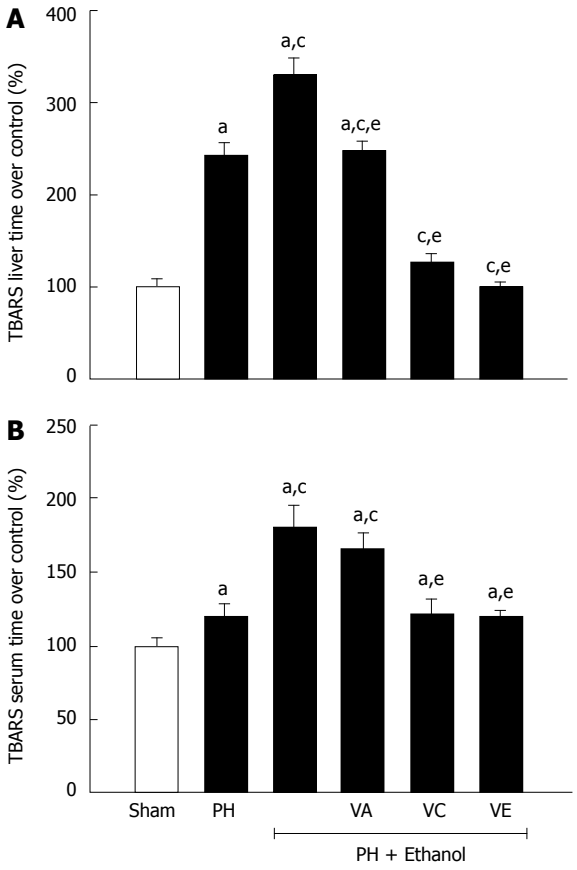

Figure 2 Effect of vitamins in both hepatic (**A**) and serum (**B**) lipid peroxidation (TBARS content) during liver regeneration and ethanol intoxication. Values are means ± SE (n = 8-10); $^{a}P < 0.05$ *vs* the sham group (sham); $^{c}P < 0.05$ *vs* the hepatectomized group (PH); $^{e}P < 0.05$ *vs* hepatectomized + ethanol group (PH + Ethanol). VA: Vitamin A; VC: Vitamin C; VE: Vitamin E.

DISCUSSION

Epidemiologic studies agree about the existing correlation between the ingestion of alcohol and the high incidence of hepatic cancer, but the exact mechanism of the hepatocarcinogenesis is still a ground research because ethanol by itself is not a carcinogenic compound[27-32]. Besides several mechanisms involved in the development of a hepatocarcinogenic process which have been identified, the formation of acetaldehyde through the oxidation of ethanol by the action of the cytochrome P-4502E1 (CYP2E1) continues to be the most accepted one because of the production of reactive oxygen species (ROS) during the biotransformation, which consequently can alter cellular regeneration[33].

It has been observed that the chronic consumption of alcohol increases the activity of CYP2E1. This enzyme has been related to the lipoperoxidation process and the excessive generation of hydroxyl ethyl radicals, resulting in a decrease in endogenic antioxidants' levels[34]. In other words, the oxidative stress produced by ethanol is critical in post alcoholic hepatogenesis due to the production of free radicals which damage the cellular structure and function, especially if natural antioxidant mechanisms cannot neutralize them[28,33].

These observations support the idea that pre-treatment with substances that reduce the activity of CYP2E1 or that inactivate the ROS, could reduce the hepatotoxic effects of ethanol. Following this hypothesis, the objective of this study was to evaluate the antioxidant potential of three vitamins A, C, and E against the hepatic damage produced by the sub chronic administration of ethanol during the cellular regeneration after a partial hepatectomy (PH).

Initially, it was observed that ethanol (1.5 g/kg) increased mortality, which supports the toxicity of ethanol when it is given in a subchronic way; confirming its capacity to produce different alterations in the organism, like nuclear condensation, cellular edema with abundant accumulation of fat, and an abnormal mitochondrial activity[35].

On the other hand, when ethanol was given in combination with the different vitamins, the survival

percentage increased (Table 1), supporting the evidence of the importance of these compounds in the adequate development of an organism and backs up the studies carried out by different researchers, showing the capacity of vitamins to interact with free radicals decreasing the toxicity to the organism[10,15]. Normally, the excessive and constant ingestion of ethanol produces a weight decrease in the individuals because alcohol modifies several metabolic pathways and at the same time, displaces an adequate diet for the necessity of alcohol consumption, but the opposite was observed in this experiment (Table 1), which may be explained by inadequate doses of ethanol or the insufficient experimentation time to be able to produce the dependency to this substance[15,36].

In relation to the ethanol effect over the liver mass, the liver/body ratio and the mgDNA/g liver (Table 2), the data of the present work gives evidence of the utility of these indicators in the evaluation of the cellular regeneration showing that the given doses of ethanol (1.5 g/kg) decreases these parameters significantly. This agrees with the study of Yoshida[37], where an immunoblotting assay was used to evaluate the same dose of ethanol over cellular regeneration that altered PH and determined that alcohol attenuated the hepatic activity of the thymidylate synthase and the thymidine kinase at 24 h altering surgery, and affecting the quantity of DNA as well. The Northern blot analysis confirmed that the protein levels of the enzymes are proportional to the quantity of mRNA, so ethanol is capable of inhibiting the synthesis of DNA by reducing the mRNA levels of these enzymes during hepatic regeneration[37].

The previous study and this one agrees with the suggestions of other authors to consider the PH as the good *in vivo* model most adequate to study cellular proliferation because it is a relatively simple technique and with the advantage that after surgery, only a short time is required to evaluate hepatic regeneration. Besides, with the quantification of liver mass, liver/body ratio and mgDNA/g liver (Table 2) hepatic regeneration is evaluated indirectly; it has been observed that it depends on the integrity of the mitochondrial respiration mechanism and the cellular capacity of ATP formation, the proper formation of proteins and therefore the synthesis of mRNA and DNA[38-40]. Unlike most other terminally differentiated cells, the hepatocytes in adult liver retain the capacity to proliferate. Indeed, following 70% partial hepatectomy, most hepatocytes proliferative at least once. Hepatocellular proliferation continues until the prehepatectomy liver mass is restored. This compensatory hyperplasia being within minutes of resection is typically completed within 2 wk in rats and in less than one month in humans[17].

Since the 80's the equilibrium between the generation of free radicals and the endogenous antioxidant mechanisms have been recognized. It has been established that this balance can be altered during oxidative stress induced by different xenobiotics and it can also be reestablished when antioxidant compounds like ascorbic acid (vitamin C), alpha-tocopherol (vitamin E), or β-carotene (vitamin A) are administrated[41,42]. The results of this study (Figure 2) support this observation, since the 3 vitamins showed a protective effect against the generation of hydroxyethyl radicals generated by the ethanol; although the most significant efficiency was with vitamin C and E, where the hepatic regeneration reached 94% and 96% respectively (Table 2). This result and previous studies support the basis of the potential protector effect of these vitamins in their capacity to scavenge free radicals, however, the difference in percentage of hepatic regeneration suggests that vitamin E might be more efficient than vitamin C. Thus, it is important to mention that there are differences between the vitamins in their physicochemical properties. For example, vitamin C is a hydrophilic compound and a strong reductor agent which reacts with O_2 and even faster with the OH groups[43]. Therefore, the treatment with vitamin C could reduce the formation of hydroxyethyl radicals by the inhibition of oxygen radical intermediates. Besides, it has been observed *in vitro*, vitamin C is capable of reducing the 1-hydroxyethyl/PBN adducts and at the same time inhibits the adducts previously formed[44].

On the other hand, vitamin E also reacts with the oxygen radicals, but it has been observed that its efficiency depends on the radical species that is attacking. This has been shown through *in vivo* studies where it has been observed that vitamin E has more capacity to scavenge peroxyl radicals than to inhibit hydroxyl radicals[45].

Navasumrit[46] determined that a pre-treatment with vitamin E (100 mg/kg; intraperitoneal for five days) inhibits the 1-hydroxyethilic radicals generated by the ethanol, and it is more effective than pre-treatment with vitamin C (400 mg/kg; intraperitoneal for four days); attributing the result to the fact that 1-hydroxyethilic radicals are primarily generated in lipid compartments of the cell. This also supports the basis that the CYP enzymes (located in membranes of the smooth endoplasmic reticulum) are the most active site for the generation of oxygen reactive radicals, and suggest the correlation between the induction of CYP2E1 and the generation of the 1-hydroxyethilic radicals. This evidence with the fluorescent analysis (laser scanner confocal fluorescence image analysis system) of hepatocytes[47] suggests that the 1-hydroxyethilic radicals are primarily located in the hepatocyte plasma membrane and therefore the lipophilic property of vitamin E gives it a major facility to inhibit the generation of those radicals in comparison with vitamin C, which is hydrophilic (Figure 2).

On the other hand, the reduced effect of vitamin A in relation to hepatic regeneration fits with the report of Portari[42], who evaluated the action of β-carotene in the chronic administration of ethanol in rats. They conclude that because it is a pro-oxidant compound, its mechanism of action could be diminished when the serum and hepatic concentrations are low. As a consequence of this, the reduced effect observed here could be attributed to the intention of the organism to recuperate the serum concentration of this vitamin which was reduced by the extreme consumption of ethanol. To support this possibility, it is important to mention that some studies have indicated that ethanol interferes in several metabolic pathways of vitamin A, that β-carotene is a precursor of this vitamin, that retinol is the alcoholic form of vitamin A. Thus, both retinol and ethanol share the same oxidant activity, and are biotransformed by dehydrogenases, so

metabolic interactions that reduce the normal concentration of vitamin A can occur[48].

As it has already been mentioned, the chronic consumption of ethanol damages hepatic cells. The serum concentrations of albumin and bilirubin and the enzymatic activities of AST and ALT are the most sensitive tests used for the diagnosis of hepatic diseases[49]. In this study, it was observed that the rats treated with ethanol presented a decrease in the concentration of albumin, as well as an increase in the serum concentrations of bilirubin, ALT, and AST (Table 3 and Figure 1). The decrease in albumin supports the previous report, where the same dose of ethanol was applied to evaluate the hepatic regeneration and it was analyzed whether toxicity was modified when ethanol was administered intraperitoneally or intragastrically. Both studies prove the hepatotoxic potential of ethanol and show evidence that low serum albumin is directly related with a decrease in the normal ATP generated in the liver; the organ which is only affected by the ethanol and not by the partial hepatectomy where the level of this protein is comparable to the sham group[40]. On the other hand, in the groups combined with ethanol and vitamins C and E, the concentrations of serum albumin and bilirubin were almost normalized (Table 3), which confirms the protective effect of this vitamin over the free radicals generated by the ethanol, as well as its efficiency in the cellular regeneration of the liver (Table 2 and Figure 2).

The enzymatic elevation can probably be attributed to the damaged structural integrity of the hepatic cells, because these enzymes are located in the cytoplasm and are released into circulation after cellular damage. If injury involves other organelles, such as mitochondria, then the soluble enzymes such as AST compartmentalized will also be similarly released indicating that alcohol consumption causes both plasma membrane and organelle membrane damage. On the administration of vitamins to alcoholic rats we observed decreased levels of serum AST and ALT, suggesting the protection capacity of these vitamins to preserve normal structural liver (Figure 1).

On the other hand, increased serum patterns of LDH, ALT and AST activities after 70% PH in rats have been reported previously[50]. The increase of these serum enzyme activities during the onset of liver proliferation could be related to cell necrosis or enhanced cell membrane permeability. Indeed, it has been concluded that increased serum activities of some enzymes after PH could be due to early release either from damaged cells or by cells with altered permeability, probably involving enhanced synthesis and release of enzymes[40].

It is known that ethanol inhibits liver regeneration, resulting in the increase in free radicals produced by the metabolism of ethanol, causing cellular damage as well as the alteration of liver functions. Our results propose that vitamin C and E which are free radical scavengers block the inhibitory effect of regeneration caused by the ethanol by decreasing the damage in the cellular membrane (MDA). This decrease in damage caused by the free radicals produced by the metabolism of ethanol also decreased the indicators of liver damage such as TGO and TGP, as well as the ones for physiological state (albumin and bilirubin) causing an increase in the indicators of liver regeneration (restitution of the liver mass, liver/body ratio and mgDNA/g liver ratio), and consequently reducing mortality.

In conclusion, in this study, the groups treated with ethanol plus the vitamins C or E had better response in terms of liver regeneration, showing less oxidative stress, and had better liver function than the PH-EtOH and the PH-Ethanol-vitamin A groups.

COMMENTS

Background

Evidence demonstrates that oxidative stress plays an important etiologic role in the development of alcoholic liver disease. Vitamins are one of the most promising antioxidant defense systems. Recently, it has become clear that antioxidant nutrients, including vitamins, are important for the liver. In addition, evidence for alcohol-induced oxidant injury comes from studies in which pretreatment with antioxidants such as vitamin E, vitamin C, and agents that enhance antioxidant capacity attenuate alcohol induced effects.

Research frontiers

The aim of this study is to analyze the effects of vitamins A, C and E in rats with liver injury induced by ethanol administration during liver regeneration, as liver protector agents.

Innovations and breakthroughs

This study clearly shows that vitamin C and E, which are free radical scavengers, block the inhibitory effect of regeneration caused by the ethanol by decreasing the damage in the cellular membrane (MDA); causing an increase in the liver regeneration indicators (restitution of the liver mass, liver/body ratio and mgDNA/g liver ratio), and consequently reducing mortality.

Applications

The treatment of vitamin C and E can be used as a hepatoprotective agent from the damage caused by ethanol. It could be used as a protector of the damaged produced by ethanol, opening a window to new therapeutic strategies, of novel agents which correct fundamental cellular disturbances resulting from excessive alcohol consumption.

Terminology

Partial hepatectomy: the operations consisted of removal of the median and left lateral lobes of the liver. Liver regeneration after partial hepatectomy in the rat has been widely employed as an experimental model to study mammalian cell proliferation.

Peer review

This is an interesting study, aiming to identify the effects of vitamins A, C and E in rats, as hepatoprotective agents of the damage produced by ethanol during liver regeneration. The authors concluded that vitamin C and E are excellent therapeutic agents against the liver damage produced by ethanol.

Abstract

AIM: To investigate whether adding ecabet sodium to the standard triple therapy for *H pylori* infection improve eradication rate.

METHODS: Two hundred and fifty-seven *H pylori*-infected patients were randomly assigned to standard triple therapy (group A, *n* = 129) or triple therapy plus ecabet sodium (group B, *n* = 128). Successful eradication was defined as a negative ^{13}C-urea breath test 6-8 wk after completion of treatment.

RESULTS: After completion of therapy, 194/257 patients showed negative ^{13}C-urea breath test results. According to intention-to-treat analysis, the infection was eradicated in 93/129 (72.1%) patients in group A and 101/128 (78.9%) in group B (*P* = 0.204). Per-protocol analysis showed successful eradication in 93/118 (78.8%) patients from group A and 101/114 (88.6%) from group B (*P* = 0.044). There were no significant differences in the side effects experienced by the patients in the two treatment groups.

CONCLUSION: Our results suggest that the addition of ecabet sodium improves the efficacy of the standard triple therapy for *H pylori*.

INTRODUCTION

H pylori is a gram-negative spiral-shaped bacterium that colonizes the human stomach and it is associated with several gastroduodenal diseases, including gastritis, peptic ulcer disease and low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Eradication of *H pylori* is the recommended treatment for these conditions[1]. The most widely endorsed treatment is triple therapy with amoxicillin, clarithromycin and a proton pump inhibitor two times daily for 7 d, and the reported efficacy of this protocol is 74%-76%[2]. The reasons for its occasional failure are unclear, although bacterial resistance and poor patient compliance are believed to be the primary factors[3]. Ecabet sodium is a dehydroabietic acid derivative that was originally purified from pine resin[4], which is now widely used for the treatment of gastric ulcer and gastritis in East Asia. This agent exhibits a bactericidal effect against *H pylori* by inhibiting bacterial urease activity[5], or by its direct bactericidal effect under acidic conditions[6,7]. Its bactericidal effect on clarithromycin- and metronidazole-resistant clinical isolates of *H pylori* has been reported[7]. Therefore, ecabet sodium has been suggested to improve the efficacy of antibiotic therapy for *H pylori* infection

in patients with peptic ulcer[8-12]. To the best of our knowledge, the efficacy and safety of standard triple therapy plus ecabet sodium has not yet been investigated. Therefore, the aim of this study was to compare the efficacy and side effects of standard triple therapy versus triple therapy plus ecabet sodium for the eradication of *H pylori*.

MATERIALS AND METHODS

Patients

This randomized prospective study was performed at three medical centers (Pusan National University Hospital, Bongseng Memorial Hospital and Maryknoll Hospital, Busan, Korea). The subjects consisted of 257 consecutive *H pylori*-positive patients who had undergone eradication therapy from May 2006 to April 2007. The criteria for exclusion included: (1) previous *H pylori* eradication therapy; (2) ingestion of antibiotics, bismuth, or proton pump inhibitors within the prior 4 wk; (3) patients with a history of allergy to the medications used; (4) patients with previous gastric surgery; (5) coexistence of serious concomitant illness (for example, decompensated liver cirrhosis or uremia); and (6) pregnant women.

All the participants were advised to undergo *H pylori* eradication therapy and they all agreed. There were 148 men and 109 women (mean age 53.9 ± 12.8 years), and these included: 128 patients with gastric ulcer (or ulcer scar); 63 with duodenal ulcer (or ulcer scar); 14 with gastroduodenal ulcer (or ulcer scar); 12 who had received endoscopic treatment for early gastric cancer or adenoma; one with gastric low-grade MALT lymphoma; and 39 with gastritis accompanied by dyspepsia or a family history of gastric cancer (Table 1).

The patients were then randomized into two groups: group A (n = 129) underwent standard triple therapy for 7 d (lansoprazole 30 mg b.i.d., clarithromycin 500 mg b.i.d. and amoxicillin 1 g b.i.d.), while group B (n = 128) patients were given treatment consisting of the same triple therapy plus ecabet sodium (1.0 g b.i.d.) for a period of 7 d. Patients were instructed to take all the drugs 30 min after breakfast and dinner. This study was performed in accordance with good clinical practice and the Declaration of Helsinki guidelines. The Institutional Review Board of Pusan National University Hospital approved this study, and informed consent was obtained from all the patients.

Methods

Before receiving therapy, all the patients underwent upper gastrointestinal endoscopy to confirm the diagnosis and the presence of *H pylori* infection. Positive *H pylori* status was confirmed by the rapid urease test, histology, serology (serum IgG antibody) and/or the ^{13}C-urea breath test. The patients were diagnosed as *H pylori*-positive when they showed positive results by at least two methods.

Possible eradication of *H pylori* was assessed by the ^{13}C-urea breath test at 6-8 wk after completion of treatment. Proton pump inhibitors and antimicrobial agents that might affect the ^{13}C-urea breath test were not given to the patients after completion of therapy.

Table 1 Demographic data and endoscopic findings of 257 patients with *H pylori* infection who were randomly assigned to standard triple therapy (group A) or triple therapy plus ecabet sodium (group B)

	Group A	Group B	*P* value
Patients	129	128	
Age (yr) (mean ± SD)	54.3 ± 13.2	53.4 ± 12.4	0.562
Gender (male/female)	68/61	80/48	0.112
BMI (kg/m^2) (mean ± SD)	23.3 ± 2.9	23.2 ± 3.0	0.768
Smoking	32 (24.8%)	32 (25.0%)	0.971
Alcohol consumption	40 (31.0%)	56 (43.8%)	0.035
Endoscopic findings			0.333
Gastric ulcer	62	66	
Duodenal ulcer	37	26	
Gastroduodenal ulcer	8	6	
Gastric cancer[1]	7	5	
Gastric MALT lymphoma	0	1	
Gastritis	15	24	

[1]Patients who had received endoscopic treatment for early gastric cancer or adenoma.

The ^{13}C-urea breath test was performed as described previously, with capsule-based modification[13]. In brief, the patients fasted for over 12 h before examination and then a gelatin capsule containing 38 mg ^{13}C-urea was ingested with 50 mL water. Breath samples before and 20 min after administration of ^{13}C-urea were collected after a mouthwash. The ^{13}C/^{12}C ratio in the breath samples was measured by mass spectrometry (Heliview; MediChems, Seoul, Korea). The changes in the ^{13}C value over baseline were expressed as Δ^{13}C. A positive result was defined as an increase of > 2‰.

The eradication rate was evaluated for each drug regimen in a per-protocol (PP) analysis based on the number of patients who completed the study, and in an intention-to-treat (ITT) analysis that took into account all the patients, including those who dropped out because of severe side effects, those who showed poor drug compliance, and those who were lost to follow-up. The patients were interviewed in their first visit to the clinic after completion of therapy to clarify their compliance with the therapy and any side effects. Poor compliance was defined as taking less than 70% of the total medication.

Statistical analysis

χ^2 or Fisher's exact tests were used to compare the characteristics of the patients and the results of two regimens. Independent t tests were also employed to compare the possible differences in the age and body mass index of the patients who were treated with the two regimens. $P < 0.05$ was considered statistically significant. Statistical calculations were performed using SPSS version 12.0 for Windows (SPSS, Chicago, IL, USA).

RESULTS

Group A consisted of 129 patients (68 men and 61 women, mean age 54.3 ± 13.2 years) and group B consisted of 128 patients (80 men and 48 women, mean age 53.4 ± 12.4 years). Data regarding the clinical

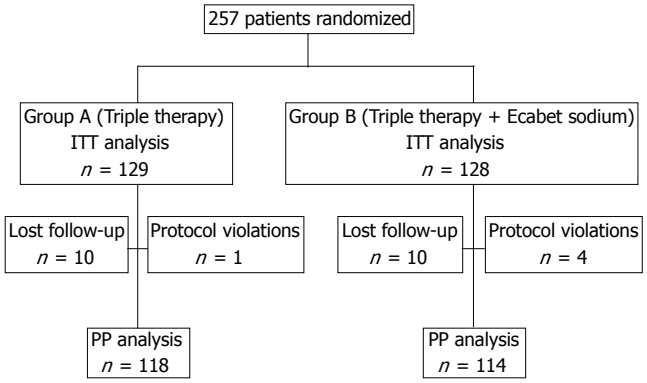

Figure 1 CONSORT flow diaphragm of the subjects' progress through the phases of the study.

characteristics of the patients at entry are summarized in Table 1. The two groups had a comparable age, gender and history of smoking. Alcohol consumption was more common in group B than in group A. There were no significant differences in the endoscopic findings between the two groups.

Five patients dropped out due to non-compliance before the final evaluation: three patients due to side effects (one from group A and two from group B) and two patients due to personal reasons. A further 10 patients from each group did not appear at the first visit after completion of therapy or for the ^{13}C-urea breath test; therefore, they were lost to follow-up (Figure 1).

After the completion of therapy, 194/257 (75.5%) patients tested negative for *H pylori* on the ^{13}C-urea breath test. ITT analysis showed that *H pylori* was eradicated in 93/129 (72.1%) patients from group A and in 101/128 (78.9%) patients from group B (P = 0.204). PP analysis showed successful eradication in 93/118 (78.8%) patients from group A and 101/114 (88.6%) patients from group B (Table 2, P = 0.044).

There were no significant differences in the side effects experienced by the patients in the two treatment groups: 26/119 (21.8%) patients in group A and 24/118 (20.3%) patients in group B reported adverse effects due to therapy (Table 3, P = 0.776). More patients in group A complained of a metallic taste than in group B (11.8% *vs* 4.2%, P = 0.033). All the side effects were self-limiting and disappeared once therapy was terminated.

Table 2 ITT and PP analysis of *H pylori* eradication in patients who were randomly assigned to standard triple therapy (group A) or triple therapy plus ecabet sodium (group B)

	Group A	Group B	*P* value
Eradication rate			
ITT[1]	72.1% (93/129)	78.9% (101/128)	0.204
PP	78.8% (93/118)	88.6% (101/114)	0.044

[1]In this analysis, the patients with unknown outcome were counted as treatment failures.

Table 3 Side effects during standard triple therapy (group A) and triple therapy plus ecabet sodium (group B)

Side effects	Group A	Group B	*P* value
Metallic taste	14	5	0.033
Nausea/vomiting	1	4	0.213
Abdominal pain	2	2	1.000
Constipation	1	0	1.000

Dizziness	1	6	0.066
Skin rash	0	3	0.122
Oral mucositis	2	1	1.000
Others	4	7	0.347

DISCUSSION

Reports about failed *H pylori* eradication therapy have been increasing[14,15]. A recent meta-analysis has demonstrated that a 1-wk course of triple therapy with amoxicillin, clarithromycin and a proton pump inhibitor had a pooled eradication rate of 74%-76% or less[2,16]. A disappointing cure rate of < 80% after 7 d triple therapy was confirmed in the present study.

Various studies are under way to evaluate new antibiotics (e.g., levofloxacin, moxifloxacin, furazolidone and rifabutin) and different therapeutic schedules to increase the efficacy of *H pylori* eradication therapy[17-20]. Data suggest that antibiotic resistance is frequent and clinicians are arriving at the conclusion that concurrent therapy with another agent may sometimes be necessary.

Ecabet sodium has local cytoprotective activity for the gastric mucosa, but is not absorbed into the systemic circulation[21]. Recent studies have demonstrated that ecabet sodium has anti-*H pylori* activity. *In vitro* studies have shown that ecabet sodium inhibits the urease activity of *H pylori* and its adhesion to the gastric epithelial cells[5,22]. In addition, ecabet sodium is reported to have a strong concentration-dependent bactericidal effect on *H. pylori* under acidic conditions[7]. Although proton pump inhibitors potently suppress acid secretion, the acid milieu (pH 3-5) is especially maintained during most of the day and night[23]. Therefore, several studies have evaluated the usefulness of ecabet sodium for eradication therapy in combination with proton-pump-inhibitor-based therapy[8,10,12].

A comparative study demonstrated an eradication rate of 26% with lansoprazole-based dual therapy with clarithromycin or amoxicillin, whereas the eradication rate achieved by adding ecabet sodium to the same regimen was 79%[12]. Another study confirmed the additive effect of ecabet sodium on proton-pump-inhibitor-based dual therapy[11]. In addition, a dose-dependent additive effect of ecabet sodium in combination with lansoprazole and amoxicillin has been demonstrated[10].

On the basis of this evidence, we thought it likely that the addition of ecabet sodium to triple therapy contributes to improving the rate of *H pylori* eradication. In fact, in this study, PP analysis showed that triple therapy plus ecabet sodium was more effective than standard triple therapy, although there was no significant difference according to ITT analysis. It is possible that triple therapy plus ecabet sodium provokes a synergistic effect by launching attacks from different directions against *H pylori*, and this may

lead to complete clearance of the bacterial infection. The bactericidal effect of ecabet sodium on clarithromycin- and metronidazole-resistant clinical isolates of *H pylori*[7] might also explain the increased eradication rate.

The majority of the recently recommended eradication therapy regimens are 1 wk in duration because these have advantages with respect to compliance and medical cost, with a similar eradication rate[24]. A good eradication rate was observed in this study after a 1-wk-long triple therapy plus ecabet sodium.

Because ecabet sodium does not have any systemic activity, it was expected that ecabet sodium-based therapy would be associated with a low occurrence of adverse events. In a previous report, the use of ecabet sodium combined with lansoprazole and amoxicillin reduced the incidence of diarrhea during therapy[11]. However, there was no significant difference of adverse events between standard triple therapy and triple therapy plus ecabet sodium in this study. The use of triple therapy plus ecabet sodium reduced the incidence of metallic taste during therapy, and this might have been due to the sweet taste of ecabet sodium.

In recent years, many studies have compared the effectiveness of triple and bismuth quadruple therapy as a primary therapy for *H pylori*[25-28]. A recent meta-analysis including five randomized trials has reported slightly higher, but not statistically significant, eradication rates with quadruple therapy: ITT and PP eradication rates were 79% and 85% for clarithromycin triple therapy and 80% and 87% for bismuth quadruple therapy, respectively[29]. However, quadruple therapy is complex to take (q.i.d. dosing regimen and high pill count) and has a perceived high frequency of side effects[30].

In conclusion, this randomized prospective study showed (based on PP analysis) that the addition of ecabet sodium improved the efficacy of standard triple therapy for *H pylori* infection. These results need to be confirmed, but triple therapy plus ecabet sodium may represent a valid alternative regimen to the standard *H pylori* eradication protocol.

COMMENTS

Background

The eradication rate of *H pylori* by standard triple therapy is only 74%-76%. Ecabet sodium has been reported to exhibit a bactericidal effect against *H pylori* by inhibiting bacterial urease activity or by its direct bactericidal effect. This study compared the efficacy and side effects of standard triple therapy versus triple therapy plus ecabet sodium for the eradication of *H pylori*.

Research frontiers

Research in this area is focused on developing more effective eradication regimens for *H. pylori* infection. Ecabet sodium is widely used for the treatment of gastric ulcer and gastritis in East Asia. Its bactericidal effect on clarithromycin- and metronidazole-resistant clinical isolates of *H pylori* has been reported. Therefore, it is presumed that adding ecabet sodium to standard triple therapy is more efficient for the eradication of *H pylori*. In our randomized prospective study, the addition of ecabet sodium may have improved the efficacy of standard triple therapy for *H pylori*.

Innovations and breakthroughs

Some reports about the efficacy of ecabet sodium for *H pylori* infection have been reported. But the efficacy and side effects of standard triple therapy plus ecabet sodium have not yet been investigated. By PP analysis, the rate of successful eradication was 78.8% for standard triple therapy and 88.6% for triple therapy plus ecabet sodium. There were no differences in the side effects in the two treatment groups. These results need to be confirmed, but triple therapy plus ecabet sodium may improve the eradication rate of *H pylori*.

Applications

This study demonstrated the efficacy of standard triple therapy plus ecabet sodium. Therefore, this may represent a valid alternative regimen to the standard *H pylori* eradication protocol.

Terminology

Ecabet sodium is a dehydroabietic acid derivative purified from pine resin and one of the local cytoprotective agents for the gastric mucosa. It is now widely used for the treatment of gastric ulcer and gastritis in East Asia. The eradication rate was evaluated for each drug regimen by PP analysis, based on the number of patients who completed the study, and in an ITT analysis that took into account all patients.

Peer review

This study compared two therapeutic regimens for the cure of *H pylori* infection: a classic triple PPI based therapy *vs* the same regimen plus ecabet sodium (a natural bactericidal compound). The study was well designed and conducted.

Abstract

AIM: To evaluate the prevalence and determined the common characteristics of patients diagnosed with non-alcoholic fatty liver disease (NAFLD) at the Philippine General Hospital, Manila, from January 1999 to December 2004.

METHODS: NAFLD was diagnosed in 134 from a total of 1102 patients, based on clinical, ultrasonographic and/or histopathological findings. Patients with conditions associated with secondary NAFLD were excluded. Chart review was done to note demographics, co-morbid illnesses, physical characteristics, hepatomegaly, aspartate/alanine aminotransferase (AST/ALT) levels, albumin, lipid levels, alkaline phosphatase, prothrombin time, and partial thromboplastin time. Data obtained were analyzed using the statistical program SPSS version 10.

RESULTS: Of the 134 patients included, 71% were female and 29% male. Mean patient age was 42.2 years. Sixty percent of patients were obese, 56% had hepatomegaly, and 69% had diabetes. AST levels were elevated in 45% of subjects and ALT levels in 64%.

CONCLUSION: The prevalence of NAFLD at our institution was 12.2%. Patients diagnosed appear to be younger in age in contrast to previous studies. Female sex, obesity, elevated liver enzymes, and diabetes were characteristic features of our NAFLD patients, which is comparable to previous studies from other countries.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is now recognized as one of, if not the most common liver diseases in the United States, with a prevalence of about 5% in the general population, and reaching 25%-75% in patients with obesity and type 2 diabetes mellitus. Data regarding prevalence in the general population of the Philippines have been lacking. NAFLD covers a spectrum of diseases that ranges from simple fatty deposition in the liver to inflammation, fibrosis and cirrhosis. Although the exact etiology is not clear, it may be a part of a metabolic syndrome associated with insulin resistance, diabetes, obesity and hypertension. Patients typically present with asymptomatic serum aminotransferase elevation of 2-3 times the normal level. Symptoms may include fatigue and abdominal pain. Physical examination may show hepatomegaly. Liver biopsy is useful and effective as a prognostic indicator, but it is an invasive and costly tool to diagnose fatty liver, and is mainly used for unexplained cirrhosis. NAFLD can be diagnosed by histology, ultrasonography, CT, and MRI. However, the imaging modalities most often used to identify hepatic steatosis include CT and ultrasonography. Hyperechogenic (bright) liver indicates steatosis, with sensitivity and specificity rates as high as 95%. The prevalence of obesity has been steadily rising in the Philippines, which may be attributed to a change in dietary habits and a sedentary life style.

NAFLD includes a spectrum of liver diseases, including fatty liver, steatohepatitis, and even cirrhosis in the absence of alcohol intake, that are known to be injurious to the liver. It has a benign course in the majority of cases, but up to 20% of these patients with NAFLD have non-alcoholic steatohepatitis NASH[1,4]. Up to one-third of these NASH cases can progress to cirrhosis, liver failure and even hepatocellular carcinoma[2]. It is now believed to be a widespread liver disease in Western countries, and most probably, even in Asian countries. Moreover, it may be the leading cause of cryptogenic cirrhosis[3,5]. Even with its preponderance, NAFLD remains something of a medical mystery. Recent studies have shown an upsurge of

interest in this liver disease and it is becoming increasingly significant[6].

A lot of work has been done on NAFLD in Western countries[6-8], but it is relatively new in the Philippines, with only a handful of studies having been done. Recent studies have proposed that obesity and type Ⅱ diabetes mellitus, which are hyperinsulinemic states with decreased tissue sensitivity to insulin, are the major players in the pathogenesis of NAFLD. This study was conducted to note characteristic features in our NAFLD patients at the Philippine General Hospital, Manila, confirmed by clinical, ultrasonographic and/or histopathological findings, and to establish if these findings were congruent with those of previous studies on NAFLD.

MATERIALS AND METHODS

This study was conducted at the Philippine General Hospital, Manila, Philippines based on case records from January 1999 to December 2004. From a total of 1102 patients with fatty liver, 134 patients were diagnosed with NAFLD, based on clinical and histopathological findings or ultrasound findings suggestive of fatty liver. Fatty liver was diagnosed by ultrasonography using an abdominal probe at 2-5 MHz. Longitudinal, subcostal, ascending, and oblique scans were performed. The ultrasonographic criteria that were used to diagnose fatty liver included liver and kidney echo discrepancy, presence of increased liver echogenicity (bright), echo penetration into the deep portion of the liver, and clarity of liver blood vessel structures. Due to the subjectivity and vagueness of some of the case records reviewed on the amount of alcohol consumption, patients included had absolutely no history of alcohol intake. HCV-antibody-positive patients were excluded. Patients with a history of various surgical procedures that can lead to secondary NAFLD, i.e. gastropexy, jejunoileal bypass, extensive small bowel resection, biliopancreatic diversion, and small bowel diverticulosis, were excluded, as were patients taking drugs or conditions that are known to cause secondary NAFLD.

Chart review was performed to note history, demographics, co-morbid illnesses, physical characteristics, physical examination findings, and laboratory findings. Detailed clinical evaluation of each subject was carried out to note patient characteristics that focused on primary causes of NAFLD. Presence of obesity, hepatomegaly, and diabetes were specifically sought. Body mass index (BMI) of each subject was noted to establish obesity. Patients with BMI < 18, 18-25, 26-29 and ≥ 30 were considered under-weight, normal, over-weight and obese, respectively. Fasting serum cholesterol and triglyceride levels of all patients were noted for lipid abnormalities, but a substantial lack of data precluded their inclusion in this study. Fasting blood sugar level in all patients was noted. Diagnosis of diabetes in these patients was made according to standard criteria.

In most patients' medical charts, serum level of alanine/aspartate transaminases (ALT/AST), albumin, prothrombin time, partial thromboplastin time, and alkaline phosphatase were documented. Data from study participants obtained from medical records included age, gender, nationality, weight, height, BMI, and clinical presentation or presence of hepatomegaly. The results were expressed as means ± SD. Data obtained was then converted into variables that were analyzed using frequency and cross tabulation functions of computer-based statistical program SPSS version 10. The test was considered to be significant if P was < 0.05.

Table 1 Distribution of BMI *n* (%)

Gender	Underweight	Normal	Overweight	Obese
Female	10 (11%)	5 (6%)	8 (9%)	64 (74%)
Male	17 (36%)	10 (21%)	4 (9%)	16 (34%)
Total	27 (20%)	15 (11%)	12 (9%)	80 (60%)

RESULTS

Demographics and physical attributes

Of the 1102 patients diagnosed with fatty liver, 134 (12.2%) met the criteria for review. As expected, a huge proportion of the cases came from metropolitan Manila (69%), with the rest of the cases coming from the southern Luzon regions (21%). Results showed that 71% of the subjects were female and 29% were male. Mean patient age was 42.2 ± 2.1 years. Half of the patients were aged 21-47 years. Mean BMI was 31.8 ± 7.2, with 60% of patients being obese or having BMI > 30, while 11% had normal BMI, 9% were overweight and 20% were underweight. Most obese patients (80%) were female (Table 1).

Clinical features

Fatigue and right upper quadrant discomfort were the most common symptoms seen in both male (34%) and female (29%) patients. Most however, had no symptoms at all (62%). Overall, a greater proportion of subjects with normal ALT were completely asymptomatic compared with those with abnormal ALT (P < 0.04, Fisher's exact test). Approximately 59% of subjects had a relatively unremarkable physical examination, with the exception of their body weight and blood pressure. A large number of NAFLD patients (92; 69%), had diabetes. Hypertensive patients accounted for 22% (29) of the sample population. Twenty-seven patients with NAFLD and normal ALT were obese, as defined by BMI > 30. Twenty-nine patients with NAFLD and normal ALT levels had diabetes, and 14 had hypertension. One patient with normal and one with elevated ALT had hypothyroidism. None of the subjects were taking medication known to be associated with the development of hepatic steatosis.

Laboratory correlation

Based on autopsy, ultrasound or physical examination, 75 (56%) patients had hepatomegaly. A total of seven autopsied patients who met the criteria for NAFLD had an average liver weight of 1722 ± 488 g (normal 1500-1800 g). AST levels were elevated in 60 (45%) of subjects and ALT levels in 86 (64%). AST levels averaged 112 ± 20 U/L for females and 164 ± 27 U/L for males. ALT levels averaged 217 ± 18 U/L for females and 187

Table 2 Laboratory characteristics of NAFLD patients at the Philippine General Hospital

Parameter	Blood chemistry values		
	Total *n* = 134 (mean)	Male *n* = 39 (mean)	Female *n* = 95 (mean)
Liver weight (g)	1722 ± 488	1505 ± 399	1952 ± 512
AST (U/L) *n* (15-137)	150 ± 19	164 ± 27	112 ± 20
ALT (U/L) *n* (30-65)	192 ± 17	187 ± 24	217 ± 18
Alkaline phosphatase (g/dL) *n* (50-136)	89 ± 20	87 ± 30	92 ± 22

Matteoni (1999)[29]	132	53	53	33	70	92
Khurram (2003)[31]	50	47	54	44	66	76
Our study (2005)	134	42	71	69	60	56

± 24 U/L for males. Bleeding abnormalities were noted in 26 (19%) patients. Mean blood glucose level for male patients was 6.7 ± 8 mmol/L and 8.1 ± 5 mmol/L for females. Alkaline phosphatase and albumin levels were within the normal range for the whole sample population. Glutamyltransferase levels and lipid profiles were not included due to scarcity of available data from charts reviewed. Details are shown in Table 2.

Risk factors

Female sex, diabetes, hepatomegaly, increased BMI (overweight and obesity) were the main risk factors noted to have a significant relationship with NAFLD ($P < 0.05$). Significant differences ($P < 0.05$) in BMI, liver weight, AST, ALT and blood sugar were also noted between female and male individuals. It was notable that a sizable proportion of our patients (20%) who were underweight also had had NAFLD. No significant relationship was found between the presence of fatty liver and age. A significant number (92; 69%) of our patients had diabetes, 69 (75%) of whom were female. The mean duration of diabetes was 9.9 ± 3.9 years. Mean HbA1C was elevated at 9.1% ± 2.6%. Hepatomegaly with fatty infiltration, as assessed by ultrasound, was reported in 66 patients (49%) with a mean liver size of 17.4 ± 5.2 cm.

DISCUSSION

NAFLD includes a wide spectrum of histological abnormalities that are similar to alcoholic liver disease, but without a prior history of alcoholic intake known to be injurious to the liver. NAFLD is a common problem in the US, Asia-Pacific region, Europe, and the Middle East. NAFLD can affect any age group but is usually encountered in the 40-60 years age group[5]. Prevalence is high even among children, with 2.6% of all children and up to 52.8% of obese children having this disease[3]. Several investigators have noted that the mean age of patients with NAFLD was 52-54 years[18,25,28,29]. In other studies mean age varied between 47 and 54 years of age[26,27,31]. Most of our patients were aged 21-47 years, which is considered a younger age group. This may reflect the changing diet of young Filipinos to caloric rich foods, which has increased the number of people with diabetes in the Philippines, or it may just reflect the limitation of our sample population.

Most of our other results, including the presence of diabetes, hepatomegaly and obesity, correlated with the findings of previous authors[18,26-30]. Up to 65%-80% of females may have this disease, as shown in our study and in some previous studies, with the exception of that of Bacon *et al*, in which there were only 42% females[18,26-30]. In our study, females constituted 71% of patients. Different studies have shown a gender-related difference in NAFLD-associated conditions such as hepatomegaly, diabetes and dyslipidemia; these conditions being more common in female NAFLD patients. Our findings were similar in most cases, i.e. 64% patients with obesity were female and 69 females or 51% of the whole population had diabetes. Diabetes mellitus is an independent risk factor for liver-related deaths in NAFLD patients[3]. In related studies, up to 75% of NAFLD patients had diabetes[18,26-30]. Our results agreed with these studies, with 60% of our population having diabetes, and there was a significant correlation with NAFLD ($P < 0.05$). It has been noted by Angulo that the prevalence of NAFLD increases by a fraction of 4.6 in patients with obesity, with up to 74%

of such patients having NAFLD[3]. In previous studies, 30% to 81% of patients diagnosed with NAFLD were found to have obesity[18,26-30]. Our results correspond with these studies, with a mean BMI of 31.8 ± 7.2. This was also significantly correlated with the presence of NAFLD ($P < 0.05$). Several studies have shown that truncal obesity is an important risk factor for development of NAFLD, even in patients with normal BMI. Truncal obesity ideally should have been included in the data collection but was not incorporated due to lack of data in case records.

On the other hand, fatty liver is associated with mild to moderate enlargement of the liver. Hepatomegaly is commonly the sole physical finding in most patients with NAFLD, which was also seen in our patients. Similar results have been found in other related studies[18,26-30]. Hepatomegaly may even be more severe due to the fact that normal values used for comparison come mainly from Caucasian data, and may not reflect true normal values in Filipinos. Hyperlipidemia has also been tagged from previous studies as a risk factor for the development of NAFLD[18,26-30]. Prevalence of hyperlipidemia in NAFLD patients is quite variable. Diehl *et al* noted it in only 20% of NAFLD patients, contrary to the results of Matteoni et al who found it in 92% of patients[28,29]. Unfortunately, our study was not able to document lipid profiles due to the non-availability of laboratory results. Characteristic features of our NAFLD patients compared with other studies are given in Table 3.

Limitations include the location of our study, which was a large tertiary hospital in the Philippines. This may not be a representative sample population for analysis. Moreover, not all cases of NAFLD were analyzed, because of the lack of data from case records. Results may have differed with inclusion of these patients. Furthermore, normal values used for BMI and hepatomegaly are based mostly on Caucasian data and may not be applicable to the Filipino population. Larger prospective studies with control groups for longer periods of time are needed to firmly establish the validity of our results.

In conclusion, NAFLD was common in our patients, with a mean age of 42 years. In a 5-year period, more females (71%) were diagnosed with NAFLD. Hepatomegaly is the most common physical finding and was noted in 56% of our patients. A younger mean age, obesity (60%), diabetes (69%), hepatomegaly (56%) and female sex (71%) were the most distinct attributes of our patients with NAFLD. Except for a younger age group, the results are comparable to previous studies from other countries.

Abstract

AIM: To investigate the effects of exogenous melatonin on bacterial translocation and apoptosis in a rat ulcerative colitis model.

METHODS: Rats were randomly assigned to three groups: group Ⅰ: control, group Ⅱ: experimental colitis, group Ⅲ: colitis plus melatonin treatment. On d 11 after colitis, plasma tumor necrosis factor-α, portal blood endotoxin levels, colon tissue myeloperoxidase and caspase-3 activity were measured. Bacterial translocation was quantified by blood, lymph node, liver and spleen culture.

RESULTS: We observed a significantly reduced incidence of bacterial translocation to the liver, spleen, mesenteric lymph nodes, portal and systemic blood in animals treated with melatonin. Treatment with melatonin significantly decreased the caspase-3 activity in colonic tissues compared to that in trinitrobenzene sulphonic acid- treated rats (16.11 ± 2.46 *vs* 32.97 ± 3.91, $P < 0.01$).

CONCLUSION: Melatonin has a protective effect on bacterial translocation and apoptosis.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are chronic relapsing conditions of unknown etiology with a high morbidity and remain largely incurable. Crohn's disease (CD) and ulcerative colitis (UC) are collectively termed as IBDs, which are characterized by chronic inflammation in the mucosal membrane at various sites in the gastrointestinal tract with periods of remission and relapse over many years. IBDs are characterized by tissue edema, increased gut epithelial permeability and excessive infiltration of the gut by inflammatory cells from the circulation. This influx results in further tissue-destructive inflammatory processes[1].

The gastrointestinal epithelium forms a barrier that separates the finely regulated homeostasis of the body interstitium from the harsh environment of the intestinal lumen[2]. In IBDs, the intestinal mocosal barrier is disrupted by inflammation and ulceration. In these circumstances, translocation of enteric bacteria and their products through the bowel wall to extra-intestinal sterile sites may occur[3]. Bacterial translocation may cause secondary infection of intra-abdominal inflammatory processes, such as intra-abdominal abscesses, or peritonitis. With regard to endotoxemia and its relationship with severity of disease, increased intestinal epithelial permeability precedes clinical relapse[4], showing that a permeability alteration may be an early event in disease reactivation[2].

The exact pathogenesis of IBD is poorly understood, but there is evidence that IBD involves interactions between immune system, genetic susceptibility and the environment[1]. Recent studies have shown the important role of antiinflammatory and antioxidant agents, including melatonin, in IBDs[5,6]. Melatonin (5-methoxy-N-acetyltryptamine), a derivative of the essential amino acid tryptop-

han, is an indolamine hormone with its blood levels varied throughout the day[7]. Melatonin is an agent that promotes sleep and is produced at night by the pineal gland. While produced primarly in the pineal gland, melatonin can also be found in cells of the bone marrow and gastrointestinal tract and plays a fundamental role in the neuroimmunoendocrine system[8]. In most of the published studies, an antioxidative effect, improved microcirculation and a stimulation of intestinal epithelium may also apply in the beneficial effects of melatonin on the symptoms of colitis induced in rats[5,9]. The purpose of this study was to determine whether exogenously administered melatonin has any antioxidative and antiinflammatory effects on the impairment of bacterial translocation and apoptosis in an experimental colitis model of rat. To our knowledge, our study is the first one showing the relation between colitis, melatonin, and bacterial translocation.

MATERIALS AND METHODS

Animals

Male Wistar-albino rats (Erciyes University Hakan Cetinsaya Experimental and Clinical Research Center, Kayseri, Turkey) weighing 225-290 g were fed *ad libitum* with a nutritionally balanced rodent diet and water. The rats were kept under constant environmental conditions. Only water was provided during the 12 h preceding the experiments. The animals used in this study were handled and treated in accordance with the strict Guiding Principles of the National Institution of Health for Experimental Care and Use of Animals. The Animal Care Committee of the University of Erciyes approved all experimental procedures in this study.

Experimental design

Thirty Wistar-albino rats (28-32 wk old) were used in the study. The rats were divided into 3 groups (10 in each group): group I (control) = normal animals, group Ⅱ (colitis) = induction of experimental colitis without further treatment, group Ⅲ (colitis + melatonin) = induction of experimental colitis plus administration of melatonin.

Experimental procedures

Colitis was induced as previously described[10]. Briefly, the rats were lightly anesthetized with halothane, and an infant feeding tube (Unoplast A/S DK 330; Hundested, Denmark) fitted onto a blunt 18-gauge needle was inserted rectally. The tip of the tube was placed nearly 8 cm into the colon and 25 mg 2, 4, 6-trinitrobenzene sulphonic acid (Sigma, St. Louis, Missouri) mixed with 0.25 mL 30% ethanol (TNBS-E) was intracolonically instilled. After instillation, the rats were supported at the supine position until recovery from anesthesia to prevent immediate anal leakage of the instillate. The rats in the control group received intracolonic saline. During the 10 subsequent days, the animals in group Ⅲ were treated with melatonin (10 mg/kg per day) intraperitoneally. Rats in the control and colitis groups received the same volume of steril saline at the same time points. All injections were given after topical application of an antiseptic solution of 10% povidone iodine.

All rats were fed with standard rat chow for 10 d. On the 11th d, all animals underwent operation. Rats were anesthetized by intraperitoneal injection of ketamine-HCl (10 mg/kg; Ketalar®, Eczacibasi, Istanbul, Turkey) and xylazine (3 mg/kg; Rompun® 2%, Bayer, Germany). The abdominal skin was cleansed with povidone-iodine after shaving. All procedures were performed under sterile conditions by a surgeon. The abdomen was opened with a midline incision, 2-mL portal and 2-mL systemic blood samples were collected for biochemical analyses and blood cultures. Samples of liver, spleen, and mesenteric lymph nodes (MLNs) were taken for the determination of bacterial translocation. Colon tissue was sampled for analysis of myeloperoxidase (MPO) and caspase-3 activity as well as for histologic examination. At the end of surgical procedure, all rats were sacrified by overdose ether inhalation.

Determination of serum tumor necrosis factor-α level

The levels of serum tumor necrosis factor-α (TNF-α) was measured using a specific enzyme-linked immunosorbent assay kit (The BioSource Rat TNF-α ELISA). The results were expressed as pg/mL.

Assay of plasma endotoxin level

Plasma endotoxin level in portal venous blood was assayed using quantitative modification of the Limulus-amebocyte-lysate test (Sigma)[11]. The results were expressed as pg/mL.

Bacterial translocation determination

Portions of the liver, spleen and MLNs were immediately homogenized in saline. Aerobic cultures were performed with blood and eosine-methylene blue agar at 37℃ for 24 h. Anaerobic cultures were performed using anaerobic blood agar in Gas-Pak jars at 37℃ for 24 h. Colonies were identified with standard microbiologic methods. Blood samples (1 mL) were cultured in tryptic soy medium at 37℃ for 7 d. Positive cultures were transferred to blood and EMB agar. Colonies were identified with standard bacteriologic methods.

Assesment of colonic damage

The distal colon was removed and opened longitudinally. Fecal material was rinsed with a gentle spray of 0.9% saline. The freshly opened colonic segments were pinned out onto a wax block and examined by a pathologist who was blinded to the treatment.

Colon macroscopic score

The extent of mucosal damage was assessed using the colon macroscopic scoring system of Wallace *et al*[12]. Macroscopic inflammation scores were assigned based on clinical features of the colon using an arbitrary scale ranging from 0-10 as follows: 0: normal appearance, 1: hyperemia, 2: hyperemia and thickening without ulceration, 3: ulceration at a single site, 4: two or more sites of ulceration or inflammation, 5: ulceration or inflammation extending > 1 cm along the colon, 6-10: damage covering > 2 cm along the colon, with the score being increased by 1 for each additional centimeter of involvement.

Colon microscopic score

The tissue samples were fixed with 10% formaldehyde solution for 24 h and transferred to 70% ethanol solution. The tissue samples were embedded in paraffin and then cut into 4-μm thick sections. Histologic examination was performed under light microscope after hematoxylin and eosin staining. A pathologist who was unaware of the animals'groupings evaluated the specimens. Tissue samples were assessed for the presence and activity of colitis as well as the extent of tissue damage using a large number of serial sections. Colonic inflammation was assessed by using a modification of the histopathologic grading system of Macpherson and Pfeifer[13]. The following criteria were used for scoring colonic damage: grade 0: no damage; grade 1: mild mocosal and/or submucosal inflammatory infiltrate and edema: punctuate mucosal erosions often associated with capillary proliferation, muscularis mucosa intact; grade 2: grade 1 changes involving 50% of the specimen; grade 3: prominent inflammatory infiltrate and edema frequently with deeper areas of ulceration extending through the muscularis mucosa into the submucosa, rare inflammatory cells invading the muscularis propria but without muscle necrosis; grade 4: grade 3 changes involving 50% of the specimen; grade 5: extensive ulceration with coagulative necrosis bordered inferiorly by numerous neutrophils and lesser numbers of mononuclear cells, necrosis extending deeply into the muscularis propria; grade 6: grade 5 changes involving 50% of the specimen.

Myeloperoxidase measurement in colon tissue

After being scored, a sample of distal colon was frozen for subsequent measurement of MPO activity as an index of granulocyte infiltration[12]. The method described by Bradley *et al*[14] was used to measure the MPO activity in colon homogenates. The previously frozen colon tissue samples were homogenized for 30 s in 4 mL of 20 mmol/L potassium phosphate buffer (pH 7.4), and centrifuged at 40 000 × *g* for 30 min at 4℃. The pellet was resuspended in 4 mL of 50-mmol/L potassium phosphate buffer (pH 6.0), containing 0.5 g/dL hexadecyltrimethyl ammonium bromide. Samples were sonicated for 90 s at full power, incubated in a 60℃ water bath for 2 h and centrifuged. The supernatant (0.1 mL) was added to 2.9 mL of 50-mmol/L potassium phosphate buffer (pH 6.0), containing 0.167 mg/mL dianisidine and 0.0005% hydrogen peroxide. Absorbance of 460 nm of visible light (A_{460}) was measured for 3 min. The results were expressed as units of enzyme activity per gram of wet tissue weight (U/g tissue).

Caspase-3 proteolytic activity

The caspase-3 activity ratio was calculated by colorimetric assay (Chemicon International, Temecula, CA). Cells harvested from different treatment groups were lysed and 200 μg protein was tested for protease activity by adding a caspase-specific substrate peptide, DVED-pnitroaniline. Caspase-3 cleavage of the peptide released the chromophore p-nitroaniline (p-NA), which was quantitated spectrophotometrically at 405 nm. The level of caspase-3 enzymatic activity in the cell lysate was directly proportional to the color reaction. The results are expressed as the fold increase of caspase activity in apoptotic cells relative to their respective controls. In background reactions, no DVED-p-NA substrate was added, and the values obtained were subtracted from experimental results before the fold increase was calculated [15].

Table 1 Comparison of macroscopic and microscopic colonic damage scores (mean ± SD)

Colonic damage score	Control	Colitis	Colitis + melatonin	*P*
Macroscopic score	0.40 ± 0.38[b]	7.1 ± 1.34	2.4 ± 0.67	< 0.01
Microscopic score	0.6 ± 0.79[a]	4.9 ± 1.23	2.0 ± 0.66	< 0.05

[b]$P < 0.01$ *vs* colitis and colitis + melatonin groups; [a]$P < 0.05$ *vs* colitis and colitis + melatonin groups.

Statistical analysis

The data are presented as mean ± SD. One-way analysis of variance (ANOVA) was used to compare serum TNF-α, endotoxin, and colon MPO and caspase-3 levels among the 3 groups. The Tamhane test was used as the post hoc test for multiple comparisons between groups. Non-parametric Kruskal-Wallis test was used to compare bacterial translocation, and macroscopic and microscopic damage scores. The data were analyzed with the Statistical Package for the Social Sciences (SPSS) for Windows (version 13.0). $P < 0.05$ was considered statistically significant.

RESULTS

Colonic damage

Macroscopic colonic damage: The results of assessment of gross and microscopic colonic injury are listed in Table 1. There was a minimal damage to the surface epithelium, and a mild inflammation of the mucosa but no transmural inflammation in the rats with an evident macroscopic respone to the treatment with melatonin. In the colitis group, the damage comprised broad mucosal ulcers with a surface layer of necrotic slough, accumulation of mesenteric fat, and fibrinous adhesions to the bowel. Macroscopic colonic damage score was the highest in colitis group (mean; 7.1) and was significantly lower in the colitis + melatonin group but higher than in the control group ($P < 0.01$).

Microscopic colonic damage: Histopathologic evaluation of microscopic colonic damage in the control group was in normal limits. Microscopic examination showed a low level of damage or inflammation in rats treated with melatonin (groups Ⅲ), whereas there was widespread destruction of the mucosa with transmural infiltration of neutrophils, monocytes, and lymphocytes in rats with colitis ($P < 0.05$) (Table 1).

Plasma TNF-α and endotoxin levels

Serum TNF-α and endotoxin levels in the colitis and colitis + melatonin groups were significantly increased on d 11 compared with the control group ($P < 0.01$, Figure 1). The increase in the colitis + melatonin group was significantly less than that in the colitis group ($P < 0.01$).

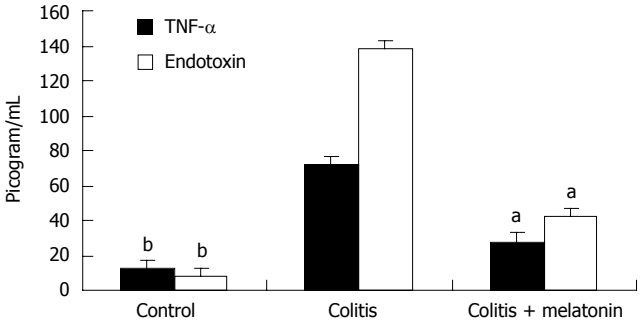

Figure 1 Serum TNF-α and endotoxin concentrations in rats. Vertical columns and error bars represent mean ± SD respectively. $^{b}P < 0.01$ *vs* colitis and colitis + melatonin groups, $^{a}P < 0.05$ *vs* colitis group.

Table 2 Incidence of bacterial translocation in different groups

Distant organ	Control[1]	Colitis[1]	Colitis + melatonin[1]	*P*
MLNs	0[b]	8	4[d]	< 0.01
Liver	0[d]	7	2[d]	< 0.01
Spleen	0[d]	6	2[d]	< 0.01
Portal blood	0[d]	6	1[d]	< 0.01
Systemic blood	0[d]	3	0[d]	< 0.01

MLNs: Mesenteric lymph nodes. Non-parametric Kruskal-Wallis test was used to compare bacterial translocation. [1]Number of positive tests for all animals tested (10 rats each group). $^{b}P < 0.01$ *vs* colitis and colitis + melatonin groups, $^{d}P < 0.01$ *vs* colitis group.

Bacterial translocation

In the control group, no bacterial growth was detected on d 11. TNBS-E colitis caused a significant increase in the frequencies of bacterial translocation in liver, spleen, MLNs, and portal blood. Compared with the colitis group, melatonin decreased the bacterial translocation in liver spleen, MLNs, and portal and systemic blood ($P < 0.05$). The incidence of bacterial translocation in different groups is shown in Table 2. Translocating bacteria were identified as Escherichia coli, Pseudomonas aeruginosa, Enterococus faecalis, and Staphylococcus aureus.

Myeloperoxidase levels in colon tissue

The colon MPO concentrations in rats are shown in Figure 2. The MPO levels in colonic tissue were higher in the colitis group than in the control and melatonin groups ($P < 0.001$). The colonic MPO activity was significantly lower in the melatonin treatment group than in the TNBS-treatment group ($P < 0.001$).

Caspase-3 levels

The caspase-3 level in colonic tissue was significantly higher in the TNBS-E treatment group than in the control group ($P < 0.001$). Treatment with melatonin significantly decreased the caspase-3 activity compared to the colitis group ($P < 0.01$, Figure 3).

DISCUSSION

Ulcerative colitis and CD are the 2 major clinical forms of IBD, clinically characterized by diarrheic attacks, weight loss, and abdominal pain. An increase in incidence has been noticed in the last decade, and the actual prevalence of IBDs is now estimated to be 150 to 200/100.000 people in Europe and North America[16].

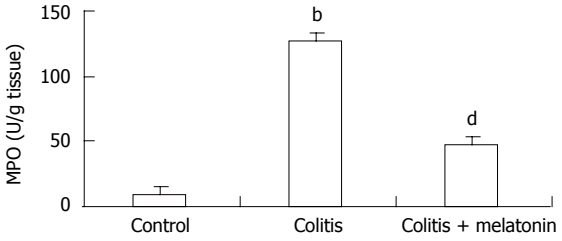

Figure 2 Colon MPO concentrations in rats. Vertical columns and error bars represent mean ± SD respectively. $^{b}P < 0.001$ *vs* control and colitis + melatonin groups, $^{d}P < 0.001$ *vs* colitis group.

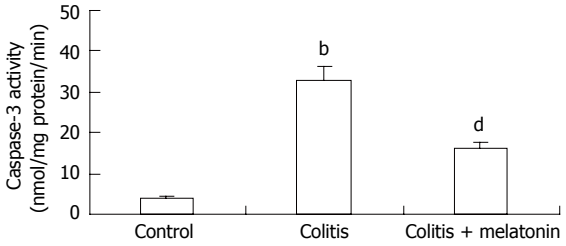

Figure 3 Colonic caspase-3 activity in all groups. Vertical columns and error bars represent mean ± SD respectively. $^{b}P < 0.001$ *vs* control group, $^{d}P < 0.01$ *vs* colitis group.

Although experimental animal models of colitis are of value in elicing some of the mechanisms of IBDs, the different models differ in their relative use[17]. Most animal models reported lack of certain characteristics of IBDs and model acute events rather than the chronic features typical of IBDs. TNBS colitis has been well characterized and has clinical, biochemical, and pathological similarities to colonic CD. It was reported that animals with TNBS colitis respond to drugs which are useful in treatment of IBDs[12]. This observation, together with the availability of a quantitative scoring system, makes it a useful system for the evaluation of new therapeutic agents. We, therefore, used TNBS-induced colitis, which has the dual advantage of chronicity and acuteness so often in patients with IBDs. Some other advantages of this model of colitis are its reasonable reproducibility and value in assessing the efficacy of therapeutic agents commonly used in the treatment of colitis[12,17].

The gastrointestinal tract is continuously exposed to toxins, microbes, microbial products, and other antigens. The intestinal epithelium has several important functions in protecting an organism from the potential deleterious effects of these agents acting as a physical barrier that limits the entry of luminal substances and microorganisms into the lamina propria[18]. Berg *et al*[19] have described bacterial translocation at the passage of viable bacteria through the epithelial mucosa into the lamina propria, and then to the MLNs and possibly other tissue. It was originally reported that bacterial translocation not only

means the migration of intestinal bacteria through the gut (the mechanisms and routes of which have never been identified) but also includes the consequences of this phenomenon, i.e., the infection of extraintestinal tissue with a subsequent systemic inflammatory response, possibly even leading to sepsis with multiple organ dysfunction[20]. The latter indicates that the immune system is no longer capable of eliminating migrating bacteria and/or inflowing toxins and that gut barrier dysfunction may be attributed to both morphological and functional disorders.

There appear to be three main mechanisms that promote bacterial translocation: impaired host defences, physical damage to the intestinal mucosa and disruption of the ecology of the indigenous gut flora resulting in intestinal bacterial overgrowth[19]. At least two of these factors are features of IBD, with an obvious physical disruption of the epithelial barrier by inflammation and ulceration and, as outlined above, disturbed bacterial defences with loss of communal stability and reduced colonization resistance[21]. Several human studies indicate that bacterial translocation also occurs in IBDs. Eade and Brooke[22] demonstrated that portal bacteremia and systemic bacteremia occur in 24% and 1% of patients being submitted to elective colectomy for ulcerative colitis, respectively. They also found that endotoxin plasma levels are positively correlated with clinical disease severity. In addition, bacteria were cultured in liver biopsies from 11% of these patients. Ambrose *et al*[23] reported that intestinal bacteria are cultured in the ileal serosa from 27% and in the MLNs from 33% of patients undergoing surgery for CD. In our study, both systemic and portal bacteremia were demonstrated, suggestingthat bacteria can be cultured in the MLNs, liver and spleen from TNBS-E colitis group. In this study, all the organ cultures were positive for enteric species, the extent of bacteria translocation from the colonic lumen correlated positively with the colon macroscopic and microscopic score, indicating that disruption of the physical barrier in this model is an important factor for promoting bacterial translocation.

It was previously demonstrated that the antioxidant melatonin exerts beneficial effects on different experimental colitis models of rats[5,6]. Mazzon *et al*[24] demonstrated that melatonin treatment significantly reduces the degree of colonic injury, proinflammatory cytokine release and apoptosis. However, the mechanism of the protective effects of melatonin has not been elucidated. The decreased free radical production, immunomodulatory effect and improvement in gut blood flow have to be considered[8]. Melatonin can protect gastrointestinal mucosa gainst damage by stimulating the immune system and fostering microcirculation and epithelial regeneration[25]. The involvement of melatonin in oxygen radical pathophysiology has been confirmed in different colitis models[26,27]. As reactive oxygen species play a significant role in the pathogenesis of colitis, melatonin may explain its protective effect on colonic inflammation. The present study showed that melatonin could exert protective effects on colonic inflammation and that reduction of bacterial translocation might be associated with the decreased cell apoptosis.

