Contents

81 Effects of primary suture and fibrin sealant on hemostasis and liver regeneration in an experimental liver injury
Demirel AH, Basar OT, Ongoren AU, Bayram E, Kisakurek M

85 C-reactive protein levels during a relapse of Crohn's disease are associated with the clinical course of the disease
Koelewijn CL, Schwartz MP, Samsom M, Oldenburg B

90 Are there tumor suppressor genes on chromosome 4p in sporadic colorectal carcinoma?
Zheng HT, Jiang LX, Lv ZC, Li DP, Zhou CZ, Gao JJ, He L, Peng ZH

95 A paradox: Insulin inhibits expression and secretion of resistin which induces insulin resistance
Liu F, Fan HQ, Qiu J, Wang B, Zhang M, Gu N, Zhang CM, Fei L, Pan XQ, Guo M, Chen RH, Guo XR

101 Lymphangiogenic and angiogenic microvessel density in human primary sporadic colorectal carcinoma
Yan G, Zhou XY, Cai SJ, Zhang GH, Peng JJ, Du X

108 Expression of phosphatase and tensin homolog deleted on chromosome ten in liver of athymic mice with hepatocellular carcinoma and the effect of Fuzheng Jiedu Decoction
Yin LR, Chen ZX, Zhang SJ, Sun BG, Liu YD, Huang HZ

114 A clinical trial of combined use of rosiglitazone and 5-aminosalicylate for ulcerative colitis
Liang HL, OuYang Q

120 Comparison of ligase detection reaction and real-time PCR for detection of low abundant YMDD mutants in patients with chronic hepatitis B
Wang XL, Xie SG, Zhang L, Yang WX, Wang X, Jin HZ

CASE REPORT

125 Intermittent gastric outlet obstruction due to a gallstone migrated through a cholecysto-gastric fistula: A new variant of "Bouveret's syndrome"
Arioli D, Venturini I, Masetti M, Romagnoli E, Scarcelli A, Ballesini P, Borghi A, Barberini A, Spina V, De Santis M, Di Benedetto F, Gerunda GE, Zeneroli ML

129 Case of clear-cell hepatocellular carcinoma that developed in the normal liver of a middle-aged woman
Takahashi A, Saito H, Kanno Y, Abe K, Yokokawa J, Irisawa A, Kenjo A, Saito T, Gotoh M, Ohira H

132 Anaplastic carcinoma associated with a mucinous cystic neoplasm of the pancreas during pregnancy: Report of a case and a review of the literature
Hakamada K, Miura T, Kimura A, Nara M, Toyoki Y, Narumi S, Sasaki M

136 Exophytic inflammatory myofibroblastic tumor of the stomach in an adult woman: A rare cause of hemoperitoneum
Park SH, Kim JH, Min BW, Song TJ, Son GS, Kim SJ, Lee SW, Chung HH, Lee JH, Um JW

140 Hyperinsulinemic hypoglycemia due to diffuse nesidioblastosis in adult: A case report
Hong R, Choi DY, Lim SC

143 Double ischemic ileal stenosis secondary to mesenteric injury after blunt abdominal trauma
Bougard V, Avisse C, Patey M, Germain D, Levy-Chazal N, Delattre JF

Abstract

Growth factors and their corresponding receptors are commonly overexpressed and/or dysregulated in many cancers including hepatocellular cancer (HCC). Clinical trials indicate that growth factor receptors and their related signalling pathways play important roles in HCC cancer etiology and progression, thus providing rational targets for innovative cancer therapies. A number of strategies including monoclonal antibodies, tyrosine kinase inhibitors ("small molecule inhibitors") and antisense oligonucleotides have already been evaluated for their potency to inhibit the activity and downstream signalling cascades of these receptors in HCC. First clinical trials have also shown that multi-kinase inhibition is an effective novel treatment strategy in HCC. In this respect sorafenib, an inhibitor of Raf-, VEGF- and PDGF-signalling, is the first multi-kinase inhibitor that has been approved by the FDA for the treatment of advanced HCC. Moreover, the serine-threonine kinase of mammalian target of rapamycin (mTOR) upon which the signalling of several growth factor receptors converge plays a central role in cancer cell proliferation. mTOR inhibition of HCC is currently also being studied in preclinical trials. As HCCs represent hypervascularized neoplasms, inhibition of tumour vessel formation *via* interfering with the VEGF/VEGFR system is another promising approach in HCC treatment. This review will summarize the current status of the various growth factor receptor-based treatment strategies and in view of the multitude of novel targeted approaches, the rationale for combination therapies for advanced HCC treatment will also be taken into account.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide. With an alerting 5 years relative survival rate of about 7% HCC is estimated to cause more than half a million deaths annually. HCC is the third most common cause of cancer deaths. The disease is most prevalent in Eastern and Southeastern Asia, and Middle Africa, with more than half of the patients being reported from China[1]. However, also in the developed countries the incidence of HCC dramatically increased in the past decades, mainly due to the increasing prevalence of chronic hepatitis C[2].

HCC is one of the few cancers with well-defined major risk factors. In Western countries > 80% of HCC develop in livers with cirrhosis mainly due to chronic hepatitis C, alcohol abuse, chronic hepatitis B or hemochromatosis. Especially in developed countries there is increasing concern regarding the epidemic of obesity which is associated with type 2 diabetes and other features of the metabolic syndrome and which frequently leads to non-alcoholic steatohepatitis (NASH). Here NASH may become to be one of the major causes of cirrhosis; diabetes and NASH are risk factors for developing HCC[2-4]. Rarer causes are cirrhosis due to hemochromatosis, autoimmune liver diseases or congenital disorders of metabolism. Cirrhosis in a setting of chronic liver cell injury, with inflammation, hepatocyte necrosis and regeneration, is a particular breeding ground for hepatocyte dedifferentiation and HCC[5]. In developing

countries, HCC frequently arises in non-cirrhotic livers, mostly on the basis of congenital infection with the hepatitis B virus which acts as mutagen due to insertion in the human genome and/or on the basis of aflatoxin exposure from contaminated food[2,4].

Unfortunately, the majority of patients suffer from advanced HCC at presentation. Therefore, curative treatment like local ablation, surgical resection or liver transplantation can be achieved in only a minority of HCC patients[6]. Local tumour destruction, chemoembolisation or systemic therapy are the treatment options of advanced HCC. Apart from transarterial chemoembolisation, which improves survival in well-selected patients with unresectable HCC, conventional palliative treatment options do not appear to improve overall outcome[5,6]. A recent meta-analysis of Simonetti and coworkers, who evaluated the results of randomized clinical trials of systemic and regional chemotherapy of HCC patients confirmed the disappointing results and revealed that nonsurgical therapies are more or less ineffective and do not prolong the survival of HCC patients, while further compromising quality of life[7].

Effective palliative treatment is hampered by the fact that advanced HCC represents a tumour entity which is extremely resistant to radiotherapy and conventional chemotherapy[8]. Moreover, the existing conventional chemotherapeutics are more or less non-selective cytotoxic drugs with significant systemic side-effects. Importantly, as most patients with advanced HCC have compromised liver function aggressive medical therapy regimens can not be applied. Thus, usually no effective therapy can be offered to these patients.

Because of the lack of any survival benefit of treatment with conventional drugs, new agents and novel therapeutic strategies are urgently needed to improve palliative treatment, prolong life expectancy and improve quality of life in patients with advanced HCC.

POTENTIAL TARGETS FOR FUTURE HCC THERAPIES

Growth factors and their related receptors are interesting targets for future therapeutic approaches. During foetal life, a large number of growth factors including the epidermal growth factor (EGF), insulin-like growth factors (IGFs), the hepatocyte growth factor (HGF), the vascular endothelial growth factor (VEGF), the fibroblast growth factor (FGF), the platelet-derived growth factor (PDGF) and the transforming growth factors -α and -β (TGF-α, TGF-β) are produced in the liver. In the adult normal liver many of them decline or are even absent. On the other hand adult hepatocytes are able to upregulate the production of particular growth factors like EGF, TGF-α, IGFs and VEGF, when liver regeneration is required after injury or damage[9,10]. This normally transient upregulation is dysregulated in the chronic injured liver leading to sustained mito-oncogenic signalling. Thus, dysregulation of the growth factor production and growth factor receptor signalling of adult hepatocytes plays an important role in hepatocarcinogenesis.

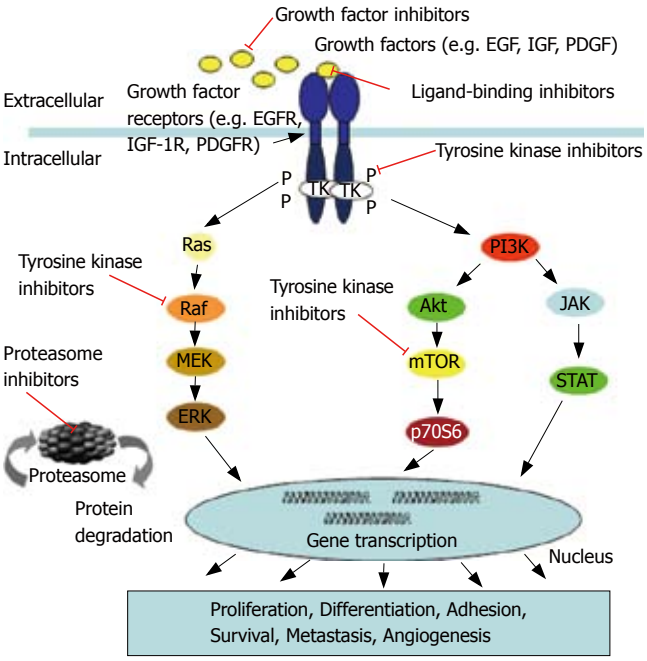

Figure 1 Major growth factor receptor signalling pathways in HCC.

Furthermore, members of the fibroblast growth factor and platelet-derived growth factor families, FGFs and PDGF play important roles in promoting liver fibrosis and HCC growth[11,12]. Like HGF, these growth factors are produced and released from non-hepatocyte sources like activated hepatic stellate cells, myofibroblasts, endothelial cells, Kupffer cells and bile duct epithelia and do also contribute to hepatocarcinogenesis.

GROWTH FACTOR RECEPTOR RELATED SIGNALLING PATHWAYS IN HCC CELLS

In the last decade some of the relevant pathways in cancer biology have been deciphered and there is emerging evidence that particularly growth factor receptors and their related downstream signalling pathways play a pivotal role in the development and maintenance of various cancers including HCC. Among the most critical cellular signalling pathways which support hepatocarcinogenesis are the receptor tyrosine kinase-activated pathways which include the rat sarcoma/rat sarcoma-activated factor (raf) /mitogen activated protein kinase/extracellular regulated kinase kinase/extracellular regulated kinase pathway (Ras/Raf/MEK/ERK), the Janus kinase/signal tranducers and activator of transcription pathway (JAK/STAT)s, and the phosphatidyl inositide 3 kinase/protein kinase B (AKT) /mammilian target of rapamycin pathway (PI3K/AKT/mTOR) (Figure 1).

Ras/Raf/MEK/ERK pathway

The Ras/Raf/MEK/ERK pathway appears to be one of the most significant cellular signalling sequences in the development and maintenance of hepatocellular cancer. This pathway transduces extracellular signals from ligand-bound tyrosine kinase receptors, such as the epidermal growth factor receptor (EGFR), the insulin-like growth

factor receptor (IGFR), the vascular endothelial growth factor receptor (VEGFR) or the platelet-derived growth factor receptor (PDGFR) to the nucleus in a series of specific phosphorylation events, starting with the activation of Ras which in turn activates serine threonine kinases of the Raf-family[1]. Activated Raf phosphorylates MEK 1/2 kinases which finally activate the extracellular regulated kinases ERK 1/2. Once activated, ERK 1/2 translocates to the nucleus where it acts as a regulator of gene expression of various proteins, including those for cell cycle progression, apoptosis resistance, extracellular matrix (ECM) remodeling, cellular motility angiogenesis and drug resistance[13]. Dysregulation of this crucial pathway occurs due to oncogenic transformation of Ras and Raf isoforms, or overexpression and/or overactivation of the Ras and Raf genes. In a recent study overexpression of the *Raf*-1 gene was shown in 50% of HCC biopsies, while increased activation of the Raf-1 protein was found even in 100% of the $n = 30$ evaluated HCC biopsies[14]. However, significant contribution of the proliferative Ras pathway to the development of HCC has long been a matter of debate. Previous studies suggested that activation of the Ras pathway might only be important in rodent, but not in human HCC, because of the low incidence of Ras gene mutations found in human HCC, while activation of the Ras cascade also occurred in the presence of wild-type Ras[15]. Recently, the components of the Ras cascade in human HCCs were characterized, demonstrating a downregulation or loss in the expression of specific members of the RAS inhibitor family. Among them the RAS association family 1 gene A (RASSF1A) and its homologue NORE1A in 100% of the $n = 35$ examined HCC[16]. The inactivation of these inhibitors resulted in a persistent activation of the Ras pathway and the authors suggested that the use of Ras inhibitors may thus be an interesting therapeutic modality for future treatment of HCC.

JAK/STAT pathway

The same holds true for the JAK/STAT pathway which plays an important role in cellular processes like differentiation, proliferation, and apoptosis[17]. STATs are latent in the cytoplasm and become activated through tyrosine phosphorylation which typically occurs through JAKs or growth factor receptor tyrosine kinases. Activated STATs enter the nucleus and serve as transcription factors. As to apoptosis and cell cycle related genes the transcriptional changes induced by STATs are similar to those described for ERK1/2.

In normal cells, ligand-dependent activation of STATs is transient, but in tumours the STAT proteins (in particular STAT-1, -3 and -5) are often constitutively activated[18,19]. This constitutive activation is partly due to inactivation of specific STAT inhibitors, the suppressors of cytokine signalling (SOCS), which normally balance and terminate STAT activity[20,21]. Thus, loss of activation of the STAT inhibitors such as cytokine-inducible SH2-protein (CIS), SOCS1, SOCS2, SOCS3, and SH2-containing phosphatases (SHP1) was shown to account for the constitutive activation of antiapoptotic and mitogenic STAT-3 and -5 in HCC[16].

In terms of both the Ras and the JAK/STAT pathway it may not be the increase in gene mutations of the respective pathway proteins, but the state of activation of these pathways due to an imbalanced interplay of activators and inhibitors, which accounts for the pivotal role of these pathways in HCC.

PI3K/AKT/mTOR pathway

The activated PI3K/AKT/mTOR pathway has only recently emerged as a novel contributor to (HCC) tumour development. PI3K associates with the intracellular domain of several growth factor receptors. Upon activation PI3K triggers the generation of phosphatidylinositol 3,4,5-triphosphate (PIP_3) which provokes the subsequent activation of AKT, a serine/threonine kinase which regulates multiple cellular target proteins. Among these proteins is proapoptotic BAD, which becomes inactivated by phosphorylation, and also the mammalian target of rapamycin (mTOR) subfamily of proteins, which become activated by AKT. mTOR proteins regulate the phosphorylation of p70 S6 serine-threonine kinase and the translational repressor protein PHAS-1/4E-BP. Both proteins regulate the translation of proliferation- and angiogenesis-relevant proteins, such as c-myc, cyclin-D1, ornithine decarboxylase, hypoxia-induced factor 1-α, and are indirectly involved in the expression of VEGF[1,22].

In nontransformed cells the PI3K/AKT/mTOR pathway is controlled by the phosphatase and tensin homolog deleted on chromosome ten (PTEN), a tumour suppressor which inhibits this pathway by reversing the PI3K reaction and blocking AKT activation. Mutation or silencing of the PTEN gene leads to activation of the pathway and promotes carcinogenesis. PTEN expression is reduced or absent in almost half of the studied HCCs, and hepatocyte-specific abrogation of PTEN expression in mice results in the development of HCC[23]. Thus, constitutive activation of this pathway can be due to enhanced stimulation of growth factor receptors, like EGFR and IGFRs, but can also result from decreased PTEN expression[1]. In non-HCC tumour models loss of PTEN expression has been demonstrated to negatively influence the sensitivity towards EGFR-TK inhibition by gefitinib[24]. Thus, it will be interesting to evaluate if this also holds true for HCC. If so, PTEN expression can serve as a novel marker for predicting the response to tyrosine kinase inhibition-based treatment strategies in HCC and therapeutic strategies in which normal PTEN expression can be restored, should be an attractive approach for combined therapeutic strategies in HCC treatment in the future.

Moreover, recent work by Boyault and coworkers demonstrated that in specific subgroups of HCC patients, namely those that are infected with low copy number hepatitis B virus (HBV) and concomitant overexpression of genes expressed in fetal liver, as well as those infected with a high copy number of HBV, but concomitant mutations in the catalytic domain of the phosphoinositide-3 kinase (*PIK3CA*) and the tumor suppressor protein 53 (*TP53*), there is a frequent upregulation of AKT expression and activation, rendering

Table 1 Agents for anti-EGFR-based therapy of solid tumours

Name	Target	Mechanism	Current status
Small molecule inhibitors			
Gefitinib (Iressa)	EGFR	Reversibly acting tyrosine kinase inhibitor	Approved for NSCLC with restricted indications Phase I for HCC[133]
Erlotinib (Tarceva)	EGFR	Reversibly acting tyrosine kinase inhibitor	Approved for NSCLC and pancreatic cancer Phase Ⅱ for hepatocellular cancer[33]
EKB-569	EGFR	Irreversibly acting tyrosine kinase inhibitor	Phase Ⅰ/Ⅱ for colorectal cancer[134] Phase Ⅱ for NSCLC[135]
Lapatinib (Tykerb)	EGFR, erbB2	Reversibly acting tyrosine kinase inhibitor	Phase Ⅲ for breast cancer Phase Ⅱ for HCC[136]
Canertinib (CI-1033)	Pan-erbB	Irreversibly acting tyrosine kinase inhibitor	Phase Ⅱ for SCC and ovarian cancer[137]
BMS-599626	EGFR, erbB2	Reversibly acting tyrosine kinase inhibitor	Phase Ⅱ for HCC [138]
Monoclonal antibodies			
Cetuximab	EGFR		Approved for colorectal cancer Phase Ⅲ for head and neck cancer, NSCLC and pancreatic cancer Phase Ⅱ for HCC[139]
Trastuzumab	erbB2		Approved for breast cancer
ABX-EGF	EGFR		Phase Ⅲ for colorectal-, head and neck-, and renal cell cancer
Matuzumab (EMD 72000)	EGFR		Phase I/Ⅱ for NSCLC[140], ovarian-[141], pancreatic cancer[142]

these patients especially susceptible to therapeutic approaches that inhibit the AKT-pathway[25].

Due to the importance of the above-described signalling pathways linked to growth factor receptors in the development and maintenance of (hepatocellular) cancer, several attempts have been undertaken to develop specific inhibitors which either block the communication of growth factors and their cognate receptors using antibodies or growth factor trapping decoy receptors, or by interrupting the transmission of growth factor receptor which signals to the respective downstream signalling cascades by membrane permeable small molecule inhibitors which block the intrinsic receptor tyrosine kinase activity. The following section will provide a concise overview of selected agents which are currently in the development and testing for the targeted treatment of solid tumours and HCC.

EGFR-based strategies

The crucial role of epidermal growth factor receptor (EGFR) in tumour proliferation and its overexpression in several solid tumours have provided the rationale for targeting and interrupting this key signalling network. EGFR blockade through monoclonal antibodies and tyrosine kinase inhibitors has translated into promising evidence of clinical benefit in gastrointestinal tumours, particularly colorectal cancer[26]. EGFR is expressed in a high proportion of HCCs, and EGFR-inhibitors, such as the monoclonal antibody cetuximab or the tyrosine kinase inhibitors gefitinib, erlotinib or ANAPD have been shown to inhibit HCC growth and metastasis formation *in vitro*[27-31] and *in vivo*[32]. Recently, Philips and coworkers conducted a phase Ⅱ trial with erlotinib for advanced HCC and could demonstrate very encouraging results, as they observed good response rates in approx. One third of the treated patients and a prolonged survival with mild and tolerable side effects after treatment with a dose of 150 mg/d[33].

Despite the encouraging findings on the general suitability of anti-EGFR-based-approaches for the treatment of HCC, only few clinical trials have been conducted so far. Most of our current knowledge on the clinical benefit of anti-EGFR-based therapies originates from studies on other tumour entities, such as colorectal cancer, renal cell carcinoma and non-small cell lung cancer (NSCLC). Nevertheless, at present several clinical trials evaluate the efficacy of anti-EGFR-interventions for the treatment for HCC (www.clinical-trials.gov), and based on the data that are available so far there is hope that anti-EGFR mono- or combination therapies will qualify for improving the treatment of advanced HCC in the near future. Currently, another phase Ⅱ trial is conducted in patients with advanced HCC which evaluates the efficacy of a combination of erlotinib and the anti-angiogenic VEGF-blocking antibody bevacizumab (NIH, NCT00365391). Dual-targeting of the HCC cells and their nutrient supply *via* the surrounding vasculature may improve the antitumoural effects as compared to monotherapy with either erlotinib or bevacizumab alone[34].

Thus the majority of the currently tested anti-EGFR-based approaches are increasingly combined either with conventional cytostatics or with other targeted-agents[28,29,35,36]. The rationale for applying combination therapies is the existence of multilevel receptor cross-stimulation or of redundant signalling pathways that lead to neoplasia. Blocking only one of these pathways allows others to act as salvage or escape mechanisms for cancer cells. Preclinical evidence of synergistic antitumour activity achievable by combining targeted agents that block multiple signalling pathways has recently emerged[37-41]. The multi-target approach can be accomplished by using either combinations of selective agents or agents which interfere with various targets[42]. Table 1 shows the current status of anti-EGFR-strategies for the treatment of solid tumours including HCC.

IGF/IGFR-based strategies

There is compelling evidence that both insulin-like growth factors IGF-Ⅰ and -Ⅱ and their receptor tyrosine kinase, IGF-1R, are involved in the development and

Table 2 Agents for anti-IGF-1R-based cancer treatment

Name	Target	Mechanism	Current status
Small moelcule inhibitors			
INSM-18	IGF-1R and HER2	Substrate competitive inhibitor	Phase Ⅰ[44]
NVP-AEW541	IGF-1R	ATP-competitive inhibitor	Preclinical[63]
NVP-ADW742	IGF-1R	ATP-competitive inhibitor, activation of proapoptotic pathways	Preclinical[62]
BMS-536924	IGF1R and IR	ATP competitive inhibitor,	Preclinical[143]
Cyclolignans	IGFR-1R	IGF competitive inhibitor	Preclinical[144]
Antibodies			
CP-751, 871	IGF-1R	IGF1R downregulation	Phase I for multiple myeloma Phase Ⅱ for Breast-[145], lung-[146], and prostate[147] cancer
A12	IGF-1R	IGF1R down-regulation, apoptosis, cell cycle arrest	Phase Ⅰ[148]
scFv-Fc	IGF-1R	IGF1R downregulation	Preclinical[149]
AVE-1642	IGF-1R	IGF1R downregulation, cell-cycle arrest, induction of apoptosis	Preclinical[69]

progression of cancer[43-46]. Interaction of IGF-Ⅰ and -Ⅱ with the IGF-1R plays a pivotal role in tumourigenesis, proliferation and spread of many cancers, by promoting cell cycle progression, preventing apoptosis, and by regulating and maintaining the tumourigenic phenotype. A wide variety of tumours including HCC show abnormal, or enhanced expression of IGFs and IGF-1R, which has been correlated with disease stage, reduced survival, development of metastases and tumour de-differentiation[47-49]. In men, obesity and diabetes are clearly associated with an increased risk of HCC, and this seems to be due to alterations in the metabolism of endogenous hormones, including sex steroids, insulin and the IGF/IGFR system. Thus, a promising approach of innovative HCC treatment may be the blockade of the IGF/IGFR, but also the mTOR-signalling system, which is functionally upregulated in HCC cells *in vitro*[50-52] and *in vivo*[47], and which has been shown to exert strong stimulatory effects on the growth of hepatoma cells[48]. In addition to the increased expression of IGF-1R and IGFs, a simultaneous reduction of IGF binding protein expression (IGFBP) and enhanced proteolytic cleavage of IGFBPs often occurs. Both mechanisms lead to an excessive increase in the amount of bioactive IGF[50,53] which further enhances the mito-oncogenic effects of IGFR-signalling in HCC and other cancer cells. The expression of IGF-1R is very low in normal hepatocytes that are poorly responsive to IGFs, whereas significant expression is found in Kupffer, endothelial and hepatic stellate cells[50].

Several approaches have demonstrated the therapeutic potential of interfering with IGF-1R mediated signalling *in vitro* and *in vivo*, including the use of IGF-1R blocking antibodies, IGF-1R antisense oligonucleotides or IGF-1R siRNA[54-57].

Recently, we and others introduced the potent and selective IGF-1R tyrosine kinase inhibitor, NVP-AEW541, as promising novel agent for the therapy of several cancers[58-60], including HCC[61]. The antineoplastic properties of NVP-AEW541 and related compounds such as NVP-ADW742[62] have been demonstrated in preclinical studies on Ewing´s sarcoma-bearing mice[63], fibrosarcoma, breast cancer and musculoskeletal carcinoma[64-66]. Specific IGFR-antibodies have also shown to suppress prostate and breast cancer cell growth in a recent preclinical study[67]. The clinically most advanced anti-IGFR antibody is CP-751,871 which is currently being tested in three phase Ⅱ trials for advanced breast cancer, NSCLC and prostate cancer (www.clinical-trials.gov). Importantly, IGFR-inhibition appears to be well-tolerated in the preliminary clinical studies conducted so far[63,68,69]. Safety is important, since IGFR-based inhibition has long been regarded as a high risk intervention, because of the high homology of the IGF-1R receptor with the related insulin-receptor, and the fear that especially IGF-1R-TK inhibitors might do also block the insulin receptor which could lead to insulin resistance and overt diabetes[70]. However, the current *in vivo* studies did not confirm this apprehension, resulting in growing interest in anti-IGFR-based therapies[71].

It is widely accepted that a therapy which inhibits IGF signalling may have to be combined with other therapies to enhance the antiproliferative overall-effect, since crosstalk between the signalling of IGF and other growth factor receptors have already been shown to be able to attenuate the antineoplastic effects of a respective monotherapeutic approach[72]. Thus, we and others could show that IGFR and concomitant EGFR-inhibition or conventional chemotherapy enhances the antineoplastic effect of the respective monotherapies[28,29,61]. Especially, dual-targeting EGFR and IGF-1R is a promising approach for future treatment of HCC. The rationale for this particular combination is derived from observations that in HCC cells the EGFR-system is activated by the IGF/IGFR-system *via* receptor cross-talk leading to mito-oncogenic EGFR-tyrosine kinase activity[73,74]. Thus inhibition of IGF-2-related signalling leads to sensitization of HCC cells to anti-EGFR-treatment with gefitinib[72], and it was postulated that inhibition of IGF/IGF-1R-signalling may not only enhance the effects of gefitinib treatment, but may also help to overcome resistance to anti-EGFR-based therapy of HCC[75]. Table 2 summarizes the most promising IGF/IGFR-targeted agents which are currently under intense investigation in preclinical and early clinical trials.

VEGF/VEGFR-based strategies

VEGF is the key angiogenic factor in tumours. The VEGF gene and protein have been reported to be transcribed, expressed, and secreted by HCC cells[76]. Endothelial

Table 3 Agents for anti-VEGF/VEGFR-based therapy of solid tumours

Name	Target	Mechanism	Current status
Small molecule inhibitors			
Sunitinib (Sutent)	PDGFR, VEGFR, c-KIT, FLT-3	Tyrosine kinase inhibitor	Approved for advanced renal cell carcinoma and GIST (with restricted indications)[87,150] Phase I for HCC[151]
Zactima (ZD6474)	VEGFR, EGFR	Tyrosine kinase inhibitor	Phase Ⅲ for NSCLC[156] Phase Ⅱ for thyroid cancer[157]
Vatalanib (PTK787/ZK 222584)	VEGFR, PDGFR, C-KIT	Tyrosine kinase inhibitor	Phase Ⅱ/Ⅲ for colorectal cancer[152] Phase I for HCC[153]
Anti-ligand targeting			
Bevacizumab	VEGF	VEGF-neutralizing antibody	Approved for colorectal cancer Phase Ⅲ for NSCLC[166] Phase Ⅱ for HCC[154]
VEGF trap	VEGF	Soluble decoy receptor which neutralizes all VEGF A isoforms	Phase I for advanced solid tumours[155]

cells which line tumour vessels express VEGFR-1 and VEGFR-2 which communicate to stimulate each other in a feedback-loop[77]. Given that VEGF protein expression is related to HCC grade[78] and given that the degree of microvascular density correlates with HCC grade[79,80], it is comprehensible that inhibitors of VEGF signalling are promising therapeutic agents for HCC treatment.

Bevacizumab is a humanized murine monoclonal anti-VEGF antibody which has entered the clinic for treatment of cancer. Standard cytostatic treatment plus bevacizumab significantly increased survival in metastatic colorectal cancer compared to standard treatment alone in a phase Ⅲ clinical trial[81] which led to its approval for treatment of colorectal cancer 2005. Comparable results were obtained in a recent phase Ⅲ clinical with bevacizumab for treatment of NSCLC. This study had to be interrupted because of the obvious survival advantage of patients in the bevacizumab arm[82]. Bevacizumab monotherapy is currently being tested in patients with unresectable HCC[83] (National Cancer Institute: NCT00162669). Moreover, a phase Ⅱ trial is currently being conducted testing the efficacy of bevacuzimab in combination with capcetabine and oxaliplatin in patients with advanced HCC. An intermediate evaluation of this trial is encouraging and shows that this combination is tolerable to patients with advanced HCC and cirrhosis[84]. As described earlier, bevacizumab is also currently tested in combination with the EGFR-tyrosine kinase inhibitor erlotinib (see above).

In addition, several agents that inhibit the tyrosine kinase activity of VEGFR have been synthesized by combinatorial chemistry. Recent clinical studies revealed the suppression of HCC growth by vatalanib (PTK787/ZK 222584), which inhibits the activities of VEGFR-1 and -2 and has shown antineoplastic effects in other solid tumours[85,86]. Another interesting agent is the tyrosine kinase inhibitor sunitinib, which inhibits the VEGFR- as well as the PDGF-βR, c-KIT and FLT-3 tyrosine kinases. Sunitinib has been approved for the treatment of renal cell carcinoma[87]. With restricted indications sunitinib is also approved for the therapy of gastrointestinal stromal tumours (GIST)[88] and is currently tested in phase I and Ⅱ trials for HCC (NIH: NCT00361309; NCT00247676).

Another promising approach is the use of dual-targeting tyrosine kinase inhibitors, which inhibit less related tyrosine kinases, such as NVP-AEE788 or zactima (ZD6474) which target both the VEGFRs and the EGFR. In recent *in vivo* studies of non-HCC tumour models (colon, cholangiocarcinoma, prostate, NSCLC) NVP-AEE788 displayed significant antineoplastic efficacy. These agents can inhibit both tumour cell proliferation and survival by blocking hepatoma EGFR and angiogenesis by inhibiting endothelial VEGFR. These promising recent results warrant further evaluation in clinical trials[89-92]. For zactima successful testing in clinical trials has already been reported for non-HCC tumour entities like NSCLC and thyroid cancer[93,94]. Table 3 summarizes the current status of anti-VEGF/VEGFR-based approaches in the treatment of solid tumours including HCC.

OTHER MULTI-KINASE AND GROWTH FACTOR RECEPTOR INDEPENDENT INHIBITORS

Multi-kinase inhibition

The novel bi-aryl urea sorafenib is an orally available multi-kinase inhibitor which targets kinases of wild-type B-Raf, mutantV559EB-Raf and C-Raf, thus blocking tumour growth. Furthermore, sorafenib potently inhibits receptor tyrosine kinases involved in angiogenesis, including human vascular endothelial growth factor receptors-2 and -3 (VEGFR-2/-3) and PDGF-βR. The principal mechanism of action of sorafenib is the competitive inhibition of ATP-binding to the catalytic domains of the respective kinases[95]. However, the fact that sorafenib is an oral multi-kinase inhibitor, with effects on several molecular targets in addition to the Raf isoforms makes it difficult to determine which of these targets contributes most to its anti-tumour activity in particular tumour types.

A recent phase Ⅱ HCC clinical trial, which identified an association between high baseline tumour p-ERK levels and improved response to sorafenib, suggests that inhibition of the Raf/MEK/ERK pathway is central to sorafenib's mode of anti-tumour action in HCC[96]. If this generally holds true for HCC remains to be determined. In other tumour entities the antineoplastic potency of

sorafenib appears to be mainly due to its antiangiogenic activity[97,98].

It is of particular clinical importance to have reliable markers to individually predict the treatment outcome. It has been suggested that rash, which is commonly associated with EGF-pathway inhibition, could be predictive of treatment outcome, and that the onset of rash could be used for optimal dose titration[99]. This might also be effective in treatment with sorafenib, as it is an inhibitor of Raf kinase, which is a downstream effector molecule of the EGFR signalling pathway. A recent report combining data from four phase I trials supported this hypothesis. Patients receiving sorafenib dosed at or close to the recommended dose of 400 mg bid, and experiencing skin toxicity and/or diarrhea, had a significantly increased time to progression compared with patients without such toxicity[100].