The extent of immune response can be assassed by measuring the level of MPO as a marker of neutrophil activity in the colon. In the present study, in all TNBS-E treated rats, colonic MPO activity was increased significantly compared to the control group, while melatonin treatment resulted in a decrease in this elevation. This finding is in agreement with earlier investigators who suggested a critical role of neutrophils in colitis[28]. Infiltration and activation of neutrophils lead to excessive generation of proinflammatory cytokines and reactive oxygen species that have been implicated in the pathogenesis of colitis[29]. The decrease in the expression of TNF-α in the melatonin-treated rats supported these findings. Melatonin is a direct antioxidant and also decreases free radical levels by stimulating the activities of enzymes involved in antioxidative defense. Melatonin prevents circulatory failure in rats with endotoxemia by inhibiting the release of TNF-α[30]. TNF-α is a multifunctional cytokine produced primarly by activated monocytes and macrophages and plays a crucial role in the initiation and continuation of mucosal inflammation and immunity[31,32]. TNF-α is involved in many cell processes including apoptotic cell death, metabolism, inflammation, thrombosis, and fibrinolysis[33] and induces the production of other cytokines including adhesion molecules, arachidonic acid metabolites, and activation of immune and non-immune cells[34]. It was reported that systemic inhibition of soluble TNF-α with infliximab (chimeric anti-TNF-α mAbs) induces remission in up to 50% of patients with CD and significantly improves clinical symptoms of most patients[35]. Worledge *et al*[36] reported that administration of TNF-α antibodies can effectively treat experimental rat colitis. In our study, TNF-α levels were parallel to the exacerbated inflammation and increased bacterial translocation in the colitis group. In contrast, TNF-α levels decreased in the melatonin group. At this point, TNF-α may be promising marker for monitoring IBDs activity and response to the treatment. Such findings indicate that blockade of TNF-α signaling has advantages in the treatment of IBDs. The results of our study also show the therapeutic potential of melatonin in human IBDs by affecting the TNF-α levels. In addition to its anti-inflammatory effect, melatonin action in the prevention of colitis may include stimulation of the immun system[37]. Although there is no direct evidence that the effect of melatonin on the immune response is enhanced in the gastrointestinal tract, indirect evidence indicates that melatonin administration to rats significantly increases the number and size of Peyer's patches[38].

Apoptosis, known as programmed cell death, is an essential physiological process required for the maintenance of tissue homeostasis. Insufficient or excessive cell death can contribute to disease. Although many factors are involved in apoptotic program, caspases have been shown to play a major role in the transduction of apoptotic signals[39]. Recent studies have also shown the induction of apoptosis in different cell lines in response to reactive oxygen species, peroxynitrite and nitric oxide[40]. In the present study, colonic caspase-3 activity was significantly higher in the TNBS-treated rats compared to the control group and treatment with melatonin significantly decreased the caspase-3 activity. Wang *et al*[41] found that melatonin inhibits hepatic caspase-3 activities and attenuates DNA fragmentation in D-galactosa-

mine-lipopolysaccharid-treated mice. Apoptosis may occur within several hours to several days after injury in some locations, thus, the suppression of cell death is clinically relevant. The role of apoptotic cell death in the inflamed intestine has not been clarified. In UC, the frequency of apoptosis is considerably increased[42] and loss of epithelial cells appears to occur mainly due to apoptosis[43]. Disregulation or inhibition of apoptosis appears to be important in cell proliferation, tissue hyperplasia, and malignant transformation of gastrointestinal epithelia[6]. These findings suggest that epithelial apoptosis may result in an alteration of the epithelial barrier function leading to pathogenic microorganism infiltration. Additonally, apoptosis regulates the lymphocyte population and may inhibit immune response at the inflammatory site[24]. Therefore, it has been proposed that an increased T-cell resistance to apoptosis may contribute to disease progression and mucosal alterations in CD[44]. These results indicate that the protective effects of melatonin against TNBS- induced colitis might be, at least in part, mediated by its anti-apoptotic effects.

In conclusion, melatonin reduces bacterial translocation in TNBS-induced colitis. The anti-inflammatory and anti-apoptotic effects of melatonin can reduce the extent of mucosal damage. Its similar effects in humans remain to be clarified.

COMMENTS

Background

Inflammatory bowel disease (IBD), Crohn's disease and ulcerative colitis have become important health problems in recent years. A growing body of data indicates that oxygen-derived free radicals and nitrogen species have been implicated as mediators of the disruption of the intestinal barrier in IBD, but their molecular targets and pathways have not been defined. It has been shown that the presence of endogenous melatonin in the gastrointestinal tract, and the melatonin's action as a scavenger of free radicals, have been implicated in the ameliorative effect on experimentaly-induced colitis.

Research frontiers

The epithelium of the colon consists of dynamic and rapidly proliferating cells that are profoundly affected by changes in luminal contents and injury. Previous experimental studies have shown that intrarectal instillation of 2, 4, 6-trinitrobenzene sulphonic acid (Sigma, St. Louis, Missouri) mixed with 30% ethanol (TNBS-E) promotes morphologic alterations in the colonic mucosa indicative of atrophy, increases apoptosis, and induces intestinal oxidative stress. Treatment with melatonin can attenuate bacterial translocation and apoptosis as shown in our study by the lower serum levels of tumor necrosis factor-α and endotoxin, the reduced colonic tissue myeloperoxidase and caspas levels.

Innovations and breakthroughs

This study demonstrated that melatonin reduced bacterial translocation in TNBS-induced colitis. The finding supports that exogenous melatonin exerts an anti-inflammatory activity. The mechanism of its anti-inflammatory effect is not entirely clear. In colitis, the frequency of apoptosis is considerably increased and loss of epithelial cells appears to occur mainly due to apoptosis. These results indicate that the protective effects of melatonin on TNBS-induced colitis might be, at least in part, mediated by its anti-apoptotic effects.

Applications

The results of the present study further demonstrate the important role of melatonin in regulating epithelial functions. The marked increase of bacterial translocation in postcolitis rats was reversed by melatonin administration due to its anti-inflammatory and anti-apoptotic effects. Further investigations are required to clarify whether melatonin is an effective and safe therapy for IBDs in human beings.

Terminology

Melatonin, the primary pineal hormone, is also synthesized from tryptophan and secreted in retina, salivary glands, thyroid, liver and intestine, and plays a fundamental role in the neuroimmuno- endocrine system. In the intestine, locally synthesized melatonin is released by enterochromaffin cells. It seems to act as a potent free-radical scavenger rendering it a strong antioxidant.

Peer review

The experiments are rational and reliable, the statistical methods used are appropriate, results show sufficient experimental evidence, and discussion is well organized and valuable.

Abstract

AIM: To investigate the persistence of side population (SP) cells in pancreatic cancer and their role and mechanism in the drug resistance.

METHODS: The presentation of side population cells in pancreatic cancer cell line PANC-1 and its proportion change when cultured with Gemcitabine, was detected by Hoechst 33342 staining and FACS analysis. The expression of ABCB1 and ABCG2 was detected by real-time PCR in either SP cells or non-SP cells.

RESULTS: SP cells do exist in PANC-1, with a median of 3.3% and a range of 2.1-8.7%. After cultured with Gemcitabine for 3 d, the proportion of SP cells increased significantly (3.8% ± 1.9%, 10.7% ± 3.7%, t = 4.616, P = 0.001 < 0.05). ABCB1 and ABCG2 expressed at higher concentrations in SP as compared with non-SP cells (ABCB1: 1.15 ± 0.72, 5.82 ± 1.16, t = 10.839, P = 0.000 < 0.05; ABCG2: 1.16 ± 0.75, 5.48 ± 0.94, t = 11.305, P = 0.000 < 0.05), which may contribute to the efflux of fluorescent staining and drug resistance.

CONCLUSION: SP cells with inherently high resistance to chemotherapeutic agents do exist in pancreatic cancers, which may be candidate cancer stem cells contributing to the relapse of the tumor.

INTRODUCTION

Pancreatic cancer is one of the most aggressive malignancies and it is virtually incurable. Even for the patients who undergo potentially curative resection, the 5-year survival is less than 24% due to local recurrence and metastasis[1,2]. Emerging evidence has shown that cancer stem cells (CSCs), a small subset of cells within a tumor, are responsible for its malignancy[3]. So far, the significance of CSCs in hematological malignancy has been well known[4]. Although the presence and roles of these stem cells in solid tumors are poorly understood, their implication in breast carcinoma[5], brain cancers[6], prostate cancer[7] and lung cancer[8] are clear. As these cells must be eliminated in curative anti-cancer therapy, it is very important to identify and study CSCs.

Side population (SP) analysis could be used to identify CSCs[9]. SP cells can rapidly efflux lipophilic fluorescent dyes to produce a characteristic profile based on fluorescence-activated flow cytometric analysis[10]. Although representing only a small fraction of the whole cell population, they appear to be enriched in stem cells. Thus, they could provide a useful tool and a readily accessible source for cancer stem cell studies[11].

In addition to the application of SP cells in bone marrow obtained from patients with acute myeloid leukemia, which might be candidate leukemic stem cells[12], they have also been identified in various human solid tumors and cancer cell lines. Therefore, we presume that pancreatic cancer might also harbor SP cells, whose intrinsic dye efflux capacity is expected to be associated with the ability to export many cytotoxic drugs, hence increasing the risk of early relapse, and they may be candidate CSCs. We analyzed pancreatic cancer cell line PANC-1 and identified SP cells. The findings suggest that SP cells represent a previously unrecognized population of human pancreatic cancer cells.

Their high drug efflux capacity is related to the strong expression of drug-transporter proteins (including ABCB1 and ABCG2), which may be responsible for the malignancy of pancreatic cancer.

MATERIALS AND METHODS

Materials

Pancreatic cancer cell lines, PANC-1, were obtained from the Cancer Research Institute of the Chinese Academy of Sciences.

Hoechst, verapamil and propidium iodide (PI): Hoechst 33342 (Sigma), verapamil (Sigma) and PI (Sigma) were dissolved in distilled deionized water at 1 g/L, 5 mmol/L, and 1 g/L, respectively. All solutions were filter sterilized. Aliquots were kept frozen at -20℃. Hoechst and verapamil were allowed to thaw at room temperature protected from light before use. Under these conditions, the same aliquot could be re-frozen and re-used multiple times for Hoechst and up to five times for verapamil. PI was also thawed at room temperature and subsequently stored at 4℃.

DMEM+: Dulbecco's modified Eagle's medium (Gibco) containing 2% (v/v) fetal calf serum (Gibco) and 10 mmol/L HEPES (Gibco) can be stored up to 4 wk at 4℃.

HBSS+: Hanks' balanced salt solution (Gibco) containing 2% (v/v) fetal calf serum and 10 mmol/L HEPES can be stored up to 4 wk at 4℃.

PANC-1 medium: DMEM with 10% FBS (Gibco), 100 U/mL penicillin, 100 μg/mL streptomycin was stored at 4℃.

Gemcitabine (Eli Lilly) was dissolved in distilled deionized water at 1 g/L.

Primers of ABCB1, ABCG2 and β-actin were synthesized by Invitrogen Shanghai, China. Sequences of human primers used for real-time PCR experiments are shown in Table 1.

Table 1 Sequences of human primers used for real-time PCR experiments

Target mRNA	Primer sequence (5'-3')	Accession number	Size (bp)
ABCB1	5'AGGTTCCAGGATTGGCGTCTT3'	AF399931	156
	5'CCAGTCATTGCTGCGGTTTCA3'		1152-1307
ABCG2	5'AATACATCAGCGGATACTACAGAG3'	AY333756	179
	5'AGCCACCATCATAAGGGTAAACAT3'		1382-1560
β-actin	5'GAACGGTGAAGGTGACAG3'	NM_001101	293
	5'TAGAGAGAGTGGGGTGG3'		915-1207

Cell culture

The human pancreatic cancer cell line, PANC-1 was cultured as described above, and maintained in a 50 mL/L CO_2 atmosphere at 37℃ in a humidified incubator.

Hoechst 33342 and Pi dual-labeled dyeing

The cells, cultured to logarithmic phase, were prepared to single cell suspension in pre-warmed DMEM+. One g/L Hoechst 33342 was added to a final concentration of 5 mg/L, the cells were then incubated in the 37℃ water bath for exactly 90 min. The cells were centrifuged at 500 × *g*, 4℃ for 5 min and resuspended in 1-3 mL ice-cold HBSS+. Finally, the cells were counterstained with 2 mg/L PI for 5 min. The stained cells were then examined and photographed under an AX70 fluorescence microscope (Olympus, Orangeburg, NY).

Flow cytometry of SP cells

The SP was isolated with the technique described by Goodell *et al*[10]. The cells were cultured to logarithmic phase, then removed from the culture flask with trypsin and EDTA, washed, suspended at 10^6 cells/mL in pre-warmed DMEM+. The cells were then labeled in the same medium at 37℃ for 90 min with 5 mg/L Hoechst 33342 dye, either alone or in combination with 50 μmol/L verapamil (a calcium channel blocker and an inhibitor of some ABC transporters). Finally, the cells were counterstained with 2 mg/L PI to label dead cells.

Then, 3-5 × 10^4 cells were analyzed in a FACSVantage fluorescence- activated cell sorter (Becton Dickinson, Mountain View, CA) using a dual-wavelength analysis (blue, 424-444 nm; red, 675 nm) after excitation with 350 nm UV light. PI-positive dead cells (< 10%) were excluded from the analysis. The SP or non-SP cells were sorted.

Efflux and survival studies for cytotoxic drug gemcitabine

To examine whether increased drug efflux results in a survival advantage, 10^4 PANC-1 cells were cultured with or without Gemcitabine at a concentration of 5 mg/L for 3 d, and the percentage of SP cells was determined subsequently by the method as described above.

Real-time RT PCR

The SP cells or non-SP cells were harvested, RNA was isolated from them separately. Real-time RT-PCR was done to detect the expression of human ABCB1 and ABCG2, β-actin was used as a control. Total RNA was extracted from 10 samples of SP cells or non-SP cells each. In RT reaction process, 4 μL mRNA and 0.5 μL Oligo (dt) were added to 6.5 μL distilled water. After annealing for 5 min at 70℃ and immediate cooling on ice, 4.0 μm of 5 × first strand buffer, 2.0 μL of 10 mmol/L dNTP, 0.5 μL of RNasin and 0.5 μL RTase were added to get a total reaction volume of 20 μL. The reaction was allowed to proceed for 60 min at 37℃, followed by 5 min at 95℃ to inactivate the enzyme. In real-time PCR assay, each cDNA sample was repeated three times. The total PCR volume consisted of 1 μL cDNA, 1 μL SYBRGreen PCR I , 5 μL 10 × buffer, 1.6 μL primers, 7 μL $MgCl_2$, 0.5 μL Taq DNA Polymerase, 1 μL dNTP and 33 μL distilled water. After denaturation of the enzyme for 2 min at 94℃, the PCR assays were carried out for 45 cycles, with denaturation at 94℃ for 30 s, annealing at 57℃ for 30 s and extension at 72℃ for 30 s. Fluorometric PCR was performed with the FTC-2000 System. The level of expression of each transporter protein gene was determined relative to the β-actin gene.

Statistical analysis

All data were expressed as mean ± SD. Student's *t* test was used to determine changes in different groups. $P < 0.05$ was considered statistically significant.

RESULTS

Morphology of SP cells under fluorescence microscope

To observe the morphology of SP cells under fluorescence microscope, we stained PANC-1 with Hoechst 33342 and PI. As SP cells are able to expel fluorescent dye, they were Hoechst 33342 negative, which were colorless, while non-SP cells were Hoechst 33342 positive, which generated blue fluorescence (Figure 1).

Prevalence of SP cells in PANC-1

To determine the prevalence of SP cells in PANC-1, we stained 10 samples with Hoechst 33342 and PI, and analyzed them by flow cytometry. PANC-1 contained SP cells ranged from 2.1% to 8.7% in the total viable cells. The SP population was decreased greatly after treatment with verapamil, indicating that the populations were bona fide SP cells (Figure 2). Thus, pancreatic cancer cell line, PANC-1, contains SP cells, despite being maintained in culture for many years.

Efflux of gemcitabine from PANC-1 SP cells

To examine whether SP cells resist anti-cancer drugs more than non-SP cells do, we tested gemcitabine, which is usually used for the treatment of pancreatic cancer. The bulk cultures of PANC-1 cells were added 5 mg/L gemcitabine. By d 3, the proportion of SP cells increased (10.7% ± 3.7%, $t = 4.616$, $P = 0.001$, < 0.05), indicating the selection of this population (Figure 3).

Gene expression analysis

To investigate the association between SP phenotype and the expression of drug transporter genes, we isolated RNA from sorted SP and non-SP cells of PANC-1 and used a real-time RT-PCR assay to quantify the relative expression of two ABC transporter genes, ABCB1 and ABCG2. They were clearly expressed at higher concentrations in SP compared with non-SP cells (ABCB1: 1.15 ± 0.72, 5.82 ± 1.16, $t = 10.839$, $P = 0.000 < 0.05$; ABCG2: 1.16 ± 0.75, 5.48 ± 0.94, $t = 11.305$, $P = 0.000 < 0.05$) (Figure 4, Table 2).

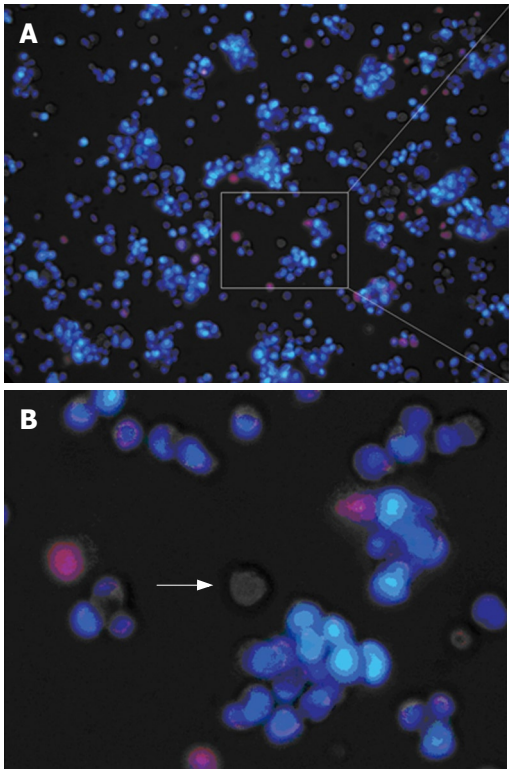

Figure 1 Hoechst 33342 and Pi dual-labeled dyeing.

DISCUSSION

The discovery of CSCs in solid tumors has changed our view of carcinogenesis and chemotherapy. In the cancer stem cell model, only a rare subset of CSCs drives tumor formation, the new therapeutic strategies should account for the potential differences in drug sensitivity or target expression between the tumorigenic cells and the more frequent non-tumorigenic cells. Therefore, to identify CSCs is very important. Up to date, only two general approaches have been adopted to identify and characterize CSCs: (1) Molecular markers, i.e. $CD44^+/CD24^-$ for breast CSCs[13], $CD44^+/alpha2\ beta1^{hi}/CD133^+$ for prostate CSCs[7], and $CD34^+/CD38^-$ for leukemia stem cells[14]; (2) SP isolated from tumors which has been proven to be an alternative to study CSCs, for they are enriched in CSC. For example, Chiba *et al*[15] found that SP cells in hepatocellular carcinoma cells possessed extreme tumorigenic potential and provided heterogeneity to the cancer stem cell system characterized by distinct hierarchy. As specific cell surface markers are largely unknown, SP analysis becomes a more useful tool for stem cell studies. In addition, malignant SP cells' intrinsic ability to expel anticancer drugs may directly improve their survival and sustain their clonogenicity during exposure to anticancer drugs, allowing disease recurrence when the therapy is withdrawn[16]. Identification of this tumor progenitor population might provide clues for improved therapeutic intervention.

Recently, SP cells have also been identified in various tumors and cancer cell lines, e.g. acute myeloid leukemia[12], neuroblastoma[17], melanoma[18], ovarian cancer[19], the C6 glioma cell line[20], human retinoblastoma cell line[21], human neuroblastoma cell lines[17], and various human gastrointestinal cancer cell lines[22]. However, no SP has been described in cell lines derived from Wilms' tumor, rhabdomyosarcoma or osteosarcoma[17]. To investigate the prevalence of SP cells in human pancreatic cancers, we stained PANC-1 with Hoechst 33342 dye and identified the SP based on its characteristic fluorescent profile in dual-wavelength analysis, as described above. PANC-1 contained SP cells ranging from 2.1% to 8.7% (median 3.3%) of the total viable cells.

Our study of the SP covers one of the most interesting areas in cancer biology, regarding carcinogenesis and drug resistance in the cancer therapy. Our findings suggest that SP cells in PANC-1 have an enhanced efflux capacity not only for Hoechst 33342 dyes but also for anti-neoplastic drugs. After 72 h exposure to Gemcitabine, the viability of the SP cells became markedly higher than that of the non-SP cells. It is the drug efflux capacity of SP cells that affords them a survival advantage. These indicate that SP cells play an important role in maintaining cancer foci,

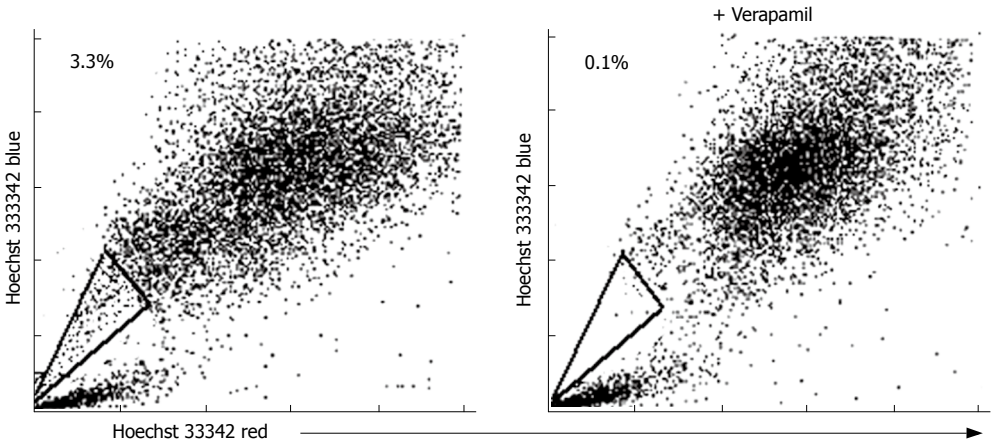

Figure 2 Existence of SP cells in PANC-1.

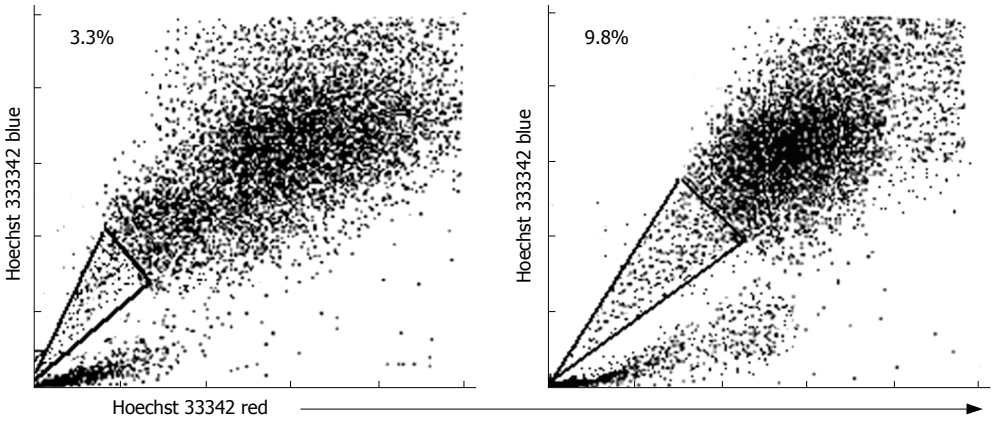

Figure 3 SP cells show a high resistance to anti-cancer-drugs.

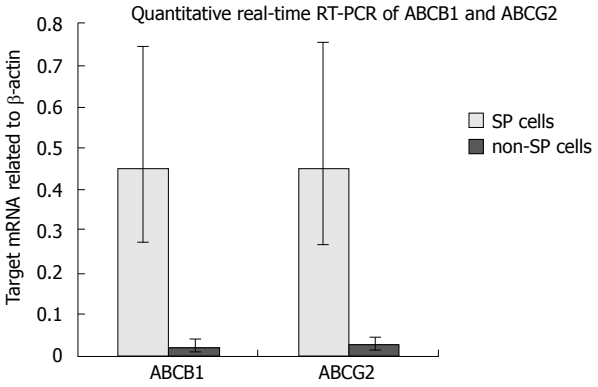

Figure 4 Relative expression of ABC transporter genes in PANC-1 SP and non-SP cells.

Table 2 Relative quantitation of mRNA using the $2^{-\Delta\Delta CT}$ method

	Target mRNA	ΔCT (Target mRNA-β-actin)	Target mRNA related to β-actin
non-SP cells	ABCB1	5.82 ± 1.16	0.0176 (0.0079-0.0393)
	ABCG2	5.48 ± 0.94	0.0224 (0.0116-0.0432)
SP cells	ABCB1	1.15 ± 0.72	0.4504 (0.2731-0.7431)
	ABCG2	1.16 ± 0.75	0.4483 (0.2662-0.7547)

which survive and proliferate after chemotherapy using their self-renewal and chemo-resistance capacities. They may be candidate pancreatic CSCs contributing to the relapse of the tumor.

The molecular mechanisms remain unclear that SP cells have intrinsic ability to expel dye and anticancer drugs. Goodell *et al*[10] demonstrated that multidrug resistance transporter 1 (MDR1), a member of ATP-binding cassette (ABC) transporter transmembrane proteins, may be involved in the efflux capacity of SP cells. But it cannot be taken as the single marker to identify and isolate SP cells, additional transporters should be analyzed. Zhou *et al*[23] demonstrated that ABCG2 has been shown to contribute to Hoechst 33342 efflux and produce an SP phenotype in a wild variety of tissues. Since SP is defined by ABC transporter activity, the expression of these transporters has been analyzed in various malignancies. For example, SP cells in a mouse glioma cell line and human neuroblastoma express high levels of ABCG2 and ABCA3[17], SP cells in hepatoma cell line, HuH7, express high levels of ABCG2 and ABCB1[22]. We also analyzed the expression of the ABC transporters in PANC-1, and found SP cells expressed higher levels of ABCB1 and ABCG2 than the non-SP cells. Therefore, ABCB1 and ABCG2 responsible for SP phenotype in pancreatic cancer could be speculated. However, some scholars proposed SP phenotype is not related to the presence of many "conventional" ABC transporter proteins such as MDR1, since MDR-1 knockout mice have normal numbers of SP cells[24]. So the

SP cells' intrinsic expel ability should be further studied.

As ABC transporters responsible for SP phenotype are implicated in drugs resistance and lower responses to cancer therapy[25,26], targeting the SP may offer an alternative option to improve drug resistance. Since ABC transporters are expressed in both normal and cancerous cells[27,28], they cannot be used to selectively target cancer cells unless specific strategies are applied. However, a whole genome DNA microarray analysis among normal SP cells, normal non-SP cells tumor SP cells and tumor non-SP cells, may be useful to identify potential candidates for specific CSCs markers, or even to define a CSCs pattern. The fact that CSCs specific surface markers are discovered, may permit isolation of this important population of cells, and revolutionize the cancer therapy and science[29,30].

COMMENTS

Background

Pancreatic cancer is one of the most aggressive malignancies and it is virtually incurable. Over the past two decades, major advances in the understanding of this cancer have shifted to only increment of survival for the patients. Recent data suggested that cancers arising from rare stem cells are biologically distinct from their more numerous differentiated progeny, which may explain this paradox.

Research frontiers

This study focuses on the persistence of side population cells in pancreatic cancer and their role and mechanism in the drug resistance.

Innovation and breakthroughs

The difference from other related or similar studies is that, it is a new point of view to study drug resistance in pancreatic cancer.

Application

Identification of side population cells in pancreatic cancer might provide clues for improved therapeutic intervention. New drug development in pancreatic cancer should focus on this tumor progenitor population.

Terminology

Side population (SP) cells are cells which can rapidly efflux lipophilic fluorescent dyes to produce a characteristic profile based on fluorescence-activated flow cytometric analysis. Although representing only a small fraction of the whole cell population, they appear to be enriched in stem cells.

Peer review

This report demonstrates that SP cells with inherently high resistance to chemotherapeutic agents exist in pancreatic cancer and may be candidate cancer stem cells contributing to the relapse of the tumor.

Abstract

AIM: To assess whether psychological intervention reduces postembolization pain during hepatic arterial chemoembolization therapy.

METHODS: Two hundred and sixty-two patients, who required hepatic arterial chemoembolization for hepatic malignancy and postembolization pain, were randomized into control group (n = 46, receiving medication) and intervention group (n = 216, receiving psychological intervention and medication in turn). The symptom checklist-90 (SCL-90) was used to scale the psychological symptoms of the patients before operation. Pain was scored with a 0 to 10 numeric rating scale (NRS-10) before and after analgesia as well as after psychological intervention (only in intervention group).

RESULTS: All psychological symptomatic scores measured with SCL-90 in the intervention group were higher than the normal range in Chinese ($P < 0.05$). The somatization, phobia and anxiety symptomatic scores were associated with pain numerical rating score before analgesia (r = 0.141, 0.157 and 0.192, respectively, $P < 0.05$). Patients in both groups experienced pain relief after medication, psychotherapy or psychotherapy combined with medication during the procedure ($P < 0.01$). Only some patients in the intervention group reported partial or entire pain relief (29.17% and 2.31%) after psychological intervention. The pain score after analgesia in the intervention group was significantly lower than that in the control group ($P < 0.01$).

CONCLUSION: Severe psychological distress occurs in patients with hepatic malignancy. Psychological intervention reduces pain scores significantly during hepatic arterial chemoembolization therapy and is thus, highly recommended as a complementary approach to drug analgesia.

INTRODUCTION

Hepatic carcinoma is one of the most common malignant visceral tumors in adults worldwide. Surgical resection remains the major treatment for hepatocellular carcinoma (HCC). However, only 8%-15% of patients meet the criteria for surgical resection[1-3] and the long-term results after resection are still unsatisfactory[4]. The liver is also the most frequent site of metastatic disease from extrahepatic primary tumors[5]. Resection of metastases can prolong the survival time of a small percentage of selected patients[6]. Transarterial chemoembolization (TACE), as a palliative therapy, is recommended for the treatment of unresectable hepatic neoplasms (primary and metastatic)[7,8]. The current routine technique of TACE is to inject iodized oil mixed with a single or a combination of chemotherapeutic agents into the neo-vasculature of hepatic neoplasms. The therapeutic goal is ischemic and cytotoxic insults to the tumor by occluding the feeding and collateral arteries of tumors. Right upper quadrant pain appears to be the most common complaint, followed by fidget, anxiety and noncompliance. Analgesia induced by drugs, such as intraarterial lidocaine and intravenous narcotic

analgesics, is required to alleviate the pain[9,10]. However, these medications have side effects and a few patients are not sensitive to sedative and analgesic medications. It is, therefore, necessary to develop non-pharmacologic approaches to improving the patient experience with painful procedures.

Non-pharmacologic practices, such as guided imagery, music therapy, hypnosis, and distraction, can effectively improve patient experiences during painful medical procedures, such as endoscopy[11]. There are few studies analyzing the effect of psychological intervention on pain suffered by hepatic cancer patients undergoing hepatic arterial chemoembolization therapy.

The aim of this investigation was to assess whether psychological intervention reduces postembolization pain during hepatic arterial chemoembolization therapy.

MATERIALS AND METHODS

Subjects

Between April 2002 and March 2006, 262 patients requiring hepatic arterial chemoembolization for hepatic malignancy (primary or metastatic) and postembolization pain agreed to participate in the study. The group comprised 186 men and 76 women with their age ranged from 13 to 76 years (mean age, 51.96 years). The diagnosis of hepatic tumor was confirmed by pathologic and histologic examination or elevated serum tumor markers. Patient exclusion criteria were as follows: (1) history of interventional diagnosis and/or therapy, (2) bellyache before embolization, (3) treatment with anxiolytic or narcotic analgesics 72 h prior to the therapy, (4) presence of encephalopathy or other significant alterations of mental status or cognitive impairment or visual and auditory deficits, (5) considerable cardiopulmonary morbidity.

Methods

Patients were randomized into control group (n = 46, receiving medication) and intervention group (n = 216, receiving psychological intervention and medication in turn). Their baseline characteristics, including demographic information (i.e., age and gender) and tumor type, were collected from the medical records.

The Chinese version of symptom checklist-90 (SCL-90), a psychiatric self-report inventory, was used to scale the psychological symptoms of the patients before operation. All patients were guided to answer 90 items with the uniform advices, and the 90 items in the questionnaire were scored on a five-point scale to reflect the psychological symptom patterns of patients. The items referred to the assessment of index for somatization dimensions, obsessive-compulsive tendencies, depression, anxiety, phobia, interpersonal sensitivity, hostility, paranoid ideations and psychotic states.

During the procedure, patients in the control group received medication when they experienced pain, whereas psychological intervention and drug analgesia were performed in turn on patients who were assigned to the intervention group for the postembolization pain. Patients in the control group and those with painful experience after psychotherapy in the intervention group received medications according to the digital subtraction angiograms and symptoms, e.g. antispasmodics for arterial spasm, narcotic analgesics for pain without characteristic signs and symptoms. The doses of medications were determined by the operator who performing the procedure according to the condition of patients. Psychological intervention was performed by two registered nurses with 7- and 10-year professional experience, respectively. Psychotherapy included encouragement, verbal suggestion, relaxation training, distraction with verbal communication on interest of the patients, therapeutic touch on face of the patients, guided imagery and intra-arterial placebo (0.5 mL of 0.9% sodium chloride injection). The pain was scored using a 0 to 10 numeric rating scale (NRS-10)[12] (0 = "no pain at all", 1-3 = "mild pain", 4-6 = "moderate pain", 7-9 = "severe pain", 10 = "unbearable pain") before and after analgesia, as well as after psychological intervention (only in intervention group).

Table 1 Baseline characteristics of patients

Characteristics	Control group (n = 46)	Intervention group (n = 216)	Significance	
Age (yr)	54.11 ± 10.85	51.50 ± 11.54	t = 1.41	P = 0.16
Gender				
Male	37	149		
Female	9	67	χ^2 = 2.42	P = 0.12
Tumor type				
Primary	27	135		
Metastatic	19	81	χ^2 = 0.23	P = 0.63

P > 0.05 for each comparison.

Statistical analysis

The data were analyzed with the Statistical Package for Social Sciences (SPSS 11.0 for Windows). The measurement data were expressed as mean ± SD and the enumeration data as proportions. Statistical tests used in bivariate analysis included χ^2 test and Student t test. The relationship between mental status and postembolization pain was evaluated with the Pearson correlation coefficient. $P < 0.05$ was considered statistically significant.

RESULTS

There were slight differences in baseline characteristics between the control and intervention groups and none of these differences was statistically significant (Table 1). No significant difference was found in psychological symptoms before the procedure between the two groups (Table 2). The psychological symptom scores in the intervention group were higher than the normal range in Chinese and the differences were statistically significant ($P < 0.05$) (Table 3).

Pearson correlation coefficients showed that the somatization dimensions and phobia were positively correlated with pain numerical rating score before analgesia in intervention group ($P < 0.05$). In addition, the anxiety level was also positively correlated with the pain numerical rating score before analgesia ($P < 0.01$) (Table 4).

Table 2 Psychological symptoms of patients measured with SCL-90 before the procedure (mean ± SD)

Psychological symptoms	Control group (n = 46)	Intervention group (n = 216)	Significance	
			t (or t')	P value
Somatization	1.55 ± 0.46	1.58 ± 0.44	0.42	0.68
Obsessive-compulsive tendencies	1.53 ±0.67	1.68 ± 0.61	1.49	0.14
Sensitivity	1.65 ± 0.57	1.58 ± 0.55	0.78	0.44
Depression	1.72 ± 0.50	1.64 ± 0.48	1.02	0.31
Anxiety	1.47 ± 0.40	1.51 ± 0.39	0.63	0.53
Hostility	1.41 ± 0.57	1.50 ± 0.60	0.93	0.35
Phobia	1.46 ± 0.38	1.40 ± 0.33	1.09	0.28
Paranoia	1.50 ± 0.49	1.42 ± 0.48	1.02	0.31
Psychosis	1.46 ± 0.30	1.41 ± 0.37	0.98	0.33

P > 0.05 for each comparison.

Table 3 Differences in psychological symptoms measured with SCL-90 in patients of intervention group and normal Chinese (mean ± SD) (Jin H *et al*, 1986)

Psychological symptoms	Intervention group (n = 216)	Norm (n = 7273)	Significance	
			t (or t')	P value
Somatization	1.58 ± 0.44	1.40 ± 0.40	5.94	< 0.01
Obsessive-compulsive tendencies	1.68 ± 0.61	1.49 ± 0.54	4.53	< 0.01
Sensitivity	1.58 ± 0.55	1.45 ± 0.52	3.61	< 0.01
Depression	1.64 ± 0.48	1.42 ± 0.49	6.51	< 0.01
Anxiety	1.51 ± 0.39	1.31 ± 0.42	6.91	< 0.01
Hostility	1.50 ± 0.60	1.37 ± 0.50	3.15	< 0.01
Phobia	1.40 ± 0.33	1.25 ± 0.40	6.54	< 0.01
Paranoia	1.42 ± 0.48	1.35 ± 0.49	2.07	< 0.05
Psychosis	1.41 ± 0.37	1.22 ± 0.37	7.44	< 0.01

Patients in both groups experienced pain relief after medication, psychotherapy or combined analgesia during the procedure. The pain scores after analgesic therapy were lower than those before analgesic therapy and the differences were statistically significant (P < 0.01) (Table 5).

Only some patients in the intervention group reported partial or entire pain relief (29.17% and 2.31%, respectively) after psychological intervention (Table 6).

The pain numerical rating scores for the control and intervention groups before analgesia showed no statistical difference, whereas the pain score after analgesia for the intervention group (psychological intervention and medication) was significantly lower than that for the control group (medication) (P < 0.01), indicating that the pain control was better in the intervention group than in the control group during the embolization procedure (Table 7).

Table 4 Correlation between psychological symptom scores (SCL-90) and pain numeric rating scores (NRS-10) before analgesia in intervention group (n = 216)

Psychological symptoms	Numerical rating score	
	Correlation coefficient (r)	P value
Somatization	0.141	< 0.05
Obsessive-compulsive tendencies	0.106	> 0.05
Sensitivity	0.097	> 0.05
Depression	0.031	> 0.05
Anxiety	0.192	< 0.01
Hostility	0.083	> 0.05
Phobia	0.157	< 0.05
Paranoia	0.124	> 0.05
Psychosis	0.08	> 0.05

DISCUSSION

TACE is an accepted palliative treatment modality for patients with primary HCC or hepatic metastases. If the tumor is unresectable, the patient is a poor surgical candidate. The clinical yield and survival rate in patients undergoing TACE have been proved[7,8,13]. More studies on TACE or combined methods, such as TACE combined with radiofrequency ablation, radiotherapy or percutaneous ethanol injection, have been reported recently[14-17]. In patients undergoing TACE, postembolization pain appears to be the most common complaint[2]. The pain usually occurs after embolization and peaks within 12-24 h. A large dose of opioid analgesics is often required in most patients when the pain is too severe to endure[2].

The etiology of pain after TACE is not well understood, but several theories have been postulated, including distention of the liver capsule, tumor necrosis, acute

ischemia of the liver parenchyma, and gallbladder ischemia secondary to inadvertent embolization of the cystic artery[2,18]. Infusion of iodized oil mixed with chemotherapeutic agents, in particular, results in acute, sharp right hypo-chondrium pain, followed by a deeper visceral pain, most likely due to swelling of the liver and stretching of the capsule that contains the nerve fibers[2]. It is believed that administration of narcotic analgesics can effectively control the pain during the procedure[9,10,19]. In our study, forty-six patients in the control group experienced a significant decrease in abdominal pain after drug analgesia ($P < 0.01$). However, the pain of most patients was not completely relieved after medication therapy.

In addition to physical suffering, psychiatric syndrome is increasingly recognized as a major component of distress in cancer patients[20-26]. Several factors, including the grief about current and anticipated losses, fear of death, concerns about loved ones and the effect of certain chemotherapeutic drugs on mood, *etc*[20-23], contribute to psychological distress[24]. Minagawa *et al*[27] and Godding *et al*[28] showed that about 30%-60% cancer patients have psychiatric disorders. Our study demonstrated that the SCL-90 factor scores for the intervention group were higher than those for the normal ($P < 0.05$), indicating that the psychological status is abnormal in patients with severe psychiatric disorders and hepatic carcinoma.

Psychological distress can result in systemic responses. Rorarius *et al*[29] performed a case-control study to evaluate the stress response and the sensitivity of clinical and biochemical stress markers in patients undergoing laparoscopically assisted vaginal or abdominal hysterectomy and showed that the most sensitive symptoms and markers of the systemic response are pain scores. Passik *et al*[25] surveyed 1109 cancer patients treated by 12 oncologists with Zung Self-Rating Depression Scale (ZSDS) and numerical rating scale, and found that the untreated psychological distress in cancer patients is associated with amplified pain. In our study, somatization, phobia and anxiety symptoms measured with SCL-90 were correlated with the postembolization pain ($P < 0.05$), which is consistent with the reported data[25].

Pariser *et al*[30] examined the effects of a telephone intervention in adults with arthritis and suggested that minimal intervention may produce positive changes in arthritis self-efficacy (ASE), depression, and pain in some adults. Other psychotherapies, e.g. hypnotic suggestion, relaxation training[31], distraction therapy[32], therapeutic touch[33,34], and imagery[35,36], are used in the treatment of disease-related pain. Our results reveal that psychological intervention decreased the pain score significantly ($P < 0.01$). However, only five patients (2.31%) reported entire pain control and most (68.52%) patients showed a slightly alleviated pain. Drug analgesia was still required by most patients in the intervention group during the procedure.

Several studies reported that psychological intervention during an invasive procedure, e.g. listening to music during endoscopy, could improve tolerance and compliance[37], alleviate pain[32] and decrease the dose of sedative drugs[38,39]. In our study, pain was well controlled after psychotherapy combined with medication, demonstrating that the pain control is better in the intervention group than in the control group ($P < 0.01$). The satisfaction of patients was increased accordingly.

In conclusion, patients with hepatic malignancy have severe psychological distress and psychological symptoms (i.e., somatization, phobia and anxiety) associated with the postembolization pain. Psychological intervention reduces pain scores significantly during hepatic arterial chemoembolization therapy and is highly recommended as a complementary approach to drug analgesia.

COMMENTS

Background

Postembolization pain is the most common complaint of patients during and after transarterial chemoembolization (TACE) for unresectable hepatic neoplasms. Drug analgesia is often required to decrease pain. However, these medications have side effects and a few patients are not sensitive to sedative and analgesic medications.

Research frontiers

Non-pharmacologic practices, such as guided imagery, music therapy, hypnosis, and distraction, can effectively improve patient experiences during painful medical procedures, such as endoscopy.

Innovations and breakthroughs

Psychological intervention can reduce pain significantly during hepatic arterial chemoembolization therapy.

Applications

Psychological intervention should be considered during hepatic arterial chemoembolization therapy.

Peer review

This is an interesting report on a complementary approach to drug analgesia during TAE for hepatic carcinoma.

Received: June 15, 2007 Revised: December 5, 2007

Abstract

AIM: To evaluate the feasibility and safety of No. 13 lymphadenectomy in radical gastrectomy for gastric carcinoma.

METHODS: Medical records of the patients undergone No. 13 lymph node dissection during D2 gastrectomy for gastric carcinoma, were reviewed from March 2003 to May 2007.

RESULTS: One hundred and fifty-eight patients underwent No. 13 lymph node dissection for D2 gastric carcinoma, of them, 4 (2.53%) were found to have metastasis in No. 13 lymph node. Metastasis to No. 12 lymph node was detected in 6 patients and 4 of them had positive No. 13 lymph node. The operative morbidity except for wound infection was 15.19% (24/158), and hospital death rate was 1.27% (2/158). No obstructive jaundice caused by No. 13 lymph node metastasis after No. 13 lymph node dissection in radical gastrectomy for gastric carcinoma was detected during the follow-up study to end of January 2007.

CONCLUSION: Dissection of No. 13 lymph node in D2 gastrectomy for gastric carcinoma is safe with a low morbidity and mortality rate. Further study is needed to explore its long-term effect.

INTRODUCTION

Although gastric carcinoma tends to decline in its incidence, it still remains the most common cancer and the leading cause for cancer-related death in China[1-3]. D2 gastrectomy has been increasingly employed to treat patients with gastric carcinoma since 1990s in China[4,5]. In some medical centers, dissection of No. 12 lymph node has been performed in combination D2 gastrectomy for several years[5-7].

Regional recurrence and distant metastasis are the main causes for death of patients with gastric carcinoma after operation[8-10]. Metastasis from gastric carcinoma to retropancreatic nodes following radical gastrectomy can result in obstructive jaundice. We assume that we could prevent obstructive jaundice resulting from No. 13 lymph node metastasis if we dissect No. 13 lymph node in D2 gastrectomy for patients with gastric carcinoma. Therefore, the present study was to evaluate the results and feasibility of No. 13 lymphadenectomy in radical gastrectomy for gastric carcinoma.

MATERALS AND METHODS

One hundred and fifty-eight patients (75 males, 83 females, average age of 67 years, range 38-75 years) with gastric carcinoma, who underwent D13 lymph node dissection in combination with D2 lymphadenectomy from March 2003 to May 2007, were enrolled in this study. Tumor TNM staging was performed, showing stage I in 20 patients, stage Ⅱ in 71 patients, and stage Ⅲ in 67 patients. No. 13 lymphadenectomy was performed for tumors located in the lower third of the stomach. Coronary artery disease, chronic obstructive pulmonary disease, immunodeficiency disease, liver cirrhosis, and diabetes, and those at the age of over 75 years were excluded from the patients who were going to receive No. 13 lymph node dissection. Signs of distal lymph

Table 1 Complications of operation

	No of complication	No of death
Injury to CBD	3	1
Injury to spleen	4	0
Injury to portal vein	1	0
Injury to splenic vein	1	0
Injury to IVC	1	0
Pancreatic fistula	1	0
Duodenal fistula	1	0
Gastrojejunostomy fistula	3	0
Pulmonary infection	9	1

CBD: Common bile duct; IVC: Inferior vena cava.

node, liver, lung, and peritoneal metastasis were found both at pre-operation and at intra-operation.

D2 lymph node dissection was performed, followed by No. 13 lymph node dissection. The No. 13 lymph node dissection procedure consisted of incision of the lateral peritoneal attachment to duodenum, sharp dissection of duodenum and head of the pancreas from the inferior vena cava (IVC), exposure of posterior aspect of the pancreas. Subsequently 1-4 lymph nodes were removed. Reconstruction of digestive continuity was performed in a fashion of Billroth-Ⅱ. Complications were recorded prospectively. Hospital death was defined as within 30 d after surgery or during hospital stay longer than 30 d. The patients were followed up by regular clinic examination and telephone.

RESULTS

Among the 158 patients who underwent No. 13 lymph node dissection and D2 gastric carcinoma removal, 4 were positive for No. 13 lymph node with a positive rate of 2.53% (4/158). The metastasis to No. 12 lymph node was detected in 6 patients and 4 of them were positive for No. 13 lymph node. Injury to the spleen occurred in 4 patients and two of them underwent splenectomy during gastrectomy because of uncontrollable hemorrhage. Injury to the common bile duct was found in 3 patients and treated with placement of a T tube and choledochojejunostomy. Of these three patients, one developed peritonitis. The three patients had massive bleeding due to the injury to portal vein, splenic vein and inferior vena cava, respectively. Homeostasis was achieved with the stitch suture. After operation, one patient had pancreatic fistula, 3 patients had enteral fistula and two of them were managed conservatively. Nine patients had pulmonary infection and one of them developed acute respiratory distress syndrome (ARDS) and died finally. The overall operative morbidity was 13.92% (22/158) except for wound infection. The hospital death rate was 1.27% (2/158) (Table 1).

During the follow-up, no obstructive jaundice was found in patients undergoing radical gastrectomy with No. 13 lymph node dissected.

DISCUSSION

Surgical resection is the only curative treatment modality available for gastric carcinoma and radical lymph node dissection is an important part of curative resection[5,11]. Theoretically, removal of lymph nodes by extended lymph node dissection increases the chance for cure. However, the extent of nodal dissection is also a significant risk factor for complications and death[12,13]. It is generally accepted that D2 dissection is the standard procedure for patients who undergo surgery with curative intend, although there is a disagreement about the optimal extent of lymph node dissection.

The D2 gastrectomy procedure is known as "extended lymphadenectomy" in Western countries, while Japanese surgeons employ D2 as a standard technique, and use the term "extended" for para-aortic dissection[6,14-17]. The mortality of D2 gastrectomy is around 5% in Western countries, whereas it is less than 2% in Japan, and less than 1% in specialized institutions [15, 17-19]. Therefore, specialized surgeons can safely perform gastrectomy in combination with D2 lymphadenectomy for gastric carcinoma with a relatively low operative risk. Furthermore, some surgeons have performed D3 lymphadenectomy at gastrectomy for gastric carcinoma, which can remove all lymph nodes located in compartment 3[13,20]. Although complications of D3 lymphadenectomy are in an accepted range, the morbidity and mortality rates for D3 lymphadenectomy are significantly higher than those for D2 lymphadenectomy.

D2 dissection in gastrectomy, defined by the Japanese Research Society for Gastric Cancer, has been performed for gastric carcinoma since 1990s in China[4,6]. No. 13 lymph node dissection in gastrectomy for carcinoma is based on the follow-up studies showing metastasis of gastric carcinoma to No. 13 lymph node[4,6]. This is the reason why we performed No. 13 lymph node dissection for gastric carcinoma. In our series, complications (except for wound infection) occurred in 24 patients (15.19%) and the mortality rate was 1.27%, which is comparable to the reported data[15,17]. In our study, injury to the inferior vena cava was the only procedure-related complication and only one patient suffering from this kind of complications could be managed with the stitch suture, suggesting that extending the surgery to lymph nodes posterior to the pancreas does not increase hospital deaths.

Patients with co-morbid diseases are not fitted for surgery, such as those suffering from liver cirrhosis and ischemic heart diseases, two important risk factors for mortality[21,22]. Interestingly, studies from UK and Holland showed that splenectomy with or without distal pancreatectomy are highlighted as a major risk factor for operative morbidity and mortality[23,24]. The relatively low morbidity and mortality in our study may be due to the following factors: patients selected with good tolerance to the extending D2 lymphadenectomy, skillful/experienced surgeons performing the surgery[25], no need for splenectomy or pancreatectomy, and rational postoperative management.

In conclusion, No. 13 lymph node dissection in combination with D2 lymph node dissection in radical gastrectomy for gastric cancer can be performed with a low morbidity and mortality rate. Further study is needed to explore its long-term effect.

COMMENTS

Background

Gastric carcinoma is the most common cancer and the leading cause for cancer-related death in China. Up to now, operation is still the first choice of treatment. However, what is the appropriate extent of radical gastrectomy remains controversial.

Research frontiers

Most surgeons believe that D2 gastrectomy is the best procedure for most patients. However, metastasis of No. 13 lymph node has been found in patients with obstructive jaundice after gastrectomy. We studied the feasibility of No 13 lymphadenectomy in radical gastrectomy for gastric carcinoma and found that No. 13 lymph node dissection in combination with D2 lymph node dissection in radical gastrectomy for gastric cancer could be performed with a low morbidity and mortality rate.

Innovations and breakthroughs

In our study, No. 13 lymphadenectomy was safe and effective, showing that No13 lymphadenectomy in radical gastrectomy is feasible.

Applications

According to our study, it is safe and effective to perform No. 13 lymphadectomy in radical gastrectomy, which can prevent obstructive jaundice due to No. 13 lymph node metastasis.

Terminology

No. 13 lymphadenectomy means that dissecting lymph nodes around the head of pancreas during radical gastrectomy.

Peer review

This is a valuable record of a large series of extended gastrectomies for gastric cancer and, with amendments, worthy of consideration for publication.

Abstract

Despite the increased incidence of tuberculosis related to human immunodeficiency virus (HIV) in recent decades, pancreatic tuberculosis has rarely been described. We report a case of pancreatic tuberculosis in a 39-year-old African man who presented with progressive dysphagia, vomiting, weight loss and productive cough, accompanied by localized epigastric pain and one episode of melena. HIV-1 testing was positive and lymphocyte subset profile showed CD_4 count of 9/mm^3. Abdominal computed tomography (CT) scan with contrast revealed a cystic mass in the body of the pancreas, significant portal and retroperitoneal cystic adenopathy, and multiple cystic lesions in the spleen and liver. CT guided cyst aspiration and node biopsy detected Mycobacterium tuberculosis. The patient responded well on antituberculosis and antiretroviral therapy. Tuberculosis rarely involves the pancreas, probably due to the presence of pancreatic enzymes which interfere with the seeding of Mycobacterium tuberculosis. Pancreatic tuberculosis is considered to be the result of dissemination of the infection from nearby lymphatic nodes. Endoscopic ultrasound or CT guided fine needle aspiration for cytology is the recommended diagnostic technique. Although the prognosis is good with anti-tuberculosis treatment, it could be fatal without correct diagnosis and treatment. The clinician's high index of suspicion of pancreatic tuberculosis and application of FNAB to obtain pathological evidence are extremely important to a correct diagnosis, especially in young HIV positive patients.

INTRODUCTION

Subsequent to the AIDS epidemic, the incidence of tuberculosis has slowly increased in developed countries[1]. However, pancreatic tuberculosis is rarely described in the literature. We report a case of pancreatic tuberculosis with abdominal dissemination which presented with progressive dysphagia, weight loss and epigastric pain.

CASE REPORT

A 39-year-old African man presented with a six months progressive dysphagia, vomiting and 30 lb weight loss, productive cough for three weeks, accompanied by localized epigastric pain and one episode of melena. He had a history of positive PPD 4 years earlier with normal chest radiograph and had not received isoniazid prophylaxis. Physical examination revealed a 101 F temperature, marked pallor, sinus tachycardia, epigastric and right upper quadrant tenderness. Investigations showed a WBC count of 1.7×10^3/mm^3 (normal range, 4.8-10.8 $\times 10^3$/mm^3), anemia with hemoglobin at 5.1 g/dL (normal range, 14.0-18.0 g/dL), amylase 148 U/L (normal range, 30-110 U/L), lipase 29 U/L (normale range, 4-66 U/L) and LDH 551 U/L (normal range, 102-190 U/L). Chest radiograph, liver and renal function were normal. HIV-1 test was positive and lymphocyte subset profile showed CD_4 count of 9/mm^3. A barium swallow showed a normal esophagus. Abdominal ultrasound revealed a cystic pancreatic mass, lymph node enlargement and cholelithiasis. The blood, urine and sputum culture were negative. Abdominal computed tomography (CT) scan with contrast revealed a cystic mass in the body of the pancreas with significant portal and retroperitoneal adenopathy and multiple cystic lesions in the spleen and liver (Figure 1). CT guided cyst aspiration and node biopsy detected inflammatory cells, necrotic tissue and many AFB bacilli. PCR testing was positive for Mycobacterium tuberculosis. The patient clinically improved on antituberculosis medications: ethambutol, isoniazid,

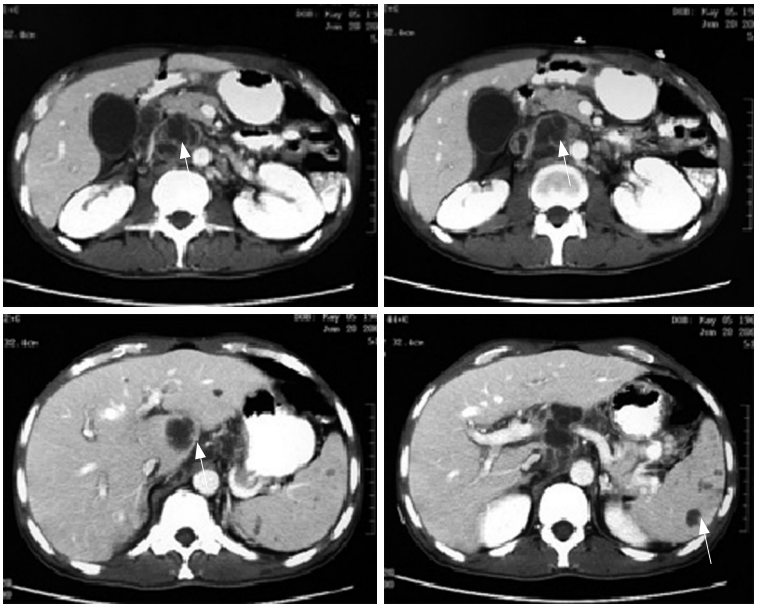

Figure 1 Abdominal CT with contrast showed cystic mass in the region of the body of pancreas and cystic lesions in the spleen and liver.

vitamin B6, pyrazinamide, rifampin and moxifloxacin. Five months later, a repeat ultrasound revealed resolution of the pancreatic cyst and adenopathy.

DISCUSSION

Tuberculosis uncommonly involves the pancreas, which is thought to be biologically protected from the infection of Mycobacterium tuberculosis. Probably, this is because the presence of pancreatic enzymes which interfere with the seeding of Mycobacterium tuberculosis[2]. Pancreatic tuberculosis is considered the result of the dissemination of the infection from near lymphatic nodes. A wide spectrum of symptoms has been reported. It ranges from abdominal pain, constitutional symptoms to such as weight loss, night sweat and anorexia, fever, obstructive jaundice[3,4], to massive gastro-intestinal bleeding[5] and iron deficiency anemia, pancreatic abscess[6]. In addition, acute pancreatitis[7], secondary diabetes[8] and chronic pancreatitis[9] have been also reported. Similar to the present case, the pancreatic cystic mass can mimic pancreatic cystic neoplasm[10,11]. Abdominal tuberculosis is independent of pulmonary disease in most patients, with the reported incidence of coexisting disease varying from 5% to 38%. Endoscopic ultrasound or computed tomography-guided fine-needle aspiration biopsy (FNAB) is recommended for diagnosis[12]. The prognosis is good with anti-tuberculosis treatment. However, it could be fatal without correct diagnosis and treatment[13]. Wide spectrum of symptoms and occurrence in the absence of chest disease make it difficult to diagnose. The clinician's high index of suspicion of pancreatic tuberculosis and application of FNAB to obtain pathological evidence are extremely important to a correct diagnosis, especially in young HIV positive patients.

Abstract

Congenital bile duct dilatation (CBD) that developed in a parent and son is presented. Familial occurrence of CBD is rare, with only a few male cases having been reported. Since the initial report of CBD occurring in siblings in 1981, a total of 20 cases (10 pairs) have been published as of 2007. Clinical and genetic features of CBD are discussed.

INTRODUCTION

Choledochal cyst is a rare congenital dilatation of the extrahepatic and/or intrahepatic biliary tract. Some possibilities have been postulated regarding inheritance of congenital bile duct dilatation (CBD), since several familial CBD cases have been reported. However, the etiology of CBD is essentially unknown. In this report, a case of familial occurrence of CBD is presented along with a review of the literature.

CASE REPORT

Case 1 was a 65-year-old woman, the mother of case 2, who was admitted to Matsusaka City Hospital, Japan, complaining of back pain and fever. Serum amylase level was normal. Liver function impairment was noted: aspartate aminotransferase (AST) 216 U/L, alanine aminotransferase (ALT) 228 U/L, and total bilirubin 1.3 mg/dL. A CT scan revealed a cystic dilatation of the common bile duct. With the diagnosis of choledochal cyst, the patient underwent cholecystectomy, resection of the dilated bile duct, and hepaticojejunostomy. Intraoperative cholangiopancreatography showed extrahepatic bile duct dilatation and an anomalous pancreaticobiliary duct junction (APBDJ) (Figure 1A and B). Amylase level in the bile was 4735 U/L. Microscopic examination of the resected specimen revealed no evidence of malignancy. The postoperative course was uneventful.

Case 2 was a 25-year-old man, the son of case 1, who was admitted to Mie University Hospital, Japan, with complaints of epigastric pain and fever. Amylase level in the serum and urine was 2639 and 56 720 U/L, respectively. Endoscopic retrograde cholangiopancreatography (ERCP) showed cystic dilatation of the extra- and intrahepatic biliary ducts associated with APBDJ (Figure 2). With the diagnosis of choledochal cyst, cholecystectomy, excision of the dilated bile duct, and hepaticojejunostomy were performed. Amylase level in the bile was 138 700 U/L. No malignancy was found histologically in the resected specimen. The patient was discharged without any complication.

DISCUSSION

Congenital choledochal cyst is a relatively rare disease and its incidence is between 1 in 130 000 and 1 in 2 million[10]. There is a female predominance (ratio 1:3)[11,12] and the lesions are more common in Asians, with the majority of reported cases in Japan[11]. Choledochal cysts usually present in infancy or childhood, which supports a congenital origin. Although anomalous pancreaticobiliary duct junction (APBDJ) is thought to be an essential causative factor of CBD, the etiology of CBD remains unclear. Since Chiba *et al* first described in 1981 cases of CBD occurring in

siblings[1], a total of 20 cases (10 pairs), including ours, of familial occurrence have been reported (Table 1). Eighteen patients (90%) were women and only two (10%) were men. Of these 10 pairs, four were siblings and six were parent and child. APBDJ was noted in 15 cases (75%). In addition, two pairs (20%) were dizygotic twins who both developed CBD. As for genetic background of CBD, Iwama *et al* have postulated two possible patterns of inheritance: an X-linked dominant trait or an autosomal dominant trait with relatively low penetrance in males[2]. The present case of CBD with APBDJ suggests a maternally inherited condition, i.e. an X-linked dominant trait. Besides our literature review, a total of six pairs of monozygotic twins have been described in which CBD appeared in one of each pair of twins[13-16]. The phenotypic discordance in monozygotic twins cannot be explained only by inheritance. Other factors, such as acquired or environmental conditions, might have a role in the development of CBD. To clarify the etiological basis of CBD, it will be necessary to accumulate more familial cases of CBD.

Abstract

A solitary Peutz-Jeghers-type hamartomatous polyp in the duodenum is rare, and few reports have described its characteristic endoscopic features. We describe three cases of solitary Peutz-Jeghers-type hamartomatous polyp and their endoscopic findings in detail. The polyp in all of our three cases showed an irregularly lobular or nodular surface, whereas adenomas often show a regularly nodular or granular surface. The color of the polyp was whitish in all of our cases. In the present cases, close observation by endoscopy revealed that the solitary Peutz-Jeghers-type hamartomatous polyps looked whitish because of the presence of diffusely scattered white spots on the surface of the polyps. Duodenal polyps that exhibit the aforementioned endoscopic characteristics may be diagnosed as Peutz-Jeghers-type hamartomatous polyps and treated by polypectomy because of the malignant potential.

INTRODUCTION

Peutz-Jeghers syndrome is a rare, autosomal-dominant disorder characterized by hamartomatous polyps in any part of the alimentary tract and mucocutaneous pigmentation[1]. Recently, a patient with a Peutz-Jeghers polyp without either mucocutaneous pigmentation or a positive family history was described as a case of solitary Peutz-Jeghers-type hamartomatous polyp. It has been suggested that this condition should be considered as a clinical entity different from Peutz-Jeghers syndrome[2]. A solitary Peutz-Jeghers-type hamartomatous polyp is histologically characterized by tree-like branching of smooth muscle fibers, with a core of smooth muscle, covered by mucosal tissue of near-normal appearance[3]. A solitary Peutz-Jeghers-type hamartomatous polyp in the duodenum is rare, and few reports have described its characteristic endoscopic features[2,4-10]. We describe three cases of solitary Peutz-Jeghers-type hamartomatous polyp and their endoscopic findings in detail. The polyp in patient 2 was unique in that a focus of adenocarcinoma was present within a solitary Peutz-Jeghers-type hamar-tomatous polyp.

CASE REPORT

Patient 1 was a 59-year-old woman. She visited our hospital complaining of epigastric discomfort. An upper gastrointestinal barium meal study revealed a polyp, 18 mm × 15 mm in diameter, in the second portion of the duodenum. Upper gastrointestinal endoscopy revealed a semi-pedunculated polyp on the oral side of the Papilla of Vater (Figure 1). Histological examination of a biopsy specimen obtained from the lesion showed hyperplastic duodenal mucosa, suggestive of the diagnosis of a hyperplastic polyp. Surgical resection of the polyp was performed under informed consent. Histologically, the polyp consisted of branching bundles of smooth muscle fibers covered by hyperplastic duodenal mucosa (Figure 2).

Patient 2 was a 68-year-old woman. She visited our hospital because of epigastralgia. Upper gastrointestinal endoscopy revealed a peduncular polyp, 10 mm × 8 mm in diameter, in the second portion of the duodenum (Figure 3). Histological examination of a biopsy specimen obtained from the lesion revealed findings suggestive of an adenoma. Endoscopic polypectomy was performed. Histologically, the polyp consisted of branching bundles of smooth muscle fibers covered by hyperplastic duodenal mucosa containing a focus of cancer near the surface (Figure 4).