Sorafenib inhibits the proliferation of a variety of human cancer cell lines and retards tumour growth in related xenograft models of NSCLC, breast, colon and pancreas carcinoma[13,101,102]. Sorafenib is also active in otherwise fairly therapy resistant cholangiocarcinoma cells. Here, it over-additively enhanced the antineoplastic effects of cytostatics such as doxorubicin or the histone deacetylase inhibitor MS-275 and acts synergistically with IGFR blockade[103,104]. Recent *in vitro* studies by our group confirmed the synergistic antiproliferative effects of a combination treatment with sorafenib and MS-275 in hepatocellular carcinoma models. Proliferation studies, with either Hep-G2 or Huh-7 cells, resulted in half-maximal growth inhibition at a sorafenib concentration of 1.6 ± 0.3 μmol/L (Hep-G2) and 4.4 ± 0.2 μmol/L (Huh-7), respectively. The IC_{50} of MS-275 amounted to 1.2 ± 0.1 μmol/L in Hep-G2 cells and 0.9 ± 0.2 μmol/L in Huh-7 cells. Co-application of sub-IC_{50} concentrations of sorafenib and MS-275 for three days resulted in significant over-additive growth inhibition of Huh-7 cells, while in Hep-G2 cells a rather additive growth inhibitory effect was observed (Figure 2). Our data support the idea of dual-targeting hepatocellular carcinoma cells for enhanced treatment efficacy and show that multi-kinase inhibition plus histone deacetylase inhibition appear to be a promising combination, warranting further elucidation in clinical trials.

A series of clinical studies have tested sorafenib's antineoplastic potency in cancer patients. Phase I trials showed a favourable safety profile of 400 mg sorafenib administered twice daily for 12 wk in patients with advanced solid tumours (e.g. colon, ovary, breast, pancreas, kidney)[100,105]. Promising antitumour activities of sorafenib were observed in a phase Ⅱ clinical study of patients with advanced melanoma[106]. Most encouraging results were seen in phase Ⅱ and Ⅲ trails of patients with metastatic renal cell carcinoma (RCC) which led to approval in the US for advanced RCC[107].

Sorafenib has also been tested for the treatment of advanced HCC in phase Ⅱ and Ⅲ trials. In a phase Ⅱ trial on 137 patients with inoperable HCC the continuous oral application of sorafenib 400 mg bid in 4-wk cycles revealed a significant attenuation of HCC growth in 1/3 of the patients[108] resulting in a further evaluation

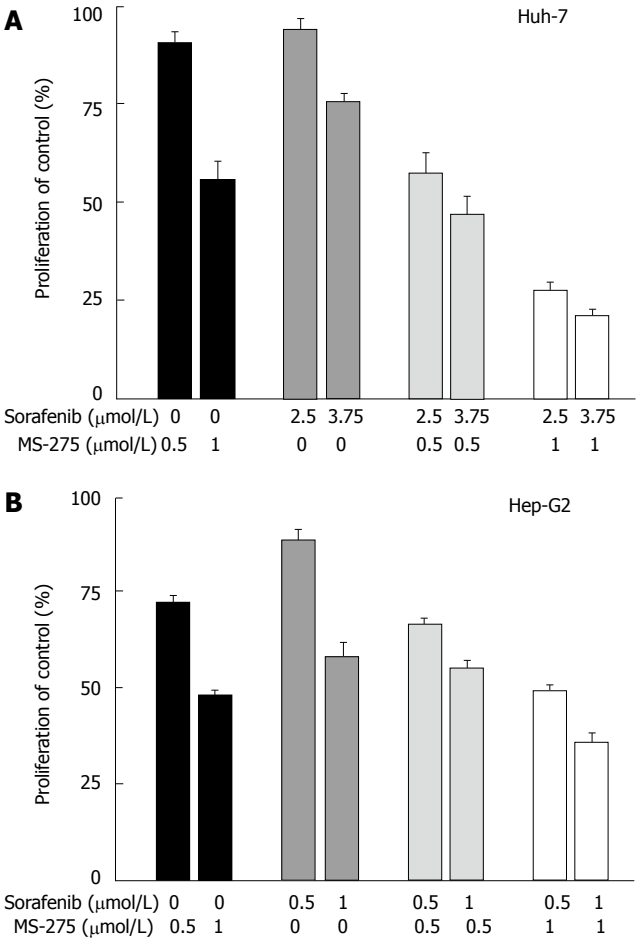

Figure 2 Antiproliferative effects of sorafenib-based combination treatment. **A**: Huh-7 and **B**: HEP-G2 cells were treated for 72 h with sub-IC_{50} concentrations of sorafenib and the histone deactylase inhibitor MS-275. Combination of both agents resulted in synergistic growth inhibition of Huh-7 cells, while rather additive growth inhibitory effects were observed in HepP-G2 cells (mean ± SEM).

in a randomized double-blinded phase Ⅲ trial with 602 patients with advanced HCC. An interim evaluation of this international multi-center SHARP-study (Sorafenib HCC Assessment Randomized Protocol) led to discontinuation, as the HCC patients treated with sorafenib achieved a significant survival benefit over the placebo-treated controls. Llovet *et al* presented the respective data for the Sharp investigators study group at the ASCO meeting in 2007 and showed that the treatment of advanced HCC patients with sorafenib leads to a 44% improvement in the overall survival as compared to the control group. The median overall survival in the sorafenib treated arm was 10.7 mo *vs* 7.9 mo in the control arm. Moreover, the median time to progression was almost doubled (5.5 mo in the sorafenib arm *vs* 2.8 mo in the control arm). The authors concluded that the effects of sorafenib treatment are clinically meaningful and establish sorafenib as first-line treatment for patients with advanced HCC[109]. Based on these findings, sorafenib has recently gained accelerated approval by the FDA for the treatment of advanced unresectable HCC.

mTOR inhibition

The natural antibiotic rapamycin is a potent inhibitor of mTOR[110]. Recently, three analogues of rapamycin with

superior pharmacokinetic and biological properties have been synthesized and tested in clinical trials for different malignancies. The cell cycle inhibitor-779 (CCI-779, temsirolimus) is a soluble ester analogue. RAD001 (40-O-[2-hydroxyethyl]-rapamycin, everolimus) is an orally bioavailable derivative of rapamycin, and finally AP23573, which is a non-pro-drug analogue of rapamycin. These agents have been tested successfully in early clinical trials for their antineoplastic potency and/or tolerability in various malignancies, such as renal, breast and lung cancers (CCI-779), or are currently being studied in open clinical trials for the treatment of colorectal, endometrial cancer, recurrent or refractory solid tumours, and brain tumours (RAD001, everolimus)[111-113]. AP23573 has been successfully tested in a phase Ⅱ trial in sarcomas[114] and two phase I studies in patients with refractory or advanced solid tumours, showing partial responses and disease stabilisation in individual patients[115].

In vitro as well as preclinical *in vivo* data of HCC show, that mTOR inhibition by rapamycin and analogues significantly reduces HCC growth and improves survival primarily *via* antiangiogenic effects[116]. A Phase Ⅰ/Ⅱ trial evaluating everolimus for advanced HCC is currently starting to recruit patients[117] (NIH, NCT00390195). Moreover, the use of rapamycin and analogues for combination treatment together with conventional cytostatic drugs such as doxorubicin or vinblastine has been demonstrated to additively or even synergistically enhance the antineoplastic potency of the respective monotherapeutic HCC treatment with either doxorubicin or vinblastine alone[118-120].

Taken together, the *in vitro* and preclinical *in vivo* data as well as the clinical trials conducted so far show that mTOR inhibitors, including the rapamycin analogues CCI-779, RAD001 and AP23573, are promising combination agents for future cancer therapy. They are well tolerated and can produce stable disease or even substantial responses in relapsed or conventional therapy resistant solid tumours[115].

Proteasome inhibition

Another interesting therapeutic approach for innovative cancer treatment is the inhibition of the 26S proteasome, which is a large protease that is present in both the nucelus and the cytoplasm of eukaryotic cells and functions as an identifier and destructor of proteins branded for destruction by the ubiquitin system. The so called ubiquitin-proteasome pathway (UPP) is the major non-lysosomal proteolytic system in eukaryotic cells and triggers degradation of proteins involved in cell cycle progression, apoptosis, nuclear factor kappaB (NF-κB) activation, and angiogenesis. UPP also degrades mutant, damaged, and misfolded proteins[121]. Since these signalling pathways are critical for cell survival and proliferation, especially in cancer cells, the inhibition of the proteasome has emerged as an attractive target for cancer therapy.

Bortezomib (Velcade™) is a proteasome inhibitor, which blocks multi-ubiquitinated protein degradation by reversibly and competitively inhibiting the active site threonine residue of the 26S proteasome[122]. Antineoplastic activity of bortezomib has already been shown in several *in vitro* and *in vivo* studies[104,123,124]. Bortezomib is the first proteasome inhibitor which has been approved for cancer therapy and is in use for the treatment of advanced multiple myeloma[121]. Based on the results of a phase Ⅱ trial on bortzezomib in the treatment of mantle cell lymphoma (ML) the FDA recently granted approval to bortezomib for the treatment of patients with ML (www.cancer.gov)[125]. Other cancers, including neuroendocrine tumours, RCC, NSCLC, or metastatic sarcomas have also been evaluated in recent phase Ⅱ clinical trials. In some of these studies a significant antineoplastic effect of monotherapy with bortezomib was observed, while in some other studies no or only marginal responses to single treatment with bortezomib were found[126-128]. However, in these cases it was recommended to investigate the role of bortezomib in combination with other antitumoural drugs. The rationale for using bortezomib in combination treatment regimes is that bortezomib's mode of action is mainly based on the inhibition of the NF-κB pathway, which has been shown to exert chemosensitizing effects when administered together with other antitumoural drugs. Combination treatment studies with encouraging results have been reported for lung cancer and lymphoma[129-131]. A phase Ⅰ/Ⅱ trial of bortezomib in patients with unresectable HCC was recently reported to result in disease stabilization in some patients and the treatment was generally well tolerated. In this study it was also suggested to especially focus on combination treatment strategies using bortezomib together with HCC-relevant cytostatics such as doxorubicin[132]. We have recently conducted an *in vitro* evaluation of bortezomib-based treatment of HCC cells. Our findings underline the suitability of bortezomib for the treatment of HCC-alone or in combination with sorafenib. In Huh-7 and Hep-G2 cells nanomolar concentrations of bortezomib induced a marked growth inhibition after three days of treatment. Moreover, the combination of bortezomib and sub-IC_{50} concentrations of sorafenib resulted in additive growth inhibition in both hepatocellular Huh-7 and hepatoma Hep-G2 cells (Figure 3). Thus, our data support the idea of dual-targeting hepatocellular carcinoma cells for enhanced treatment efficacy using bortezomib as a combinatory drug. Our data strengthen the conception of multi-kinase inhibition plus bortezomib to be a promising combination for future HCC treatment, warranting further elucidation in clinical trials. Table 4 summarizes the current status of multi-kinase inhibitors and growth factor independent inhibitors for the treatment of solid tumours.

CONCLUSION

The concept of targeted-therapies which specifically inhibit growth factor receptors and their related signalling pathways emerged to be a promising approach for the innovative and effective medical treatment of various cancers, including hepatocellular carcinoma. Thus, advanced HCC is no longer a tumour disease without specific medical treatment options. The recent findings and clinical trials clearly demonstrate that especially combination treatments inhibiting more than just one

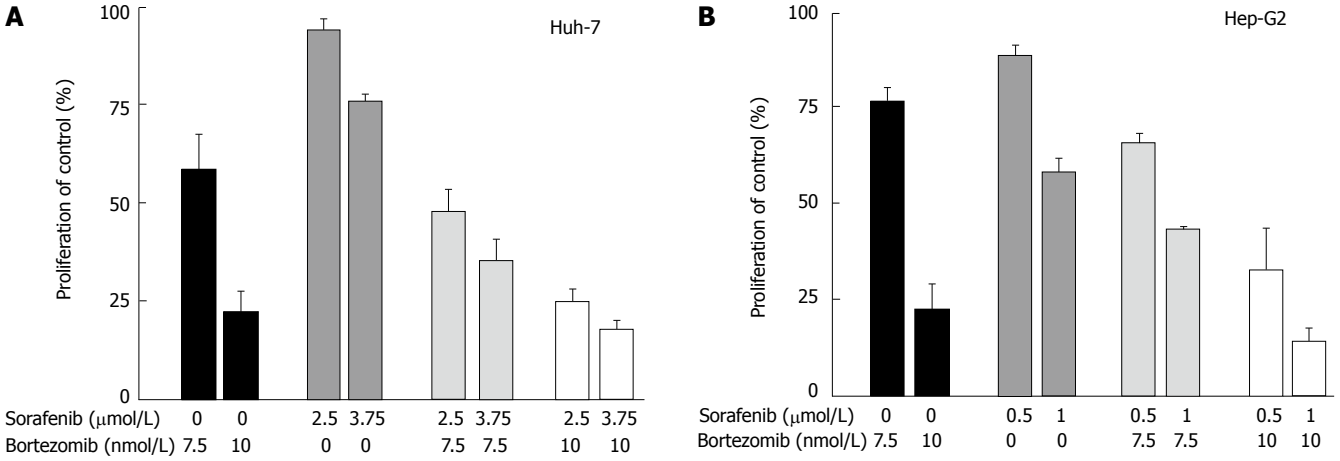

Figure 3 Antiproliferative effects of combination treatment with bortezomib and sorafenib in hepatocelluar carcinoma cells. **A**: Huh-7 and **B**: Hep-G2 cells were treated for 72 h with sub-IC_{50} concentrations of sorafenib and the proteasome inhibitor bortezomib. Combination of both agents led to additive growth inhibition both in Huh-7 as well as in Hep-G2 cells (mean ± SEM).

Table 4 Agents of multi-kinase- and growth factor independent inhibition for the therapy of solid tumours

Name	Target	Mechanism	Current status
Sorafenib	c-Raf-1, B-Raf, VEGFR, PDGFR	Tyrosine kinase inhibitor	Approved for advanced RCC Phase Ⅲ for advanced HCC[108] Phase Ⅱ for melanoma[106], breast cancer[158] and NSCLC[159] Phase Ⅰ for advanced solid tumours[160]
Everolimus (RAD001)	mTOR	Tyrosine kinase inhibitor	Phase Ⅱ for colorectal cancer[165] Phase Ⅰ / Ⅱ for advanced HCC[117,116] Phase Ⅰ for endometrial and brain tumours[111,112]
Temsirolimus (CCI-779)	mTOR	Tyrosine kinase inhibitor	Phase Ⅱ for metastatic breast cancer[161], advanced RCC[162], and mantle cell lymphoma[163] Phase Ⅰ for advanced solid tumours (e.g. colorectal, ovarian, lung cancer)[164]
AP23573	mTOR	Tyrosine kinase inhibitor	Phase Ⅱ for sarcomas of soft tissue and bone[114] Phase Ⅰ for advanced solid tumours
Bortezomib (Velcade)	Proetasome	Proteasome inhibitor	Approved for multiple myeloma and mantle cell lymphoma[125] Phase Ⅱ for colorectal cancer[166], neuroendocrine tumours[128], sarcoma[126], RCC[127], and NSCLC[129] Phase Ⅰ / Ⅱ for unresectable HCC[132] Phase Ⅰ for advanced solid tumours[167]

signalling pathway will be particularly efficient, as it leaves less mechanisms of escape for the tumour cells.

In addition, there are several other promising new drugs which are currently being tested or which should be investigated in future HCC trials. In this respect combinations with drugs such as multi-kinase inhibitors are particularly intriguing. Thus in the future agents like the multi-kinase inhibitor sorafenib will likely be combined with growth factor receptor inhibitors, proteasome inhibitors, HDAC inhibitors or cytostatics as to effectively control advanced HCC. The advantage of such novel combination therapies is their higher efficacy at lowered toxicity as compared to monotherapeutic approaches. The novel combination treatments will offer new chances for drug therapy even in HCC patients with underlying cirrhosis. Fortunately, most of the new drugs can be taken orally.

Abstract

Living donor liver transplantation (LDLT) has gone through its formative years and established as a legitimate treatment when a deceased donor liver graft is not timely or simply not available at all. Nevertheless, LDLT is characterized by its technical complexity and ethical controversy. These are the consequences of a single organ having to serve two subjects, the donor and the recipient, instantaneously. The transplant community has a common ground on assuring donor safety while achieving predictable recipient success. With this background, a reflection of the development of LDLT may be appropriate to direct future research and patient-care efforts on this life-saving treatment alternative.

INTRODUCTION

Living donor liver transplantation (LDLT) has been rapidly growing and evolving since its debut in 1989[1], while deceased donor liver transplantation (DDLT) had already been a standard procedure for a decade[2,3]. LDLT being the legitimate remedy for the refractory shortage of deceased donor liver grafts is characterized by its technical complexity and ethical controversies.

In 1963, Starzl described in detail three cases of DDLT. The first recipient was a 3-year-old boy with biliary atresia and died from intra-operative hemorrhage. The other two recipients were adult males with primary liver cancer. Both succumbed to pulmonary embolism 7 and 22 d after transplantation. These three cases, though ended up in hospital mortality, established the technical feasibility of liver transplantation in human[4]. Only four years later, long survivals were achieved in four DDLT recipients[5]. To become a reliable treatment modality for end-stage liver diseases of a number of etiologies, DDLT has taken two important steps: the clinical use of calcineurin inhibitor - cyclosporine A[6] and improvement of graft preservation techniques by hypothermic perfusion utilizing University of Wisconsin solution[7].

Soon after DDLT had become a standard clinical practice, it outstripped the supply of deceased donor liver grafts. The shortage of pediatric deceased donor liver grafts was even more marked. To overcome size disparity of the graft and the child recipient, reduced-size liver transplantation was devised by Bismuth in 1984[8]. Through extension of this concept, split-graft liver transplantation was then developed by Pichlmayr in 1988[9]. This enables transplanting one more recipient and circumventing graft size discrepancy in one go. The first series was reported by Broelsch in 1990[10].

BIRTH OF LIVING DONOR LIVER TRANSPLANTATION

Experience gained from in-situ donor hepatectomy in reduced-size and split-graft DDLT paved the way for LDLT, an idea proposed by Smith as early as 1969[11]. When harvesting was performed on the living donor, much more technical ingenuity was required. The first attempt was made by Raia[1] and first success achieved by Strong of Australia[12] in July 1989. Under stringent review and auspices of the internal review board[13], the Chicago group led by Broelsch developed the first adult-to-child LDLT program[10]. Small series of adult-to-child LLDT were then reported from the United States[14] and Europe[15].

The problem of deceased donor liver graft shortage has been particularly severe in Asia[16]. In Japan, where deceased donor graft donation was non-existent[17] and liver surgery already well-developed, LDLT flourished[18,19]. For adult-to-adult LDLT (ALDLT), the left liver was used initially and was reported by the Shinshu group[20]. The left lobe used for adults was very often handicapped by the inadequate graft size. In 1993, Kyoto reported their improvisation of using the right lobe in a case of adult-to-child LDLT for a 9-year old recipient. The intention in this particular case was to avoid precarious arterial anatomy of the donor's left lobe[21]. The first case of right lobe ALDLT was performed at Queen Mary Hospital, the University of Hong Kong on May 10th 1996. *A priori*, the right liver

graft design included the middle hepatic vein (MHV). This was to address the problem of small-for-size syndrome[22]. The first series was reported shortly[23].

Donor right hepatectomy is one of the most major surgical living donor procedures. Subjecting a donor who has no medical indication for surgery to a major surgical operation with attendant risks is an ethical challenge. It was viewed by the medical community and the society with caution and skepticism[24-26]. Such donor procedure could only be partially justified by the benefit on the recipient and exhaustion of alternatives. This view is not universally accepted. Our common ground is the commitment to provide care of the highest standard to the living liver donor. Efforts for the betterment of care for the donors and yet not depriving them of the chance of saving or improving the life of their beloved recipients should worth dedication and ingenuity of the transplant community.

DONOR SAFETY AND WELLBEING

Donor safety is central to LDLT. As the application of LDLT extended from children to adults, and from using the left liver graft to the right liver graft, the dilemma between recipient success and donor risk came to the spotlight. The reported overall complication rate of donors is around 20%, but as high as 67% in one review[27]. A unified system of complication reporting[28] may narrow this range. Not only does the complication rate vary amongst different centers, the types of complications reported also vary. The most common complications are wound infection, ileus, and bile leakage. With accumulation of experience, donor morbidity could be lower than 20%. The majority of complications are of Grade I and were wound infections. With careful attention to biliary anatomy and guidance from intraoperative cholangiography, biliary complications are avoidable[29]. While one donor mortality is too many for the transplant community, there are already 14 known donor deaths[30]. Donor right hepatectomy carries a 0.5% donor mortality rate[30]. Similarly, the causes of donor mortality also vary[31]. A widely publicized case is a male donor in New York who succumbed to gas gangrene of *Clostridium perfringens* 3 d after donor right hepatectomy[32]. A hypertensive lady in Japan died from liver failure after right liver donation with a residual left liver with nonalcoholic steatohepatitis 28% of the total liver volume[33]. Fatal pulmonary embolism also occurred in a left liver donor[34]. A donor mother with a history of substance abuse also died from drug overdose 2 mo after donation to her 3 year-old son[35]. In other words, achieving a five-year recipient survival of 80%, it takes one donor life to save 160 recipients. Less tangible is the quality of life changes of the donor in comparison to the predonation state. The long-term biological consequences of donor hepatectomy are not fully known. Nevertheless, there are demonstrable drops in white cell count, platelet counts and elevation of liver transaminases even two years after right liver donation[36]. Quantification of such is mandatory in defining the field strength of LDLT. Detail of the holistic care of living liver donors deserves elaboration in a separate synopsis.

As agreed by the liver transplant community, living liver donors should be of good health[30] and the donor operation performed by experienced centers[37]. There should be no compromise of accepting potential donors with suboptimal physical and mental health. This is the only way to maintain or decrease donor mortality and morbidity.

RECIPIENT SHORT-TERM OUTCOMES

Graft size

Recipient survival is dependent on adequate graft size in relation to recipient body size[38]. Pathophysiology of the small-for-size graft and small-for-size syndrome is then defined[39]. Features include hepatocyte ballooning, steatosis, centrilobular necrosis, and parenchymal cholestasis. Pre-existing portal hypertension of the recipient increases the size requirement of graft[40].

Anecdotal success of using a very small graft for ALDLT 25% of the estimated standard liver weight[41] and even 20% with portosystemic shunting[42] had been reported. The paradigm shift from the left liver to the right liver enables adult recipients to undergo LDLT[43]. With technical maturity, 35% of the estimated standard liver weight remains the minimum requirement of a graft for predictable recipient success[44]. Portal hyperperfusion[45] and portal hypertension[46] are now conceived as possible mechanisms conducive to damage of small-for-size grafts. A battery of techniques for alleviation of portal venous flow was described. This includes superior mesenteric vein to mesocaval shunt[47], hemiportocaval shunting[48], inflow modulation by splenic artery ligation[49]. With portosystemic shunting using a saphenous vein interpositional graft between the right portal vein and right hepatic vein stump, a left lobe 20% of the estimated standard liver mass had been transplanted successfully in one patient[42]. Pharmacological manipulation is on the horizon as well[50].

More basic to these is the accurate assessment of standard liver volume of the recipient and thus the minimum graft size requirements. There have been a number of formulae developed from the west[51,52] and one from Japan[53]. A formula derived from Chinese and for application in Chinese which is also gender dependent has been developed and for validation[54].

Middle hepatic vein

Center to the controversy of right lobe ALDLT is inclusion of the MHV or otherwise. Deleterious effects of no drainage to the segments 5 and 8 include severe venous congestion and necrosis of these segments[55]. Surgical decision of not including the MHV includes demonstration of collaterals between segment 5 and 8 tributaries and the right hepatic vein[56]. Kyoto University devised an algorithm which includes the MHV when the graft is MHV dominant, or the graft to recipient weight ratio less than 1%, and in all cases, remnant left lobe larger than 35%[43]. Chang Gung Memorial Hospital includes the MHV when the graft to estimated standard liver volume is 50% or less, or when segment 5 and 8 hepatic veins are large and the right hepatic vein small[57]. Tokyo University ingeniously observed congestion of segments 5 and 8 of the graft after temporary clamping of the right hepatic artery before determining venous interpositional grafting[58].

We include the MHV in all right liver grafts for simplicity and familiarity of the technique[59]. Irrespective of the venous drainage pattern of segment 4 of the remnant left liver, the segment 4b hepatic vein is preserved. Utmost care is needed for its preservation when it drains into the MHV[60]. The outflow capacity is guaranteed by venoplasty on the back-table of the MHV and right hepatic vein into a single cuff[61]. The venoplasty is further marked by a more expedient hepatic vein to inferior vena cava anastomosis and higher outflow capacity of the right liver graft[62].

In summary, adequate graft size and quality, excellent venous outflow, and moderate portal inflow are keys to success of ALDLT[63].

High urgency LDLT

ALDLT under high urgency was impetus to development of liver transplant in our center[23]. Early experience of a number of centers showed inferior surgical outcomes of ALDLT in the high urgency situation[64-66]. With accumulation of experience and right liver graft incorporating the MHV, surgical outcomes of ALDLT is not compromised[67]. We also showed that ALDLT improves the survival of potential recipients[68]. The question of when a patient becomes too sick for liver transplantation is to be answered[69]. To justify ALDLT, good recipient outcome and acceptable donor morbidity, and voluntarism of the donor are the least that could be expected. The Live Organ Donor Consensus Group has largely supported this viewpoint[70]. The Model for End-Stage Liver Disease score has been validated as a factor predictive of recipient short-term survival in DDLT[71]. Data from ALDLT in North America[72] and Europe[73], however, do not support this view. Outside Asia, ALDLT is gradually considered a standard treatment for acute liver failure.

Biliary reconstruction

Biliary complication justifies itself the Achilles' heel of DDLT and is even more convincing in ALDLT[67]. Hepaticojejunostomy and duct-to-duct anastomosis have no substantial difference in the incidence of biliary complications. Nonetheless, duct-to-duct anastomosis reduces the operating time and avoids contamination of the operation field, expedites return of bowel functions, and avoids internal herniation of bowel loops. It also allows subsequent intervention by endoscopic retrograde cholangio pancreatography. In some centers, duct-to-duct anastomosis is stented to minimize the chance of stensosis and leakage. Whether the stent plays a role in the postoperative period, or in facilitating anastomosis, or both, has not been validated. Furthermore, whether continuous or interrupted sutures makes a difference is unknown. A study on DDLT which showed no difference[74] may not be applicable to ALDLT. Randomized controlled trials of recipients allocated to both arms may answer these questions.

RECIPIENT LONG-TERM OUTCOMES

Hepatocellular carcinoma

Early efforts of transplanting patients with advanced unresectable primary liver cancers were tempered by invariable relapse of malignancy[75]. Further work of the same group established the correlation between poor prognosis and high pathological tumor-node-metastasis staging[76]. Vascular invasion by tumor is the single most important factor in treatment failure of ALDLT for unresectable small hepatocellular carcinoma (HCC). Major vascular invasions though apparent for large tumors, may not be so for the small ones. Now called the Milan Criteria[77] and the University College of San Francisco Criteria (UCSF)[78], the tumor size and number are used as surrogate parameters for likelihood of vascular invasion. The Milan criteria are based on pretreatment imaging, whereas the UCSF criteria on liver explant histopathology. Accuracy of preoperative imaging in staging is inadequate[79]. The tendency is toward underestimation of tumor load. Even in studies with good image to histopathology correlation, underestimation is common. Tumor grade[80] and tumor size[81,82] are predictors of vascular invasion. Tumor size itself is also a predictor of tumor grade[81,82].

In our own series of ALDLT for HCC, there is a tendency of a higher recurrence rate compared with DDLT. It is postulated that the higher regeneration rate and reperfusion injury of small grafts in ALDLT provides an environment favorable for HCC cell implantation and growth in the graft[83]. It is also possible that in ALDLT, for preservation of the inferior vena cava, more liver manipulation is required leading to tumor compression and cancer cell dissemination. However, it is not unlikely that patients who have received DDLT are the self-selected patients because only candidates with slowly growing HCC who could wait for deceased donor liver grafts could receive the transplantation as the cancer cells are less aggressive. In fact, fast-tracking ALDLT for HCC had a higher recurrence rate[84]. Further studies on patient selection criteria and innovation of surgical technique are required to improve the long-term outcome of ALDLT for HCC. A recent series from Korea, nonetheless, has comparable results as DDLT[85].

In a series of 316 recipients with HCC who underwent ALDLT in Japan, the patient and recurrence-free survival rates were significantly worse if the Milan's criteria were not met. However, within this series, 171 (54.1%) of the recipients did not fulfill the Milan's criteria, and 176 were staged IVa. The alpha-fetoprotein level, tumor size, vascular invasion, and bilobar distribution were independent risk factors for HCC recurrence. The grade of histological differentiation of HCC showed close correlation with tumor characteristics and recurrence. Multifocal HCC verified by histopathology after transplantation with no recurrence was reported[86]. A policy of extended indication beyond the Milan and UCSF criteria is being validated[87].

The first use of sirolimus in liver transplantation was in patients with liver cancer, using the reported antitumor effects of the drug[88]. Subsequent work has shown efficacy of the drug in the inhibition of hepatocellular tumor cell lines[89,90]. Recipients transplanted for HCC and received sirolimus and low dose tacrolimus survived longer[91].

Sequelae of long-term immunosuppression

Calcineurin inhibitors greatly improve graft and recipient

Table 1 Landmark publications of liver transplantation in chronological order

Author	Discovery and application	Year of publication
Starzl[4]	First attempts of DDLT in human (1963)	1963
Starzl[5]	First long survival DDLT recipients (1967-1968)	1968
Smith[11]	Conceptualization of LDLT (1969)	1969
Calne[6]	Cyclosporin A used in solid organ transplantation	1979
Bismuth[8]	First adult-to-child reduced-size DDLT (1981)	1984
Pichlmayr[9]	Split-graft DDLT for 2 recipients (1988)	1988
Belzer[7]	Clinical use of University of Wisconsin Solution	1990
Raia[1]	First attempt of LDLT (December 1988)	1989
Strong[12]	First successful LDLT from adult to child (July 1989)	1990
Yamaoka[21]	First report of right liver graft from adult to child (1992)	1994
Hashikura[20]	First successful left liver adult-to-adult LDLT (November 1993)	1994
Lo[22]	First right liver adult-to-adult LDLT using right liver (May 1996)	1997

survivals. The lowest permissible serum drug level is employed to minimize the side effects. Nonetheless, two undesirable results still occur in recipients, i.e. renal impairment and tendency toward diabetes. A trend toward steroid-sparing immunosuppression seems workable[92]. The added benefit of the potential antineoplastic property of sirolimus makes it very attractive for recipients with renal impairment transplanted for resectable HCC[93].

Prompted by development of immune tolerance of noncompliant liver recipient after cessation of immunosuppressant therapy, weaning programs were incorporated into a long-term strategy of liver transplant programs. Drug-free tolerance was observed more frequently in humans after transplantation of the liver than of any other organs. Clinical application of cyclosporine[6] and then tacrolimus[94] dramatically prevented acute rejection of transplanted organs. However, drug-free tolerance became rare with the dominance of multiagent prophylactic immunosuppression[95].

Development of tolerance to the graft obviates the use of immunosuppressant with the side effects. The equivalence of solid organ and bone marrow transplantation is substantiated by documentation of systemic microchimerism[96]. Liver cells were identified in distant organs and host cells were also identified in liver grafts. The mirror image of solid organ and bone marrow transplantation envisioned by Starzl brings to light the practicality of long-term donor specific tolerance. The liver as a privileged graft[97] is a constant source of donor leukocyte, thus facilitates the process of clonal exhaustion-deletion especially in the early post-transplant phase under low immunosuppression pretransplant by antilymphocyte globulin. The concept of prope tolerance is also proposed as a means to a similar condition at a lesser degree[98]. Utilizing a powerful lymphocyte-depleting antibody, Campath 1H, half-dose cyclosporine monotherapy became workable. During a window of opportunity for immunologic engagement (WOFIE), it is hypothesized that there is engagement of donor and recipient marrow cells. Not until the availability of transgenic xenografts, effective and specific immunosuppression remains the practical way to graft maintenance. Nonetheless, continual assessment of the risk of chronic subclinical rejection is necessary[99].

CONCLUSION

At a minimum, recipient success is high and donor risk low. This brings donor and recipient issues into a close relationship. Conceptually, it would be inappropriate to accept a higher risk for the donor simply because of the improvement of recipient outcome. It is nonetheless our common goal to improve the standard of recipient and donor operations. What the public should change is, however, the better acceptance of ALDLT in the face of better safety and success, while the effort to make more deceased donor grafts available is never be forgotten.

Now we have near perfect graft harvesting and implantation techniques. Excluding patients with prohibitive conditions, e.g. uncontrolled sepsis and poor cardiac conditions, the short-term success is predictable. We still require selecting patients with a low recurrence rate of HCC and hepatitis C after transplantation. A lower biliary complication rate is welcome and could only be reduced by better preservation of biliary vasculature on the donor and the recipient and careful anastomotic techniques.

Donor safety and recipient success are inseparable. While donor mortality is a reality, it is by lowering donor mortality and improving recipient survival the justification of LDLT becomes stronger.

Although the major interest of the liver transplant community was in ALDLT in the last decade, the success of ALDLT has been a result of the ground works laid since the sixties. Key publications documenting the major achievements in liver transplantation leading to the ever improving results of ALDLT are listed in chronological order in Table 1.

Abstract

Nonalcoholic fatty liver disease (NAFLD) is highly prevalent and can result in nonalcoholic steatohepatitis (NASH) and progressive liver disease including cirrhosis and hepatocellular carcinoma. A growing body of literature implicates the peroxisome proliferators-activated receptors (PPARs) in the pathogenesis and treatment of NAFLD. These nuclear hormone receptors impact on hepatic triglyceride accumulation and insulin resistance. The aim of this review is to describe the data linking PPARα and PPARγ to NAFLD/NASH and to discuss the use of PPAR ligands for the treatment of NASH.

BACKGROUND ON NAFLD/NASH

An estimated 30% of adults and 10% of children and adolescents in the United States have nonalcoholic fatty liver disease (NAFLD), defined as liver fat content exceeding 5% (Figure 1)[1-3]. Non-alcoholic fatty liver disease is associated with obesity, non-insulin dependent diabetes, and hypertriglyceridemia and represents the hepatic manifestation of the metabolic syndrome[4]. A subset of persons with NAFLD progresses to nonalcoholic steatohepatitis (NASH), consisting of hepatic steatosis accompanied by inflammation and fibrosis (Figure 1)[5]. Nonalcoholic steatohepatitis affects approximately 3% of the lean population and 19% of obese persons, making it the most prevalent cause of chronic liver disease in the country[6]. Moreover, NASH represents a progressive form of liver disease. Cirrhosis developed in 5% of patients with NASH in a community-based cohort and 20% of NASH patients in a referral population[7,8]. Nonalcoholic steatohepatitis accounts for up to 75% of cases of cryptogenic cirrhosis and patients with NASH and cirrhosis are at risk for hepatocellular carcinoma[9,10].

The pathogenesis of NASH is often conceptualized as a two-step process, consisting of hepatic triglyceride accumulation, followed by the development of oxidative stress and cytokine expression leading to steatohepatitis[11]. Multiple metabolic processes can result in hepatocellular triglyceride accumulation including: (1) Excess dietary intake. Dietary triglycerides are delivered to the liver in the form of chylomicrons. In addition, dietary calories stored in adipose tissue as fat represent a source of fatty acids and triglycerides that can be delivered to the liver in the form of lipoprotein particles and free fatty acids. (2) Increased rates of lipogenesis resulting from the *de novo* synthesis of fatty acids and triglycerides in the liver. (3) Decreased rates of β-oxidation of fatty acids in the liver. (4) Decreased rates of export of cholesterol esters and triglycerides from the liver as very low density lipoprotein (VLDL)[12]. As shown in Figure 2, the PPARs impact on multiple processes involved in lipid trafficking and metabolism.

Insulin resistance and hyperinsulinemia seem to be central to the development of NAFLD. Insulin resistance is associated with increased lipolysis and reduced postprandial uptake and storage of fatty acids in adipose tissue, leading to increased fatty acid flux to the liver[13]. In turn, increased liver fat content contributes to hepatic insulin resistance[14]. Hyperinsulinemia induces sterol regulatory element-binding protein-1c (SREBP-1c) expression and hyperglycemia activates carbohydrate response element binding protein (ChREBP), both of which increase hepatic fatty acid synthesis[15].

THE PPARS

PPARs play a key role in modulating hepatic triglyceride

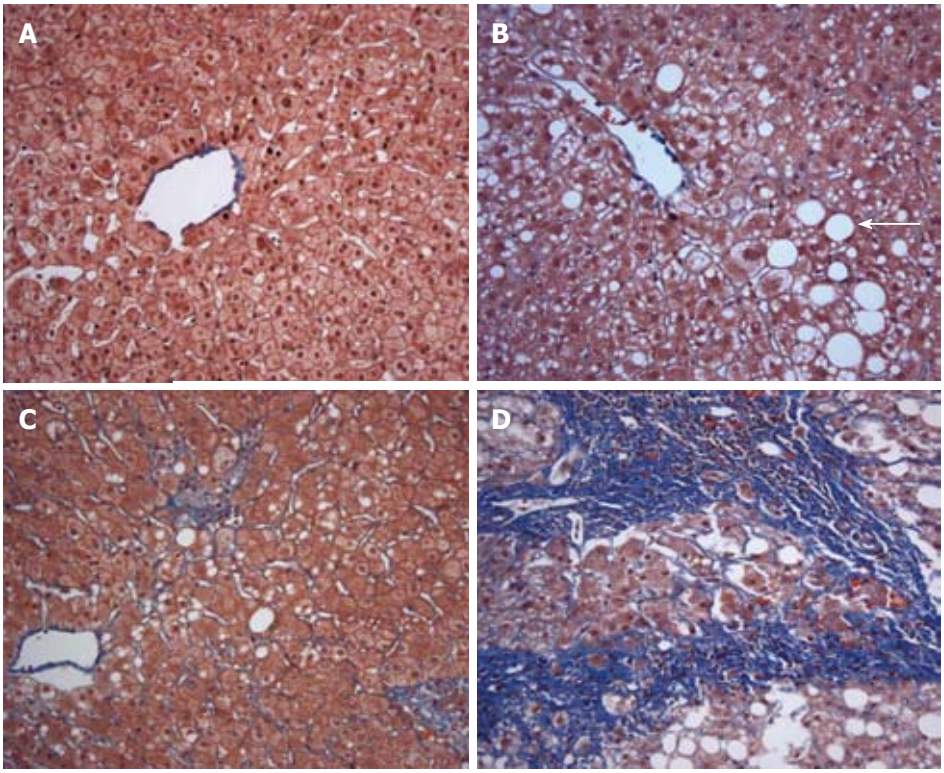

Figure 1 Liver histology ranging from normal liver to steatohepatitis with fibrosis. **A**: Normal liver. Cytoplasmic fat globules are absent in hepatocytes and there is no fibrosis in this trichrome stained specimen (× 20); **B**: Steatosis without steatohepatitis. Moderate cytoplasmic fat infiltration (arrow) is present without fibrosis (× 20); **C**: Steatohepatitis with minimal fibrosis. There is focal hepatocyte ballooning, inflammation, and minimal fibrosis (accentuated in blue by trichrome stain) (× 20); **D**: Steatohepatitis with fibrosis. There is nodular scarring in this fat laden liver with advanced fibrosis depicted in blue by trichrome stain (× 20).

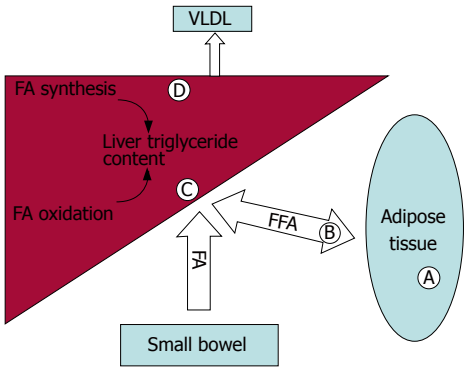

Figure 2 Mechanisms by which PPARs and their ligands can modulate triglyceride accumulation are highlighted by letters in the figure. A: PPARγ increases expression of genes associated with fatty acid uptake and triglyceride storage in adipocytes. Release of adiponectin from adipocytes improves insulin sensitivity and activates PPARα; B: PPARγ increases lipoprotein lipase expression, liberating circulating fatty acids from lipoproteins for import into adipocytes; C: PPARα activity up regulates β-oxidation of fatty acids in the liver; D: PPARα and TZDs upregulate stearoyl-CoA desaturase-1, a necessary enzyme for VLDL synthesis and export, and TZDs increase arachidonic acid content in triglycerides, which is associated with increased insulin sensitivity.

accumulation. PPARα regulates fatty acid β-oxidation. PPARγ increases insulin sensitivity as well as regulating triglyceride storage in adipose tissue. Fat labeling studies indicated that the majority of hepatic triglycerides originate from adipose tissue as non-esterified fatty acids[16].

PPARs are part of the nuclear receptor superfamily[17]. There are three isotypes in mammals designated PPARα [NR1C1], PPARδ [NR1C2] and PPARγ [NR1C3][18]. PPARα is activated by ligands termed peroxisome proliferators, which were named for their effects on peroxisomes in rodent livers[19,20]. Lipids are natural PPAR ligands, leading to regulation of lipid metabolism and fuel partitioning[17]. PPARs form a heterodimer with the retinoid X receptor (RXR). The PPAR:RXR heterodimer, when bound to a ligand, changes conformation and binds to DNA at PPAR response elements, resulting in gene transcription[21,22].

PPARα AND NAFLD

PPARα is expressed in the liver and other metabolically active tissues including striated muscle, kidney and pancreas[23,24]. Many of the genes encoding enzymes involved in the mitochondrial and peroxisomal fatty acid β-oxidation pathways are regulated by PPARα. In particular, the acyl-CoA synthetase, the carnitine palmitoyl transferase I, the very long-chain acyl-CoA dehydrogenase and the tri-functional protein genes encoding enzymes in the mitochondrial fatty acid β-oxidation pathway are induced by peroxisome proliferators that activate PPARα[25-28]. Similarly, the acyl-CoA synthetase, the straight-chain acyl-CoA oxidase, the L-bifunctional protein and the 3-ketoacyl-CoA thiolase genes encoding enzymes in the peroxisomal fatty acid β-oxidation pathway are induced by peroxisome proliferators that active PPARα[26,27,29,30]. Loss of expression of the PPARα gene in mice results in hepatic steatosis under conditions of increased fatty acid metabolism in the liver such as fasting or a high fat diet[31,32]. Administration of a potent PPAR agonist decreases hepatic steatosis in mice receiving a methionine and choline deficient diet[33]. These observations indicate that under conditions of increased hepatic fatty acid influx or decreased hepatic fatty acid efflux, PPARα activation prevents the accumulation of triglycerides by increasing the rate of fatty acid catabolism.

Additional factors appear to interact with PPARα to regulate hepatic triglyceride content. These include adiponectin, which is an adipocyte produced peptide

hormone that limits fat accumulation in the liver by a number of mechanisms including activation of PPARα to increase hepatic fatty acid oxidation[34]. In cell culture models, treatment with adiponectin resulted in increased activity of PPARα target genes such as acyl-CoA oxidase, carnitine palmitoyl transferase- I , and fatty acid binding protein[35]. PPARα ligands can increase steaoryl-CoA desaturase-1 (SCD1) activity, which is necessary for VLDL secretion[36]. A PPAR response element was found in the SCD1 promoter[37]. Adiponectin is upregulated by PPARγ, providing a connection between the two isotypes[38].

Most of the data regarding PPARα and hepatic lipid homeostasis comes from mouse models. However, there are important differences in PPARα activity between rodents and humans. PPARα DNA binding activity and PPARα expression in human hepatocytes is less than 10-fold that observed in mice[39,40]. Certain PPAR response elements, such as the acyl CoA oxidase gene, do not respond to PPAR ligands in humans as they do in rodent models[41]. Finally, PPARα activation in rodent models resulted in peroxisomal proliferation, hepatomegaly, and hepatocellular carcinoma[39,42,43], whereas similar changes were not observed in humans[44,45]. Further research is needed to determine the relative importance of PPARα in regulating hepatic triglyceride metabolism in humans.

PPARα AS A TARGET FOR THE TREATMENT OF NAFLD

Fibric acid derivatives, which are available for use in humans as lipid lowering agents, serve as PPARα activators[46,47]. In a mouse model of fatty liver disease, fenofibrate treatment improved steatosis and increased expression of genes involved in fatty acid metabolism[48]. Trials with fibrates in humans have yielded mixed results. A study involving potential living liver donors with steatosis showed that a combination of diet, exercise, and benzafibrate significantly reduced steatosis and resulted in normalization of alanine aminotransferase levels[49]. However, it was not clear whether the therapeutic benefit was related to benzafibrate or to a 1000 kilocalorie/day diet and a 600 kilocalorie/day exercise regimen. In addition to being a PPARα ligand, benzofibrate activates PPARγ and improves insulin sensitivity in animal models[46,47], an effect not seen with fenofibrate[50]. Another study demonstrated that 42% of 62 patients with NAFLD had biochemical and ultrasound improvement on fenofibrate, but histologic data were not collected[51]. A small controlled study of gemfibrozil *versus* placebo for four weeks found improved aminotransferase levels with the use of gemfibrozil in patients with NAFLD[52]. These studies are in contrast to a another small series, which demonstrated no change in aminotransferases and no histologic improvement after one year of clofibrate therapy for NAFLD[53].

Omega-3 polyunsaturated fatty acids (PUFA) present in fish oil, and their metabolites, provide another source of PPARα ligands. Omega-3 PUFA also inhibit lipogenesis by antagonizing activation of LXR[54,55], thus reducing expression of SREBP-1c[56], which results in the down regulation of key enzymes involved in hepatic lipid biosynthesis. In mouse models, omega-3 PUFA supplementation was associated with improvement in hepatic steatosis and insulin sensitivity, as well as lower fasting free fatty acid concentrations and lower serum triglyceride levels[57,58]. Two human studies reported a decline in serum aminotransferase levels and improvement in ultrasound features of fatty liver with omega-3 PUFA supplementation[59,60]. However, no histologic data were provided. Omega-3 PUFA supplementation also reduces serum triglyceride levels in the fasting and postprandial state[61-63], but was not found to improve insulin sensitivity in humans[62,64,65].

PPARγ AND NAFLD

PPARγ is expressed in high levels in adipose tissue[66] and plays a role in increasing insulin sensitivity as well as in promoting fatty acid uptake into adipocytes and adipocyte differentiation. The net effect of these processes is to increase triglyceride storage in adipocytes, reducing delivery of fatty acids to the liver. Patients with dominant negative mutations in PPARγ have NAFLD and the metabolic syndrome while lacking adipose tissue suggesting increased triglyceride delivery to the liver[67]. PPARγ is present in the liver to a lesser degree than in adipose tissue. Liver-specific PPARγ deficient mice are protected against the development of steatosis suggesting a role for hepatic PPARγ in liver triglyceride accumulation[68,69].

Insulin resistance is integral to the development of NAFLD, leading to increased fatty acid flux to the liver and increased hepatic fatty acid synthesis[13,15]. PPARγ increases insulin sensitivity by upregulating GLUT4, an insulin dependent glucose transporter in adipose tissue and striated muscle[70], and inducing expression of the c-Cbl associated protein, which is involved in insulin signaling[71]. Additionally, in mouse models of insulin resistance, PPARγ activation attenuated induction of supressor of cytokine signaling 3 (SOCS3), which is involved in the development of insulin resistance[72].

PPARγ also promotes adipocyte differentiation and expression of proteins in adipocytes involved in fatty acid uptake[17,73], fatty acid transport[74,75] and fatty acid synthesis[76]. Differentiation of preadipocytes to adipocytes requires transcription factors including the CCAT-enhancer-binding proteins (C/EBPs) and the adipocyte differentiation and determination factor (ADD)-1/SREBP-1[77-80]. C/EBP plays an important role in inducing and maintaining PPARγ expression in adipogenesis[81,82]. ADD-1/SREBP-1 is strongly adipogenic, is enhanced by PPARγ, and results in the expression of lipogenic genes including fatty acid synthase[80]. These transcription factors guide the cell through proliferation, clonal expansion, growth arrest, and eventually adipocyte specific genes are activated resulting in lipid accumulation[82]. PPARγ also increases expression of lipoprotein lipase, an enzyme that serves to partition fat to adipocytes, limiting fatty acid flux to the liver. Similar to PPARα, PPARγ ligands upregulate SCD1 activity, which promotes VLDL secretion. Thiazolidinediones (TZDs), ligands for PPARγ have also been shown to increase arachidonic acid content in triglycerides through SCD1, which has been associated with increased

insulin sensitivity[83]. Other effects of PPARγ include induction of uncoupling protein-2, which might decrease hepatic triglyceride accumulation by increasing energy expenditure[84]. PPARγ expression also might reduce hepatic inflammation by decreasing expression of proinflammatory cytokines, such as TNFα[85].

PPARγ AS A TARGET FOR THE TREATMENT OF NAFLD

TZDs are PPARγ agonists, which improve glycemic control in patients with type 2 diabetes mellitus by increasing insulin sensitivity[86]. The TZD-mediated increase in insulin sensitivity was demonstrated in adipose tissue, the liver, and skeletal muscle[87,88]. TZD therapy increases adiponectin levels, which are associated with improved insulin sensitivity[89]. Furthermore, adiponectin impacts on hepatic fat accumulation by enhancing fatty acid oxidation in muscle, and by activating PPARα to increase fatty acid oxidation in the liver[34].

Thiazolidinediones also increase expression of AMP-activated protein kinase[88,90]. This protein kinase increases fatty acid oxidation as well as decreasing lipogenesis[91,92]. The reduction in lipogenesis is mediated through phosphorylation and inhibition of acetyl-CoA carboxylase, which decreases malonyl CoA formation and down regulates SREBP and the carbohydrate response element binding protein (ChREBP)[93]. Finally, TZDs have anti-inflammatory and anti-fibrotic properties that might be beneficial in NASH. Serum high-sensitivity CRP, IL-6 and IL-18 levels were significantly reduced in patients on TZD therapy[94,95] and the TZD pioglitazone reduced activation of hepatic stellate cells in an animal model[96]. Increased adiponectin may also contribute to the anti-inflammatory effects of TZD therapy. Adiponectin was shown to block TNFα activation of inflammatory genes in endothelial cells[97], decrease macrophage growth and function[98-100], and increase release of the anti-inflammatory cytokines IL-10 and IL-1RA with a concomitant decrease in interferon-γ production[100].

Studies of the TZDs rosiglitazone and pioglitazone demonstrated reduction in aminotransferase levels and improvement in liver histology in patients with NASH[87,101-106]. One study that compared pioglitazone plus vitamin E to vitamin E alone for the treatment of NASH found significant improvement in steatosis, hepatocellular ballooning, and pericellular fibrosis in the combination therapy arm, but not in patients treated with vitamin E alone[103]. In a study of pioglitazone plus diet versus placebo plus diet in patients with biopsy proven NASH and insulin resistance, pioglitazone therapy was associated with a significant reduction in mean serum aminotransferase levels and improved glycemic control[107]. There were significant improvements in hepatic insulin resistance as well as histologic parameters including hepatic steatosis, ballooning, and inflammation, although not fibrosis with six months of treatment. Further evaluation of the efficacy and the cardiovascular risk of TZD therapy[108] is needed before this class of medications is routinely prescribed for the treatment of NASH.

CONCLUSION

The nuclear hormone receptors PPARα and PPARγ appear to play an important role in modulating hepatic triglyceride accumulation, the primary process in the development of NAFLD. PPARα activity reduces liver fat by increasing β-oxidation of fatty acids and PPARγ increases insulin sensitivity as well as reducing fatty acid flux to the liver. PPAR ligands show promise in the treatment of NAFLD, although further human studies are needed to define the therapeutic role of these agents.

Abstract

AIM: To assess the effect of notoginsenoside R1 on hepatic microcirculatory disturbance induced by gut ischemia/reperfusion (I/R) in mice.

METHODS: The superior mesenteric artery (SMA) of C57/BL mice was ligated for 15 min to induce gut ischemia followed by 30-min reperfusion. In another set of experiments, R1 was continuously infused (10 mg/kg per hour) from 10 min before I/R until the end of the investigation to study the influence of R1 on hepatic microcirculatory disturbance induced by gut I/R. Hepatic microcirculation was observed by inverted microscopy, and the vascular diameter, red blood cell (RBC) velocity and sinusoid perfusion were estimated. Leukocyte rolling and adhesion were observed under a laser confocal microscope. Thirty and 60 min after reperfusion, lactate dehydrogenase (LDH), alanine aminotransferase (ALT) and aspartate transaminase (AST) in peripheral blood were determined. The expression of adhesion molecules CD11b/CD18 in neutrophils and tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6) and monocyte chemotactic protein-1 (MCP-1) in plasma were evaluated by flow cytometry. E-selectin and intercellular adhesion molecule-1 (ICAM-1) in hepatic tissue were examined by immunofluorescence.

RESULTS: After gut I/R, the diameters of terminal portal venules and central veins, RBC velocity and the number of perfused sinusoids were decreased, while the leukocyte rolling and adhesion, the expression of E-selectin in hepatic vessels and CD18 in neutrophils, IL-6, MCP-1, LDH, ALT and AST were increased. R1 treatment attenuated these alterations except for IL-6 and MCP-1.

CONCLUSION: R1 prevents I/R-induced hepatic microcirculation disturbance and hepatocyte injury. The effect of R1 is related to its inhibition of leukocyte rolling and adhesion by inhibiting the expression of E-selectin in endothelium and CD18 in neutrophils.

INTRODUCTION

It is well recognized that gut ischemia/reperfusion (I/R) induces injury of distant organs, such as liver and lung[1-3]. A rate-limiting step in the pathogenesis of I/R injury of liver and other organs is the recruitment of leukocytes to vascular endothelium[2,4,5]. Oxygen free radicals produced by gut I/R activate nuclear factor kappa-B (NF-κB)[6,7], initiate expression of selectin and adhesion molecules[8-10], and elicit release of proinflammatory mediators like tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6)[10]. The expression of L-selectin on leukocytes and E-selectin on endothelial cells induces the rolling of leukocytes along the vascular endothelium[11,12], which further promotes the expression of adhesion molecules CD11b, CD18 on

leukocytes and intercellular adhesion molecule-1 (ICAM-1) on endothelial cells, resulting in adhesion of leukocytes to vascular endothelial cells[2,4,13,14]. In addition, proinflammatory mediators produced by I/R enhance the expression of selectins and adhesion molecules, and aggravate the rolling and adhesion of leukocytes[8,15]. The adhesion of leukocytes to the vascular endothelium results in release of oxygen free radicals and proteinase, thus inducing hepatic injury[16]. In line with these findings, studies indicate that inhibition of the expression of selectins and adhesion molecules on leukocytes and endothelial cells ameliorates the adhesion of leukocytes to the hepatic vascular endothelium after gut I/R and attenuates hepatic microcirculation disturbance and injury[2,4,17].

Panax notoginseng (PN) is the dried root of *Panax notoginseng* (Araliaceae), a Chinese herb medicine widely used in China, Korea, Japan and other Asian countries in the treatment of microcirculatory disturbance-related diseases, such as cardiovascular disease, cerebral vascular diseases and liver dysfunction[18,19]. PN contains more than 30 different types of saponin, of which ginsenoside Rg1 (Rg1), ginsenoside Rb1 (Rb1) and notoginsenoside R1 (R1) are the eminent members[20]. Previous studies have proved that *Panax notoginseng saponins* (PNS) improve I/R-induced hepatic microcirculation disturbance[19], inhibit platelet aggregation and adhesion molecule expression, and improve vascular endothelium function[21]. It was also reported that PNS inhibit adhesion of leukocytes to rat mesentery venules and expression of neutrophil adhesion molecules CD11b and CD18 induced by lipopolysaccharide (LPS)[22]. The expression of LPS-induced vascular endothelial TNF-α is inhibited by R1 by inhibiting degradation of the inhibitor kappa-B (I-κB)[23]. It has been shown that cardiotonic pills (CP, a traditional Chinese medicine containing PN, *salvia miltiorrhiza* and *borneol*) can inhibit adhesion of leukocytes to the hepatic vascular endothelium in rats induced by gut I/R and chronical ethanol feed, and blunt the concentration increment of peripheral blood alanine aminotransferase (ALT), TNF-α and LPS[24]. However, whether R1 improves gut I/R-induced hepatic microcirculation disturbance has not yet been reported, although it is highly anticipated as a major component of PNS, and the structure of R1 has been identified (Figure 1). Therefore, by virtue of intravital microscopy the present study explored the dynamic effects of R1 on a mouse hepatic microcirculation disturbance model induced by gut I/R, especially on leukocyte rolling and adhesion on the vascular endothelium. The expression of E-selectin and ICAM-1 was also determined by immunofluorescent technique. The expression of neutrophil adhesion molecules CD11b and CD18, and the concentration of proinflammatory mediators such as TNF-α, IL-6 and monocyte chemotactic protein-1 (MCP-1) was measured by flow cytometry. The concentrations of lactate dehydrogenase (LDH), ALT and aspartate aminotransferase (AST) were also determined.

MATERIALS AND METHODS

Notoginsenoside and reagents

R1 (purity > 98%) was supplied by Tianjin Talsy Group (Tianjin, China). Other reagents used in experiments were as follows: rhodamine 6G (purity > 99.0%, Lot No.2350994, Fluka Co., Switzerland), FITC-rat anti-mouse CD18 monocolonal antibody (Lot No.553293, BD Biosciences PharMingen, USA), FITC-rat anti-mouse CD11b monoclonal antibody (Lot No.557396, BD Biosciences PharMingen, USA), goat polyclonal antibody against mouse E-selectin (M-20) (sc-6939, Santa Cruz Biotechnology, Inc. USA), goat polyclonal antibody against mouse ICAM-1 (M-19) (sc-1511, Santa Cruz Biotechnology, Inc. USA), rhodamine conjugated rabbit anti-goat lgG-R (Lot No.B1006, Santa Cruz Biotechnology, Inc. USA), Hoechst33342 (Lot No.6538, Santa Cruz Biotechnology, Inc. USA), mouse MCP-1 flex set (Lot No.558342, BD Biosciences, USA), mouse TNF flex set (Lot No.558299, BD Biosciences, USA), mouse IL-6 flex set (Lot No.558301, BD Biosciences, USA).

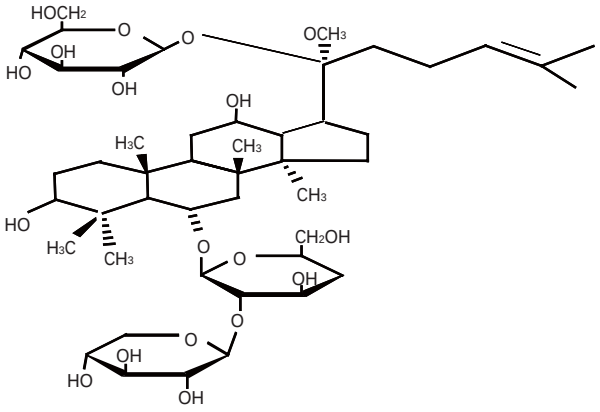

Figure 1 Chemical structure of notoginsenoside (R1).

Animals

C57/BL mice, weighing 22-26 g and aged 8-10 wk (the animal certificate number was SCXK 2002-2001) were purchased from the Animal Center of Peking University Health Science Center. The animals were caged at 24℃ ± 1℃ with a humidity of 50% ± 5% in a 12 h light/dark cycle, and starved with free access to water for 12 h before the experiment. All animals were handled according to the Guidelines of the Peking University Animal Research Committee.

Intravital microscopy

C57/BL mice were anesthetized with 20% urethane (10 mL/kg body wt, im), as previously described[25]. The left jugular vein was cannulated for drug administration with a polyethylene pipe (0.96 mm in diameter). Immediately after laparotomy, the mice were placed on an observation board in lateral position. The liver was placed on an adjustable Plexiglas microscope stage within a thermo-controlled (37℃) observation box and carefully handled to minimize the influence of respiratory movements. The left lateral lobe of liver was observed under an inverted intravital microscope (DM-IRB, Leica, Germany) assisted by a 3CCD colour camera (JK-TU53H, 3CCD camera, Toshiba, Japan). Areas (400 μm × 320 μm) were selected that included both terminal portal venules

and central veins without adherent leukocytes for observation. Images of the microcirculation of liver surface were monitored through a × 20 objective, and the dynamics of hepatic microcirculation was recorded on DVD discs using a DVD recorder (DVR-R25, Malata, China). The liver surface for observation was moisturized with 37℃ physiological saline drops throughout the whole procedure, and the liver surface around the observation region was covered with saline-soaked cotton gauze[26].

Procedure for ischemia and reperfusion

The surface of liver was observed for 10 min before ligation of the superior mesenteric artery (SMA) to ensure that all parameters measured were in a steady state. The SMA was then ligated with a snare created from polyethylene tubing (1.00 mm) for 15 min. After ischemia, the ligation was gently released for reperfusion. Venular diameter, RBC velocity, sinusoidal reperfusion, and leukocyte rolling and adhesion were determined immediately before ischemia (baseline) and every 15 min after reperfusion for half an hour.

Experimental protocols

Mice in the I/R group were continuously infused with vehicle saline through the jugular vein from 10 min before I/R until the end of the observation. Mice in the R1 + I/R group were continuously infused with R1 (10 mg/kg per hour) from 10 min before I/R until the end of the observation. Mice in the sham-operated control group were treated in an identical fashion as those in the I/R group, but not subjected to ligation of the SMA. Six mice (three males, three females) were included in each group.

Determination of microcirculatory parameters

The diameters of terminal portal venules and central veins were on replayed DVD images using Image-Pro Plus 5.0 software[27]. The result was presented as the ratio of the value determined at 15 min or 30 min to the baseline.

To access the sinusoidal perfusion, the number of hepatic sinusoids with red blood cells (RBCs) flowing through in the hepatic terminal portal venule and central vein regions was scored on the DVD replay, and presented as the perfused hepatic sinusoids/field of view (250 μm × 300 μm)[26]. The result was presented as the ratio of the value determined at 15 min or 30 min to the baseline.

The RBC velocity in hepatic terminal portal venule and central vein was recorded at a rate of 1000 frames/s by changing the monitor from CCD to a high speed video camera system (FASTCAM-ultima APX, photon, Japan), and the recordings were replayed from the high speed stored images at a rate of 25 frames/s. The RBC velocity in venules was measured with Image-Pro Plus 5.0 software[26,27]. The velocity was presented as μm/s. The result was presented as the ratio of the value determined at 15 min or 30 min to the baseline.

To evaluate the leukocyte rolling and adhesion the fluorescence tracer 0.2 mL Rhodamine 6G (0.5 mg/mL in physiological saline) was administrated *via* the left jugular vein for the selective staining of white blood cells *in vivo*[28-32]. Under the inverted laser confocal microscope system (BIO-RAD, Radiance 2100, A xiovert 200, Carl Zeiss Shanghai Co, Ltd, German), with 20 × fluorescent object lens, irradiated with the argon laser beam (wavelength = 543 nm), the rolling and adhesion of leukocytes in hepatic terminal portal venules and central veins were recorded. At each time point, a total of 10 successive frames were recorded at a scanning speed of 1 frame/s, and adhered leukocytes were defined as those that appeared at the same position in the 10 successive frames[24]. The adhered leukocytes in hepatic terminal portal venules and central veins were presented as the number of leukocytes/200 μm, while those within the hepatic sinusoid were counted as the number per field of view of 200 μm^2. The leukocytes that stayed at the same position in hepatic terminal portal venules and central veins for less than 10 s were designated as rolling leukocytes, and presented as the number/200 μm.

Analysis of immnofluorescent staining of hepatic endothelial adhesion molecules E-selectin and ICAM-1

After 30-min reperfusion, liver was fixed with 4% paraformaldehyde perfusion, removed and frozen with liquid nitrogen, then cut into sections of 6 μm by a cryostat (LEICA CM 1800, Leica Co., German). The sections were further fixed with 4% paraformaldehyde at room temperature for 10 min and washed with PBS. The samples were then immunohistochemically stained as routing. Goat polyclonal antibody against mouse E-selectin or goat polyclonal antibody against mouse ICAM-1 was applied at dilution of 1:50. The secondary antibody (Rhodamine-labeled rabbit anti goat IgG diluted at 1:200) was added and incubated at 37℃ for 30 min, followed by washing with PBS and incubation with Hoechst 33342 (2 μg/mL) at room temperature for 3 min[33]. After washed with PBS, the specimen was sealed and observed under Laser confocal microscope with 63 × object lens. Fluorescence intensity was detected at excitation wavelength 543 nm for R-phycoerythrin and 405 nm for Hoechst (nuclear staining). Five fields of view (1.6×10^4 μm^2 each) were evaluated in mouse hepatic sinusoids for each condition. Fluorescence intensities of E-selectin or ICAM-1 were estimated by Image Pro Plus software and expressed as an average proportion, positive area/area of one field of view (1.6×10^4 μm^2).

Assessment of the expression of adhesion molecules CD11b and CD18 in peripheral neutrophils

After 30-min reperfusion, blood was collected via inferior vena cava and anticoagulated with heparin (20 unit/mL whole blood). The sample was incubated with 1 μg FITC-labeled antibody against CD18 or CD11b for 20 min at room temperature in dark. RBCs were lysed by addition of hemolysin and the samples were then washed twice with PBS. Flow cytometry (FACS Calibur, B.D. Co, USA) was used to assess the mean fluorescence intensity of CD11b or CD18 for 5000 neutrophils in each condition[22].