Patient 3 was a 60-year-old woman. Upper gastro-intestinal endoscopy as part of a health checkup revealed a semi-pedunculated polyp, 10 mm × 10 mm in diameter, in the duodenal bulb (Figure 5). Histological examination

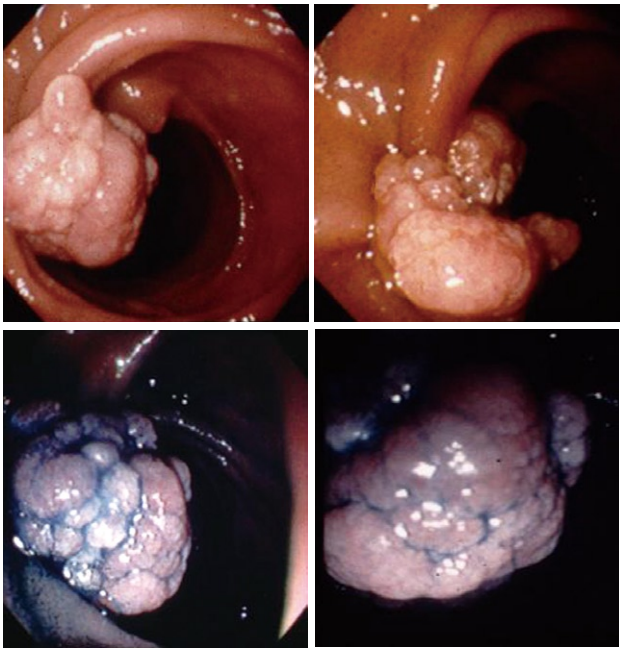

Figure 1 Upper gastrointestinal endoscopy in patient 1 revealed a semi-pedunculated polyp, 18 mm × 15 mm in diameter, on the oral side of the Papilla of Vater. The polyp showed an irregularly lobular surface and slightly whitish color with diffusely scattered white spots on the surface.

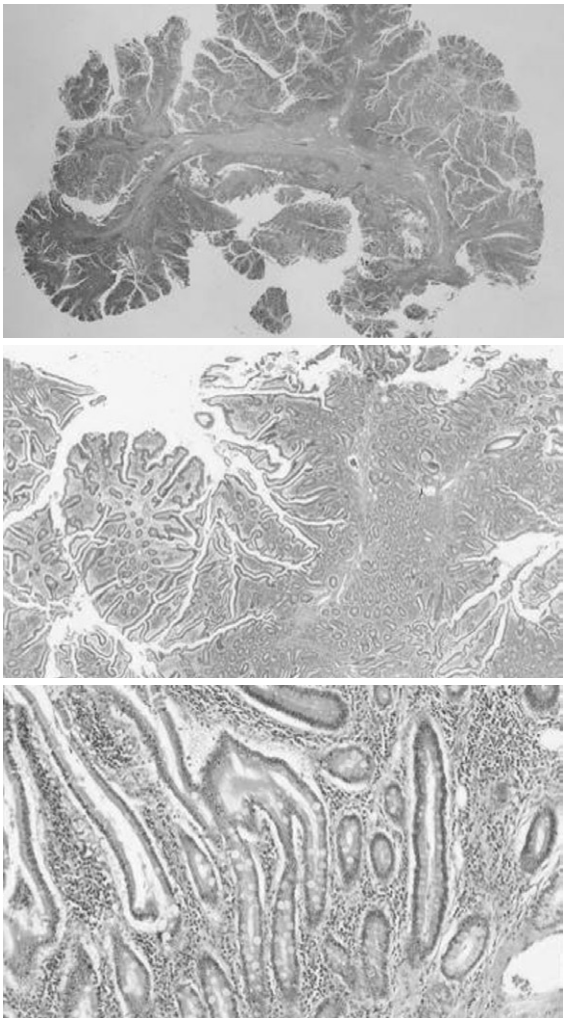

Figure 2 Histologically, the polyp consisted of branching bundles of smooth muscle fibers covered by hyperplastic duodenal mucosa.

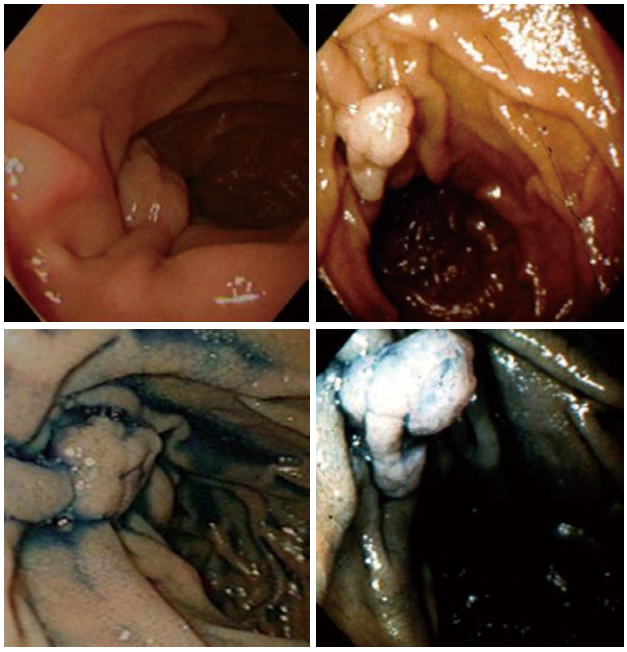

Figure 3 Upper gastrointestinal endoscopy in patient 2 revealed a peduncular polyp, 10 mm × 8 mm in diameter, in the second portion of the duodenum. The polyp showed an irregularly lobular surface and slightly whitish color with diffusely scattered white spots on the surface.

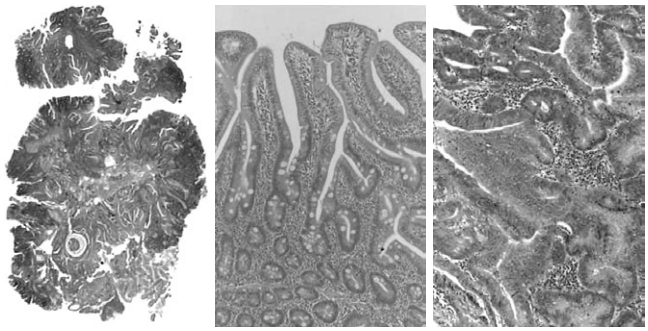

Figure 4 Histologically, the polyp consisted of branching bundles of smooth muscle fibers covered by hyperplastic duodenal mucosa containing a focus of cancer near the surface.

of a biopsy specimen obtained from the lesion showed hyperplastic duodenal mucosa. Endoscopic polypectomy was performed. Histologically, the polyp consisted of branching bundles of smooth muscle fibers covered by normal duodenal mucosa. Brunner's glands existed in the central part of the polyp (Figure 6).

All of the polyps showed an irregularly lobular or nodular surface and slightly whitish color with diffusely scattered white spots on the surface (Figures 1, 3 and 5). None of the three patients showed mucocutaneous pigmentation or a history of familial polyposis. We found no other polyps on colonoscopy or small-bowel follow-through examination with barium in any of the three patients.

DISCUSSION

A MEDLINE search of the English language literature revealed only nine well-documented cases of a solitary Peutz-Jeghers-type hamartomatous polyp of the

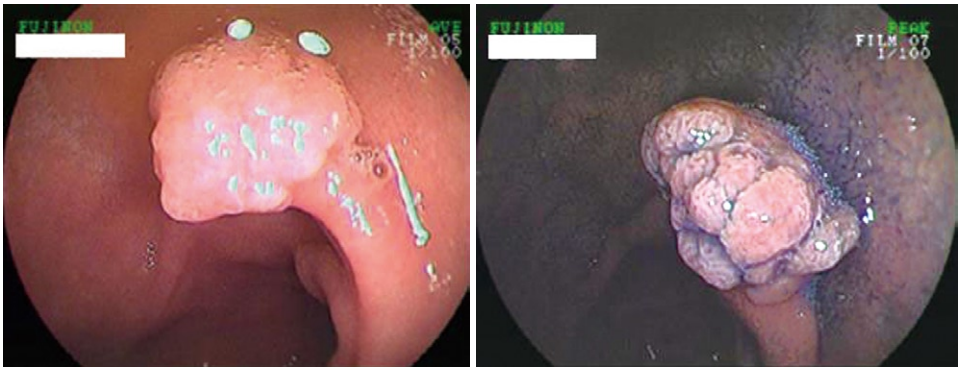

Figure 5 Upper gastrointestinal endoscopy in patient 3 revealed a semi-pedunculated polyp, 10 mm × 10 mm in diameter, in the duodenal bulb. The polyp showed an irregularly nodular surface and slightly whitish color with diffusely scattered white spots on the surface.

duodenum (Table 1)[2,4-9]. Few of these reports have described the endoscopic characteristics of these polyps in detail. The polyp in each of our three cases showed an irregularly lobular or nodular surface, whereas adenomas often show a regularly nodular or granular surface; this finding was compatible with previous reports[2,5-9]. The color of the polyp was whitish in all of our cases, whereas previous reports have described the polyps to be red to normal color[6,7,9]. In the present cases, close observation by endoscopy revealed that the solitary Peutz-Jeghers-type hamartomatous polyps looked whitish because of the presence of diffusely scattered white spots on the surface of the polyps as Sugimoto *et al* reported[10]. We could not confirm the diagnosis by endoscopic biopsy in any of our cases because the polyps were covered by mucosal tissue of near-normal appearance. We consider that duodenal polyps that exhibit the aforementioned endoscopic characteristics may be diagnosed as Peutz-Jeghers-type hamartomatous polyps.

The polyp in patient 2 was unique in that a focus of adenocarcinoma was present within the solitary Peutz-Jeghers-type hamartomatous polyp and histological examination of a biopsy specimen revealed findings suggestive of an adenoma. Hamartomatous polyps are generally considered to have very low malignant potential[11]. However, some reports described areas of neoplastic change, such as adenomatous or carcinomatous change in 3%-6% of the polyps in Peutz-Jeghers syndrome[12,13].

Ichiyoshi *et al* also reported a case of solitary Peutz-Jeghers-type hamartomatous polyp of the duodenum containing a focus of adenocarcinoma[7]. Therefore, because of the malignant potential, a solitary Peutz-Jeghers hamartomatous polyp of the duodenum should be removed.

In conclusion, a solitary Peutz-Jeghers-type hamartomatous polyp of the duodenum is endoscopically characterized by a lobular or nodular surface and whitish color with diffusely scattered white spots on the surface. Duodenal polyps that exhibit the aforementioned endoscopic characteristics may be diagnosed as Peutz-Jeghers-type hamartomatous polyps and treated by polypectomy because of the malignant potential.

CASE REPORT

Toothpick impaction with sigmoid colon pseudodiverticulum formation successfully treated with colonoscopy

Abstract

Foreign bodies in the colon are encountered with increasing frequency, but only sporadic reports concerning their management have appeared in the literature. While most ingested foreign bodies usually pass through the gastrointestinal tract uneventfully, sharp foreign bodies such as toothpicks infrequently cause intestinal perforation and may even result in death. We report our experience with a patient with a sigmoid colon pseudodiverticulum formation, a complication of accidental ingestion of a toothpick that was diagnosed and successfully managed colonoscopically.

INTRODUCTION

If an ingested foreign body successfully navigates the esophagus, it will frequently pass through the entire gastrointestinal tract. Opposition to passage beyond the esophagus, however, can be caused by anatomic conditions or factors specific to the foreign body. Impaction generally occurs at sites of narrowing, such as the pylorus, the ligament of Treitz, the ileocecal valve, or the rectosigmoid junction[1]. Furthermore, long, narrow, or pointed foreign bodies are associated with a higher risk of impaction, as well as complications such as perforation.

We describe here a case of abdominal pain caused by a toothpick impacting the sigmoid colon, which resulted in a pseudodiverticulum formation. The foreign body was diagnosed and managed successfully with colonoscopy. To our knowledge, colonic pseudodiverticulum caused by toothpick impaction has not been reported.

CASE REPORT

A 52-year-old man presented with lower abdominal pain of 1-mo duration. The pain began in the epigastric area and migrated to the lower abdominal area. He had a history of traumatic subdural hematoma 3 mo ago and has been treated with an anticonvulsant drug. He was not a smoker and his use of alcohol was described as only social. Physical examination revealed mild lower abdominal tenderness without rebound tenderness. Laboratory and endoscopic examinations were recommended, but he refused further evaluation. Seven days later, he revisited our hospital with severe lower abdominal pain. On physical examination, aggravated tenderness was noted in the lower abdominal region without rebound tenderness. Laboratory examination revealed only mild leukocytosis of 11 000/mm^3 with elevated C-reactive protein (38.90 mg/L). The next day, colonoscopy was performed and revealed a fixed sigmoid loop with a toothpick of 6 cm length that had impacted the distal sigmoid colon with surrounding mucosal erythema and edema. The toothpick was cautiously removed using foreign-body extraction forceps (Figure 1A). There were some yellowish discharge and hyperemia on the surface of impacted colonic mucosa, but no bleeding was observed (Figure 1B). Subsequent questioning yielded a history of accidental toothpick ingestion during an afternoon nap 2 wk ago. Abdominal CT revealed severe wall thickening, pericolic fat infiltration and peritoneal thickening in the distal sigmoid colon. In addition, a small air-containing cavity lined by thin epithelium was noted in the serosal surface of the distal sigmoid colon, which was consistent with pseudodiverticulum (Figure 2). There was no evidence

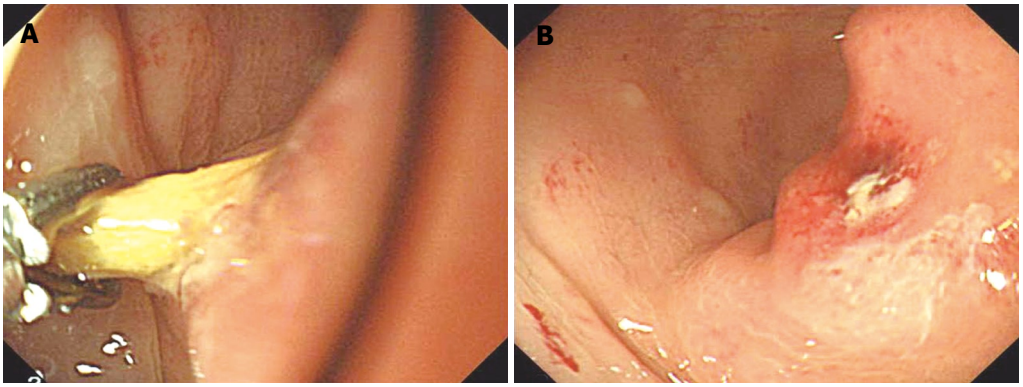

Figure 1 **A**: The endoscopic appearance of the toothpick in the sigmoid colon and removal of the toothpick was achieved using foreign-body extraction forceps. **B**: The endoscopic appearance of impacted colonic mucosa after removal of toothpick.

Figure 2 Initial abdominal CT shows severe wall thickening, pericolic fat infiltration and peritoneal thickening in the distal sigmoid colon. In the serosal surface, a small air-containing cavity lined by thin epithelium (arrow) is noted, which is consistent with a pseudodiverticulum.

Figure 3 Follow-up CT shows improvement of sigmoid colonic inflammation and disappearance of the pseudodiverticulum.

of free air or pneumoperitoneum. Treatment with broad spectrum parenteral antibiotics was started and continued for 7 d. The patient had an uneventful hospital course; the white blood cell count and C-reactive protein returned to normal within 48 h. Follow-up abdominal CT 4 d later revealed interval improvement with disappearance of the pseudodiverticulum (Figure 3). The patient did well after discharge.

DISCUSSION

About 80%-93% of ingested foreign bodies entering the stomach will be passed through the gastrointestinal tract uneventfully[2]. However, if the ingested foreign bodies are long, narrow, sharp such as toothpicks, the incidence of perforation could be as high as 15%-35%[3]. Patients may manifest symptoms due to bowel wall penetration, peritonitis, or an obstructive process. Toothpick ingestion appears to be commonly implicated in intestinal perforations due to the length and bilateral pointed ends of this foreign body[1]. The most frequent site of injury from ingested toothpicks is duodenum, followed by sigmoid colon[4]. Toothpicks seem to be benign materials from its wooden composition comparing to metallic pin, but surprisingly high mortality rate of toothpick injury (18%) was reported in one study[4]. Moreover, the mortality of patients presenting in shock or with enteric-vascular fistulas was extremely higher (70% and 80%, respectively)[4].

Until recently, toothpick impaction in the lower gastrointestinal tract has been managed by early surgery. One possible explanation for this fact is that most toothpicks are made of wood and may not apparent on imaging studies. Li *et al* reported that toothpicks were apparent on imaging studies only in 14% of the cases[4]. The definite diagnosis was most commonly made at laparotomy (53%), followed by endoscopy (12%)[4]. Another possible explanation is that most patients do not remember swallowing a toothpick. This may lead the physicians to hardly consider toothpick impaction as the cause of patients' symptoms. However, as the skills and devices of endoscopist improve, this approach to management should be reconsidered. Obviously, operative removal of a frankly perforating toothpick is prudent, but it appears that in some cases endoscopic intervention may be accomplished at acceptable rates of morbidity and mortality. In several cases, endoscopic removal of toothpicks injury was described in the literature[1,5-9]. Preceding 5 cases presented with colonic perforation and the last one presented with toothpick impaction in the transverse colon without evidence of perforation. By contrast, severe sigmoid colonic inflammation with pseudodiverticulum formation was noted in our case. Free air or pneumoperitoneum, which is a sign of perforation, was not evident. To our knowledge, colonic pseudodiverticulum associated with toothpick impaction has not been reported. Colonoscopic removal of the foreign body and antibiotics treatment led to an uneventful

recovery.

In summary, we report a case of toothpick impaction with sigmoid colon pseudodiverticulum formation successfully managed with colonoscopy. This case emphasizes the uncommon but possibly mortal hazards associated with the ingestion of toothpicks. Such sharp objects may cause acute inflammation without obvious perforation and present with signs of an acute abdomen. If this unusual but important cause of abdominal pain is taken into account and diagnosed in time, endoscopic management is possible.

Abstract

Sister Mary Joseph's nodule is an inconspicuous and uncommon clinical sign of advanced malignant disease, especially gastric cancer. Pregnancy-associated gastric cancer is an extremely rare condition and can be difficult to diagnose, due to the absence or misinterpretation of symptoms as pregnancy-related. Diagnostic aids, such as a basic chemistry panel and imaging techniques, may not show any abnormalities. We present a case of a 37-year-old pregnant patient whose umbilical nodule was the first presenting physical sign of gastric cancer, which had metastasized throughout the abdominal and pelvic regions.

INTRODUCTION

Sister Mary Joseph's nodule is a rare umbilical lesion most commonly related to advanced malignant abdominal disease, including gastric cancer[1]. Moreover, gastric cancer associated with pregnancy is in itself an extremely rare occurrence. The available information on this subject is scarce and consists mainly of case reports and studies on large patient populations, in which some cases of pregnancy-associated malignancies are included[2-5]. Diagnosis is usually delayed due to non-specific symptoms that are often misinterpreted as pregnancy-associated. The lack of suspicion and general reluctance to perform invasive investigations during pregnancy contribute to late diagnosis. The delay in diagnosis and, consequently, treatment leads to the extremely poor prognosis associated with this disease. We report a case of a 37-year-old woman, whose umbilical metastasis was the first presenting sign of gastric cancer during wk 34 of gestation.

CASE REPORT

A 37-year-old, gravida 3, para 3 woman was admitted during wk 36 of gestation to our obstetrics department for further evaluation. The patient had a history of preprandial, crampy, epigastric pain and diarrhea for several years. Her father died of colorectal cancer in his late fifties and her mother had breast cancer. However, neither Amsterdam II nor Bethesda criteria for hereditary nonpolyposis colorectal cancer (HNPCC) were met by the family[6].

Years previously, the symptoms had been attributed to lactose intolerance. A prescribed diet did not provide any relief, but gastroscopy performed 2 years prior to definitive diagnosis of gastric cancer was normal. Infection with *H pylori* was diagnosed by using the ^{13}C-urea breath test, and its eradication led to amelioration of her symptoms. The complaints recurred less than a year later, with the cardinal symptom of preprandial epigastric pain.

The patient noticed at this time a red, pressure-sensitive lesion with a diameter of 2 cm on her umbilicus. Her general practitioner did not perform any additional investigation of the lesion because he deemed it as harmless. Two months later, her fourth pregnancy was achieved. Melena and intermittent rectal bleeding occurred in wk 10 of gestation, but the symptoms were attributed to pregnancy-related hemorrhoids. Since the umbilical lesion evolved into a nodule with a bumpy irregular surface (Figure 1), she was referred to the department of dermatology. A biopsy was performed at wk 34 of gestation; histological examination revealed a diffuse, undifferentiated, growing carcinoma of unknown origin

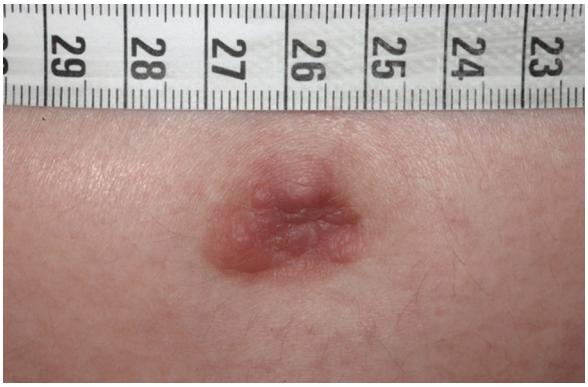

Figure 1 Sister Mary Joseph's nodule.

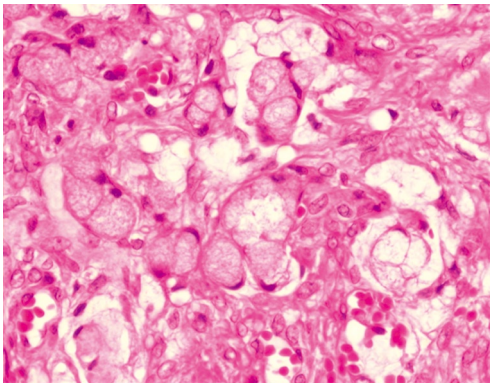

Figure 2 Histology of Sister Mary Joseph's nodule with diffuse, undifferentiated growing carcinoma cells, some containing cytoplasmatic mucin.

(Figure 2), and some cells containing cytoplasmatic mucin. Sister Mary Joseph's nodule was confirmed as the first presenting sign of cancer during pregnancy.

Physical examination upon admission was unremarkable, except for normal signs of pregnancy and pallor. The patient was slightly anemic at the time of presentation, with a hemoglobin level of 7.3 mmol/L and a hematocrit of 34%. Other laboratory data, which included liver function tests and a basic chemistry panel, were within normal limits. Tumor marker assessment revealed elevated serum concentrations for carcinoembryonic antigen (CEA, 293.8 U/mL, normal range < 39.0 U/mL) and cancer antigen-125 (CA-125, 39.8 U/mL, normal range < 35.0 U/mL). Other tumor markers stood within normal range. On ultrasound scan and color duplex sonography, the fetus was developing well with no pathological findings.

The patient was referred to our gastroenterology department where she underwent gastroscopy. A rough ulcer, about 3 cm in diameter, originated from the angular notch. Biopsy revealed a poorly differentiated gastric adenocarcinoma with signet ring cells. Diagnostic imaging (abdominal ultrasonography, thoracic CT and abdominal MRI) showed no clear evidence of metastases. Breast and thyroid sonography showed no abnormalities.

The patient delivered by cesarean section a healthy, 3.2 kg female (Apgar score, 10/10/10). Cesarean section was followed by abdominal and pelvic exploration, which revealed bilateral ovarian tumors (Krukenberg tumors), metastatic spread to the lymph nodes throughout the peritoneal cavity, and tumor infiltration of the spleen and transverse colon. Extensive carcinomatosis of the parietal peritoneum and of the surfaces of the gall bladder and small intestine was present. Total gastrectomy, splenectomy, cholecystectomy, extended right-sided hemicolectomy, bilateral adnexectomy and excision of the umbilicus were performed followed by reconstruction by Roux-en-Y gastrojejunostomy. All the visible tumor tissue was removed. Histological examination showed a poorly differentiated gastric adenocarcinoma with signet ring cells, of mixed type according to Laurén's classification, which was identified in large proportions of the entire stomach, and not only located in the previously described ulcer. The pathologist confirmed stage Ⅲ disease because of peritoneal carcinomatosis, and interpreted the umbilical lesion as metastatic spread and not as continuous skin infiltration by the tumor. The placenta and umbilical cord, however, were free of metastases. Palliative chemotherapy began immediately postpartum. The further postoperative course was complicated by a leak at the blind end of the jejunal loop of the esophagojejunostomy, and a subphrenic abscess with peritonitis. Surgical reintervention was carried out and chemotherapy stopped temporarily. At present, the patient is recovering from surgery and the chemotherapy has been resumed. The baby is doing well.

DISCUSSION

An extended review of literature revealed no previously reported cases of umbilical metastasis as the first presenting sign of gastric cancer during pregnancy.

The term "Sister Mary Joseph's nodule" was coined by Sir Hamilton Bailey in his book, *Physical Signs in Clinical Surgery*, in honor of Sister Mary Joseph, Dr. William Mayo's surgical assistant in the early days of the Mayo Clinic. Sister Mary Joseph identified the relationship between umbilical nodules and advanced intra-abdominal malignancy[7,8]. Sister Mary Joseph's nodule is an umbilical metastasis most commonly found in advanced-stage adenocarcinomas of the upper gastrointestinal tract and ovary. Less commonly, the nodule may be a metastatic lesion from colon or pancreatic cancer[9,10]. The presence of an umbilical metastasis indicates a poor prognosis and is a sign of advanced malignant disease. The survival of these patients has been reported to range from 2 to 11 mo from the time of initial diagnosis[10-13].

Gastric cancer primarily occurs in patients over 50 years of age. The described proportion of young patients with gastric cancer varies from 2% to 15% depending on the age defined as young[14,15]. Female patients have a relative dominance in this group and the incidence of gastric cancer is higher in women over the age of 30 years. The frequency of pregnancy has been increasing in these women and this may lead to a higher coincidence of pregnancy and gastric cancer[2]. Pregnancy-associated gastric cancer is currently attributed to 0.1% of all cases[16]. There is an increased risk of diffuse and scirrhous type carcinomas in this group of patients[4,17,18].

Common presenting signs and symptoms of gastric cancer include dyspepsia, epigastric pain, early satiety,

nausea, vomiting, anorexia, anemia, dysphagia, weight loss and melena. Except for weight loss and melena, all of these symptoms are common in pregnancy. Weight loss can be caused by hyperemesis gravidarum or compensated and masked by the weight gain in pregnancy, and melena may be initially attributed to pregnancy-related hemorrhoids.

In our case, the tumor was advanced at the time of diagnosis. We can only speculate that the delay between the first symptoms and diagnosis might have been several years, possibly due to multiple pregnancies concealing the symptoms during that time. To diagnose diffuse-type gastric cancer is sometimes difficult, if there is no typical lesion and an adequate number of biopsies is taken during gastroscopy. In our case, the cancer was spread throughout the stomach and was not only located in the ulcer region. An adequate number of biopsies taken during previous endoscopies would have made an earlier diagnosis possible. Marconi *et al* have reported a mean delay, from first symptoms to final diagnosis, of 29.3 ± 9.9 wk in young patients without alarm symptoms[19]. The initial diagnosis of gastric carcinoma is often delayed because up to 80% of patients are asymptomatic during the early stages of gastric cancer[20]. When symptoms are present, they can be misinterpreted as simply pregnancy-related. Hormonal stimulation and pregnancy in young women may accelerate the growth of gastric cancer[3,21]. Therefore, we tested for estrogen and progesterone receptors in our patient's tumor and the results were negative. Our patient had consecutive pregnancies with continuous, worsening symptoms. The presence of the umbilical lesion 2 mo before the latest pregnancy strongly suggests that the disease was already at an advanced stage at that time. Gastric cancer should be included, therefore, in the differential diagnosis of unusual or prolonged gastrointestinal symptoms after the first trimester of pregnancy, and in women who have recently been pregnant[15,21]. Coexistent risk factors such as positive family history should trigger immediate further investigation through gastrointestinal endoscopy, which is not contraindicated during pregnancy.

The unique presenting sign of Sister Mary Joseph's nodule indicates an advanced malignant disease with poor prognosis for the mother, but not for the baby. Such nodules might be misinterpreted as eczematous lesions. Based on our case, it is evident that a skin lesion in the umbilical area might indicate malignant disease, and biopsy should be considered if short-term (1-2 wk) local treatment is not successful.

Abstract

Intestinal pseudo-obstruction (IPO) either acute or chronic is a condition including features of intestinal ileus in absence of mechanical obstruction. Our paper presents such a rare case of idiopathic IPO in a 53-year-old male patient with recurrent episodes of pseudo-obstruction, which were successfully resolved by anticholinesterase agents, motilin agonists or colonic decompression. However, the patient finally underwent total colectomy. Huge colonic dilatation was identified intraoperatively, while histology showed a neuropathic variant of chronic intestinal pseudo-obstruction. Etiologic mechanisms and current therapeutic methods are reviewed in this paper, which concludes that IPO is a condition in which conservative treatment usually fails. Total colectomy with ileoanal pouch may be the only solution in these situations.

INTRODUCTION

Intestinal pseudo-obstruction is a condition characterized by intestinal obstruction in the absence of any mechanical obstructing lesion. Pseudo-obstruction can exist in the small bowel or in the colon and can be either acute or chronic. Acute colonic pseudo-obstruction (ACPO), also known as Ogilvie syndrome, is the most common form of intestinal obstruction. It occurs commonly in postoperative period of surgical patients, or as a response to a nonsurgical acute illness. Chronic intestinal pseudo-obstruction (CIP) is a rare and heterogeneous clinical syndrome, with a relapsing and remitting pattern that appears either in idiopathic (as consequence of a primary abnormality of the gut, namely a visceral myopathy or neuropathy) or in other non-intestinal disorders.

Our paper presents a rare case of idiopathic CIP in a 53-year-old Caucasian male showing the neuropathic variant with hypoplasia of ganglionic cells of the rectum, sigmoid and descending colon.

CASE REPORT

The patient complained of abdominal distension, vomiting and no bowel movements for 5-7 d. He had this history three or four years ago, with episodes of progressive abdominal distension and constipation, and was diagnosed as irritable bowel disease. In the last year, these episodes increased in severity and frequency, leading to food abstention and secondary denutrition.

The episodes of bowel movements were more and more severe. However, as mechanical obstruction was systematically ruled out, the patient was discharged after certain symptomatic treatment each time. Finally, after four or five such episodes of "unexplained" pseudo-occlusion, he was admitted to the gastroenterology unit for further investigation.

Physical examination during these obstructive episodes revealed huge abdominal distension with hypoactive bowel, but no abdominal mass or peritoneal signs. The patient had no history of metabolic, neurological, cardiovascular or pulmonary disease, abdominal or pelvic operations, abdominal cancer, intra-abdominal inflammation or abdominal trauma. He did not take other concomitant medication.

Biologic screening showed normal serum electrolyte concentration, hemoglobin, hematocrit, white blood cells, blood glucose, creatinine, and coagulation profile. There was no evidence of metabolic diseases like diabetes, porphyria, amyloidosis. Pulmonary imaging was normal. Abdominal ultrasound did not find any sign of small bowel or colonic mechanical obstruction. Distended

Figure 1 Supine radiograph with no preparation showing massive colonic distention especially the transverse colon, but without air-fluid levels.

Figure 3 Laparotomy showing massive distension of the whole colon with no perforation or volvulus. Total colectomy removed a completely atonic colon which was 2.5 m in length and 25 cm in diameter. Ileoanal pouch was made subsequently.

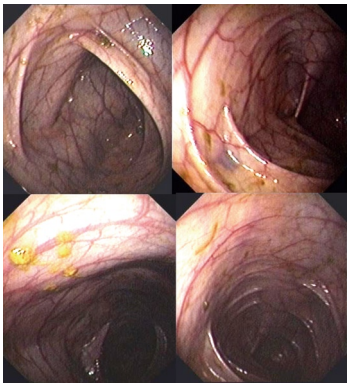

Figure 2 Colonoscopy showing huge colonic distension involving all segments, with a diameter of the rectosigmoid and descending colon greater than 12 cm, and that of the ascending colon and cecum greater than 16-18 cm.

bowel segments were observed, but free peritoneal fluid, pendulating peristalsis, bowel wall edema, or fixed masses of aperistaltic, fluid-filled distended intestinal loops were not observed. Radiographs showed signs of marked colonic dilatation (Figure 1) especially in the cecum and ascending colon, but no air-fluid levels were found in the colon or in the small intestine. Abdominal CT-scan showed nothing apart of bowel distension and aerobilia while the pulmonary and cranial scans were normal.

Colonoscopy showed incredible colonic distension (Figure 2) up to the cecum and decompressed the abdomen. No obstructive, diverticular or mucosal changes were noticed. Randomized multiple mucosal biopsies were also normal. CIP syndrome was strongly suspected, which was enforced by the fact that after intravenous administration of neostigmine (2 mg) rapid evacuation of flatus and stool and significant decrease in abdominal distention were observed.

The patient was discharged and oral neostigmine was administered regularly (15 mg per day). Two weeks after apparent amelioration of bowel habits, the patient had a new pseudo-obstructive accident, which remitted again with colonoscopic decompression and intravenous neostigmine. Oral erythromycin was introduced at discharge, at a dose of 500 mg, three times per day, resulting in fewer episodes of constipation, pain and vomiting and more regular bowel actions, which increased from 1.5 per week to 3 per week for a period of three months. Unfortunately, after this period, recurrence occurred and because of failure in all other conservative therapies (including prokinetics, octreotide, propranolol) the patient finally underwent colectomy.

Intra-operation examination revealed massive colonic distension, the large bowel length was more than 2.6 meters and the cecum diameter was larger than 15 cm (Figure 3). After a total colectomy with ileoanal pouch, the condition was resolved satisfactorily. Full thickness colonic sections were histologically analyzed. No myopathic abnormality was found but ganglionic cells were absent in the last 7 cm of the rectum, and marked depletion of neural plexuses with hypertrophy of the external muscular layer was identified in sigmoid and descending colon (Figure 4), thus diagnosis of neuropathic CIP was established.

No postoperative complication and obstructive episode occurred after colectomy. Prokinetics were discontinued, and the weight of the patient became normal. Apart from some diarrheal stools, which occurred in the first two months after operation, the bowel movements did not exceed 7.5/wk, with no need for antidiarrheal drugs or nutrient supplementation.

DISSCUSION

Megacolon is a descriptive term, without etiologic and pathophysiologic implication. It can be acute or chronic, each category being subdivided in idiopathic and secondary to various disorders. Idiopathic forms are usually assigned to variants that lack decisive elements for diagnosis on routine stains, although specialized immunohistochemical techniques frequently reveal unrecognized disorders, such as primary biochemical disorders of the gut muscle[1]. Toxic megacolon is classically not included in these categories.

When colonic obstruction is acute[2] and associated with a recent, major organic disorder, trauma, or surgical procedure as shown in Table 1, the term of Ogilvie's syndrome is commonly used. Imbalance in the autonomic nervous system is the presumed physiopathologic factor postulated by Sir Heneage Ogilvie when he firstly described ACPO in 1948[3]. In his original work, Ogilvie considered that high parasympathetic tone combined with low sympathetic activity of the colon leads to regional contraction and thus, functional obstruction, but little direct evidence supports this theory. Conversely, many recent observations suggest that parasympathetic deprivation combined with high sympathetic tones is the main factor contributing to pseudoobstruction[4,5]. The

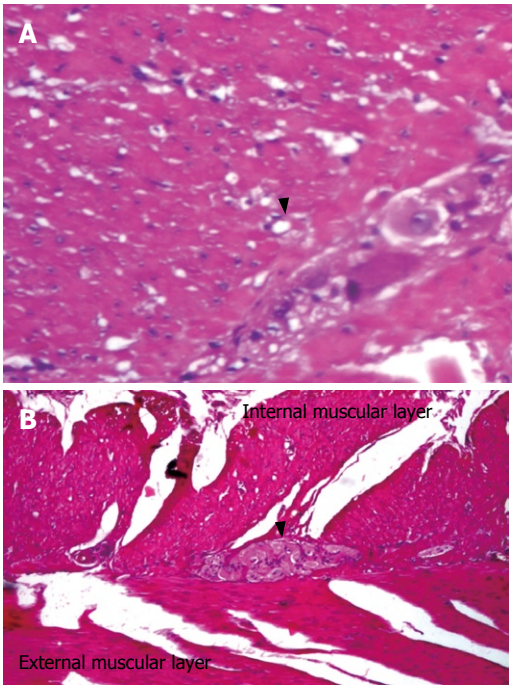

Figure 4 Full-thickness serial biopsies stained with haematoxylin-eosin (× 100) from the removed colon showing no ganglionic cells in the last 7 cm of the rectum. Marked depletion of ganglionic cells (arrow) and hypertrophy of the external muscular layer were identified in sigmoid (**A**) and descending colon (**B**).

efficacy of cholinesterase inhibitors in reversing ACPO[6,7], as well as observations regarding colonic atony similar to Hirschsprung disease after interruption of the sacral parasympathetic nerves suggest that a high sympathetic and/or low parasympathetic activity[8] is more likely to induce ACPO. Some other factors may also contribute, like increase in nitric oxide production[9] or inhibition of motilin receptors to ACPO[10].

Chronic intestinal pseudo-obstruction can be congenital or acquired, both forms can be subdivided into neuropathic and myopathic variants (Table 2).

The most common form of *neuropathic CIP* is Hirschsprung disease, caused by a congenital absence of intramural plexuses that mediate relaxation (aganglionosis), leading to narrowing of a segment of large intestine that impairs progression of colonic content and secondarily generates upstream dilatation. Aganglionosis results from arrest of caudal migration of embryonic cells that will form the myenteric plexus from the neural crest in early embryogenesis, and, consequently this disease is included in a group of disorders called neurocristopathies [11]. The aganglionic segment usually does not exceed 5-15 cm in length, being located in the distal rectum, but in certain cases, it can be longer, extending to the sigmoid or even may exceptionally extend to the entire colon.

Variants of Hirschsprung disease include type Ⅱ (b) multiple endocrine adenomatosis[12] and some other conditions as hypoganglionosis and neuronal intestinal dysplasia. In type Ⅱ multiple endocrine neoplasia (MEN Ⅱ) and Hirschsprung's disease, a mutation of an autosomal dominant gene localized to a 250-kilobase interval containing the RET proto-oncogene is mapped to chromosome 10q11.2[13,14]. The mutation enhances the function of a tyrosine-kinase receptor in MEN Ⅱ, while in Hirschsprung disease it inactivates the protein. Apart from the four variants of this mutation that damages the structure of the tyrosine kinase domain of the RET protein, other mutations have been also recently described[15] in Hirschsprung's disease. In animal models,

Table 1 Major causes for acute intestinal pseudo-obstruction (adapted from 2)

Post-surgery	Abdominal, orthopedic, neurologic, urologic, cardiac interventions, caesarean section, gynecological/pelvic surgery, renal transplantation
Pulmonary diseases	Pneumonia, mechanical ventilation, adult respiratory distress syndrome
Electrolyte disturbances and metabolic disorders	Hyponatremia, hypokalemia, hypocalcaemia or hypocalcaemia, hypomagnesaemia, alcohol abuse, liver and renal failure
Cardiovascular diseases	Myocardial infarction, cerebrovascular accident, congestive heart failure
Malignancy	Retroperitoneal neoplasia, leukaemia, metastatic cancer, pelvic radiotherapy
Infective/inflammatory	Acute cholecystitis, pancreatitis, peritonitis, systemic sepsis, herpes zoster infection, gram-negative infections,
Neurologic	Parkinson's disease, Alzheimer, multiple sclerosis, low spinal cord disease
Traumatic	Pelvic trauma, spinal cord injuries, femoral fracture
Medications	Narcotics, opiates, anticholinergics, clonidine, amphetamines, phenothiazines, steroids

Table 2 Major causes for chronic intestinal pseudo-obstruction (adapted from 11)

	Neuropathic	Myopathic
Idiopathic	-Hirschsprung disease	-Nonfamilial hollow visceral myopathy
Acquired	-Familial visceral neuropathies -von Recklinghausen disease -Infiltrative diseases (amyloidosis) -Metabolic, endocrine and electrolyte diseorders (porphyrias, diabetes mellitus, hypothyroidism, hypokalemia) -Neurologic diseases (brainstem tumors, multiple sclerosis, dysautonomias) -Infectious diseases (trypanosomiasis, cytomegalovirus infections) -Neoplastic diseases (bronchial small cell carcinoma, carcinoids, pheochromocytoma) -Drugs (narcotics, antihypertensives, antidepressants)	-Familial visceral myopathies -Infiltrative diseases (amyloidosis, systemic sclerosis) -Myotonic and other dystrophies

Parisi *et al*[16] investigated the regulation of Hox11L1, a gene expressed by enteric neurons in Hox11L1- transgenic null mice and concluded that expression of the transgene and penetrance of pseudo-obstruction are influenced by one or more modifier genes depending on the genetic background, some of them having a putative role in human disease.

Congenital aganglionosis is associated with other genetic disorders like Down's and Laurence Moon Bardet Biedel syndromes. Type IV Waardenburg-Shah syndrome (WS4) is characterized by association of Waardenburg features (WS, depigmentation and deafness) and absence of enteric ganglia in the distal part of the intestine. Mutations in the genes EDN3, EDNRB and SOX10 have been reported in patients presenting either the classical form of WS4, or chronic intestinal pseudo-obstruction and WS features[17].

Among acquired conditions that generate CIP, Chagas disease is widely known. In this disease, the neurotoxin generated by Trypanosoma cruzii has a deleterious effect on the enteric nervous system. Other infections, like cytomegalovirus can have similar consequences by unknown mechanisms. Metabolic disorders like diabetes mellitus and porphyria, as well as infiltrative diseases (systemic sclerosis, amyloidosis) can also lead to neuropathic variants of CIP. Some drugs (antidepressants, anticholinergics, vincristine) can interfere with myenteric plexus activity. Mechanisms of neuronal damage may be toxic or immune, as in patients treated with buserelin[18], an analogue of gonadotropin-releasing hormone (GnRH) in which formation of buserelin-induced anti-GnRH antibodies can destroy GnRH-producing neurons of the myenteric plexus.

Little is known about the mechanisms generating pseudo-obstruction in neuropathic forms of CIP, either idiopathic or acquired. It seems that lack of normal pacemaker activity, usually generated by the interstitial cells of Cajal (ICC), could account for obstruction[19]. ICC, normally located between the myenteric plexus ganglia, can be stained immunohistochemically with CD117 as well as with CD34, which also stains a population of fibroblasts intimately associated with ICC. In some CIP patients, both CD117 and CD34 are absent or severely reduced, while in controls ICC staining is normal, and moreover, the CD34-positive fibroblasts associated with ICC are absent in these cases[20].

In aganglionosis, the aganglionic segment still exhibits spontaneous phasic contractions that contribute to pseudoobstruction. The mechanism that generates these myogenic contractions and the generation of Ca(2+) waves that underlie contractions of the longitudinal muscle (LM) and circular muscle (CM) was recently studied by Spencer *et al*[21] in a mouse model of Hirschsprung's disease. In control mice, during the intervals between colonic migrating motor complexes (CMMCs), Ca(2+) waves discharged asynchronously between the LM and CM, while a burst of discreet Ca(2+) waves firing simultaneously was noticed in both muscle layers, with an increased propagation velocity of Ca(2+) waves. In aganglionic mice, CMMCs were absent and Ca(2+) waves between the two muscle layers fired asynchronously, despite an increased propagation velocity, resulting in a sporadic and sustained asynchrony in Ca(2+) waves firing between the LM and CM.

Neurotransmitters like nitric oxide (NO) can also play a role in generating pseudo-obstruction. NO is synthesized by the activation of neuronal NO synthase (nNOS) in the myenteric plexus in response to nerve stimulation and determines relaxation of the smooth muscle. Reduction in nNOS expression, associated with impaired local production of NO, may be responsible for some motility disorders including Hirschsprung's and Chagas diseases[9] where it is conceivable that extrinsic denervation may up regulate nNOS expression, resulting in enhanced muscular relaxation and disturbed peristalsis.

Myopathic variants of CIP have been intensively studied, although there are a lot of controversies regarding this inhomogeneous group. Visceral myopathy is a form of CIP characterized by vacuolar degeneration, atrophy and fibrosis of the intestinal muscle layer without inflammatory cells[22]. The familial form occurs in about 30% of cases having a transmission mostly autosomal recessive.

Mitochondrial DNA defects, as well as mitochondrial beta-oxidation disorders can also determine intestinal pseudo-obstruction associated with or not with progressive skeletal myopathy and neuropathy in some cases. Defects in mitochondrial proteins like mitochondrial trifunctional protein[23], an enzyme complex catalyzing the last three steps in the beta-oxidation cycle, causes intestinal pseudo-obstruction by activation of extramitochondrial fatty acid oxidation pathways with generation of excessive reactive oxygen species, leading to visceral myopathy. The muscle biopsies in such cases show intestinal smooth myocytes with bulbous protrusions filled with lateralized mitochondria, while histochemistry can show a decreased reactivity of cytochrome-c oxidase and marked reductions in other mitochondrial enzyme activities like NADH: Q1 and NADH: O2 oxidoreductases. Although considered as causative factors for myopathic CIP, mitochondrial disorders can also determine neuropathic pseudo-obstructions, or at least, can be associated with other neuronal intestinal malformations[24].

Deficiencies of alpha smooth muscle actin (ASMA) expression in intestinal smooth muscle are associated with CIP. Knowles *et al*[25] found that 24% of CIP patients have absent or partial ASMA immunostaining in the circular muscle layer, while smooth muscle alpha-actin staining is preserved in the longitudinal muscle and controls. Other authors[26] also tested the hypothesis that deficient ASMA expression in intestinal smooth muscle is specifically associated with clinical evidence of CIP using primary antibodies to ASMA, smooth muscle myosin heavy chain and desmin. While the staining for the later two antibodies was similar in patients and controls, ASMA expression was absent or minimal in all CIP patients but also in a great number of controls, leading to the conclusion that there is not enough evidence to confirm this theory. In contrast, Silk and his group[27] found that 58% of CIP patients have complete or partial deficiency of alpha-actin epitope staining in the inner circular layer of small intestinal smooth muscle, considering this deficiency as a biomarker of disease rather than a cause of CIP.

Immune disorders can seldom determine CIP. Intestinal pseudo-obstruction has been described in less than 20 cases in association with systemic lupus erythematosus[28] and, in extremely rare situations, autoimmune enteric leiomyositis[29] can determine pseudo-obstruction. It seems that coexisting disorders like autoimmune hepatitis can favor expansion of autoreactive T cells to homologous self-antigens in the muscularis propria, with smooth muscle fibers degenerated but with the myenteric neuronal plexus preserved.

Treatment of CIP is not standardized. Propulsive laxatives, prokinetics, anticholinesterase agents, motilin receptor agonists, and even octreotide, clonidine and propranolol have been tried in small series, but given the rarity of this condition, few controlled trials have been conducted. A number of reports have evaluated the efficacy of a prokinetic agent, cisapride, in the treatment of chronic intestinal pseudo-obstruction[30,31], showing some evidence for short-term improvements, but because of cardiac toxicity, this agent is actually restricted. It has been demonstrated that intravenous administration of neostigmine, 2.5 mg over 2 to 3 min, leads to prompt resolution of acute colonic pseudo-obstruction[32,33] by inhibiting the destruction of acetylcholine by acetylcholinesterase, which facilitates transmission of impulses across the myoneural junction. However, in CIP the results are not so obvious, and the role of neostigmin in treating these patients has not been formally evaluated, except in sporadic case reports[34,35]. Some papers[10] report improvement in gut function with use of erythromycin, given orally or intravenously in a small number of patients with CIP, suggesting that it can be of benefit for preventing and attenuating the episodes of pseudo-obstruction. Erythromycin inhibits the binding of motilin to the receptors on gastrointestinal smooth muscle, and, despite the relative absence of motilin receptors in the lower gut, there is evidence that supports its role in accelerating colonic transit in patients with CIP[36,37].

Colonoscopic decompression[38-40], with or without placement of a decompression tube, is accepted as a standard method to remove air from the colon in CIP, allowing decompression and reducing the risk of perforation. Although this procedure may be hazardous and sometimes difficult to perform because of poor preparation, it is usually efficient and passage of the endoscope to the hepatic flexure always permits decompression of the cecum in most patients. Unfortunately, dilatation usually recurs following decompression.

Surgical treatment is usually reserved to refractory situations, on a case-by-case basis. The options include total abdominal colectomy with ileorectal anastomosis, total proctocolectomy with ileostomy, or with ileoanal anastomosis[41-43] depending on the site of the colon affected.

In conclusion, CIP is a rare disease in which colonic dilatation can be impressive. Its etiology is not obvious, since multiple neuropathic and myopathic abnormalities can account for it. Although conservative treatment with anticholinesterase agents, motilin agonists or colonic decompression is recommended, its long-term efficacy is doubtful and colectomy is sometimes needed.

Abstract

Solid-pseudopapillary tumor (SPT) is a rare neoplasm of the pancreas that usually occurs in young females. It is generally considered a low-grade malignant tumor that can remain asymptomatic for several years. The occurrence of infiltrating varieties of SPT is around 10%-15%. Between 1986 and 2006, 282 cystic tumors of the pancreas were observed. Among them a SPT was diagnosed in 8 patients (2.8%) with only one infiltrating variety. This was diagnosed in a 49-year-old female 13 years after the sonographic evidence of a small pancreatic cystic lesion interpreted as a pseudocyst. The tumor invaded a long segment of the portal-mesenteric vein confluence, and was removed with a total pancreatectomy, resection of the portal vein and reconstruction with the internal jugular vein. Histological examination confirmed the R-0 resection of the primary SPT, although a vascular invasion was demonstrated. The postoperative course was uneventful, but 32 mo after surgery the patient experienced diffuse liver metastases. Chemotherapy with different drugs was started. The patient is alive and symptom-free, with stable disease, 75 mo after surgery. Twenty-five patients with invasion of the portal vein and/or of mesenteric vessels were retrieved from the literature, 16 recent patients with tumor relapse after potentially curative resection were also retrieved. The best treatment remains a radical resection whenever possible, even in locally advanced or metastatic disease. The role of chemotherapy, and/or radiotherapy, is still to be defined.

Aggressive behaviour of solid-pseudopapillary tumor of the pancreas in adults: A case report and review of the literature. *World J Gastroenterol* 2008; 14(6): 960-965 Available from: URL: http://www.wjgnet.com/1007-9327/14/960.asp DOI: http://dx.doi.org/10.3748/wjg.14.960

INTRODUCTION

Solid pseudopapillary tumor (SPT) of the pancreas was first reported by Frantz in 1959[1], and represents a rare tumor that occurs most frequently in young women (90%). The widespread use of imaging techniques, together with a better knowledge of the disease, has prompted a rapidly increasing number of case reports. A recent review of the English literature from 1933 to 2003 collected a total of 718 SPTs, including pediatric cases[2].

Although SPT is considered an indolent lesion with a low malignant potential and a favorable prognosis after surgical resection, some cases of locally infiltrating and metastatic variety, or recurrences after surgery, have been reported. Moreover, long-term survival is described even for metastatic disease, suggesting a widely variable and not clearly elucidated biology of this tumor.

We report a patient with an infiltrating SPT that underwent total pancreatectomy and wide vascular resection. The tumor recurred in the liver 32 mo after surgery and chemotherapy was started. Between 1986 and 2006, we observed 8 SPTs among 282 cystic tumors of the pancreas (2.8%), the remaining 7 patients were cured by surgery and are alive and disease-free (Table 1).

A literature review of infiltrating SPTs allowed us to find 25 patients with invasion of the portal vein and/or of mesenteric vessels, and 16 recent patients with tumor relapse after potentially curative resection.

CASE REPORT

A 49-year-old woman was admitted to another hospital

in February 2001 because of an 8 mo history of palpable abdominal mass. A 2-cm cystic lesion of the tail of the pancreas was detected by an abdominal ultrasonography 13 years ago, and interpreted as a pancreatic pseudocyst. Physical examination revealed a hard mass in the left upper quadrant of the abdomen. Routine laboratory tests including carcinoembryonic antigen (CEA) and CA 19-9 were within the normal range. A CT-scan showed a 10-cm abdominal mass with an irregular low density pattern in the body and tail of the pancreas. At laparotomy a neoplastic mass involving the body and tail of the pancreas, with encasement of the portal and superior mesenteric vein confluence, was found. A core biopsy of the mass was performed, but it was referred as non diagnostic. The tumor was judged unresectable. Soon after the patient was referred to our department, MRI showed a mass of about 8 cm in diameter with an irregular intensity both in T1 and in T2 enhanced-images, surrounded by a capsule (Figure 1). The splenic vessels were encased by the tumor, but the portal vein, superior mesenteric vessels, and celiac trunk were apparently free. A positron emission tomography with 18-fluorodeoxyglucose (^{18}FDG-PET) showed a peripheral, pathologic uptake with central absence of metabolism (SUV = 3.5). In the presumption of a cystadenocarcinoma of the pancreas the patient underwent explorative laparotomy. A thick-walled encapsulated mass, 10 cm × 10 cm in size, was found in the body and tail of the pancreas. There were no metastatic lesions in the liver or distant organs, but the portal-mesenteric vein confluence was infiltrated by the tumor. A pylorus-preserving total pancreatectomy with resection of the portal vein was performed. The mesenteric-portal vein was reconstructed with the interposition of the right internal jugular vein.

The postoperative course was uneventful and no adjuvant therapy was given. The patient was discharged from the hospital 16 d after surgery.

Histopathology

The pathological investigation showed a 10.0 cm × 10.0 cm × 9.5 cm pancreatic tumor partially demarcated by a fibrous capsule. Gross pathomorphology of the cut surface showed an inhomogeneous solid appearance with areas of extensive necrosis. Although the mass was partially encapsulated, it directly invaded the peripancreatic fat tissue and the muscular layer of the portal vein with no involvement of the resection margins. Microscopically, solid areas composed of monomorphic epithelioid cells showing venous invasion and a moderate cellular atypia without mitotic activity were noted. Characteristic pseudopapillary formations were frequently observed. Twenty-seven lymph nodes examined were free of tumor. Immunohistochemistry was uniformly positive for vimentin, alfa-1-antitrypsin and CD10 staining. Strong immunoreactivity was also found for neuron-specific enolase (NSE). Focal reactivity was detected for synaptophysin, while negative reactions were found for cytokeratins (pan-cytokeratin, CAM 5.2), CEA, progesterone and estrogen receptors.

On the basis of these characteristic morphologic and immunohistochemical findings, the diagnosis of locally invasive SPT of the pancreas was made.

Follow-up

Follow-up included clinical examination, routine laboratory tests, abdominal US and/or CT/MRI every 6 mo. Thirty-two months after surgery, abdominal CT showed multiple metastatic lesions throughout the entire liver (Figure 2). The greater lesions (from 1.0 cm to 2.5 cm) were present in segments Ⅳ, Ⅵ, Ⅶ, and Ⅷ of the liver. The patient was asymptomatic. A whole body ^{18}FDG-PET confirmed some areas of pathological metabolic activity in the liver. A percutaneous liver biopsy under US guidance was performed. The histology showed a metastatic SPT of the

pancreas. Immunoreactivity for estrogen and progesterone receptors was negative.

Radical excision of metastatic nodules was considered unfeasible, and chemotherapy was started. The patient received 6 cycles of weekly gemcitabine (1000 mg/m^2) and tolerated it quite well. Afterwards, different regimens of drugs were tested because of slow disease progression (size and number of liver metastases, lymph node metastases): 3 cycles of gemcitabine + irinotecan, 8 cycles of oxaliplatin + irinotecan + capecitabine, 6 cycles of gemcitabine + capecitabine, 2 mo of weekly 5-FU. Finally, from September 2006 until present, the patient received capecitabine (2000 mg/m^2). CT-scan showed stable disease, and the patient was alive and symptom free at the time we wrote this paper.

DISCUSSION

SPT is a rare neoplasm of the pancreas, accounting for only 1%-2% of all exocrine pancreatic tumors[3]. We observed 8 SPTs among a total of 282 (2.8%) cystic tumors of the pancreas from 1986 to 2006 (Table 1). SPT is generally considered a tumor with a low malignant potential, usually occurring in young females in their second or third decade of life[2,4]. Although resection of the tumor provides a 5-year survival rate of 97%, local recurrence or distant metastases can occur in a significant number of patients[4]. Moreover, in a minority of patients a locally advanced or metastatic disease is discovered at their initial presentation, as in our 49-year-old patient. However, when she was 36-year-old, a 2-cm cystic mass was incidentally discovered in the tail of the pancreas and misinterpreted as a pancreatic pseudocyst and no further investigation was made until the palpable abdominal mass was discovered. Therefore it is reasonable to believe that a SPT was present at least 13 years before the mass was discovered. The doubling time, based on the Schwartz' formula[5], was 677, a value between 240 and 765 d of the two other patients in whom the doubling time was reported[6]. This finding, together with the absence of mitotic activity, confirms the slow growing pattern of this neoplasm, but also the need of a regular follow-up for pancreatic cystic lesions left unresected.

At presentation, the tumor showed an infiltrative pattern invading a segment of the portal vein that was *en-bloc* resected with the entire gland in order to achieve tumor-free margins. Locally infiltrative SPTs of the pancreas occur infrequently. A recent review of the English literature until December 2003[2] showed that among 497 patients with data on invasion or metastases,

portal vein was involved in 26 patients (5%), other organs (spleen, colon, duodenum, *etc*.) in 44 (9%), but the details on treatment and outcome of these patients were not reported. We retrieved 13 patients[7-15] previously reported as "invasion of portal and/or mesenteric vein" by Mao *et al*[3], two of them[14] were actually "histological venous invasion" and were then excluded from further consideration. Fourteen patients reported after 1995 were also retrieved[16-28] for a total of 26 patients including our patient, with SPT involving vascular structures (Table 2). Liver metastases were also present in three patients[10,16,23], invasion of colon[22] or peritoneal dissemination[11] in one each. Seventeen patients[7,8,12,13,15,16,19-24,28] underwent vascular resection and reconstruction without operative mortality. Liver metastases were also removed in two patients together with the primary tumor[16,23]. One died of unrelated disease[15] and all the others are still alive: one after enucleation of liver metastasis 18 mo after pancreatic resection, one (our patient) with liver metastases. The mean and median survival periods of time were 36.9 and 36 mo (range 5-84). Nine patients[9-11,15,17,25-27] were unresectable because of vascular infiltration, liver metastases or peritoneal dissemination. The mean and median survival periods of time were 55.5 and 47 mo (range 8-156). Two of them died of disease after 47 and 99 mo, one died of unrelated cause after 71 mo and one is alive with disease after 60 mo. Based on these data, vascular resection seems not so useful, but we must consider a publication bias due to the usual earlier publication of the results of resective surgery when compared to palliative and explorative surgery or to no surgery at all. Unfortunately, the long term results of many patients who underwent vascular resection have not been reported.

Recurrence after apparently radical resection of a SPT can occur in 10%-15% of cases, and the liver is the most common site[2-4,16,29] (Table 3). Resection of liver metastases is possible if liver involvement is limited[16,23,32,34,36,37]. In our patient, the tumor recurred diffusely in the liver 32 mo after a R-0 resection. Unfortunately, radical excision of liver metastases was not possible, and the patient received chemotherapy with a substantially stable disease 77 mo after initial diagnosis and 45 mo after tumor relapse. The long term survival after appearance of liver metastases has been reported in some patients after surgical treatment[32,34,37], and even without radical treatment[17,39], because of the indolent nature of the disease. However, other patients died within 2 years from appearance of liver metastases[17,30,33,35-38]. Also the appearance of hepatic metastases varies greatly from patient to patient, from a minimum of 2[38] to a maximum of 168[35] mo. At present, there are no established clinical or histological criteria to predict the biological behavior of SPT. While invasion of blood vessels, perineural infiltration, invasion of adjacent structures, high degree of cellular polimorfism, and elevated mitotic rate are suggested to be associated with metastases and recurrence[3,11,14,20,27,33]. Absence of these features does not preclude malignant behavior[30,33,38]. Our patient showed only venous invasion and a moderate

cellular atypia without mitotic activity. In a retrospective study on 33 patients (11 suggestive of malignant potential), Kang *et al*[36] failed to find features able to predict SPT malignant behavior in the clinical setting, although both patients with metastasis and recurrence belonged to a patient group with histopathology suggesting malignant potential. Thus, all patients require long-term follow-up.

In our patient, several different regimens were used. However, we do not know if the long term survival is due to the chemotherapy, or due to the natural course of a less aggressive tumor. The usefulness of chemotherapy for patients with SPT is substantially unknown, although some anecdotal studies have reported its benefit[11,31,40,41] or non benefit[10,17,36]. Two cases of resectable tumor underwent chemotherapy with cisplatin and 5-fluorouracil[40] or gemcitabine[41], but in the latter patient previous treatment with fluorouracil and 50.4 Gy failed to decrease the tumor size. Radiotherapy is seldom used for unresectable tumor[11] or as an adjuvant after tumor resection[8]. Two cases of radio sensitivity in unresectable tumors[9,26] are reported.

Transcatheter arterial embolization (TAE) or chemoembolization (TACE) are seldom used[10,30,36]. One patient was reported to have significant reduction metastases in the right lobe[10], one died after the procedure[30], one remained unchanged[36]. Radiofrequency is also seldom used[35,36].

In conclusion, malignant SPT is a low grade tumor with a good prognosis. Adequate surgical intervention is necessary for the long term survival of patients. Whenever possible, aggressive and reiterative surgery is justified for locally invasive or metastatic SPT. Regular follow-up is mandatory for all patients having undergone potentially curative resection. Particular attention should be paid to the patients with tumors larger than 5 cm in diameter and/or with histology suggesting a possible malignant behavior. The role of chemotherapy, radiotherapy, TAE, TACE, radiofrequency is still under scrutiny. Careful follow-up also for unresectable pancreatic cystic lesions may prevent tumor progression.

Abstract

Duplications of the alimentary tract are uncommon congenital malformations that can present diagnostic difficulties. We report a rare case of a cystic colonic duplication in a female adult. Preoperative investigations were suggestive of pancreatic tumor. The diagnosis was established based on the histopathological examination of the resected specimen. We concluded that, though uncommon, intestinal duplication should be considered in differential diagnosis of abdominal mass.

INTRODUCTION

Duplications of the alimentary tract are uncommon congenital malformations that can occur anywhere in the tract, and are most commonly detected in childhood. Depending on the age of patient, localization, size and shape of the duplications, they may present a diagnostic challenge[1]. We report a rare case of a cystic colonic duplication in an adult mimicking a tumor of the pancreas.

CASE REPORT

A 43-year-old woman was admitted with a 2-mo history of abdominal pain and mass. Ultrasonography (US) and computerized tomography (CT) showed a cystic mass (Figure 1) in left upper abdomen. In laboratory studies, serum amylase level was elevated at 332 U/L (normal, 0-125 U/L). The preoperative diagnosis was pancreatic tumor and fine needle aspiration biopsy was not performed preoperatively. At laparotomy, a mass was found in the mesenteric border of the transverse colon attached to the colon and pancreas. A distal pancreatectomy was performed with resection of the cyst. On gross examination, the cyst was 6 cm in diameter and contained a serous fluid (Figure 2). Microscopically, the cyst was lined by ulcerated gastric mucosa, submucosa and muscular wall (Figure 3); pancreatic tissue was normal. The patient's pain improved following surgical resection of the mass.

DISCUSSION

Duplications of the alimentary tract are characterized by attachment to at least one part of the tract, a layer of smooth muscle and epithelial lining resembling some part of the tract[2]. These malformations are formed before differentiation of the lining epithelium, and therefore, are named depending on the associated part of the bowel and not according to the mucosal lining[3]. Gastric mucosa, for example, is frequently observed in the wall of duplications, irrespective of their site of origin in the alimentary tract[4]. The duplications are located on the mesenteric border of the associated native bowel, vary in size and shape (cystic or tubular) and communicate or not with the lumen of the adjacent bowel; the duplication of cystic type usually does not communicate with the lumen of the adjacent bowel and contains serous fluid[1]. In the present case, the duplication was cystic and there was no communication with lumen of the colon.

The diagnosis of intestinal duplication may be difficult and usually is not made preoperatively. The patient may remain asymptomatic or present with a variety of nonspecific signs and symptoms[5]. Similar to our case, these signs and symptoms usually include abdominal mass and pain, often confusing colonic duplication with

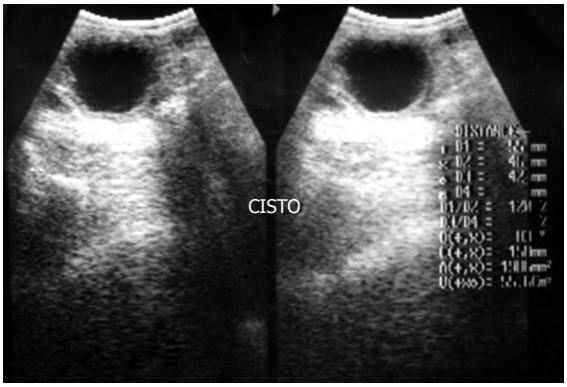

Figure 1 Ultrasonography demonstrating a cystic lesion.

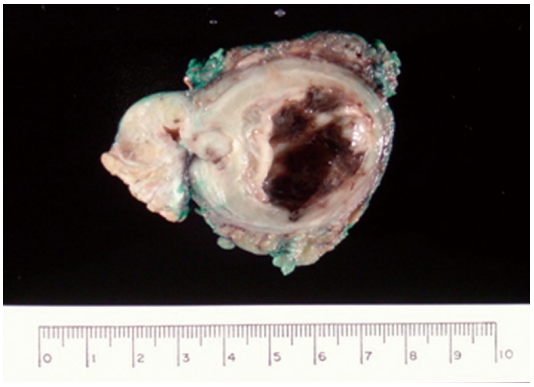

Figure 2 Surgical specimen including distal pancreas and the cyst.