Peripheral blood hepatic enzyme assay

In some mice, at 30 min and 60 min, respectively after reperfusion, blood samples were withdrawn *via* inferior vena cava and anticoagulated with heparin (20 unit/mL whole blood). The blood serum was isolated by

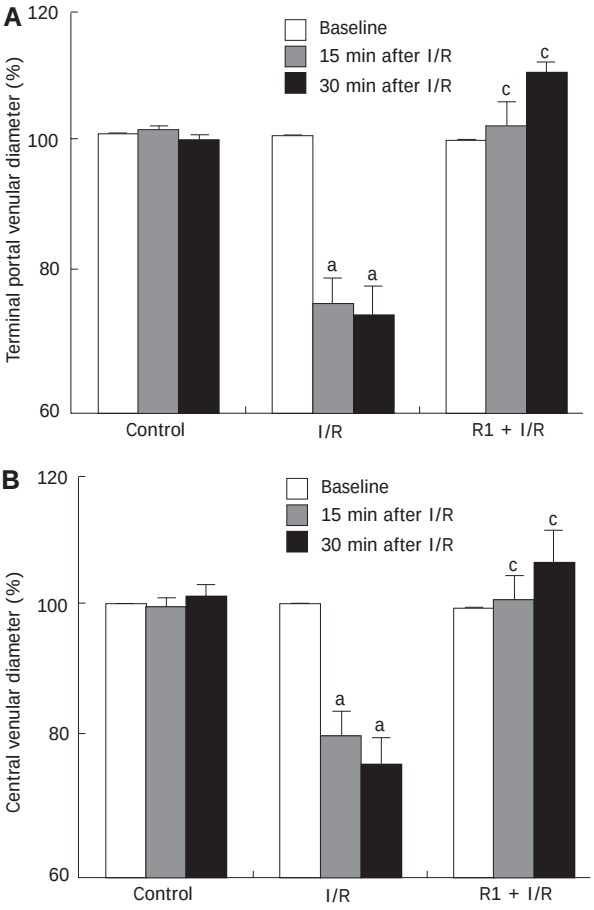

Figure 2 Effect of R1 on the terminal portal venular diameter (**A**) and central venular diameter (**B**) of hepatic venules of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the ratio of the diameter value at a time point to the baseline. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

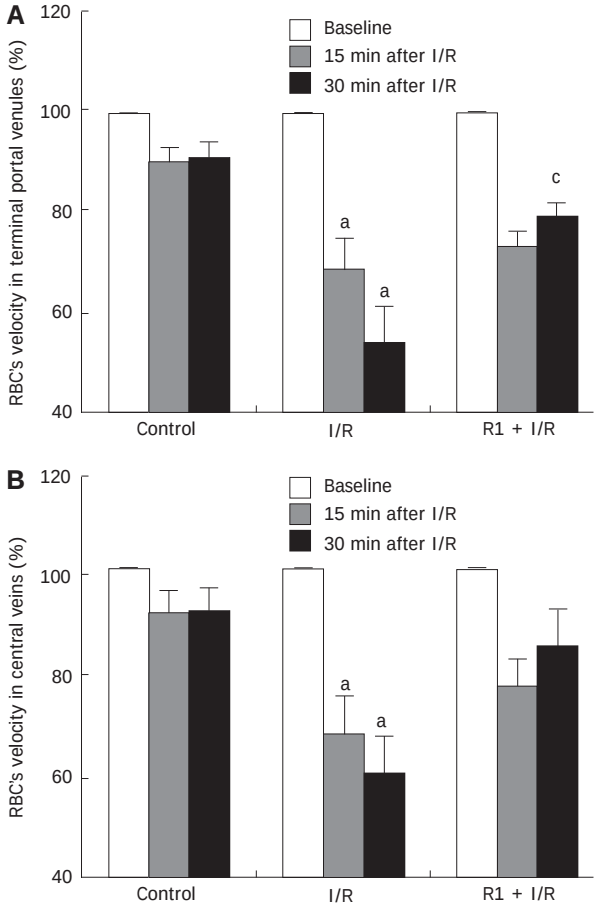

Figure 3 Effect of R1 on the RBC velocity in terminal portal venlues (**A**) and in central veins (**B**) of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the ratio of the RBC velocity value at a time point to the baseline. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

centrifugation (Allegra™ 64R Centrifuge, Beckman Coultertm, German) at 4000 r/min for 10 min at 4℃ and stored at -20℃. The activities of LDH, ALT, and AST were measured respectively using lactate dehydrogenase, alanine aminotransferase and aspartate aminotransferase kits with parameter rate-A[34], following their manufacturer's instructions, with an automatic enzyme analyzer (7170A Automatic Analyzer, Hitachi, Japan).

Peripheral blood TNF-α, IL-6 and MCP-1 assay

At 30 min after reperfusion, blood was collected *via* inferior vena cava, and anticoagulated with heparin (20 unit/mL whole blood). The blood serum was isolated by centrifugation (Allegra™ 64R Centrifuge, Beckman Coultertm, German) at 4000 r/min for 10 min at 4℃ and stored at -20℃. The concentrations of TNF-α, IL-6 and MCP-1 were measured by flow cytometry with a BD cytometric bead array kit (BD Biosciences Pharmingen, USA)[35]. Fifty μL bead was added into 50 μL blood plasma or standard substance and incubated at room temperature in dark for 1 h for bead capture. Fifty μL PE-labelled detecting antibody was then added and incubated at room temperature for 2 h to form a sandwich complex. After incubation, the samples were washed thoroughly with 1 mL washing buffer (BD Biosciences Pharmingen, USA). The mean fluorescence intensity of TNF-α, IL-6 and MCP-1 was detected respectively by flow cytometry (FACS Calibur, B.D. Co., USA) and the data were analyzed using the BD cytometric bead array analysis software.

Statistical analysis

Values are presented as mean ± SE ($n = 6$), *F*-test was performed using SPSS 10.0 statistical software. $P < 0.05$ was considered statistically significant.

RESULTS

The effect of R1 on the diameter of hepatic terminal portal venule and central vein of mice subjected to SMA I/R are shown in Figure 2. In the control group, the diameters of both terminal portal venules and central veins remained nearly constant over the entire observation period. SMA I/R decreased the diameter of vessels in a time-dependent manner, while treatment with R1 significantly relieved SMA I/R-induced decrease in the vessel diameters.

The influence of R1 on the RBC velocity in hepatic terminal portal venules and central veins of mice after SMA I/R is shown in Figure 3. In the control group, no significant change was observed in the RBC velocity of both

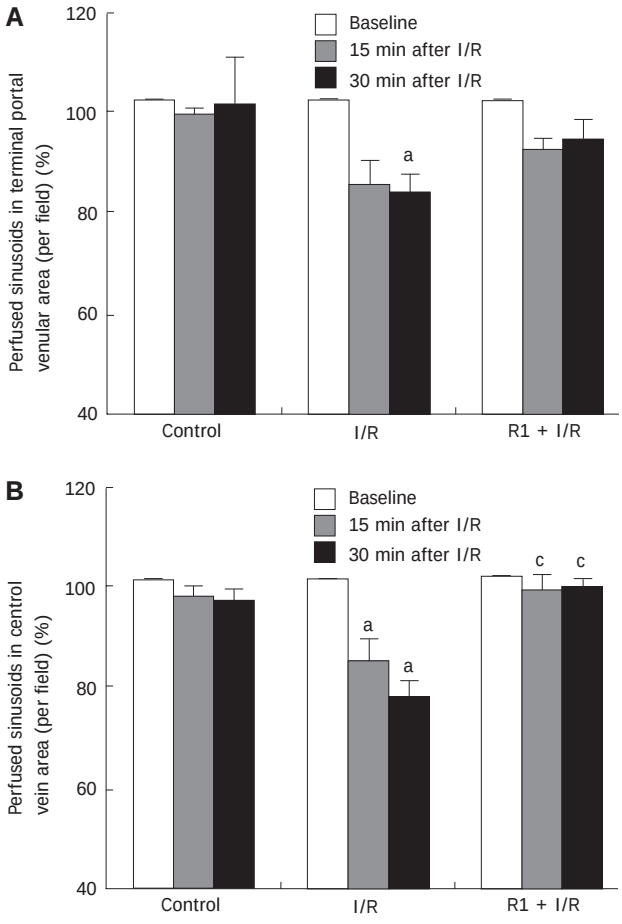

Figure 4 Effect of R1 on the perfused hepatic sinusoids in the areas of terminal portal venules (**A**) and in the area of central veins (**B**) of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the ratio of perfused sinusoids at a time point to the baseline. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

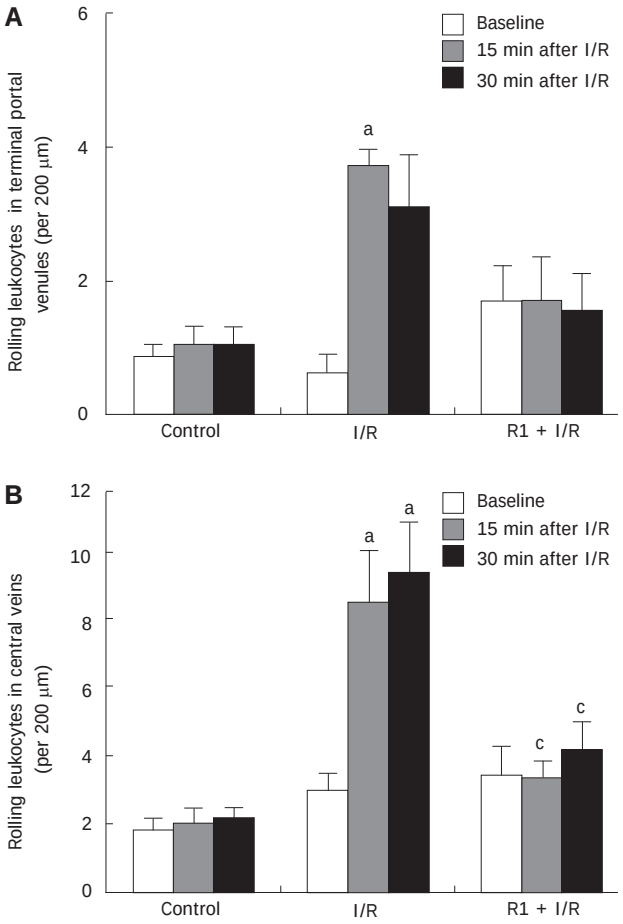

Figure 5 Effect of R1 on the rolling leukocytes in the areas of terminal portal venlues (**A**) and central veins (**B**) of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the number of rolling leukocytes per 200 μm. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

types of vessels during the period of observation. SMA I/R significantly decreased the RBC velocity of vessels in a time-dependent fashion. R1 treatment blunted the SMA I/R-induced decrease in the RBC velocity of both types of vessels at 30 min after reperfusion, being significant in terminal portal venules (Figure 3A) but not in central veins (Figure 3B), in comparison with the I/R group.

The effect of R1 on the number of reperfused sinusoids in hepatic terminal portal venule and central vein areas after SMA I/R is depicted in Figure 4. In the control group, no significant change in the number of reperfused sinusoids was detected either in the terminal portal venule area or in the central vein area through the entire observation. SMA I/R exposure elicited a time-dependent decrease in the number of reperfused sinusoids, which became statistically significant at 15 min of reperfusion in the central vein areas and at 30 min of reperfusion in the terminal portal venule areas compared to the control group. I/R-induced decrease in the number of reperfused sinusoids in central vein areas was attenuated significantly after treatment with R1 (Figure 4B), and this effect was not observed in the terminal portal venule areas (Figure 4A).

The effect of R1 on the number of rolling leukocytes in mouse hepatic terminal portal venules and central veins after SMA I/R is depicted in Figure 5. I/R challenge significantly increased the number of rolling leukocytes in both terminal portal venules and central veins when compared with the control group, although a small number of rolling leukocytes could be observed in the control group during the period of examination. R1 treatment reduced the enhancement in the leukocyte rolling induced by I/R, which was statistically significant in the central veins (Figure 5B), but not in terminal portal venules (Figure 5A).

Figure 6 shows the effect of R1 on the adhesion of leukocytes induced by SMA I/R. SMA I/R increased the number of adherent leukocytes in both hepatic terminal portal venule and central vein regions, which was attenuated after treatment with R1, being significant in the terminal portal venules (Figure 6A), but not in the central veins (Figure 6B).

The effect of R1 on the leukocyte adhesion in sinusoids of hepatic terminal portal venule and central vein areas was determined (Figure 7). As in the hepatic terminal portal venules and central veins, only a small number of adherent leukocytes were visualised within sinusoids either of either the terminal portal venule area or the central vein area in the control group. A remarkable increase in the number of adherent leukocytes within sinusoids of

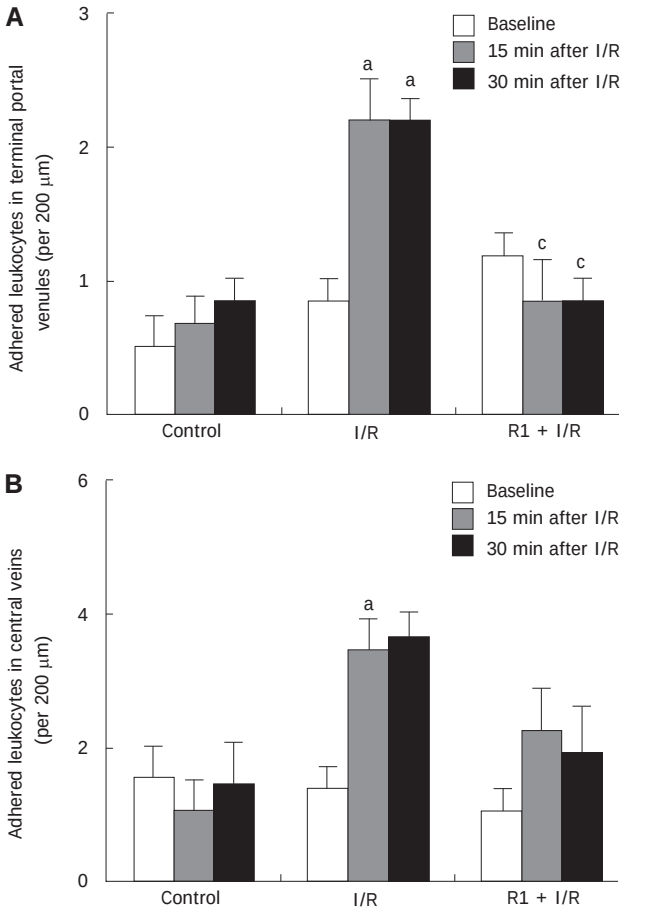

Figure 6 Effect of R1 on the adherent leukocytes in terminal portal venlues (**A**) and central veins (**B**) of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the number of adherent leukocytes per 200 μm. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

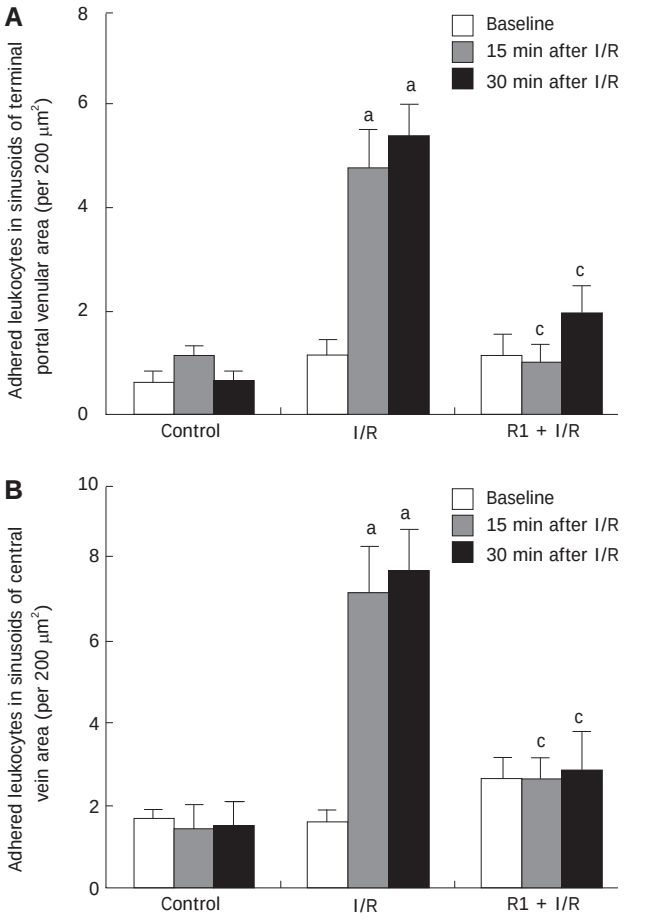

Figure 7 Effect of R1 on the adherent leukocytes in the hepatic sinusoids in the areas of terminal portal veins (**A**) and central veins (**B**) of mice subjected to SMA I/R at 0 min before ischemia (Baseline) and 15 min, 30 min after reperfusion. Abscissa represents the number of adherent leukocytes per field of view of 200 μm². The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

both areas was observed when the mice were subjected to SMA I/R, which was inhibited significantly after treatment with R1 (Figure 7) starting from 15 min after reperfusion.

Figure 8 shows the expression of E-selectin in mouse hepatic sinusoids in the sham, I/R and R1 + I/R groups after 30 min of reperfusion. Thirty minutes after reperfusion, the expression of E-selectin increased (Figure 8B) compared with the sham group (Figure 8A), and treatment with R1 (Figure 8C) suppressed the increase in I/R-elicited E-selectin expression.

The influence of R1 on the expression of E-selectin in mouse hepatic sinusoids after 30 min of reperfusion was quantitatively evaluated (Figure 9A). Thirty-minute reperfusion significantly enhanced the expression of E-selectin. The SMA I/R-induced increase in the expression of E-selectin was completely ablated after treatment with R1.

The expression of ICAM-1 in mouse hepatic sinusoids after 30 min of reperfusion had no significant change. Treatment with R1 had no significant influence on the expression of ICAM-1 either (data not shown).

After 30 min of reperfusion, the blood was collected and used to evaluate the role of R1 in the expression of adhesion molecules CD18 and CD11b of mouse peripheral neutrophils. As illustrated in Figure 9B, 30-minute reperfusion significantly enhanced the expression of both CD18 and CD11b compared to the control group. R1 treatment significantly inhibited the increment in the mean fluorescence intensity of CD18 induced by I/R, and also diminished, although not significantly, the increment in the fluorescence intensity of CD11b induced by I/R.

The influence of R1 on the concentration of enzymes in mouse peripheral blood was determined after 30 and 60 min of reperfusion (Figure 10). Thirty-minute or 60-minute reperfusion obviously increased the concentration of LDH, ALT and AST. However, treatment with R1 could not significantly blunt these increases, except for the activity of AST after 60-min reperfusion. I/R significantly increased the concentrations of IL-6 and MCP-1, but not TNF-α compared to the control group. R1 did not influence the increase in the concentration of IL-6 and MCP-1 induced by I/R (data not shown).

DISCUSSION

Terminal portal venules and central veins are two major types of vessels consisting of hepatic microvasculature, in addition to sinusoids. Using intravital microscopy, the present study demonstrated that the mouse SMA I/R induced a variety of disorders in hepatic microcirculation,

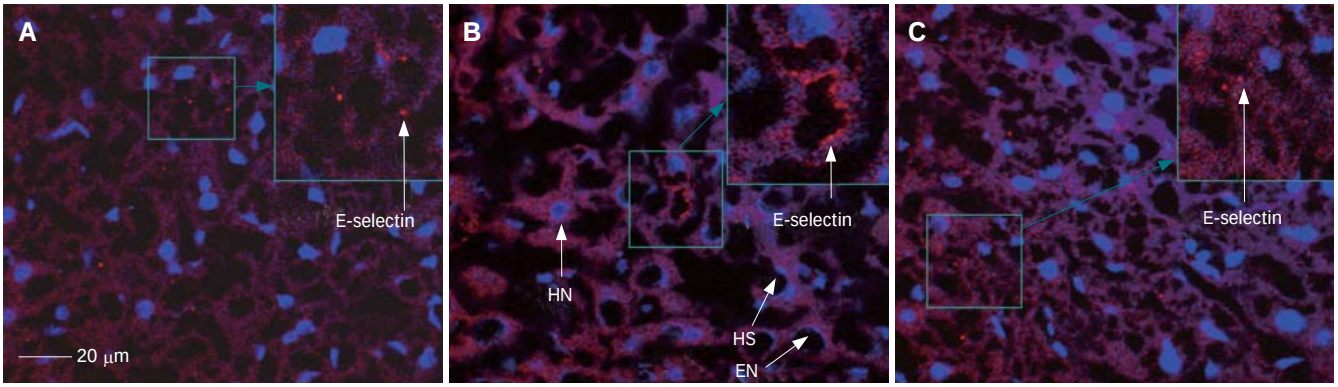

Figure 8 Expression of E-selectin in mouse hepatic sinusoid in sham (**A**), I/R (**B**) and R1 + I/R (**C**) after 30 min of reperfusion. HN: hepatocyte nucleus; EN: endothelium nucleus; HS: hepatic sinusoid; Bar indicates 20 μm.

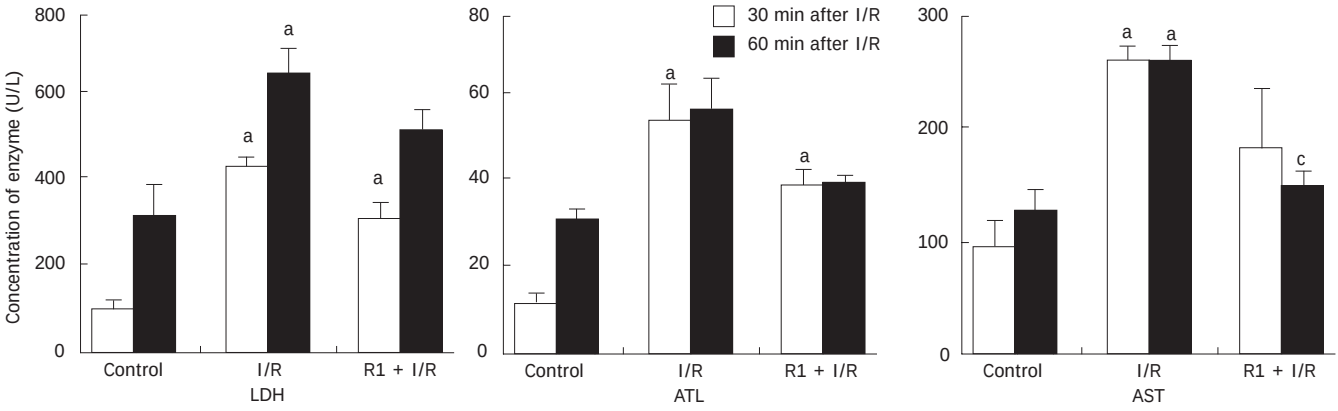

Figure 10 Effect of R1 on the concentration of LDH, ALT and AST in serum of mice subjected to SMA I/R. The results are presented as mean ± SE from 6 animals. $^{a}P < 0.05$ *vs* control, $^{c}P < 0.05$ *vs* I/R.

including the decreased diameters of terminal portal venules and central veins, RBC velocity in venules and the number of perfused sinusoids. Besides, leukocyte rolling and adhesion in hepatic venules and sinusoids were also promoted by the SMA I/R challenge. These results are in agreement with previous findings[2,4,24-26,30]. In the current study, treatment with R1 could remarkably attenuate hepatic microcirculatory disturbances in mice evoked by SMA I/R. PNS improved gut I/R-induced hepatic microcirculation disturbances and CP inhibited the adhesion of leukocytes to the hepatic vascular endothelium in rats induced by gut I/R, suggesting that R1 is at least one of the components of PNS that are responsible for its beneficial effect on hepatic microcirculation[19,24].

The concentration of ET-1 increases in serum and hepatic parenchyma in response to I/R[36], while NO is depleted by combination with I/R-evoked $^{-}O^{\cdot-}$[37], which concurs to bring about unbalance between ET-1

and NO, resulting in contraction of hepatic vessels. The present study revealed that administration of R1 attenuated I/R-elicited contraction of hepatic terminal portal venules and central veins that profoundly improved microcirculation in mice, suggesting that R1 may exert its action on the production of ET-1 and NO in the situation of I/R, which merits further study.

I/R-induced microcirculatory dysfunction and subsequent tissue injury are a complicated process consisting of multiple reactions, among which leukocyte recruitment is a crucial step mediated by the expression of a group of adhesion molecules on neutrophils and endothelial cells. It was reported that peroxide produced by SMA I/R degrades I-κB for activation of NF-κB and induces the expression of vascular endothelial E-selectin and ICAM-1[6-10], and also transfers L-selectin and adhesion molecules CD11b and CD18 from leukocyte cytoplasm to the cell surface[11-13,38], which initiates leukocyte rolling and adhesion ultimately. The ability of R1 to attenuate gut I/R-induced leukocyte rolling and adhesion in hepatic venules found in the present study is most probably due to its inhibiting effect on the expression of adhesion molecules on both leukocytes and endothelial cells, as suggested by the fact that pre-treatment with R1 could significantly blunt SMA I/R-induced expression of E-selectin on endothelium and CD18 on neutrophils.

It has been demonstrated that SMA I/R provokes a surge of peroxide release which activates NF-κB[6,7], leading not only to the expression of adhesion molecules on leukocytes and endothelium and subsequent leukocyte rolling and adhesion, but also to the explosive release of cytokines from leukocytes, endothelial and Kupffer cells[39-41], including TNF-α, IL-6 and MCP-1. The present experiment revealed that mouse gut I/R significantly increased the concentration of IL-6 and MCP-1, but not TNF-α in plasma. The reason is so far unknown. Moreover, no study is available to date concerning the antioxidant effect of R1 in I/R-induced hepatic microcirculatory disturbance, and it merits clarification if taking into account the fact that R1 depresses I/R-induced expression of adhesion molecules, but does not interfere with the increased concentrations of IL-6 and MCP-1 induced by I/R.

As expected, results of the present study show that the activities of ALT, AST and LDH of peripheral blood could slightly increased in response to 60-min SMA I/R, indicating that intestine I/R-induced microcirculatory disturbance in liver leads to injury of hepatic cells and dysfunction of the liver. Treatment with R1 significantly suppressed the activity of AST 60 min after reperfusion, suggesting that R1 can protect against hepatocyte injury induced by I/R. This beneficial effect is most likely related to its improving effect on hepatic microcirculatory disturbance, as mentioned above.

In summary, treatment with R1 considerably attenuates SMA I/R-induced hepatic microcirculatory disturbances, including decreased venular diameters, RBC velocity, the number of perfused sinusoids, as well as the increased leukocyte rolling and adhesion. R1 ameliorates SMA I/R-induced increase in the leukocyte rolling and adhesion in hepatic venules by inhibiting the expression of adhesion molecules on endothelial cells and neutrophils. We propose that it is the improving effect of R1 on microcirculatory disturbance that underlines its protecting function against I/R-induced hepatic injury.

COMMENTS

Background

Major abdomen surgery or organ transplantation initiates gut ischemia and reperfusion (I/R) leading to hepatic microcirculatory disturbance and subsequent liver injury, a manifestation that is closely correlated to the outcome of operation or transplantation and the living quality of patients as well. Thus, attenuating hepatic microcirculatory disturbance and liver injury elicited by gut I/R is of pivotal significance in clinic. Notoginsenoside R1 (R1), one of the saponins derived from *Panax notoginseng*, is reported to attenuate endotoxin-induced mesenteric microcirculatory disturbance in rats by inhibiting oxygen peroxide production and expression of adhesion molecules CD11b/CD18. It has been shown that R1 containing compound Chinese medicine preparation (cardiotonic pills) is able to ameliorate hepatic microcirculatory disturbance and liver injury elicited by gut I/R. R1 containing Chinese medicines is extensively applied in treatment of microcirculatory disturbance related diseases in China. However, no report is available regarding its attenuating effect on hepatic microcirculatory disturbance and liver injury induced by gut I/R.

Research frontiers

In present study, an animal model of hepatic microcirculatory disturbance was established by ligation of the superior mesenteric artery (SMA) in C57/BL mice for 15 min followed by 30-min reperfusion. The dynamics of vascular diameter, RBC velocity, rolling and adherent leukocytes was investigated in the hepatic terminal portal venule and central vein regions under inverted intravital microscope assisted by a 3CCD color camera and high speed video camera as well as a laser confocal microscope. Thirty minutes after reperfusion, the expression of adhesion molecules CD11b and CD18 on leukocytes in peripheral blood was estimated, and the expression of E-selectin and ICAM-1 in hepatic tissue was determined by immunohistochemistry. Sixty minutes after reperfusion, the levels of LDH, ALT, AST in peripheral blood were measured to explore the possible protective effect of R1 on hepatic microcirculatory disturbance and liver injury elicited by gut I/R.

Innovations and breakthroughs

By using a visualized microcirculatory research, results of the present study provide evidence for the first time that a pulse prior administration of R1 is able to prevent hepatic microcirculatory disturbance in mice induced by intestine I/R, including ameliorating contraction of hepatic terminal portal venule and central vein, resuming reduced velocity of RBCs, and inhibiting leukocyte rolling and adhesion in hepatic terminal portal venule and central vein, the later may be correlated to the inhibition of the expression of adhesion molecules and E-selectin on vascular endothelial cells and CD18 on leukocytes. R1 treatment could suppress AST level in peripheral blood, suggesting that R1 is able to prevent intestine I/R-induced hepatic microcirculatory disturbance and subsequent liver injury.

Applications

The findings in the present work support the utilization of R1 as a remedy in clinic to prevent hepatic microcirculatory disturbance and liver injury following major abdomen surgery or transplantation.

Peer review

This is a very interesting paper examining the effects of notoginsenoside R1 (R1) on hepatic microvascular function after gut I/R. The data are largely convincing. R1 has both vasodilatory and anti-inflammatory functions.

Abstract

AIM: To study the association of three common *ABCB11* and *ABCC2* polymorphisms (*ABCB11*: 1331T>C → V444A; *ABCC2*: 3563T>A → V1188E and 4544G>A → C1515Y) with intrahepatic cholestasis of pregnancy (ICP) and contraceptive-induced cholestasis (CIC).

METHODS: *ABCB11* and *ABCC2* genotyping data were available from four CIC patients and from 42 and 33 ICP patients, respectively. Allele-frequencies of the studied polymorphisms were compared with those in healthy pregnant controls and Caucasian individuals. Furthermore, serum bile acid levels were correlated with the presence or absence of the 1331 C allele.

RESULTS: The *ABCB11* 1331T>C polymorphism was significantly more frequent in cholestatic patients than in pregnant controls: C allele 76.2% (CI, 58.0-94.4) *vs* 51.3% (CI 35.8-66.7), respectively (P = 0.0007); and CC allele 57.1% (CI 36.0-78.3) *vs* 20% (CI 7.6-32.4), respectively (P = 0.0065). All four CIC patients were homozygous carriers of the C allele. In contrast, none of the studied *ABCC2* polymorphism was overrepresented in ICP or CIC patients. Higher serum bile acid levels were found in carriers of the 1331CC genotype compared to carriers of the TT genotype.

CONCLUSION: Our data support a role for the *ABCB11* 1331T>C polymorphism as a susceptibility factor for the development of estrogen-induced cholestasis, whereas no such association was found for *ABCC2*. Serum bile acid and γ-glutamyl transferase levels might help to distinguish *ABCB4*- and *ABCB11*-related forms of ICP and CIC.

INTRODUCTION

Intrahepatic cholestasis of pregnancy (ICP) and oral contraceptive-induced cholestasis (CIC) are two acquired forms of cholestasis, which are observed in otherwise healthy young women with a normal medical history. Both syndromes are rapidly reversible upon discontinuation of the hormonal challenge, which suggests that female sex hormones play a key pathogenic role in these forms of cholestasis[1,2]. In line with these observations, ICP usually occurs during the third trimester of pregnancy, when serum concentrations of estrogens and progesterone reach their peak[3,4]. Furthermore, women with ICP and female family members of ICP patients have an increased susceptibility to develop intrahepatic cholestasis under oral contraception[5].

A genetic predisposition for both types of hormonal cholestasis has been suspected based upon the strong regional clustering[6], the higher prevalence in female family members of patients with ICP[5,7] and the co-incidence with hereditary cases of progressive familial intrahepatic cholestasis[5,7]. Recently, mutations in the *ABCB4* gene that encodes the canalicular phospholipid flippase multidrug resistance protein

3 (MDR3) have been implicated in the development of ICP and CIC in a subset of affected patients[5,8-12]. MDR3-associated cases of hormonal cholestasis are associated with elevated serum γ-glutamyl transferase (γ-GT) levels in 80% of affected patients, which reflects cholangiocytic damage characteristic of MDR3 dysfunction[11].

In the same study, the majority of ICP women without *ABCB4* mutations exhibited normal γ-GT levels[11], which suggests a different pathogenic mechanism in this subset of patients. Dysfunction of the bile salt export pump (BSEP) or the multidrug resistance associated protein 2 (MRP2) have, therefore, been proposed as alternative candidate proteins involved in the pathogenesis of hormonal cholestasis. BSEP constitutes the predominant bile salt efflux system of hepatocytes, which mediates the cellular excretion of numerous conjugated bile salts into the bile canaliculus[13-16]. In contrast, the bilirubin transporter MRP2 is the main driving force for bile-salt-independent bile flow through canalicular excretion of reduced glutathione[17,18]. Given their important roles in bile formation and bilirubin secretion, inherited and acquired dysfunction of these proteins can lead to severe cholestatic syndromes and conjugated hyperbilirubinemia, respectively[19-21].

In hormonal cholestasis, *in vitro* inhibition of BSEP by estrogen and progesterone metabolites has been proposed as an underlying pathophysiological mechanism[22]. BSEP inhibition by estrogen and progesterone metabolites takes place from the luminal side of the bile canaliculus (so-called trans inhibition), which requires previous MRP2-mediated canalicular secretion of conjugated metabolites[22,23]. Therefore, MRP2 dysfunction might contribute to this form of cholestasis. While sequencing of *ABCB11* in unrelated ICP women has not revealed the presence of disease-causing BSEP mutations[11], only little attention has so far been paid to the possible pathogenic role of functional *ABCB11* and *ABCC2* polymorphisms. Recent observations have suggested that a non-synonymous polymorphism in exon 13 of the *ABCB11* gene (1331T>C) is overrepresented in drug-induced cholestatic liver injury[24]. The same polymorphism has recently been observed more frequently in ICP women compared to healthy controls, pointing towards a possible role of this polymorphism as a susceptibility factor for ICP and CIC[25]. Furthermore, two non-synonymous *ABCC2* polymorphisms (V1188E and C1515Y) showed significant differences in hepatic MRP2 expression levels compared to the wildtype sequence, which could be relevant for the extent of BSEP trans inhibition[25].

The aim of the present study was, therefore, threefold: (1) to compare allele frequencies of the aforementioned *ABCB11* and *ABCC2* polymorphisms in a prospectively recruited group of patients with ICP and CIC; (2) to define the relative risk of the different polymorphisms for the development of ICP; and (3) to determine the extent of the increase in serum bile acid levels as marker of cholestasis in the presence of the different *ABCB11* 1331T>C genotypes.

MATERIALS AND METHODS

Patients and controls

After approval by the Ethics Committee of the University Hospital of Zurich and written informed consent from all participating individuals, blood samples for DNA extraction were obtained from Caucasian patients with ICP or CIC. The total population of analyzed individuals consisted of two different groups: 25 patients (21 ICP_{new} patients and four CIC patients) were prospectively recruited for this study, and a second group of 20 patients (ICP_{old}) had already been described in a previous study by Pauli-Magnus and coworkers[11].

Two hundred and five Caucasian volunteers and patients without cholestasis, as well as Caucasian women with uneventful pregnancies (n = 40), served as a control population for BSEP (*ABCB11*) and MDR3 (*ABCB4*) genetic variants. These controls have already been described in previous studies[11,25,26]. Specifically, pregnant controls were all healthy, as defined by normal serum levels of transaminases, bilirubin, γ-GT, alkaline phosphatase (AP) and bile acids. Caucasian controls from the study of Pauli-Magnus and coworkers[26] (n = 95) were healthy volunteers recruited for participation in phase I studies, with uneventful medical history and normal blood biochemistry. Neither of these two control groups took any regular medication. In the case of the Caucasian control population of Meier and coworkers[25] (n = 110), most patients suffered from extrahepatic malignancies, and cholestatic disease was excluded in all patients. Furthermore, none of these patients used medication known to be associated with the development of cholestasis.

For lack of DNA availability, only 110 out of 205 Caucasian controls could be used for MRP2 sequencing. For the same reason, a new group of Caucasian women with uneventful pregnancies (n = 42) had to be collected for the MRP2 variants. Demographic data and pregnancy course of these women did not differ from the previous control group.

Diagnosis of ICP was based upon: (1) a clinical history of pruritus, which occurred in the third trimester of pregnancy; (2) the presence of laboratory abnormalities suggestive of ICP: fasting serum bile acid $\geqslant$ 1.5 ULN (upper limit of normal) and/or serum AP levels $\geqslant$ 1.5 ULN and/or alanine aminotransferase (ALT) levels $\geqslant$ 1.5 ULN; and (3) spontaneous resolution of clinical symptoms and laboratory findings after delivery. Diagnosis of CIC was based upon laboratory abnormalities as defined for ICP and the exclusion of preexisting liver disease defined by: (1) a negative serology for hepatitis A, B and C; (2) the exclusion of other preexisting medical conditions that could explain liver injury, such as congestive heart failure, systemic infection, or malignancy; (3) normal liver ultrasound; and (4) a clear causal relationship to drug intake. Each case of ICP and CIC was evaluated by at least one obstetrician and one hepatologist, as well as by a clinical pharmacologist.

Full length *ABCB4* and *ABCB11* sequencing data were already available from the control groups, as well as from ICP_{old} patients. To allow detection of additional *ABCB4* and *ABCB11* mutations in the new group, complete sequencing of these two genes was also performed in the 25 newly recruited patients. Genotyping of *ABCC2* included all CIC patients, as well as 17 out of 21 patients from the ICP_{new} group and 16 of 21 patients in the ICP_{old} group, which yielded a total number of 33 patients for *ABCC2*

Table 1 Primers and probes of real-time PCR for allelic discrimination of *ABCC2* SNPs in Caucasians

[1]cDNA sequence from GenBank accession numbers NM_000392 starting at the ATG; [2]For each SNP two probes were designed and labeled with the fluorescent reporter dyes VIC (allele 1) and FAM (allele 2). SNP: Single nucleotide polymorphism.

genotyping. In nine patients (four ICP_{new} and five ICP_{old}), no *ABCC2* genotyping could be performed for lack of DNA availability.

Sequencing and genotyping

Isolation of DNA and DNA sequencing was done at Epidauros Biotechnology AG, Bernried, Germany. Genomic and cDNA sequences were derived from known sequences (*ABCB4*: AC005068.2 for non-coding exons -3 to 1 and coding exons 2 and 3; AC006154.1 for exons 4 to 12; AC0005045.2 for exons 13 to 28; and NM_000443.2 for cDNA; *ABCB11*: GenBank accession number AC008177.3 for promoter and exons 1 to 21; AC069165.2 for exons 22 to 28 and NM_003742.2 for cDNA).

ABCB4 and ABCB11: Sequencing of *ABCB4* covered a proximately 8000 bp, including (1) 2000 bp of the upstream promoter region and non-coding exon -3 to 1 and, (2) coding exons 2-28 and 100-350 bp of the intronic sequence around each exon. For *ABCB11*, sequencing covered 10000 bp including (1) non-coding exon 1 and 2400 bp of the upstream promoter region and, (2) coding exons 2-28 and 100-350 bp of the intronic sequence around each exon. Primers for genomic DNA were designed to span all exons and at least 100 bp of the flanking intronic sequence at the 5' and 3' end of each exon. The DNA sequence of purified PCR fragments was analyzed on an ABI3700 capillary sequencer (ABI, Weiterstadt, Germany) and assembled using the phredPhrap, Consed and PolyPhred software (University of Washington). Details regarding the primers, optimized PCR conditions and subsequent purification and sequencing of the fragments are available at info@epidauros.com.

ABCC2: Three non-synonymous polymorphisms with a potential impact on MRP2 function and expression were chosen for genotyping[25]: 1249G>A variant (V417I, rs2273697), 3563T>A (V1188E, rs17222723) and 4544G>A (C1515Y, rs8187710). Genotyping was performed with the Custom TaqMan SNP Genotyping Assays procedure (Applied Biosystems, Foster City, CA, USA) which contained a sense- and an antisense primer and two probes, labeled with fluorescent reporter dyes, either VIC or 6-Fam at the 5' end and a non-fluorescent quencher at the 3' end to distinguish between alleles 1 and 2, respectively. Primer and probe sequences for individual SNPs are given in Table 1. Probe solution (0.625 μL) and 12.5 μL of 2 × Universal PCR Master Mix (Applied Biosystems) were brought to 25 μL with 20 ng of genomic DNA. PCR reaction (2 min at 50℃, followed by 10 min at 95℃ and 40 cycles of 15 s at 92℃ and 1 min at 60℃). Allelic discrimination was processed with an ABI PRISM 7700 Sequence Detector.

Statistical analysis

Genotype distribution, allelic frequencies and odds ratios (ORs) are given with 95% CI. In *ABCB11*, formal statistical analysis was only performed for the 1331T>C polymorphisms (rs2287622), whereas for *ABCC2* analysis, it included two highly linked polymorphisms. No correction according to Bonferroni was, therefore, required. Differences investigated in our study apply to a proportion of diseased *versus* non-diseased individuals within the whole population, using an unmatched case control design. Response (ICP *versus* non-ICP) and predictors (T *versus* C) were both binary variables and were therefore best condensed into a 2 × 2 table. Differences in genotype distribution between patients and controls were calculated with the χ^2 test, and difference in allelic frequencies between two groups was performed using a 2 × 2 Fisher exact test. $P \leqslant 0.05$ was considered statistically significant.

RESULTS

Patient characteristics

A total of 25 unrelated patients with estrogen-associated intrahepatic cholestasis were prospectively enrolled in this study, 21 with ICP and four with oral CIC. Demographic data and laboratory findings in ICP patients are given in Table 2. Only two patients showed elevated γ-GT levels > 1.5 ULN, while total bile acid levels were elevated in all patients in whom it was determined (16 out of 21; range, 1.7-17.3 ULN). Three patients had a previous history of ICP; three pregnancies were twin pregnancies, and one patient experienced cholestasis under previous oral contraception.

Characteristics of patients with CIC are given in Table 3. One patient showed elevated γ-GT levels. Total bile acid levels were elevated in all three patients in whom it was determined (three out of four; range, 1.6-22.3 ULN). Oral contraceptive preparations used in the four patients contained comparable amounts of ethinylestradiol (20-35 μg) while the progesterone-like portion ranged from 50 to 150 μg. All patients had a liver biopsy done for strictly diagnostic reasons, which showed intrahepatic cholestasis in three patients. One patient had a previous history of ICP.

Sequence analysis

ABCB4 and ABCB11: Sequence analysis in the 25 newly recruited patients with estrogen-associated cholestasis revealed no disease-associated non-synonymous mutations in *ABCB4* or *ABCB11*. Furthermore, in line with previous findings[11], no *ABCB4* polymorphism was found to be overrepresented in the ICP and CIC groups compared to pregnant women without cholestasis and healthy Caucasian individuals. All of the detected genetic variants in *ABCB11* and *ABCB4* were in Hardy Weinberg equilibrium.

In contrast, the *ABCB11* 1331T>C → V444A polymorphism was significantly more frequent in ICP and CIC patients compared to the two control groups. Specifically, the CC genotype was encountered in 57.1% of all ICP patients (ICP$_{new}$, 47.6% and ICP$_{old}$, 67.7%) and 100% of CIC patients compared to 20 and 32.2% in pregnant

[1]Could not be determined, as TT = 0.

women without cholestasis and healthy Caucasian controls, respectively (Table 4). In line with these findings, the ORs of C *versus* T were 3.0 (1.7-6.4) for all ICP patients (ICP_{new} + ICP_{old}) *versus* healthy pregnant control women (ICP_{new}, 2.1; 1.0-4.7 and ICP_{old} 4.8; 2.2-15.0) (Table 5 and Figure 1). With the exception of this polymorphism and two intronic variants that were found to be closely linked to the 1331T>C polymorphism in previous studies [intron 13: (+70) C>T and intron 14 (+32) T>C][26], the allele frequency of the remaining common variants in the patients with ICP and CIC was comparable to that observed in healthy pregnant and Caucasian controls. Due to the small sample size, no significance levels could be calculated for the CIC group. However, all patients in this group were homozygous for the C at position 1331, which is highly suggestive of an overrepresentation of this allele compared to the control groups.

ABCC2: The 1249G>A polymorphism was not found in our patients. In contrast, 3563T>A and 4544G>A were strongly linked and distributed similarly in all groups (Table 4). No significant difference in the frequency of these two polymorphisms was observed between affected ICP and CIC patients and healthy controls. Heterozygous carriers of the 3563A and the 4544A alleles were found in 15.2% of ICP patients (ICP_{new}, 23.5% and ICP_{old}, 3.1%) compared to 11.9 and 12.7% in pregnant women without cholestasis and healthy Caucasian controls, respectively (Table 4). Furthermore, one CIC patient was a heterozygous carrier for the two variant alleles at positions 3563 and 4544.

Relation of serum bile acid levels and the ABCB11 1331T>C genotype

For correlation of bile acid levels with the corresponding genotype at position 1331 of *ABCB11*, ICP and CIC samples were analyzed together. Bile acid levels were available for 16 out of 21 ICP_{new} patients, seven out of 20 ICP_{old} patients, and three out of four CIC patients, which yielded a total of 26 samples (CC, 14 patients; CT, 10 patients; and TT, two patients). Interindividual variability in serum bile acid levels was high and ranged from 1.7 to 22.3 ULN and 1.7 to 17.3 ULN in CC and CT patients, respectively. Serum bile acid levels gradually increased from carriers of the TT genotype to carriers of the CC genotype, with medians of 2.3 ULN (Q1, 2.2; Q3, 2.5), 3.2 ULN (Q1, 2.4; Q3, 6.2) and 4.4 ULN (Q1, 2.2; Q3, 7.8) for TT, TC and CC, respectively (Figure 2).

DISCUSSION

We investigated the risk association between different *ABCB11* and *ABCC2* polymorphisms in ICP and CIC, and correlated different genotypes with serum bile acid levels

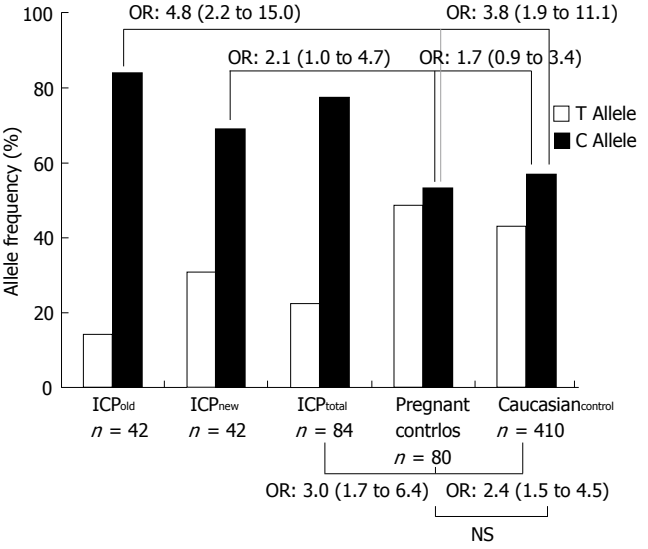

Figure 1 Allelic frequency of the T allele (white panel) and C allele (black panel) of the ABCB11 1331T>C (1331T>C) polymorphism. 21 ICP_{new} patients (42 alleles); 21 ICP_{old} patients (42 alleles); 42 ICP_{total} patients (84 alleles); 20 $ICP_{control}$ patients (40 alleles); 205 $Caucasian_{control}$ patients (410 alleles). Allelic frequencies and ORs are given with 95% CI. Groups were compared with Fisher's exact test.

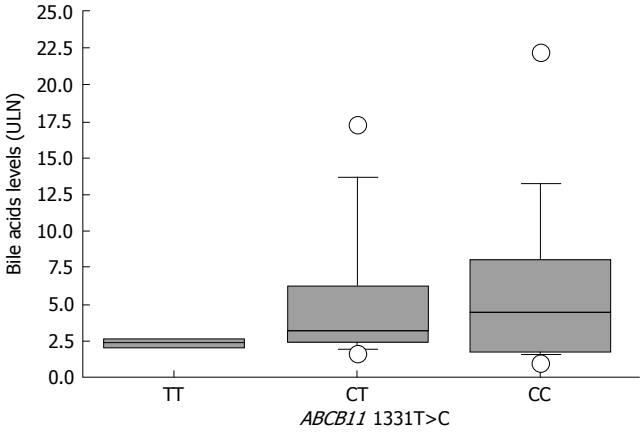

Figure 2 Bile acid levels in patients harboring different 1331C>T genotypes. TT: two patients; CT: 10 patients; CC: 14 patients.

as a marker of cholestasis. In our group of 25 patients with estrogen-associated cholestasis (21 with ICP and four with CIC), there was a highly significant association between the presence of the C allele at position 1331 of *ABCB11* and the presence of cholestasis, which confirms preliminary results from another collective of ICP women, in whom such an overrepresentation was first observed[11]. While *in vitro* function of both BSEP variants, as measured by taurocholate transport activity, is comparable[24], BSEP expression in healthy liver tissue of Caucasian individuals has recently been found to be lower in carriers of the 1331C allele[25]. Such differences in hepatic BSEP expression levels might offer one valuable explanation for the increased susceptibility to the development of cholestasis under specific circumstances, such as hormonal challenges. Furthermore, serum bile acids as a marker of *in vivo* BSEP function was influenced by the underlying genotype. Lowest bile acid levels were observed in patients with the TT genotype and highest levels in carriers of the CC genotype. Although the accepted level of statistical significance was not reached due to high interindividual variability, this observation is in line with the hypothesis that the underlying genotype at position 1331 is a determinant of BSEP function, and hence contributes to the individual risk of developing cholestasis.

The homozygous state for the 1331T>C polymorphism has only recently been observed in a very severe case of pregnancy-associated cholestasis with serum bile acid levels > 40-fold above the ULN. Interestingly, decreased BSEP expression levels were found in a liver biopsy obtained from this patient[27]. Although this patient carried an additional *ABCB4* mutation, the presence of decreased hepatic BSEP expression and highly elevated bile acid levels strongly support a BSEP-related mechanism as a predominant pathogenetic factor. The same patient also developed severe cholestasis under previous use of oral contraceptives, which supports the notion that the same polymorphism also predisposes to oral CIC.

In our group, seven patients (from ICP_{old}) carried additional *ABCB4* mutations, while no such mutations were detected in the remaining 35 out of 42 ICP patients (ICP_{old}, 14 and ICP_{new}, 21). This finding suggests that the *ABCB11* 1331T>C polymorphism independently contributes to an individual's risk for developing cholestasis under certain conditions. On the other hand, it can be speculated whether the combination of the 1331T>C polymorphism with *ABCB4* mutations might be a risk constellation for a severe disease course, as observed by Keitel and coworkers[27].

In contrast, no association was found between the presence of the non-synonymous polymorphisms at positions 1188 and 1515 of MRP2 and the presence of ICP or CIC. A possible pathogenic role of these two polymorphisms in ICP and CIC was suspected based upon the genotype-dependent alteration in hepatic MRP2 expression levels in healthy human liver tissue[25]. Specifically, heterozygous carriers of the glutaminic acid at position 1188 and tyrosine at position 1551 showed significantly higher levels of MRP2 in their liver than homozygous carriers of valine and cysteine, respectively[25]. As BSEP inhibition by estrogen and progesterone metabolites requires prior MRP2-mediated secretion into the bile canaliculus, high MRP2 expression was suspected as a risk factor for the development of estrogen-dependent cholestasis[22].

Several conclusions can be drawn from this study. First, our data point toward a pathogenic relevance of the *ABCB11* 1331T>C polymorphism in ICP and CIC. While these types of cholestasis are so far mainly attributed to different disease-causing mutations in *ABCB4*[5,11,12], our data support a clear association between the presence of a frequent *ABCB11* polymorphism and ICP. Interestingly, all of the patients with CIC were homozygous carriers of the C allele at position 1331. It can be speculated that lower estrogen levels in CIC compared to second or third trimester pregnancy require two low-function alleles to result in cholestasis. Furthermore, the 1331T>C variant was also found to be associated with other inherited and acquired forms of cholestasis, such as benign recurrent intrahepatic cholestasis and drug-induced cholestasis[24,28,29]. This suggests a role for this polymorphism as a risk factor for different cholestatic conditions, which have so far been regarded as different disease entities[20,30].

Second, while γ-GT levels are elevated in ICP patients who carried a disease-causing *ABCB4* mutation[11], serum bile acid levels are influenced by the BSEP genotype at position 444 of *ABCB11*. It can, therefore, be speculated that these two parameters allow us to clinically distinguish between MDR3- and BSEP-related forms of estrogen-related cholestasis, as it is already done for progressive forms of inherited familial intrahepatic cholestasis[5,21]. From a prognostic point of view, this might help to distinguish patients that carry a common susceptibility factor from those who carry a disease-causing *ABCB4* mutation, which in some cases, has been associated with disease progression[7,11,12,31]. Third, although a pathogenic involvement of MRP2 in estrogen-induced cholestasis has longly been suspected, common *ABCC2* polymorphisms have not been associated with the development of cholestasis. We did not exclude the presence of disease-associated *ABCC2* mutations in our group, but normal bilirubin levels in all but one patient suggests no major MRP2 dysfunction, which should result in a Dubin Johnson phenotype[32].

In summary, our data support a role for the *ABCB11* 1331T>C polymorphism as a susceptibility factor for the development of estrogen-induced cholestasis, whereas no such association was found for *ABCC2*. Serum bile acid and γ-GT levels might help to distinguish *ABCB4* and *ABCB11*-related forms of ICP and CIC.

COMMENTS

Background

Intrahepatic cholestasis of pregnancy (ICP) and oral contraceptive-induced cholestasis (CIC) are two acquired forms of cholestasis, which are observed in otherwise healthy young women with a normal medical history. The bile salt export pump (BSEP, *ABCB11*) and the multidrug resistance protein 2 (MRP2, *ABCC2*) might be of pathogenetic importance in both conditions.

Research frontiers

A genetic predisposition for both types of hormonal cholestasis has been suspected based upon the strong regional clustering, the higher prevalence in female family members of patients with ICP, and the co-incidence with hereditary cases of progressive familial intrahepatic cholestasis. While mutations in the *ABCB4* gene that encodes the canalicular phospholipid flippase multidrug resistance protein 3 (MDR3) have been implicated in the development of ICP and CIC in a subset of affected patients, the role of genetic variants in *ABCB11* and *ABCC2* remains unclear.

Innovations and breakthroughs

Our data support a role of the *ABCB11* 1331T>C polymorphism as a susceptibility factor for the development of estrogen-induced cholestasis, whereas no such association was found for *ABCC2*. Serum bile acid and γ-GT levels might help to distinguish *ABCB4*- and *ABCB11*-related forms of ICP and CIC.

Applications

While the clinical consequences of such findings are still uncertain at this time, they provide important new insights in the role of genetically determined differences in canalicular transporter expression and function for the development of estrogen-induced cholestasis. In the future, the integration of different factors that predict cholestasis might be used to counsel pregnant patients or to avoid certain medications in susceptible patients.

Terminology

ICP: Intrahepatic cholestasis of pregnancy; CIC: contraceptive-induced cholestasis; BSEP: Bile Salt Export Pump (*ABCB11*); MRP2: Multidrug Resistance Protein 2 (*ABCC2*); MDR3: Multidrug Resistance Protein 3 (*ABCB4*).

Peer review

The study characterized a potential underlying defect in the subgroup of normal γ-GT ICP patients and contributes to a clinical risk assessment for the future. This study from a group with longstanding experience in transporter genomics is well designed and presented in a clearly written manuscript.

Abstract

AIM: To evaluate the factors involved in the impairment of health-related quality of life (HRQOL) in patients with celiac disease.

METHODS: A multicenter, cross-sectional prospective study was performed in patients with celiac disease who completed two HRQOL questionnaires: the gastrointestinal quality of life index (GIQLI) and the EuroQol-5D (EQ).

RESULTS: Three hundred and forty patients (163 controlled with a gluten-free diet, and 177 newly diagnosed with a normal diet) were included. The GIQLI score was significantly better in patients on a gluten-free diet (GFD) than in non-treated patients on their usual diet, both in terms of the overall score (3.3 *vs* 2.7, respectively; $P < 0.001$), as well as on the individual questionnaire dimensions. Both the preference value of the EQ as the visual analogue scale were significantly better in treated than in non-treated patients (0.93 *vs* 0.72 $P < 0.001$ and 80 *vs* 70 $P < 0.001$, respectively). Variables significantly associated with a worse HRQOL score were female gender, failure to adhere to a GFD, and symptomatic status.

CONCLUSION: In untreated celiac disease, the most important factors that influence patient perception of health are the presence of symptoms and a normal diet. HRQOL improves to levels similar to those described in the general population in celiac disease patients well controlled with a GFD.

INTRODUCTION

Celiac disease (CD) is a chronic immuno-inflammatory enteropathy that appears in genetically predisposed patients. Patients with this disease develop characteristic small-intestinal-mucosal changes, due to hypersensitivity to gluten. Several epidemiological factors, including a dramatic increase in the diagnosis of CD[1] and changes in its presentation, with the appearance of atypical forms, that may even mimic functional diseases, as well as the fact that it affects people of any age[2] mean that CD is currently considered a common and important health-care problem. It affects approximately 1%-2% of adults in Western European populations[3].

Although the understanding of the immunology and physiopathology of CD is extensive[4,5], the impact of the disease from the patient's point of view has received less attention. The chronic nature of the condition, together with the limitations imposed by the need to follow a permanent restrictive diet, substantial numbers of physician visits, the risk of associated diseases and potential complications, mean that CD can have a considerable negative impact on health-related quality of life (HRQOL). Due to the lack of disease-specific instruments to measure HRQOL in CD patients, generic questionnaires, such as the SF-36 or EuroQol-5D (EQ), have been used. Overall perception of HRQOL is rated

as bad or fair by 63% of patients before diagnosis of CD, and improves to 77% after treatment[6]. However, at least one study has indicated that treated CD patients rate their overall well-being, as measured with a visual analog scale (VAS), quite highly, with 83.6% of patients being rated as 'very well' or 'well'[7]. Apart from dietary treatment, other factors have been suggested to influence the HRQOL in CD patients. Some disease-related factors, such as the presence of symptoms or associated co-morbidity, as well as the type of diagnosis used (symptom-detected *vs* screening-detected), have also been shown to impair CD patients' HRQOL[8,9]. Non-disease-related factors, such as female gender, also have a negative impact on HRQOL[10], although this is also true in other chronic diseases[11]. The impairment of HRQOL in untreated celiac disease and its improvement after treatment with a gluten-free diet (GFD), has been confirmed using generic multidimensional HRQOL measures[12]. However, there is no agreement as to whether the HRQOL of treated CD patients is similar[8,13,14] or not[15,16] to that of the general population.

The aims of the present study were to measure and compare the HRQOL in treated and untreated CD patients using condition-specific and generic measures of HRQOL, and to analyze the factors impacting on HRQOL in these patients. A further objective was to compare scores on the generic measure of HRQOL for the two study groups with general population reference scores for the same instrument (EQ). To this end, we performed a multicenter study in a representative sample of patients from different parts of Spain, including both large and small cities, and both island and mainland regions.

MATERIALS AND METHODS

Study subjects

Subjects were adult outpatients with CD who attended the Digestive Services Units of seven different Spanish hospitals, over a one-year period. Diagnosis was based on current serological and histological criteria[17]. A total of 340 CD patients were included. At the time of inclusion, patients were stratified into two groups, according to whether they were already following a GFD (GFD group) or whether they had not yet started on the GFD (pretreatment group).

Procedure

All patients completed a questionnaire on demographic details, current symptoms, information on the disease, and issues related to the GFD. They also completed the Gastrointestinal Quality of Life Index (GIQLI) questionnaire and the EQ, two generic HRQOL instruments.

Patient compliance following the GFD was measured using an adapted version of the self-administered questionnaire developed by Morisky *et al*[18]. The questionnaire consisted of four items which measure the degree of treatment compliance, answered using dichotomous response options (yes/no). Two questions asked about unintentional lack of compliance ("sometimes I forget my diet/sometimes I do not comply carefully with my diet"), while the other two questions dealt with intentional lack of compliance ("when I feel well I sometimes discontinue my diet/when not feeling well I sometimes discontinue my diet"). If either question 3 or 4 was answered affirmatively, the patient was considered to have voluntarily discontinued his or her diet. If either question 1 or 2 was answered in the affirmative, the patient was considered to have involuntarily neglected or forgotten his or her diet. This questionnaire was originally developed to measure compliance with medication, and was adapted for use in the current population by substituting drugs with GFD. In a previous study[2], many patients suggested that they never forgot about their diet; for that reason, a fifth option was added to the scale ("I never forget about my diet"). Patients checking this answer were considered good compliers.

In an ancillary study, 17 patients from the pre-treatment group completed the questionnaires both at inclusion, when they had not yet started on the GFD, and at least 6 mo following treatment with GFD.

HRQOL assessment

HRQOL was assessed using two generic questionnaires. GIQLI is a self-administered questionnaire designed to assess HRQOL in patients with gastrointestinal diseases. It was chosen because it has been translated and validated for use in Spain[19]. The GIQLI consists of 36 items grouped into five domains of health (gastrointestinal symptoms, physical dysfunction, social dysfunction, emotional dysfunction and treatment effects). Responses are scored on a 4-point Likert scale, in which 4 corresponds to the highest level of functioning. The instrument produces five dimension scores and an overall score ranging from 0 to 4, with a higher score reflecting better HRQOL.

EQ is a short self-administered generic utility measure that provides both a descriptive profile and an overall index for HRQOL. The EQ includes five dimensions (mobility, personal care, daily activities, pain and anxiety-depression) answered on a 3-point scale ranging from no problems (level 1) to extreme problems (level 3). Combining one level of severity from each of the five dimensions generates a number of discrete health states that can be assigned preference values ranging from 0, which represents worst health status, to 1 (best health status). The EQ also includes a VAS that ranges from 0 (worst imaginable health status) to 100 (best imaginable health status), on which patients were asked to mark the point that best reflected their health status on the day of the interview. The EQ has also been translated and validated in Spanish[20]. As a reference, normal values for a representative sample of 12245 members of the Spanish general population also exist for the EQ, and we used these as a control for the patients included in the present study[21,22].

Statistical analysis

The Kolmogorov-Smirnov test showed that most of the study variables did not have a normal distribution. Descriptive analyses of socio-demographic, clinical and HRQOL data were therefore performed using medians and 25th and 75th percentiles. Qualitative variables were described as proportions. Comparisons between variables were performed using the Mann-Whitney *U*, Kruskal-Wallis or Fisher tests as appropriate. In the pre-treatment group, HRQOL was also analyzed depending on whether the diagnosis was performed on the basis of symptoms or on positive serology.

Table 1 Socio-demographic and clinical characteristics of patients *n* (%)

	Pre-treatment	GFD
Number	177	163
Age (yr)	44 (30-50)	37 (28-47)[a]
Sex (male/female)	74/103	42/121
Smoking status		
Smoker	29 (16)	33 (25)
Non-smoker	148 (84)	130 (75)
City of residence		
< 100 000 inhabitants	69 (43)	61 (39)
100 000-500 000	72 (45)	65 (41)
> 500 000	18 (12)	31 (20)
Family status		
Single	57 (33)	67 (42)
Married	108 (63)	84 (53)
Widowed	5 (4)	8 (5)
Educational level		
No studies	7 (4)	4 (2)
Primary	56 (33)	38 (24)
Secondary	55 (32)	61 (38)
University studies	52 (31)	55 (36)
Occupational status		
Employee/self-employed	67 (41)	94 (62)
Retired/pensioner	36 (22)	14 (9)
Housewife	30 (18)	16 (10)
Student	12 (7)	19 (12)
Unemployed	17 (12)	10 (7)
Disease duration (mo)	-	48 (24-84)
Duration of symptoms before diagnosis (mo)	24 (7-84)	12 (5-40)
Presence of symptoms at inclusion	118 (80)	52 (33)[b]
Presence of associated diseases at inclusion	42 (41)	41 (37)

Results are expressed as medians and (25th and 75th percentiles) or absolute values and (percentage). [a]$P < 0.05$, [b]$P < 0.01$.

Three multiple linear regression models were developed to identify independent variables that influence HRQOL. Dependent variables in the three models were the overall GIQLI score, the EQ preference value index, and the EQ VAS scores. Independent variables in all models were GFD, sex, age, duration of symptoms, and the binary variables were existence of symptoms and presence of CD-associated diseases. Results obtained for the multiple linear regression model were the regression coefficient, *t*-test statistics, *P* values, and the variance inflation factor. The *t* test established whether the independent variables contributed to predicting the dependent variables. Higher *t*-test values indicate that the independent variable more strongly predicts the dependent variable. It has been considered that each independent variable contributes to predicting the dependent variable when $P < 0.05$. The variance inflation factor, a measure of multicollinearity, measures the inflation of the standard error of each regression coefficient for an independent variable due to redundant information in other independent variables. If the variance inflation factor is 1.0, there is no redundant information in the other independent variables. The level of statistical significance for the multiple regression model was set at $P < 0.05$.

RESULTS

Patient and disease characteristics

A total of 340 patients from seven hospitals in different areas of Spain were included. Table 1 summarizes the socio-demographic and clinical characteristics, according to whether they were in the GFD group ($n = 163$) or the pre-treatment group ($n = 177$).

There were no relevant differences in demographic characteristics between the two groups. Age ranged from 15 to 78 years. Treated patients were younger than non-treated patients [median age 37 (28-47) *vs* 44 (30-50) years, respectively; $P < 0.05$], but the difference was not considered clinically relevant. The sample characteristics were also in accordance with the results of previous epidemiological studies of CD in Spain[2], with patients being young adults and predominantly female and non-smokers. Most patients lived in small to medium-sized cities, with < 500 000 inhabitants.