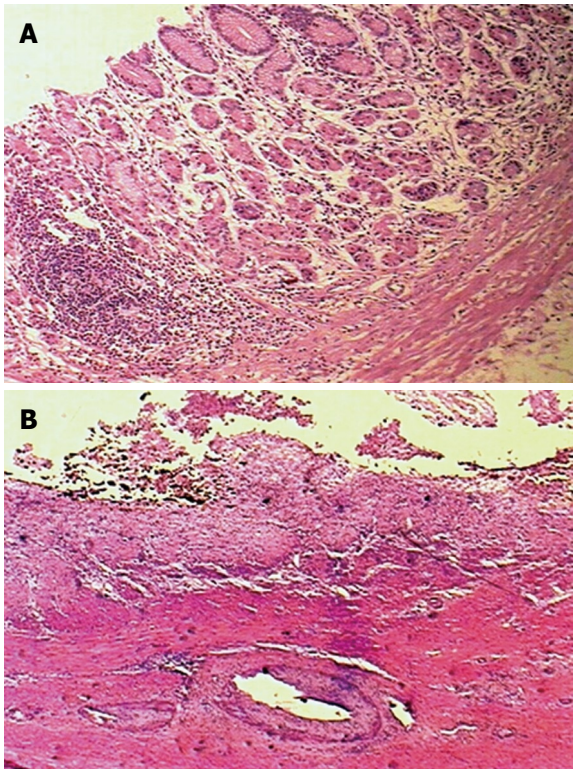

Figure 3 Histological section of the cyst wall. **A**: Ectopic gastric mucosa with gastritis (HE, x 100); **B**: Ectopic gastric mucosa with ulceration (HE, x 25).

other diagnoses. Intestinal obstruction[6], bleeding[7] and malignant transformation[8] are all recognized complications. Ulceration, perforation and peritonitis may also occur in cases with ectopic gastric mucosa[9], which is probably the cause of ulceration in our case. In addition, various urogenital and vertebral malformations have been reported but, in the present report, no associated congenital abnormality was observed[5].

In our case, elevated serum amylase, probably owing to compression of the pancreatic duct, associated with the findings of US and CT were suggestive of pancreatic cyst, but some image findings may be helpful in establishing preoperative diagnosis of intestinal duplication. On US, the duplication is characterized by "gut signature" which refers to the hiperechoic inner layer produced by the mucosa surrounded by a hypoechoic outer layer caused by smooth muscle[10]. Peristalsis of the cyst wall has also been noted on ultrasound scan[11]. Contrast barium enema may show communication between the duplication and the normal bowel, with opacification of the two colons[12]; the communication between the duplication cyst and main pancreatic duct may be seen by endoscopic retrograde cholangiopancreatography[13]. Besides this, technetium scan may demonstrate ectopic gastric mucosa in duplication[14].

Previous reports[15-17] have described gastrointestinal duplications mimicking pancreatic tumor. Among them, a case of transverse colon duplication in a child, like in our case, was not suspected before surgery[18]. The differential diagnosis includes in these cases, all neoplastic and non-neoplastic cystic lesions of the pancreas as intraductal papillary-mucinous neoplasm and pseudocyst[19].

The recommended treatment for duplication is complete resection. Sometimes resection of normal intestine must accompany removal of the lesion because of the intimate attachment of the common wall or because isolated resection would compromise blood flow to the adjacent intestine segment[20]. Generally, duplications of the cystic type are easily removed from their attachments to the surrounding tissues[21]. During surgery, diagnosis may be made based on the frozen sections examination of the wall of the duplication[22] but, in our case, it was not performed.

On histopathological examination, ectopic gastric mucosa showed chronic inflammation, lymphoid follicles and ulceration but no *H pylori* was identified in haematoxilin-eosin and Warthin-Starry silver stains. Previous reports about the role of *H pylori* in complications of the ectopic gastric mucosa in intestinal duplication were not found. But in most cases of ectopic gastric mucosa in Meckel's Diverticulum, *H pylori* also is not identified and seems that its presence is not essential to induce "heterotopic gastritis" and its complications[23-25]. In our case, the endoscopic examination was normal, and gastric biopsy was not performed.

In conclusion, we reported a case of cystic colonic duplication in an adult and illustrated the difficulties in making this rare diagnosis that should be considered in differential diagnosis of abdominal mass.

Abstract

The incidence of synchronous colorectal and lung cancer is relatively rare. We report three cases of patients with tumors located in the rectum, ascending colon, the lower lobe of the left lung, and the upper lobe of the right lung. Synchronous curative resection of the two lesions was performed in two patients, whereas colectomy was performed in an elderly patient with a poor lung function. Pathological examination showed the colorectal cancer was a moderately differentiated adenocarcinoma and the lung cancer was a squamous cell carcinoma. Surgical treatment and postoperative adjuvant chemotherapy for the lung cancer were different from those for colorectal cancer with pulmonary metastasis. If possible, radical resection should be performed for each cancer when synchronicity is found.

INTRODUCTION

Curative resection is regarded as a safe and effective treatment for colorectal cancer. The liver is the first and most common site of colorectal cancer metastases. Because of its abundant circulation, the lung is the second most common site of metastases[1]. Coya *et al*[2] reported that lung metastases develop in 10%-20% of patients with colorectal cancer. Using medical imaging methods (e.g. CT scan), pulmonary metastasis of colorectal cancer almost always shows multiple lesions in both lungs because of the distribution of primary tumor via the circulation. However, about 10% of pulmonary metastases consist of a single solitary pulmonary nodule[2]. When a patient with a current or previous colorectal cancer develops a solitary pulmonary nodule, surgeons always judge it to be a metastasis of colorectal cancer in the first instance. However, in some rare cases, patients can develop synchronous colorectal and lung cancer. In these patients, not only surgical resection but also chemotherapy regimens are quite different from those for colorectal cancer patients with pulmonary metastasis. Therefore, effectively distinguishing synchronous cancers from colorectal cancer with pulmonary metastasis has important implications in therapy for these patients. Although it is reported rarely, three patients with synchronous colorectal and lung cancer were admitted to our department between September 2004 and February 2006.

CASE REPORT

Case 1

A 63-year-old female patient presented with blood in stools for 4 mo. She had no prior family history of malignancy and no record of carcinogen exposure. A polypoid mass was found 4 cm from the anal verge at colonoscopy. Biopsy of the mass revealed a moderately differentiated adenocarcinoma. CT scan of the pelvic showed the thickening wall of rectum (Figure 1A). Serum carcinoembryonic antigen (CEA) was elevated to 7.9 ng/mL. No metastases were found in the abdomen or chest by CT scan. We performed low anterior resection, and microscopic examination of the surgical resection specimen showed a moderately differentiated adenocarcinoma (2 cm in diameter). The lesion infiltrated the proper muscular layer but not the lymph nodes or vessels. Immunostaining was positive for c-met, p53, p27, cd44, p170, ToPo-Ⅱ, and MMP-7. According to the National Comprehensive Cancer Network (NCCN) guidelines for rectal cancer, the tumor in this patient was classified as T2N0M0, and not treated with adjuvant chemotherapy after operation. Five months later during routine follow-up, serum CEA was elevated to 28.9 ng/mL. CT scan of the chest showed an irregularly shaped solid mass (3.5 cm in diameter) in the lower lobe of the left lung (Figure 1B), which was an adenosquamous cell carcinoma confirmed by biopsy. The mass in the lung was diagnosed as a metastasis of rectal cancer and a lower lobectomy of the left lung was performed. Microscopic

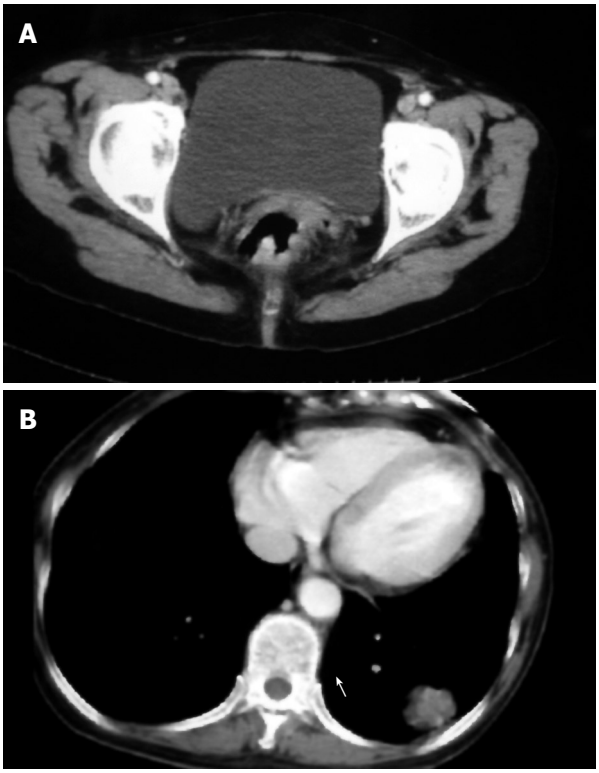

Figure 1 CT scan of the pelvic (**A**) and chest (**B**) showing the thickening wall of rectum and an irregularly shaped solid mass (3.5 cm in diameter) in the lower lobe of the left lung of case 1.

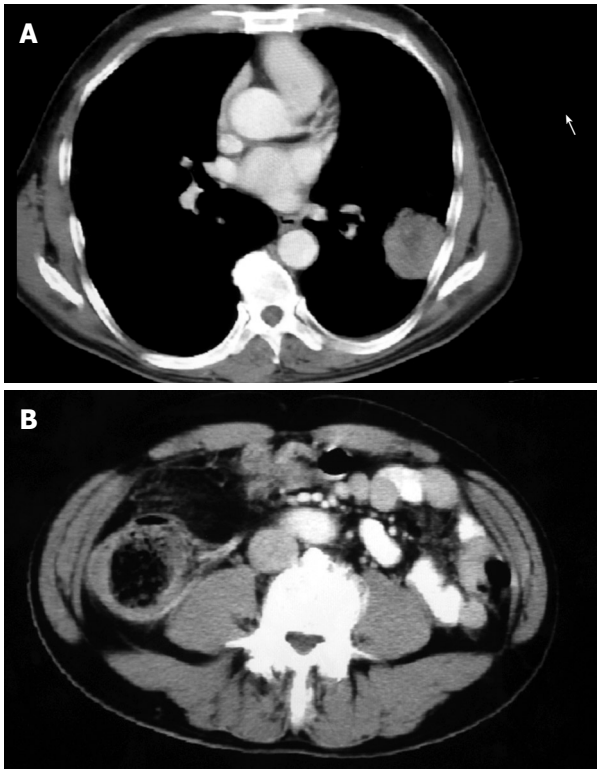

Figure 2 CT scan of the chest (**A**) and abdomen (**B**) showing an anomalous round solid mass in the lower lobe of the left lung and an intraluminal mass in the ascending colon with an irregular and stenotic lumen in case 2.

examination of the surgical resection specimen showed an adenocarcinoma (3 cm in diameter) with neuroendocrine differentiation. The lesion invaded the lymph nodes (7/13) and vessels. Immunostaining was positive for CK, EMA, and Syn, but negative for Vim. The final diagnosis was a primary lung cancer. Eighteen months after resection of the lung cancer, the patient died of multiple metastases of the lung cancer.

Case 2

A 60-year-old male patient was admitted for irritant cough in the previous three months. He had no family history of malignancy and alcohol or cigarette abuse, and his dietary habits were normal. CT scan of the chest showed an anomalous round solid mass in the lower lobe of the left lung (Figure 2A). The density of the mass was not uniform, and its margin was blurred. The mass was diagnosed as a primary lung cancer, and we decided to perform a radical lobectomy of the left lung. However, routine B-ultrasonography of the abdomen showed a mass in the right lower abdomen, colonoscopy revealed a polypoid mass in the ascending colon, obstructing the lumen, and a biopsy revealed a moderately differentiated adenocarcinoma. A CT scan of the abdomen showed an intraluminal mass in the ascending colon, the lumen was irregular and stenotic (Figure 2B). Serum CEA was elevated to 7.5 ng/mL. We diagnosed it as colon cancer with metastasis of the lung, and performed a right colectomy and lower lobectomy of the left lung on the same day (Figures 3A and 3B).

Pathological examination of the mass from the colon revealed a moderately differentiated adenocarcinoma, which

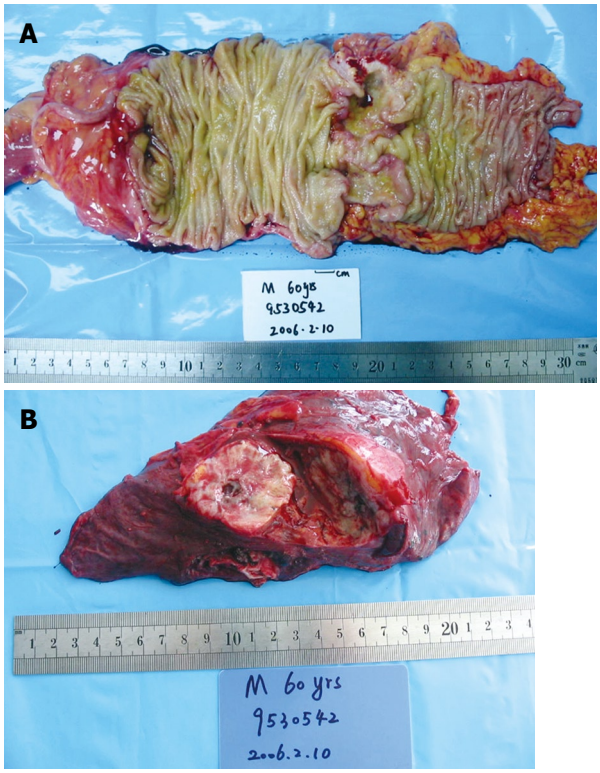

Figure 3 Surgical specimens of the colon cancer (**A**) and ascending cancer (**B**) from case three.

infiltrated the serosa but not the vessels or lymph nodes (0/12). Immunostaining was positive for CEA, CK20, p53,

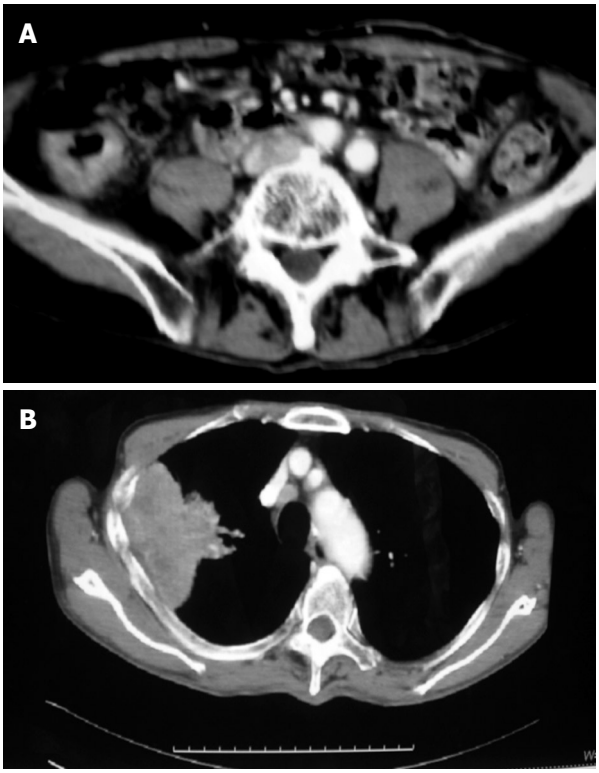

Figure 4 CT scan of the abdomen (**A**) and chest (**B**) showing a mass in the ascending colon and an irregularly shaped mass in the upper lobe of the right lung.

CDX-2, p27, p170, and Topo-Ⅱ, while negative for CK7, CD44, and TTF-1.

Pathological examination of the mass (3 cm in diameter) from the lung also revealed a moderately differentiated adenocarcinoma, invading the pleura and lymph nodes (1/11) but not the vessels. Immunostaining was positive for CEA, CK7, p53, CDX-2, and TTF-1, while negative for CK20. The final diagnosis was synchronous colon and lung cancer. After operation, the patient received chemotherapy (3 wk/cycle) with taxol (75 mg/m^2) and oxaliplatin (100 mg/m^2) on d 1, with a total of 6 cycles. The patient was still alive 11 mo after operation.

Case 3

An 81-year-old male patient had heme-positive stools for three months, and was difficult to pass stools for one week. He had no family history of malignancy and alcohol or cigarette abuse. Physical examination was normal, colonoscopy showed an ulcerous mass in the ascending colon, involving the hemi-cycle of the lumen, a biopsy revealed a moderately differentiated adenocarcinoma. B-ultrasonography of the abdomen showed multiple lesions in the liver, and a diagnosis of colon cancer with metastasis of the liver was made. CT scan of the abdomen showed a mass in the ascending colon (Figure 4A). A chest X-ray before operation demonstrated a mass in the upper lobe of the right lung. CT scan of the chest revealed an irregularly shaped mass (5 cm in diameter) in the upper lobe of the right lung, invading the pleura, enlarged mediastinal and hilar lymph nodes (Figure 4B). A CT-guided fine needle biopsy of the mass revealed a poorly differentiated squamous cell carcinoma. Serum CEA was 1.53 ng/mL, CYFRA21-1 and NSE were elevated to 22.90 ng/mL and 14.32 ng/mL. A pulmonary function test showed significant loss of ventilatory function. Since the patient could not tolerate a lobectomy of the lung and had incomplete obstruction of the colon, right hemi-colectomy and biopsy of the lesion on the liver were performed (Figure 5). Pathological examination of the colonic mass (4 cm in diameter) indicated a moderately differentiated adenocarcinoma, invading the serosa but not vessel or lymph nodes (0/5). The liver biopsy revealed a metastatic adenocarcinoma. Immunostaining was positive for c-met, p53, p27, p170, and Topo-Ⅱ, while negative for CD44. The final diagnosis was colon cancer with multiple metastases in the liver and synchronous primary squamous cell lung cancer. After operation, the patient received chemotherapy (3 wk/cycle) with taxol (175 mg/m^2) on d 1, 5-fluorouracil (5-FU) (500 mg/m^2) and CDDP (20 mg/m^2) on d 1-5, for 3 cycles. The primary lung cancer and liver metastases of the colon cancer were controlled well. The patient was still alive 8 mo after the operation.

Figure 5 Surgical resection specimens of the ascending colon.

DISCUSSION

Colorectal cancer is the most common cancer, and also most prone to blood-borne metastasis. The liver and lung are the most common sites of metastasis. About 50% of patients develop liver metastases and about 20% develop lung metastases. Therefore, when multiple pulmonary lesions are found in patients with a history of colorectal cancer, most physicians consider them as lung metastases. However, sometimes pulmonary metastases show up as a single solitary lesion. There are a few reports on colorectal cancer with primary lung cancer as a type of multiple primary malignant neoplasm (MPMN) the references is just the Evans *et al*[3]. Evans *et al*[3] investigated the incidence of primary lung cancer in 127 281 patients with colorectal cancer and found that the incidence of primary lung cancer is 0.6% (801 cases), while the incidence of synchronous colorectal and lung cancer is much lower. The pathogenesis and biological behavior of synchronous colorectal and lung cancer *vs* colorectal cancer with pulmonary metastasis are quite different, and so is their treatment. Therefore, when a single solitary pulmonary lesion is found in a colorectal cancer patient, it is important to distinguish between these two possibilities

for their appropriate surgical treatment and postoperative adjuvant chemotherapy.

Because of the rare incidence, physicians lack the knowledge of and vigilance towards synchronous colorectal and lung cancer. This situation may lead to misdiagnosis and delay in treatment. When synchronous colorectal and lung cancer are misdiagnosed as colorectal cancer with pulmonary metastasis, adjuvant chemotherapy for colorectal cancer is very unfavorable for the patient.

In our group, two male patients admitted to our department were initially suspected of having a tumor in a single organ. The 60-year-old male patient complained of irritating cough. CT scan revealed a mass in the lower lobe of the lung. Pre-operative abdominal ultrasound examination accidentally found the mass in the right lower abdomen because there were no clear abdominal symptoms, colonoscopy revealed a mass in the ascending colon and adenocarcinoma was confirmed by biopsy. The 81-year-old male patient was admitted to hospital because he felt weak and emaciated with a palpable mass in the right lower abdomen for one week. Colonoscopy found a mass in the ascending colon, which was confirmed as an adenocarcinoma by biopsy. However, conventional preoperative chest radiography showed a suspicious mass in the left upper lobe of the lung, which was confirmed as a squamous cell carcinoma by CT guided fine-needle aspiration. In the female patient with rectal cancer who received the radical LAR procedure, a moderately differentiated adenocarcinoma was confirmed by postoperative pathology. Five months after the operation, conventional chest radiography revealed a nodule in the left lung, which was considered a lung metastasis of rectal cancer and a lower lobectomy of the left lung was performed. The pulmonary nodule was a differentiated adenocarcinoma with neuroendocrine differentiation confirmed by pathology. In the three patients, the symptoms of secondary primary cancer found by conventional preoperative examination or postoperative review were relatively unobvious, suggesting that although the incidence of MPMN is relatively low, when the first primary cancer is found, the surgeon cannot simply be satisfied with a single diagnosis and meticulous systemic examinations of the patient are necessary to avoid misdiagnosis. Further examination of the suspicious lesions should be conducted. If necessary, biopsy can confirm the diagnosis.

When colorectal and pulmonary lesions are found synchronously in a patient, how to distinguish between the pulmonary lesion and primary cancer or the metastasis of colorectal cancer warrants attention.

First, a medical history is helpful for judging the characteristics of pulmonary lesions. Quint *et al*[4] evaluated 149 patients with extrapulmonary malignant neoplasm and solitary pulmonary nodule and found that a single solitary pulmonary nodule is more likely diagnosed as primary lung cancer than metastasis of other cancers in elderly patients or patients with a history of smoking. They also evaluated the characteristics of solitary pulmonary nodule in patients with a history of colorectal cancer and found the proportion of primary lung cancer and metastases of other cancers is statistically identical. Furthermore, they found that the longer the interval between the detection of primary colorectal cancer and solitary pulmonary nodule is, the more likely the diagnosis of primary lung cancer is. However, in our study, the three patients were non-smoker, and the interval between the detection of colorectal and lung cancer was less than six months.

Second, Quint *et al*[4] reported that analysis of nodule morphology may provide important information on the lesion etiology and a mass with a smooth margin can be an indication of a benign lesion or a metastasis, whereas a mass with an irregular or blurry margin may be theoretically suggestive of a new lung cancer. Except for patients with melanoma, sarcoma, and testicular carcinoma, the presence of mediastinal lymph node enlargement is strongly suggestive of a primary lung cancer because lymph node enlargement results from metastasis of a primary lung cancer. In our group, the margins of solitary pulmonary nodules in the three patients were all blurry and irregular. On this point, our results are in agreement with the literature reports. However, we found that only one patient had enlarged mediastinal lymph nodes, the other two did not.

Third, sometimes, the characteristics of a pulmonary nodule in a patient with colorectal cancer cannot be determined before operation. In this case, pathological examination of the surgical resection specimen becomes crucial. For example, tumors of different histological findings (e.g. carcinoma and sarcoma) may develop in the same patient. The diagnosis of synchronous MPMN is then without argument. In the 81-year-old male patient, pathology showed the rectal lesion was an adenocarcinoma, whereas the pulmonary lesion was a squamous cell carcinoma. In the female patient, pathology revealed that the rectal lesion was a moderately differentiated adenocarcinoma, whereas the pulmonary lesion was an adenocarcinoma with neuroendocrine differentiation invading the vessels and lymph nodes. Thus, a diagnosis of MPMN was conclusive for these two patients.

However, when similar histological results (e.g. adenocarcinoma) are found in colorectal and pulmonary lesions, the question is whether both lesions are primary cancer or the pulmonary lesion is a metastasis of the colorectal cancer. Microscopy of a conventional pathological section is not enough. Kummer *et al*[5] used immunohistochemical staining as an effective differential diagnosis method because primary lung cancer shows a CK7(+)/CK20(-) cytokeratin pattern while a metastatic adenocarcinoma shows a CK7(-)/CK20(+) pattern, and found that in their 102 tumor samples, the CK7/CK20 pattern was able to identify lung and colorectal adenocarcinoma in 95% of cases, suggesting that cytokeratin staining is a cost-effective screening tool. Others have reported the use of thyroid transcription factor-1 (TTF-1) for distinguishing between primary and metastatic lung adenocarcinomas[6]. TTF-1 is a common thyroid and peripheral lung antigen, positively stained in primary lung and thyroid adenocarcinoma, whereas metastatic adenocarcinomas from other sites do not express TTF-1. It was reported that over 75% of primary pulmonary adenocarcinomas show strong staining for TTF-1 and a further 11% show weak staining. In their series, apart from a new neuroendocrine tumor, none of the 106 non-

pulmonary adenocarcinomas showed staining for TTF-1, indicating that TTF-1 staining is useful in the differential diagnosis of pulmonary adenocarcinoma. The pathology of our 60-year-old male patient showed that colon and pulmonary lesion were a moderately differentiated adenocarcinoma. Therefore, immunohistochemical staining was performed for CK7, CK20 and TTF-1, to distinguish between primary and metastatic lung adenocarcinoma. We found that adenocarcinoma of the colon showed a CK7(-), CK20(+), TTF-1(-) pattern, whereas adenocarcinoma of the lung showed a CK7(+), CK20(-), TTF-1(+) pattern, indicating that it is a primary tumor. Recently, Takashi *et al*[7] reported that protein TA02 (napsin A), detected by two-dimensional polyacrylamide gel electrophoresis (2-DE), is a valuable marker for discriminating between primary and metastatic lung adenocarcinomas. Using monoclonal antibody to TA02, immunohistochemical staining for TA02 has greater specificity and sensitivity in distinguishing a primary from a metastatic lung adenocarcinoma than TTF-1.

Surgical treatment for patients with synchronous colorectal and lung cancer is quite different from that of colorectal cancer patients with pulmonary metastasis. Pulmonary metastases of colorectal cancer are always multiple lesions in both lungs which are unresectable. Chemotherapy or other palliative therapy is the first choice of treatment for such patients. Curative resection is performed only for patients with single or a few pulmonary metastatic lesions. For patients with synchronous colorectal and lung cancer, if the condition of the patient permits, synchronous curative resection of the two lesions is the first choice. Patient with a poor general state cannot tolerate synchronous curative resection, and the surgeon should first deal with the tumor with a poor prognosis that directly endangers the patient life.

According to the NCCN guidelines, 5-FU and leucovorin combined with oxaliplatin (FOLFOX) or CPT-11 (FOLFIRI) are the first-line chemotherapy regimens for colorectal cancer[8], and cisplatin or carboplatin combined with taxol or docetaxel (TP) or gemcitabine (GP) is the first-line chemotherapy regimen for non-small cell lung cancer[9]. Because few cases of synchronous colon and lung cancer have been reported, a postoperative chemotherapy regimen has not been explicitly specified.

After surgical resection of the synchronous colon and lung cancers in our 60-year-old male patient, we discussed the chemotherapy regimen with the pathologist and oncologist. According to the type of the two primary tumors and stages of pathology, with reference to the NCCN treatment guidelines, a combination of both chemotherapy regimens for primary tumor, a 3-wk/cycle regimen with taxol (175 mg/m^2) and oxaliplatin (100 mg/m^2) on d 1 was used. After six cycles, no recurrence was found in this patient.

Literature reports indicate that patients with MPMN have a better prognosis than those with a metastasis or recurrent lesion. Tichunsky *et al*[10] reported that when surgical resection combined with postoperative chemotherapy is performed for colorectal cancer patients with a secondary malignant tumor in another organ, the five-year survival rate is 49%.

Since our 83-year-old male patient had a poor lung function and was unable to tolerate lobectomy of the lung, only colectomy was performed. The other two patients underwent radical resection of both primary tumors. The female patient died of multiple metastases 18 mo after operation, while the 83-year-old male patient with a lung tumor survived for 12 mo and the 60-year-old male patient survived and was disease-free for 13 mo after operation.

Therefore, careful examination, early detection of multiple primary cancers, and active surgical approach can improve the therapeutic effects in MPMN patients.

In conclusion, the incidence of synchronous colorectal and lung cancer is relatively low. When the first primary cancer is found, a meticulous examination of every organ should be conducted until no other malignant neoplasm is found. When suspicious lesions are found, further examination should be performed immediately. If necessary, biopsy can reduce the probability of misdiagnosis and rule out metastatic lesions.

Synchronous radical resection should be performed when the condition of the patient permits. After radical resection, according to the pathological type and stage of the tumors, appropriate adjuvant chemotherapy should be given. The prognosis of synchronous colon and lung cancer is relatively good after careful treatment.

Abstract

Graft-verse-host disease (GVHD) is an uncommon fatal complication following liver transplantation (LTx). In mainland China, only six cases have been reported with a morbidity rate up to 1%-2%. Definitive diagnosis was achieved by molecular techniques (HLA typing or PCR-STR) in only two cases and the remaining cases were diagnosed based on typical clinical features with exclusion of other possible causes. All patients died of septic shock or multiple organ failure even after administration of increased corticosteroids and supportive therapy, and reduced immunosuppressive agents. In our center, two cases of GVHD were found among 128 (1.56%) patients. One case was diagnosed by detecting lymphocyte macrochimerism through DNA-STR. Both of them died even after aggressive treatment. In China, the incidence of GVHD is similar to that reported by foreign centers except for an extremely bad prognosis. Rapid diagnosis is crucial for a better prognosis. In China, only 37.5% of cases are diagnosed by molecular methods. We recommend detecting lymphocyte macrochimerism through DNA-STR to get a rapid diagnosis, and interleukin 2-receptor antibody (basiliximab or daclizumab) therapy seems to be a good choice for the disease.

INTRODUCTION

The rapid increase of liver transplantation (LTx) and the development of immunosuppressive agents are followed by an increased incidence of graft-verse-host disease (GVHD) after liver transplantation. GVHD is a rare but extremely severe complication from LTx. The incidence is about 1%-2% and the mortality rate over 75%[1,2]. Although the total number of LTx performed in 2005 reached 3500 in mainland China, less than 10 cases of GVHD after LTx have been reported and many cases were under-diagnosed because of poor clinical awareness and no qualified diagnostic methods. We review in this article the literature on the disease in China, including the incidence, clinical features, diagnostic methods, treatment and prognosis and report about our own experience on GVHD after LTx. This study was approved by the ethical committee of our hospital and conforms to the ethical guidelines of Helsinki Declaration.

CASE REPORT

We reviewed the records of 124 adults and 4 pediatric LTx in our organ transplantation center from December 2005 to December 2006, and found two patients with OLT associated GVHD (an incidence rate of 1.56%).

Case 1

Case one is a 50-year-old man admitted for liver cirrhosis secondary to hepatitis B and hepatocellular carcinoma (HCC). Before admission, the patient received regional therapy for HCC, including ethanol injection and radio-frequency ablation. And he also received chemotherapy (arsenious acid injection 10mg QD for 4 d) just before the operation because his waiting time was longer than expected. He received a modified Piggy-back procedure and two doses of daclizumab on post-transplantation d 1 and d 4 for induction. Donor's blood type was identical

to the recipient's. Postoperative immunosuppressant regimen consisted of tacrolimus and methylprednisolone. FK506 trough level ranged from 2.9 μg/L to 21.2 μg/L (mean value 11.7 μg/L) (Figure 1). The patient had an uneventful early recovery and could take care of himself. Liver function tests (LFTs), electrolytes, blood film and ultrasonography were all normal. Discharge would be made if he had not complained of fever and headache. Remittent fever persisted until the patient died. Rash appeared one day after fever, so did the constipation. Eruption was maculopapular, accentuated the abdomen at the very beginning and then developed into the back and neck but not palms and toes (Figure 2), subsequently oral ulcer and sore throat occurred one week later. Considering the possibility of drug rash, we discontinued all suspected drugs and gave an injection of dexamethasone. A biopsy of skin showed no classical pathological change of GVHD. The patient also presented with nausea and vomiting without gas and stool passing. The abdominal film revealed lower incomplete intestinal obstruction (Figure 3). Nasogastric suction was used without improvement. On post-transplantation d 40, upper gastrointestinal bleeding developed with severe nausea and vomiting. Pancytopenia appeared suddenly with white blood cell count dropping from 4500/μL to 330/μL within one day, platelet 170 000/μL and hemoglobin 77 g/L. Bone marrow cellular study showed aplastic anemia. We suspected GVHD and a blood sample was sent to laboratory for DNA PCR-short tandem repeat (PCR-STR) which confirmed the diagnosis (Table 1 and Figure 4).We initiated G-CSF injection (Filgrastim 300 μg BID) and increased steroids dosage (methylprednisolone 100 mg QD for 6 d, then tapered gradually). Broad-spectrum antibiotics, anti-fungals and IVIG were also used to prevent infection. Unfortunately, the patient died of sepsis and multiple organ failure 19 d after the first onset of disease. Figure 5 shows the post-transplantation clinical course.

Case 2

Case 2 is a 56-year-old man with end-stage liver disease secondary to HBV infection. He received chemotherapy preoperatively for tuberculosis infection of chest wall for 6 mo. Modified Piggy-back liver transplantation was performed and he was treated with the immunosuppressive agents tacrolimus plus corticosteroids. The patient had an initial uneventful recovery in post-transplantation first week with LFTs dropping to the normal range. From postoperative d 8, the patient suffered from acute rejection which rapidly recovered in 10 d after MMF and corticosteroid impulse therapy was added. The patient experienced unidentified remittent fever without chill,

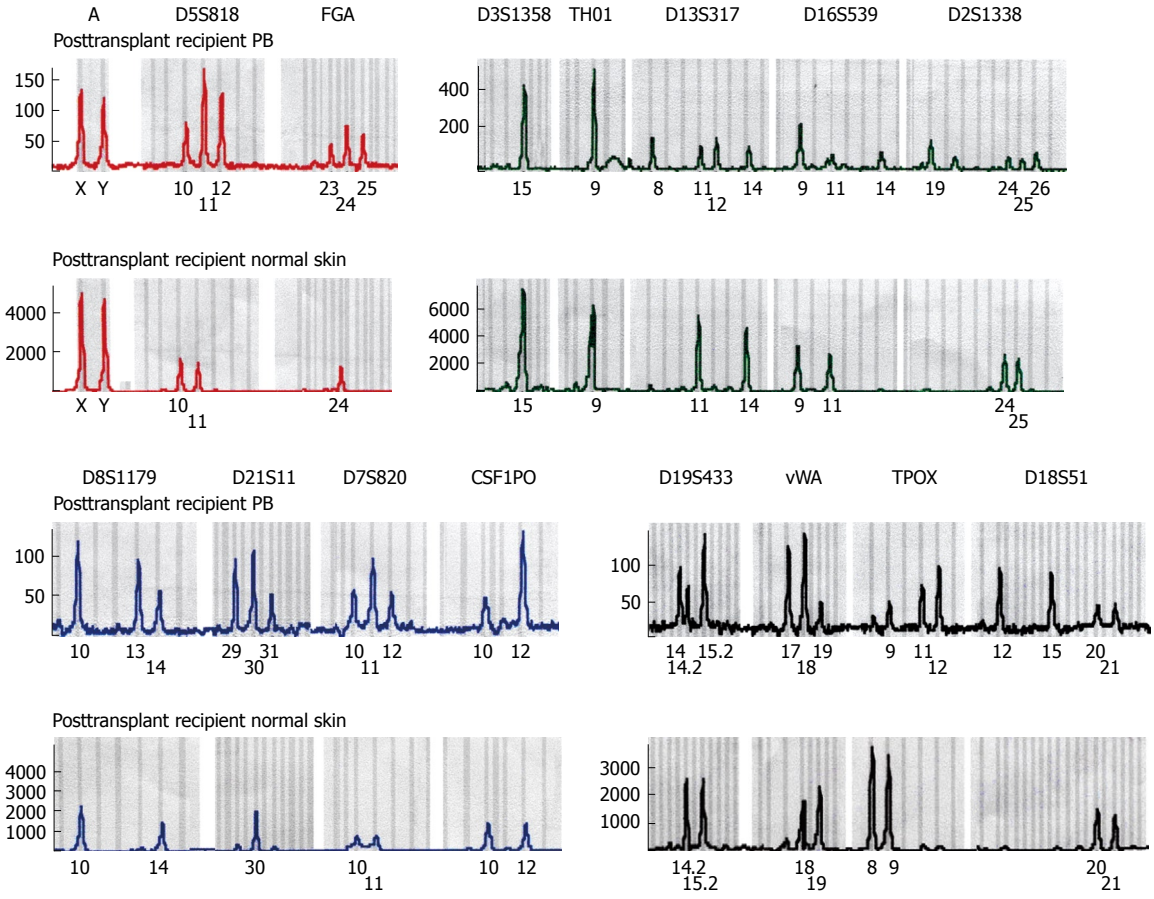

Figure 4 DNA-STR results of peripheral blood and normal skin in the transplanted recipients. The X axis corresponds to the size of amplified products as noted in base pairs. The Y axis illustrates the amount of fluorescent PCR products. Donor alleles are visible on makers D5S818, FGA D13S317, D16S539, D2S1338, D8S1179, D21S11, D7S820, D19S433, vWA, TPOX, D18S51.

accompanied by severe diarrhea, and maculopapular rash in face and neck. Since the patient had a history of tuberculosis infection, disseminated tuberculosis was suspected and he was started on chemotherapy. Multiple TB culture of urine and sputum (over 10 times respectively) and repeated bacterial culture and fungal culture of urine and peripheral blood showed no pathogen. Both CMV-Ag and EB-IgA were negative. And pancytopenia developed one week later. Then drug reaction and GVHD were suspected. The disease progressed even after withdrawing all suspected drug, corticosteroids therapy and supportive therapy were added, including broad-spectrum antibiotics, anti-fungals, G-CSF (Filgrastim 300 μg bid) and IVIG. Gastrointestinal bleeding occurred on post-transplantation d 59 and the patient died of pneumonia and multiple organ failure 5 d later. No definitive diagnosis was made at the end, however, GVHD was highly suspected because: (1) the clinical features were characteristic; (2) All symptoms started from post-transplantation wk 3, and no pathogen was found in the clinical course; (3) the disease progressed after withdrawing all suspected drugs; and (4) LFTs were within normal range when the disease developed and deteriorated at the end of clinical course.

DISCUSSION

GVHD is an increasing common fatal complication after LTx. The reported incidence of this complication varied from 0.1% to 2% with a high mortality rate of over 75%[1,2]. Its mechanism is still unclear although there are three known essential requirements[3]: (1) the graft must contain immunocompetent cells, (2) the recipient must be recognized as foreigner by the graft, and (3) the recipient must be unable to reject the graft before it mounts an effective immune response. A three-phase model is useful as a framework for understanding the pathogenesis of GVHD following LTx[4]. Phase 1 comprises the preparative regimen (chemotherapy and/or radiotherapy); phase 2 is the activation and proliferation of alloreactive donor T cells; and phase 3 is the effector phase. To date more and more research focuses on the cytokines network in the disease course. The clinical features consist of fever, rash, intestinal symptoms and neutropenia or pancytopenia which is undistinguished from drug reaction and viral infections. The diagnosis is based on the characteristic clinical presentations, histological proof of target tissue damage and molecular manifestation of invasion of recipient target tissue by donor T cells. The latter is most important because it is specific for GVHD and the remaining two may also be found in other diseases. The treatment regimen is generally disappointing, including corticosteroid therapy, reduced or increased immunosuppressant, prevention of infection and supportive treatment, although interleukin-2 receptor antibodies (basiliximab and daclizumab) are recommended

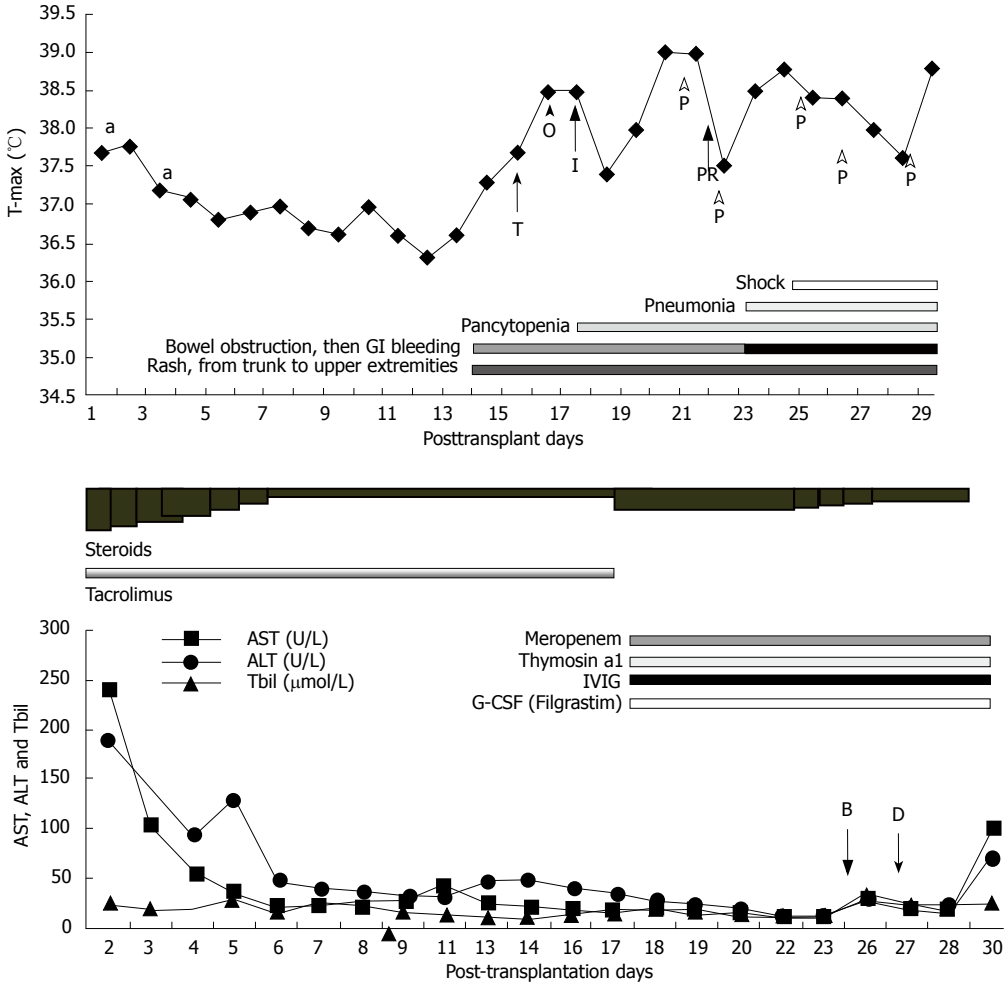

Figure 5 The posttransplant clinical course of case 1. a: Daclizumab, T: Tazime; O: Ornidazole; I: Isepamicin; P: Platelet; PR: Platelet and packed red blood cell; B: Biopsy of skin and bone marrow tapping; D: DNA-STR test of peripheral blood.

as an important treatment choice[5-7].

In a thorough search of Chinese language medical literatures and English language literatures by Chinese organ transplant institutions, we could find only two case reports by two different organ transplantation centers in mainland China (up to January 2007)[8,9]. Six cases with GVHD after LTx are summarized in Tables 2 and 3. Four cases were diagnosed by characteristic clinical presentation, the remaining two by PCR-SSP for detecting the peripheral lymphocyte macrochimerism. None of the six cases survived after empirical treatment.

The incidence and clinical presentations resemble that reported by others. We must take GVHD into consideration when a recipient presents with fever, rash, diarrhea and neutropenia or pancytopenia without known causes since the incidence of this disease is not so low as expected and the outcome is terribly bad. The diagnosis is difficult in the beginning of the clinical course, which poses a great challenge in treatment. In China, only 3/8 cases are diagnosed with specific molecular techniques which detect the lymphocyte macrochimerism or skin invasion by donor T cells, and 5/8 cases are diagnosed based on the classical clinical features with or without histology of rash skin biopsy and other causes. Without rapid molecular methods to confirm the diagnosis, early initiation of specific treatment is impossible and the poor outcome is unavoidable. No percentage of donor lymphocyte has been reported by other Chinese authors except our article, the so-called confirmed diagnosis may not be accurate because microchimerism is a common phenomenon within 3-4 wk after LTx[10]. The diagnosis needs to be supported by lymphocyte macrochimerism usually detected by HLA typing through PCR-SSP or by DNA PCR-STR with or without flow cytometric tests[11,12]. Fluorescent *in situ* hybridization (FISH) can also be used to confirm the diagnosis with limited function because unmatched gender is needed for this test. R.Domiati-Saad *et al*[13] compared different molecular techniques used for confirming the lymphocyte macrochimerism. They recommended: (1) Repeat HLA class I typing by serologic methods using purified T cells and/or class Ⅱ typing by PCR-SSP; (2) since PCR-SSP is too sensitive to normal levels, a level above 10% should be detected by serologic method, while PCR-SSP may detect levels around 1%; (3) STR method can be used to quantify the contribution of donor T cells when donor HLA antigens are detected, CD3 donor fraction above 20% is highly suggestive of GVHD; and 4) STR testing of CD3 or CD8 populations should be performed twice a week to monitor the patients' response to treatment. In our case 1, DNA-STR was used to detect lymphocyte macrochimerism. Lymphocytes of donor origin occupied over 60% of lymphocyte population and the diagnosis was confirmed although the patient did not have diarrhea and the histology of skin biopsy was not so clear. In our study, no patient survived after aggressive treatment. The extremely poor prognosis was attributed

Table 2 General data of the patients, onset of GVHD and diagnostic methods

Case	Gender	Age (yr)	Indication for LTx	Onset of GVHD	Diagnostic method
1	M	47	HCC	PD28 (rash)	Clinical diagnosis
2	M	58	HCC	PD27 (fever)	Clinical diagnosis
3	F	58	LC	PD25 (fever)	HLA typing by PCR-SSP
4	M	48	LC	PD21 (fever)	Clinical diagnosis
5	M	69	LC	PD21 (fever)	HLA typing by PCR-SSP
6	M	43	LC and HCC	PD27 (fever)	Clinical diagnosis

HCC: Hepatocellular carcinoma; LC: Lliver cirrhosis; HLA: Human leukocyte antigens; PCR-SSP: PCR-sequence specific primer; PD: Post-transplantation day.

Table 3 Treatment, time point of treatment and patient outcome

Case	Treatment	Time point of treatment after onset (d)	Outcome
1	Decreased immunosuppressant; G-CSF; IVIG	16	Death, infection
2	Decreased immunosuppressant; Methylprednisolone 80 mg × 10 d, then taper rapidly; G-CSF; IVIG	6	Death, gastrointestinal bleeding, infection, MOF
3	Decreased immunosuppressant; Methylprednisolone 80 mg × 10 d, then taper rapidly; G-CSF; ATG; IVIG	16	Death, gastrointestinal bleeding, infection, ARDS
4	Decreased immunosuppressant; Methylpredprednisolone impulse treatment, then taper; G-CSF	5	Death, gastrointestinal bleeding, infection, MOF
5	Discontinued immunosuppressant; Methylprednisolone impulse 480 mg/d, then taper; G-CSF; IVIG	6	Death, infection, gastrointestinal bleeding, respiratory failure
6	Non-specific treatment	?	Death, infection

G-CSF: Granulocyte colony-stimulating factor; IVIG: Intravenous immunoglobin therapy; MOF: Multiple organ failure; ARDS: Acute respiratory distress syndrome.

mostly to the failure in confirming early diagnosis and lack of specific treatment. The common treatment includes reducing or even withdrawing immunosuppressant, increasing corticosteroids and supportive therapy (broad-spectrum antibiotics, anti-fungals, antivirus, IVIG and G-CSF if neutropenia or pancytopenia develops). The dosage and duration of corticosteroids varied among different centers. No interleukin-2 receptor antibody (basiliximab or daclizumab) has been used as a treatment choice.

In summary, GVHD following OLT is under-diagnosed in China with a 100% mortality rate due to the poor awareness of the disease and lack of specific molecular techniques for diagnosis, and this is why we could only select the cases from 2005 to 2006. It is reported that HLA and age may increase the chance of GVHD development after OLT[1]. We believe that immunocompromise status of the recipients is important in the development of this disease because both of our patients received chemotherapy preoperatively. For the recipients suspected of having GVHD, we would suggest that: (1) when a recipient is presented with unidentified fever, rash, gastrointestinal symptoms and bone marrow failure, GVHD must be taken into consideration as the failed early diagnosis would endanger the patient with the edge of death; (2) biopsy of rash skin or damaged gut should be done as soon as possible, which can support the diagnosis of GVHD even though it is not specific for this disease. And HLA typing of both recipients and donors should be performed preoperatively so that lymphocyte macrochimerism can be detected by HLA typing through PCR-SSP or serologic methods. Quantified the contribution of donor T cells is crucial for establishing the diagnosis since lymphocyte microchimerism is a common phenomenon in the early stage after OLT. STR is a valid and rapid technique for this purpose; (3) when GVHD is highly suspected or confirmed and infection is ruled out, specific treatment should be initiated as soon as possible which includes corticosteroids, reduced immunosuppressive agents, prevention of infection and supportive therapy. Interleukin-2 receptor antibody (basiliximab or daclizumab) should also be tried since it has been reported to be successful in several cases.

ACKNOWLEDGMENTS

Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Lee Bouwman, Dr
Leiden University Medical Centre, department of surgery, Albinusdreef 2 PO Box 9600, 230 RC Leiden, The Netherlands

Filip Braet, Associate Professor
Australian Key Centre for Microscopy and Microanalysis, Madsen Building (F09), The University of Sydney, Sydney NSW 2006, Australia

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008
Istanbul

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG*, World J Gastroenterol ISSN 1007-9327/ CN 14-1219/R) is a weekly journal with a circulation of more than 15 707, published on the 7th, 14th, 21st and 28th of every month. WJG is a peer-reviewed journal. In 2007 the number of unique overseas visitors to the *WJG* website was 15 600, representing 123 countries worldwide. Original research, reviews, comments, and case reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted elsewhere simultaneously.

Publication model

WJG has a non-profit publication model, which is a combination of an Open Access and commercialized publication model (i.e. payment by a third party). This publication model has proven to be very effective. By 21st December 2007, the number of visitor hits to the *WJG* website reached 21 350 084. *WJG* advocates the tenet that research funding granted to scientists should be used to serve scientists so that high quality scientific articles can be published.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/ Science Edition, Index Medicus, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology* and *Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381901-600. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. font with ample margins. The preferred font is Book Antiqua. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/ analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve DOIs for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item for to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

The junction between the esophagus and the stomach is a specialized region, composed of lower esophageal sphincter (LES) and its adjacent anatomical structures, the gastric sling and crural diaphragm. Together these structures work in a coordinated manner to allow ingested food into the stomach while preventing reflux of gastric contents across the esophago-gastric junction (EGJ) into the esophagus. The same zone also permits retrograde passage of air and gastric contents into esophagus during belching and vomiting. The precise coordination required to execute such a complicated task is achieved by a finely-regulated high-pressure zone. This zone keeps the junction between esophagus and stomach continuously closed, but is still able to relax briefly *via* input from inhibitory neurons that are responsible for its innervation. Alterations of the structure and function of the EGJ and the LES may predispose to gastroesophageal reflux disease (GERD).

INTRODUCTION

The junction between the esophagus and the stomach is a specialized region, composed of the lower esophageal sphincter (LES) and its adjacent anatomical structures, the gastric sling and the crural diaphragm. Together these structures work in a coordinated manner to allow ingested food into the stomach while preventing reflux of gastric contents across the esophago-gastric junction (EGJ) into the esophagus. The same zone also permits retrograde passage of air and gastric contents into the esophagus during belching and vomiting. The precise coordination required to execute such complicated tasks is achieved by a finely-regulated high-pressure zone. This zone keeps the junction between esophagus and stomach continuously closed, but is still able to relax briefly via input from inhibitory neurons[1] that are responsible for its innervation. Alterations of the structure and function of the EGJ and the LES may predispose to gastroesophageal reflux disease (GERD) (Table 1).

ANATOMY, INNERVATION AND NEURAL PATHWAYS

At the EGJ, the LES and the crural diaphragm constitute the intrinsic and extrinsic sphincters, respectively. These two sphincters are anatomically superimposed and are anchored to each other by the phreno-esophageal ligament[2]. The LES is a specialized thickened region of the circular muscle layer of the distal esophagus, extending in humans over an axial distance of 2-5 cm. Sensory information from LES to the brain is conveyed by both spinal and vagal sensory afferents[3,4]. The spinal afferents have their cell bodies in the dorsal root ganglia at T1 to L3, and are believed to detect mainly nociceptive stimuli[5]. The vagal afferents, with their cell bodies in nodose ganglia, transmit non-painful sensory information to the brain stem where the central terminations synapse in the nucleus tractus solitarius[1]. The neurons of this nucleus are closely connected to dorsal motor nucleus of vagus nerve. The latter provides the motor innervetion to the LES and contains the efferent neurons that can either increase or decrease LES tone by stimulation of inhibitory or excitatory motor neurons in the myenteric plexus of the sphincter[1]. The excitatory myenteric neurons in LES are cholinergic in nature and act to stimulate muscarinic receptors on the smooth muscle[6]. Inhibitory motor neurons to LES are abundant and receive powerful

Table 1 Factors that regulate LES function

Factors that increase tLESRs	Factors that decrease tLESRs
Gastric distention	GABA agonists
Pharyngeal stimulation	Anticholinergics
High-fat meals	Opioid receptor agonists
CCK-A receptor agonists	Nitric oxide synthase inhibitors
	Endoscopic therapy
	Fundoplication

cholinergic nicotinic inputs from vagal efferents[6]. Although the vagal nerve innervates both excitatory and inhibitory myenteric motor neurons, vagal stimulation in experimental models invariably results in LES relaxation[7-9]. On the contrary, splachnic nerve stimulation relaxes the LES by activating adrenergic neurons, probably *via* nicotinic and non-nicotinic mechanisms of neural transmission, which in turn elicit beta-adrenergic inhibitory effects on the sphincter[10]. The inhibitory myenteric neurons innervating the LES are nitrergic in nature.

MECHANISMS OF GASTRO-ESOPHAGEAL REFLUX

The movement of gastric contents into the esophagus, or gastro-esophageal reflux, is due to a defective sphincter mechanism at the EGJ. An understanding of the two lower esophageal sphincters would lead one to expect weakness in either of the two to cause reflux. Indeed, some patients with reflux disease have a weak lower esophageal sphincter, some have a weak crural diaphragm, and some have both[2]. Reports suggest that it is possible to distinguish between two main mechanisms causing reflux: low basal sphincter pressure leading to free reflux, mostly occurring at night in the supine position, and increased frequency of transient lower esophageal sphincter relaxations with normal or increased resting LES pressure leading to reflux during the day in an upright position[11]. For example, in patients with mild-to-moderate (typically non-erosive) reflux disease, the pressures exerted by the lower esophageal sphincter[12] and the crural diaphragm[13] are normal. In such patients, the mechanism of reflux is due to transient spontaneous and inappropriate sphincter relaxations (tLESRs)[14].

A tLESR is a long period (lasting 10 to 60 s) of simultaneous relaxation of both the intrinsic distal esophageal sphincter and the crural diaphragm[2] representing a neural reflex that is mediated through the brain stem[2]. The efferent pathway for such relaxation is in the vagus nerve, and nitric oxide is the postganglionic neurotransmitter[15]. The mechanism of relaxation of the crural diaphragm is not known. Gastric distention and pharyngeal stimulation are two possible mechanisms by which the afferent stimulus that initiates transient relaxation of the LES may originate[16]. Gastric distention, upright and right lateral decubitus postures, and high-fat meals increase the frequency of such relaxation[16].

Diet

Patients with GERD are usually counseled on lifestyle changes that decrease the incidence of reflux, such as reducing fat in the diet. High dietary fat intake, particularly saturated fat, is associated with an increased risk of GERD symptoms and the likelihood of erosive esophagitis. These associations are independent of energy intake and therefore do not reflect a mere increase in total dietary intake. However, the effects are not completely independent of body mass index and are statistically significant only in overweight individuals. Other findings include a possible protective effect for high-fiber intake relative to GERD symptoms and a non-significant unfavorable trend for total energy intake[17].

An important role for dietary fat in causing temporary episodes of reflux is supported by studies of human volunteers that have shown increased frequency of tLESRs and increased esophageal acid exposure with high-fat consumption in both healthy volunteers[18,19] as well as patients with GERD[20,21]. Several food items have been associated with precipitating reflux symptoms in cross-sectional epidemiological surveys[22]. Previous case control studies reported a significant positive effect of fat intake on the rising rates of GERD and esophageal adenocarcinoma in the general population[23-25]. The fat content of the US food supply has increased 38% between 1909 and 1988[26]. These secular trends are consistent with the notion that high fat intake may be at least partially responsible for rising rates of esophageal adenocarcinoma, which were first observed in the late 1970s[17].

Sleep impairs esophageal acid clearance resulting in a prolongation of esophageal mucosal contact with acid[27]. Therefore avoiding meals two hours before lying down and sleeping with the head of the bed elevated prevents nocturnal acid reflux as nocturnal reflux *portends* a greater risk of erosive esophagitis and other GERD complications. Marked hyperglycemia has been shown to increase the frequency of tLESRs[28] and this may be a factor underlying the high rate of gastroesophageal reflux in patients with diabetes mellitus.

Pharmacologic control of LES

Since tLESRs represent the major mechanism responsible for episodic reflux, patients with GERD without mucosal disease or with mild erosive disease could potentially benefit from anti-tLESR therapy alone. Yet, this therapy could also be of value to treat some more severe forms of erosive esophagitis in combination with acid suppressants.

γ-GABA-b agonists: GABA is the major inhibitory neurotransmitter within the central nervous system, and GABA receptors are present at many sites within the central and peripheral nervous systems. GABA receptors are abundant pre-synaptically on vagal afferents in the dorsal medulla[29] and have been shown to inhibit neurotransmitter release in vagal nuclei[30]. Baclofen, a GABA analog, has recently been shown to be effective in reducing gastro-esophageal reflux[31,32]. Unlike acid suppressing agents, baclofen reduces the frequency of tLESRs and decreases the number of gastro-duodenal reflux episodes[33]. The drug has several advantages over other agents tested to date. It is available in an oral formulation and appears to have no adverse effects on other aspects of esophageal motor function, such as

basal LES pressure or acid clearance[34]. It also increases gastric pH in both GERD patients and controls even after repeated administrations. Since baclofen addresses a different factor in the pathophysiology of GERD, it can be used as add-on therapy in GERD patients with incomplete relief by acid suppression and/or in patients with more severe GERD[35]. However, baclofen has several limitations, including the need for frequent dosing due to its short half-life (3-4 h), and its limited absorption in the lower gastrointestinal tract, which precludes the development of a controlled-release formulation. The drug is nevertheless approved for treatment of spasticity, and its potential utility for the treatment of GERD has been demonstrated in clinical studies[36,37].

Recently, its active stereoisomer R-baclofen, has been incorporated into an experimental prodrug, XP19986. XP19986 overcomes the pharmacokinetic limitations of baclofen; it can be administered in a controlled-release formulation that allows for once- or twice-daily dosing. A recent Phase 1 clinical trial assessed the safety, tolerability and pharmacokinetics of XP19986 dosed once (QD) or twice (BID) daily in healthy adult volunteers. The trial was conducted sequentially in four separate cohorts of 12 subjects, three of whom received placebo per cohort. Following an up-titration period, the first cohort received 30 mg QD of XP19986 for seven days, followed by 30 mg BID for seven days and ending with a down-titration period. Subsequent cohorts received 60 mg and 90 mg QD and BID following a similar protocol. The final group of subjects received 120 mg QD only. Subjects were monitored for adverse events, and blood and urine were sampled to determine pharmacokinetic profiles and bioavailability. The trial demonstrated that repeated QD dosing of XP19986 resulted in sustained levels of R-baclofen in blood over 24-h, which reached steady-state within three days. Repeated BID dosing reduced the steady-state peak-to-trough ratio of R-baclofen by approximately 50% compared to QD dosing. Exposure to R-baclofen increased linearly with dose. This clinical trial also indicated that XP19986 was well tolerated. The most commonly reported adverse events were somnolence, dizziness and nausea that were generally mild in severity and generally increased in incidence compared to placebo with daily doses above 60 mg. In the 120 mg cohort, one subject experienced episodes of slurred speech and tremor, which are reported side effects of baclofen[38].

Cholecystokinin: The cholecystokinin A (CCK-A) receptor subtype is involved in the occurrence of tLESRs induced by gastric distension. Loxiglumide, a CCK-A antagonist, inhibits tLESRs and attenuates the fall in LES pressure following a meal, but has only modest effects on postprandial gastro-esophageal acid reflux[39].

Atropine: As mentioned earlier, the motor innervation to the LES and proximal gastric motor function is under cholinergic control[1]. Distension of the proximal stomach is a major stimulus for triggering tLESRs. Atropine, by acting centrally within the dorsal vagal complex, decreases the rate of tLESRs, despite the fact that it relaxes the proximal stomach and increases the degree of gastric distension under pressure-controlled conditions[40]. Anticholinergic agents are unlikely to have a therapeutic role because of the substantial deleterious effects on acid clearance[41].

Opioid receptor agonists: Opioid nerves have been demonstrated in the myenteric plexus of normal LES in humans[42] and opossum[43]. Morphine inhibits LES relaxation induced by swallowing and by balloon distension of the esophagus[44], thereby increasing residual LES pressure. On this basis, it seems likely that morphine might prevent reflux during tLESRs by rendering them incomplete. In one study[45] of patients with GERD, intravenous morphine inhibited tLESRs by 50%, and this effect was associated with a concomitant decrease in the rate of reflux episodes. Morphine also reduced the rate of tLESRs in normal subjects but by a lesser degree, and there was no decrease in the rate of reflux episodes, perhaps because the control rate was already relatively low. Interestingly, morphine did not appear to affect the residual pressure during tLESRs. The effect of morphine is completely blocked by naloxone, suggesting that it is mediated through μ-receptors. The effect of morphine is presumably central, because the peripherally active opiate loperamide does not influence the rate of tLESRs[46]. The effect of morphine on transient LES relaxations is dependent on the decrease in volume of the proximal stomach. Pharmacological interventions which decrease fundic volume should result in control of transient LES relaxation-mediated gastro-esophageal reflux[47]. Unwanted effects, such as addiction and constipation, are major barriers to the use of opioids[34].

Nitric oxide synthase inhibitors: Nitric oxide is the major post-ganglionic inhibitory neurotransmitter to the LES[34]. Nitrergic neurons are also present in the dorsal motor nucleus of the vagus, the source of pre-ganglionic motor neurons to the LES, and recent evidence suggests that there may be a novel nitrergic, pre-ganglionic, vagal pathway involved in LES relaxation[48]. It seems logical therefore, that blockade of nitric oxide synthesis might inhibit tLESRs. Indeed, in one study[49] the nitric oxide synthase inhibitor, NG-nitro-L-arginine-methyl ester (L-NAME), inhibited the rate of tLESRs, and this effect was reversed by L-arginine but not D-arginine. Other studies have found that, in normal humans, NG-monomethyl-L-arginine (L-NMMA) inhibited tLESRs induced by gastric distension by more than 75%[50], but reduced meal-induced tLESRs by only 25%[51]. Chronic administration of nitric oxide substrate, L-arginine, prolongs the postprandial increase in tLESRs[52].

The therapeutic potential of nitric oxide inhibition remains to be determined. At present, no orally effective agents exist. Inhibition of nitric oxide is associated with effects on motility in other areas of the gastrointestinal tract as well as in the cardiovascular system, urinary bladder, and respiratory tract. Unless specific and well-targeted antagonists of neuronal nitric oxide synthesis can be developed, unwanted side effects are likely to preclude this pharmacologic approach to the treatment of GERD[34].

Endoscopic methods that regulate LES function

Endoscopic endo-luminal anti-reflux approaches have

been recently introduced aiming to prevent acid reflux by construction of a functional or controlled barrier in the LES zone[53]. These endoscopic therapies offer the potential for significant symptomatic improvement while obviating many of the potential drawbacks associated with long-term medical therapy with acid suppressive or neutralizing medications, or the complications and side effects of anti-reflux surgery. These techniques include the delivery of radiofrequency energy to the EGJ (Stretta), injection of bulking agents (Enteryx), implantation of a bioprostheses into the LES (Gatekeeper), and suture plication of the proximal fundic folds (EndoCinch, NDOplicator)[54]. All these approaches are less invasive than antireflux surgery, and are performed in the outpatient setting. However, only limited data are available on their respective mechanisms of action[55]. Stretta increases the barrier between the stomach and the esophagus by either collagen deposition or disruption of vagally-mediated tLESRs[56]. The decrease in transient LES relaxation is presumably caused by either altering the mechanics of the cardia or interrupting afferent nerve transmission to the brainstem control mechanisms. Human and animal studies suggest that radiofrequency energy may decrease GERD symptoms[57] by decreasing the frequency of transient LES relaxations associated with reflux episodes, increasing the intra-gastric pressure needed to induce reflux, and hastening gastric emptying[58-61]. Another potential mechanism of the improved symptoms is decreased visceral sensitivity, as witnessed by the observation that the time needed to report symptoms during esophageal acid perfusion was significantly longer 6 mo after Stretta compared with baseline[62]. Although neurolysis with impairment of sensory afferent pathways is indeed a potential mechanism, other factors may include esophageal exposure to hydrogen ions, mucosal permeability, number and activation state of acid-sensitive nerve endings, and central processing of incoming sensory information. Radiofrequency energy delivery may influence several of these mechanisms as well as the compliance of the EGJ, increasing the resistance of the LES to a distending pressure[58] and decreasing the volume of refluxate during LES relaxations[57].

A variety of injectable agents have been studied for bulking the gastroesophageal junction, including Plexiglas microspheres, ethylene vinyl alcohol co-polymer (Enteryx), and hydrogel prosthesis (Gatekeeper). It is hypothesized that Enteryx leads to an increased barrier to reflux, whereas the hydrogel prosthesis may exert its effect by decreasing the aperture through which refluxate may flow, thus resulting in less proximal migration of the refluxate. Endoscopic plication is hypothesized to impede reflux by approximating tissue at or below the EGJ. The resulting effect of all these endoscopic techniques on LES pressure and 24-h intra-esophageal pH profiles is modest and complete normalization of acid exposure is uncommon. Nevertheless, all these techniques reduce GERD symptoms, improve quality of life, and decrease esophageal acid exposure and the need for anti-secretory medications[63,64].