The duration of disease since diagnosis was not evaluated in the normal diet group because they were included at the time of diagnosis. There were no statistically significant differences in duration of symptoms before diagnosis of CD between treated and pre-treated patients. The disease presented in the classic form in 47 (32%) patients in the GFD group and in 13 (11%) patients in the normal diet group ($P < 0.01$). The most frequently presenting non-classical forms of CD included anemia (32%), cutaneous lesions (9%), and hypertransaminasemia (6%). Approximately 40% of patients had associated diseases, such as thyroid diseases (7%), selective IgA deficiency (3%), type I diabetes mellitus (5%), depression (11.1%), and chronic inflammatory arthropathy (8%). The percentage of asymptomatic patients at inclusion was significantly higher in the treated GFD group than in the normal diet group (80% *vs* 33%, $P < 0.01$). In the GFD group, 117 patients (73%) were classified as good compliers on the basis of their Morisky scores, 36 (22%) reported that they occasionally involuntarily neglected or forgot the diet, and eight (5%) had voluntarily discontinued the diet. Again in the GFD group, 47% of patients reported complete disappearance of symptoms since being on the diet, and 43% reported a significant improvement in symptoms. Eight per cent of patients reported a small improvement in symptoms, and 2% considered that their symptoms had not changed with treatment.

Description of HRQOL in CD

Figure 1 shows the overall score and the five dimensions of GIQLI for the GFD and pre-treatment groups. Patients in the GFD group reported significantly ($P < 0.001$) better HRQOL than patients in the pre-treatment group for the overall score and the gastrointestinal symptoms, and in the physical, social and emotional dysfunction dimensions.

Patients in the pre-treatment normal diet group scored best on GIQLI treatment effects domain [4.0 (3.0-4.0)], while the domains with the worst scores were physical dysfunction [2.3 (1.4-2.9)], emotional dysfunction [2.4 (1.8-3.0)], and gastrointestinal symptoms [2.8 (2.4-3.3)]. These results suggested that most impaired domains of health in newly diagnosed CD patients were related to symptomatic and emotional dimensions. In GFD patients, the best scored domain was also the treatment domain [4.0 (3.0-4.0)] and the worst scored was emotional dysfunction [3.0 (2.4-3.4)], which

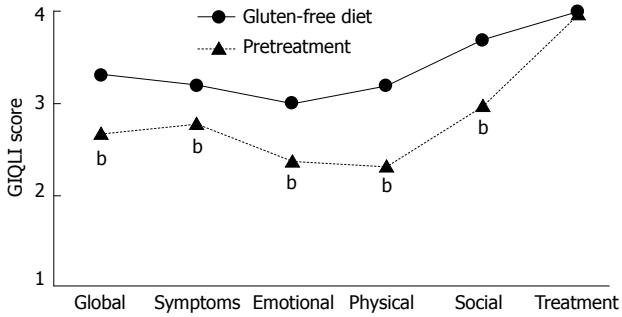

Figure 1 Median global and dimension scores of GIQLI for GFD (circles) and untreated (triangles) patients. Scores were significantly higher ($P < 0.001$) for all dimensions except treatment. [b]$P < 0.001$.

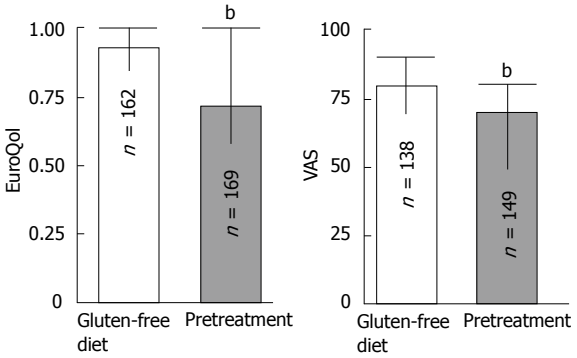

Figure 2 Median scores and 25th and 75th percentiles for the tariff and VAS of the EQ for GFD (white columns) and normal diet (grey columns). Scores were significantly better ($P < 0.001$) for patients in the GFD group. [b]$P < 0.001$.

suggested that, although improved by treatment, the most sustained impairment affected the emotional dimension.

Median scores on the EQ preference value index and VAS are shown in Figure 2. The median EQ preference value was significantly higher in GFD patients than in the normal diet group [0.93 (0.85-1.0) *vs* 0.72 (0.58-1.0) respectively, $P < 0.001$]. The median VAS score was also significantly higher in GFD patients than in the normal diet group [80 (70-90) *vs* 70 (50-80) respectively, $P < 0.001$]. Presence (levels of severity 2 and 3) or absence (level 1) of problems for each EQ dimension for the GFD and normal diet patients are shown in Table 2. At diagnosis, the normal diet group patients reported problems with significantly greater frequently than those in the GFD group on all five dimensions of the EQ, which confirmed that GFD improved patient perception of health. In the normal diet group, problems were reported most frequently in the pain/discomfort (62%) and anxiety/depression (54.5%) dimensions, and least frequently in the self-care dimension (10.2%). In the GFD group, problems were reported most frequently on the EQ anxiety/depression dimension (33.9%), in consonance with the low score of the emotional dimension in the GIQLI observed in this group of patients.

Factors influencing HRQOL in CD

Table 3 shows the results of the multiple regression analysis, which took the GIQLI overall score as a dependent variable for all patients. The analysis suggested

Table 2 Description of presence or absence of problems for each EQ dimension according to treatment *n* (%)

Variable	Pre-treatment		Gluten-free diet	
	No problems	Some problems	No problems	Some problems
Mobility	130 (74.3)	45 (25.7)	146[b] (90.1)	16 (9.9)
Self-care	158 (89.8)	18 (10.2)	161[b] (99.3)	1 (0.7)
Usual activities	113 (64.5)	62 (35.5)	135[b] (83.3)	27 (16.7)
Pain/Discomfort	67 (38)	109 (62)	117[b] (72.8)	45 (27.7)
Anxiety/Depression	80 (45.5)	96 (54.5)	107[b] (66.1)	55 (33.9)

[b]$P < 0.001$.

Table 3 Results of the multiple regression modeling with global GIQLI score as a dependent factor

Presence of symptoms	-5.09	< 0.001	1.31
Associated diseases	-2.61	0.01	1.18

that the presence of symptoms, normal diet and female gender were the strongest determinants ($P < 0.001$) for a worse perception of HRQOL.

Similar results were obtained using the linear regression analysis with the EQ preference value index (Table 4) and the EQ VAS (Table 5) as the dependent variables, and included the same independent variables as described earlier. Presence of symptoms and normal diet represented significant determinants of worse HRQOL. In this case, the presence of CD-associated diseases was also associated with poorer HRQOL.

In the pre-treated normal diet group, results of the comparison of patients diagnosed according to the presence of symptoms or a positive serology ($n = 26$) are shown in Figure 3. HRQOL was significantly worse in patients diagnosed through symptoms rather than through serologic tests without observable symptoms. The worst HRQOL was, therefore, found in women who had been recently diagnosed due to the presence of symptoms, who were in the normal diet group, and who had associated diseases.

In the GFD group, specific potential factors that may be related to HRQOL, such as compliance or response to

Table 5 Results of the multiple regression modeling with the VAS of the EQ score as a dependent factor

Independent variable	*t*-test statistics	*P* value	Variance inflation factor

diet, were assessed. There were no statistically significant differences in median overall GIQLI score between patients classified as good compliers (n = 117), and those who involuntarily neglected or forgot their diet (n = 36), and those who had voluntarily interrupted their diet (n = 8) [median GIQLI (IQR) scores, 3.3 (2.8-3.5), 3.2 (2.8-3.4), and 2.9 (2.6-3.3), respectively]. In contrast, GIQLI scores were significantly higher (better HRQOL) in the 73 patients who reported achieving complete control of symptoms with the GFD, than in patients reporting a partial or non-response (n = 84) [3.4 (3.1-3.6)] *vs* [3.0 (2.7-3.4), $P < 0.001$]. With reference to the potential effect of GFD duration on HRQOL, the duration of treatment and GIQLI overall score were slightly correlated ($r = 0.19$, $P < 0.05$) according to the Spearman rank correlation test. Similar correlation was observed with the EQ preference value index and the EQ VAS ($r = 0.20$, $P < 0.05$ and $r = 0.15$, P = NS).

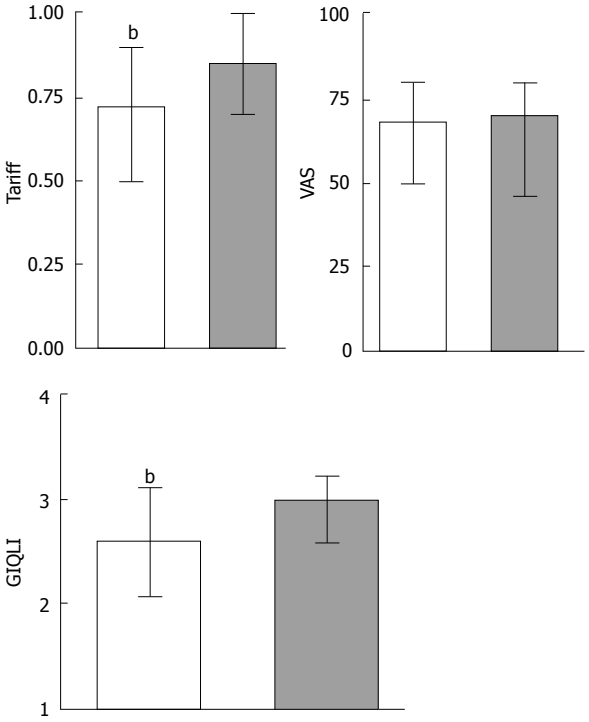

Figure 3 Median scores and 25th and 75th percentiles for the global GIQLI (left panel) and EQ index and VAS (right panel) in the pre-treated normal diet CD patients (white columns represents patients diagnosed due to symptoms and grey columns those diagnosed by serological tests). Scores were significantly worse ($P < 0.05$) for patients diagnosed due to symptoms compared to those with isolated serologic tests. [b]$P < 0.001$.

Intensity of impairment of HRQOL in CD

Although statistical comparisons between CD patients' EQ scores and those described for the Spanish general population (median preference value of 1.0 and VAS score of 80) were not performed, it seems apparent that treated patients do not have different preference values and VAS scores to the Spanish general population. In contrast, preferences and VAS scores of the normal diet group were worse than those of the general population. According to the distribution of EQ VAS scores in the Spanish general population (21), CD patients perceive their health as good to excellent (VAS scores between 70 and 100), while untreated patients with newly diagnosed CD have VAS scores corresponding to fair health.

Changes in HRQOL of CD before and after treatment

Seventeen newly diagnosed patients [11 women, six men, median age 48 (34-60) years] completed the HRQOL questionnaire before initiating treatment and after 6-23 mo with GFD. Paired comparisons using the Wilcoxon signed rank test showed that treatment improved significantly the GIQLI overall score [from a median of 2.6 (2.3-3.0) to 2.9 (2.7-3.4), P <0.001] and the VAS score [from 70 (55-70) to 77 (70-87) respectively, $P < 0.01$]. However, the median EQ preference value increase after treatment did not reach statistical significance [0.85 (0.69-1.0) to 0.87 (0.71-1.0), P = NS].

DISCUSSION

To analyze how CD affects HRQOL and to determine which factors are associated, we administered two generic instruments to measure HRQOL in two groups of CD patients: 163 patients following a GFD and 177 newly diagnosed patients who were on a normal diet. A potential limitation of the study is a selection bias for patients because we only included hospital-controlled patients. Results on the GIQLI and EQ questionnaires suggest that the HRQOL of untreated recently diagnosed CD patients is significantly impaired, on almost all of the dimensions on both instruments and on the overall score. It is not surprising then that these patients' assessment of their overall health on the EQ should be equivalent to a rating of only fair health. Patients before starting a GFD only scored well on the treatment effects dimension on the GIQLI questionnaire. Although these patients have not initiated the GFD, the highly-scored dimension was treatment, probably because this item refers to "feeling let down by treatment effects" and most patients have received prior diet or drug recommendations, or because patients tend to respond neutrally to items in this domain. By contrast, CD patients controlled with a GFD reported significantly better HRQOL, and in fact had EQ scores that were very similar to those of a representative sample of the Spanish general population[21,22]. These results study are in line with those reported very recently by the Canadian Celiac Association[23]. In that study, it was found that SF-12 summary scores for CD patients were similar to the normative Canadian data, except for females and newly diagnosed patients.

The importance of adequate compliance with a GFD is confirmed by the multivariate analysis, in which it was shown that GFD exerted a major influence on HRQOL,

whether using the condition-specific GIQLI or the generic EQ instrument. To avoid the problem of between-person variability in the determination of the effect of GFD on HRQOL, in a subgroup of newly diagnosed patients, the HRQOL was re-measured after at least 6 mo on GFD. Results of that ancillary study confirmed that treatment of CD improves HRQOL. The multivariate analysis also indicated that the presence of symptoms and comorbidity were other independent variables that significantly influenced HRQOL in CD patients. These results suggest that compliance with GFD and adequate control of symptoms are decisive, in terms that CD patients may recover to satisfactory levels of self-perceived health. The duration of improvements in HRQOL in CD patients following a GFD could not be deduced from our study, but it has been suggested that such improvements may be maintained for as long as 20 years[14].

Although our study confirmed that a GFD improves symptoms, with 90% of patients reporting a clinically significant improvement, as well as raising CD patients' levels of HRQOL to those reported by the general population, other studies, such as that by the Westchester Celiac Sprue Support Group have observed negative effects of a GFD on HRQOL in areas such as dining out, travel and family life[24]. These aspects were not covered in depth by either of the HRQOL instruments included here, and they should be considered for inclusion in future studies.

Advances in the serologic diagnosis of CD mean that the disease is recognized at increasingly early times, even in asymptomatic patients. Presumably as a result of the absence of symptoms in patients diagnosed by serologic screening, as opposed to patients diagnosed by clinical symptoms, it has been suggested that screening-detected CD patients have better HRQOL than those diagnosed based on symptoms[10,25]. There is no agreement as to whether a GFD improves HRQOL independently of whether diagnosis was based on serologic screening or on symptoms, with some evidence suggesting that improvements in HRQOL occur in both types of patients[25], and other evidence pointing out that they are only found in symptom-detected patients[10]. Our study also provides some evidence that symptom-detected patients have significantly lower overall scores on the GIQLI and on the EQ preference index than serologic-detected patients, which suggests that the former have better self-perceived health on diagnosis. However, the nature of the present study meant that it was not possible to determine whether diet-induced improvements in HRQOL were related or not to the type of diagnosis.

The only non-disease-related variable that had a significant influence on HRQOL was gender, with women scoring significantly poorer on the GIQLI questionnaire. It has been suggested that in treated CD patients, low scoring of SF-36 is confined to female patients[15]. However, in our study, the influence of gender on HRQOL was less clear because, although female sex was a significant independent variable for poorer perception of HRQOL as measured by the GIQLI, the effect was not seen on either the EQ preference value index or on the EQ VAS.

Our results suggest that untreated newly diagnosed CD has a significant negative impact on several domains of HRQOL, and that HRQOL is more impaired in symptomatic patients and in those with CD-associated diseases. On the other hand, HRQOL improves to levels observed in the general population when CD is controlled with a GFD. From our observations, it can be concluded that the assessment of HRQOL in CD patients is relevant because it improves physicians' knowledge of the implications of the disease, and helps patients to recognize the general impact of the disease. Additionally, the fact that patients following a GFD report similar levels of HRQOL as members of the general population should encourage patients to adhere to the GFD.

COMMENTS

Background

Celiac disease (CD) is a chronic immuno-inflammatory enteropathy that appears in genetically predisposed patients, who develop characteristic small-intestinal-mucosal changes, due to hypersensitivity to gluten. The chronic nature of the condition, together with the limitations imposed by the need to follow a permanent restrictive diet, substantial numbers of physician visits, the risk of associated diseases and potential complications, mean that CD can have a considerable negative impact on health-related quality of life (HRQOL). The impairment of HRQOL in untreated CD and its improvement after treatment with a gluten-free diet (GFD), has been suggested using generic multidimensional HRQOL measures.

Research frontiers

There is a lack of information relative to some areas in the research of HRQOL in CD. There is no agreement as to whether the HRQOL of treated CD patients reaches that of the general population, the factors involved in HRQOL impairment, and in the use of more specific instruments to measure the HRQOL of CD patients.

Innovations

Two instruments to measure HRQOL in two groups of CD patients: 163 patients following a GFD and 177 newly diagnosed patients who were on a normal diet containing gluten. Results on the gastrointestinal quality of life index GIQLI and EuroQol-5D EQ questionnaires suggested that the HRQOL of untreated, recently diagnosed CD patients was significantly impaired, on almost all of the dimensions on both instruments and on the overall score. Patients, before starting a GFD, considered their overall health equivalent to a rating of only fair. CD patients controlled with a GFD reported significantly better HRQOL, and in fact had EQ scores that were very similar to those of a representative sample of the Spanish general population. The importance of diet on CD was confirmed in an ancillary study in which HRQOL was re-measured after at least 6 mo on GFD. Results of that ancillary study confirm that treatment of CD improves HRQOL. Our study also provided some evidence that symptom-detected patients had significantly lower overall scores on the GIQLI and on the EQ preference index than serologic-detected patients, which suggested that the former had better self-perceived health on diagnosis. To determine the factors involved in HRQOL impairment in CD, a multivariate analysis using the condition-specific GIQLI or the generic EQ instrument was performed. Results of that analysis suggested that the variables significantly associated with a worse HRQOL were female gender, failure to follow a GFD, and symptomatic status.

Applications

The results of the present study suggest that compliance with a GFD and adequate control of symptoms are decisive in terms that CD patients may recover to satisfactory levels of self-perceived health. The assessment of HRQOL in CD patients is relevant because it improves physicians' knowledge of the implications of the disease and helps patients to recognize the general impact of the disease. The fact that patients following a GFD reached similar levels of HRQOL as members of the general population should encourage patients to adhere to a GFD.

Terminology

HRQOL has a recognized importance to evaluate, manage and follow patients with chronic diseases, such as CD. Different types of instruments for measuring HRQOL have been introduced, with the most important being the questionnaires. There are generic questionnaires and disease-specific questionnaires. Although a specific questionnaire for CD has recently been published, the most widely used instruments to measure HRQOL in CD are the generic questionnaires. GIQLI is a self-administered questionnaire designed to assess HRQOL in patients with gastrointestinal diseases. The GIQLI consists of 36 items grouped into five domains of health (gastrointestinal symptoms, physical dysfunction, social dysfunction, emotional dysfunction and treatment effects). Responses are scored on a 4-point Likert scale, in which 4 corresponds to the highest level of functioning. EQ is a self-administered generic utility measure that provides both a descriptive profile and an overall index for HRQOL. The EQ includes five dimensions (mobility, personal care, daily activities, pain and anxiety–depression) answered on a 3-point scale ranging from no problems (level 1) to extreme problems (level 3). Combining one level of severity from each of the five dimensions generates a number of discrete health states that can be assigned preference values ranging from 0, which represents worst health status, to 1 (best health status). The EQ also includes a VAS that ranges from 0 (worst imaginable health status) to 100.

Peer Review

This is a well designed study addressing an important aspect of celiac disease which adds considerably to what is already known.

Abstract

AIM: To investigate possibility and clinical application of fecal calprotectin in determining disease activity of ulcerative colitis (UC).

METHODS: The enzyme-linked immunosorbent assay (ELISA) was used to measure the concentrations of calprotectin in feces obtained from 66 patients with UC and 20 controls. C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), acid glycoprotein (AGP) were also measured and were compared with calprotectin in determining disease activity of UC. The disease activity of UC was also determined by the Sutherland criteria.

RESULTS: The fecal calprotectin concentration in the patients with active UC was significantly higher than that in the inactive UC and in the controls (402.16 ± 48.0 μg/g *vs* 35.93 ± 3.39 μg/g, 11.5 ± 3.42 μg/g, $P < 0.01$). The fecal calprotectin concentration in the inactive UC group was significantly higher than that in the control group ($P < 0.05$). A significant difference was also found in the patients with active UC of mild, moderate and severe degrees. The area under the curve of the receiver operating characteristics (AUC^{ROC}) was 0.975, 0.740, 0.692 and 0.737 for fecal calprotectin, CRP, ESR and AGP, respectively. There was a strong correlation between the fecal calprotectin concentration and the endoscopic gradings for UC ($r = 0.866$, $P < 0.001$).

CONCLUSION: Calprotectin in the patient's feces can reflect the disease activity of UC and can be used as a rational fecal marker for intestinal inflammation in clinical practice. This kind of marker is relatively precise, simple and noninvasive when compared with other commonly-used markers such as CRP, ESR and AGP.

Key words: Fecal calprotectin; Disease activity; Ulcerative colitis; Enzyme-linked immunosorbent assay

INTRODUCTION

Ulcerative colitis (UC) is a chronic, idiopathic inflammatory bowel disease characterized by remission of disease activity. The incidence and the prevalence rates of UC are increasing in China[1]. It is important to accurately evaluate intestinal mucosa inflammation in the management of these patients, particularly for the assessment of therapeutic effectiveness. Colonoscopy and biopsy are useful in the assessment of intestinal mucosa inflammation of patients with UC, but these examinations can be a heavy burden to the patient[2,3]. Clinical evaluations including laboratory tests such as C-reactive protein (CRP)[4-6], erythrocyte sedimentation rate (ESR)[7], acid glycoprotein (AGP)[8], and platelet count[9,10], have been used for the determination of disease activity of UC, but none of them are specific for gut inflammation[11]. Therefore, a new marker that will be more sensitive and specific for determination of disease activity of UC is urgently needed in clinical practice.

An alternative approach to the assessment of the presence of intestinal inflammation[12] is to analyze the whole gut lavage fluid or to quantitate the protease resistant neutrophil derived proteins such as lactoferrin[13,14] in the patient's feces, and this approach can be non-invasive for the patient. Calprotectin is one of these proteins. It is a major protein in the neutrophilic granulocytes and the macrophages[15], which accounts for 60% of the total protein in the cytosol fraction in these cells[16,17]. This kind of protein can resist metabolic degradation caused by intestinal bacteria, and the protein is relatively stable in stools for up to one week at room temperature[18]. It can differentiate between patients with organic or non-organic intestinal disease, and can be useful in detecting colorectal cancer and inflammatory disorders, and can also be useful in predicting a relapse of inflammatory bowel disease[19].

Our study was aimed at the measurement of the concentration of calprotectin in the feces of the UC patient and at the comparison of it with commonly-used markers in clinical practice, such as CRP, ESR and AGP.

MATERIALS AND METHODS

Study subjects

Sixty-six patients with UC (age, 38.97 ± 2.39 years) were enrolled in the study, including 15 patients with proctitis, 22 with left-sided colitis, and 29 with pancolitis. Of the patients, 44 were hospitalized. The patients' disease activities were assessed according to the Sutherland criteria[20] in which a score of more than two was considered to indicate the active stage of the disease. The control group consisted of 20 subjects (age, 38.95 ± 3.59 years) with no confirmed abnormality in the upper or lower digestive tract.

Methods of stool collection

The patients were instructed to defecate directly into a polystyrene container. The stool samples were stored at -70℃ until the time of measurement.

Measurement of fecal calprotectin by ELISA

The stool samples were thawed, and 50-100 mg of the sample was suspended with 2500-5000 μL of the fecal extraction buffer, and was homogenized; then, the suspernatant was diluted to 1:50, and the calprotectin was analyzed by the enzyme-linked immunosorbent assay (ELISA) using the Nycotest Phical ELISA kit (Nycomed, Norway). Microcapture and immunoaffinity-purified rabbit anticalprotectin conjugated with alkaline phosphatase was used for the development. The ELISA read the absorbance at 405 nm for 96-well plates. The results of the sample tests were evaluated from the standard curves. CRP, ESR and AGP were measured in the clinical laboratory, West China Hospital, based on the instructions provided by the reagent manufacturer.

Statistical analysis

Statistical analysis was performed using the statistical package SPSS 11.5. The data were expressed as means ± SD. The Mann-Whitney test was used to assess differences in the laboratory parameters between the groups, and Spearmans' correlation was used to analyze the correlation between the parameters. All the P values were two tailed; P values < 0.05 were considered statistically significant. The receiver operating characteristics (ROC) (sensitivity and specificity) were assessed by the curve analysis as described by Henderson[21].

RESULTS

Concentrations of fecal calprotectin, CRP, ESR and AGP in patients with UC and in controls

There was a significant difference in the fecal calprotectin concentration between the patients with active UC and the patients with inactive UC ($P < 0.01$) (Table 1, Figure 1). The calprotectin concentration was significantly greater in the patients with inactive UC than in the controls ($P < 0.05$). The patients with active UC had higher levels of CRP, ESR and AGP than the patients with inactive UC and the controls ($P < 0.05$), but there was no significant difference between the patients with inactive UC and the controls.

Relationship between the concentrations of fecal calprotectin, CRP, ESR and AGP and the disease activity index (DAI) in UC

As shown in Figure 2, the concentrations of fecal calprotectin, CRP, ESR and AGP in UC had a good correlation with DAI. The correlation coefficients between DAI and the concentrations of fecal calprotectin, CRP, ESR and AGP were 0.866, 0.492, 0.433 and 0.533, respectively. This association was strongest for fecal calprotectin and weakest for ESR.

Specificity and sensitivity

The correspondence between the DAI-based classification of the active or the inactive disease status and the classification based on the parameter cut-offs was analyzed for each parameter (Table 2) and was expressed as the percentage of the samples that were correspondingly identified (specificity and sensitivity). Specificity was highest for fecal calprotectin, and lowest for AGP. The specificity rates for fecal calprotectin, CRP, ESR and AGP were 79.4%, 69.0%, 68.9% and 65.5%, respectively. The sensitivity for fecal calprotectin was relatively high, but was relatively low for CRP. The sensitivity rates for fecal calprotectin, CRP, ESR and AGP were 91.9%, 62.2%, 64.9%, and 67.6%, respectively. The ROC curves showed the trade-off between specificity and sensitivity for fecal calprotectin (the area under the curve, AUC, 0.975 ± 0.015; $P < 0.001$), for CRP (AUC, 0.740 ± 0.061; $P < 0.001$), for ESR (AUC, 0.692 ± 0.064; $P < 0.01$), and for AGP (AUC, 0.737 ± 0.062; $P < 0.001$) (Figure 3). The AUC^{ROC} of fecal calprotectin was greater than that of CRP, ESR or AGP ($P < 0.01$).

DISCUSSION

Chronic relapsing and remitting inflammation of the gastrointestinal tract is the hallmark of UC. One of the most prominent histological features observed in UC is infiltration of the neutrophils into the inflamed mucosa at an early stage of inflammation. The neutrophils are major sources of inflammatory cytokines, chemokines proteases, active lipids, and reactive oxygen derivatives, as well as a full complement of factors needed to exacerbate mucosal inflammation and tissue injury[22-25] The fecal calprotectin excretion of indium-labeled autologous granulocytes has for a long time been suggested as the gold standard test in assessing bowel inflammation in inflammatory bowel disease. However, as it involves an exposure to radiation and prolonged fecal collection, which is unpopular with patients and laboratory staff, it is only used as a research tool. In patients with inflammatory bowel disease, a three day excretion of indium-labeled granulocytes correlated well with a daily excretion and a one-off fecal calprotectin level[26].

In this study, we focused on the evaluation of any relationship that might exist between the mucosal neutrophil infiltration represented by calprotectin, CRP, ESR, AGP and the UC disease activity represented by the Sutherland criteria. The DAI score of UC is the sum score of the following four parameters (each scoring

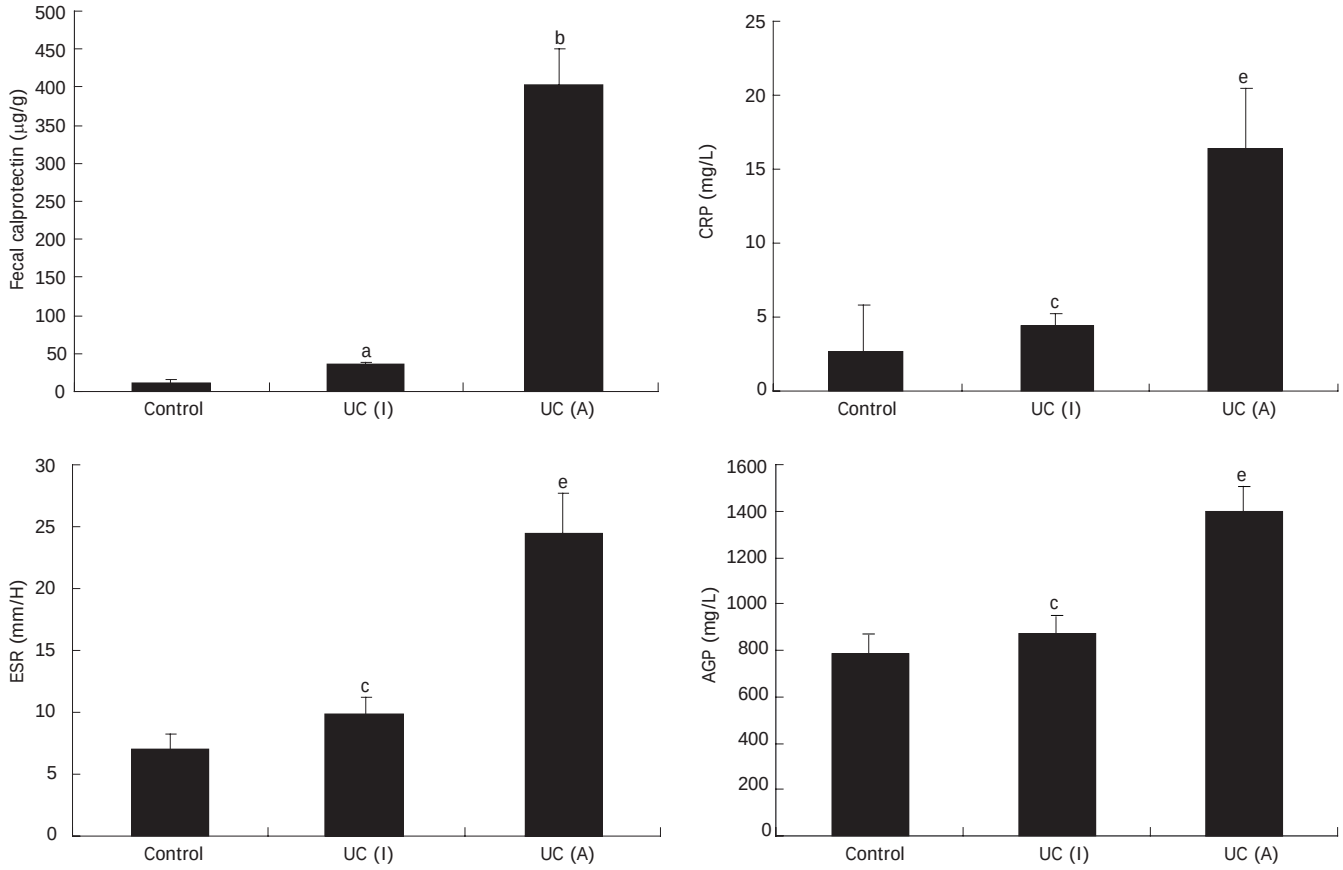

Figure 1 Concentrations of fecal calprotectin, CRP, ESR and AGP in the UC patients and the controls. UC (A): Ulcerative colitis (active phase); UC (I): Ulcerative colitis (inactive phase). [a]$P < 0.05$ *vs* the control, [b]$P < 0.01$ *vs* UC (I) and the control, [c]$P > 0.05$ *vs* the control, [e]$P < 0.05$ *vs* UC (I) and the control.