Surgery

Laparoscopic fundoplication (LF) tightens the EGJ through a set of suture placations, resulting in significant increases in LES resting and post-deglutition relaxation pressures in both left lateral and upright positions and after gastric distention[65]. Post-fundoplication patients exhibit a diminished rate of tLESRs both at rest and during isobaric gastric distension compared with both normal controls and GERD subjects. Further, tLESRs in fundoplication patients are characterized by a higher residual pressure and a lower efficacy of facilitating gastric venting[66]. The reduction of tLESRs after a successful LF, is possibly due to disruption of the efferent vagal pathways to the LES. An adequate dissection of the EGJ alone prior to the actual fundoplication is sufficient to significantly disrupt the efferent pathway of this neural reflex, which may underscore the importance of performing a circumferential mobilization of the EGJ in all patients. Moreover, the wrap itself appears to further inhibit efferent neural impulses to the LES, thereby decreasing tLESRs[67].

Although the receptive field for triggering tLESRs is not completely clear[66], mechanoreceptors in the region of the gastric cardia are commonly implicated[16,68]. On the basis of studies in ferrets[69], two types of mechanoreceptors have been proposed: receptors in series with smooth muscle fibers, responding to wall tension variation, and receptors in parallel with smooth muscle fibers, responding to elongation of the gastric wall. Both types of receptors are activated during gastric distension[70,71]. However, after fundoplication the gastric cardia is situated within the fundic wrap, and has a reduced ability to stretch or elongate[72]. Thus an identical and constant distension stimulus likely leads to a diminished cardiac cross-sectional area compared with what would be observed if the same stimulus were applied in normal or GERD subjects. Reduced cross-sectional area would, in turn, result in decreased wall tension and elongation, thereby reducing the activation of both types of receptors potentially responsible for triggering tLESRs. Furthermore, because tLESR elicitation and gastric receptive relaxation are both mediated by the vagal nerve and since gastric accommodation is not affected by fundoplication[73], it is tempting to speculate that the vagal afferent field for triggering tLESRs is either independent of, or contained within a larger area responsible for elicitation of gastric receptive relaxation and that only the first is substantially reduced by fundoplication[66].

Postprandial epigastric fullness and bloating appear in 10%-80% of patients after Nissen fundoplication[74,75], and an inability to relieve this discomfort by belching is frequently reported[76]. Beyond the reduction in the number of tLESRs, a significant reduction of the percentage of tLESRs associated with a common cavity phenomenon is also found in fundoplication patients[77], and this potentially explains the frequently reported symptoms related to increased amounts of intestinal gas[66].

CONCLUSION

Given the increasing prevalence of GERD the efforts to regulate the EGJ and the LES continue along many fronts, pharmacologic, endoscopic, or surgical. Promising new ways to favorably alter the structure and function of the

EGJ and to reduce tLESRs may eventually replace acid suppression as the primary treatment of GERD or be used as adjunctive therapies.

Abstract

Venous thrombosis and thromboembolism appear to be increased in patients with inflammatory bowel disease. Although several acquired and genetic risk factors are known, about half that develop a thromboembolic event have no identifiable risk factor. Control of the inflammatory process is thought to be the key factor in risk reduction for thrombotic events. Prophylactic use of anticoagulants is not universally recommended, but possible use should be reviewed in an individual patient after evaluation of the risks, such as hemorrhage, compared to potential benefits. Particular consideration should be given if there has been a prior thrombotic event, if hospitalization will require surgery, or if an underlying coagulation disorder is present.

INTRODUCTION

Some studies[1-5], but not all[6], have suggested that there is a higher incidence of venous thrombosis and thromboembolism in the clinical course of inflammatory bowel disease, especially in hospitalized patients[5]. In a population-based study[3], the risk was estimated to be about three-fold. Moreover, thromboembolism appears to develop with inflammatory bowel disease at a younger age[7]. Finally, thrombosis has also been reported in children with inflam-matory bowel disease[8].

ACQUIRED RISK FACTORS

Several risk factors have been hypothesized to contribute to development of thrombosis with inflammatory bowel disease. Some include the inflammatory process per se (with associated reactive thrombocytosis)[9], prolonged immobilization, surgical treatment, fluid depletion, central venous catheters (often for nutritional support), hyperhomocyteinemia, vitamin deficiencies, smoking and use of oral contraceptives[10]. Although hemostatic changes are frequent in inflammatory bowel disease patients, the precise reasons for thromboembolism during the course of inflammatory bowel disease are not known. Importantly, approximately half of the patients with inflammatory bowel disease that develop a thromboembolic event have no identifiable risk factor[11].

A number of specific coagulation abnormalities have been recorded in patients with inflammatory bowel disease that may lead to a thromboembolic event. Increased levels of factors V, Ⅶ and Ⅷ, lipoprotein(a) and fibrinogen, all risk factors for thrombosis, may occur. In addition, a reduction in natural anticoagulant factors including antithrombin Ⅲ, protein C and protein S may develop[10]. Homocysteinemia, another prothrombotic risk factor, may result from reduced folate, vitamin B6 or vitamin B12 levels. All of these vitamins may become deficient in patients with inflammatory bowel disease because of drug interference, impaired intake or malabsorption. To date, however, no consistent relationship with homocysteinemia and development of thromboembolism has been defined in patients with inflammatory bowel disease[12,13]. Finally, changes associated with subclinical activation of the coagulation cascade[14-16] along with diminished factor XⅢ have been reported[16,17].

GENETIC RISK FACTORS

Genetic factors may also play a role in patients with inflammatory bowel disease and have been reviewed elsewhere[18]. Some may be more significant during remission or less active phases of inflammation[19]. Factor V Leiden causes the activated form of factor V to be relatively resistant to degradation by activated protein C with

increased generation of thrombin. Factor V Leiden is often detected with venous thrombosis, but, to date, no difference between patients with inflammatory bowel disease and those without inflammatory bowel disease has been defined[18]. In addition, a genetic variation of the prothrombin gene, *G20210A*, may be associated with deep venous thrombosis, but no definite association between this gene mutation and inflammatory bowel disease has been detected[18]. Also, a mutation in the methylenetetrahydrofolate reductase gene, *C677T*, may cause hyperhomocysteinemia but no differences have been detected between inflammatory bowel disease patients with thrombosis compared to controls with thrombosis[18]. Finally, an inherited Val34Leu factor XIII polymorphism has been found to be similar in inflammatory bowel disease compared to the general population[20,21].

MANAGEMENT OF THROMBOTIC RISK AND THROMBOSIS

The key to reduction of risk for thombotic events in inflammatory bowel disease patients appears to be the control of the inflammatory process *per se*. Also, some of the medications used to treat ulcerative colitis and Crohn's disease may directly inhibit platelet activation. These include 5-aminosalicylic acid (5-ASA)-containing medications (eg., mesalazine, olsalazine)[22], azathioprine and its metabolite, 6-mercaptopurine (6MP)[23] and infliximab[24]. Correction of altered nutrition and vitamin deficiencies is also important, especially if surgery and prolonged periods of immobilization are expected. Smoking should be discouraged and ongoing use of medications associated with increased thrombosis risk should be reviewed, specifically, oral contraceptives.

Use of prophylactic anticoagulation (eg., subcutaneous heparin) is not universally recommended, but should be considered on an individual patient basis after evaluation of the potential risks compared to the potential benefits of prophylaxis. In a New York series, the risk of death due to pulmonary embolism was recorded in a single patient after surgical treatment from among 1000 patients with Crohn's disease (0.1%)[25]. Such information must be balanced by the potential risk of heparin treatment in inflammatory bowel disease, including the risk of hemorrhage[26]. Certainly, a case can be made for prophylaxis if there has been a prior thrombotic or thromboembolic event, if the patient is hospitalized for surgery, or if an underlying inherited coagulation disorder is known to be present.

Heparin and drugs that specifically target platelets may play a role in the treatment of the inflammatory process per se owing to their anti-inflammatory properties[27,28], but their precise role needs further evaluation in clinical trials. If thrombosis does supervene during the course of inflammatory bowel disease, management should not be different from treatment of patients without inflammatory bowel disease. However, acquired risk factors should be minimized and exclusion of genetic defects, if tests are available, should be considered. Clearly, additional fundamental studies are needed to further elucidate the role of this inflammatory process and its mediators in the pathogenesis of thromboembolism followed by large multicenter clinical studies that might define the role of emerging treatments, including newer biologic therapies.

Recurrent acute pancreatitis: From the editor

This special issue of *World Journal of Gastroenterology* contains a number of articles focusing on acute recurrent pancreatitis, a clinical entity that still remains a complex diagnostic and therapeutic challenge in clinical practice. Recurrent bouts of pancreatitis mainly occur in a gland which shows a normal morphology of both parenchyma and pancreatico-biliary ductal system at the time of diagnosis, when standard investigation is used; however, the introduction of ultrasound endoscopy (EUS) in clinical practice allowed us to identify mild to moderate ductal and parenchymal alterations in a relevant part of these patients, suggesting a chronic process, observed either at the onset of the disease or during the follow-up period. These pancreatic abnormalities can either suggest the presence of an underlying chronic process which evolves over time with recurrent attacks of acute pancreatitis or can be the consequence of multiple, self-limiting acute inflammatory episodes that induce persistent lesions within the gland with time.

It is generally believed that, in about 70% of cases, a correct aetiological diagnosis is achieved by means of clinical history, laboratory tests, and standard imaging techniques, including CT scan, magnetic resonance cholangio-pancreatography (MRCP), and endoscopic retrograde cholangio-pancreatography (ERCP).

Another significant improvement in the knowledge of aetiological factors has been achieved by the introduction of sphincter of Oddi manometry, microscopic search for bile crystals in the collected bile, and testing for cystic fibrosis transmembrane conductance regulator-gene (CFTR) and other genetic (SPINK1, PRSS1) mutations. Sphincter of Oddi manometry and the search for bile crystals may improve the diagnostic yield in patients in whom both pancreatico-biliary junction and ductal system have a normal appearance. By these techniques, the major role played by the sphincter of Oddi dysfunction, either of the biliary or pancreatic segment, and bile sludge or microlithiasis has been revealed in the occurrence of idiopathic recurrent pancreatitis. However, manometric investigation of the sphincter of Oddi may fail to document some dysfunction in a progressively increased percentage of patients in type 2 and 3 dysfunction, respectively, when the need for definite findings is highest. The introduction of the Secretin test, done by either MRCP or EUS investigation, has been documented to provide a more detailed visualization of the pancreatic ductal system and indirect information about the sphincter of Oddi function, avoiding ERCP-related risks.

The aim of the present topic highlights is to provide a comprehensive overview of the current knowledge and unsettled issues on recurrent acute pancreatitis, including aetiological factors, diagnostic and therapeutic procedures, and clinical management.

Abstract

Whether acute recurrent pancreatitis is a chronic disease is still debated and a consensus is not still reached as demonstrated by differences in the classification of acute recurrent pancreatitis. There is major evidence for considering alcoholic pancreatitis as a chronic disease *ab initio* while chronic pancreatitis lesions detectable in biliary acute recurrent pancreatitis (ARP) seem a casual association. Cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation, hereditary and obstructive pancreatitis seem an acute disease that progress to chronic pancreatitis, likely as a consequence of the activation and proliferation of pancreatic stellate cells that produce and activate collagen and therefore fibrosis. From the diagnostic point of view, in patients with acute recurrent pancreatitis Endoscopic ultrasound (EUS) seems the more reliable technique for an accurate evaluation and follow-up of some ductal and parenchymal abnormalities suspected for early chronic pancreatitis.

THE CLASSIFICATION PROBLEM

Acute recurrent pancreatitis (ARP) is defined as the presence of at least two documented episodes of pancreatitis in a patient without chronic pancreatitis (CP) at imaging. The classification, however, is still a debated and controversial issue. Is this a relapsing acute disease with *restitutio ad integrum* of the pancreatic gland when the cause is eliminated or does it progress to chronic disease when the cause is not removed? There is also debate about whether ARP is actually a chronic disease *ab initio*, regardless of whether the cause persists, so that recurrences of pancreatitis are the clinical expression of CP in an early phase.

The term ARP was reported in the first Marseille classification of pancreatitis[1] that strictly divided ARP from CP. ARP is also reported in the classification of TIGAR-Ot[2], so-called from the acronym of the major predisposing risk factors, but was eliminated in the revised classifications of Marseille[3] and Marseille-Rome[4] because of the difficulties of distinguishing between a relapse of acute pancreatitis (AP) and an exacerbation of CP. In the paper referring to the Marseille-Rome classification the majority of the authors commented that the progression of acute to chronic pancreatitis was extremely uncommon.

In contrast, when pancreatitis is interpreted as a "hydraulic" obstructive problem, as a consequence of ductal lesions secondary to periductal inflammatory infiltrates[5] or post-necrotic scars[6,7], ARP can develop into CP over time if the cause of the disease persists. According to these pathogenic hypotheses, backed by experimental findings, the duration and grade of the pancreatic ductal obstruction are pivotal factors for differentiating the types of pancreatitis: partial, temporary pancreatic ductal obstruction (e.g. biliary lithiasis in humans) can lead to AP, while partial but long-lasting obstruction (e.g. stenosis of Oddi's sphincter or the Wirsung duct) is a cause of CP. When the ductal obstruction is complete and long-lasting (e.g. neoprene injection after surgery) the consequence is pancreatic atrophy.

AP, ARP and CP, according to this concept of "progression", are therefore not different diseases but different stages of the same disease. While biliary lithiasis and sphincter of Oddi dysfunction are the most frequent causes of AP and its recurrences, alcohol, smoking, genes and necrosis can all facilitate the progression from ARP to CP. A recent review[8] concluded that probably each of these classification concepts contains part of the truth, each providing one piece of the puzzle named pancreatitis.

ALCOHOLIC PANCREATITIS

Does acute recurrent alcoholic pancreatitis really exist or develop in a pancreas already affected by chronic disease? This question is still much debated. There are two schools

of thought: those who sustain that the relapses are an expression of acute disease that evolves to a chronic condition only if repeated over time, and those who maintain that the relapses are the expression of a chronic disease from the very start.

The differences are due to a different reading of the same results, the first more focused on the clinical picture, the second on histological data. The histological evidence of both acute necrotic and chronic lesions in tissue samples from six patients operated for a first acute attack of necrotic pancreatitis seems to support the idea that acute alcoholic pancreatitis develops in a pancreas already suffering from CP[9]. The same group[10] found similar results in 42 patients with alcoholic pancreatitis operated within two years of the clinical onset of the disease, investigated for histological evidence of diffuse or focal acute necrotic pancreatitis. However, only 7% of the patients had necrotic areas in the pancreatic tissue though all had the typical alterations of CP, such as perilobular and intralobular fibrosis, dilated inter- and intralobular ducts and protein plugs within the dilated ducts surrounded by periductal fibrosis, as already described several years ago[1]. These recent histological data confirm the detection of chronic lesions, in addition to the acute changes, previously reported in 12 patients with acute alcoholic pancreatitis, five of them at the first acute episode[11]. The authors suggested that alcoholic pancreatitis begins as a chronic disease and that the idea that repeated episodes of acute necrotic alcoholic pancreatitis cause CP is purely speculative since it is not supported by histology.

Ammann *et al*[12] conducted a sequential histological study of the pancreas in patients with alcoholic pancreatitis and concluded that it does progress from AP to CP, as suggested first by Comfort[6] and later by Kloppel[7], according to the "necrosis-fibrosis sequence" theory. Further evidence that recurrent pancreatitis can result in CP seems to come from studies of hereditary pancreatitis[13,14]. Whitcomb defined "sentinel acute pancreatitis (SAPE)" as an episode of sufficient severity to trigger the series of events that can lead to CP and proposed that a SAPE must occur for the development of CP[13].

The idea that ARP develops into a chronic disease has come under fire because, for example, in Amman's clinico-morphological study[12] all the patients had mild or severe chronic histologic pancreatic lesions already at their first histologic evaluation. Not only, the necrosis-fibrosis hypothesis fails to explain why some alcoholic patients with recurrent pancreatitis seem to progress to CP despite little evidence of necrosis and consequent pancreatic scarring.

The identification and characterization of stellate cells in the pancreas[15] and their vital role in fibrogenesis has led to further progress in understanding the pathogenesis of fibrosis in AP and CP, especially when caused by alcohol. The pathogenesis of alcoholic pancreatic fibrosis may involve two pathways: (a) a necro-inflammatory pathway involving cytokine release and activation of pancreatic stellate cells; (b) a non-necro-inflammatory pathway involving direct activation of stellate cells by ethanol through its metabolism to acetaldehyde and the generation of oxidant stress[16].

BILIARY PANCREATITIS

Gallstones are the most frequent cause AP. Sometimes patients with biliary ARP have ERCP findings of CP although it is not clear whether the two disease are linked by a cause-effect relationship (lithiasis as an etiological factor for CP) or by a casual association. While there are no data on patients with biliary ARP, abnormalities of the main pancreatic duct have been reported in about half of patients undergoing ERCP for biliary lithiasis[17].

In a retrospective study[18], biliary lithiasis in itself was not an etiological factor for CP: the frequency of main pancreatic duct abnormalities suggestive of CP by ERCP (increased diameter, irregular profiles, stenosis, dilation of the secondary ducts, cysts) was not significantly different in patients with biliary lithiasis, 68.4% of them with bile duct stones, and controls.

"GENETIC" PANCREATITIS

CFTR gene mutations

Recent studies showed that the frequency of cystic fibrosis transmembrane conductance regulator gene (CFTR) mutations is underestimated and that these have an important etiological and pathogenic role in so-called "idiopathic" ARP[19]. The proportion of patients with misdiagnosed cystic fibrosis and pancreatitis is 2%-3%, which is up to 75 times higher than the percentage reported in the general population [20,21]. The incidence of a single CFTR gene mutation in patients with ARP is significantly lower than in idiopathic CP (7.4% *vs* 15.5%, $P = 0.007$). However, it is difficult to establish whether a single CFTR gene mutation is sufficient to cause the clinical onset of pancreatitis or whether it is only a predisposing factor that needs some other cause, such as biliary microlithiasis, sphincter of Oddi dysfunction or other genetic mutations (SPINK1 or PRSS1).

CP patients with a single CFTR gene mutation had a significantly longer history of recurrent episodes of AP before the diagnosis of CP than patients with CP with a normal CFTR gene (7.4 ± 5.8 *vs* 2.1 ± 2 years; $P < 0.0001$). The mean interval between the first and second episode of AP was three years (range 1-6)[20].

The natural history of pancreatitis associated with CFTR gene mutation seems to be characterized by the onset of AP that can recur, leading, over variable periods of time, to dilation of the main pancreatic duct and hence to a diagnosis of CP. The CFTR gene mutation seems to confirm the possibility of progression from AP to CP as in hereditary and obstructive pancreatitis, but in a longer time than usually observed for CP[20]. However, it remains difficult to decide whether ARP associated with CFTR gene mutation is truly an acute condition that evolves to a chronic disease and not already chronic when it starts.

Hereditary pancreatitis (HP)

Patients with (HP) develop repeated episodes of AP that are indistinguishable from pancreatitis due to other causes. In their follow-up, patients with HP often present typical clinical, morphological and functional findings of CP, similar to those of the classic forms of CP[13].

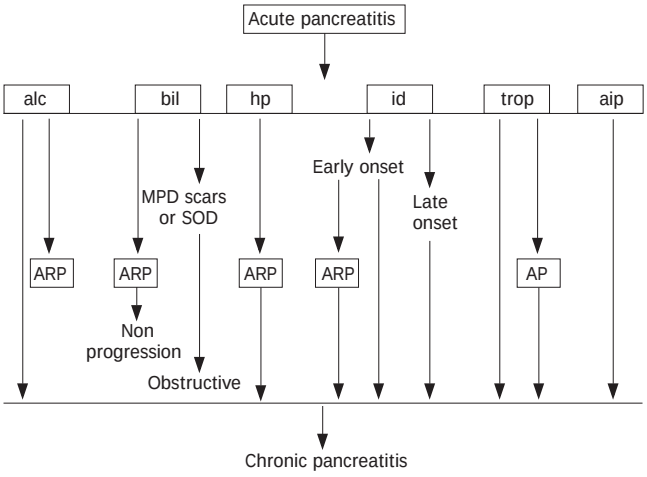

Figure 1 Progression from acute (AP) to chronic pancreatitis (CP). alc: Alcoholic; bil: Biliary; hp: Hereditary pancreatitis; id: Idiopathic pancreatitis; trop: Tropical; aip: Autoimmune; ARP: Acute recurrent pancreatitis; MPD: Main pancreatic duct; SOD: Sphincter of Oddi disfunction. (From ref. 23, with permission).

Recurrent attacks of mild or severe AP are more frequent in patients with the N9I mutation[22] and are associated with disabling pain, especially during the first years of the disease. Whitcomb thinks that the necrosis-fibrosis sequence hypothesis has some limitations in explaining why some patients with HP develop CP without significant pancreatic necrosis. He suggested that ARP might progress to CP when cytokines and chemokines are released from acinar cells during the acute episode and stimulate macrophages, with consequent infiltration, differentiation and/or proliferation of pancreatic stellate cells that produce collagen and therefore drive fibrosis. This might help explain the progression from ARP to CP as outlined by Uomo[23] (Figure 1).

IDIOPATHIC PANCREATITIS

An etiological diagnosis can be established in about two thirds of patients with ARP. No immediate cause is found in the remainder and ARP is considered "idiopathic". However, in some of these patients Endoscopic ultrasound (EUS) investigations have identified some ductal and parenchymal abnormalities suggesting a diagnosis of CP. Most of these patients had fewer than four EUS diagnostic criteria for CP[24] so that only those with pre-study high-risk conditions could be diagnosed as having CP. The recurrences of pancreatitis in these patients are quite likely the expression of a chronic disease *ab initio*. The frequency of the diagnosis of CP in patients with ARP, on the basis of EUS criteria, ranges from 10% to 30%[25,26]. Prospective randomized studies on ARP patients and controls, matched for sex and age, are therefore still needed to further verify the value of these criteria for this diagnosis.

In conclusion, the classification of ARP is still open to discussion. When CP is present, the diagnosis can usually be established on average almost five years after the second episode of AP. Episodes of pancreatic necrosis and gene mutations are suspected risk factors for the progression from ARP to CP, which may explain why, when genetic tests are available, the rate of ARP patients with a diagnosis of CP is higher.

Abstract

In this review article, we will briefly describe the main characteristics of autoimmune pancreatitis and then we will concentrate on our aim, namely, evaluating the clinical characteristics of patients having recurrence of pain from the disease. In fact, the open question is to evaluate the possible presence of autoimmune pancreatitis in patients with an undefined etiology of acute pancreatitis and for this reason we carried out a search in the literature in order to explore this issue. In cases of recurrent attacks of pain in patients with "idiopathic" pancreatitis, we need to keep in mind the possibility that our patients may have autoimmune pancreatitis. Even though the frequency of this disease seems to be quite low, we believe that in the future, by increasing our knowledge on the subject, we will be able to diagnose an ever-increasing number of patients having acute recurrence of pain from autoimmune pancreatitis.

INTRODUCTION

In 1961, Sarles *et al*[1] reported the case of a non drinker patient suffering from pancreatitis associated with hypergammaglobulinemia. The authors hypothesized that the disease in this patient was an autonomous pancreatic disease of autoimmune origin. After this report, other authors around the world reported similar cases and they named the disease in several manners: chronic pancreatitis with diffuse narrowing of the pancreatic duct, primary inflammatory pancreatitis, non-alcoholic duct destructive chronic pancreatitis, lymphoplasmacytic sclerosing pancreatitis, granulomatous pancreatitis, idiopathic tumefactive chronic pancreatitis, and sclerosing pancreatocholangitis[2,3]. In 1995, Yoshida[4] suggested the term "autoimmune pancreatitis" for this disease and, therefore, this term has become largely accepted for pancreatic disease of an autoimmune origin. In the last 10 years, there have been an increasing number of cases reported in Japan and Europe[5]. In this review article, we will briefly describe the main characteristics of autoimmune pancreatitis and then we will concentrate on our aim, namely, evaluating the clinical characteristics of patients having recurrence of pain from the disease.

Incidence

At present, the exact incidence of the disease is not known. The only available data are those reported in Japan and in Italy. In these two countries, the estimated incidence of autoimmune pancreatitis is quite similar, 4.6% and 6.0% in Japan and in Italy, respectively[5] and we are awaiting data from the United States as well as from other countries in order to define the real incidence of the disease around the world. Autoimmune pancreatitis seems to have a preference for the male gender; in fact, about 80% of the cases described are males[5]. However, a geographic variation may be observed because, in Italy, the male: female ratio is 1:1. At diagnosis, the patients were more than 55 years of age[5]. Diabetes mellitus is present in about half of the patients[5].

Pathogenesis

From a pathological point of view, the disease is characterized by diffuse or focal pancreatic swelling with a narrowing of the pancreatic duct and/or common bile duct and the histological hallmark of this type of pancreatitis is lymphoplasmacytic infiltration, especially concentrated on the pancreatic ducts[6-8]. Some authors have defined autoimmune pancreatitis[9] as the simultaneous involvement of the pancreas, the salivary glands and the liver (primary biliary cirrhosis) by means of an immune-mediated inflammatory process. Thus, the still open question is the differentiation of autoimmune pancreatitis as a primary or a secondary disease based on the absence or presence of other autoimmune diseases.

Clinical aspects

From a clinical point of view, patients with autoimmune

pancreatitis rarely complain about the typical severe abdominal pain of pancreatitis and are usually hospitalized for painless jaundice[10]; other symptoms of autoimmune pancreatitis include non-specific mild abdominal pain and weight loss. The diagnosis is sometimes quite intriguing because the disease may be mistaken for pancreatic cancer[11].

Laboratory data

Laboratory analysis is undergoing continuous evolution. Serum amylase and lipase may often be normal or a mild elevation of the serum pancreatic enzymes may be observed, and in only a few cases is there a marked elevation of these pancreatic damage markers[12]. Hypergammaglobulinemia and IgG serum increase have been reported in percentages ranging from 37% to 76%[13,14]. Japanese authors have claimed that elevated serum levels of IgG4, a subtype of IgG, are a biochemical hallmark of autoimmune pancreatitis[15]; however, other authors have recently questioned the specificity of the IgG4 because elevated IgG4 levels are present in patients suffering from pancreatic carcinoma and other types of chronic pancreatitis[5].

Non-specific autoantibodies, such as antinuclear antibodies, antimitochrondial antibodies and so on have a low sensitivity in diagnosing autoimmune pancreatitis; the detection rate of specific antibodies such as antilactoferrin antibodies and anticarbonic anhydrase Ⅱ antibodies have not been widely assessed in clinical setting because they require a special laboratory for their measurement which is available to only a low number of clinicians. A number of groups have tried to find other laboratory indicators of autoimmune pancreatitis and evaluation of the alleles of major histocompatibility complex genes seems to be a promising tool for identifying patients susceptible to autoimmune pancreatitis. One report mentioned that DRB1*0405 and DQB1*0401 are significantly more frequent in patients with autoimmune pancreatitis when compared to chronic calcifying pancreatitis[16]. At the present time, however, further studies are required to evaluate the value of each laboratory indicator and to find a more reliable one.

Imaging evaluation

Imaging evaluation is essential in the diagnosis of autoimmune pancreatitis[17]. Ultrasound is often the first imaging technique to be utilized in a patient with obstructive jaundice or with upper abdominal pain and a hypoehoic diffuse swelling in the pancreas (sausage-like appearance), or a focal swelling of the pancreas simulating a neoplastic lesion can be observed as well as a dilation of the extrapancreatic bile duct, secondary to an involvement of its intrapancreatic portion. Contrast-enhanced ultrasonography can successfully visualize fine vessels in pancreatic lesions and may play a pivotal role in the depiction and differential diagnosis of pancreatic tumors. In particular, some Authors have analyzed the enhancement of focal pancreatic lesions and it has been shown that, while most of the inflammatory pancreatic masses show a pattern of enhancement similar to the normal pancreatic gland ("isovascular"), a focal pancreatic tumor is hypovascular to the surrounding normal parenchyma At both computed tomography and magnetic resonance imaging, a focal or diffuse swelling of the pancreatic gland can be observed. Dynamic imaging at computed tomography or magnetic resonance imaging shows a delayed enhancement of the segments of the gland, which are involved. In some cases, minimal peripancreatic stranding suggesting inflammation can be seen. Moreover, a capsule-like smooth rim can be observed which is hypodense on computed tomography and hypointense on T2 weighted images, showing delayed enhancement on dynamic imaging. This is thought to correspond to an inflammatory process involving peripancreatic tissues and appears to be a characteristic finding of autoimmune pancreatitis. Pancreatic calcifications are rarely seen in autoimmune pancreatitis. Involvement of the main pancreatic duct and the biliary duct is well-described in the literature. Endoscopic retrograde cholangiopancreatographic criteria for the diagnosis of autoimmune pancreatitis include diffuse irregular narrowing of the main pancreatic duct and abnormalities which normalized after steroid therapy. The same alterations can be observed at MR cholangiopancreatography. The invasion of vessels, vascular encasement, mass effect and fluid collections are absent in autoimmune pancreatitis.

Diagnostic criteria

The diagnostic criteria currently used for autoimmune pancreatitis are those proposed by the Japan Pancreas Society[18] and are reported in Table 1; interestingly, the criteria do not include symptoms or common laboratory findings as they are not specific to autoimmune pancreatitis[12,19]. Italian criteria include some differences with respect to the Japanese diagnostic criteria (Table 2)[5] such as the association with other autoimmune diseases and the response of the disease to steroid treatment. Korean researchers utilize a third classification which takes into account the Japanese and the Italian diagnostic criteria (Table 3)[20]. Furthermore, a fourth classification system has been proposed from the same Korean researchers (Table 4)[20]. It seems that there is a need for a classification system for such a rare disease; therefore, an international consensus statement releasing widely accepted guidelines for autoimmune pancreatitis would be welcome.

Open questions

The open question is to evaluate the possible presence of autoimmune pancreatitis in patients with an undefined etiology; in fact, a recent study has reported that clinical or biochemical autoimmune stigmata are present in 40% of patients with idiopathic chronic pancreatitis and, therefore, autoimmune mechanisms may be frequent in idiopathic pancreatitis[21]. We also need to know the possible cause of failure of steroid therapy in some patients; finally, we need to evaluate the reason why some patients experience more attacks of pain in a disease characterized by a painless course. We carried out a search in the literature in order to explore this latter issue.

Table 1 Diagnostic criteria for autoimmune pancreatitis released by the Japan Pancreas Society

Criteria	Definition
Ⅰ Imaging criterion	Diffuse narrowing of the main pancreatic duct with an irregular wall (more than 1/3 length of the entire pancreas) and enlargement of the pancreas
Ⅱ Laboratory criterion	Abnormally elevated levels of serum gammaglobulin and/or IgG, or the presence of autoantibodies
Ⅲ Histopathologic criterion	Marked lymphoplasmacytic infiltration and dense fibrosis

For diagnosis, criterion Ⅰ must be present, together with criterion Ⅱ and/ or Ⅲ.

Table 2 Italian diagnostic criteria for autoimmune pancreatitis

Criteria	Definition
Criterion Ⅰ	Histology and cytology
Criterion Ⅱ	Association with other postulated autoimmune disease
Criterion Ⅲ	Response to steroid therapy

One or more criteria must be present in order to diagnose autoimmune pancreatitis.

DEFINITION OF RECURRENT PANCREATITIS

For the aim of this study, we defined acute recurrent pancreatitis as the presence of an attack of pancreatic pain in patients with proven autoimmune pancreatitis.

SEARCH LITERATURE PROCEDURE

On August 1st 2006, we performed a search using three different data bases (MEDLINE, Web of Science and Scopus) in order to find the data existing in the literature on the presence of recurrent pancreatitis in patients with autoimmune pancreatitis. The terms "recurrent pancreatitis" and "autoimmune pancreatitis" were searched as topics for MEDLINE, as Topic terms (TS) for Web of Science (WoS) and as article titles, abstracts and keywords containing the two terms for Scopus. One-hundred and twenty-six papers on MEDLINE, 15 on WoS, and 14 on Scopus were found. Only papers regarding studies carried out on humans, in English and in full text were considered. Fourteen duplicate papers were found among the various databases; 10 of these were present simultaneously in MEDLINE, WoS and Scopus, three were present in both Scopus and WoS while the remaining one was present in both MEDLINE and Scopus. One-hundred and thirty-one papers were found. Of these, 24 papers were excluded because they were review articles[4,12,22-43] and one was an editorial letter to the editor not reporting original data[3]. The remaining 106 original papers were considered for the purpose of this study. Of these 106 original papers, 18 were excluded because they reported data not useful for the aim of this study[44-61]. Therefore, 88 studies satisfied the aim of our study; however, 79 of these papers do not report data on the recurrence of acute pancreatitis in the follow-up of patients with autoimmune pancreatitis[6,14,62-138]. Therefore, 9 papers were evaluated for the purpose of this study[13,139-146].

Table 3 Korean diagnostic criteria for autoimmune pancreatitis released by the Asian Medical Center

Criteria	Definition
Criterion Ⅰ	Pancreatic imaging (essential): (1) CT: Diffuse enlargement (swelling) of pancreas and (2) ERCP: Diffuse or segmental irregular narrowing of main pancreatic duct
Criterion Ⅱ	Laboratory findings: (1) elevated levels of IgG and/or IgG4 or (2) detected autoantibodies
Criterion Ⅲ	Histopathologic findings: Fibrosis and lymphoplasmacytic infiltration
Criterion Ⅳ	Response to steroids

Definite diagnosis: Criterion Ⅰ and any of criteria Ⅱ-Ⅳ.

Table 4 A proposal of revised Korean diagnostic criteria for autoimmune pancreatitis

Criteria	Definition
Criterion Ⅰ	Pancreatic imaging (essential): (1) CT: Diffuse enlargement (swelling) of pancreas and (2) ERCP: Diffuse or segmental irregular narrowing of main pancreatic duct
Criterion Ⅱ	Laboratory findings: (1) elevated levels of IgG and/or IgG4 or (2) detected autoantibodies
Criterion Ⅲ	Histopathologic findings Fibrosis and lymphoplasmocytic infiltration
Criterion Ⅳ	Association with other postulated autoimmune disease

Definite diagnosis: Ⅰ + Ⅱ + Ⅲ + Ⅳ or Ⅰ + Ⅱ + Ⅲ or Ⅰ + Ⅱ or Ⅰ + Ⅲ; Probable diagnosis: Ⅰ + Ⅳ (Rediagnosed as "definite" if "response to steroids" is present); Possible diagnosis: Ⅰ (Rediagnosed as "definite" if "response to steroids" is present).

RESULTS

A total of 15 patients with recurrent episodes of acute pancreatitis during the course of autoimmune pancreatitis are reported with a clinical follow-up ranging from 5 to 276 mo and their data are shown in Tables 5 and 6.

Taking into consideration only the studies of Hardacre[142], Weber[145] and Zamboni[146] which reported a high number of patients, the frequency of autoimmune pancreatitis patients with recurrent abdominal pain was 2.7% (1/37), 3.2% (1/31) and 4.5% (1/22) in the three above-mentioned studies with a mean frequency of 3.3%.

Considering all the cases reported with recurrence of pain, most of the patients were under 50 years of age and the ratio male: female was near to one. The major part of the patients (5/8, 62.5%) had more than one recurrence; some experienced more than 4 recurrences of pain in the follow-up period and most of them were operated on. In the study of Wayne *et al*[144], two of the five patients with recurrent pancreatitis underwent pancreatic surgery 2 and

3 times. Information about the presence of pancreatic complications was reported in nine patients; pseudocysts and pancreatic calcifications developed in more than 50% of the cases. It is worth noting that, in most of the patients studied, the diagnosis was only histologically proven and the Japanese criteria for diagnosis acute pancreatitis were carried out in only two studies[13,143]. Therefore, imaging techniques in patients having autoimmune pancreatitis with a recurrent attack of pain seem to have a limited role in preoperatively diagnosing the disease; furthermore, the serological indices of autoimmunity were carried out in only a limited number of patients. Regarding medical therapy, steroids had no beneficial effects on 2 of the 4 patients on whom the treatment was carried out.

PRACTICAL CONSIDERATIONS

The frequency of recurrent pancreatitis in patients with autoimmune pancreatitis seems to be very low. In fact, if we considered that the frequency of autoimmune pancreatitis is of about 5%, in these patients, the frequency of recurrent attacks of pain is of about 3%. Furthermore, in these patients, steroids seem to be effective only in an half of them and the number of pancreatic operations is quite high in. We probably need to utilize more extensively the information given by imaging techniques and serological indices compatible with the disease in order to decrease a false diagnosis in autoimmune pancreatitis patients with recurrent attacks of pain. However, in this regard we need to remember that, in recent years, the accuracy of IgG4 in diagnosing the autoimmune forms

of pancreatitis seems to be lower than that reported in the past[5]. Furthermore, we need a world consensus on the diagnostic work-up of autoimmune pancreatitis because the criteria utilized until now seem to be inadequate[5,91]. We also need a well-executed international study in order to obtain more information regarding the recurrent pain in patients with autoimmune pancreatitis in order to increase our knowledge of the risk factors of recurrence, diagnosis, and therapy.

CONCLUSION

In cases of recurrent attacks of pain in patients with "idiopathic" chronic pancreatitis, we need to keep in mind the possibility that our patients may have autoimmune pancreatitis. Even though the frequency of this disease seems to be quite low, we believe that in the future, by increasing our knowledge on the subject, we will be able to diagnose an ever-increasing number of patients having acute recurrence of pain from autoimmune pancreatitis. The possibility of finding these diagnostic possibilities and treatment for this disease is still a challenge.

Abstract

Acute recurrent pancreatitis (ARP) is a common clinical condition that may be difficult to diagnose. Endoscopic ultrasound (EUS) is proposed to be a safe first line test of choice in the majority of patients. When interventions are needed to remove biliary stones, evaluate sphincter of Oddi or pancreas divisum, endoscopic retrograde cholangiopancreatography (ERCP) is recommended. Magnetic resonance cholangiopancreatography (MRCP) can be a suitable alternative from a diagnostic standpoint although may not be widely available. Finally, genetic testing is increasingly used to detect certain mutations that are associated with this diagnosis.

INTRODUCTION

Acute recurrent pancreatitis (ARP) is a common, potentially life-threatening condition that requires a combination of sophisticated medical and interventional skills to diagnose, determine the etiology and treat. After an initial episode of pancreatitis studies suggested that 30% of the patients will become experience recurrence[1]. he etiology of ARP has been evaluated in a number of classic studies with alcohol and gallstones were found to be the major contributors[1-3], accounting for 70% of the cases[4].

According to Tandon *et al*[5], "idiopathic acute pancreatitis" was defined as pancreatitis with no etiology established after initial laboratory (including lipid and calcium level) and imaging (either transabdominal ultrasound and/or CT scan) tests. However, there is no consensus on the duration of an "acute attack", as pancreatic parenchymal changes such as edema and fluid collection may persist after the complete normalization of pancreatic enzymes and resolution of patient's symptoms. The definition is less specific if the interval between the acute attacks is short, where inflammation and edema may persist. For the purposes of this discussion, we will define acute pancreatitis according the Atlanta Symposium[6] as an acute inflammatory process of the pancreas, usually associated with severe pain in the upper abdomen with a 3-fold rise in amylase and lipase. ARP is defined as at least 2 episodes of acute pancreatitis with complete or near complete resolution of symptoms and signs of pancreatitis between episodes.

DIAGNOSTIC EVALUATION

ARP remains a diagnostic dilemma. It is estimated that 10% of a single pancreatitis cases and up to 30% of recurrent pancreatitis remain undiagnosed after history, laboratory testing, and routine imaging[7,8].

Initial laboratory testing should include serum calcium and triglycerides. Although an uncommon complication, hypercalcemia of any cause can lead to acute pancreatitis[9,10]. Suggested mechanisms include deposition of calcium in the pancreatic duct and calcium activation of trypsinogen within the pancreatic parenchyma[10]. Serum triglyceride concentrations above 1000 mg/dL (11 mmol/L) can precipitate attacks of acute pancreatitis[11], although the mechanism of inflammation in this case remains unclear.

The combination of bile crystal analysis and endoscopic retrograde cholangiopancreatography (ERCP) with or without sphincter of Oddi manometry (SOM) has led to identifying the underlying etiology up to 76% of cases of otherwise unexplained acute pancreatitis[1,8]. The advent of EUS and the rapid evolution of various imaging modalities have provided a less invasive highly accuracy alternative for studying the pancreas and the biliary tree. In this review, we will focus on the diagnostic approach to patients with ARP including medical testing, imaging and endoscopy.

EUS OR ERCP?

ERCP has been used for decades in the evaluation of idiopathic recurrent pancreatitis. The role of ERCP emerged prominently in the diagnosis of underlying cholelithiasis[12,13], papillary stenosis[1], pancreas divisum[14] and sphincter of Oddi dysfunction[1]. The major limitation of ERCP is the risk of inducing acute pancreatitis, which may be as high as 20% in patients being evaluated for SOD and is 5%-6% in the general population[15]. Over the past 10 years, EUS has replaced ERCP for most diagnostic evaluations due to its high accuracy (at least for bile duct stones, tumors, pancreas divisum and cysts) and lower risk of complications[16]. The major limitation of EUS is the inability to clearly diagnose SOD.

Coyle *et al*[13] studied the diagnostic utility of ERCP with SOM, bile analysis and EUS in patients with acute and ARP. A diagnosis was found in the majority of the cases (80%), where SOD was the most common finding (31%), while pancreatic divisum was found in 20% of patients. EUS was very useful in the diagnosis of biliary diseases and detected all tumors. Endoscopic ultrasound (EUS) was able to identify 9 patients with chronic pancreatitis, which ERCP did not identify. However, EUS was not able diagnose any patient with SOD.

In a similar study by Fossard *et al*[17] EUS identified the cause of acute pancreatitis in 77% of patients. EUS was abnormal EUS were compared with other investigations, EUS correctly identified the cause of the "idiopathic" pancreatitis in 155 (92%) of the patients, most commonly being biliary tract disease. EUS missed the diagnosis in 5 patients with biliary stones and one patient with intraductal papillary mucinous neoplasm (IPMT). The authors concluded that EUS is valuable in determining the cause of acute pancreatitis in patients initially considered to have idiopathic pancreatitis.

According to Tandon *et al*[5], EUS was successful in determining the etiology of idiopathic acute pancreatic in 21 out of 31 patients (68%). The diagnoses made by EUS were: chronic pancreatitis (45%), microlithiasis (16%), pancreas divisum (6.5%) and pancreatic carcinoma (3.2%), and was not diagnostic in 10 (32%) The mean follow up was 16 mo. Thirteen patients in this study had further recurrent pancreatitis or pancreatic symptoms and underwent further investigations. Only nine of these patients required ERCP and four patients had a change of their previous EUS diagnoses. Hence, 87% (27 of 31 patients) of the initial EUS diagnoses were *unchanged* at the end of follow up. Two patient groups were included in this study and provoked criticism: patients with significant alcohol consumption and patients with only single episode of pancreatitis.

A prospective study of 300 patients of single episode and recurrent pancreatitis by Yusoff *et al*[18] concluded that it is reasonable to perform EUS after the first episode of pancreatitis. Diagnostic yield of EUS was comparable between the 2 groups (single *vs* recurrent episodes). Patients with significant alcohol intake and with features of chronic pancreatitis were excluded from this study.

WHEN CAN EUS REPLACE ERCP?

The most likely area where EUS can replace ERCP, at least as the initial diagnostic test, is when biliary tract disease such as stones, are suspected. Prat *et al*[19] studied the value of early EUS to avoid unnecessary cannulation of the bile duct in patients with acute biliary pancreatitis. ERCP was only performed if biliary stones were seen by EUS. There were no false positive EUS results and no EUS related complications. Also, Napoleon and his colleagues[20] found that the negative predictive value of EUS for the diagnosis of CBD stones was 95.4%. Therefore, they concluded that EUS should effectively replace ERCP as the initial diagnostic test of choice.

Two other studies also examined the utility of EUS in idiopathic pancreatitis suspected to be of biliary origin. Norton and Alderson[21] found that pancreato-biliary causes of idiopathic acute pancreatitis can be established in at least 18 of 44 patients (41%) studied. Although this diagnostic yield is lower compared with 68% suggested by Tandon[5], patients with significant alcohol intake were excluded in the Norton study. In addition, Liu *et al*[22] found that EUS led to the correct diagnosis in 14 of 18 patients (78%) with idiopathic pancreatitis of choledocholithiasis and/or cholelithiasis. Although this study excluded patients with history of excess alcohol ingestion, it included patients with only one episode of pancreatitis. As for IPMT, EUS has a sensitivity of 86% and specificity of 99% in diagnosing IPMT[23].

Autoimmune pancreatitis (AIP) is a rare but increasingly diagnosed clinical entity[24,25], which can present as pancreatic or biliary strictures, acute recurrent pancreatitis or even pancreatic mass. Elevated serum levels of IgG4 provide a strong marker for the disease[26,27]. Serum IgG4 accounts for only 5 to 6 present of the total IgG4 in healthy subjects but is elevated in patients with AIP. A large study by Hamano *et al*[27] compared serum IgG4 levels in 20 patients with AIP with 20 healthy controls, and 154 patients with a variety of malignant and non-malignant pancreatic diseases. The median serum IgG4 concentration in patients with AIP was 663 mg/dL compared with 51 mg/dL in healthy controls. The serum IgG4 concentrations in the other group of patients were similar to those in healthy subjects with no values above 135 mg/dL. Using a cutoff of 135 mg/dL, the sensitivity and specificity of the serum IgG for distinguishing AIP from pancreatic cancer were 95 and 97 percent, respectively. Levels of IgG4 declined during treatment with corticosteroids. Classic endosonographic features include diffusely hypoechoic, enlarged pancreas together

with chronic inflammatory cells on aspirated cytologic specimens[28]. However, EUS fine needle aspiration (FNA) is usually insufficient to diagnose autoimmune pancreatitis due to the small sample size and lack of tissue architecture. In a study by Levy *et al*, five patients in whom the diagnosis was considered were evaluated. A mean of 2.8 EUS truecut biopsy (range 2-5) was obtained per patient[29]. Truecut biopsy specimens were diagnostic of AIP in two patients and were strongly suggestive but not diagnostic in two others. In one patient only nonspecific changes of chronic pancreatitis were seen on histology. EUS FNA (mean 4.3 passes, range 2-7 passes) was performed in four of five patients and failed to establish or suggest the diagnosis in any of these patients. Serum IgG4 and EUS should be considered first line tests in cases where AIP is suspected.

A major advantage of ERCP compared to EUS is the ability to perform manometry and, if needed, intervention if specific etiologies have been found in the same setting. For the common causes found in patients with unexplained pancreatitis, sphincterotomy (either biliary or pancreatic) or stent insertion could be performed. To overcome this disadvantage, Rocca *et al* recently presented a prototype oblique-viewing echoendoscope capable of performing EUS and ERCP in the same session[30]. Nineteen patients with acute abdominal pain associated with increased liver tests entered the study and underwent EUS. When biliary stones or sludge were found, bile duct cannulation and sphincterotomy were performed in the same session. Bile duct cannulation failed in only one patient and no procedure-related complications were observed. The authors concluded that this approach was accurate, safe and feasible for the treatment of common bile duct stones when needed. Further larger studies are needed to confirm these findings.

MRCP

MRCP represents a very useful radiographic tool for the assessment of the intra and extrahepatic biliary tree and pancreatic duct. In the recent years, the concurrent use of secretin makes MRCP an attractive first line test for ARP to assess for structural underlying etiologies. Until recently, sphincter of Oddi evaluation remained almost completely dependent on endoscopic approach. However, a study by Mariani *et al* compared secretin MRCP and pancreatic sphincter of Oddi manometry for evaluation of sphincter of Oddi function in patients with idiopathic ARP[31]. Eighteen patients and a similar number of controls underwent both tests and data from 15 patients was available for analysis. Secretin MRCP and sphincter of Oddi manometry were concordant in 13/15 patients (86.7%); positive and negative diagnoses for sphincter of Oddi dysfunction agreed in, respectively, 81.8% and 100% (kappa value 0.706).

Another study by Khalid *et al*[32] evaluated pancreatic duct outflow obstruction in cases of idiopathic ARP. Ten patients with idiopathic acute recurrent pancreatitis underwent secretin-stimulated magnetic resonance pancreatography with subsequent endoscopic retrograde pancreatogram with or without manometry. It was found that secretin stimulated magnetic resonance pancreatography provides high quality pancreatic duct images and has high specificity for diagnosing pancreatic duct outflow obstruction using manometric and clinical criteria.

GENETIC TESTING

Cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations were noted to be associated with cystic fibrosis (CF)-related conditions, including idiopathic recurrent pancreatitis in otherwise non-symptomatic patients. A prospective study by Bishop *et al* included idiopathic ARP, healthy controls, CF heterozygotes, and CF patients (pancreatic insufficient or sufficient) for evidence of CFTR gene mutations. At least one CFTR mutation or variant was carried in 6 of 16 patients (38%) with idiopathic ARP but in only 11 of the 50 controls (22%, $P = 0.005$). Identified mutations were rare and are not usually identifiable with the routine screening test. While genetic testing may carry more significance in the diagnostic work up of chronic pancreatitis, acute pancreatitis can be viewed as an event that leads to the process of chronic pancreatitis. The role of other mutations involving cationic trypsinogen (PRSS1) and in serine protease inhibitor Kazal type 1 (SPINK1) genes seen in idiopathic chronic pancreatitis is less established in ARP and further studies are required[33,34].

CONCLUSION

Each of the above-described modalities to diagnose ARP has its pros and cons. Despite the fact that there are limitations in using EUS to investigate ARP, it remains a reasonably accurate and less invasive alternative to ERCP for patients with only one episode of pancreatitis. For certain cases of recurrent pancreatitis, besides being able to perform interventions, ERCP offers additional information about sphincter of Oddi function, and also in cases of pancreas divisum where the sensitivity and specificity of EUS needs further evaluation. In other cases where biliary stones or IPMT are suspected, EUS remains a less invasive and equally accurate test of choice. The risks and benefits of these procedures should be individually evaluated in each case. MRCP with secretin stimulation is a non-invasive, promising tool but requires advanced interpretation skills and may not be widely available. In a subset of patients where structural causes have been ruled out, genetic testing may be helpful in the appropriate clinical set-up.

Abstract

There was remarkable progress in the understanding of the role genetic risk factors in chronic pancreatitis. These factors seem to be much more important than thought in the past. The rare autosomal-dominant mutations N29I and R122H of PRSS1 (cationic trypsinogen) as well as the variant N34S of SPINK1 (pancreatic secretory trypsin inhibitor) are associated to a disease onset in childhood or youth. Compared to chronic alcoholic pancreatitis the progression is slow so that for a long time only signs of acute-recurrent pancreatitis are found. Only at later time points (more than 10-15 years) there is evidence for chronic pancreatitis in the majority of patients. Acute recurrent pancreatitis may therefore be regarded as a transition state until definite signs of chronic pancreatitis are detectable.

INTRODUCTION: FROM ACUTE TO ACUTE-RECURRENT AND TO CHRONIC PANCREATITIS

Pancreatitis is general is divided into acute and chronic forms. Acute pancreatitis is defined as a disease in which both exocrine and endocrine function of the gland may recover to normal (restitution ad integrum). In some patients with severe acute pancreatitis, a residual functional defect may persistent but there is no recurrent episode (Figure 1). Whereas acute pancreatitis may be related to either bile duct stones or alcohol, the main cause of chronic pancreatitis is heavy alcohol consumption[1]. Patients presenting with an acute flare of alcoholic pancreatitis often show evidence for chronic alteration of the duct, therefore already having definite signs of chronic pancreatitis. The pathogenesis of alcoholic chronic pancreatitis is under debate. Whereas one group of investigators believe that acute alcoholic pancreatitis proceeds to chronic pancreatitis, others think that this is primarily a chronic disease. It is furthermore under discussion whether alcoholic pancreatitis, when initiated, may, even at complete cessation of alcohol consumption, ever recover to normal or not.

Acute-recurrent pancreatitis may be regarded as a transition state between acute and chronic pancreatitis that is characterized by repetitive acute episodes without evidence for chronic inflammation (Figure 1). This patient group is difficult to define as we only have a description of the disease within a limited time interval. It is unclear at the moment of the investigation whether the pancreatitis resumes completely or progresses to chronic disease. Only the investigation of the long-term course of the disease will show us to what group the respective patient belongs to.

In the recent years several genetic risk factors were identified in pancreatitis[2]. In particular, mutations of the cationic trypsinogen (PRSS1), secretory pancreatic trypsin inhibitor 1 (SPINK1), and the cystic fibrosis transmembrane conductance regulator (CFTR) were described. The mutation G191R of the anionic trypsinogen (PRSS2) was shown to act as a factor protecting from pancreatitis[3]. In patients with autosomal- dominant traits the mutations N29I and R122H of PRSS1 as well as a triplication of the trypsinogen was found[4]. The other mutations were mainly found in sporadic, but also in alcohol-induced disease[5]. In this short review I will discuss the classification of hereditary or idiopathic pancreatitis, but mainly focus on the description of the course of disease in patients with genetic risk factor in order to rule out whether an acute-recurrent form exists at all. These data are mainly based on an investigation of patients and their families[6,7].

HEREDITARY OR IDIOPATHIC PANCREATITIS

The term "hereditary pancreatitis" was created in the

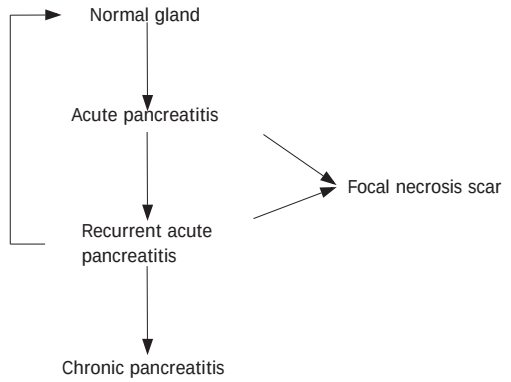

Figure 1 Relationship between acute, acute-recurrent and chronic pancreatitis.

fifties of the last century and described an accumulation of patients with pancreatitis in one family[8]. Its use is not uniform as several different definitions can be found in the literature. Most authors request 2 patients within one generation or more than 2 patients in more than one generation. Due to its origin in the pre-genetic area the term is purely phenomenological. After identification of mutations of the cationic trypsinogen (PRSS1), of the pancreatic secretory trypsin inhibitor (SPINK1) and of the cystic fibrosis transmembrane conductance regulator (CFTR) in patients with pancreatitis[2] it became evident that only less than 5% of the patients with genetic risk factors fulfil any of these definitions of "hereditary pancreatitis". In our group of patients, for example, 35% of families with autosomal-dominant trypsinogen mutations (N29I and R122H) cannot be classified as suffering from "hereditary" pancreatitis. In consequence, the definition of "hereditary pancreatitis" will have to be changed.

Another problem is the use of "idiopathic" pancreatitis in patients with genetic risk factor. Recently, even the term "familial-idiopathic pancreatitis" was created for those families having 2 members with pancreatitis[9]. Both concepts are contradictions in term as "idiopathic" means absence of any risk factor and familial accumulation or mutations always point to a risk factor. It is my suggestion to substitute the term "idiopathic" by "sporadic" that is also used in other diseases. "Autosomal-dominant" and "familial pancreatitis" (in case of absence of an autosomal -dominant trait) could be used to formally describe the familial association of the disease.

HOW FREQUENT ARE MUTATION IN PANCREATITIS?

After the first description of trypsinogen mutations several reports were published which showed up to 10% of autosomal-dominant mutations N29I or R122H in patients with "idiopathic" pancreatitis[10,11]. This is typical for an initial enthusiasm that overestimates the significance of a new finding. Later, the investigation of larger groups of patients revealed that trypsinogen mutations were present much less frequently. Interestingly, the smaller the study was, the larger were the percentages of mutations and the higher were the impact factors of the journals in which the data were published. As noted already[12] this was nice example for a publication bias favouring "positive" findings that are preferably published in journals with high impact factor.

Table 1 Mutations in different groups of patients suffering from pancreatitis

Clinical characteristic of chronic pancreatitis	% of all patients	With mutation		Without mutation
		Type of mutation	%	%
Autosomal-dominant	1	PRSS1:R122H, N29I	70-80	10-20
		PRSS1:triplication	10-20	
Familial	3	PRSS1:R122H, N29I	15	50
		PRSS1:A16V	< 5	
		SPINK1:N34S	30	
		Other SPINK1 mutations	5	
Sporadic	20	PRSS1:R122H, N29I	<< 1	15-50
		PRSS1:A16V	< 5	
		SPINK1:N34S	20-40	
		CFTR:various	20-40	
Alcoholic	75-80	SPINK1:N34S	5	85
		CFTR:various	10	
Pancreas divisum	3	CFTR:various	20	80
Tropical pancreatitis	?	SPINK1:N34S	50	50
All groups: protective mutation	1	PRSS1:G191R	In controls: 3	

Table 1 shows an overview on the frequency of the various mutations in the different groups of patients. The data largely based on our own genetic findings in more than 1000 patients with non-alcoholic chronic pancreatitis[5,12] and on several other studies[13-17]. The different groups are defined by family history (autosomal-dominant, familiar, sporadic) and the alcohol consumption. In approximately 75% of the patients with autosomal-dominant disease mutations of the cationic trypsinogen (N29I or R122H) were found. Recently a triplication of the trypsinogen was identified[4], but its frequency is unclear at the moment. A positive family history without clear autosomal-dominant trait (familial pancreatitis) predisposes to the SPINK1 mutation N34S, but also PRSS1 variants (A16V, N29I, R122H) can be seen. In patients with sporadic disease all three genes (PRSS1, SPINK1, CFTR) contribute to the risk of the disease, but, as already mentioned above, autosomal-dominant mutations are extremely rare.

In alcoholic chronic pancreatitis 15% of the patient exhibit SPINK1 or CFTR mutations[13,14]. In 22% of patients with pancreas divisium, mutations of the CFTR molecule can be identified[16]. In tropical pancreatitis half of the patients were affected from the variant N34S of SPINK1[17]. Recently Witt *et al*[3] reported the identification of a PRSS1 mutation (G191R) protecting from pancreatitis. This supports the central role of trypsin in the pathogenesis of pancreatitis. Taken together, in approximately 25% of the patients with chronic pancreatitis a genetic risk factor can be identified. A regularly updated list of PRSS1 and SPINK1 mutations can be found in the internet (http://www.uni-leipzig.de/pancreasmutation).

MUTATIONS AND RISK OF PANCREATITIS

The different mutations in pancreatitis confer a different

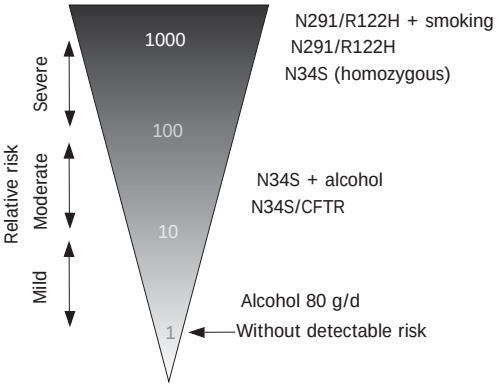

Figure 2 Strength of genetic and environmental risk factors of chronic pancreatitis.

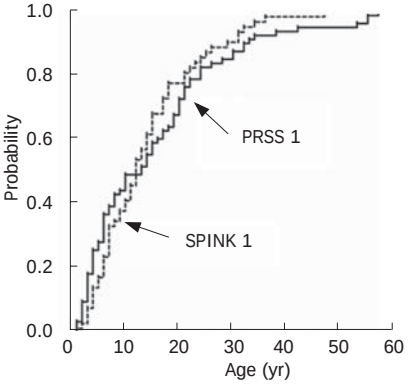

Figure 3 Age at onset of pancreatitis in patients with mutations N29I and R122H of the cationic trypsinogen and mutation N34S of SPINK1.

risk of pancreatitis. This may be calculated from the frequencies of mutations in the healthy general publication and in patients. In trypsinogen mutations N29I and R122H approximately 80% of the subjects suffer from disease[7,16]. Apart from families with autosomal-dominant disease the mutations are obviously absent in healthy subjects. At a prevalence of chronic pancreatitis of 50-100/100.000 it may be estimated that PRSS1 mutation increase the risk for pancreatitis by a factor of at least 1000-2000. The homozygous SPINK1 N34S is detected in healthy subjects at a rate of 1/10.000, and in patients with pancreatitis it is found in approximately 5%-10% of those with N34S-associated disease[19]. Therefore it may be assumed that the homozygous N34S increased the risk by a factor of about 500. The heterozygous N34S of SPINK1 as well as CFTR mutations are associated with a 20-40-fold risk of pancreatitis[18]. This is in difference to the role of alcohol that increased the risk of disease only by a factor of 3, 5-11[20]. A conclusion from these data would be that genetic risk factors confer a much higher risk than the consumption of alcohol. It may also be concluded that alcohol is a very frequent but weak risk factor of chronic pancreatitis.

Figure 2 shows an attempt for a graphical representation of these data. Autosomal-dominant trypsinogen mutations or homozygous N34S may be regarded as strong risk factors (× 100-1000). Variants of SPINK1 or CFTR confer an intermediate risk (× 10-100). Weak factors (increase up to 10 fold) like

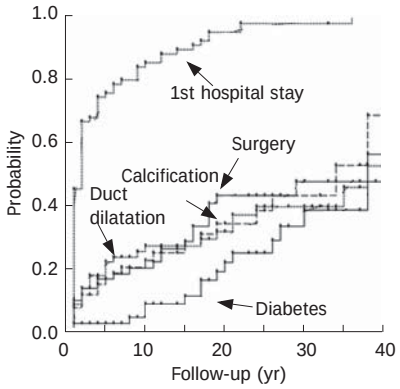

Figure 4 Progression of pancreatitis in patients with PRSS1 mutations N29I and R122H.

alcohol consumption are supplementary and may modify the course of chronic pancreatitis. The graph shows that interaction of environmental and genetic factors (i.e. N34S + alcohol or PRSS1 + smoking) further increased the probability of a disease. It is also shown that SPINK1 mutations are stronger risk factors than CFTR variants and in their homozygous form they were similar to the autosomal-dominant trypsinogen mutations. Therefore, it is no longer justified to degrade them to "disease modifier" as done recently[21].

PROGRESSION OF GENETIC PANCREATITIS

The majority of subjects with autosomal-dominant trypsinogen mutations N29I and R122H get ill in childhood[6], but this is also true for those with the variant N34S of SPINK1[7] and a considerable number of patients without any detectable risk factor ("early onset idiopathic"). The data from our patient group were shown in Figure 3[7]. The progression of disease was analysed in both patient groups. As shown in Figure 4, in the majority of the patients with the PRSS1 mutations N29I and R122H the initial event was a severe acute episode leading to treatment in a hospital. At the same time point there was no evidence for definite signs of chronic pancreatitis in the majority of these patients. Only several years later there is a slowly increasing rate of duct dilatation or calcification that may be regarded as definite prove of chronic pancreatitis. However, even after a follow-up time of 20 years after the first symptoms, only 30% of the patients show evidence for calcifications or duct dilatation. The onset of diabetes seems to be even later as after 10 years less than 10% and after 20 years less than 20% were diabetic (Figure 4). This shows that the signs of chronic pancreatitis may be absent when patients were not observed long enough.

The progression of disease in patients with N34S of SPINK1 was rather similar. There was a hospital stay early in the course of the disease, a slow appearance of duct dilatation or calcifications and a late onset of diabetes (Figure 5). Compared to patients with alcoholic chronic pancreatitis (Figure 6) the progression of disease is much slower, as in more than 50% of the alcoholics diabetes and calcification were observed already after a follow-up time of less than 15 years.

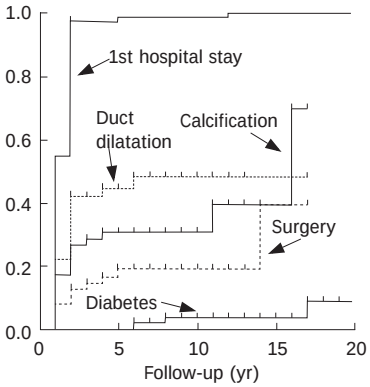

Figure 5 Progression of pancreatitis in patients with mutation N34S of SPINK1.

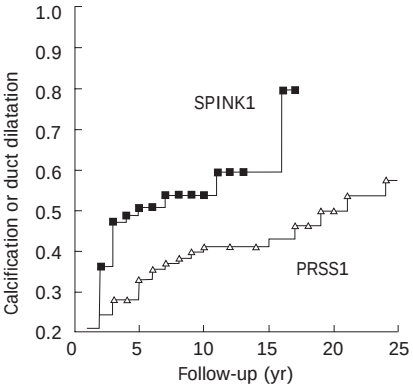

Figure 7 Probability of either calcification or duct dilatation in patients with N34S mutation of SPINK1.

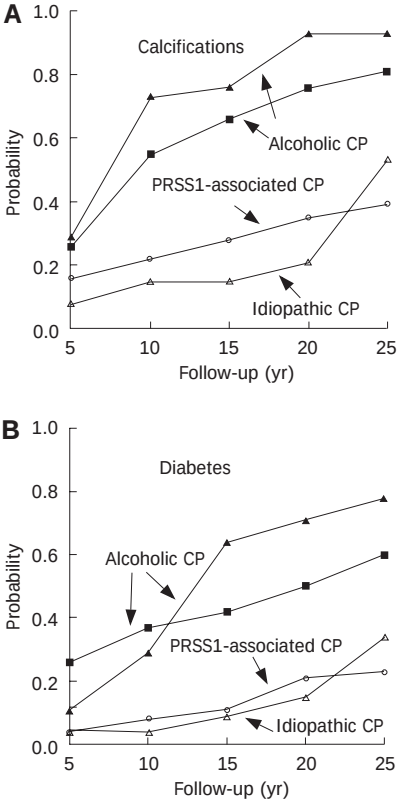

Figure 6 Progression of pancreatitis in patients with alcoholic, idopathic or PRSS1-induced disease.

DOES ACUTE RECURRENT PANCREATITIS EXIST IN PATIENTS WITH GENETIC RISK FACTORS?

The data shown above suggest that in a significant number of patients definite signs of chronic pancreatitis may be found only after a long follow-up time. From this finding it may be suspected that acute-recurrent pancreatitis is only a transition state that finally ends in chronic pancreatitis. To analyse this presence of either calcifications or duct dilatations in patients with PRSS1 (N29I and R122H) or SPINK1 (N34S) mutations were analysed by Kaplan-Meier. As shown in Figure 7 in approximately 80% of the patients with SPINK1 show at least one of the definite signs of chronic pancreatitis after a follow-up time of 15-20 years. In 50% of the patients with a PRSS1 mutation a chronic pancreatitis can be diagnosed after 25 years of follow-up. This may, however, be an underestimation of chronic pancreatitis as only two signs were evaluated. Histological specimens were available in only a few patients and the retrospective study design tends to overlook patients with chronic disease. The data suggests that recurrent acute pancreatitis is present in patients with genetic risk factors, but with time there is a slow progression to chronic pancreatitis. In the majority of patients, however, one has to wait a long time and in some others recurrent pancreatitis may persist.

CONCLUSION

The autosomal-dominant mutations N29I and R122H of PRSS1 (cationic trypsinogen), N34S of SPINK1 (pancreatic secretory trypsin inhibitor) lead to a disease onset in childhood or youth. Compared to chronic alcoholic pancreatitis the progression is low so that for a long time only signs of acute-recurrent pancreatitis are found. At later time points (more than 15-20 years) there is evidence for chronic pancreatitis (duct dilatation, calcification, histological prove of chronic pancreatitis). In patients with genetic risk factors acute recurrent pancreatitis may therefore be regarded as a transition state until definite signs of chronic pancreatitis are detectable. The progression of disease, however, is slow so that the clinical picture is compatible with an acute-recurrent pancreatitis for a very long time.

Abstract

Acute recurrent pancreatitis (ARP) is still a complex diagnostic and therapeutic challenge in clinical practice. In up to 30% of cases of ARP, it is not possible to establish the etiology of the disease. In the other 70%, many factors play an etiological role in ARP: microlithiasis, sphincter of Oddi dysfunction (SOD), pancreas divisum, hereditary pancreatitis, cystic fibrosis, a choledochocele, annular pancreas, an anomalous pancreatobiliary junction, pancreatic tumors or chronic pancreatitis are diagnosed. EUS should be useful in ARP as it is sensitive for diagnosing bile duct stones, gallbladder sludge, pancreatic lesions, ductal abnormalities and chronic pancreatitis. Endoscopic ultrasound (EUS) appears to be diagnostic in the majority of patients with previously unexplained pancreatitis, and offers an alternative to endoscopic retrograde cholangiopancreatography (ERCP) as the initial diagnostic test in patients with ARP.

INTRODUCTION

Acute recurrent pancreatitis (ARP) is still a complex diagnostic and therapeutic challenge in clinical practice. Defining the diagnosis itself is already problematic; it is sometimes impossible to differentiate clearly between recurrent attacks of acute pancreatitis and the early stages of chronic pancreatitis. The history and presenting symptoms may be non-specific, and as a consequence up to four out of ten patients may be initially misdiagnosed as having "non-specific dyspepsia"[1]. It is difficult to assess the significance of mild or early changes in the pancreatic duct system and the pancreatic parenchyma, particularly because the normal appearance of the pancreas already varies widely with age. In up to 30% of cases of recurrent acute pancreatitis, it is not possible to establish the etiology of the disease, despite a detailed history and extensive investigations[2], so as a result the patient is diagnosed as having "idiopathic" ARP.

In the other 70%, many factors play an etiological role in ARP; in fact, virtually any case of acute pancreatitis may lead to recurrent episodes if it is not corrected. In these patients, more extensive evaluation may lead to a diagnosis of microlithiasis, sphincter of Oddi dysfunction (SOD), or pancreas divisum. Less commonly, hereditary pancreatitis, cystic fibrosis, a choledochocele, annular pancreas, an anomalous pancreatobiliary junction, pancreatic tumors or chronic pancreatitis are diagnosed. Gullo *et al*[3] reported that 288 (27%) of the total of 1068 acute pancreatitis patients had recurrence, and alcohol was the most frequent factor.

In virtually all patients with normal upper gastrointestinal anatomy, endoscopic ultrasound EUS makes it possible to visualize the entire pancreas, the neighboring blood vessels, and the common bile duct from various scanning positions in the stomach and duodenum. This is not always possible with abdominal US because the images can be compromised by intestinal gas or fat, and the local resolution provided by the endosonographic images is unsurpassed by any other imaging method because of the close proximity of the pancreas to the stomach and proximal duodenum. In contrast to endoscopic retrograde cholangiopancreatography (ERCP), EUS makes it not only possible to view changes in the pancreatic duct, but changes in the parenchyma can also be taken into account for diagnostic considerations.

The normal endosonographic appearance of the pancreas should meet specific criteria for size, contour, parenchyma, and ducts. Wiersema *et al*[4] evaluated the endosonographic features of a small group of healthy volunteers, with no history of abdominal pain or alcohol abuse. To diagnose

Figure 1 Conventional endosonographic imaging (7.5 MHz) of choledocholithiasis. A 9.6 mm stone (A) is seen as an hyperechoic structure with acoustic shadowing (C) in the intrapancreatic tract of the common bile duct (B).

Figure 2 Common bile duct (CBD) stone with dilation of the biliary tract. PAP: Vater papilla.

pathological changes in the pancreas, it is important to take account of the normal anatomical variants. Normally, the pancreatic parenchyma is homogeneous and slightly hyperechoic. The main pancreatic duct is seen as a thin, anechoic, smooth linear structure coursing centrally through the parenchyma. There is also usually a clearly detectable difference in the echo-density of the ventral and dorsal pancreas, the ventral part being more hypoechoic[5]. Age-related changes can also vary widely. In a large prospective study, Rayan *et al*[6] found that 28% of patients with no history or symptoms of pancreaticobiliary disease had at least one pancreatic parenchymal or ductular finding similar to those seen in chronic pancreatitis. There was a tendency, albeit not significant, for the frequency of abnormalities to rise with age, particularly after the age of 60[6].

Mechanical factors promote recurrent episodes of pancreatitis by inducing a transient, or less frequently, a persistent obstruction to the flow of pancreatic juice into the duodenum, with a consequent rise in intraductal pancreatic pressure. The mechanical obstruction may also allow the bile to flow back into the main pancreatic duct with intrapancreatic activation of pancreatic zymogens; Opie first proposed this theory in 1901[7] for the pathogenesis of gallstone pancreatitis. Conditions inducing mechanical obstruction are either congenital or acquired and may be at the level of Vater's papilla, the bilio-pancreatic junction or the main pancreatic duct.

If EUS and MRCP exclude mechanical causes of pancreatitis, an autoimmune form should be considered, especially if the patient has any other "rheumatologic" conditions such as sicca syndrome, and has elevated serum IgG 4 levels. EUS shows an irregular narrowing of the pancreatic duct, with swelling of the parenchyma. There may be diffuse parenchymal enlargement, sometimes also of the pancreatic main duct. Obstructive jaundice can be a common feature. The lesion sometimes mimics a pseudotumor and differential diagnosis with adenocarcinoma becomes difficult. In autoimmune pancreatitis the Wirsung is often narrowed, but not disrupted as in cancer. Fine-needle aspiration shows lympho-plasmacytic infiltration and fibrosis, more evident in cases with a long history of recurrent pain.

CHOLEDOCHOLITHIASIS AND BILIARY MICROLITHIASIS

Pancreatitis results from gallstone disease (Figure 1) in almost 40% of cases[8]. With the US probe positioned in the genu superior, the common bile duct (CBD) can be examined in longitudinal sections as far proximally as the hepatic duct and distally to the ampulla (Figure 2). Withdrawal from the bulb under traction allows examination of the gallbladder and CBD, from its origin in the hilum to the convergence of the cystic and hepatic ducts and the proximal portion of the CBD. With this method, the hepatic duct and CBD can be visualized in 95%-100% of patients, as reported in several studies[9].

In a prospective and competitive blinded study in patients with CBD obstruction EUS gave 100% accuracy for the diagnosis of choledocholithiasis; it was also significantly more sensitive than transabdominal ultrasonography or CT[10]. In patients with unexplained ARP the use of EUS with high resolution increases the chances of detecting microlithiasis (Figure 3), a frequent cause of pancreatitis[2,11,12].

A large study by Frossard *et al* evaluated 168 patients referred with diagnosis of idiopathic pancreatitis. EUS identified an abnormality in 80% of these patients, and 62% of them had biliary tract pathology such as stones, sludge, or microlithiasis. Compared to the final diagnosis at surgery, ERCP, bile crystal analysis, or medical follow-up, EUS correctly established the causes of pancreatitis in 92% of patients[13] (Figure 4).

Microlithiasis may lead to pancreatitis through several mechanisms: transient impaction of small stones at the papilla, obstructing the pancreatic duct, or the repeated passage of stones (which may lead to papillary stenosis or SOD, both of which are associated with pancreatitis)[14]. Surgical or endoscopic treatment of occult microlithiasis significantly reduces the recurrent episodes of acute pancreatitis compared with untreated patients[5-21].

Three recent studies maintain that EUS should replace ERCP as the first procedure in patients with mild to moderate acute pancreatitis to avoid unnecessary ERCP and thus reduce ERCP-induced morbidity[22-24]. One study also suggested that the rate of morbidity and mortality

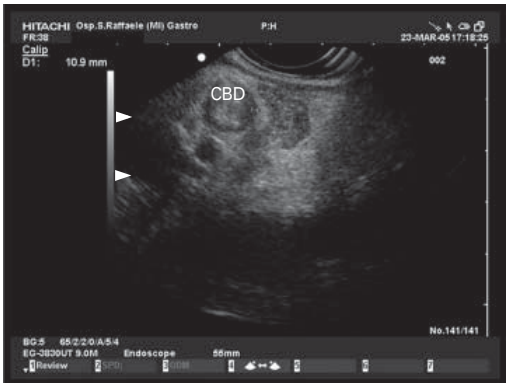

Figure 3 View of the proximal tract of the common bile duct (CBD) from the duodenum: the duct is dilated and completely obstructed by minuscule concrements (microlithiasis).

could be reduced by systematically using EUS in cases of acute pancreatitis, followed by ERCP with sphincterotomy when EUS has indicated CBD stones[25].

When gallstone disease is excluded as a cause of pancreatitis, EUS remains obligatory in the work-up of patients with idiopathic pancreatitis because it permits combined exploration for parenchymal and ductal abnormalities.

PANCREAS DIVISUM

Pancreas divisum (PD) is the most common congenital anatomic variant in the pancreas, present in 5%-8% of the general population, with reports of prevalence ranging from 1.3% to 7.5% in series based on ERCP findings[26-29]. PD occurs when the ventral and dorsal pancreatic ducts fail to fuse during embryogenesis. As a result, the ventral duct only drains the ventral pancreas. The majority of the pancreas then drains through the dorsal duct from the minor papilla. In these patients, the minor papilla is often stenotic and therefore slows the flow of pancreatic juice. Even relative obstruction of pancreatic exocrine secretory flow through the minor papilla can result in pancreatitis in some patients. Patients with PD and ARP respond favourably to surgical sphincteroplasty of the minor papilla or endoscopic minor papilla sphincterotomy[30].

By definition, EUS findings are indicative of PD if the course of the pancreatic duct cannot be followed from its origin at the ampulla of Vater through the ventral part to the dorsal pancreas, or if the duct cannot be visualized within the ventral pancreas. It may also sometimes be possible to visualize the separate orifices of the CBD at the major papilla and of the dorsal pancreatic duct at the minor papilla (Figure 5). Conversely, PD can be excluded if the pancreatic duct can be followed continuously from the ventral to the dorsal pancreas, or between the papilla of Vater and the pancreatic neck[31,32].

Bhutani *et al* described the possibility of accurately diagnosing PD by EUS using radial instruments[33] and suggested that divisum was present if an image simultaneously showing the portal vein, CBD, and main pancreatic duct could not be obtained[33]. In another study, Lai *et al*[32] showed that linear-array EUS appeared to be a promising, minimally invasive diagnostic imaging approach for the detection of PD, with 97% accuracy (Figure 6). Catalano *et al*, using dynamic endosonography with secretin stimulation, were able to identify patients with chronic pancreatitis and PD who subsequently benefited from endoscopic stent placement[34].

ANOMALOUS PANCREATOBILIARY JUNCTION

The CBD and PD normally unite in the wall of the

Figure 7 A malignant lesion (A) in the pancreatic head occluding the main pancreatic duct wich is dilated (B).

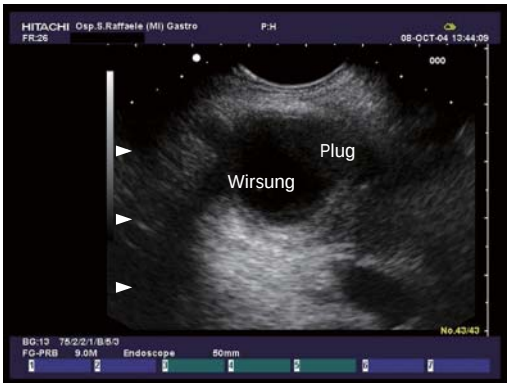

Figure 8 Dilation of the main pancreatic duct and collateral duct with evidence of plugs in the lumen in a patient with IPMT.

duodenum at the ampulla of Vater and are surrounded by a muscular sheath, the sphincter of Oddi. The ampulla is easily visualized with the probe placed in the second part of the duodenum with the balloon and the lumen filled with water, and it is seen as a clearly outlined hypoechoic structure, from which the two ducts can be followed into the pancreatic head.

An anomalous pancreatobiliary junction (PBJ) is defined by an abnormally long (> 15 mm) common pancreatobiliary channel[35]. This anomaly is associated with idiopathic ARP, choledochal cyst, and cholangiocarcinoma[36]. The sphincter does not separate the bile and pancreatic ducts, so pancreatic and bile juices may freely flow between ducts and lead to pancreatitis. ERCP and injection of the major papilla reveal the long common channel and simultaneous filling of the bile and pancreatic ducts. EUS may also establish the diagnosis.

In a prospective study Sugiyama *et al*[37] assessed the diagnostic value of EUS for anomalous PBJ. They examined 188 patients with pancreatobiliary disease, and the length of the common channel indicated by EUS was compared with that found by ERCP. EUS showed the common channel was longer than 12 mm in 88% of cases of anomalous PBJ.

ANNULAR PANCREAS

Annular pancreas is a rare congenital anomaly of the pancreas that consists of an aberrant band of pancreatic tissue arising from the head of the pancreas and either partially or completely encircling the second portion of the duodenum[38]. This abnormality is detected in 1/7000 autopsies and about 1/1500 ERCPs[39]. Adults may present with abdominal pain, ARP, or chronic pancreatitis. Although CT or MRCP may suggest the diagnosis, ERCP is usually required for confirmation. Gress *et al* described two cases where the addition of EUS aided in the diagnosis of annular pancreas visualized as "salt and pepper" parenchyma around the duodenum[40].

PANCREATIC TUMORS

Five to seven percent of patients with benign or malignant pancreatic tumors present with ARP[41]. Patients with adenocarcinoma (ADC) may suffer attacks of pancreatitis for months before cross-sectional imaging identifies a mass. EUS can be helpful in these cases but though a negative EUS result is reassuring if there is a strong clinical suspicion of ADC, it is mandatory to repeat the procedure periodically (3-6 mo) (Figure 7). Cystic lesions that cause duct compression or involvement of the main pancreatic duct tend to cause pancreatitis. EUS identified all tumoral causes in a recent series of 90 patients with undetermined causes of acute or recurrent pancreatitis[2].

Cystic neoplasms of the pancreas are traditionally organized according to the type of lining epithelium since this feature dominates the risk of malignancy and management. There are three types of mucinous lesion, benign mucinous cystadenoma, malignant mucinous cystic lesions, and intraductal papillary neoplasms. The non-mucinous lesions include serous cystadenomas and can be generally managed with observation alone. It is sometimes difficult to distinguish between serous and mucinous tumors, since the latter may contain enzyme-rich fluid, communicate with the ductal system, and may be seen more frequently in patients with symptoms of ARP. EUS can provide the means of distinguishing between serous and mucinous neoplasms by revealing a mass composed either of many tiny cysts (microcystic), with a solid-appearing hypervascular tumor, or several large cysts (macrocystic)[42].

Mucinous cystadenomas consist of one or more macrocystic spaces lined with mucus-secreting cells and are typically found in the body or tail of the pancreas. When the diagnosis of a mucinous cystadenoma is made, the lesion should be resected, on account of the high potential for malignant change.

A more frequent cause of single or recurrent episodes of acute pancreatitis is intraductal papillary mucinous tumors (Figure 8) of the pancreas (IPMT)[43]. These are villous or papillary tumors of the main pancreatic duct and/or its branches. IPMT have been subdivided (Kuroda *et al*) into a main duct and a branch duct based on the anatomical involvement of the pancreatic duct (Figure 9). EUS findings in IPMT include segmental or diffuse, moderate to marked dilatation of the main pancreatic duct, often with intraductal nodules. Pancreatic parenchymal atrophy is frequent[44] (Figure 10). Dilation

of the pancreatic duct to over 10 mm and cysts larger than 20 mm are suggestive of malignancy. EUS-FNA of the dilated pancreatic duct, including mural nodules and especially solid components of the tumor, may be helpful in the diagnosis. Histologically, the normal ductal epithelium is replaced by a mucinous metaplasia, with a broad spectrum of histopathological disorders from hyperplasia to ADC. IPMTs have been reported in elderly men, with an average age between 60 and 70 years, but can sometimes arise in younger patients. In comparison with mucinous cystadenomas, they have a lower but still relatively high malignant potential.

Ampullary tumors too-either benign or malignant - may present with ARP. Specifically, the papilla consists of the circular muscle of the CBD and an additional circular muscle enclosing the two ducts. It is seen as a hypoechoic structure from which the CBD and the main pancreatic duct can be traced and followed into the pancreatic head (Figure 11).

CHRONIC PANCREATITIS

Although patients may present clinically with ARP, many will be found, after pancreatic function tests and EUS, to have already developed some degree of chronic pancreatitis (CP). The first diagnostic endosonographic criteria of CP were suggested by Lees *et al* in 1979[45]. In 1993, Wiersema *et al*[4] refined these criteria, which can be divided into two groups: parenchymal and ductal.

Parenchymal criteria include reduced echogenicity, lack of homogeneity, loss of ventral/dorsal distinction, atrophy, hyperechoic foci, hyperechoic strands (Figure 12), and lobularity[5]. They should be sought in the dorsal gland only because the hypoechoic ventral pancreas can show features such as hyperechoic foci and strands even in normal individuals. Reduced echogenicity and lack of homogeneity are presumably caused by edema and/or reduced fat content. These changes in the dorsal gland would explain the loss of ventral/dorsal distinction. Hyperechoic foci and strands correspond respectively to small hyperechoic dots and thin, hyperechoic lines scattered in the parenchyma. When there are enough strands, they divide the parenchyma up into distinct "lobules" that may give the gland a honeycomb appearance. Information on the histologic correlates of these features is scant, but they may represent thickened fibrous deposits or may simply reflect increased visibility of normal connective tissue because of surrounding edema[46].

Ductal criteria specific to EUS include obvious to more subtle ductal dilation (> 3 mm in the head, ⩾ 2 mm in the body, > 1 mm in the tail), hyperechoic main duct margins, irregular main duct margins, and visible side branches[5].

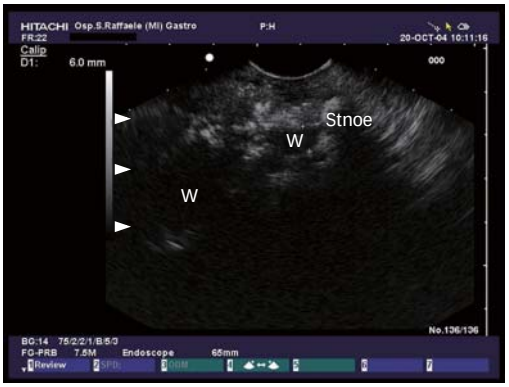

Figure 13 Advanced chronic pancreatitis with calcifications, pancreatic stone and dilation of the pancreatic duct.

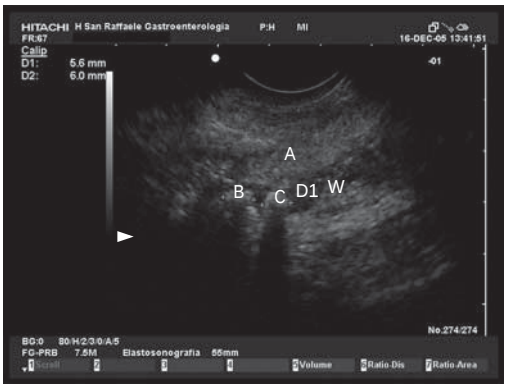

Figure 14 Pancreatic head (A) and pancreatic duct stones (B and C).

Normally, the duct walls are invisible; if they become visible, they may be considered hyperechoic.

A quantitative analysis with nine possible criteria (hyperechoic foci, hyperechoic strands, lobularity, ductal dilation, ductal irregularity, hyperechoic duct margins, visible side branches, calcifications, and cysts) suggests that, in a population at low to moderate risk of CP EUS is most reliable only when it is either clearly normal (< 2 criteria) or clearly abnormal (> 5 criteria). If three or four criteria are present, the outcome is equivocal.

With aging, the pancreas may become atrophic and appear less homogeneous, and the pancreatic duct may become slightly dilated[6]. Alcohol consumption is also associated with parenchymal changes. In a group of 19 alcohol abusers with chronic abdominal pain, 17 (89%) had chronic pancreatitis as indicated by EUS[47].

Agreement is moderate between experienced examiners in making a diagnosis of chronic pancreatitis, with either radial systems or curvilinear EUS systems. All studies agree, however, that "calcification" and "calculi" provide the highest diagnostic power (Figures 13 and 14).

If the initial workup following an attack of acute pancreatitis is negative and successive attacks occur, the evaluation has to include imaging techniques such as EUS, MRCP and blood tests, depending on individual presentation.

In conclusion, EUS should be useful in ARP as it is sensitive for diagnosing bile duct stones, gallbladder sludge, pancreatic lesions, ductal abnormalities and chronic pancreatitis. EUS appears to be diagnostic in the majority of patients with previously unexplained pancreatitis, and offers an alternative to ERCP as the initial diagnostic test in patients with ARP.

Abstract

Although there are numerous causes of acute pancreatitis, an etiology cannot always be found. Two potential etiologies, microlithiasis and sphincter of Oddi dysfunction, are discussed in this review. Gallbladder microlithiasis, missed on transcutaneous ultrasound, is reported as the cause of idiopathic acute pancreatitis in a wide frequency range of 6%-80%. The best diagnostic technique for gallbladder microlithiasis is endoscopic ultrasound although biliary crystal analysis and empiric cholecystectomy remain as reasonable options. In contrast, in patients who are post-cholecystectomy, bile duct microlithiasis does not appear to have a role in the pathogenesis of acute pancreatitis. Sphincter of Oddi dysfunction is present in 30%-65% of patients with idiopathic acute recurrent pancreatitis in whom other diagnoses have been excluded. It is unclear if this sphincter dysfunction was the original etiology of the first episode of pancreatitis although it appears to have a causative role in recurring episodes since sphincter ablation decreases the frequency of recurrent attacks. Unfortunately, this conclusion is primarily based on small retrospective case series; larger prospective studies of the outcome of pancreatic sphincterotomy for SOD-associated acute pancreatitis are sorely needed. Another problem with this diagnosis and its treatment is the concern over potential procedure related complications from endoscopic retrograde cholangiopancreatography (ERCP), manometry and pancreatic sphincterotomy. For these reasons, patients should have recurrent acute pancreatitis, not a single episode, and have a careful informed consent before assessment of the sphincter of Oddi is undertaken.

INTRODUCTION

Sphincter of dysfunction (SOD) is a benign, noncalculous obstructive disorder that occurs at the level of the sphincter of Oddi (SO) (Figure 1). The pathogenesis of SOD relates either to passive obstruction at the SO caused by fibrosis and/or inflammation or to active obstruction caused by sphincter muscle spasm. These two mechanisms of functional obstruction at the SO are not mutually exclusive.

SOD is a possible cause of three clinical conditions: (1) persistent or recurrent biliary pain following cholecystectomy in the absence of structural abnormalities, (2) acute idiopathic pancreatitis, and (3) biliary pain in patients with intact gallbladders but without cholelithiasis (the least studied and most controversial clinical association). SOD also has been described in patients who have had liver transplantation, have the acquired immunodeficiency syndrome, and have hyperlipidemia. This manuscript will discuss only the association of SOD with acute idiopathic pancreatitis (AIP).

Microlithiasis is another possible cause of acute idiopathic pancreatitis. This is best studied in patients with intact gallbladders, and is felt to be one of the most common causes of AIP. Although it seems intuitive that microlithiasis may also occur *de novo* in the bile duct in patients with prior cholecystectomy, this entity is not well described.

MICROLITHIASIS AS A POTENTIAL CAUSE OF ACUTE IDIOPATHIC PANCREATITIS

Gallbladder in situ

Microlithiasis has been defined as tiny stones (1-2 mm) that are missed on imaging studies. In contrast, biliary sludge is a collection of crystals (seen only by microscopic

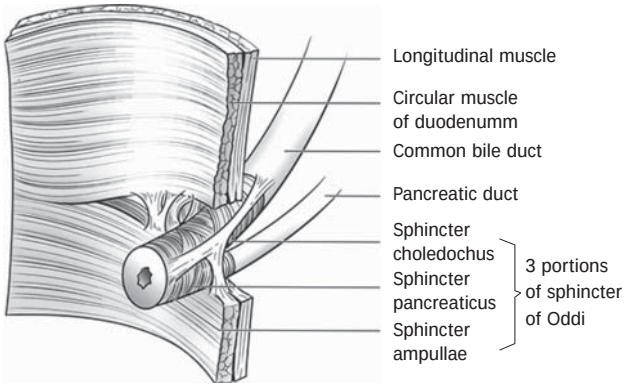

Figure 1 Sphincter of Oddi anatomy.

exam), glycoproteins, protein, cellular debris and mucin. In practice, since biliary sludge may contain microlithiasis these two terms have been used interchangeably[1]. In patients with intact gallbladders, it has been estimated that up to 60%-80% of acute idiopathic pancreatitis may be due to microlithiasis[2-4]. Other centers have found a much lower incidence of 6%-8% of "missed gallbladder disease" in AIP patients[5].

For AIP patients with an intact gallbladder and a normal transcutaneous gallbladder ultrasound, several diagnostic and therapeutic options exist. First is empiric cholecystectomy. This is still commonly practiced and is not unreasonable if the incidence of "missed stones or sludge" is common in your area. Alternatively, duodenal aspiration of bile after CCK stimulation can be utilized for diagnostic confirmation. The sensitivity of this procedure is 66%[6,7]. Direct common bile duct aspiration at ERCP has also been performed although requires CCK administration to ensure collection of gallbladder bile[8]. Technical problems with crystal analysis have limited its popularity for the confirmation of microlithiasis despite its long history of use. Endoscopic ultrasound has become a popular alternative for further diagnostic testing due to its higher sensitivity for microlithiasis and sludge[9]. (Table 1) EUS also has the advantage of evaluating several alternative causes for AIP including pancreas divisum, neoplasms, and undiagnosed chronic pancreatitis[10].

Therapy for microlithasis/sludge is generally laparoscopic cholecystectomy although endoscopic biliary sphincterotomy in the poor operative candidate[11] or long-term treatment with ursodeoxycholic acid[3] are alternatives.

Post cholecystectomy

Bile duct stones that present within 2 years of cholecystectomy are usually stones that originated in the gallbladder that were missed at the time of surgery. If they present more than 2 years after cholecystectomy, they are de novo bile duct stones. Both types can be missed on traditional imaging tests and may be small stones or "microlithiasis". Endoscopic ultrasound is the most sensitive test to detect bile duct stones and appears more cost effective and sensitive than MRCP[12]. Bile obtained from the common bile duct at ERCP for crystal analysis in patients who have had prior cholecystectomy does not have diagnostic value in AIP patients[13]. Bile crystals are rare in patients with manometrically proven sphincter of Oddi dysfunction (SOD)[14]. The fact that empiric biliary sphincterotomy benefits less AIP patients compared to dual or pancreatic sphincterotomy also suggests that biliary sludge/microlithiasis is not a likely cause of AIP in patients post cholecystectomy. Indeed the benefit of biliary sphincerotomy alone in AIP patients has been attributed to a decrease of pancreatic sphincter pressure that may occur after bilary sphincterotomy[15] rather than a treatment for microlithiasis.

Table 1 Diagnostic yield of EUS in acute idiopathic pancreatitis[10]

EUS finding	No cholecystectomy (%) (n=246)	Post-cholecystectomy (%) (n = 124)
Stones (GB or BD)	7	3
GB Sludge	11	-
Pancreas division	5	11
IPMN/neoplasm	2.8	4.8
Chronic pancreatitis (⩾ 5 criteria)	31	27
Other	4.8	4.8

SPHINCTER OF ODDI DYSFUNCTION IN AIP

Several studies have demonstrated a high frequency (30%-65%) of sphincter hypertension in patients with acute idiopathic pancreatitis, and a 50% to 87% frequency in those with chronic pancreatitis. Elevated pancreatic sphincter pressure in humans has been shown to correlate to increased intrapancreatic ductal pressure presumably playing a role in the pathogenesis of pancreatitis[16]. Whether this pancreatic duct obstruction causes the initial injury or is the result of prior pancreatic inflammation is unknown. Elevated pancreatic basal SO pressure and concomitant elevated PD pressure also occurs in patients with pain only and no prior evidence of pancreatitis arguing that it is not the sole determinant of pancreatitis. However, since pancreatic sphincter ablation does decrease future attacks of pancreatitis (although studies are primarily retrospective and uncontrolled), it appears that pancreatic SOD plays a role in the pathogenesis of recurrent attacks even if it was not the original cause.

A classification system similar to the three types of suspected biliary SOD has been proposed for possible pancreatic SOD[17]. In the contemporary proposed system, pancreatic type I patients have pancreatic-type pain, a serum amylase or lipase level of 1.1 times normal on one occasion, and pancreatic duct dilation (> 6 mm in the head and > 5 mm in the body); pancreatic type Ⅱ patients have pain and one of the preceding criteria; type Ⅲ patients have pancreatic-type pain only. This classification system is not widely utilized for several reasons: (1) Few patients with type I pancreatic SOD are reported, the vast majority of AIP patients have normal pancreatic duct caliber, (2) AIP patients would fit into the pancreatic type Ⅱ category and are the primary patients of interest, and (3) Pancreatic type pain only is not sufficiently specific to be a widely accepted diagnosis.

The gold standard for making the diagnosis of SOD

is SO manometry during ERCP. Water perfused catheters are the most commonly utilized systems although microtransducer manometry is also reported[18]. Although some experts have argued for attention to abnormalities of sphincter manometry other than baseline sphincter pressure, such as phasic wave frequency and propagation direction, only basal pressures are widely used clinically. Abnormal basal sphincter pressures are usually concordant for the pancreatic and bile ducts but may occur in only one portion of the sphincter. It has been shown that increased basal sphincter pressure is more likely to be confined to the pancreas in patients with pancreatitis and more likely confined to the bile duct in persons with elevated levels of serum liver enzymes[19].

PANCREATIC SOD TREATMENT CHOICES

Medical therapy with sphincter relaxing medications has been used in biliary SOD although data is sparse supporting their benefit. There are no trials of medical therapy in the treatment of AIP, although intravenous gabexate[20] and somatostatin[21] given during pancreatic SOM have been shown to either alter phasic wave frequency or lower pancreatic basal sphincter pressure. Endoscopic injection of botulinum toxin in patients with AIP is reported to decrease pancreatitis episodes in 80% of patients[22] although the benefit is not prolonged and there is concern about possible long-term side effects.

Endoscopic sphinctertomy results in clinical benefit for pancreatic SOD in AIP patients although the studies are mostly small case series[13,23,24]. There continues to be disagreement about the type and method of sphincterotomy. Some experts continue to perform biliary sphincterotomy alone as a first line treatment[25]. It is known that this will decrease pancreatic sphincter pressure in some patients and is thought to be a safer first line therapy. It is also a treatment for possible biliary microlithiasis. Other experts direct their endoscopic treatment to the pancreatic sphincter alone when the indication is IAP and pancreatic SOD[17]. This avoids unnecessary biliary sphincterotomy although a small one likely occurs during septotomy. Other experts advocate dual complete sphincterotomies[26]. Current literature supports temporary pancreatic stenting in all of these patients to lower their risk of procedure-induced pancreatitis. There is also some evidence suggesting a lower rate of subsequent pancreatic orifice stenosis and procedure-induced pancreatitis if the pancreatic sphincterotomy is performed with a needle knife over a pancreatic stent instead of a traction type sphincterotome[27].

Surgical sphincteroplasty has also been performed for pancreatic SOD in AIP patients[28]. Although clinical response was reported in 58% of AIP patients in this case series, it is unlikely that the more aggressive surgical approach is warranted unless endoscopic therapy is not feasible due to altered anatomy or in other unusual circumstances.

TREATMENT OUTCOMES IN IAP

There are few prospective data and only one controlled trial that address the outcome of endoscopic therapy in patients with IAP. The controlled trial used serial pancreatic stents over 9 mo *vs* serial ERCP without stent insertion and was performed in patients without sphincter hypertension so it is uncertain if the results pertain to the AIP patients with documented pancreatic SOD. The rate of recurrent pancreatitis was reduced from 53% to 11% over the 3-year study period in the stented group[29]. This positive result in manometrically normal AIP patients highlights our lack of understanding of the sensitivity and specificity of SOM.

Several case series report excellent response to biliary sphincerotomy alone[30,31] although Guelrud in an abstract found that patients who underwent dual sphincterotomy fared better (86%) than those treated by biliary sphincterotomy alone (28%)[32]. Most experts believe that treatment of the pancreatic sphincter should occur at the initial therapy although strong evidence is lacking. However, it seems rational to first incise the sphincter that correlates with the presentation of the patient, meaning that pancreatic or dual sphincterotomy should be considered the treatment of choice for AIP patients with documented pancreatic SOD. A rational approach to an AIP patient is to perform EUS to rule out other potential causes of pancreatitis and to proceed to ERCP with manometry if the patient is anxious for treatment and understands that treatment success occurs in only 60%-80% of patients and that the treatment is not without complications[33]. Some experts would limit ERCP with manometry and possible pancreatic sphincterotomy to patients with recurrent AIP since some patients may have only one attack or have attacks separated by many years.

Skeptics continue to point out that there are many problems with endoscopic therapy for AIP[34]. First, there is a variable natural history of AIP patients making it difficult to assess treatment outcome. It is clear that some patients may go years between attacks of pancreatitis making long-term follow up mandatory. Second, endoscopic therapy is not without risks even with prophylactic pancreatic duct stent placement. A prospective randomized controlled trial is needed.

CONCLUSION

Two potential causes of acute idiopathic pancreatitis are microlithiasis and sphincter of Oddi dysfunction. Microlithiasis is common in patients with an intact gallbladder and acute idiopathic pancreatitis although the reported incidence varies widely. It is best detected by endoscopic ultrasound although empiric cholecystectomy remains a reasonable choice, especially in high incidence centers. Microlithiasis has not been found to be associated with acute idiopathic pancreatitis in post-cholecystectomy patients.

Sphincter of Oddi dysfunction is also common in patients with acute recurrent idiopathic pancreatitis. It remains unclear if SOD is the initial cause of the pancreatitis or is due to prior attacks. Irregardless, sphincter ablation decreases the frequency of subsequent attacks although this conclusion is based on the few available studies that are retrospective and small. Despite

this lack of data, it is reasonable to pursue ERCP with manometry and possible pancreatic sphincterotomy in patients with frequent recurrent attacks since there are no other treatment options. However, a careful discussion with the patient of the risks versus benefits of pancreatitic sphincterotomy in acute recurrent pancreatitis is required.

Abstract

Acute recurrent pancreatitis is a clinical entity largely associated with pancreatic ductal obstruction. This latter includes congenital variants, of which pancreas divisum is the most frequent but also controversial, chronic pancreatitis, tumors of the pancreaticobiliary junction and sphincter of Oddi dysfunction. This review summarizes current knowledge about diagnostic work-up and therapy of these conditions.

INTRODUCTION

Acute recurrent pancreatitis (ARP) represents a clinical entity in which acute pancreatitis occurs more than once in the setting of a normal morpho-functional pancreas[1].

The diagnosis of acute pancreatitis is generally based on clinical and laboratory findings. Imaging studies are obtained to confirm clinical diagnosis, to rule out mechanical factors that may induce a transient obstruction of pancreatic juice flow, to assess the extension of the inflammatory process in and around the pancreas, and to detect possible complications.

In patients presenting with ARP and a normal gland visualized on transabdominal ultrasound and abdominal CT, a primary role for secretin-enhanced magnetic resonance cholangiopancreatography (S-MRCP) has been suggested[2].

Indeed, the exogenous administration of secretin stimulates the secretion of fluid and bicarbonate by the exocrine pancreas[3]. Consequently, the volume of fluid in the pancreatic ducts increases which permits a more accurate visualization of the pancreatic ductal system, a better detection of anatomical variants, an evaluation of the pancreatic flow dynamics and therefore an indirect assessment of the sphincter of Oddi and of the pancreatic exocrine reserve[4].

S-MRCP offers several advantages over endoscopic retrograde cholangiopancreatography (ERCP) such as its non invasiveness, the absence of procedure-related complications, the absence of contrast injection or radiation exposure and its performance in post-surgical patients. Secretin administration is safe, even in the setting of acute pancreatitis[5] but additional time and cost are required, therefore restricting the use of secretin in warranted indications i.e. assessment of ARP.

ERCP should be performed only in those patients in whom the etiology of pancreatitis cannot be achieved by S-MRCP (for inspection of the papilla, for brush cytology and biopsy sampling, for bile or pancreatic juice aspiration) or for therapeutic purposes.

An etiology can be found in 70%-80% of patients after an attack of acute pancreatitis, with alcohol abuse and gallstone disease most often implicated[6,7]. Any factor capable of causing an initial episode of acute pancreatitis has the potential to initiate recurrent episodes[2].

The purpose of this review focuses on mechanical factors that promote recurrent episodes of pancreatitis by inducing a persistent or transient obstruction to pancreatic juice flow into the duodenum with a subsequent rise in intraductal pancreatic pressure.

Potential causes of pancreatic ductal obstruction include: (1) anatomical congenital variations of the biliopancreatic ductal system; (2) acquired obstructive conditions at the level of major/minor papilla, the level of the main pancreatic duct (MPD), or the level

Table 1 Potential causes of pancreatic ductal obstruction in acute recurrent pancreatitis

Potential causes	Diagnostic evaluation patient selection	Potential treatment strategies
Congenital variants		
-PD ± Santorinicele	S-MRCP	ERCP ± EPS at the minor papilla ± transient dorsal duct stenting
-APBU	S-MRCP	ES
-Choledochocele	S-MRCP	EBS
-Type Ⅰ & Ⅳ choledochal cyst	S-MRCP	Surgical resection + HJ
-Duodenal duplication cyst	S-MRCP	Endoscopic snare resection or surgical resection
-Annular pancreas	S-MRCP	ERCP + EPS or surgical gastrojejunostomy
Acquired obstructive conditions		
-Suspected neoplasm		
ampullary tumor	EUS, S-MRCP	Curative/palliative endotherapy
MPD stricture	EUS, S-MRCP	or
IPMT	EUS, S-MRCP	surgery
-Suspected early CP	EUS, S-MRCP	ERCP + EPS ± transient MPD stenting
-Groove pancreatitis (CDDW)	EUS, S-MRCP	ERCP + dual ES + MPD stenting or surgery or somatostatin
-Pancreatic SOD type Ⅰ, type Ⅱ, type Ⅲ	S-MRCP	ERCP + dual ES + transient MPD stenting

of the duodenal wall; (3) pancreatic sphincter of Oddi dysfunction (SOD) (Table 1).

A detailed discussion of pancreatic ductal system obstruction as specific causes of ARP follows with emphasis on recent developments.

ANATOMICAL VARIATIONS OF THE BILIOPANCREATIC DUCTAL SYSTEM

Pancreas divisum

Pancreas divisum (PD) is the most common congenital variant of the pancreas, affecting 5%-14% of the Caucasian population[6,8-10]. This variant occurs when the embryological ventral and dorsal ducts fail to fuse during the second month of life in utero. In this case, the ventral duct only drains the ventral pancreas through the major papilla, whereas the majority of the pancreas drains *via* the dorsal duct through the minor papilla. The diagnosis of PD can be done safely and accurately by S-MRCP showing the dorsal pancreatic duct crossing the common bile duct anteriorly and separated from a smaller ventral duct[11] (Figure 1). A relative obstruction at the small papillary orifice of the minor papilla overburdened by draining the larger dorsal pancreas has been proposed more than 25 years ago as the mechanism of pancreatitis associated with PD[12].

However, the clinical significance of PD remains controversial. Indeed, only a minority of patients with PD (less than 5%) becomes symptomatic with ARP, chronic pancreatitis or chronic abdominal pain[10,13].

In a large ERCP series, we failed to find a significantly increased frequency of pancreatic disease among patients with PD compared with control patients[14].

Recruitment bias (greater frequency of PD diagnosis in patients referred after unsuccessful opacification of the pancreatic ductal system) may have resulted in an

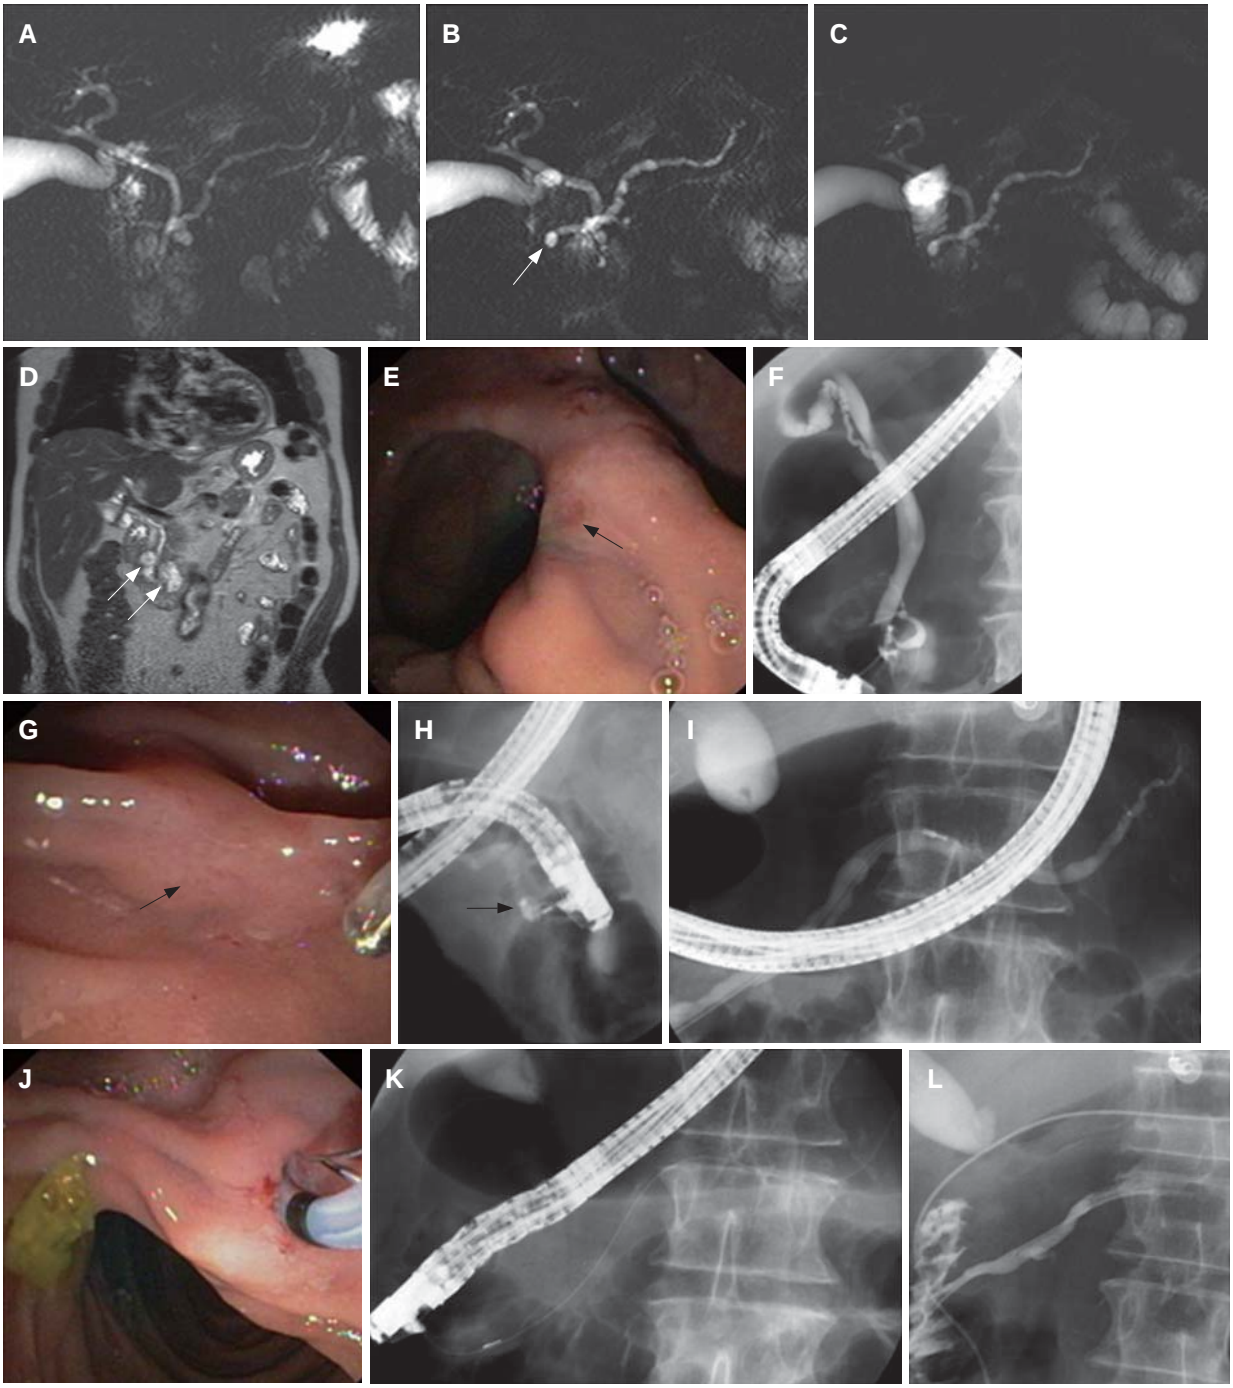

Figure 2 An 80-year-old man presented with 3 attacks of acute pancreatitis over 5 yr. There was no history of alcohol abuse, smoking, nor medications. There were no gallbladder stones at transabdominal ultrasound and no common bile duct stones at endoscopic ultrasonography. Unenhanced (**A**) and secretin-enhanced magnetic resonance cholangiography (**B**) 3 min after secretin injection and **C**: 10 min after secretin injection). Ectasia of the minor papilla (Santorinicele) (arrow in **B**) is seen only after secretin administration. Dilatation of the main pancreatic duct persists 10 min after secretin stimulation (**C**), suggesting obstruction at the level of the minor papilla. Coronal view on T2-weighted magnetic resonance imaging (**D**) shows 2 paraduodenal diverticula (arrows in **D**). The major papilla is located on a fold between 2 diverticula (arrow in **E**), whereas the minor papilla is extremely difficult to locate even after secretin injection and methylene blue staining (arrow in **G**). During ERCP, cannulation of the major papilla allows opacification of a normal common bile duct and a short ventral pancreatic duct (**F**). Cannulation of the minor papilla using the needle, in the long scope position, allows opacification of a cystic dilatation of the distal part of the dorsal pancreatic duct (Santorinicele, arrow in **H**). The main dorsal pancreatic duct is dilated (maximal diameter: 8.3 mm after correction for magnification) (**I**). Endoscopic minor papillotomy is performed with a standard pull-type sphincterotome (**J-K**) and subsequently a 6 Fr nasopancreatic catheter is inserted for 24 h (**L**). After sphincterotomy, contrast medium flows freely alongside the nasopancreatic catheter into the duodenum.

overestimation of the prevalence of PD in previous other ERCP studies investigating ARP and PD[15].

More recently, in an S-MRCP study (where the bias of referral to a tertiary center after failure of ERCP was avoided), the frequency of PD was similar in 54 control patients, in 68 patients with established chronic pancreatitis and in 157 patients in whom pancreatic disease was suspected on the basis of idiopathic acute pancreatitis (n = 67), increased serum levels of pancreatic enzymes (n = 42) or pancreatic-type pain (n = 48)[16].

As most patients with PD do not develop pancreatitis, a stenosis of the minor papilla or a Santorinicele (Figure 2)

(defined as a cystic dilatation of the distal dorsal duct just proximal to the minor papilla and considered as resulting from a combination, either acquired or congenital, of relative obstruction and weakness of the distal ductal wall) could be the additional necessary factors to cause an acute pancreatitis in a few patients with PD[17].

Identification of a Santorinicele at S-MRCP (Figure 2B) or a minor papillary stenosis (suggested by an abnormal response to secretin, i.e. persistent dilatation of the MPD greater than 3 mm at 10 min after secretin injection in patients younger than 60 years) might be helpful in selecting a subset of patients with PD and ARP who might benefit from pancreatic ductal drainage[16-18].

Indeed, patients with PD and Santorinicele showed a larger MPD in the head of the gland compared with that in patients with only PD (compare Figures 1B and 2B), both at rest and after secretin stimulation[17]. Moreover, the mean interval between the injection of secretin and the onset of duodenal filling was significantly longer in patients with Santorinicele compared with that in patients without Santorinicele[17]. These observations suggest the presence of impeded pancreatic secretion outflow at the level of the minor papilla with subsequent increased intraductal pressure.

In a prospective study including 279 patients investigated by S-MRCP, an abnormal response of the MPD to secretin stimulation could be detected in 12% of the patients with ARP but the dynamics of pancreatic duct filling after secretin stimulation did not differ between patients with or without PD[16]. Whether the observation of an abnormal response of the dorsal pancreatic duct to secretin stimulation at S-MRCP is clinically relevant still remains to be demonstrated.

There is also no consensus regarding the appropriate treatment for ARP associated with PD but available data suggest that some patients may benefit from dorsal duct drainage[19]. For example, it was reported that patients with Santorinicele may benefit from endoscopic papillotomy of the minor papilla (Figure 2G-L) as evidenced by a remarkable reduction in size of the MPD and of the Santorinicele on follow-up S-MRCP images and by symptomatic improvement[17]. The same might be true for patients with a persistent ductal dilation after secretin administration visualized at MRCP or ultrasound.

Dorsal duct drainage could be achieved by surgical sphincteroplasty of the minor papilla[20] or endoscopic therapy including minor papilla sphincterotomy, transient dorsal duct stenting or combination[13,19,21]. The overall success rate of endoscopic therapy is similar to the results of surgical sphincteroplasty. Patients with well defined bouts of pancreatitis had a significantly higher response rate (70% to 80%) to dorsal duct drainage than those with chronic pancreatitis or chronic abdominal pain[13,22].

Endoscopic minor papillotomy may be performed with a standard pull-type sphincterotome (Figure 2J-K) and subsequent placement of a 5 Fr unflanged stent into the dorsal pancreatic duct to protect against early scarring and post-ERCP pancreatitis, or with a needle knife over a previously placed dorsal pancreatic duct stent. The stent should be removed within 2-4 wk if it has not migrated spontaneously into the duodenal lumen to avoid stent-induced damage to the pancreatic duct[21].

The majority of therapeutic trials are small, retrospective case series with only one randomized controlled trial on 19 patients presenting with ARP and PD, showing a clinical benefit after dorsal duct stenting at a mean follow-up of 12 mo after retrieval of the stent[23]. However, prolonged stenting of the dorsal MPD should be avoided because of the risk of inducing pancreatic damage mainly when the ductal morphology is normal initially[22]. Complication and papillary restenosis rates were reported in 9% and 16% respectively among 69 patients with ARP and PD treated by pancreatic sphincterotomy of the minor papilla[21].

Further studies using S-MRCP should evaluate the outcome of minor papilla sphincterotomy in patients with PD and ARP in order to provide selection criteria that indicate which patients would be most amenable for therapy.

Other congenital variants

Various congenital abnormalities of the pancreaticobiliary system are associated with ARP[24]. In 1.5% to 3% of individuals there is an anomalous union of the pancreatic and bile ducts outside the duodenal wall, which results in an unusually long common channel measuring more than 15 mm proximal to the duodenum[25]. This common channel facilitates free reflux of bile and pancreatic juice into the alternative duct. Bile entering the pancreas may potentially induce acute pancreatitis by increasing intraductal pressure, and reflux of pancreatic enzymes into the bile duct predisposes to the development of the choledochal cyst[26].

Pathogenesis of ARP in cases of anomalous pancreaticobiliary union (APBU) has also been associated with temporary occlusion of pancreatic secretion by stone, protein plugs, or sphincter of Oddi dysfunction, all leading to a rise in pancreaticobiliary intraductal pressure[25]. Endoscopic ultrasonography and S-MRCP show a good overall accuracy for detecting ductal variations[27] and demonstrating associated reflux[28].

Acute pancreatitis was reported to occur in 3% to 31% of APBU patients[24]. It was usually mild and resolved in a few days with conservative treatment. Sphincter ablation by endoscopic sphincterotomy may decrease the risk of ARP[9].

Choledochocele is a rare congenital or acquired condition, depicted as a dilatation of the intraduodenal segment of the common bile duct. It was initially included in the Todani classification of the choledochal cysts as type Ⅲ[29], but recently type Ⅱ (diverticulum of the common bile duct related to a form of gallbladder duplication), type Ⅲ (choledochocele) and type Ⅴ (Caroli disease associated with congenital hepatic fibrosis) were considered as unrelated to choledochal cysts[30].

Pancreatitis develops when the cystic dilatation or its content (sludge or stones) obstruct pancreatic duct outflow. Recommended treatment consists of uprooting the choledochocele by endoscopic sphincterotomy[31].

Types Ⅰ and Ⅳ choledochal cysts (congenital dilatation of the extrahepatic bile ducts with a variable amount of intrahepatic involvement) account for more than 90% of the patients with choledochal cysts and among them, 16% presented with pancreatitis[30]. In such patients, the entire extrahepatic biliary tree and gallbladder should be removed

with reconstruction by a Roux-en-Y hepaticojejunostomy to prevent the risk of further cholangiocarcinoma.

Duodenal duplication is a cyst-like structure bulging into the duodenal lumen just distal to the papillary orifice. The duodenal duplication cysts contain Brunner's glands within their wall. The association of pancreatitis with duodenal duplication is infrequent[32]. Pancreatitis may result from occlusion of the pancreatic ductal system by the distended duodenal cyst filled with secretions or stones. Endoscopic snare resection of the top of the cyst has been described[33,34].

Annular pancreas refers to a part of pancreatic tissue partially or completely encircling the duodenum usually at the level of or just proximal to the major papilla. This anomaly occurs when the ventral bud fails to rotate with the duodenum during embryological development. This rare variant is often associated with duodenal or biliary obstructive symptoms and pancreatitis may affect the annulus or the remaining pancreas. Recommended treatment consists in gastrojejunostomy[35] in case of duodenal occlusion.

Congenital variants of the biliopancreatic ductal system provide interesting challenges when discovered during the diagnostic workup of ARP. However, most of these variants are clinically irrelevant. Therefore methods to select patients who are likely to benefit from therapy would be of the utmost importance.

ACQUIRED OBSTRUCTIVE CONDITIONS

Tumors of the pancreaticobiliary junction

It is estimated that 5% to 7% of patients with pancreaticobiliary tumors, benign or malignant, present with idiopathic ARP[9]. Mechanical blockage of the papillary orifice by ampullary tumors, may lead to painless jaundice, anemia, but also idiopathic ARP. Therefore careful papilla inspection for size and shape should be included in the diagnostic workup of ARP of unknown etiology and papilla biopsies should be taken when indicated.

Adenomas are the most common ampullary tumors and represent premalignant conditions which need endoscopic snare resection or surgical resection according to their size and histological grade[36]. Surveillance remains an option, especially for those occurring in the setting of familial adenomatous polyposis which are not symptomatic[37].

Similarly, unexplained ARP in a patient 45 years or older requires that an underlying pancreatic carcinoma be excluded[38]. The incidence of malignant pancreatic neoplasm as the underlying cause of acute pancreatitis is low (only 3%) in patients younger than 40 years of age compared to patients aged 40 to 60 years (21%) and to patients aged older than 60 years (25%)[39].

Endoscopic ultrasonography and S-MRCP are helpful procedures in assessing strictures of the MPD and associated parenchymal and ductal changes.

Cytologic and histologic intraductal sampling of pancreatic ductal strictures, tumoral molecular markers searched on pure pancreatic juice or brushing samples may help to unravel the suspicion of malignancy.

Chronic pancreatitis

ARP may also be the clinical presentation of early chronic pancreatitis (CP). Indeed, according to the recently proposed Sentinel Acute Pancreatitis Event (SAPE) hypothesis, repeated attacks of acute pancreatitis may evolve to a clinically chronic disease[40].

Early stages of chronic pancreatitis can be specifically detected by endoscopic ultrasonography (3 to 5 positive criteria among echogenic duct walls, irregular duct contour, dilated side branches, parenchymal echogenic foci or strands, lobularity of the gland,..)[41] and by S-MRCP (abnormal ductal response to secretin, progressive enhancement of the pancreatic parenchyma related to a loss of ductal or parenchymal compliance, characteristic side-branch involvement, changes in gadolinium uptake,…)[4,42].

It was shown that a substantial number of patients with ARP indeed have evidence of CP (42%-47%) during follow-up evaluation[41,43] and that CP was twice as frequent in patients with ARP compared with those with a single episode of pancreatitis[41].

Strictures of the MPD, generally due to inflammation or fibrosis around the MPD and obstructing pancreatic stones may contribute to abdominal pain or ARP in patients with CP. In these advanced stages of CP (which are not called ARP anymore), S-MRCP demonstrates the ductal anatomy, the degree and level of pancreatic duct obstruction, the associated complications (pseudocysts, common bile duct stricture) and the possible duodenal filling impairment suggesting pancreatic exocrine insufficiency. This imaging procedure is mainly useful before planning therapy and also for follow-up after relief of ductal obstruction[2].

Groove pancreatitis or cystic dystrophy of the duodenal wall is an uncommon type of CP affecting the "groove" between the head of the pancreas and the duodenum. The most characteristic finding is a sheet-like mass between the head of the pancreas and the thickened duodenal wall associated with cystic changes[44]. The cysts in the duodenal wall develop from foci of heterotrophic pancreas lying close to the pancreas. In a series of CP patients, the frequency of cystic dystrophy of the duodenal wall is to the order of 25% with a strong male predominance, a mean age of 45 years and frequent weight loss and vomiting associated to the ARP clinical presentation[45].

Endoscopic ultrasonography is the exploration of choice to search for cystic dystrophy of the duodenal wall. MR imaging can also visualize cystic formations and a band of low-intensity signals on T1 and T2 sequences, lying between the second portion of the duodenum and the pancreas, and corresponding to heterotopic pancreatic tissue.

Pancreaticoduodenectomy remains the most effective treatment since the diseased tissue is removed but endoscopic cystic and pancreatic ductal drainage and somatostatin analogs are also alternatively proposed therapies[44].

Pancreatic sphincter of Oddi dysfunction

Sphincter of Oddi dysfunction (SOD) is defined as a benign, non-calculous partial obstruction (organic or functional) of the biliary and/or the pancreatic segment of the sphincter of Oddi, giving rise to episodic upper abdominal pain or pancreatitis[46].

SOD is reported to be present in about 30% of

patients with ARP of unknown etiology[7,9]. Organic or functional obstruction of the sphincter of Oddi may promote reflux of bile into the MPD or impairment of pancreatic duct outflow, causing pancreatitis.

Patients with pancreatic SOD may be classified similarly to those with biliary SOD[6]. Pancreatic type I SOD corresponds to a papillary stenosis and is thought when pancreatic-type pain or documented ARP are associated with elevated serum amylase/lipase and a dilated MPD (> 5 mm in the body of the pancreas). In pancreatic type Ⅱ SOD, pancreatic-type pain or ARP are combined with one additional factor defining type I , and pancreatic type Ⅲ SOD includes patients having recurrent pancreatic type pain alone with none of the above findings[1,6,9].

Type I is considered to be due to a chronic inflammatory process which becomes a fibrosis with subsequent stenosis of a part or the entire sphincter. Pancreatic type Ⅱ SOD patients are thought to suffer from sphincter of Oddi dyskinesia that means a functional alteration of the physiological motility of the sphincter which causes some delay in the passage of pancreatic juice into the duodenum[47].

In suspected pancreatic type Ⅲ SOD, an objective diagnosis of dysfunction should rely on sphincter of Oddi manometry (basal pancreatic sphincter pressure > 40 mmHg) or less invasively on MRCP evaluation of changes in the size of the MPD after secretin stimulation (1). However, data regarding pancreatic SOD are sparse, making the management of this disorder even more controversial than its biliary counterpart[13].

Nowadays, sphincter of Oddi manometry tends to be replaced by the non-invasive S-MRCP[48,49] providing information regarding the sphincter of Oddi function by measuring changes in MPD diameter over time, after secretin injection. At S-MRCP, the diagnosis of pancreatic SOD may be suggested when MPD diameter remains increased by greater than 1 mm compared with baseline, throughout the 15 min testing interval. Based on MPD kinetics at S-MRCP, Mariani *et al* found concordant results between S-MRCP and sphincter of Oddi manometry in 13 of 15 patients with idiopathic ARP[48]. Moreover, a recent study suggests that S-MRCP may be useful in selecting those patients with suspected SOD who might benefit from endotherapy[49]. Interestingly, S-MRCP could replace sphincter of Oddi manometry more effectively in type Ⅱ SOD than in type Ⅲ, this latter group being the most controversial for potential therapy[49].

Available data suggest that, in suspected pancreatic SOD (on the basis of either a basal dilatation of the MPD, or an abnormal dynamic response of the pancreatic duct at S-MRCP), a dual endoscopic biliary and pancreatic sphincterotomy, whether at single or separate sessions, yields significantly better response than endoscopic biliary sphincterotomy alone[50]. However, patients with SOD have a complication rate from endoscopic sphincterotomy 5 times higher than that of patients with bile duct stones[51]. Placement of a transient pancreatic stent reduces this risk especially when the accessory duct is not patent[52]. This stent usually migrates spontaneously but in case migration does not occur, it should be removed 10-14 d following dual endoscopic sphincterotomy.

CONCLUSION

ARP should be evaluated in referral centers as diagnosis is time-consuming, usually expensive and may expose the patient to a substantial morbidity. Initial modalities of choice involve CT scan and S-MRCP to detect alterations in the pancreatic parenchyma including calcifications and tumors and in order to obtain a high resolution imaging of the pancreatic ducts.

Endoscopic ultrasonography and ERCP are the next logical steps for the detection of early CP, unappreciated malignancy and for a trial of transpapillary ductal drainage.

Future prospective trials should define which patients, with idiopathic ARP, whether or not it is associated with anatomical variants, are most likely to benefit from pancreatic ductal drainage.

These studies should allow appropriate patient selection and the development of novel, effective, preventive and therapeutic strategies to improve the clinical condition of these patients.

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) has evolved from a largely diagnostic to a largely therapeutic modality. Cross-sectional imaging, such as computed tomography (CT) and magnetic resonance imaging (MRI), and less invasive endoscopy, especially endoscopic ultrasound (EUS), have largely taken over from ERCP for diagnosis. However, ERCP remains the "first line" therapeutic tool in the management of mechanical causes of acute recurrent pancreatitis, including bile duct stones (choledocholithiasis), ampullary masses (benign and malignant), congenital variants of biliary and pancreatic anatomy (e.g. pancreas divisum, choledochoceles), sphincter of Oddi dysfunction (SOD), pancreatic stones and strictures, and parasitic disorders involving the biliary tree and/or pancreatic duct (e.g Ascariasis, Clonorchiasis).

INTRODUCTION

As endoscopic retrograde cholangiopancreatography (ERCP) has evolved from a mainly diagnostic to a predominantly therapeutic modality, so have the indications for pancreatic endotherapy. ERCP is no longer a "first line" investigation but used selectively for patients identified by less- or non-invasive imaging techniques to have a problem that may benefit from endoscopic therapy. Idiopathic acute recurrent pancreatitis (ARP) is a frequent reason for referrals to ERCP endoscopists[1,2]. Conditions causing ARP amenable to endoscopic diagnosis and treatment include: (1) Choledocholithiasis, including microlithiasis ("biliary sludge"); (2) Congenital abnormalities of biliary and pancreatic anatomy (e.g. choledochocele, duodenal duplication/diverticulum, pancreas divisum); (3) Ampullary lesions, benign and malignant; (4) Mucin-secretin pancreatic tumors, including cystic neoplasms in communication with the pancreatic duct, and intrapancreatic mucin-secretin neoplasms (IPMNs); (5) Pancreatic duct strictures, stones and neoplasms; (6) Sphincter of Oddi dysfunction (biliary and pancreatic); (7) Biliary and pancreatic parasites.