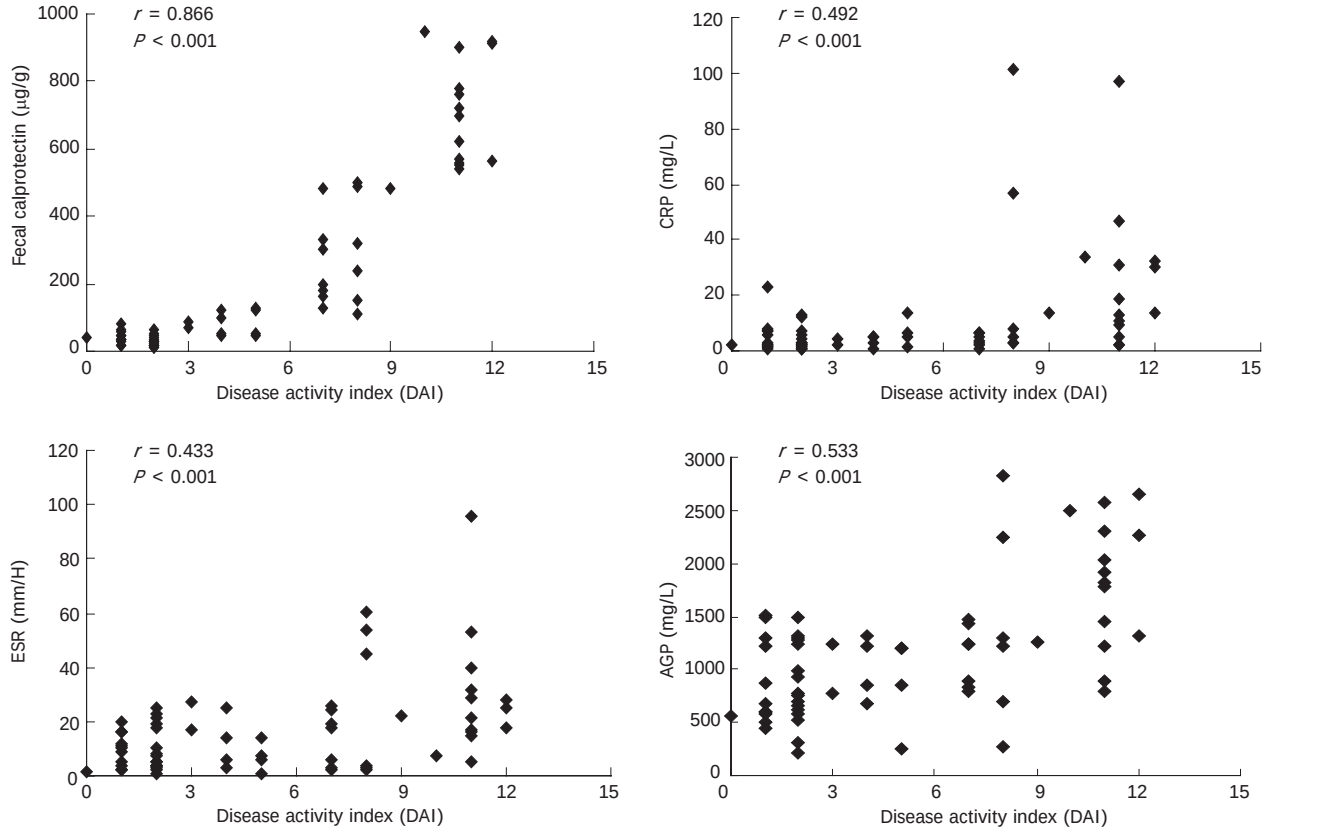

Figure 2 Concentrations of fecal calprotectin, CRP, ESR and AGP in UC and the DAI score of UC.

Table 1 Concentrations of fecal calprotectin, CRP, ESR and AGP in the UC patients and the controls (mean ± SD)

Group	Calprotectin (μg/g)	CRP (mg/L)	ESR (mm/H)	AGP (mg/L)
Control	11.5 ± 3.42	2.66 ± 3.2	7.05 ± 1.2	786.65 ± 77.65
Inactive UC	35.93 ± 3.39	4.39 ± 0.89	9.84 ± 1.36	870.14 ± 71.04
Active UC	402.16 ± 48.0	16.45 ± 3.98	21.44 ± 3.29	1394.9 ± 109.3

UC: Ulcerative colitis; CRP: C-reactive protein; ESR: Erythrocyte sedimentation rate; AGP: Acid glycoprotein.

Table 2 Specificity and sensitivity for fecal calprotectin, CRP, ESR and AGP

Marker	Cut-off	Specificity (%)	Sensitivity (%)
Fecal calprotectin	50.0 μg/g	79.4	91.9
CRP	5.0 mg/L	69.0	62.2
ESR	15.0 mm/h	68.9	64.9
AGP	1200 mg/L	65.5	67.6

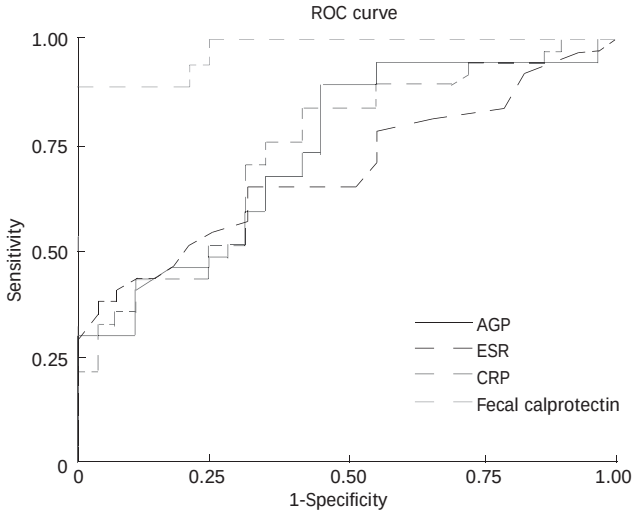

Figure 3 The ROC curve analysis on the abilities of calprotectin, CRP, ESR and AGP to make a difference between active UC and inactive UC.

between nought and three, making 12 the worst score): stool frequency, rectal bleeding, mucosa appearance, and physician's global assessment[27]. It reflects the clinical representation of UC and is the most extensive and simplest DAI. It is adopted by the guidelines for the management of inflammatory bowel disease in the fourth Asia Pacific Digestive Week[28]. Our results showed that fecal calprotectin concentrations were significantly higher in the patients with active UC than in the patients with inactive UC and in the controls. In addition, our results showed that fecal calprotectin concentration was higher in the patients with inactive UC than in the controls. In the patients with UC, the fecal calprotectin concentration had a better correlation with DAI than the CRP, ESR or AGP concentration.

The ROC curve is adopted not only to ensure the right cut-off point, but also to compare the diagnostic values of two or more diagnostic tests. The ROC analysis on the fecal calprotectin concentrations under these circumstances, showed that a cut-off point of 50.0 μg/g for calprotectin had a 91.9% sensitivity and a 79.4% specificity for making a differentiation between active UC and inactive UC. These were significantly better than those obtained with CRP, ESR and AGP.

In this study, ELISA was used to determine the fecal calprotectin concentrations in the patients with UC and in the controls. In comparison to endoscopy this method is simple, noninvasive and inexpensive. However, fecal calprotectin can only reflect the excretion of neutrophils. Many infective diseases can cause a large number of neutrophils to infiltrate, so that fecal calprotectin is elevated in a number of organic gastroenterological disorders[29-31]. Therefore, fecal calprotectin is not desirable as a method that is required to differentiate efficiently between UC and infective colitis, so it cannot take the place of an endoscope in diagnosing UC. Regardless of how sensitive the calprotectin technique may be in the detection of disease activity in patients with previously diagnosed UC, its greater potential use is in identifying patients with UC and in differentiating between patients with UC and patients with non-inflammatory disorders, still requires further study.

In conclusion, the determination of fecal calprotectin is an objective approach to grading the mucosal disease activity in patients with inflammatory bowel disease. The advantages of fecal calprotectin are simplicity, noninvasiveness, and relatively low cost. Fecal calprotectin can be useful not only in research but also in clinical practice.

COMMENTS

Background

The incidence and the prevalence rates of ulcerative colitis (UC) are increasing in China. It is important to accurately evaluate intestinal mucosa inflammation in the management of these patients, particularly for the assessment of therapeutic effectiveness. No clinical evaluations are specific for gut inflammation. Therefore, a new marker that will be more sensitive and specific for determination of disease activity of UC is urgently needed in clinical practice.

Research frontiers

Calprotectin can resist metabolic degradation caused by intestinal bacteria, and the protein is relatively stable in stools for up to one week at room temperature. Some foreign research has shown that fecal calprotectin concentrations were significantly higher in patients with active UC than in patients with inactive UC and in the controls.

Innovations and breakthroughs

Our study improved the originality of the manuscript assessing the relationship between calprotectin level and extension of colitis. This question was not described enough in the medical literature.

Applications

The aim of our study was to investigate the possibility and clinical application of fecal calprotectin in determining disease activity of UC. Our findings suggest that calprotectin in the patient's feces can reflect disease activity of UC and can be used as a rational fecal marker for intestinal inflammation in clinical practice.

Terminology

Receiver operating characteristics (ROC) curve is adopted not only to ensure the right cut-off point but also to compare the diagnostic values of two or more diagnostic tests. The accuracy of diagnostic test is characterized by the sensitivity and specificity. A ROC curve displays the sensitivity of a diagnostic test over all possible false-positive rates.

Peer review

This manuscript provided compelling evidence that fecal calprotectin was a better marker than C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) or acid glycoprotein (AGP) and improved the originality of the manuscript assessing the relationship between calprotectin level and extension of colitis. It deserves to be published.

Abstract

AIM: To compare the prognosis of patients who underwent hepatectomy and ablation using the modified Japan Integrated Staging score (mJIS).

METHODS: We examined the clinicopathologic records and patient outcomes in 278 HCC patients including 226 undergoing hepatectomy and 52 undergoing ablation therapy.

RESULTS: Cirrhosis was more frequent in the ablation group. Tumor size, number and presence of vascular invasion were significantly higher in the operation group compared to the ablation group. The local recurrence rate adjacent to treated lesions was significantly higher in the ablation group compared to the operation group ($P < 0.05$). The 3- and 5-year survival rates in the ablation and the operation group were 66% and 78%, and 50% and 63%, respectively, but not significantly different. Over 50% survival rates were observed in patients with a mJIS score of 0-2 in both groups. However, survival rates with a score of 3-5 in both groups were significantly lower.

CONCLUSION: According to the mJIS system, both local treatments could be selected for patients with a score of 0-2. However, for patients with a score more than 3, liver transplantation might be a better option in patients with HCC.

INTRODUCTION

Although hepatic resection is supposed to be the best curative local treatment for hepatocellular carcinoma (HCC)[1-3], sufficient hepatic functional reserve is necessary. In recent years, various treatment modalities have become available for HCC patients and the appropriate treatment should be selected according to tumor staging and liver function[4]. In the past decade, combined staging systems with tumor factors and liver function in HCC patients have been proposed worldwide[4-7]. We also proposed the modified cancer of the liver Italian program (mCLIP) score and the modified Japan Integrated Staging score (mJIS)[8,9]. Comparing the various staging systems using multivariate survival analysis, mJIS is the best available system to predict survival in HCC patients after hepatectomy[10]. The Liver Cancer Study Group of Japan subsequently showed that the mJIS system had good predictive accuracy for survival of Japanese patients with HCC by the records of 42269 patients diagnosed with HCC registered between 1992 and 1999 in a nationwide Japanese database[11].

Liver transplantation (LT) has recently been considered a good option to cure some HCC patients with poor hepatic function, such as Child-Pugh C cirrhosis[12]. The usefulness of cadavaric liver transplantation (LT) for HCC treatment has been clarified in Western countries[13] and, furthermore,

Todo *et al* reported good results in HCC treatment with the living related LT in Japan[14]. Therefore, LT seems to be a better treatment option in some patients who undergo local treatments in Japan. At this stage, Milan or University of California, San Francisco (UCSF) criteria using tumor factors and the Barcelona Clinic Liver Cancer (BCLC) system using tumor, liver function and performance status, have been used to decide the indication of LT[4,15,16]. It has not yet been clarified whether the mJIS system could be useful in the selection of LT in HCC patients.

In this study, we compare patient demographics, preoperative liver function, tumor parameters and long-term patient survival prognosis of 278 HCC patients who underwent hepatectomy and ablation using mJIS at several cancer institutions in Nagasaki prefecture, Japan. We then discuss the selection of treatment by comparing results by LT. Our aim is to clarify the treatment selection criteria for HCC patients using mJIS.

Table 1A Definition and criteria of the TNM stage for HCC according to the Liver Cancer Study Group of Japan[17]

Factor of T category	
1 Number of tumors: 1	
2 Tumor size: no more than 2 cm	
3 No vascular or bile duct invasion	
T category	T1: Fulfilling all three factors
	T2: Fulfilling two factors
	T3: Fulfilling one factor
	T4: Fulfilling none of the factors
N category	N0: Absence of lymph node metastasis
	N1: Presence of lymph node metastasis
M category	M0: Absence of distant metastasis
	M1: Presence of distant metastasis
Stage Ⅰ	T1 N0 M0
Stage Ⅱ	T2 N0 M0
Stage Ⅲ	T3 N0 M0
Stage Ⅳ-A	T4 N0 M0 or T1-T4, N1M0
Stage Ⅳ-B	T1-4, N0 or 1, M1

MATERIALS AND METHODS

Patients

We analyzed 278 patients with HCC who underwent surgical resection or ablation treatments in the Division of Surgical Oncology and the First and Second Department of Internal Medicine, Nagasaki University Graduate School of Biomedical Sciences (NUGSBS), and its related hospitals between 1994 and 2005. The study design was approved by the Human Ethics Review Board of our institution. Informed consent for data collection was obtained from each patient during this period. Anesthetic and patient data were retrieved from the NUGSBS database. Tumor stage and curability were determined according to the *Classification of Primary Liver Cancer*[17]. Subjects were divided into two groups: (1) Operation group with 226 patients. Preoperative treatment was performed in 78 patients including chemoembolization in 69 and thermal ablation in nine. Operative procedures included hemihepatectomy in 56 patients, anatomical sectriectomy in 74 and partial resection in 96. (2) Ablation group with 52 patients, including alcohol injection in 15 patients, radio-frequency ablation (RFA) in 32, and microwave coagulation therapy (MCT) in five patients.

Treatment indications, procedures and follow-up

The volume of liver to be resected was estimated according to results of the indocyanine green retention rate at 15 min (ICG R15) using Takasaki's formula[18]. Furthermore, hepatic function for hepatectomy was limited as ICGR15 < 40%, Child-Pugh classification A or B, and total bilirubin level < 2 mg/dL according to Miyagawa's criteria[19]. The expected liver volume for resection, excluding the tumor (cm^3), was measured by computed tomography (CT) volumetry[20]. Radical hepatectomy was performed to remove the hepatic tumor without leaving any residual tumor. The indications for hepatic resection of the size and the number of HCC were more than 2 cm, and less than or equal to three lesions, respectively. Distant metastasis was an extra-indication for hepatectomy. The assessment of tumor factors in the operation group was confirmed by histopathological examination of the resected specimen. We used the histopathological factors and curability by hepatectomy of the *Liver Cancer Study Group of Japan* by the *Classification of Primary Liver Cancer*[17].

For RFA or MCT, the indication for hepatic resection of the size and the number of HCC were less than 3 cm, and less than or equal to three lesions, respectively[21]. Hepatic function for ablations is limited as Child-Pugh classification A or B, platelet counts more than 50 000/mm^3, prothrombin activity more than 50% and total bilirubin level less than 3 mg/dL. When the appropriate coagulation was estimated to be incomplete by percutaneous puncture, ablations under laparoscopy, thoracoscopy or laparotomy were selected[22,23]. Evaluation of vascular involvement was performed by image analysis, such as enhanced computed tomography or magnetic resonance imaging.

After discharge from hospital, the patient status, laboratory data, and disease recurrence were checked every two to three months.

Staging criteria of the modified Japan Integrated Staging score (mJIS)

The assessment of each factor was confirmed by histopathological examination of the resected specimen, or by computed tomography scan, ultrasonography, magnetic resonance image or angiography. We used the pathological tumor-node-metastasis (pTNM) classification system of the Liver Cancer Study Group (LCSG) of Japan in 2000[17]. T category is determined by three factors of number, size and vascular or bile duct invasion. N category is the presence of lymph node metastasis and M category is the presence of distant metastasis. TNM staging has four stages according to T, N and M categories (Table 1A). Classification of Child-Pugh[24] and liver damage grade by LCSG[17] are shown in Table 1B. The original JIS score proposed by Kudo *et al* comprised the sum of points for two variables of the Japanese TNM classification and Child-Pugh classification[6]. In the modified JIS score proposed by our institute[9,10], the Child-Pugh classification score was replaced by that of liver damage grade by the LCSG of Japan (Table 1C).

Table 1B Definition and criteria of Child-Pugh classification and liver damage grade

Child-Pugh classification[24]	A	B	C
Encephalopathy	none	mild	coma
Ascites	none	responsive	unresponsive
Serum bilirubin (mg/dL)	< 2.0	2.0-3.0	> 3.0
Serum albumin (g/dL)	> 3.5	2.8-3.5	< 2.8
Prothrombin activity (%)	> 70	40-70	< 40
Liver damage grade[17]	A	B	C
Ascites	none	responsive	unresponsive
Serum bilirubin (mg/dL)	< 2.0	2.0-3.0	> 3.0
Serum albumin (g/dL)	> 3.5	3.0-3.5	< 3.0
ICG R15 (%)	< 15	15-40	> 40
Prothrombin activity (%)	> 80	50-80	< 50

	Score			
	0	1	2	3
Original JIS score[6]				
Japanese TNM stage	I	II	III	IV
Child-Pugh Classification	A	B	C	
Modified JIS score[9]				
Japanese TNM stage	I	II	III	IV
Liver damage grade	A	B	C	

TNM: Tumor-node metastasis.

Statistical analysis

Continuous data were expressed as the mean ± SD. Data from different groups were compared using one-way analysis of variance (ANOVA) and examined by student's *t*-test or Dunnet's multiple comparison test. For univariate analysis, categorical data were analyzed by the Fisher's exact test. Disease-free and overall survival rates were calculated according to the Kaplan-Meier method, and differences between groups were tested for significance using the log-rank test. Multivariate analysis was performed using the proportional hazards regression model. A two-tailed *P* value of < 0.05 was considered significant. Statistical analyses were performed using SAS software (Statistical Analysis System Inc., Cary, NC).

RESULTS

Patient age, gender and period of treatment were not significantly different between groups (Table 2). Rates of cirrhosis and Child-Pugh B were significantly higher in the ablation group. Thirty-five percent of patients underwent pretreatment in the operation group; however, no patients underwent other treatments in the ablation group. Tumor size in the operation group was significantly larger than that in the ablation group. The number of tumors and rate of vascular involvement were significantly higher in the operation group compared to the ablation group. Posttreatment adjuvant treatments were similarly performed in both groups.

In the ablation group, tumor relapse was observed in 22 patients (42%) including 10 with intrahepatic metastasis and 12 with local recurrence adjacent to the ablated site (Figure 1). On the other hand, in the operation group, tumor relapse was observed in 122 patients (62%), which included 117 with intrahepatic metastasis and five with local recurrence adjacent to the resected margin. The local recurrence rate adjacent to the treated lesion was significantly higher in the ablation group compared to the operation group ($P < 0.05$).

By applying mJIS, discrimination of survival in each score was remarkable (Figure 2). The 3- and 5-year survival rates in the ablation and operation group were 66% and 78%, and 50% and 63%, respectively (Figure 3); however, there were no significant differences between groups. Child-Pugh B was significantly associated with poor disease-free and overall survival (Table 3). Multiple tumors were associated with overall survival. However, difference of treatment modality was not associated with prognosis in the present study. Table 4 shows 3-year survival rates in each score of mJIS; however, there were no significant

Table 3 Survival between two groups in HCC patients by multivariate analysis

	Disease-free survival		Overall survival	
	HR (95% CI)	*P*-value	HR (95% CI)	*P*-value
Child-Pugh classification				
B *vs* A	2.05 (1.25-3.35)	0.004	2.46 (1.38-4.41)	0.002
Tumor size				
⩾ 5 *vs* < 5 cm	1.26 (0.83-1.92)	0.282	1.30 (0.75-2.25)	0.350
Macroscopic findings[1]				
Confluent type *vs* Simple nodular type	1.10 (0.75-1.61)	0.626	1.58 (0.92-2.72)	0.098
Number of tumor				
Multiple *vs* Solitary	1.23 (0.82-1.85)	0.306	1.73 (1.03-2.91)	0.037
Vascular involvement				
Yes *vs* No	1.24 (0.68-2.27)	0.481	1.76 (0.93-3.31)	0.080
Alpha-feto protein level				
⩾ 400 *vs* < 400 ng/mL	1.41 (0.93-2.11)	0.103	1.36 (0.81-2.28)	0.250
Treatment modality				
Ablation *vs* Hepatectomy	0.75 (0.46-1.22)	0.239	0.64 (0.39-1.34)	0.334

[1]Macroscopic findings defined by the *Classification of Primary Liver Cancer*[17].

Table 4 The 3-year survival rates in each score of mJIS after treatments in HCC patients

	Operation group (*n* = 226) (%)	Ablation group (*n* = 52) (%)
mJIS 0	96	98
mJIS 1	80	73
mJIS 2	66	70
mJIS 3	39	48
mJIS 4	35	28
mJIS 5	25	-

differences between the two groups. Overall survival rates between score 2 and 3 were remarkably different in both groups. Over 50% survival rates were obtained up to score 2 in both groups; however, survival rates over score 3 in both groups were lower.

DISCUSSION

With recent advances in the ablation technique, local tumor control has improved[25]. In comparison with alcohol injection, the modality option or patient survivals have been remarkably improved in the era of RFA or MCT[25-28]. Alcohol injection is not recommended at present[29,30]. In the present study, the ablation group included patients undergoing alcohol injection; however, local control was relatively good because of the small HCC in our series. At this stage, we mainly performed RFA regardless of tumor size, number and location and we also applied RFA under laparotomy or laparoscopy to achieve complete ablation. Selection bias for treatment was shown by our results. Hepatectomy was mainly selected in patients with chronic hepatitis or Child-Pugh A, while ablation was used in patients with impaired liver function such as cirrhosis or Child-Pugh B. In the latter, surgical resection is usually avoided. Concerning tumor factors, hepatectomy was preferably selected for tumors of larger size, and solitary and vascular involvement by the image examinations. Ablation tended to be selected for small and multiple tumors. Wakai *et al* also showed a similar tendency to select the treatment modality[31]. However, Shiina *et al* described the superiority of RFA compared to hepatectomy[32]. Therefore, superiority or selection criteria between both treatments are still controversial. In the recent Japanese guidelines for HCC, the indication of these treatments was not clearly discriminated[33]. In the operation group, other treatments were preferably performed in one-third of all patients. In these patients, ablation therapy was included as well. Based on these results, the background in both groups was remarkably different, which was also the case in Wakai's report[31].

The pattern of tumor relapse was different in the present study and local recurrence adjacent to the ablated section was significantly higher regardless of careful ablations with a sufficient ablation margin more than 5 mm[34]. Some investigators reported that the complete ablation rate is around 90% with HCC and less than 5 cm could be treated[27-29,35]. However, local recurrence in patients undergoing thermal ablation therapy ranged between 9.2% and 13.6%[26-28]. Hong *et al* reported that the local recurrence rate in ablation therapy was higher than that in hepatic resection[36]. Therefore, local control by hepatectomy is superior to that by thermal ablation at this stage, based on the above reports[26-28,31,35] and our results. Although the rate of distant liver metastasis might not be remarkably different based on previous reports[26-28,35,36], tumor recurrence in the distant liver was still high in the operation group in the present study, which might be

associated with the advanced stage of HCC as shown in the results.

With respect to patient survival after treatment, superiority between both groups was not clarified, in addition to survival rate, in our results. We applied the mJIS system in this study, which is the best available to predict HCC patient survival after curable treatments[9-11]. By applying this system, survival in each score in the present series was well discriminated. At this stage, indication of treatment modality in HCC patients with early tumor stage and Child-Pugh A or B between hepatectomy and thermal ablation has been controversial[31,32,34,37]. In patients with small HCC less than 2 cm or in patients with impaired liver function such as a Child-Pugh B, survival benefit was similar between both groups[31,34,37,38]. As described above, local recurrence rate by thermal ablation was higher compared to that by hepatectomy; however, overall survival was not significantly different by previous reports[26-28,34-37]. The guideline for diagnosis and treatment in HCC patients was first proposed by Makuuchi *et al*[33]; however, ablation and hepatectomy were at similar locations in HCC patients with less than four sites and good liver function. Our results showed that the overall survival was similar between both groups, which also had similar mJIS scores, although the included tumor factor and liver function were different between groups, as shown in patient demographics. By multivariate analysis, the difference of treatment modality was not observed in the present study. Up to mJIS score 2, the 3-year survival rate was well maintained; however, survival rate over mJIS score 3 was significantly decreased in both groups. We considered that this border between a score of 2 and 3 might be important to decide the limitation of both conventional treatments. The ultimate curable option should be a liver transplantation. Todo *et al* reported posttransplant survival in HCC patients who met Milan criteria undergoing living-related liver transplantation in Japan[14]. The 3-year survival rates with or without Milan criteria was 79% and 60%, respectively. This report was a satisfactory result at this stage. Compared to this result, even in a group with Milan criteria not met, survival rates over score 3 in both groups were lower than those in HCC patients undergoing living-related LT. In HCC patients with mJIS score 3-5, patients without remarkable vascular involvement would be included in the indication of liver transplantation. By comparing the survival benefit, transplantation is strongly recommended to improve patient prognosis. In patients with score 0-2, the definition of treatment criteria between groups seemed to be difficult on the present evidence and consensus[39,40]. A study with a large series in Japan will clarify this problem in the near future. Our results did not show superiority or definite indication between both treatment modalities in the present study. To improve the survival results in HCC patients, a combination of both treatments[41], chemoembolization[42], or intra-operative ablation under laparoscopy or laparotomy should be used[22,43].

In conclusion, hepatectomy tended to be selected in patients with better functional liver reserve and, hence, ablation therapy tended to be selected in patients with poor hepatic function in our series. In the ablation group, local recurrence near the treatment region tended to be more than that in the hepatectomy group. By multivariate analysis, macroscopic finding and vascular invasion were significant risk factors, but treatment modality was not a prognostic factor. According to the mJIS system, both treatments could be selected for patients with score 0-2; however, for patients with a score more than 3, liver transplantation might be a better option compared to conventional local treatments.

Abstract

AIM: To evaluate the role of positron emission tomography using 18F-fluorodeoxyglucose (FDG-PET) in the surgical management of patients with pancreatic cancer, including the diagnosis, staging, and selection of patients for the subsequent surgical treatment.

METHODS: This study involved 53 patients with proven primary pancreatic cancer. The sensitivity of diagnosing the primary cancer was examined for FDG-PET, CT, cytological examination of the bile or pancreatic juice, and the serum levels of carcinoembrionic antigens (CEA) and carbohydrate antigen 19-9 (CA19-9). Next, the accuracy of staging was compared between FDG-PET and CT. Finally, FDG-PET was analyzed semiquantitatively using the standard uptake value (SUV). The impact of the SUV on patient management was evaluated by examining the correlations between the SUV and the histological findings of cancer.

RESULTS: The sensitivity of FDG-PET, CT, cytological examination of the bile or pancreatic juice, and the serum levels of CEA and CA19-9 were 92.5%, 88.7%, 46.4%, 37.7% and 69.8%, respectively. In staging, FDG-PET was superior to CT only in diagnosing distant disease (bone metastasis). For local staging, the sensitivity of CT was better than that of FDG-PET. The SUV did not correlate with the pTNM stage, grades, invasions to the vessels and nerve, or with the size of the tumor. However, there was a statistically significant difference (4.6 ± 2.9 *vs* 7.8 ± 4.5, $P = 0.024$) in the SUV between patients with respectable and unresectable disease.

CONCLUSION: FDG-PET is thus considered to be useful in the diagnosis of pancreatic cancer. However, regarding the staging of the disease, FDG-PET is not considered to be a sufficiently accurate diagnostic modality. Although the SUV does not correlate with the patho-histological prognostic factors, it may be useful in selecting patients who should undergo subsequent surgical treatment.

INTRODUCTION

Today, despite advances in diagnosing modalities, most patients with pancreatic cancer are still unresectable at the time of diagnosis. Surgery remains the only potential for long-term survival, with a resectability rate of around 15%-20% in the latest review[1]. Even in patients with resectable disease, the 5-year survival rate is still around 20%[1-3]. For patients with unresectable disease, chemotherapy with or without radiation therapy is usually chosen, and the survival benefit of chemotherapy with Gemcitabine over 5-fluorouracil has recently been reported[4]. Clearly, an effort has to be made for diagnosing early stage cancer, also by determining its clinical stage and by accurately predicting the prognosis, thus avoiding unnecessary surgical explorations.

Recently, the advantages of positron emission tomography using 18F-fluorodeoxyglucose (FDG-PET) on diagnosing pancreatic cancer, especially small lesions less than 2 cm in size, over the conventional modalities, including computed tomography (CT), have been reported[2]. Furthermore, FDG-PET has also been reported to possibly play a role in predicting the prognosis of pancreatic cancer[2,5,6]. However, the significance of FDG-PET imaging in the management of pancreatic cancer, including diagnosis, staging, or

predicting prognosis, has not yet been established. In this study, we explored the role of FDG-PET in surgery for pancreatic cancer by examining its sensitivity in diagnosing and staging, and its potential for predicting prognosis by comparing the standard uptake value (SUV) and the histological findings.

MATERIALS AND METHODS

Patients

This study involved 53 patients with histologically (30 patients) or clinically (23 patients) proven primary pancreatic cancer who had undergone FDG-PET from January 2004 to January 2007. In clinically proven pancreatic cancer patients metastatic lesions were detected in the liver, lymph nodes, or the other organs, by the following up CT retrospectively, and the patients died of the primary pancreatic cancer. The patients' mean age was 70.1 years (range from 44 to 84 years). The patients consisted of 33 males and 20 females. The localisation of the cancer was in the head of the pancreas in 32 patients and in the body and tail in 21 patients. Twenty-eight patients presented with diabetes requiring insulin therapy. Among the 53 patients, 28 patients were diagnosed to be unresectable, and 25 patients eventually underwent surgery with a curative intention, although in 7 of them the cancer turned out to be unresectable because of the intraoperative findings.

Methods

The sensitivity of diagnosing pancreatic cancer was examined for FDG-PET, CT, cytological examination of the bile or pancreatic juice, and the serum levels of carcinoembrionic antigens (CEA) and carbohydrate antigen 19-9 (CA19-9). Next, the accuracy of staging of the disease and the impact on patient management was evaluated and compared between FDG-PET and CT. Finally, FDG-PET was analyzed semiquantitatively using the standard uptake value (SUV). In the patients who underwent surgery, a correlation was found between the preoperatively obtained SUV and the histological findings of the specimen in regard to the pathological stagings of cancer classified based on the UICC TNM classification (6th edition, 2002), histological differentiation, lymphatic invasions, vascular invasion, and intrapancreatic nerve invasion. The SUV was compared between the resectable and unresectable disease patient groups. A correlation between the SUV and the maximum diameter of the primary lesion, which was determined on CT, was examined. All of the studies were performed retrospectively by collecting and analyzing data from the patient records.

Cytological examination of the bile or pancreatic juice

The bile or pancreatic juice, which was collected from 28 patients after brushing endoscopic retrograde cholangiopancreatography (ERCP), was subjected to a cytological examination. This was performed using the Papanicolaou staining, and the diagnosis established according to the Papanicolaou classification. The results in Classes Ⅰ, Ⅱ, or Ⅲ were counted as negative in this study; the results in Classes Ⅳ or Ⅴ were counted as positive.

CT

For multidetector CT scans, a contrast enhancement was performed for each patient. Helical images of the abdomen were routinely obtained and reconstructed with 5 mm thickness. The CT images were interpreted independently and consecutively by two radiologists with extensive experience of more than 10 years in CT scanning. The findings of the CT scans were considered positive when both of the radiologists strongly suspected malignant disease due to a discrete low-attenuation mass within the pancreas, and/or involving the adjacent vessels, and/or swelling of the regional lymph nodes.

FDG-PET

The FDG-PET images were acquired with PET machine (Siemens EXACT HR+, CTI, Knoxville, TN, USA). The patients were required to fast for at least 4 h before PET imaging. One hour after the intravenous administration of 5 mCi of FDG, the emission images were acquired. The transmission images were acquired to correct for attenuation. The FDG-PET images were interpreted independently and consecutively by two radiologists with extensive experience in FDG-PET imaging. The findings were considered to be positive when both of the radiologists strongly suspected malignant disease. In addition, the images were analyzed semiquantitatively using the SUV, as reported elsewhere[7]. Briefly, regions of interest measuring 1.0 cm^2 were drawn over the area of maximum activity in a lesion. The SUV was calculated as follows:

SUV = (activity in region of interest in mCi)/(injected dose in mCi/weight in kg).

Statistical analysis

The chi-square test was employed for a statistical comparison of the sensitivity of FDG-PET and CT. The Student's *t* test was used to compare the values of the SUV between the two groups. Finally, correlations between the SUV and the maximum diameter of the primary lesion determined on CT were examined by the Pearson's correlation test. All statistical analyses were performed using the SPSS software program (SPSS, Chicago, USA). A P value < 0.05 was considered statistically significant.

RESULTS

Sensitivity for diagnosing pancreatic cancer

The sensitivity of FDG-PET, CT, cytological examination of the bile or pancreatic juice, and the serum levels of CEA and CA19-9 were 92.5% (49/53), 88.7% (47/53), 46.4% (13/28), 37.7% (20/53) and 69.8% (37/53), respectively.