CHOLEDOCHOLITHIASIS, INCLUDING BILIARY SLUDGE (MICROLITHIASIS)

In the West, bile duct stones (choledocholithiasis), including microlithiasis (biliary sludge), are by far the commonest cause of ARP. Cholecystectomy will usually take care of the problem. However, when ARP patients have apparently normal gallbladders without stones on cross-sectional imaging, the diagnosis is often questioned. Transabdominal ultrasound (TUS) provides useful information about gallbladder wall and the diameter of bile ducts, but lacks sensitivity for small stones (< 5 mm) and biliary sludge. Endoscopic ultrasound (EUS), a less invasive test than ERCP, is an excellent tool for diagnosing microlithiasis[3]. In my practice, we frequently schedule EUS with ERCP available immediately afterwards (under the same sedation) when we are looking for bile duct stones in patients with recent acute pancreatitis or biliary colic with transiently elevated liver tests, or assessing obstructive jaundice. If the EUS is negative for stones or ampullary lesions, we do not proceed to ERCP. Typically, small gallstones migrate spontaneously out into the small intestine within 24 h. If the liver tests (e.g. bilirubin, alkaline phosphatase, alanine and aspartate aminotransferase (ALT, AST) normalize quickly, and the bile duct resumes a normal diameter, it is very likely that the offending stone has passed. Patients with an intact gallbladder who can be shown by EUS to have microlithiasis should be offered cholecystectomy. Not all surgeons believe that microlithiasis is a satisfactory

explanation for gallstone-like symptoms, but the results of cholecystectomy are convincing to this author! Is there a role for "empiric" ("best guess") biliary sphincterotomy in patients with ARP who have an intact gallbladder but cannot be shown by EUS to have stones or biliary sludge? This intervention would also address biliary sphincter of Oddi dysfunction (SOD) (see below). Preserving the sphincter of Oddi is important in young patients. However, elderly patients with comorbidities that render them "high risk" for surgery may be safely managed by empiric sphincterotomy for symptomatic choledocholithiasis, whether or not the offending sludge or stones can be identified by other imaging[4]. Oral dissolution therapy (i.e. ursodeoxycholic acid) for suspected biliary sludge seems a logical alternative to endotherapy in ARP. However, as the sludge is rarely comprised of pure cholesterol the results are unpredictable and often disappointing.

CONGENITAL ABNORMALITIES OF BILIARY AND PANCREATIC ANATOMY

Choledochal cysts are congenital abnormalities of the biliary tree[5]. Five types are recognized by the Todani classification. Fusiform dilatation of the extrahepatic bile duct (Type Ⅰ) is the commonest choledochal cyst encountered by ERCP endoscopists. Choledochoceles (Type Ⅲ) involve the distal bile duct and protrude as a symmetrical, smooth-surfaced mass into the duodenum at the expected level of the main duodenal papilla. Choledochoceles often are associated with anomalous pancreatico-biliary ductal drainage, such that the patients are predisposed to develop ARP. Blind-ending choledochoceles drain poorly, accumulating sludge and stones, which cause a variety of problems, including cholangitis, obstructive jaundice and gallstone pancreatitis. All choledochal cysts carry some risk of malignant transformation (to cholangiocarcinoma), but this is considered minor for choledochoceles (Type Ⅲ cysts), which are effectively treated by exposing the cyst lumen (usually by needle knife papillotomy) and thereby improving bile flow. Another congenital defect that can interfere with bile and pancreatic juice flow is a duplication cyst of the descending duodenum. This is amenable to endoscopic therapy: a needle knife is used to incise the typical septum that is present. A unique form of duodenal diverticulum - the so-called "windsock" diverticulum, is also a risk factor for ARP. This "billowing" duodenal diverticulum can be managed endoscopically. The commonest abnormality of pancreatic duct anatomy seen in routine ERCP practice is pancreas divisum (P Div), in which the dominant drainage of the pancreas (the dorsal duct) is through the minor duodenal papilla[6]. The ventral pancreatic duct (PD) in P Div is typically small and may be "invisible" (the unsuspected presence of a tiny ventral duct is a common cause of a "failed pancreatogram". The P Div anomaly occurs in 7%-8% of American of European ("Causasian") descent. It is much rarer in African Americans, Asians, Hispanics and other non-Caucasian ethnic groups. P Div is certainly associated with ARP but why a few patients are affected while the majority are spared is unknown. Several studies have suggested that a heterozygous defect in the cystic fibrosis transmembrane regulator (CFTR) gene may predispose patients with P Div to ARP[7]. Improving the drainage of the dorsal PD by minor papillotomy stops the attacks in 70%-80% of cases if chronic pancreatitis (CP) is not already established. Once CP is present, minor papillotomy may only benefit 40%-50%. Patients with a "pancreatic pain syndrome" and P Div but no other objective evidence of pancreatitis do even worse, with symptomatic benefit in only 20% or so. Annular pancreas is a congenital defect resulting in an incomplete ring of pancreas encircling the descending duodenum. This is said to be a cause of ARP, but as annular pancreas is frequently associated with P Div, the predisposition to pancreatitis is more likely a manifestation of the latter. Patients with annular pancreas may exhibit partial gastric outlet obstruction (from constriction of the descending duodenum by a swollen pancreas) during attacks of pancreatitis.

AMPULLARY LESIONS, BENIGN AND MALIGNANT

Ampullary adenomas and carcinomas create an obstruction to pancreatic exocrine secretion and bile flow[8]. Duodenoscopy is mandatory in the investigation of ARP. This author believes that every trainee in gastroenterology should learn to use a side-viewing duodenoscope, not for ERCP but to be able to assess duodenal lesions, including those involving the major and minor papilla. For adenomas and cancers limited to the mucosa (T1 lesions) by endoscopic ultrasound (EUS) examination, endoscopic resection is an option[9]. The main duodenal papilla is a site of predilection for polyp formation in both sporadic and familial adenomatous polyposis (FAP). Polyps < 3 cm in diameter can be removed endoscopically without prior EUS. This is usually accomplished by hot snare cautery, followed by stenting of the pancreatic duct orifice to reduce the risk of procedure-related acute pancreatitis[10]. Piecemeal resection is also an option, but carries a higher risk of recurrence. Polyps ⩾ 3 cm should be assessed by EUS looking for extension of adenomatous tissue into the bile duct and/or pancreatic duct, and to determine the depth of invasion should tumor be present. Clearly malignant tumors of the duodenal papilla (ampullary cancers) are not suitable for endoscopic resection. Biliary and pancreatic drainage may be improved by papillotomy. However, biliary stenting without papillotomy is a safer way to treat obstructive jaundice in ampullary cancer, as these lesions are often quite vascular and bleed when incised. Polyps and tumors involving the minor duodenal papilla rarely cause ARP. However, a cystic dilatation of the distal (duodenal) end of dorsal pancreatic duct in pancreas divisum, called a Santorinicele, may indicate obstruction to flow in patients with P Div and ARP[11]. Incision of the Santorinicele with a re-establishes good flow and may resolve the clinical problem.

CYSTIC TUMORS OF THE PANCREAS, INCLUDING MUCIN-SECRETING CYSTADENOMAS AND IPMNS

Cystic tumors of the pancreas may present with ARP[12]. Serous cystic (or microcystic) tumors have a typical "honeycomb" appearance due to clusters of tiny

cysts. Microcystic adenomas rarely undergo malignant transformation. On the other hand, mucinous cystic tumors can undergo malignant transformation. These tumors may be difficult to distinguish from pancreatic pseudocysts on cross-sectional imaging, but EUS with fine needle aspiration (FNA) of the contents usually makes the diagnosis. About 50% of mucinous cysts of the pancreas have high levels of carcinoembryonic antigen (CEA), the fluid stains positive for the presence of mucin, viscosity is increased (> water) and amylase levels are generally normal or much lower than would be expected in a communicating pseudocyst. The cyst aspirate is also sent for cytologic examination to look for signs of malignant transformation (to cystadenocarcinoma). It used to be said that cystic tumors never communicated with the pancreatic duct (PD), but this is patently untrue. Mucinous cysts communicating with the duct may cause it to become quite dilated. Another source of mucinous distension of the PD is the presence of small tumors of the PD side branches (intrapancreatic mucin-secretin neoplasm, or IPMN)[13,14]. Typically, these present with ARP and imaging showing gross dilatation of the PD. EUS may also reveal nodules within the main PD or side branches. Pancreatoscopy using "mini-'scopes" may identify villous-looking tumors within the PD. At endoscopy with a side-viewing instrument, the main papilla may appear to "wink" open and discharge gelatinous material. Due to the malignant potential of mucinous tumors of the pancreas, surgery is the treatment of choice. In patients unfit for surgery, periodic aspiration of large cysts may reduce the frequency of ARP. Endoscopic stenting of PD is rarely helpful in IPMN as the stent lumen quickly becomes occluded with mucus. Other cystic tumors of the pancreas may occasionally present with ARP (e.g. neuroendocrine tumors which have undergone cystic degeneration, cystic metastases).

PANCREATIC DUCT STRICTURES, STONES AND NEOPLASMS

Pancreatic endotherapy is becoming important in the management of a number of mainly benign pancreatic disorders[15-17]. Strictures of the main PD may be benign or malignant. Benign strictures are usually seen in chronic pancreatitis, but may form after trauma (blunt or penetrating) or instrumentation (e.g. duct stenting). Benign strictures may be solitary or multiple, the latter creating the so-called "chain of lakes" or "string of pearls" appearance. Pancreatic stones frequently form in association with PD strictures, presumably reflecting poor drainage of exocrine secretions. Often these stones are an epiphenomenon, and not truly obstructing. Should pancreatic duct stones be removed? Certainly, it is tempting to try to clear the duct of stones in symptomatic patients, but the results are often disappointing. Pain in chronic pancreatitis is often multifactorial. Endotherapy of presumed obstructing stones and benign PD strictures may be considered a "trial of therapy": if the patient gets symptomatic relief, formal surgical drainage of the pancreas (e.g. by lateral pancreaticojejunostomy, or Puestow procedure) with or without parenchymal resection may help the patient long term. After pancreatic sphincterotomy, small pancreatic stones can usually be removed using a basket or balloon catheter. Large stones that completely obstruct the lumen cannot be recovered this way, and require contact or extracorporeal shockwave lithotripsy (ESWL) to fragment them first[18]. The Brussels group (Drs Deviere and Cremer) have reported excellent results using ESWL for PD stones. PD strictures are typically managed by endoscopic stenting. There are few data on metal mesh stenting in benign pancreatic disease, although several European studies have suggested benefit. At present, metal mesh stenting is not recommended in the US for the management of benign PD strictures[19]. Plastic pancreatic duct stents can induce focal pancreatitis and strictures by occluding small side branches. The recently-introduced "star-shaped" stents that facilitate flow of pancreatic secretions around them may address this problem. As migration of plastic stents into the PD creates a difficult management problem, non-flanged stents intended to spontaneously dislodge into the bowel are made with a curl - or "pigtail" - at their distal end. An interesting application of metal mesh stents in benign pancreatic disease has been tried by the ERCP group from Indiana University (Drs Lehman and Sherman), with some success. They had a group of P Div patients with ARP who failed to improve despite repeated minor papillotomies. As their dorsal PDs were not dilated, they were considered unsuitable for surgical drainage procedures. Drs Lehman and Sherman used expandable metal mesh stents inserted through the minor papilla to cause the dorsal PDs to progressively dilate over time[20]. After this treatment, surgeons were able to perform lateral pancreaticojejunostomies on these patients. Pancreatic cancer (adenocarcinoma) is an unusual cause of ARP, but it should always be considered in elderly patients with unexplained bouts of pancreatitis. EUS may identify small lesions in the PD before a mass is appreciated on CT or MRI scan. Pancreatic stents are rarely indicated in pancreatic cancer, but there have been reports of patients with intractable pain or steatorrhea benefiting from relief of malignant PD obstruction. As mentioned previously, cystic neoplasms, IPMNs and neuroendocrine tumors of the pancreas that can present with ARP.

SPHINCTER OF ODDI DYSFUNCTION (SOD)

When no other cause of ARP is identified in a patient with prior cholecystectomy, SOD should be considered[21,22]. At present, the only way to measure biliary and pancreatic sphincter pressures is perform ERCP using a manometry catheter[23]. Historically, this has been associated with increased risk of post-ERCP pancreatitis (compared to non-manometry ERCP). As Freeman has pointed out, it is not the manometry itself that is dangerous but the instrumentation of a hypersensitive sphincter and (typically) non-dilated bile duct and pancreatic ducts[24]. Prophylactic stenting of the PD after manometry in cases of suspected SOD has significantly reduced the risk of post-ERCP pancreatitis (PEP), and virtually abolished severe (necrotizing) PEP. Most experts now recommend same-session biliary and pancreatic sphincter pressure measurements in ARP patients, as 60%-70% of those

with elevated biliary sphincter pressure have concurrent pancreatic sphincter hypertension[25]. That is, if only biliary pressures are measured and sphincterotomy performed for sustained elevations in ARP, more than 1/2 of these patients will continue to have attacks of pancreatitis. The exact mechanism of ARP in sphincter of Oddi dysfunction (SOD) is unknown[26]. Pharmacologic maneuvers aimed at reducing sphincter of Oddi (SO) pressure, including nitrates and calcium channel blockers, have been disappointing. One small study using intrasphincteric botulinum toxin injection claimed an 80% success rate (12 of 15 patients) for relief of ARP[27], but others have failed to reproduce this impressive outcome. Stenting the PD orifice alone (i.e. without sphincterotomy) is not helpful in SOD: it is likely to exacerbate rather than improve pancreatic pain in the setting of a hypertensive sphincter.

BILIARY AND PANCREATIC PARASITES

A rare cause of ARP, usually limited to tropical climates, is the presence of parasites within the bile ducts or pancreatic duct. Certain liver flukes (e.g. Fasciola hepatica[28], Clonorchis sinensis[29]) like to live and lay their eggs in the bile ducts, where they cause irritation and obstruction (especially when they die). Ascaris lumbricoides worms like to live in the pancreatic duct, where they obstruct flow of exocrine secretions[30]. In the North of India (Kashmir), Ascariasis is the commonest cause of acute pancreatitis. The treatment of these parasites is principally pharmacologic, but occasionally the ERCP endoscopist is called upon to decompress ducts obstructed by parasites, usually by sphincterotomy and trawling (by balloon or basket catheter).

Abstract

One of the most important causes of relapsing pancreatitis is a cystic neoplasm of the pancreas. These low grade malignancies may cause pancreatitis by obstructing or communicating with a pancreatic duct. Patients with relapsing pancreatitis and a focal fluid fluid collection should be investigated for the possibility of a mucinous cystic neoplasm. Cross sectional imaging can provide a diagnosis with the imaging findings of a low attenuation cystic lesion containing mural calcification (CT scanning) or a lobular T2 enhancing lesion (MRCP). Endoscopic ultrasound can provide more detailed imaging with the ability to guide fine needle aspiration of the cyst fluid. Cyst fluid analysis can provide a diagnosis of a mucinous cystic lesion with the combination of cytology (mucinous epithelium), elevated carcinoembryonic antigen (CEA), and the presence of DNA mutations. Management of these patients consists of surgical resection and monitoring in patients not able to withstand surgery.

INTRODUCTION

Acute and chronic relapsing pancreatitis may be caused by a number of structural abnormalities of the pancreas. Of the malignant and pre-malignant lesions of the pancreas associated with pancreatitis, cystic and intraductal tumors are the most common. Patients with these lesions may experience pancreatitis at the time of diagnosis or suffer from relapsing pancreatitis throughout their medical illness. Approximately 9% of patients with recurrent pancreatitis will have an associated pancreatic malignancy[1]. The most likely cause of malignancy-associated pancreatitis is ductal obstruction. Since intraductal papillary mucinous tumors commonly involve the main pancreatic duct and its side branches, recurrent pancreatitis is particularly common in these patients[2].

CLINICAL PRESENTATION

Patients with relapsing pancreatitis present with discrete episodes of abdominal pain often accompanied by nausea and vomiting[3]. After the initial clinical evaluation with laboratory testing, cross sectional imaging is obtained in order to confirm the diagnosis and to determine the extent and severity of the pancreatic inflammation.

The most common abnormality encountered on cross sectional imaging in patients with relapsing pancreatitis is a cystic lesion or a focal fluid collection[4]. In this context, the chief differential is a pseudocyst versus a cystadenoma of the pancreas[5]. Pseudocysts represent a focal collection of inflammatory fluid, leaking from the pancreas. Pseudocysts may persist after resolution of pancreatic necrosis, and the presence of a ductal stricture may contribute to persistence[6]. In contrast, a cystadenoma of the pancreas represents a benign, pre-malignant, or malignant cyst and may also be responsible for the episode of pancreatitis[7]. It is often difficult to determine if a focal fluid lesion is responsible for the episode of pancreatitis or is a consequence of the pancreatitis (pseudocyst). In general, focal fluid collections that are surrounded by a well-defined, thin-walled rim of tissue are more likely to be a form of malignancy, in contrast to thick-walled pseudocysts containing inflammatory debris.

Clinically, there are few clues to differentiate between focal inflammatory fluid collections and cystic neoplasms. However, the findings of jaundice and the recent onset of diabetes should raise the possibility of occult malignancy[8]. Pseudocysts may become apparent with complications

such as hemorrhage or infection. In general, small cystic lesions are rarely responsible for chronic abdominal symptoms.

PATHOGENESIS

The pathogenesis of cystic neoplasms of the pancreas is based on mutations in the epithelial cells lining the pancreatic duct[9]. Serous cystadenomas are strongly associated with mutations of the Von Hippel Lindau (VHL) gene. The VHL gene is likely to play an important role in the pathogenesis of sporadic serous cystadenomas. In one study, 70% of the sporadic serous cystadenomas studied demonstrated a mutation in the VHL gene which probably results in hamartomatous proliferation of these centroacinar cells[10].

The pathogenesis of mucinous cystic neoplasms (MCN) and intraductal papillary mucinous neoplasms (IPMN) involves a separate set of mutations. K-ras mutations are present only in mucinous cystic neoplasms and not in serous microcystic adenomas. The frequency of K-ras mutation in mucinous cystic neoplasms is linearly related to the grades of atypia and the imposition of other mutations is thought be important in the pathogenesis of malignancy. The detection of mutations in tumor suppressor genes is the basis of a newly developed cyst fluid diagnostic test[11].

PATHOLOGY

Serous cystadenomas are benign, solitary, cystic tumors that arise from centro-acinar cells (Figure 1). Microcystic serous cystadenomas are composed of multiple small thin-walled cysts with a honeycomb-like appearance on cross section[12]. The most characteristic finding is a central fibrotic or calcified scar. Macrocystic serous cystadenomas are composed of far fewer cysts, and the diameter of each cyst varies from microcystic to large cavities[13]. The presence of discrete, large cystic cavities mimics the appearance of mucinous lesions. However, the cyst fluid from serous cystadenomas is non-viscous, contains low concentrations of tumor markers and may contain blood as a result of the vascular nature of the lesions[14].

Mucinous cystic neoplasms (MCNs) are composed of discrete individual cystic compartments that vary in diameter. The epithelium lining MCNs is a mucinous columnar epithelium (Figure 2). The World Health Organization classification catalogues MCNs into three types, based on the degree of epithelial dysplasia: benign, borderline, and malignant[15]. The degree of atypia of the tumor is classified according to the most advanced degree of dysplasia/carcinoma present.

Beneath the lining of MCNs lies a band of ovarian tissue. Many authorities have restricted the very definition of MCNs to include only those cystic mucinous tumors that contain ovarian stroma[2]. The role of the ovarian tissue in the pathogenesis is not known. However, when this definition is used, MCN's are rarely found in males.

IPMNs are similar to MCNs in that they are cystic tumors that secrete mucin into the cystic cavities. However, IPMNs are characterized by a unique papillary epithelium and arise from the ductal epithelium. The presence of a papillary neoplasm infiltrating the ductal lining causes the pancreatic duct to dilate. The presence of the tumor itself is a cause of duct dilation, as well as the obstruction induced by the papillary fronds and mucus globules. Mucin production may be so excessive that mucin may be spontaneously extruded through the pancreatic sphincter and out of the ampulla. The degree of dysplasia exhibited by the epithelium may range from mild to moderate to severe (carcinoma *in situ*), and the foci of early malignancy may be evident by the presence of mural nodules[16]. The solid malignancies that arise from IPMN are more likely to have papillary features, as compared to typical pancreatic malignancies that arise from the main pancreatic duct.

CLINICAL PRESENTATIONS

Most patients with a pancreatic cystic lesion have non-specific symptoms[22]. The cystic lesion is usually found with CT or US imaging performed for the evaluation of another condition. When symptoms are present, the most common presentation is recurrent abdominal pain, nausea, and vomiting as result of mild pancreatitis[17]. Cystic lesions that cause duct compression or involvement of the main pancreatic duct are prone to cause pancreatitis. Chronic abdominal pain and jaundice are a rare presentation of a cystic lesion and suggests a malignancy or a pseudocyst. Patients with a cystic malignancy will present with symptoms and signs similar to pancreatic cancer, i.e. pain, weight loss, and jaundice[18]. Pseudocysts may arise after an

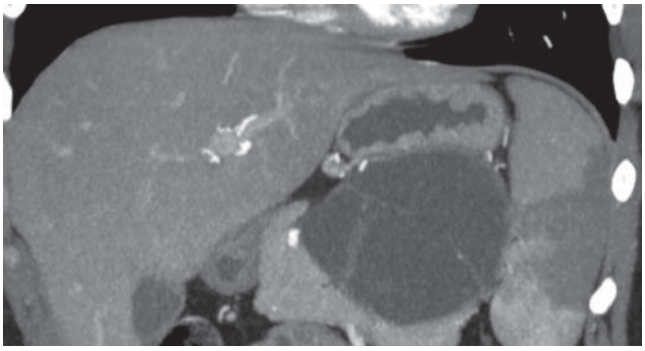

Figure 3 Reformatted CT demonstrating a mucinous cystic neoplasm indenting the stomach. Note the presence of septations.

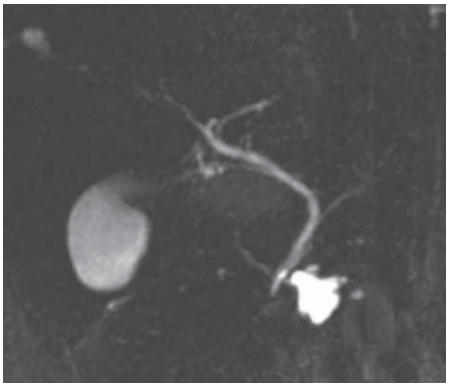

Figure 4 MRCP of side branch IPMN.

episode of acute pancreatitis or insidiously in the setting of chronic pancreatitis and are associated with chronic abdominal pain. It is common for cystic lesions associated with pancreatitis to be diagnosed as pseudocysts and be confused with cystic neoplasms that also cause pancreatitis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a cystic lesion of pancreas is very wide and often causes confusion. Since the treatment of a pseudocyst and cystic neoplasm are so different, it is incumbent on the clinician to first differentiate between these major categories of lesions. Although it is unusual for a patient with a pseudocyst to present without preceding symptoms, it may occur in mild chronic pancreatitis. Evidence of inflammatory changes or calcifications in the pancreas is suggestive of a pancreatic pseudocyst. However, in the initial setting of mild pancreatitis it may be difficult to differentiate between a cystic neoplasm that has caused pancreatitis and a small pseudocyst that has formed as a result of pancreatitis. If a cystic lesion has been present for many years, it is highly likely that the lesion represents a cystic neoplasm. Congenital cysts of the pancreas are rare[19].

DIAGNOSIS WITH CROSS SECTIONAL IMAGING

CT is an excellent test for cystic lesions of the pancreas because of its widespread availability and ability to detect cysts[4]. MR imaging is used increasingly because of its ability to determine if there is involvement of the main pancreatic duct[20]. Both imaging modalities offer diagnostic strengths.

CT is often the initial modality with which a cystic lesion is suspected or diagnosed, although clinical and imaging findings of chronic pancreatitis may obscure the correct diagnosis. The most common finings are a diffusely dilated pancreatic duct, cystic lesions, and parenchymal changes. The finding of a solitary septated cystic lesion in the tail of the pancreas is highly diagnostic of a mucinous cystic neoplasm (Figure 3). A grapelike cluster of involved side-branch ducts is the most common finding and represents IPMN. Thin-section contrast enhanced CT and multiplanar reconstruction may reveal communications between cystic dilated segments and the main pancreatic ducts, common findings of IPMN. Septa and excrescent nodules seen along the dilated duct have been described as features of the main pancreatic duct type in IPMT. CT is relatively poor in the diagnosis of malignant transformation. The most specific signs of malignancy with CT are a solid mass, main pancreatic duct dilatation greater than 10 mm, diffuse or multifocal involvement, and attenuating or calcified intraluminal content[21]. Serial CT imaging is often used to detect recurrence of IPMT after resection[22].

MR AND MR CHOLANGIOPANCREATOGRAPHY (MRCP)

T2-weighted MRCP images provide a detailed set of images of the main pancreatic duct and associated cystic lesions. A diffusely dilated main pancreatic duct containing mucinous filling defects is highly diagnostic of main duct IPMN. Side branch IPMN lesions appear as grape-like clusters associated with the pancreatic ductal system (Figure 4). The diagnostic accuracy using MRCP is 80% for the main duct-type and 100% for branch duct type tumors. Because of increased spatial and contrast resolution, increased sensitivity of fluid and mucin on MRCP as well as the increased sensitivity of MRI to gadolinium, the internal architecture of IPMT should be better defined with MRI and MRCP when compared to ERCP. MRCP is more sensitive than endoscopic retrograde cholangio-pancreatography (ERCP) in detecting mural nodules and wall thickening, which are of decreased signal on heavily T2 weighted MRCP sequences and are associated with malignancy.

MR imaging can reveal the full extent of ductal involvement, particularly when obstructing mucus prevents diagnostic opacification of the entire duct and is much less invasive than ERCP. MRCP findings suggestive of malignancy include: (1) filling defects/mural nodules (64% of tumors with mural nodules show invasion), (2) diffuse main pancreatic duct dilatation greater than 15 mm in main duct type. In contrast to ERCP, MRCP images the extraductal structures, and therefore is more accurate in preoperative assessment of disease. The sensitivity in the diagnosis of IPMN was highest by MRCP (88%), followed by endoscopic retrograde cholangiopancreatography (ERCP) (68%), and computed tomography scan (CT scan) (42%) and sonography (10%)[23]. Other reports

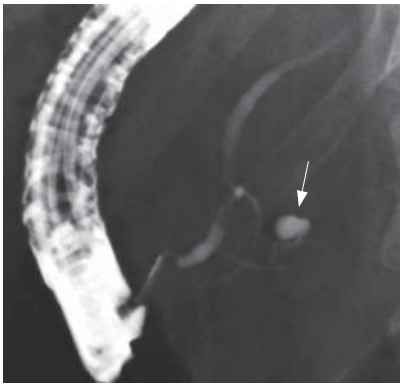

Figure 5 Pancreatogram during ERCP demonstrating a small side branch IPMN.

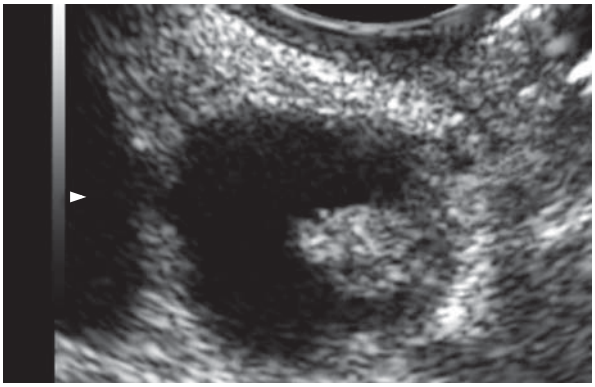

Figure 6 Linear EUS Imaging of a mucinous cystic neoplasm containing a mural nodule.

have suggested that preoperative assessment of extent using pancreatoscopy and MRCP may reduce the rate of operative positive margins and decrease postoperative recurrence. As MRCP can be performed quite rapidly without instrumentation and avoids the complications associated with ERCP, some have suggested that MRCP is superior to ERCP because it can consistently demonstrate the extent and internal architecture.

Although seen in less than 20 percent of lesions, demonstration of a central area of fibrosis by CT or MR is a highly diagnostic feature of a serous cystadenoma. The honey-combed or microcystic appearance of the lesion is commonly used to provide a diagnosis. Mucinous cystic neoplasms, in contrast, are commonly diagnosed with CT based on the unilocular or macrocystic characteristics. Although not frequently seen, the finding of peripheral calcification of the wall is specific for a mucinous cystic neoplasm. Intraductal papillary mucinous neoplasms (IPMN) may involve the main pancreatic duct exclusively, a side-branch or both. MRCP can demonstrate the diagnostic findings of pancreatic duct dilation, mural nodules, and ductal connection better than ERCP.

Despite these imaging features, the ability to accurately diagnose a specific cystic lesion and to determine whether malignancy is present by CT and MR remains uncertain. The diagnosis of a pancreatic pseudocyst is more dependent upon the clinical history and the associated findings of chronic pancreatitis. Pancreatic pseudocysts appear as unilocular fluid-filled cavities associated with parenchymal changes such as calcifications and atrophy.

THE ROLE OF ENDOSCOPY

An endoscopic evaluation may be obtained when cross sectional imaging has detected a cystic lesion, but no diagnostic features are apparent[24]. In selected patients, endoscopy is used to provide the cause of recurrent pancreatitis[3]. ERCP and EUS are powerful tools in the diagnosis of cystic and intraductal neoplasms. ERCP excels at the detection of main duct IPMNs and can provide cytologic material from strictures, nodules, or intraductal masses (Figure 5). Side branch IPMN lesions appear as fluid-filled dilated ductal branches filled with mucin (Figure 6). The finding of a focal pancreatic duct stricture in the setting of a cystic lesion is highly suggestive of a malignant process[25].

Pancreatography and pancreatoscopy are very sensitive techniques for the diagnosis of IPMNs[26]. The diagnostic features of IPMN include frond-like epithelial protuberances that are active in the secretion of intraductal mucin[26]. During ERCP, diagnostic tissue can be obtained from the ductal epithelium and analyzed using cytology as well as molecular markers[27]. Intraductal pancreatoscopy can be supplemented with the use of intraductal ultrasound to detect early malignancies arising from IPMN lesions[28]. 88% of fish-egg- like villous masses protruding more than 4 mm were found to be malignant.

The disadvantages of ERCP for the evaluation of patients with relapsing pancreatitis and suspected cystic neoplasm include the risk pancreatitis, poor quality of epithelial samples, and the technical difficulties of placement of a small probe through the pancreatic duct and sphincter. Many of the challenges will be overcome in the near future when small diameter high resolution digital probes are released for use.

ROLE OF EUS

EUS is often performed in the evaluation of relapsing pancreatitis when cross sectional imaging has not provided a definitive diagnosis. In nearly 60% of patients, EUS can provide a cause of recurrent pancreatitis[29]. The most common EUS finding in patients with recurrent pancreatitis is parenchymal changes suggestive of chronic pancreatitis[30]. EUS findings were similar in those with a single episode of idiopathic pancreatitis *vs* those with recurrent episodes. There is now some evidence in the literature suggesting that these early changes detected by EUS correlate with the histological changes of chronic pancreatitis and may predict progression to more advanced disease[31]. The EUS diagnosis of chronic pancreatitis relies on quantitative parenchymal and ductal criteria. It is generally accepted that, in the absence of any criteria, chronic pancreatitis is unlikely, whereas in the presence of 5 or more criteria (out of 9-11) chronic pancreatitis is likely. Diffuse changes may also represent autoimmune pancreatitis[32].

IPMN of the pancreas is the most common malignancy associated with recurrent pancreatitis[33]. Although there is considerable overlap between the parenchymal features of IPMN and chronic pancreatitis, EUS is fairly reliable in

Table 1 Characteristics of cystic neoplasms

	Morphology	Location	Ductal communication	Associated with pancreatitis	Cyst fluid CEA (pg/mL)
Serous	Microcystic	Evenly distributed	No	Rare	< 0.5
MCN	Macrocystic	Tail	Rare	Occasionally	> 200
IPMT	Mixed	Head	Yes	Yes	> 200
Pseudocyst	Unilocular	Evenly distributed	Yes	Yes	< 200

differentiating between IPMN and CP[33]. When compared with patients with chronic pancreatitis, the EUS features of dilation of pancreatic duct, cysts, and pancreatic atrophy were the most common findings of IPMN. The majority of IPMNs at the time of diagnosis are non-invasive and benign[34]. In a small percentage of patients, EUS will demonstrate a focal malignancy[29]. Pancreatic malignancies may arise from IPMN or from remote sites within the pancreas[35].

Mucinous cystic neoplasms (MCN) are a rare cause of recurrent pancreatitis. Nevertheless, these solitary cystic lesions may be encountered during EUS (Figure 6). Morphologically, these mucinous lesions are usually thin-walled and contain a few thin septations. FNA reveals thick, translucent fluid characterized by a mucinous epithelium. Cyst fluid CEA > 200 pg/mL is the most diagnostic parameter[36] (Table 1).

Serous cystadenomas, just like MCNs, rarely communicate with the main pancreatic duct and therefore rarely cause pancreatitis. Morphologically, the EUS appearance of serous cystadenoma is unique. The multiple fine septations coursing across the cyst result in a microcystic or a honeycomb appearance. At times, the septations are so dense that the lesion appears as a solid mass. The increased vascularity of the lesion, driven by high levels of vascular endothelial growth factor (VEGF) results in bloody contamination of cyst fluid during FNA.

TREATMENT

Pre-malignant cystic lesions should be resected surgically unless the risks of surgery are excessive. The decision to resect a lesion, however, is based on the presence or absence of symptoms, the risk of malignancy, and the surgical risk of the patient. High risk patients with low grade cystic neoplasms may be monitored with periodic CT/MRI scanning or EUS-FNA. Small cystic lesions in the elderly can be safely monitored.

The increasing safety of surgical resection has encouraged the use of surgical resection for a wider range of lesions (Table 2). However, many cystadenomas do not require resection except for relief of symptoms. Furthermore, mucinous lesions are slow growing lesions and small lesions pose little risk. The risk of surgical resection, particularly of the head has raised questions about management[37]. Justification of surgery is readily obtained with high risk lesions as defined by cyst fluid analysis[38]. Since most mucinous cystic neoplasms are located in the tail of the pancreas, a distal pancreatectomy is sufficient for these pre-malignant lesions. Lesions in the body of pancreas can be selectively resected with a middle segmentectomy. The highest risk surgical approach is for lesions in the head of the pancreas.

Table 2 Traditional therapeutic approach to the management of cystic lesions

Location	Mucinous	Malignant	Serous	Pseudocyst
Head	Monitor	Resect	Monitor	Drain
Body	Resect	Resect	Monitor	Drain
Tail	Resect[1]	Resect	Resect[1]	Resect

[1]Approach varies with risk of surgery.

CONCLUSION

Patients with relapsing pancreatitis associated with a cystic lesion pose an important challenge to the clinician. A diagnosis of a cystic neoplasm is very important because this finding will provide an opportunity to resect a lesion responsible for pancreatitis and a risk of malignancy. An accurate diagnosis requires a thorough clinical evaluation combined with high resolution pancreatic imaging. Cyst fluid analysis will often complement and strengthen the diagnosis of a cystic neoplasm and provide the basis for a surgical resection.

Abstract

AIM: To characterise expression of known *E-cadherin* repressors; *Snail*, *Slug* and *Twist* in the development of esophageal adenocarcinoma.

METHODS: *E-cadherin*, *Slug*, *Snail* and *Twist* mRNA expression in Barrett's metaplasia and esophageal adenocarcinoma specimens was examined by real-time reverse transcription-polymerase chain reaction (RT-PCR). Semi-quantitative immunohistochemistry was used to examine cellular localisation and protein levels. The effect of *Slug* on epithelial mesenchymal transition (EMT) markers was examined by transfection of Slug into an adenocarcinoma line OE33.

RESULTS: Cellular localisation of Slug in Barrett's metaplasia was largely cytoplasmic whilst in adenocarcinoma it was nuclear. Semi-quantitative analysis indicated that *Slug* was more abundant in adenocarcinoma compared to matched Barrett's metaplastic specimens. Snail and Twist were expressed in adenocarcinoma but were cytoplasmic in location and not induced compared to Barrett's mucosa. These observations were supported by mRNA studies where only *Slug* mRNA was shown to be over-expressed in adenocarcinoma and inversely correlated to E-cadherin expression. Overexpression of *Slug* in OE33 mediated *E-cadherin* repression and induced the mesenchymal markers vimentin and fibronectin.

CONCLUSION: Progression to adenocarcinoma is associated with increased Slug expression and this may represent a mechanism of *E-cadherin* silencing.

INTRODUCTION

The incidence of esophageal adenocarcinoma is currently rising faster than any other cancer in the Western world. Alarmingly the cause of this increase is largely unknown[1]. The strongest known risk factor for esophageal adenocarcinoma is the condition Barrett's metaplasia which is characterised by a replacement of the native squamous lined esophagus with a columnar epithelium: a possible consequence of prolonged reflux of gastric contents into the lower esophagus[1,2].

To date, numerous proteins have been implicated in the malignant progression of Barrett's metaplasia to adenocarcinoma including E-cadherin[3-6]. E-cadherin is a calcium dependent cell adhesion molecule which is essential in the establishment of homotypic adhesion junctions[7]. In nearly all epithelial cancers E-cadherin has been reported to be repressed: an essential step for increased invasiveness and metastasis[8-10], thus this event commonly occurs during late tumourigenesis. In particular in the development of esophageal adenocarcinoma, E-cadherin repression has been reported to be a late event associated with high grade dysplastic Barrett's metaplasia

and adenocarcinoma[4-6].

However, it remains unclear what directs repression of E-cadherin expression in esophageal adenocarcinoma. Unlike in hereditary diffuse gastric cancer *E-cadherin* is not subject to mutation and neither is there evidence of *E-cadherin* promoter methylation as is common in colorectal cancers[11,12]. A possible mechanism of *E-cadherin* silencing, which to date has not been addressed, is transcriptional repression by proteins involved in epithelial mesenchymal transition (EMT) including proteins in the Snail family: Snail and Slug and the transcription factor *Twist*[13-15].

Several studies have elegantly demonstrated in a variety of cell types that overexpression of Snail and Slug causes an EMT and this is associated with E-cadherin repression[16,17]. Furthermore, it has been demonstrated that these effects are mediated through interaction with specific *E-pal* elements of the *E-cadherin* proximal promoter[16,17]. In support of a role for these EMT regulators in E-cadherin repression and carcinogenesis, several studies have shown overexpression in several epithelial cancers including overexpression of Slug in gastric carcinomas[18], Snail in colorectal cancers[19] and Twist in pancreatic cancers[20].

The primary aim of this study was to determine the expression profile of Snail, Slug and Twist in the development of esophageal adenocarcinoma and determine if overexpression of these proteins in an esophageal background is able to mediate a repression in E-cadherin.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. This study was approved ethically by University Hospital Birmingham Trust (LREC 2002/166). All patients provided informed written consent.

Patient tissue

Esophageal adenocarcinoma resection specimens: Samples of normal squamous esophagus (n = 40) and esophageal adenocarcinoma (n = 40) were collected during surgery. Half of the esophageal adenocarcinoma resection specimens (n = 20) collected also had associated intestinal Barrett's metaplasia. In addition, samples (n = 20) of long segment ($\geqslant$ 3 cm) Barrett's metaplasia, defined as columnar mucosa with intestinal type goblet cells were also collected during endoscopy. All specimens were divided in two, half for RNA extraction and half for immunohistochemistry.

Immunohistochemistry: Immunohistochemistry for E-cadherin was performed using microwave antigen retrieval as previously described with an E-cadherin monoclonal antibody (clone 36, BD Biosciences, Oxford, UK) used at a concentration of 1:300[21]. Immunohistochemistry for Snail, Slug and Twist was performed as follows: Slides were immersed in W-cap buffer (Bio-Optica, Milan, Italy) and cycled in a Pixel antigen retriever (CellPath, Newtown, UK) for 60 min, washed in running water and placed in methanol:hydrogen peroxide (10:1) for 5 min. Sections were then incubated in a primary antibody to either Snail, 1:10, (SNAI1 clone E18, Autogen Bioclear, Wiltshire, UK), Slug, 1:20 (SNAI2 clone G18 Autogen Bioclear, UK) or Twist, 1:50 (clone C17 Autogen Bioclear, UK) in TBS 7.5 × buffer (Bios Europe Ltd, Skelmersdale, UK) at 4℃ overnight, washed with TBS and reacted with peroxidase-linked rabbit anti-sheep antibody (Dako, Ely, UK) at a 1:100 dilution in TBS for 1 h. The immunoreactivity was then revealed as above using DAB. Slides were then dipped in hematoxylin, dehydrated and mounted. The slides were scored by a previously described method for (1) intensity of staining (0 = negative, 1 = weak, 2 = moderate, 3 = intense) and (2) percentage of epithelial cells staining (0 = 0%-5%; 1 = 6%-25%; 2 = 26%-50%; 3 = 51%-75%; 4 = 76%-100%); these two scores were multiplied to yield a final staining score[39]. In addition, cellular localisation (nuclear, cytoplasmic, cell surface) was assessed. All sections were scored independently by two observers (PJ and CT).

In the series of immunofluorescent experiments following primary antibody incubations, sections were washed extensively and then incubated with either FITC goat anti-mouse or goat anti-rabbit (Jackson Immunoresearch, USA, 1:500) for 1 h. Sections were then washed and incubated in 4', 6-Diamidino-3-phenylindole dihydrochloride hydrate (DAPI) (1:10 000) for 1 min prior to visualisation. Omission of primary antibody was employed as a negative control. Images were visualised using an Olympus BX40 microscope and digital images taken using a Sensys Photometrics camera (Middlesex, UK). Desksoft SmartCapture 2 software was used for image acquisition (Desksoft, USA).

Real time RT-PCR

Real time RT-PCR reactions were performed as previously described using 18S ribosomal RNA as an internal standard (PE Biosystems, Roche, USA)[21]. Each reaction was performed in triplicate and contained one of the following sets of probes and primers: (1) *E-cadherin* (probe 5'FAM AAATTCACTCTGCCCAGGACGCGGTAMRA3'), forward primer (5'-GGCGCCACCTCGAGAGA-3') and reverse primer (5'-TGTCGACCGGTGCAATCTT3'); (2) *Slug* (probe 5'FAM'CACATACAGTGATTATTTC CC CGTATCTCTATGAGAGTTAMRA3'), forward primer (5'-AAAAGCCAAACTACAGCGAACTG-3') and reverse primer (5'-AGAATCTCTGCTTGTGGT ATG ACA-3'); (3) *Snail* (probe 5'FAMTGCAGGACTCTA ATCCAGAGTTTACCTTCCAGCTAMRA3'), forward primer (5'-CCCAATCGGAAGCCTAACTACAG-3') and reverse primer (5'-CAGGTGGGCCTGGTCGTA-3'), or (4) *Twist* (probe 5'-FAMACAATGACATCTAGG TCTC-3'), forward primer (5'-GCTCCAGAGTCTCTA GACTGTCCATT-3') and reverse primer(5'-GGGGCCTGGTCCATGTC-3').

Western blotting

Western blotting was performed as previously described[21] with antibodies to (1) E-cadherin (1:2 000, clone 36, Autogen Bioclear UK); (2) Fibronectin (1:1000, Clone

P1F11 Autogen Bioclear, UK); (3) Vimentin (1:1000, clone C-20, Autogen Bioclear, UK); (4) Cytokeratin 19 (CK-19) (1:2000; Oncogene Research Products USA) and (5) GFP (1:2000, Clone AB290 Abcam, UK). Immunoreactive bands were then subject to densitometry using NIH Image 1.62 software.

Cell culture

Cell lines derived from esophageal adenocarcinoma (OE33[22], SEG-1[23] and oesophageal squamous carcinoma TE-7[24]) were all routinely cultured in Dulbecco's modified Eagles medium (Gibco, USA) with 10% fetal calf serum supplemented with 1×10^5 Units/L penicillin and 1 g/L streptomycin. Upon reaching 70% confluence cells were lysed into Trizol reagent (Gibco, UK) for mRNA extraction and evaluation of *Slug* mRNA expression by Real Time PCR.

Transfection studies

Cell line OE33 was transiently transfected with either control empty vector, pMSCV-GFP or full-length human *Slug*-GFP tagged construct, pMSCV-*Slug*-GFP[25] or beta-galactosidase plasmid (beta-GAL) using Lipofectamine Plus according to manufacturers instruction. 48 h post transfection cells were either assayed for transfection efficiency using beta-galactosidase assay to determine transfection efficiency, lysed into RIPA buffer for Western blotting or lysed in Trizol for real time RT-PCR studies. Data analysis was only performed in experiments where a minimum of 40% transfection efficiency was achieved as determined by beta-galactosidase assay.

To determine the effect of *Slug* on the human *E-cadherin* promoter, an *E-cadherin* promoter assay was performed as previously described[21]. Briefly, OE33 cells were transiently transfected with full length human *slug* (pCDNA3-*Slug*[25]), *Renilla* luciferase plasmid pRL TK and the wild-type human *E-cadherin* promoter cloned into the pGL3basic luciferase reporter plasmid (EproWT) a kind gift from Professor Frans van Roy). Controls included empty pCDNA3 and empty pGL3basic vectors. 48 h post transfection cells were assayed for firefly and *Renilla* luciferase activities using the dual-reporter assay kit Stop 'N' Glow (Promega) according to manufacturer's instruction. Firefly luciferase activity was normalised to *Renilla* luciferase activity as a transfection control. Promoter activity was expressed as a fold change in relative luciferase units (RLU) compared to that obtained in pGL3basic control transfected cells. Results shown represent the means ± SE of three independent experiments.

Statistical analysis

All data are presented as means ± SE. Statistical significance was calculated using unpaired Student's *t* test. To assess the association between *Slug* and *E-cadherin*, linear regression analysis was performed on log-transformed mRNA fold change values using log *Slug* expression as the independent variable and log *E-cadherin* expression as the dependent variable. The R^2 value was determined to demonstrate the extent to which expression of *Slug* was correlated to *E-cadherin*. A Bonferroni adjustment was applied to *P* values attained from multiple comparisons during the analysis of prognostic factors. In univariate analyses significance was accepted at $P \leqslant 0.05$, following Bonferroni adjustment, $P \leqslant 0.0125$ was considered significant. All analyses were performed using SPSS version 10.0 (SPSS Inc, USA).

Table 1 Semi-quantitative analysis of Snail, Slug and Twist in malignant progression of Barrett's metaplasia to adenocarcinoma (Immunoreactivity score)

	S	BM (-ve)	BM (+ve)	ADC
Snail	2.4	2.5	2.9	8.7[a]
Slug	6.7	2.6	3.5	10.5[a,c]
Twist	4.5	4.7	5.2	7.1

Semi-quantitative analysis of immunoreactivity for Snail, Slug and Twist in specimens of squamous esophagus (S); Intestinal type Barrett's metaplasia without associated adenocarcinoma BM (-ve), intestinal Barrett's metaplasia with associated adenocarcinoma BM (+ve) and esophageal adenocarcinoma (ADC). The mean staining scores were calculated for each type of mucosa and the mean fold change in protein expression was calculated. [a]denotes significant ($P < 0.05$) differences between adenocarcinoma and intestinal type Barrett's metaplasia without associated adenocarcinoma. [c]denotes significant ($P < 0.05$) differences between adenocarcinoma and intestinal type Barrett's metaplasia with associated adenocarcinoma.

RESULTS

Immunolocalisation of Snail, Slug and Twist in esophageal adenocarcinoma

In normal stratified squamous esophagus, there was no detectable expression of Snail and only weak diffuse cytoplasmic immunoreactivity for Twist, while there was strong nuclear immunoreactivity for Slug in basal and supra-basal layers (Figure 1). In Barrett's metaplasia, Snail and Slug were generally localised to the cytoplasm with staining being patchy and diffuse in nature. In contrast, Twist was largely nuclear in localisation (Figure 1). In esophageal adenocarcinoma, all three proteins were abundantly expressed with Snail and Twist being mostly localised in the cytoplasm whilst Slug was almost exclusively nuclear in all adenocarcinoma specimens ($n = 20$) (Figure 1).

In addition, all slides were scored and data are shown in Table 1. To determine if Snail, Slug and Twist were over-expressed in adenocarcinoma specimens relative to non-matched Barrett's metaplastic specimens (BM-ve), statistical analysis was performed and results showed that both Slug and Snail were significantly over-expressed ($P < 0.05$) in esophageal adenocarcinoma. Twist, however, was not significantly induced. To validate this data, we further performed immunohistochemistry on a further 20 sections of adenocarcinoma with matched Barrett's metaplastic tissue (BM+ve). When comparing the staining scores of matched Barrett's metaplastic specimens with adenocarcinoma, only Slug was significantly over-expressed ($P < 0.05$).

Since there is a growing body of evidence implicating Slug as a repressor of E-cadherin, we further sought to address if Slug overexpression was associated with depressed E-cadherin expression in sections of both Barrett's metaplasia and adenocarcinoma using dual immunofluorescence with anti-Slug (FITC) and E-cadherin antibodies (Texas Red) (Figure 2). Sections of Barrett's

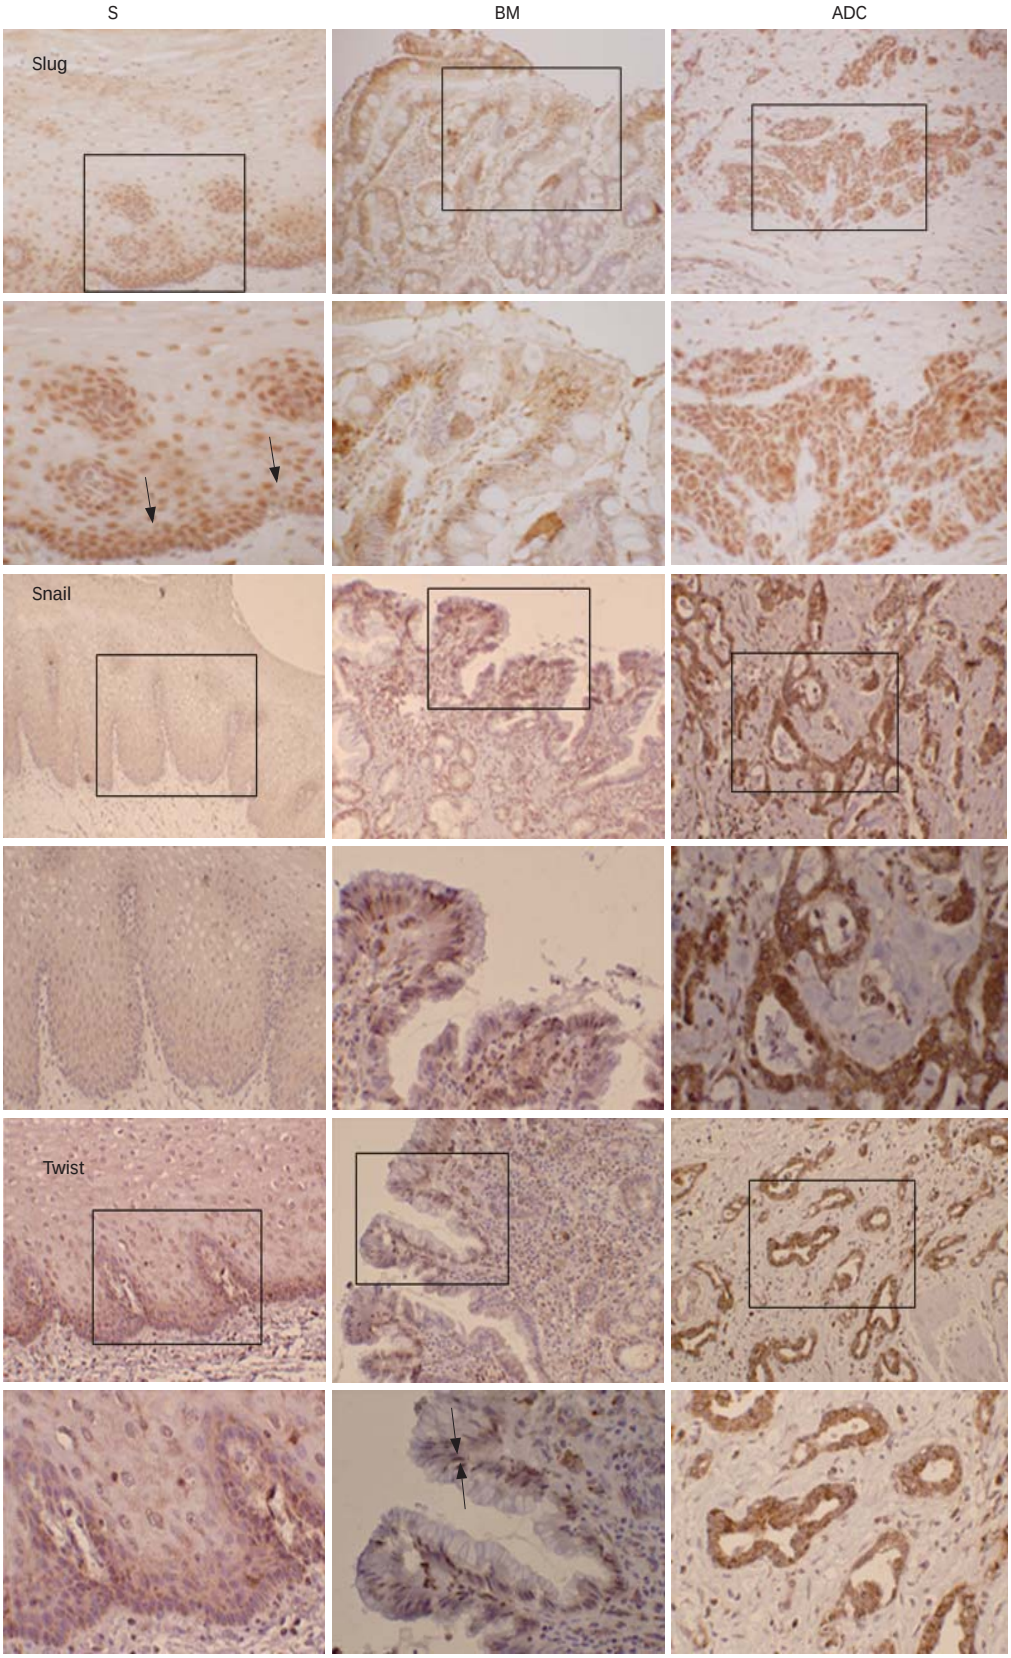

Figure 1 Immunolocalisation of Slug, Snail and Twist in normal esophagus, intestinal type Barrett's metaplasia and oesophageal adenocarcinoma. Normal squamous esophagus (S), intestinal type Barrett's metaplasia (BM) and esophageal adenocarcinoma (ADC) were subjected to immunohistochemistry using antibodies to Slug, Snail and Twist. Arrows denote areas of positivity (× 20, × 40).

metaplasia mostly demonstrated preserved cell border E-cadherin immunoreactivity consistent with its role in cell-cell adhesion whilst there was little detectable expression of Slug. Conversely in sections of adenocarcinoma in areas of abundant Slug immunoreactivity, there was almost a complete loss of E-cadherin immunoreactivity with the expression mostly localised to the cytoplasm.

mRNA expression of E-cadherin, Slug, Snail and Twist in Barrett's metaplasia and esophageal adenocarcinoma specimens

To determine if *Slug*, *Snail*, *Twist* and *E-cadherin* were modulated at the transcriptional level in esophageal adenocarcinoma, 10 specimens of esophageal adenocarcinoma each with matched intestinal Barrett's

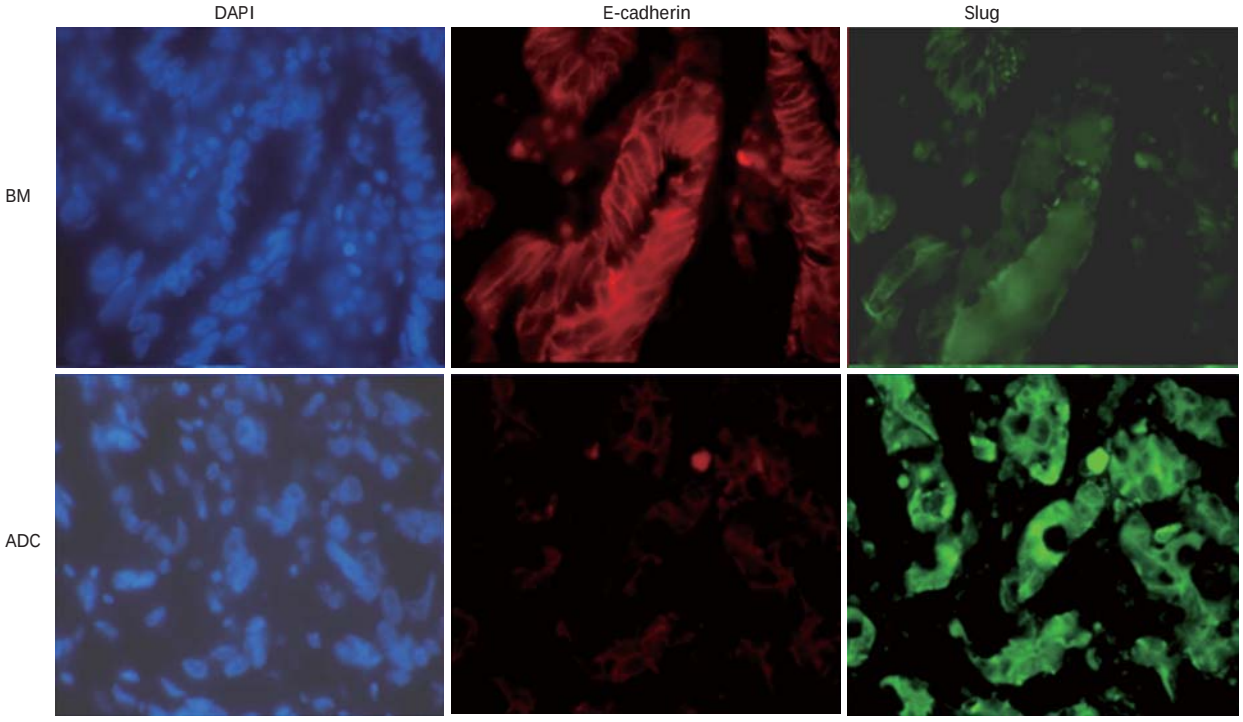

Figure 2 Co-immunofluoresence of Slug and E-cadherin in Barrett's metaplasia and esophageal adenocarcinoma. Sections of Barrett's metaplasia (BM) mostly demonstrate preserved cell border E-cadherin (Texas Red) immunoreactivity consistent with its role in cell-cell adhesion. Slug (FITC) immunoreactivity in BM however was minimal and appeared non specific. Conversely in sections of adenocarcinoma (ADC) in areas of abundant Slug immunoreactivity, there was negligible E-cadherin immunoreactivity. DAPI staining was used to highlight nuclei in sections ($\times$ 40).

metaplasia were analysed by real-time PCR (Figure 3).

E-cadherin mRNA was repressed in 70% of adenocarcinoma specimens whilst *Slug*, *Snail* and *Twist* was over-expressed in 70%, 40% and 50%, respectively. The mean fold decrease for *E-cadherin* in the ten specimens examined was 0.73 whilst *Slug*, *Snail* and *Twist* had mean fold increases of 2.07, 1.47 and 1.50 respectively. We then sought to determine if the mean fold changes for *Slug*, *Snail* and *Twist* across the ten specimens were significantly different from *E-cadherin* values. This revealed that only *Slug* was significantly elevated compared to *E-cadherin* expression ($P < 0.005$). Additionally we assessed the association between *E-cadherin* and these EMT regulators using linear regression analysis. Results of this showed that again only *Slug* was negatively correlated with *E-cadherin* expression (R^2 0.677, $P < 0.03$) (Figure 4).

Exogenous overexpression of Slug in the cell line OE33 induces an EMT phenotype

Slug mRNA expression was examined in a panel of three esophageal cell lines OE33, SEG1 and TE-7 by real-time PCR and results showed that the cell line OE33 had the lowest expression of *Slug* mRNA whilst the highest *Slug* expressing cell line was TE-7. In this regard, the cell line OE33 was chosen for *Slug* overexpression studies.

The cell line OE33 was transiently transfected with either full length human *Slug*-GFP vector or the control empty GFP vector. Forty-eight h after transfection, cells were either lysed and processed for mRNA and protein analysis or fixed for immunofluorescence.

mRNA analysis revealed an approximate 6.5 $\times$ induction in *Slug* mRNA in cells transfected with full length human *Slug*-GFP compared to cells transfected with empty-GFP vector ($P < 0.05$) (Figure 5A). Exogenous *Slug* expression was further verified indirectly (due to a lack of a commercially available *Slug* antibody suitable for Western blotting) by Western blotting for GFP (Figure 5B).

To ascertain whether overexpression of *Slug* in OE33 cells mediated an EMT phenotype, Western blotting was performed to examine protein expression of three EMT markers *E-cadherin*, vimentin and fibronectin (Figure 6). Densitometric analysis of Western blots ($n = 6$) revealed *Slug* overexpression was associated with a repression in *E-cadherin* (mean fold decrease of 53% $\pm$ 15%, $P < 0.05$) and increased vimentin (41% $\pm$ 11%, $P < 0.05$) and fibronectin expression (32% $\pm$ 12%, $P < 0.05$). In addition, the cell adhesion and signalling molecule beta-catenin was also examined and shown to be significantly repressed (57% $\pm$ 19%, $P < 0.05$).

To address whether *Slug* mediated *E-cadherin* protein repression was through a direct effect at the level of the *E-cadherin* promoter and consequently a transcriptional effect, a luciferase *E-cadherin* promoter assay and real-time PCR was employed respectively as previously described[21,25]. Overexpression of *Slug* in OE33 resulted in a significant reduction (35% $\pm$ 10%, $P < 0.05$) in *E-cadherin* promoter activity (Figure 7A) which was mirrored by decreased *E-cadherin* mRNA expression (20% $\pm$ 5%, $P < 0.05$) (Figure 7B).

DISCUSSION

Recent reports have highlighted the importance of

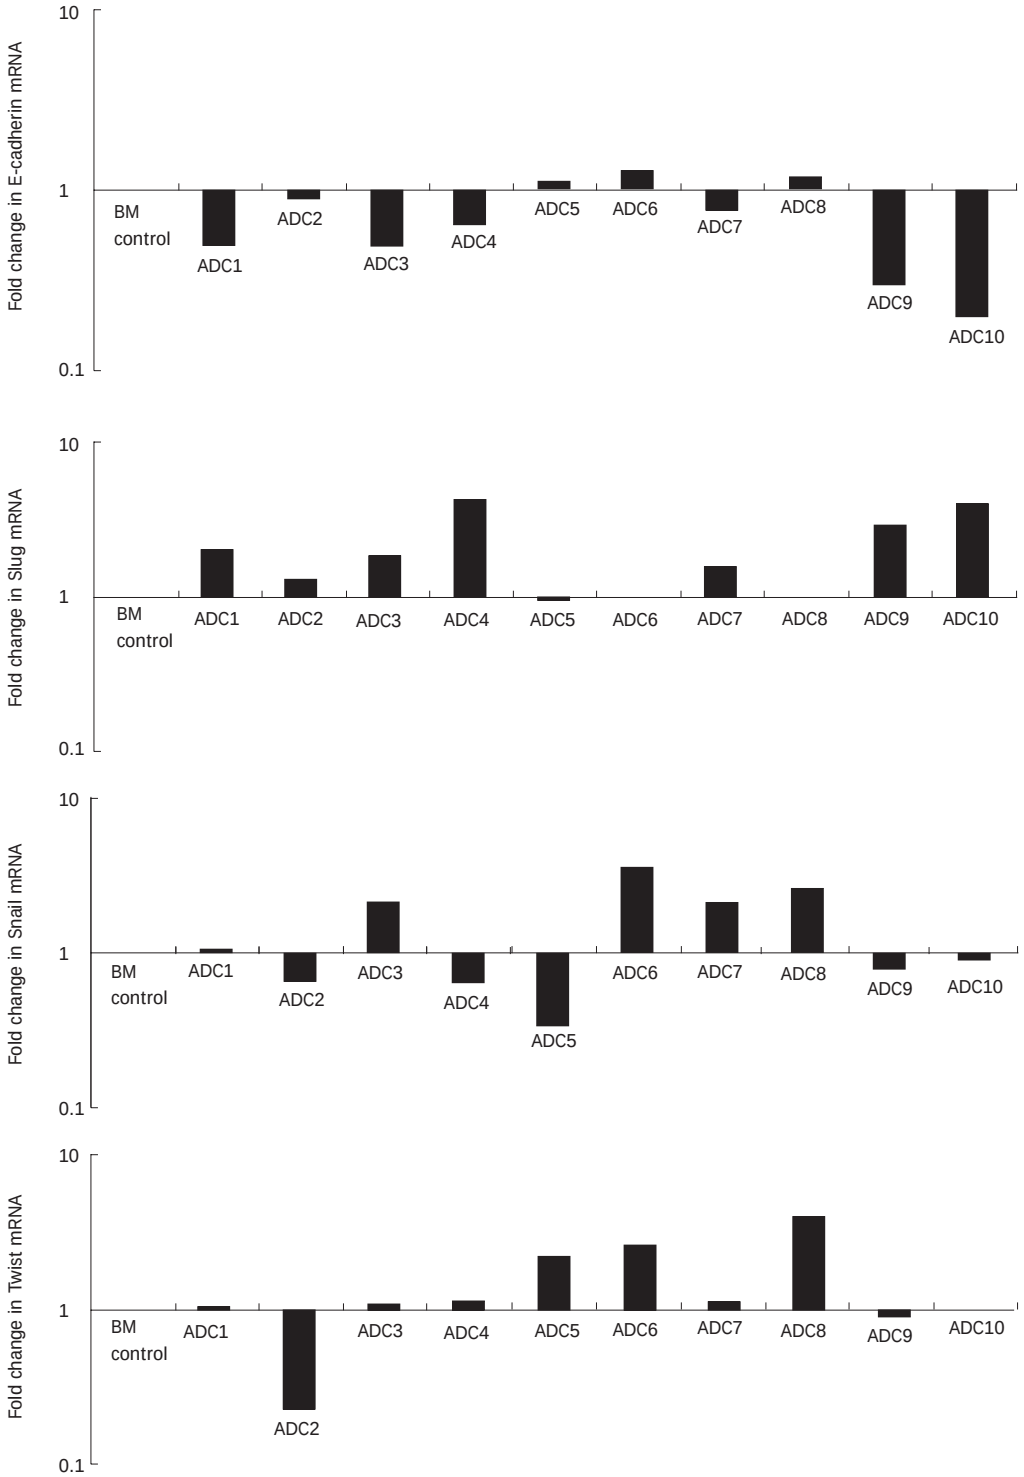

Figure 3 mRNA expression of *E-cadherin*, *Slug*, *Snail* and *Twist* in esophageal adenocarcinoma. Real time RT-PCR was employed to examine the expression of *E-cadherin*, *Slug*, *Snail* and *Twist* in ten esophageal adenocarcinoma specimens (ADC1-ADC10) each compared to Barrett's metaplastic tissue collected from the same resection specimen. Barrett's metaplastic tissue control (BM), normalised to 1.0.

epithelial mesenchymal regulators including Snail, Slug and Twist in gastrointestinal carcinogenesis[18,19,26-28]. We have demonstrated for the first time a modulation in the expression and localisation of these proteins in the malignant progression of normal squamous esophagus to adenocarcinoma.

Twist was only weakly expressed in squamous esophagus consistent with the results of Yuen *et al*[28]. Their studies reported over 95% of non-neoplastic squamous esophageal samples were either negative or weak for Twist immunoreactivity as assessed by immunohistochemistry. However, in our studies we did observe nuclear Twist staining in Barrett's metaplasia which in adenocarcinoma had become cytoplasmic in localisation. This pattern of cytoplasmic expression for Twist in cancer has also been observed in squamous cell cancers of the esophagus[28]. We were unable to show a difference in Twist expression between matched Barrett's and adenocarcinoma specimens

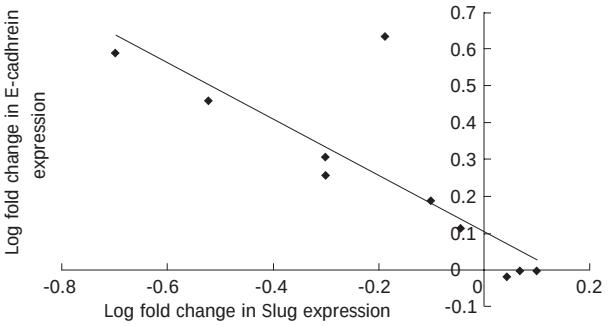

Figure 4 Correlation of *E-cadherin* and *Slug* mRNA expression in esophageal adenocarcinoma specimens. Using linear regression analysis, *Slug* mRNA expression was demonstrated to be negatively correlated with *E-cadherin* expression in the ten adenocarcinoma specimens examined (ADC1-10) (R^2 0.677, $P < 0.03$).

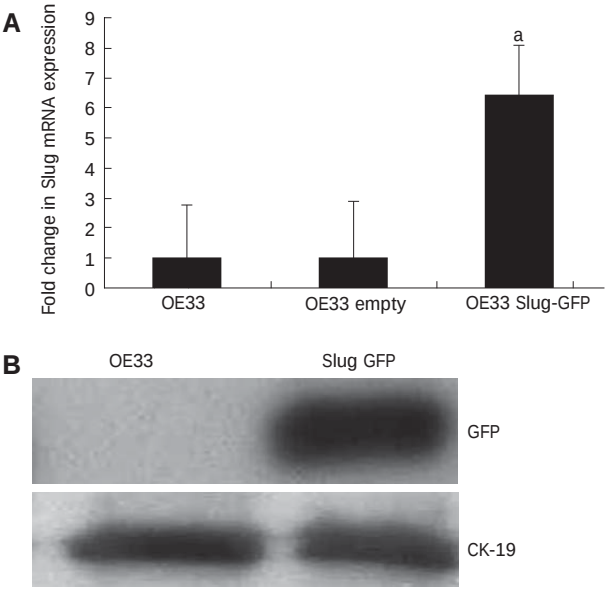

Figure 5 Overexpression of *Slug* in the esophageal adenocarcinoma derived cell line OE33. Cell line OE33 was transiently transfected with either full length human *Slug*-GFP vector (OE33 *Slug*-GFP) or with the control empty GFP vector (OE33 empty). 24 h post transfection, (**A**) *Slug* mRNA and (**B**) GFP protein expression was determined. CK-19 was used as an epithelial control. $^aP < 0.05$ using Student's *t* test.

at both the mRNA and protein level, and neither was its expression associated with prognostic end points such as stage and modal involvement.

In the case of Snail, this was comparably either very weak or nondetectable in stratified squamous oesophagus whilst in both Barrett's metaplastic tissue and adenocarcinoma Snail was detectable in the cell cytoplasm. Despite moderate expression of Snail in adenocarcinoma specimens, there was no difference in expression between matched adenocarcinoma and Barrett's specimens at both the protein and mRNA level. A recent study has also reported Snail immunoreactivity in adenocarcinomas of the upper gastrointestinal tract including the esophagus[29]. In their study Snail expression was reported in 11% of esophageal adenocarcinomas examined and no correlation was found between the expression of Snail and tumor grade and stage.

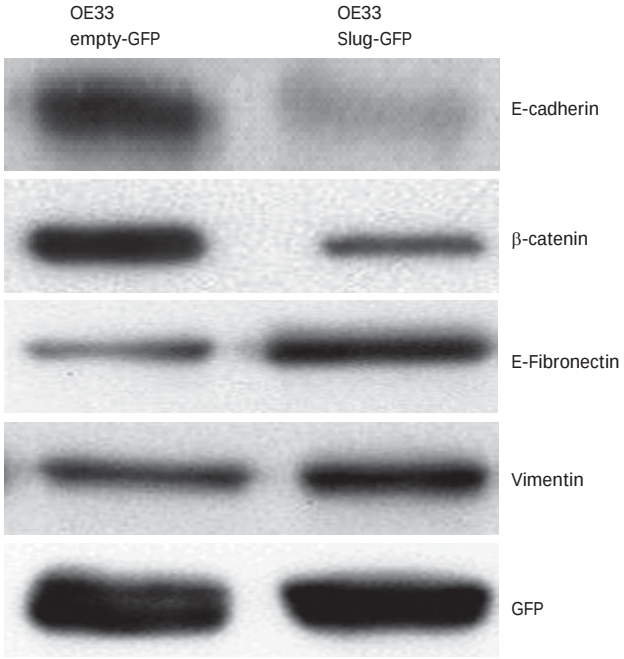

Figure 6 The effect of Slug overexpression on proteins implicated in EMT. Expression of E-cadherin, beta-catenin, fibronectin and vimentin were all examined in Slug over-expressing (OE33 Slug-GFP) and control cells (OE33 empty-GFP). Lysates were normalised using GFP expression.

Why both Snail and Twist are localised to the cytoplasm in esophageal adenocarcinoma is unclear though a recent study has suggested that Snail's localisation could in part be determined by post-translational phosphorylation with proteins such as p21-activated kinase 1 (Pak1)[30]. Interestingly, when Pak1 mediated phosphorylation of Snail was inhibited, this not only caused a nuclear to cytoplasmic accumulation but also attenuated its repressor activity[30].

Immunolocalisation studies for the transcription factor Slug showed that it was strongly expressed in nuclei of basal and suprabasal esophageal keratinocytes of the stratified squamous epithelium consistent with previous reports in murine studies[31] and other human stratified epithelia including epidermis[25]. Whilst Slug nuclear expression was lost in Barrett's metaplasia, it was retained in adenocarcinoma and furthermore there appeared to be an overexpression of this protein in adenocarcinoma compared to matched Barrett's metaplasia at both the mRNA and protein level.

Interestingly Uchikado *et al* have reported that Slug is also over-expressed in esophageal squamous cell carcinomas (SCC)[27]. Their study showed that the presence of Slug was associated with depth of tumor invasion, lymph node metastasis, stage and lymphatic invasion. Consistent with our study, Slug expression in SCC was significantly correlated with reduced E-cadherin expression.

Thus our data would suggest that of the three EMT regulators examined, Slug was the only transcription factor to show a significant increase at both the mRNA and protein level in the progression from Barrett's metaplasia to adenocarcinoma. This coupled with nuclear expression in adenocarcinoma and an association with E-cadherin repression suggests functionality in oesophageal tumourigenesis.

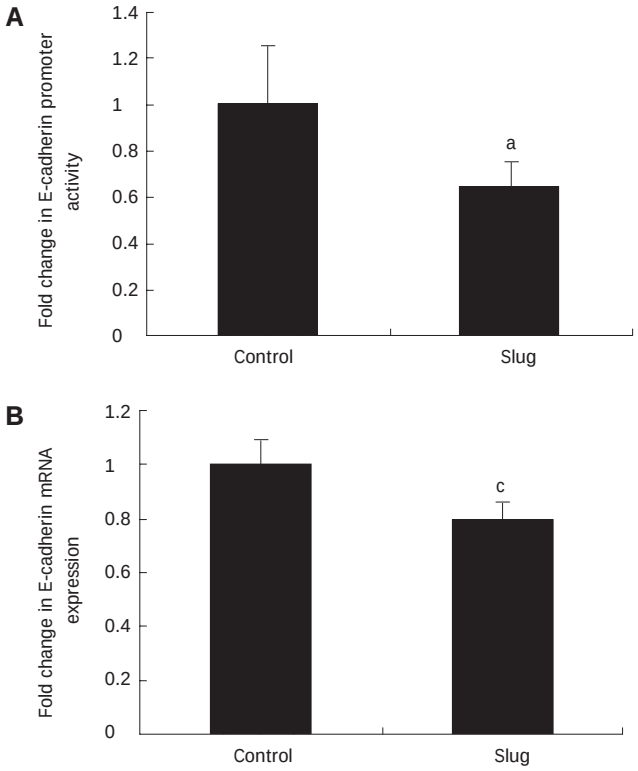

Figure 7 *Slug* expression causes a decrease in *E-cadherin* promoter activity and mRNA expression. **A**: OE33 cells transfected with full length human *Slug* (*Slug*) showed decreased *E-cadherin* promoter activity compared to sham transfected control cells. Promoter activity was expressed as a fold change in relative luciferase units (RLU) compared to control cells. Results represent the means ± SE of three independent experiments. $^{a}P < 0.05$ using Student's *t* test; **B**: Expression of *E-cadherin* mRNA in *Slug* over-expressing cells (*Slug*) was also repressed in comparison to control cells (control). Relative gene expression was normalised to 1.0 (100%) of controls. Error bars = 2 mean ± SE. $^{c}P < 0.05$ using Student's *t* test. These data are the mean of three independent experiments.

The consequence of overexpression of Slug in adenocarcinoma is likely to be complex, as exemplified by the ever-growing list of direct and indirect downstream target genes attributed to be modulated as a consequence of its expression[25,32,33]. As anticipated, many of these targets appear to be involved in cellular survival, proliferation and mesenchymal transition. The latter was exemplified by E-cadherin, a protein commonly silenced in epithelial cancers including esophageal adenocarcinoma[4-6,8-10,17].

To support our hypothesis that *Slug* might be responsible for the observed repression of *E-cadherin* in adenocarcinoma, Slug was exogenously over- expressed in an oesophageal cell line OE33. Our results demonstrate that *Slug* could repress *E-cadherin* transcription at the level of the *E-cadherin* promoter. *Slug* mediated *E-cadherin* promoter repression has been previously demonstrated in other lineages and this is likely to be mediated through one or more of the *E-box* elements present within the promoter[17].

To verify the extent of EMT, we further examined the expression of the mesenchymal proteins vimentin and fibronectin[34]. Indeed both proteins were induced as a consequence of Slug expression and consistent with other studies Slug also mediated a repression in beta-catenin, a protein involved in both cell-cell adhesion and *Wnt* signalling[35].

Abrogating Slug induction may thus represent a potential therapeutic strategy since it appears central to the EMT phenotype observed in esophageal adenocarcinoma. A potential approach might be to silence or block known inducers of Slug. In this regard, the extracellular signals *FGF*, *TGF-beta*, and *Wnt*, which have been reported to be over-expressed and implicated in the pathogenesis of esophageal adenocarcinoma, have been found to induce *Slug* expression[13,14,36-38]. Thus abrogating the expression of these extracellular signals might represent a mechanism of repressing *Slug* and potentially mediating a mesenchymal to epithelial transition which is likely to impact on development of disease and ultimately patient survival.

In summary of the EMT regulators examined, *Slug* appears to be the only transcription factor over-expressed in esophageal carcinogenesis. A downstream consequence of *Slug* overexpression is likely to be silencing of *E-cadherin* and ultimately in concert with other signalling molecules induction of invasion and metastasis.

COMMENTS

Background

The incidence of esophageal adenocarcinoma is currently rising faster than any other cancer in the Western world though the cause of this increase is largely unknown. Progression of this disease is associated with a repression in the cell adhesion molecule E-cadherin; a crucial event in invasion and metastasis.

Research frontiers

E-cadherin silencing is a common event in nearly all epithelial malignancies and in several cancers this is either due to mutation, gene deletion or promoter methylation. However, how *E-cadherin* is silenced in esophageal adenocarcinoma has not been unequivocally addressed. In this study, the authors demonstrate that the overexpression of *Slug* could be a potential mechanism for mediating *E-cadherin* repression.

Innovations and breakthroughs

Recent reports have highlighted the importance of epithelial mesenchymal regulators including *Snail*, *Slug* and *Twist* in gastrointestinal carcinogenesis. In particular in esophageal squamous cell cancers, Slug is over-expressed. This is the first study to report that Slug is also over-expressed in esophageal adenocarcinomas. Furthermore, our *in vitro* studies would suggest that this protein may be the cause of the repression in E-cadherin observed in this cancer.

Applications

By understanding how Slug is induced and by blocking its expression, this study may represent a future strategy for therapeutic intervention in the treatment of patients with esophageal adenocarcinoma.

Terminology

Slug, Snail and Twist are all proteins involved in the process called epithelial mesenchymal transition. This is when epithelial cells lose cell-cell adhesion and behave more like fibroblasts. Such a mechanism is thought to be crucial in invasion and metastasis of cancer. Non-surprisingly, the cell adhesion molecule E-cadherin is repressed during this process.

Peer review

The authors examined the expression of E-cadherin and its repressors; Snail, Slug and Twist in squamous esophagus, Barrett's metaplasia and esophageal adenocarcinoma. It revealed that *Slug* was increased in adenocarcinoma and in OE33 cells, the increase of *Slug* expression was inversely correlated to *E-cadherin* expression (mRNA and promoter activity) and induced EMT. The results are interesting and may represent a molecular mechanism of esophageal carcinogenesis.

Abstract

AIM: To investigate the polymorphic simple sequence repeat in intron 1 of the epidermal growth factor receptor gene (*EGFR*) (CA-SSR Ⅰ), which is known to affect the efficiency of gene transcription as a putative target of the mismatch repair (MMR) machinery in colorectal tumors.

METHODS: The CA-SSR Ⅰ genotype was analyzed in a total of 86 primary colorectal tumors, selected upon their microsatellite instability (MSI) status [42 with high frequency MSI (MSI-H) and 44 microsatellite stable (MSS)] and their respective normal tissue. The effect of the CA-SSR Ⅰ genotype on the expression of the *EGFR* gene was evaluated in 18 specimens using quantitative real-time reverse transcription PCR and immunohistochemistry.

RESULTS: Mutations in CA-SSR Ⅰ were detected in 86% (36 of 42) of MSI-H colorectal tumors and 0% (0 of 44) of MSS tumors, indicating the *EGFR* gene as a novel putative specific target of the defective MMR system ($P < 0.001$). Impaired expression of *EGFR* was detected in most of the colorectal tumors analyzed [6/12 (50%) at the mRNA level and 15/18 (83%) at the peptide level]. However, no association was apparent between *EGFR* expression and CA-SSR Ⅰ status in tumors or normal tissues.

CONCLUSION: Our results suggest that CA-SSR Ⅰ sequence does not contribute to the regulation of *EGFR* transcription in colon, and should thus not be considered as a promising predictive marker for response to *EGFR* inhibitors in patients with colorectal cancer.

INTRODUCTION

The epidermal growth factor receptor EGFR (HER1/ERBB1) is a member of the erbB family. It plays a pivotal role in the control of processes occurring during oncogenesis and tumor progression, such as cell survival, proliferation,

angiogenesis and metastasis (for review[1]). Overexpression of this receptor is observed in a large range of human cancers, correlating with an aggressive tumor phenotype, poor prognosis and decreased survival[2,3]. EGF, which is faintly expressed in normal colon, is seen overexpressed in approximatively 25%-77% of colorectal cancers depending on the technique used[2]. Overexpression of EGFR in colorectal tumors led to the development of targeted therapies against this receptor. Cetuximab (Erbitux®), a monoclonal antibody that specifically blocks the EGFR, has been recently approved for treatment of patients with chimiotherapy-refractory metastatic colorectal cancer. Clinical trials showed response rates of approximately 10% for cetuximab alone and 20% for cetuximab in combination with irinotecan[4]. A recent key finding was a lack of a close correlation between EGFR expression in colorectal tumors, at least as measured by immunohistochemistry, and clinical response[5]. There is therefore urgency to identify robust biological predictive markers for response to *EGFR* inhibitors.

Mechanisms underlying EGFR overexpression in colon are not fully understood. This overexpression can be attributed in part to gene amplification as previously shown in glioblastoma[6]. However, EGFR amplification is infrequent in colorectal cancers[7]. Furthermore, the *EGFR* gene contains a highly polymorphic simple sequence repeat in intron 1 (CA-SSR I), which consists of a variable number of CA dinucleotide repeats[8]. This sequence has been shown to modulate gene transcription in skin, mammary, head and neck, and gastric cell lines, with transcription activity declining with increasing number of CA repeats[9,10]. This finding was confirmed in breast tumors[11]. The mechanism is not fully understood, but it has been proposed that CA-SSR I could act like a joint, bringing the promoter in proximity to a putative repressor protein bound downstream of the repeat sequence[12]. Moreover, a recent study performed on head and neck cell lines reported that cell lines with a lower number of CA repeats are more sensitive to the inhibitory effect of erlotinib (Tarceva®), a small *EGFR* tyrosine kinase inhibitor[10]. Transferring these data to *in vivo*, this would lead to the hypothesis that patients would display different responses to therapy with EGFR inhibitors depending on the status of their tumor for CA-SSR I . Altogether, these data present preliminary evidence that the genotype of CA-SSR I determined in the tumor may be a promising marker to predict the clinical response to anti-EGFR therapy. However, very little is known regarding CA-SSR I in colorectal cancer.

Colorectal cancers can be subdivided into two major categories reflecting different mechanisms of carcinogenesis[13]. Almost 85% of colorectal tumors display chromosomal instability, which is characterized by aneuploidy, chromosomal rearrangements, allelic imbalance (AI) with amplifications and losses of heterozygosity (LOH). On the other hand, 12%-15% of colorectal tumors show high frequency microsatellite instability (MSI-H), which reflects a failure in the DNA mismatch repair (MMR) system. Most of them occur sporadically, but they can also occur (2%-5%) in the context of hereditary non-polyposis colorectal cancer (HNPCC). A great number of microsatellite repeat sequences distributed throughout the genome have been found (by targeted or systematic search) to be affected by MSI. However, only a small number are accepted as real targets of MSI, as they are assumed to play a role in the progression of MMR-deficient tumors[14-17]. Most of them have been described in coding sequences of genes implicated in the regulation of cell growth or cell survival. However, some non-coding repeat sequences affecting gene expression have also been proposed as targets of MMR[18].

In this context, we investigated the CA-SSR in intron 1 of *EGFR* in a total of 86 colorectal cancers selected upon their MSI status (42 MSI-H and 44 MSS) and in their respective normal tissue. Furthermore, we evaluated the influence of CA-SSR I mutations and length polymorphisms on EGFR expression and tested the hypothesis that CA-SSR I could be a target of MSI in MMR-deficient colorectal tumors.

MATERIALS AND METHODS

Patients and tumors

A total of 86 colorectal cancers were included in the study. Cancers were selected among 250 colorectal tumors we previously analyzed for MSI using the Bethesda panel[14] or the pentaplex mononucleotide panel[19] in order to enrich our series into MSI-H tumors. They comprised 42 MSI-H tumors and 44 microsatellite stable (MSS) tumors. All were from patients who had undergone surgery for primary colorectal cancer in various hospitals from northern France. Patients followed the revised Bethesda criteria for MSI testing and identifying individuals with HNPCC (for review, see[20]).

CA-SSR I genotyping and data analysis

CA-SSR I genotype analysis was conducted on tumoral tissue DNA and on respective constitutional DNA from normal colon taken at a distance from the tumor. DNA was extracted from formalin-fixed paraffin-embedded tissues using the EZ1 DNA Tissue kit with the BioRobot® EZ1 (Qiagen, Courtaboeuf, France). CA-SSR I was then amplified by PCR using previously described primers[10], the forward primer being labelled with 6-FAM at the 5' end. Genotypes were resolved on Applied Biosystems 377XL analyzer using GeneScan software (Applied Biosystems, Courtaboeuf, France). The (CA)n dinucleotide repeat length was confirmed by direct sequencing of some samples. Alleles were compared between the tumor and the normal matching tissue. The tumor was considered as presenting MSI for CA-SSR I when additional alleles were observed compared to the matching normal tissue. The tumor was considered as presenting AI when the AI score was < 0.6 or > 1.67, as determined previously by Canzian *et al*[21]. AI score = T1 × N2 / T2 × N1, where T is tumor, N is normal and 1 is the area under the peak corresponding to the shorter allele, 2 is the area under the peak corresponding to the longer allele. This threshold allows for the possibility of contaminating normal tissue or tumor heterogeneity in some samples[21].

Quantitative real-time reverse transcription-PCR (QRT-PCR) analysis

QRT-PCR analysis was conducted in 12 out of the 86 patients for whom quick-frozen tumor and normal colonic tissues were available in the tissue bank of Lille (CHRU de Lille). Total RNA was extracted from frozen tissues with the NucleoSpin® RNA II kit (Macherey-Nagel) and treated with RNase-free DNase to remove any contaminating genomic DNA. RNA (900 ng) was reverse transcripted using oligodT and the Advantage® RT-for-PCR kit (BD Biosciences Clontech) according to the manufacturer's instructions. Expression of EGFR was investigated by QRT-PCR using SybrGreen methodology on a LightCycler (Roche) and previously described primers[22]. β-actin mRNA was used as the endogenous control gene. All real-time assays were performed in triplicate. Relative expression of EGFR in tumor samples (compared with their respective normal tissue) and in normal tissues (compared with normal tissues with a 16/16 genotype) was calculated using the $2^{-\Delta\Delta Ct}$ method.

Immunohistochemical (IHC) analysis

Immunohistochemical analysis was performed using the monoclonal anti-EGFR antibody Clone 31G7 from Zymed Laboratories (CliniSciences, Montrouge, France). The staining procedure was conducted using an automated immunostainer Benchmark XT (Ventana medical Systems, Strasbourg, France) and a three-step indirect process based on the biotin-streptavidin-peroxidase method. Briefly, after proteinase pretreatment (Ventana medical Systems), tissue sections were incubated with fresh 3% hydrogen peroxide in methanol to block endogenous peroxidase. The sections were then sequentially incubated with the mouse monoclonal anti-EGFR antibody (dilution 1:20, 20 min), a biotinylated rabbit anti-mouse antibody and streptavidine-peroxidase conjugate. The sections were then developed with diaminobenzidine and counterstained with hematoxylin. A section of esophagus known to express EGFR was used as a positive control.

Specimens were examined for the distribution of the immunostaining (membranous and/or cytoplasmic). Only cells showing membranous staining (alone or in association with cytoplasmic staining) were considered as positive and scored. EGFR expression was assessed according to the percentage of positive cells using the 0 to 3+ scale as follows: score 0, absence of positive cells; 1+, > 0%-1%; 2+, 2%-50%; 3+, > 50%.

Statistical analysis

Ordinal data were compared with the χ^2 test or Fisher's exact test, as appropriate. Continuous data, specifically the relationship between the number of CA repeats in normal tissues and EGFR mRNA expression levels was assessed by the Mann-Whitney *U* test. All statistical tests were two-sided with the threshold of significance set at $P < 0.05$.

RESULTS

CA-SSR I genotypes

Germline alleles determined in normal colonic tissues ranged in length from 14 to 21 CA repeats. Heterozygosity was 58% (50/86) for this series of patients. The most common alleles consisted of 16 CA repeats [85 of 172 chromosomes (49%)], 18 CA [31/172 (18%)], and 20 CA [38/172 (22%)]. The most common genotype was found to be homozygous for 16 CA repeats [24/86 (28%)] (Table 1).

Table 1 Allelic and genotype distribution of *EGFR* CA-SSR I polymorphism in normal tissues of patients with colorectal tumors *n* (%)

Genotypes in normal colon	CA-SSR I status of the tumor[a]		Total (*n* = 86)
	CA-SSR I MSI (*n* = 36)	CA-SSR I MSS (*n* = 50)	
14/20	1 (2.8)	0 (0)	1 (1.2)
15/20	1 (2.8)	0 (0)	1 (1.2)
16/16	10 (27.8)	14 (28)	24 (27.9)
16/17	2 (5.6)	2 (4.0)	4 (4.7)
16/18	4 (11.1)	11 (22.0)	15 (17.4)
16/19	0 (0)	1 (2.0)	1 (1.2)
16/20	6 (16.7)	9 (18)	15 (17.4)
16/21	0 (0)	2 (4.0)	2 (2.3)
17/20	0 (0)	1 (2.0)	1 (1.2)
18/18	2 (5.6)	2 (4.0)	4 (4.7)
18/19	1 (2.8)	0 (0)	1 (1.2)
18/20	2 (5.6)	3 (6.0)	5 (5.8)
18/21	1 (2.8)	1 (2.0)	2 (2.3)
19/21	1 (2.8)	0 (0)	1 (1.2)
20/20	4 (11.1)	3 (6.0)	7 (8.1)
20/21	1 (2.8)	0 (0)	1 (1.2)
21/21	0 (0)	1 (2.0)	1 (1.2)

[a]$P = 0.673$, CA-SSR I MSI *vs* CA-SSR I MSS according to the allele lengths (patients with at least one allele ⩾ 20 CA (17/19) *vs* both alleles < 20 CA (19/23), respectively) (χ^2 test).

Comparison of alleles in MSS colorectal tumors and respective normal colonic tissues showed a perfect correlation of allele lengths. In contrast, instability of CA-SSR I was detected in 36 of the 42 (86%) MSI-H tumors (compared to 0 of the 44 (0%) MSS tumors, $P < 0.001$, χ^2 test) (Table 2). Instability consisted in shortening of the CA-SSR I in 6 tumors (6/36, 17%), elongation of the CA-SSR I in 18 tumors (18/36, 50%), and combined shortening and elongation of the CA-SSR I in 12 tumors (12/36, 33%) (Figure 1). In most cases, tumors displayed multiple alleles in addition to normal germline alleles, hardly suggesting tumor cell heterogeneity. New alleles ranged in length from 12 CA repeats to 27 CA repeats for major alleles (from 12 CA repeats to 29 CA repeats for all alleles). Tumors from patients presenting at least one long allele with ⩾ 20 CA in the germline were not more frequently unstable than tumors from patients with both alleles shorter (< 20 CA) [17/19 (89%] *versus* [19/23 (83%)], ($P = 0.673$, χ^2 test) (Table 1), indicating that long CA-SSR I alleles are not particularly prone to MSI.

Moreover, comparison of alleles in tumors and respective normal tissues allowed detection of AI in 5 of the 30 (17%) MSS tumors from patients heterozygous for CA-SSR I and that were thus informative (AI scores = 0.47, 0.59, 2.27, 3.03, and 4.46, respectively) (Table 2).

Relationship between CA-SSR I genotype and EGFR mRNA levels

To investigate the influence of CA-SSR I mutations and allele lengths on *EGFR* gene transcription, we used QRT-

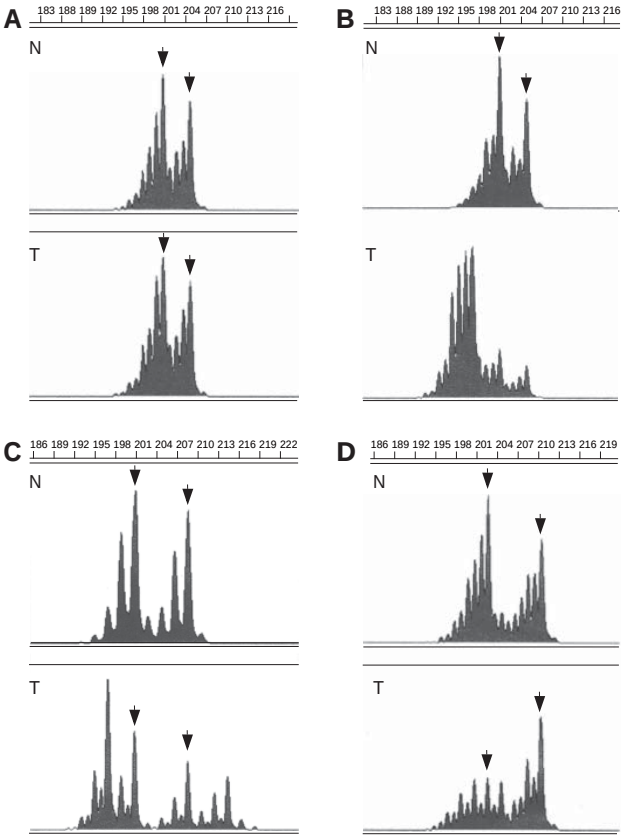

Figure 1 Examples of MSI and AI of EGFR CA-SSR I in colorectal tumors. (**A**, **B**, **C**, and **D**) show heterozygosity for CA-SSR I in normal tissue (N). (**A**) shows no instability nor AI (AI score = 0.99) in colorectal tumor (T) of the same patient; (**B**) shows MSI with additional shortened alleles in colorectal tumor; (**C**) shows MSI with combined shortened and elongated alleles in colorectal tumor; and (**D**) shows AI (AI score = 3.03) in colorectal tumor. Arrows indicate germline alleles.

PCR to evaluate EGFR mRNA expression in both tumor and normal tissues from 12 patients we previously analyzed for CA-SSR I genotype. Comparison between tumors and matching normal tissues showed impaired expression of *EGFR* mRNA in half of the cases (6/12 with fold change > 2 or < 0.5) (Table 3). However, no association was apparent between *EGFR* mRNA expression levels measured in tumors and the length of CA-SSR I alleles, the presence of CA-SSR I instability or AI. Furthermore, EGFR mRNA expression levels measured in normal tissues were similar among individuals, whatever their CA-SSR I genotype status, indicating no association between expression of *EGFR* mRNA and the number of CA repeats in normal colon (two by two comparisons, $P > 0.468$, Mann-Whitney *U* test) (Figure 2).

Relationship between CA-SSR I genotype and EGFR peptide expression by immunohistochemistry

EGFR peptide expression was evaluated by immunohistochemistry in 18 tumors previously analyzed for CA-SSR I genotype. Overexpression of *EGFR* with membranous staining or both membranous and cytoplasmic staining (score ⩾ 2+) was observed in 15 out of the 18 (83%) tumors analyzed (Table 3, Figure 3). *EGFR* immunostaining level appeared to be not associated with the length of CA-SSR I alleles, the presence of CA-SSR I instability or AI. Moreover, no association could be observed between *EGFR* immunostaining and *EGFR* mRNA expression levels. Noteworthy, cytoplasmic staining alone (without membranous staining) was observed in 6 of the 7 tumors (86%) with CA-SSR I instability compared to 0 of the 11 tumors (0%) without CA-SSR I instability ($P < 0.001$, χ^2 test). This observation could not be related to a particular histopathological feature such as the degree of differentiation.

Table 2 Status of EGFR CA-SSR I in patients with MSI-H and MSS colorectal tumors *n/n* (%)

	CA-SSR I MSI[b]	CA-SSR I MSS[b]	CA-SSR I MSS[1]	
			AI+	AI-
MSI-H (n = 42)	36/42 (85.7)	6/42 (14.3)	0/1 (0)	1/1 (100)
MSS (n = 44)	0/44 (0)	44/44 (100)	5/30 (16.7)	25/30 (83.3)

[1]Tumors from informative patients for AI score determination, i.e. heterozygous for CA-SSR I. [b]$P < 0.001$, regarding the comparison of CA-SSR I MSI *vs* CA-SSR I MSS distribution according to the MSI status (χ^2 test).

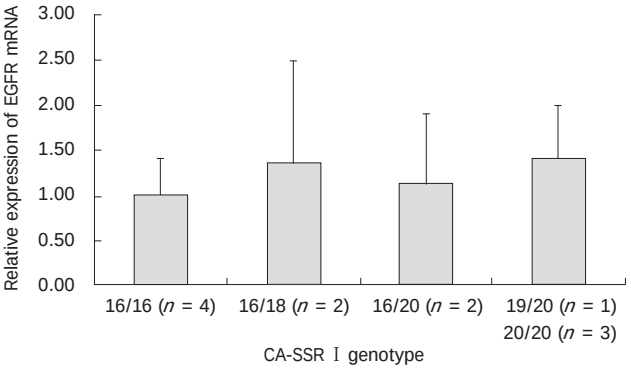

Figure 2 Graphical representation of the influence of the CA-SSR I genotype on EGFR mRNA expression in normal colon. Expression levels were determined by QRT-PCR. Relative expression levels are given in percent, relative to expression levels determined in normal colons with a 16/16 genotype. Median values with the corresponding standard deviations are indicated. Two by two comparisons, $P > 0.468$ (Mann-Whitney *U* test).

DISCUSSION

Here, we have analyzed primary colorectal tumors selected by their MSI status (42 MSI-H and 44 MSS) and their respective normal tissue for CA-SSR I mutations and length polymorphisms. Furthermore, we evaluated the effect of CA-SSR I genotype with respect to EGFR expression in colorectal tumors.

The distribution of CA-SSR I alleles and genotypes that were determined in normal tissues were similar to those reported previously in Caucasian reference pedigrees, with the most common alleles consisting of 16, 18, and 20 CA repeats and the most common genotype being homozygous for 16 CA repeats[8]. Interestingly, whereas allele lengths were perfectly conserved in MSS tumors, frequent instability of CA-SSR I was detected in MSI-H tumors. This instability consisted in shortening, elongation, or combined shortening and elongation of the CA-SSR I;

Table 3 Relationship between *EGFR* CA-SSR I genotypes and EGFR expression levels in colorectal tumors

	CA-SSR genotypes[1]		CA-SSR I status[2] of the tumor	EGFR expression	
	Normal colon	Tumor		QRT-PCR[3]	IHC[4]
1	16/16	16/20	MSI	0.87	++ m
2	16/16	16/16	MSS	0.70	++ m
3	16/18	16/18	MSS	2.68	++ m
4	16/16	14/16/20/(21/22/23)	MSI	5.10	+++ m, c
5	20/20	16/25/26/27	MSI	0.27	++ m, c
6	20/20	20/20	MSS	0.76	++ m
7	16/20	16/20	MSS (AI +)	1.11	+++ m
8	20/20	20/20	MSS	0.48	++ m
9	16/20	16/20	MSS	3.68	++ m
10	16/16	16/16	MSS	1.32	++ m

18	18/18	18/18	MSS	ND	++ m

[1]CA-SSR I alleles determined in colorectal tumors and corresponding normal tissues (germline alleles). All observed alleles are indicated, with minor alleles in brackets; [2]MSI, presence of CA-SSR I instability; MSS, absence of CA-SSR I instability; AI +, presence of allelic imbalance; [3]Relative expression of EGFR mRNA levels (tumor relative to matching normal tissues), as assessed by QRT-PCR and calculated using the $2^{-\Delta\Delta Ct}$ formula. Values corresponding to a fold change > 2 or < 0.5 are indicated in bold. ND: not determined; [4]Expression of EGFR peptide determined by immunohistochemistry. Score 0, 0% of positive cells with membranous staining; 1+, > 0%-1%; 2+, 2%-50%; 3+, > 50%. m: Membranous staining; c: Cytoplasmic staining.

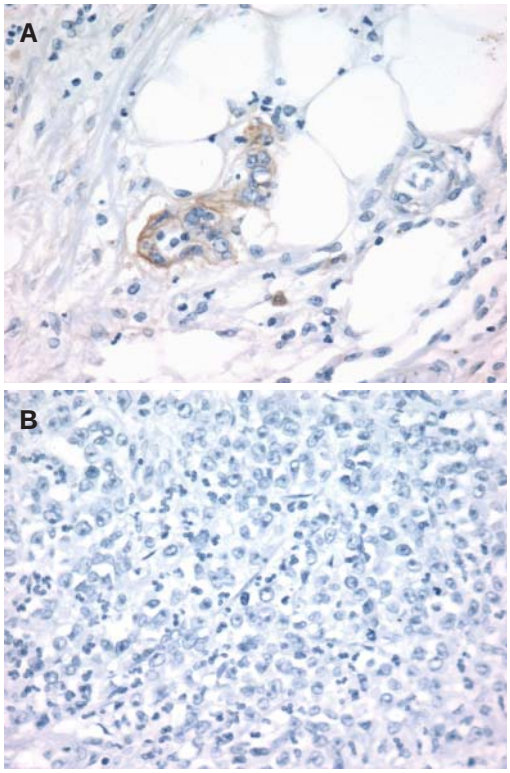

Figure 3 Examples of EGFR immunohistochemical stainings in colorectal tumors harboring identical EGFR CA-SSR I status and genotype. (**A** and **B**) are CA-SSR I MSS colorectal tumors with genotype 16/20; (**A**) shows a moderate membranous staining for EGFR (score ++), whereas (**B**) is negative (x 400; hematoxylin counterstain).

it was independent of the length of alleles determined in normal tissues. The frequency of instability was particularly high, accounting for 86% of MSI-H colorectal tumors. *EGFR* CA-SSR I may thus be of interest as an alternative marker for the determination of the MSI status in colorectal tumors[14]. It is noteworthy that this study was performed on tumors without previous microdissection. Enriching for tumor cells using microdissection would still enhance the likehood of detecting novel shifted alleles. One could argue that this study was performed on tumors of patients following the Bethesda criteria, and thus suspected to have a HNPCC syndrome, introducing some biases in the data. However, previous studies revealed similar frequencies in instability for a given marker in both sporadic and HNPCC tumors[16]. Moreover, 15 of 24 patients with MSI-H who were screened for germline mutations in MMR genes by direct sequencing and by multiplex ligation-dependant probe amplification displayed mutations in *MLH1*, *MSH2* or *MSH6*, indicating that approximately 1/3 of MSI-H tumors tested here were likely to be sporadic (data not shown). Of note, CA-SSR I analysis of two MSI-H keratoacanthomes and one MSI-H endometrial tumor from three independent HNPCC patients showed CA-SSR I instability in one keratoacanthome indicating that CA-SSR I instability is probably not restricted to colorectal tumors (data not shown). To our knowledge, there has been no previous report demonstrating such alteration of *EGFR* CA-SSR I polymorphism in MSI-H tumors.

Most of the non-coding repeat mutations observed in MSI-H tumors are considered as background events, since they are unlikely to participate to oncogenesis processes. In this respect, mutation frequencies in these sequences, in the absence of selection pressure, are generally low[14,15,17]. However, mutations in non-coding sequences may contribute to the manifestation of the malignant phenotype if they occur in gene regulatory regions that control levels of expression[17,23]. For example, a T repeat in intron 4 of the *MRE11* gene is frequently mutated in MSI-H tumors. These mutations have been shown to cause a splicing defect with reduced mRNA and protein levels[18]. Here, we have shown that 86% of MSI-H colorectal tumors harbor mutations of CA-SSR I , which is indicative of a possible positive selection pressure. Moreover, the CA-SSR I sequence has been shown in various tissues and cell lines to modulate *EGFR* gene transcription[9-11]. These findings led us to consider *EGFR* as a novel putative target gene of the defective MMR machinery and to hypothesize that *EGFR* CA-SSR I mutations, as well as CA-SSR I length polymorphism, could alter the transcriptional activity of the *EGFR* gene and explain, at least in part, variations of EGFR expression between colorectal tumors.

In addition to the presence of frequent CA-SSR I mutations in MSI-H tumors, CA-SSR I analysis allowed us to detect AI in 17% of MSS tumors. *EGFR* gene amplification has been recently shown to occur in 12% to

31% of colorectal tumors, as determined by chromogenic[7] and fluorescent *in situ* hybridization[24]. Therefore, the presence of AI in some MSS tumors probably reflects amplification of the *EGFR* gene in these tumors, as demonstrated previously for breast tumors[25]. Interestingly, Moroni *et al*[24] have shown that assessment of *EGFR* copy number might identify patients who are likely to respond to cetuximab.

In order to evaluate potential functional consequences of CA-SSR I mutations and polymorphisms, we investigated EGFR expression at both the mRNA and peptide levels. As expected, EGFR peptide was found to be overexpressed in most of the tumors analyzed (83% in the present series). EGFR mRNA expression was also altered in most colorectal tumors, as assessed by QRT PCR. However, *EGFR* mRNA and peptide expression appeared to be not associated with the CA-SSR I allele length, nor with the presence of MSI or AI. Our data regarding *EGFR* peptide expression are in accordance with those obtained by McKay *et al*[26] who showed no association between the distribution of CA-SSR I alleles in colorectal tumors and *EGFR* peptide expression. More intriguingly, the CA-SSR I genotype identified in normal colon samples was not predictive of *EGFR* mRNA expression levels. Our results differ from those obtained in other tissues. *EGFR* transcription activity has been shown *in vitro* and *in vivo* in mammary cell lines to decline with increasing number of CA repeats[9]. In accordance, *EGFR* peptide expression was subsequently found in breast tumors to correlate with the length of CA-SSR I alleles[11]. A direct correlation between *EGFR* expression levels and CA-SSR I has also been demonstrated in skin, gastric, and head and neck cell lines[9,10], but these findings remain to be confirmed in corresponding tissues. Altogether, our present data hardly suggest that in colorectal cancer and normal colon, unlike in breast cancer, CA-SSR I does not contribute to the regulation of *EGFR* transcription.

In conclusion, we have shown that the CA-SSR polymorphism in intron 1 of *EGFR* is frequently altered in MMR-deficient colorectal tumors, as well as in a subset of MSS tumors However, *EGFR* CA-SSR I polymorphisms and mutations seem to be not associated with EGFR expression. Our data indicate that the *EGFR* gene is more likely to be a 'bystander' rather than a 'real functional' target of the MMR machinery. Given the present data, CA-SSR I should not be considered as a promising marker for predicting the clinical response to EGFR inhibitors in patients with colorectal tumors.

COMMENTS

Background

Cetuximab (Erbitux®), a monoclonal antibody that specifically blocks the epidermal growth factor receptor (*EGFR*), has been recently approved for treatment of patients with chimiotherapy-refractory metastatic colorectal cancer. Clinical trials showed limited response rates for cetuximab alone or in combination with irinotecan. There is therefore urgency to identify robust biological predictive markers for response to EGFR inhibitors.

Research frontiers

Our article focuses on genetic alterations of the *EGFR* gene in colorectal cancers.

Innovations and breakthrought

The polymorphic simple sequence repeat in intron 1 of the *EGFR* gene (CA-SSR I) has been investigated in various cancers, including colorectal cancers. No abnormality has been found in this sequence, except in breast cancers in which allelic imbalance has been extensively described. The present study shows very frequent mutations of CA-SSR I in mismatch repair-deficient colorectal cancers, indicating the *EGFR* gene as a novel putative specific target of the defective mismatch repair system.

Applications

Impaired expression of EGFR was detected in most of colorectal tumors analyzed, but without apparent association with CA-SSR I status. Although these results are preliminary, they hardly suggest that CA-SSR I sequence does not contribute to the regulation of EGFR transcription in colon and should thus not be considered as a promising predictive marker for response to *EGFR* inhibitors.

Peer review

The manuscript from Dr. Buisine *et al* presents an interesting review of mismatch repair deficient cancers looking at polymorphism and mutations of the CA simple sequence repeat in intron-1 of EGFR receptor.

Abstract

AIM: To investigate the predictive value of Ki67 and p53 and their correlation with thymidylate synthase (TS) gene expression in a rectal cancer patient cohort treated according to a standardized recommended neoadjuvant treatment regimen.

METHODS: Formalin fixed, paraffin embedded pre-therapeutical tumor biopsies (n = 22) and post-therapeutical resection specimens (n = 40) from patients with rectal adenocarcinoma (clinical UICC stage Ⅱ/Ⅲ) receiving standardized neoadjuvant 5-fluorouracil (5-FU) based chemoradiotherapy were studied for Ki67 and p53 expression by immunohistochemistry and correlated with TS mRNA expression by quantitative TaqMan real-time PCR after laser microdissection. The results were compared with histopathological tumor regression according to a standardized semiquantitative score grading system.

RESULTS: Responders (patients with high tumor regression) showed a significantly lower Ki67 expression than non-responders in the pre-therapeutical tumor biopsies (81.2% *vs* 16.7%; $P < 0.05$) as well as in the post-therapeutical resection specimens (75.8% *vs* 14.3%; $P < 0.01$). High TS mRNA expression was significantly correlated with a high Ki67 index and low TS mRNA expression was significantly correlated with a low Ki67 index in the pre-therapeutical tumor biopsies (corr. coef. = 0.46; $P < 0.01$) as well as in the post-therapeutical resection specimens (corr. coef. = 0.40; $P < 0.05$). No significant association was found between p53 and TS mRNA expression or tumor regression.

CONCLUSION: Ki67 has, like TS, predictive value in rectal cancer patients after neoadjuvant 5-FU based chemoradiotherapy. The close correlation between Ki67 and TS indicates that TS is involved in active cell cycle processes.

INTRODUCTION

According to the results of the German Rectal Cancer Study Group (CAO-/AIO-/ARO-94 trial) pre-operative (neoadjuvant) 5-fluorouracil (5-FU) based chemoradiotherapy (CT/RT) is now the recommended therapy regimen for rectal cancer UICC stage Ⅱ/Ⅲ[1].

The antimetabolite 5-FU plays a central role in the treatment of colorectal cancer and, additionally, was shown to enhance the effectiveness of radiation therapy in the treatment of rectal cancer[2,3]. One of the most important molecular targets of 5-FU is thymidylate synthase (TS), which is essential for the de novo DNA synthesis[4].

Several clinical studies have shown that high TS expression is a predictive marker for a low sensitivity to adjuvant 5-FU-based chemotherapy in colorectal cancer.

Furthermore, high TS expression is also a prognostic marker for poor disease free and overall survival in colorectal cancer patients not treated with chemotherapy after surgery[5]. Recently, we demonstrated that high TS gene as well as protein expression predicts low therapy-induced tumor regression in neoadjuvantly treated rectal cancer, thus indicating poor treatment efficacy[6,7]. In addition, we showed that persistent positive lymph node status and high TS gene expression after pre-operative 5-FU-based CT/RT are predictive for the development of cancer recurrence and therefore for an unfavorable prognosis in patients with rectal cancer UICC stage Ⅱ/Ⅲ[8].

Since TS is mandatory for DNA synthesis, there is a close relationship between TS expression and proliferation rate: the faster the cell proliferation, the higher the TS expression and activity[9,10].

The Ki67-antigen recognises the nuclei of proliferating cells throughout the cell cycle, with the exception during the G0 and early G1 phases. Several studies showed that a high S-phase fraction is associated with a greater risk for tumor recurrence and diminished survival in the adjuvant setting, although this has not been universally observed[11,12].

Mutations in p53 were found in 40% to 60% of patients with colorectal cancer[13]. Several clinical studies showed a variable, and particular controversial role of the p53 status with regard to therapy response and prognosis in the neoadjuvant and adjuvant setting, respectively, depending on the kind of treatment and the p53 detection technique used[14-17]. Generally, mutation or overexpression of p53 seems to be associated with an unfavorable prognosis for patientss with locally advanced colon cancer[18-20]. However, there are also investigations with contrary results or without any associations[11,21-24]. Thus, the role of p53 as a predictive or prognostic marker is still controversial.

The aim of this study was to examine the predictive value of p53 and Ki67 alone or in combination with TS in patients with locally advanced rectal cancer neoadjuvantly treated with 5-FU based CT/RT. Furthermore, the association between both markers and TS was investigated.

MATERIALS AND METHODS

Patients and treatment

Surgical specimens from 40 patients (male: $n = 33$; female: $n = 7$; median age = 62 years) with rectal adenocarcinoma (cUICC stage Ⅱ/Ⅲ), histopathologically proven by rectal biopsy between 1998 and 2001 at the Department of General Surgery, University Medical Center, Göttingen, Germany were analyzed[6]. In all patients, locally curative (R0) tumor resection was achieved after standardized pre-operative CT/RT. During radiotherapy with a total dose of 50.4 Gy (single dose 1.8 Gy delivered in 28 fractions) 5-FU was administered as a 120-h continuous intravenous infusion of 1000 mg/m^2 per day during the first and fifth weeks. Standardized surgery including total mesorectal excision was scheduled 5 wk after completion of pre-operative treatment and clinical restaging. All patients of this study received the same therapy protocol according to the CAO-/AIO-/ARO-94 trial of the German Rectal Cancer Study Group[1]. Treatment was completed by post-operative application of 4 cycles of bolus 5-FU chemotherapy. The trial was approved by the medical ethics committee of the University of Göttingen (No 20-9-95).

Assessment of tumor regression

Histopathological tumor regression was graded according to the semiquantitative 5-point tumor regression grading (TRG) system proposed by Dworak *et al*: TRG 0 = no regression; TRG 1 = dominant tumor mass with obvious fibrosis or mucin; TRG 2 = dominantly fibrotic or mucinous changes with few tumor cells or groups; TRG 3 = very few tumor cells in fibrotic or mucinous tissue; TRG 4 = no tumor cells, only fibrotic or mucinous mass (total regression or response)[25]. As previously described, samples with dominant fibrous tissue (TRG 2 to 4) were defined as responders, those with dominant tumor mass (TRG 0 and 1) were defined as non-responders[6].

Microdissection, RNA extraction, and quantitation of TS gene expression

Microdissection of the tumor was performed by laser microbeam technique using the P.A.L.M. Robot-Microbeam (P.A.L.M. Bernried, Germany). Tumors in form of macroclusters (> 3 mm) or tumor areas with little fibrosis were manually microdissected using sterile needles. Extraction of total RNA from formalin-fixed, paraffin-embedded tissue was done as previously described[6]. RNA was transcribed into cDNA using M-MLV reverse trancriptase (Invitrogen, Karlsruhe, Germany) and random hexamers (Amersham Pharmacia, Freiburg, Germany) according to the manufacturer's instructions. TS-cDNA was quantified by TaqMan real-time PCR in relation to beta-actin cDNA using the standard curve method. cDNA obtained from HT29 cell line was used as a standard. Primer sequences were based on the GenBank accession numbers AB004047 (gene sequence of beta-actin) and X02308 (gene sequence of TS). PCR conditions used have been described[26].

Immunohistochemistry

Protein expression was assessed on 2-μm sections of paraffin-embedded tissue samples. Deparaffinization and heat-induced antigen retrieval were done in PT Module™ (PTM) buffer (Lab Vision Corporation, Fremont, CA, USA) in a pressure steam-cooker at 98 ℃ for 45 min. The slides were cooled down at room temperature for 20 min and then loaded onto a Lab Vision Microm 2D automated cell stainer (Microm, Walldorf, Germany). Endogenous peroxidase activity was inhibited by incubating the slides in 3% H_2O_2 for 10 min. The tissues were incubated at room temperature with the primary MIB1 antibody (DAKO, Hamburg, Germany) at a 1:400 dilution for 30 min and the primary p53 D0-1 antibody (Calbiochem, Frankfurt, Germany) at a 1:50 dilution for 30 min, respectively. The slides were then incubated with a biotinylated secondary antibody for 15 min, and after this incubated with avidin-biotinylated peroxidase complex (ABC) for 15 min. The chromogen

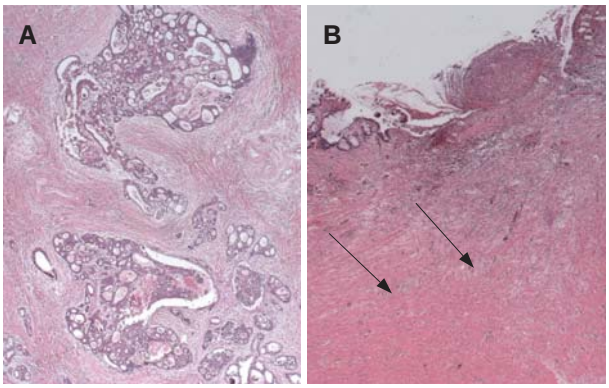

Figure 1 Rectal adenocarcinomas with different tumor regression grade (TRG) after preoperative chemoradiotherapy: dominant tumor with obvious fibrosis in a non-responder, TRG1 (**A**); dominant fibrosis with very few tumor cell groups in a responder, TRG3 (**B**).

3, 3-diaminobenzidine (DAB; 0.6 mg/mL) was applied for 2 min × 4 min. The tissues were counter-stained with Mayer's hematoxylin. In each experiment positive and negative controls were included; isotype controls were done and proved negative.

Evaluation of immunohistochemistry

The immunostained sections were independently reviewed by two investigators (CJ and DEA). Conflicts in scores were resolved by consensus. For the tissue evaluation of Ki-67, each slide was scored based on the percentage of positively stained malignant nuclei. The following ranges were used: 0% to 20%, > 20% to 40%, > 40% to 60%, > 60% to 80%, and > 80% to 100%. According to the recommended classification in previous studies[21,27], samples with Ki67 nuclear staining equal or above 40% were considered having a high proliferative index, whereas nuclear positivity below 40% was considered a low proliferative index. P53 was considered overexpressed when ⩾ 10% of the malignant nuclei were positive. If fewer than 10% of the nuclei were stained, the slide was scored as having normal p53 expression.

Statistical analysis

The correlation between expression levels in tumor biopsies and resection specimens was evaluated with linear regression analysis. The correlation between TS and Ki67 or p53, respectively, was evaluated with the students-*t*-test. For TS gene expression, the maximal χ^2 method was adapted to determine which cut-off value best separates tumors into low and high expression subgroups[28,29]. The correlation between TS, Ki67, and p53 expression and tumor regression was assessed with the chi-square test. The combination of the marker expressions was tested regarding a better discrimination between responders and non-responders with a multivariate discriminant analysis. *P* values < 0.05 were considered statistically significant.

RESULTS

Pre- and post-therapeutical tumor stage and histopathological tumor regression

The results of the histopathological tumor regression after neoadjuvant CT/RT with respect to downsizing and downstaging have been reported previously[6]. The data are summarized in Table 1. According to our criteria, eight tumors were non-responders and 32 were responders. Representative examples of tumors with different regression grades are shown in Figure 1.

TS gene, p53 and Ki67 protein expression

The median of TS gene expression in pre-therapeutical tumor biopsies and post-therapeutical resection specimens was 1.07 and 0.70, respectively.

Tumor cells showed a nuclear staining pattern for Ki67 or p53. Cytoplasmic (without nuclear) immunoreactivity was not encountered. Epithelial cells located in the generative zone and the basal layers of normal rectal mucosa were consistently immunoreactive for Ki67. No apparent p53 expression was detected in the non-neoplastic cells. Representative immunohistochemical staining examples are shown in Figures 2 and 3.

Correlation between TS, Ki67, and p53 expression and tumor regression in pre-therapeutical rectal biopsies and post-therapeutical resection specimens

Low TS gene expression and low Ki67 expression, respectively, were significantly associated with high tumor regression (response) in the pre-therapeutical tumor biopsies as well as in the post-therapeutical resection specimens. No significant association was found between TS gene and p53 protein expression. The results are summarized in Tables 2 and 3.

Comparison of expression levels between pre-therapeutical biopsies and post-therapeutical resection specimens

A significant correlation between pre-therapeutical tumor

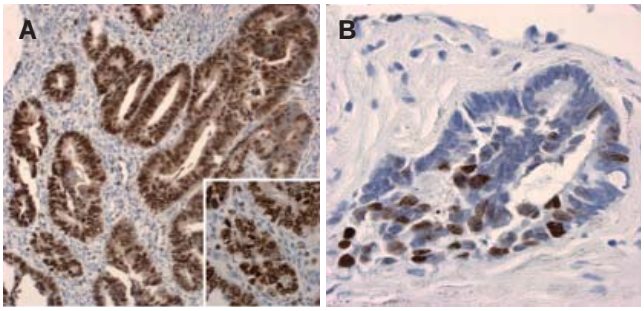

Figure 2 Ki67 expression in post-therapeutical resection specimens. High proliferative index with more than 90% positive nuclei (magnification × 10; insert: × 40) (**A**), and low proliferative index with less than 40% positive nuclei (magnification × 20) (**B**).

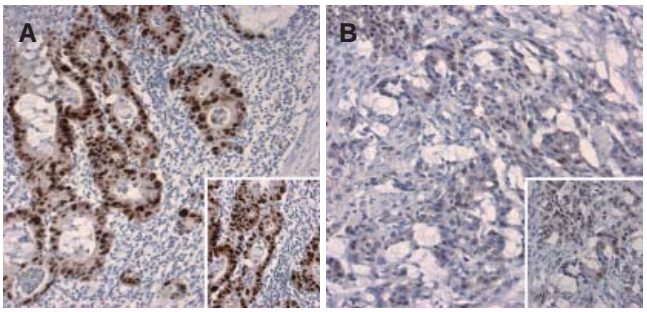

Figure 3 P53 expression in post-therapeutical resection specimens. Overexpression of p53 with more than 75% (**A**) and about 25% positive nuclei (**B**) (magnification x 10; inserts x 20).

biopsies and post-therapeutical resection specimens was observed for the TS gene expression ($P < 0.05$) and p53 expression ($P < 0.05$). No significant correlation was found for Ki67.

Correlation between TS gene expression and Ki67 or p53 expression

High TS mRNA expression was significantly correlated with a high Ki67 index and low TS mRNA expression was significantly correlated with a low Ki67 index in the pre-therapeutical tumor biopsies ($P < 0.01$) as well as in the post-therapeutical resection specimens ($P < 0.05$). No significant correlation was found between TS and p53.

Multivariate analysis

Although both, TS gene and Ki67 expression were significantly correlated with histopathological tumor regression, a combination of the markers did not significantly improve the discrimination between responders and non-responders.

DISCUSSION

There is very little and conflicting data about the predictive value of Ki67 and p53 in rectal cancer after neoadjuvant CT/RT[14-17] and almost no data on the correlation with TS expression. The aim of this study therefore was, to define the predictive value of Ki67 and p53 and their correlation with TS gene expression in a patient cohort treated according to the standardized recommended neoadjuvant treatment regimen[1]. We used histopathologically assessed tumor regression as a surrogate endpoint for early determination of the treatment efficacy[6].

Table 2 Correlations in pre-therapy tumor biopsies

Marker expression	Responders	Non-responders	*P*
TS < 1.20[1]	10	1	
TS ⩾ 1.20	0	3	< 0.05
Ki67 < 40%	13	1	
Ki67 ⩾ 40%	3	5	< 0.05
p53 < 10%	6	3	
p53 ⩾ 10%	10	3	0.60

TS < 0.88[1]	26	2	< 0.01
TS ⩾ 0.88	4	4	
Ki67 < 40%	22	1	< 0.01
Ki67 ⩾ 40%	7	6	
p53 < 10%	10	3	0.98
p53 ⩾ 10%	19	4	

[1]cut-off value.

TS is mandatory for DNA replication, and thus a critical target for fluoropyrimidines. Furthermore, TS is a cell cycle enzyme and is present in proliferating cells[9,10]. Previous observations in cell lines showed that the TS expression and activity in asynchronously growing cancer cells were significantly related to the cell doubling time: the faster the cell proliferation, the greater the expression and activity of TS. The expression and activity of TS were strongly related to the doubling time, and not to the number of cycling cells or to the number of cells in S phase[10]. Rapidly proliferating cells have to synthesise a greater amount of DNA- and consequently need a greater amount of TS- than slowly proliferating cells. Thus, TS expression is closely correlated with the cell proliferation rate. The positive association between TS and Ki67 expression in our study supports this thesis. Additionally, on the basis of our results, this relationship seems not to be influenced by (neoadjuvant) therapy because we found it in the pre-therapeutical biopsies as well as in the post-therapeutical resection specimens. As a consequence of the close relationship of Ki67 and TS, we could show that non-responders had a significantly higher Ki67 expression than responders. The combination of both markers (Ki67 and TS expression) did not significantly improve the response prediction.

In the light of the known relationship between tumor cell kinetic and efficacy of chemotherapy our results are somewhat surprising, since one would expect that rapidly growing tumors with high TS and/or high Ki67 levels would benefit more from chemotherapy. Though Ki67 reflects active cell cycling, it does not necessarily quantitate the speed of the cell cycling process that may be the critical factor in sensitivity to chemotherapy[30]. Thus, it is

conceivable that cancers with relatively high Ki67 levels may still have relatively slow doubling times.

In contrast to the expectation that tumors with high proliferation and therefore high TS expression would benefit most from chemotherapy, high TS expression was associated with poor response to 5-FU and poor survival in most patients with colorectal cancer in the majority of the published studies[5]. Therefore, other-obviously TS-independent - events seem to be involved in 5-FU resistance. Inherent or acquired resistance to 5-FU based chemotherapy is obviously multifactorial, since 5-FU sensitivity is for instance influenced by the expression of dihydropyrimidine dehydrogenase[31], the genetic status of p53[32,33], nuclear factor (NF)-kappa B[34], DNA mismatch-repair genes[35], and cell cycle disturbance[36].

The relationship between TS and p53 was investigated in several clinical studies, mostly in the adjuvant setting. Generally, it has been suggested that mutation of the p53 gene or p53 overexpression (as a surrogate marker for p53 mutation) is significantly and independently associated with resistance to 5-FU therapy and with poor prognosis in colorectal cancer[18-20]. Some studies showed that p53 expression may be used to improve the predictive value of TS for response to 5-FU therapy[21,23,37]. However, some investigations failed to demonstrate such an association[38], and others have shown an improved clinical outcome and overexpression of p53[39].

There are only very rare data of p53 and TS in the neoadjuvant setting. Kamoshida *et al*. demonstrated in gastric cancer neoadjuvantly treated with S-1/cisplatin chemotherapy that high expression of TS and/or p53 in the pre-treatment biopsies predicted chemoresistance[40]. Other investigators[41] were not able to find any correlation between p53 and either TS or tumor regression. Our data do not suggest a predictive value of p53 immunohistochemistry in the neoadjuvant therapy of rectal cancer, either. Like us, most investigators have used immunohistochemistry to detect mutant p53, with the assumption that overexpression of p53 is often associated with a mutation, while the lack of expression is usually associated with a wild-type p53 genotype. This assumption has been validated in approximately 60% to 80% of the cases in which mutational analysis and p53 detection by immunohistochemistry were compared[42,43]. But there may be discrepancies between p53 protein expression and p53 mutation status which may at least partly explain the missing correlation between p53, TS and tumor regression.

In conclusion, we demonstrated that Ki67 has, like TS, predictive value in rectal cancer patients after neoadjuvant 5-FU based CT/RT as responders had a significantly lower Ki67 expression than non-responders. The positive association between Ki67 and TS indicates that TS is involved in active cell cycle processes.

COMMENTS

Background

In locally advanced rectal cancer, neoadjuvant 5-fluorouracil (5-FU) based chemoradiotherapy is now the recommended therapy regimen. One of the most important molecular targets of 5-FU is thymidylate synthase (TS), essential for de novo DNA synthesis. A number of clinical studies have shown that TS expression is a predictive marker in colorectal cancer. Since TS is mandatory for DNA synthesis there seems to be a close relationship between TS expression and other cell cycle related markers like p53 and Ki67, which could serve as predictive markers for response to neoadjuvant 5-FU based therapy in rectal cancer.

Research frontiers

Despite the advances in cancer therapy, there are still a number of patients who do not benefit from treatment. Hence, there is a need to identify novel molecular markers discriminating between patients who will benefit from treatment and those who will not.

Innovations and breakthroughs

To date, there is very little and conflicting data about the predictive value of Ki67 and p53 in rectal cancer after neoadjuvant CT/RT. The results of our study suggest that Ki67, like TS, may be used as a predictive marker in rectal cancer patients treated with neoadjuvant 5-FU based chemoradiotherapy.

Applications

The integration of predictive markers like TS and Ki67 into the therapeutical planning will support the advance of individualized treatment, maximizing therapeutic effect and minimizing exposure toxicity.

Terminology

Prognostic markers distinguish between patients with more or less favourable outcome. Predictive markers determine the likelihood of response to therapy and also the potential toxicity; they are always treatment specific.

Peer review

This paper is valuable particularly to colorectal surgeons, oncologists and gastroenterologists interested in rectal cancer biology and biomarkers. It is overall well designed, well written, with interesting results.