Sensitivity for preoperative staging

Among the 53 patients, 28 patients were diagnosed to be unresectable based on the following preoperative imaging findings: invasion to major arteries such as the supramesenteric artery, celiac trunks, or common hepatic artery in 9 patients, para-aortic lymph node metastasis in 12 patients, detection of hepatic metastasis in 14 patients,

Table 1 Histological findings of the patients

Histological findings			Number of patients	SUV (mean ± SD)	Difference
Pathological stage (TNM)					
pT	pN	stage			
1	0	ⅠA	1	3.59	
1	1	ⅠB	1	3.14	
3	0	ⅡA	8	4.1 ± 0.9	NS
1, 2, 3	1	ⅡB	8	5.9 ± 4.5	
Histological differentiation					
Well			7	3.7 ± 0.7	NS
Moderately-poorly			11	5.6 ± 3.6	
Lymphatic invasions					
Negative			9	5.3 ± 3.9	NS
Positive			9	4.5 ± 2.1	
Venous invasions					
Negative			6	6.2 ± 5.1	NS
Positive			12	4.4 ± 1.9	
Intrapancreatic nerve invasions					
Negative			11	4.8 ± 3.5	NS
Positive			7	5.1 ± 2.3	

SUV: Standard uptake value; NS: Not significant.

detection of bone metastasis in 7 patients, strongly suspected peritoneal dissemination in 5 patients, general complications associated with aging in 4 patients. Among the 25 patients who eventually underwent surgery with a curative intention, the cancer turned out to be unresectable in 7 of them because of the following intraoperative findings: detection of hepatic metastasis (5 to 8 mm in diameter) in 5 patients, histologically confirmed metastases in the para-aortic lymph node (less than 1 cm in diameter) in 2 patients, and cytologically positive ascites in 2 patients. Therefore, the staging diagnostic sensitivity of FDG-PET and CT was 2/9 (22.2%) and 9/9 (100%) for invasion into the major arteries, 8/14 (57.1%) and 11/14 (78.6%) for para-aortic regional lymph nodes metastases, 10/19 (52.6%) and 14/19 (73.7%) for hepatic metastases, 8/8 (100%) and 1/8 (12.5%) for bone metastases, 3/7 (42.9%) and 4/7 (57.1%) for peritoneal dissemination, respectively. There was a statistically significant difference in the sensitivity detecting invasion into the major arteries ($P = 0.001$) and bone metastases ($P = 0.001$), based on the chi-square test.

Correlation between the SUV and histological findings

In 18 patients, a surgical resection with a lymphadenectomy was performed. A pancreaticoduodenectomy was performed in 11 patients, while a distal pancreatectomy was performed in 7 patients. In these patients, a pathohistological examination was performed. As Table 1 shows, no statistically significant difference was found in any of the histological findings listed in Table 1.

Comparison of SUV between resectable and unresectable disease

As Figure 1 shows, the SUV of the primary lesion was 4.6 ± 2.9 (mean ± SD) in the resectable disease cases, while it was 7.8 ± 4.5 in the unresectable cases, with a statistically significant difference ($P = 0.024$) by the Student's *t*-test. On the other hand, the maximum diameter of the primary lesion measured on CT was 27.9 ± 10.9 mm in the resectable cases, and 40.5 ± 21.4 mm in the unresectable ones ($P = 0.053$). Furthermore, we found no correlation between the SUV and the maximum diameter of the primary lesion measured on CT by using Pearson's correlation test ($P = 0.274$), as shown in Figure 2.

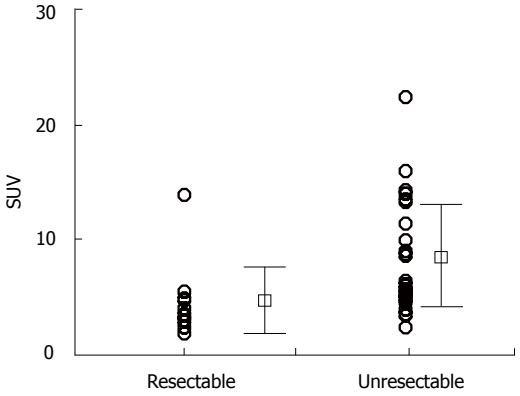

Figure 1 Comparison of the SUV of the primary lesion between patients with resectable and unresectable disease. SUV: Standard uptake value.

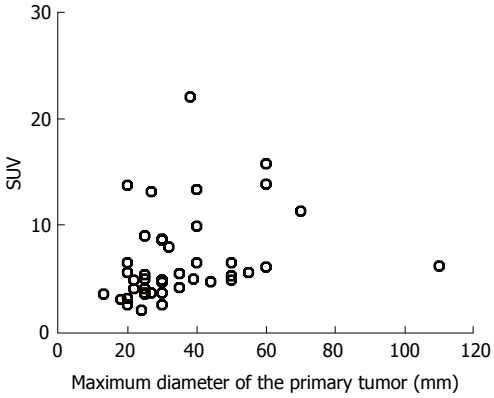

Figure 2 Relationship between the SUV and the maximum diameter of the primary lesion.

DISCUSSION

Pancreatic cancer is one of the most lethal human cancers and it continues to be a major unsolved health problem worldwide. Despite efforts in the past 50 years, conventional treatment approaches, such as surgery, radiation, chemotherapy, or combination of these, have had little impact on the course of this aggressive neoplasm[1]. Although recent progress in systemic chemotherapy has been reported[8], surgery remains the only hope for long-term survival[9]. In surgery for pancreatic cancer, a great deal of effort has been made to expand the resection with an extended lymphadenectomy in order to improve the outcome[10]. However, only patients with localized disease and a tumor size less than 2 cm with no lymph node metastases can expect long-term survival after surgery[1,2,11]. Therefore, increased efforts should be focusing not only on diagnosing the early stage disease, but also on staging and predicting prognosis so that unnecessary surgical exploration may be avoided.

Recently, PET has been reported to have superiority to CT, US, and EUS in its sensitivity and specificity in diagnosing pancreatic cancer[2,12]. Furthermore, regarding the role of PET in diagnosing the disease, the metabolic activity of the tumor may be of prognostic significance[5,6]. However, the role of PET in the management of pancreatic cancer has yet to be established.

The role of FDG-PET in diagnosis of primary cancer

The sensitivity of FDG-PET was 92.5%, and it was better than that of CT, cytological examinations of the bile or pancreatic juice, and the serum levels of CEA and CA19-9. Our findings also correlate with those of previous reports, in which the sensitivity of FDG-PET, CT, and US has been reported to be 94%, 89%, and 89%, respectively[12]. On the other hand, in another study, the sensitivity of FDG-PET was found to be lower than or equal to CT[13-15] and these findings thus remain controversial. In particular, when a multidetector CT is performed routinely with thin sections (1 mm), the sensitivity of the CT may further improve[2]. This study was conducted among patients with the histologically or clinically proven pancreatic cancer, and therefore the specificity was not evaluated.

The role of FDG-PET in staging of the disease

This study showed that, as far as staging is considered, FDG-PET was superior to CT only in diagnosing distant disease. On the other hand for local staging the sensitivity of CT was better than that of FDG-PET. As described[2], the poor spatial resolution of FDG-PET limits the local staging of pancreatic cancer. Therefore, the anatomical imaging modalities with CT are better suited to demonstrate the relationship of the tumor, adjacent organs, and vascular structure.

In the nodal staging of the disease, there was no difference between FDG-PET and CT, since both performed poorly. The reported sensitivities of FDG-PET have varied between 46% and 71%[2,16]; thus the results of this study are considered to correlate with these previous reports. It has been said that one possible reason for the apparent low sensitivity of FDG-PET is the close proximity of the peripancreatic and paraaortic lymph node basins to the primary tumor, which can obscure their detection[2,16].

The important impact of FDG-PET on staging has been in its ability to identify distant metastases[17]. According to the previous reports[18], the sensitivity of FDG-PET for detecting hepatic metastases is about 70%, while that of this study was 52.6%. In particular, small lesions less than 1 cm could not be detected. It has also been reported that the sensitivity for lesions less than or greater than 1 cm is 43% and 97%, respectively[19]. Direct spread into the peritoneum is also not uncommon and often is missed on conventional imaging. However, in this study, both FDG-PET and CT failed to demonstrate a high degree of accuracy in these diagnostic analyses.

The prognostic significance of FDG-PET

Some researchers have shown the SUV in FDG-PET to be an independent prognostic factor in a subpopulation of patients with pancreatic cancer. Nakata *et al*[5] showed that in patients with unresectable disease, a high SUV correlated with a shorter survival. Maemura *et al*[20] reported that pancreatic tumors with distant metastasis showed significantly higher SUV levels than tumors without metastasis. Sperti *et al*[6] also demonstrated that a high SUV (> 4.0) was associated with shorter survival. For prognostic factors for pancreatic cancer, the tumor stage and grade[21], R0 resection[21], levels of serum tumor marker[22], size of the primary lesion[3], and status of nodes metastases[3,11], have been reported. On the other hand, the increased glycolytic activity of the tumor detected by the SUV may represent tumor growth and also resemble the tumor's biological behavior[23-25]. Therefore, in this study we examined the correlation between the SUV and the patho-histological findings. The results were that the SUV did not correlate with the pTNM stage, grades, invasions to the vessels and nerve, or size of the tumor. Sperti *et al*[6] also found no difference between a high SUV (> 4.0) and a low SUV patients group in regard with TNM staging and histological grading, as shown in this study. Nevertheless, they found SUV to be an independent prognostic factor in patients with pancreatic cancer, and therefore advocated that the different biological aggressiveness of the tumor, detected by the SUV, might explain the difference in survival in patients with otherwise similar prognostic valuables. In the present study, there was a statistically significant difference in the SUV between the patients with resectable and unresectable disease. This may support the findings of previous reports which describe the SUV to be an independent prognostic factor. Therefore, although in staging FDG-PET did not perform precisely enough except for detecting bone metastases, by evaluating the SUV, FDG-PET may provide such additional information on the biological aggressiveness of the tumor, and thus play an important role in helping to select patients for subsequent surgical therapy. Some small studies reported that the tumor SUVs were useful in predicting the effectiveness of chemotherapy for unresectable pancreatic cancer[17,26,27]. However, conclusions must await further studies including larger population of patients.

In conclusion, FDG-PET was found to be useful for diagnosing pancreatic cancer. However, in staging of the disease, FDG-PET does not perform precisely enough. Although the SUV does not correlate with the patho-histological prognostic factors, it may be useful in selecting patients who should undergo the subsequent surgical treatment. Therefore, FDG-PET may play an important role in the decision making process and surgical management for patients with pancreatic cancer. However, this study suffers from the limitation of a small population of patients. Therefore, a definite conclusion may have to wait for further studies involving a larger population of patients. Furthermore, the use of image fusion with PET/CT[28,29] or with PET/MRI[30] may improve the accuracy when staging pancreatic cancer.

COMMENTS

Background

Pancreatic cancer is one of the most lethal human cancers and it continues to be a major unsolved health problem worldwide. Only patients with localized disease and

a tumor size less than 2 cm with no lymph node metastases can expect long-term survival after surgery. Therefore, increased efforts should be focusing not only on diagnosing the early stage disease, but also on staging and predicting prognosis so that unnecessary surgical exploration may be avoided. Recently, positron emission tomography (PET) has been reported to be superior to computed tomography (CT), ultrasound (US), and endoscopic US (EUS) in its sensitivity and specificity in diagnosing pancreatic cancer. Furthermore, the metabolic activity of the tumor evaluated by uptake value of fluorodeoxyglucose (FDG) (standardized uptake value: SUV) may be of prognostic significance. However, the role of PET in the management of pancreatic cancer has yet to be established.

Research frontiers

As is described above, pancreatic cancer is one of the most lethal human cancers and it continues to be a major unsolved health problem worldwide. Despite efforts in the past 50 years, conventional treatment approaches, such as surgery, radiation, chemotherapy, or combination of these, have had little impact on the course of this aggressive neoplasm. Although recent progress in systemic chemotherapy has been reported, surgery remains the only hope for long-term survival. In surgery for pancreatic cancer, a great deal of effort has been made to expand the resection with an extended lymphadenectomy in order to improve the outcome. However, only patients with localized disease and a tumor size less than 2 cm with no lymph node metastases can expect long-term survival after surgery. Therefore, breakthrough for pancreatic cancer may be achieved in diagnosing an early stage disease.

Innovations and breakthroughs

The present study showed that FDG-PET was useful for diagnosing pancreatic cancer. However, in staging of the disease, FDG-PET does not perform precisely enough. Although the SUV does not correlate with the patho-histological prognostic factors, it may be useful in selecting patients who should undergo the subsequent surgical treatment. Therefore, FDG-PET may play an important role in the decision making process and surgical management for patients with pancreatic cancer.

Applications

By using FDG-PET in combination with conventional diagnostic modalities, such as computed tomography (CT), ultrasound, magnetic resonance imaging, and endoscopic pancreatography, the ability to diagnose the early stage pancreatic cancer, or to select candidates for surgery can be improved. At the same time, as the increased glycolytic activity of the tumor detected by SUV may represent tumor growth and resemble the tumor biological behavior, the SUV may provide additional information on the biological aggressiveness of the tumor.

Terminology

FDG-PET: 18F-fluorodeoxyglucose (FDG) is a positron-emitting radio-tracer that is transported intracellularly *via* glucose transporters which are highly expressed in various cancer cells, then FDG is phosphorylated by hexokinase to FDG-6-PO4. However, further metabolism of FDG-6-PO4 is not possible in the neoplastic cells due to insufficient phosphatase levels and tracer accumulation. Therefore, FDG-PET can image cancer cells based on such specific tissue metabolism. SUV: To perform a quantitative analysis for accumulation of FDG, the standardized uptake value (SUV) is calculated in the suspected neoplastic foci. The SUV was calculated as follows:

SUV = (activity in region of interest in mCi)/(injected dose in mCi/weight in kg).

Peer review

This is a good clinical research on the diagnosis, staging and choice of operation in patients with pancreatic carcinoma.

Abstract

AIM: To disclose geographic differences in genetic changes involved in gallbladder carcinogenesis between two distinct high-incidence areas of Japan and Hungary.

METHODS: We examined 42 cases of gallbladder carcinoma: 22 Japanese and 20 Hungarian cases. *p53* mutations at exons 5 to 8 and K-*ras* mutations at codon 12 were tested by direct sequencing. Microsatellite instability was determined from fluorescent dye-labeled PCR amplifications of five-microsatellite markers (*BAT-25*, *BAT-26*, *D2S123*, *D5S346*, and *D17S250*).

RESULTS: Mutations of *p53* were detected in 11 of 22 Japanese cases and 6 of 18 Hungarian cases (11/22 *vs* 6/18, $P = 0.348$). Transition at CpG sites was found in none of 11 Japanese cases and 2 of 6 Hungarian cases; the difference was marginally significant (0/11 *vs* 2/6, $P = 0.110$). K-*ras* mutations were detected in only one of the Hungarian cases. Eight of 19 (42.1%) Japanese cases were MSI-high (presence of novel peaks in more than one of the five loci analyzed), whereas only 1 of 15 (6.7%) Hungarian cases was MSI-high ($P = 0.047$).

CONCLUSION: It appears that the *p53* mutations and MSI differ in patients with gallbladder carcinoma between two distinct high-incidence areas. Geographic variation might exist in the process of gallbladder carcinogenesis.

INTRODUCTION

Although considerable progress has been made regarding the molecular pathogenesis of human neoplasms such as colorectal carcinoma[1,2], pancreatic carcinoma[3,4], and breast carcinoma[5,6], there is only limited information about the genetic changes involved in gallbladder carcinogenesis[7,8]. Gallbladder carcinoma shows striking geographic and ethnic variation[9,10]. The high-incidence areas are scattered throughout the world: Latin America, Eastern Europe, northern India, and Japan[9-13]. The highest mortality rate of gallbladder carcinoma in the world, 35 per 100 000 inhabitants, is found in Southern Chile[9]. Japanese standardized mortality rates for gallbladder carcinoma were world's second highest for males and fifth highest for females in 1996 with a steady increase in incidence (up to 5 per 100 000)[9,10,14]. On the other hand,

Zatonski reported that Hungarian mortality rates of this tumor were the highest in Europe (4 per 100 000 males and 7 per 100 000 females)[13]. This marked geographic variation implies that a combination of genetic and environmental etiologic factors affects the process of carcinogenesis of the gallbladder[10]. Previously, we revealed the geographic variation of gallbladder carcinogenesis between Japan and Chile (a representative of Latin American countries), both of which were known as distinct high-incidence countries, in terms of the *p53* mutational spectra[14]. Only a few other investigators also have reported such geographic and ethnic differences in genetic changes of this tumor[15-17]. Thus, there has been a paucity of evidence regarding the geographic diversity of genetic changes involved in gallbladder carcinogenesis.

The aim of this study was to disclose geographic differences in genetic changes involved in gallbladder carcinogenesis by comparing gallbladder carcinomas from two distinct high-incidence areas, Japan and Hungary (a representative country of Eastern Europe), in terms of *p53* mutations, K-ras mutations, and microsatellite instability (MSI).

MATERIALS AND METHODS

Tissue specimens

From 1982 to 1996, 22 patients with gallbladder carcinoma underwent a resection at Niigata University General Hospital and its affiliated institutions in Niigata Prefecture; the surgical specimens were collected and stored (Japanese cases). All the patients were Japanese. The Japanese cases in this study were identical with the Japanese cases in our previous study[14]. From 1982 to 2001, 20 patients with gallbladder carcinoma underwent a resection in hospitals in Budapest, Hungary; the surgical specimens were collected and stored (Hungarian cases) through the courtesy of a Hungarian oncologist (I.L.) and surgical pathologist (Z.S.). All the patients were residents in Budapest. Both the Japanese cases and the Hungarian cases (a total of 42 cases) formed the basis of this retrospective study. All of the patients gave informed consent for pathologically examining the specimens. No patient in this series was diagnosed with anomalous union of the pancreatic and biliary ducts (AUPBD), and had a family history suggestive of hereditary nonpolyposis colorectal cancer (HNPCC).

The surgical specimens were fixed in formalin and embedded in paraffin. One or two representative sections of each specimen were used for DNA analysis. Histopathological findings were described according to the tumor-node-metastasis (TNM) staging system[18].

DNA preparation

Five serial slices 10-μm thick were cut from each representative histologic section and deparaffinized. Cancer tissue in each slice was dissected under microscopic guidance as described previously[14]. Non-neoplastic tissue in each slice was used as a source of constitutional DNA. DNA was extracted using a DNA Isolator PS Kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan) as described previously[14].

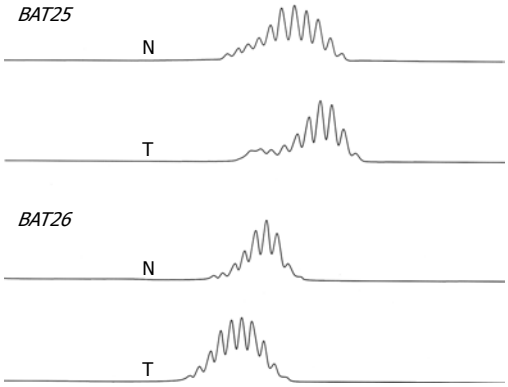

Figure 1 Fragment pattern of case No 1 (Table 1) showing microsatellite instability at two loci (*BAT25*, *BAT26*). N: Normal DNA; T: Tumor DNA.

Analysis of p53 mutations

p53 mutations at exons 5 to 8 were tested by nested polymerase chain reaction (PCR) and direct sequencing as described previously[14].

Analysis of K-ras mutations

K-*ras* mutations at codon 12 were tested by nested PCR, PCR-restriction fragment length polymorphism, and direct sequencing as described elsewhere[19].

Analysis of MSI

Fluorescent dye-labeled PCR amplification was performed using the five microsatellite markers (*BAT-25*, *BAT-26*, *D2S123*, *D5S346*, and *D17S250*) recommended by the National Cancer Institute workshop[20,21]. Fluorescent dye-labeled and unlabeled primers were obtained (Applied Biosystems Japan Ltd., Tokyo, Japan); the 5' oligonucleotide was end-labeled with 6FAM (*BAT-25*, *D2S123*), VIC (*BAT-26*, *D17S250*), or NED (*D5S346*) fluorescent dyes. Amplification by PCR was performed using the Temp Control System PC-700 (ASTEC Co., Ltd., Fukuoka, Japan) in 30-μL reaction volumes containing 100 ng of DNA, 0.75 U of AmpliTaq Gold (Applied Biosystems Japan Ltd.), and 10 pmol of each primer. The cycling profile was: denaturation at 95℃ for 2 min, annealing at 55℃ for 40 s and extension at 72℃ for 40 s followed by a 7-min final extension step. A 1.0-μL aliquot of each fluorescent dye-labeled PCR product was combined with 12 μL of formamide and 0.5 μL of the GENESCAN 350 [ROX] size standard (Applied Biosystems Japan Ltd.) and analyzed on an ABI PRISM 310 Genetic Analyzer using GeneScan Analysis Software (Applied Biosystems Japan Ltd.). MSI experiments were repeated twice to exclude the possibility of a false positive result due to PCR amplification artifacts in an independent PCR reaction. The sequencing results were verified by a second independently generated PCR product.

The presence of MSI was determined from the PCR amplifications of the five-microsatellite markers. Microsatellite instability was defined as the presence of novel peaks that were not found in non-neoplastic tissue (Figure 1). A tumor was defined as having high microsatellite instability (MSI-high) if more than one of

the five loci analyzed showed unequivocal instabilities; a tumor was defined as having low microsatellite instability (MSI-low) if only one locus showed instability; and a tumor was defined as microsatellite stable if no microsatellite instability was found. In this study, MSI-low tumors and microsatellite-stable tumors were categorized together into one group (MSI-low/none), as proposed by recent authors[16,22].

Statistical analysis

Fisher's exact test was used to compare the frequencies of genetic alterations between the two groups. All statistical evaluations were performed using the SPSS 11.5J software package (SPSS Japan Inc., Tokyo, Japan). All tests were two-sided and a P value < 0.05 was considered statistically significant.

RESULTS

p53 mutation

Mutations of *p53* at exons 5 to 8 were detected in 11 of 22 (50.0%) Japanese cases and 6 of 18 (33.3%) Hungarian cases ($P = 0.348$; Table 1). Among the 17 cases with *p53* mutations, transversion was found in 4 of 11 Japanese cases and 1 of 6 Hungarian cases ($P = 0.600$). Transition at CpG sites was found in none of 11 Japanese cases and 2 of 6 Hungarian cases; the difference was marginally significant ($P = 0.110$).

K-ras mutation

K-*ras* mutations at codon 12 were detected in none of 22 Japanese cases and 1 of 20 Hungarian cases ($P = 0.476$) (Table 1).

MSI

Eight of 19 (42.1%) Japanese cases were MSI-high, whereas only one of 15 (6.7%) Hungarian cases was MSI-high; the difference was statistically significant ($P = 0.047$; Table 1).

Association between p53 mutation and MSI in gallbladder carcinoma

Both *p53* mutation and MSI were analyzed successfully in 34 cases: 19 Japanese cases and 15 Hungarian cases (Table 1). When the cases were stratified into Japanese cases and Hungarian cases, *p53* mutations were not associated significantly with MSI in both groups. In all 34 cases, *p53* mutations were associated significantly with MSI (Table 2; $P = 0.033$).

DISCUSSION

Although earlier epidemiologic studies have suggested that the incidence of gallbladder carcinoma varies geographically or ethnically[9,10], there is a paucity of evidence regarding the geographic diversity of molecular changes associated with this tumor[7,8]. This prompted us to conduct the current study. In 1998, we reported that the *p53* mutational spectra of gallbladder carcinoma differed considerably between Japan and Chile, both of which were known as high-incidence countries[14]. The current study first demonstrates that the process of gallbladder carcinogenesis differs in terms of *p53* mutations and microsatellite instability between two distinct high-incidence areas: Japan and Hungary (a representative country of Eastern Europe).

Reported prevalences of *p53* mutation for gallbladder carcinoma ranged from 31% to 70%[14,23-26], suggesting that *p53* mutation plays an important role in the development of this tumor[8]. The prevalences of *p53* mutation in this series (50% in Japanese cases and 33% in Hungarian cases) are comparable with the reported figures. In various malignancies, endogenous carcinogenesis is characterized by transitions at CpG sites, whereas transversions imply the presence of an exogenous mutational process[27-29]. In our previous study, the prevalence of transitions at CpG sites was significantly higher in the Chilean cases than in the Japanese cases[14]. In the current study, there was a trend toward a higher prevalence of transitions at CpG sites in the Hungarian cases. Taken together, these observations suggest that an endogenous mutational process contributed considerably to carcinogenesis of the gallbladder in the Chilean and Hungarian cases. In contrast, considering that there were no transitions at CpG sites and four transversions in the Japanese cases, it appears that exogenous mutations often happen during the process of carcinogenesis in the Japanese cases. Therefore, geographic variation might exist in carcinogenesis of the gallbladder among three distinct areas.

Reported prevalences of K-*ras* mutation for gallbladder carcinoma without AUPBD ranged from 0% to 17%[16,30-33], suggesting that frequency of K-*ras* mutation is relatively low in gallbladder carcinoma without AUPBD. This is consistent with our results: K-*ras* mutation was found in only one of the Hungarian cases. Taken together, most gallbladder carcinoma appears to develop from a K-*ras*-independent pathway.

Microsatellite instability, which represents replication errors, results from DNA mismatches due to environmental or hereditary factors and leads to genomic instability[34,35]. Reported prevalences of MSI-high for sporadic gallbladder carcinoma range from 0% to 10%[15,16,36-38], whereas the prevalence was high (42.1%) in our cases. This suggests that environmental or hereditary factors contribute to carcinogenesis of the gallbladder in some of our cases. In the current study, the prevalence of MSI-high was significantly higher in the Japanese cases than in the Hungarian cases. Considering that there were no patients with HNPCC in this series, the above finding suggests that the high prevalence of MSI-high in the Japanese cases may be due to environmental factors, which remain unknown.

There are inverse relationships between *p53* mutations and MSI in colorectal cancer[39,40]. Regarding gallbladder carcinoma, earlier authors have failed to identify such relationships between *p53* mutations and MSI[16,38]. In this study, *p53* mutations were associated significantly with MSI in all cases. When the cases were stratified into Japanese cases and Hungarian cases, no such associations between *p53* mutation and MSI were found, probably due to the small sample size. Taken together, the above observations suggest that the pathway of carcinogenesis differs between the gallbladder and the colon and rectum.

The current study has limitations. Firstly, it was a

retrospective analysis of a small number of patients. Secondly, DNA preparation from paraffin-embedded tissue sections was unsuccessful in some patients. Thirdly, only limited clinical information was available in the Hungarian cases to protect the patients' privacy. To our knowledge, however, this study demonstrates more clearly the geographic diversity of gallbladder carcinogenesis than earlier reports[15-17].

In conclusion, it appears that the *p53* mutations and MSI differ in patients with gallbladder carcinoma between two distinct high-incidence areas. Exogenous mutations

and unknown environmental factors may play roles in gallbladder carcinogenesis in the Japanese cases, whereas the Hungarian cases are characterized by an endogenous mutational process. Thus, geographic variation might exist in the process of gallbladder carcinogenesis.

COMMENTS

Background

Although considerable progress has been made regarding the molecular pathogenesis of human neoplasms, there is only limited information about the genetic changes involved in gallbladder carcinogenesis. Gallbladder carcinoma shows striking geographic and ethnic variation, however there is a paucity of evidence regarding the geographic diversity of molecular changes associated with this tumor.

Research frontiers

In 1998, we reported that the *p53* mutational spectra of gallbladder carcinoma differed considerably between Japan and Chile, both of which were known as high-incidence countries. Only a few other investigators also have reported such geographic and ethnic differences in genetic changes of this tumor. The aim of this study was to disclose geographic differences in genetic changes involved in gallbladder carcinogenesis by comparing gallbladder carcinomas from two distinct high-incidence areas, Japan and Hungary.

Innovations and breakthroughs

The current study first demonstrates that the *p53* mutations and MSI differ in patients with gallbladder carcinoma between two distinct high-incidence areas: Japan and Hungary. Exogenous mutations and unknown environmental factors may play roles in gallbladder carcinogenesis in the Japanese cases, whereas the Hungarian cases are characterized by an endogenous mutational process. Thus, geographic variation might exist in the process of gallbladder carcinogenesis.

Applications

Gallbladder carcinoma is a highly lethal disease with a poor prognosis. Therefore, it would be very beneficial to identify the molecular mechanism responsible for this condition. Advances in the understanding of the genetic changes of this tumor will help in understanding the pathogenesis of this miserable disease.

Terminology

Microsatellite instability (MSI) is caused by a failure of the DNA mismatch repair system to repair errors that occur during the replication of DNA and is characterized by the accelerated accumulation of single nucleotide mutations and alterations in the length of simple, repetitive microsatellite sequences that occur ubiquitously throughout the genome. MSI is seen in most HNPCC tumors and proportion of nonhereditary colorectal tumors. The presence of MSI in tumor tissue is associated with certain unique clinical and pathological characteristics.

Peer review

This study aimed to determine the difference of some genetic changes involved in gallbladder carcinogenesis in high-prevalence areas of Japan and Hungary. This is a well written paper and has a nice finding. While it is simply an observational study, I think it is an important observation.

Abstract

AIM: To evaluate role of midkine secretion during Cadmium (Cd) exposure in the human hepatocyte cell line Hep3B cells.

METHODS: Different dosages of Cd (0.5-1-5-10 μg/mL) were applied to Hep3B cells and their effects to apoptosis, lactate dehydrogenase (LDH) leakage and midkine secretion were evaluated as time dependent manner. Same experiments were repeated with exogenously applied midkine (250-5000 pg/mL) and/or 5 μg/mL Cd.

RESULTS: Cd exposure induced prominent apoptosis and LDH leakage beginning from lower dosages at the 48th h. Cd induced midkine secretion with higher dosages (P < 0.001), (control, Cd 0.5-1-5-10 μg/mL respectively: 1123 ± 73, 1157 ± 63, 1242 ± 90, 1886 ± 175, 1712 ± 166 pg/mL). Exogenous 500-5000 pg/mL midkine application during 5 μg/mL Cd toxicity prevented caspase-3 activation (control, Cd toxicity, 250, 500, 1000, 2500, 5000 pg/mL midkine+ Cd toxicity, respectively: 374 ± 64, 1786 ± 156, 1545 ± 179, 1203 ± 113, 974 ± 116, 646 ± 56, 556 ± 63 cfu) LDH leakage and cell death in Hep3B cells (P < 0.001).

CONCLUSION: Our results showed that midkine secretion from Hep3B cells during Cd exposure protects liver cells from Cd induced cellular damage. Midkine has anti-apoptotic and cytoprotective role during Cd toxicity. Further studies are needed to explain the mechanism of midkine secretion and cytoprotective role of midkine during Cd exposure. Midkine may be a promising therapeutic agent in different toxic hepatic diseases.

INTRODUCTION

Cadmium (Cd) exposure occurs widely in the general population, especially low-level chronic exposure through smoking and dietary sources, but it is known as one of the most toxic environmental and industrial pollutants. Cd accumulates in the body because of slow excretion[1]. Cd causes toxicity in different organs. Acute and chronic Cd exposure mostly results in hepatotoxicity[2]. It seems that the level of damage depends on the dosage and duration of Cd application. Exposure of cells to toxic chemicals is known to up-regulate the expression of a number of stress proteins and results in activation of apoptotic pathways and consequently cellular damage. *In vivo* and *in vitro* studies showed that inflammation and oxidative damage are main mechanisms of Cd induced toxicity[3-6]. Cd induces mitochondria-dependent apoptotic pathways where caspase-3 and caspase-9 are activated[7].

Midkine is a heparin binding growth factor. It takes part in cancer and inflammation[8]. Although midkine is a mitogenic factor during carcinogenesis, it plays a critical role in ischemia induced inflammatory damage[9]. It was demonstrated that midkine acts as an antiapoptotic factor in HepG2 cells; furthermore, midkine suppressed the activity of caspase-3, which plays a significant role in the apoptotic pathway. Pretreatment with midkine prevents tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) mediated apoptosis in the HepG2 cells[10]. TRAIL alone triggered massive apoptosis accompanied by caspase activation in tissue explants from patients with liver steatosis or hepatitis C viral

infection[11]. TNF-alpha, released from nonparenchymal cells as well as associated cytokines, are responsible for clinical expression and tissue damage observed with cadmium-induced hepatotoxicity[12]. It was shown that midkine expression was upregulated in a marine gastropod limpet patella caerulea after they were exposed to sublethal doses of Cd[13]. But, whether midkine takes part in Cd induced mechanisms in human cells is still unknown. In this study we aimed to evaluate effects of Cd induced midkine secretion in the human hepatocyte cell line Hep3B cells, and its effects to cellular proliferation, apoptosis and biochemical parameter of cellular integrity during Cd exposure.

MATERIALS AND METHODS

Cell lines, chemicals and materials

Human hepatoma cell line Hep3B cells were obtained from the ATCC. Cells were cultured in Roswell Park Memorial Institute (RPMI)-1640 medium (PAA, Austuria), supplemented with fetal calf serum (FCS), (PAA, Austuria), L-glutamine (Sigma, USA), streptomycin (Sigma, USA) and penicillin (Sigma, USA). Cadmium ($CdCl_2$, Sigma Chemical Co., St. Louis, MO, USA) was dissolved in water, sterilized by 0.22 μm pore size cellulose acetate membrane filters, and added to cultures at the indicated time and concentrations. $CdCl_2$ toxicity was studied in Hep3B cell line. Human recombinant midkine was obtained from Peprotech (UK). Cell counts were tested by 3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyltetrazolium bromide (MTT, Sigma, USA). For evaluation of apoptosis caspase-3 levels were measured by a flourometric kit (Biotium, USA). Lactate Dehydrogenase (LDH) level was measured with a kit using an automatic multianalyzer (Roche; P800). Midkine levels were measured by an ELISA development kit (Peprotech,UK).

Cell culture and experimental protocol

The human hepatoma cell line Hep3B was cultured in RPMI-1640 medium, supplemented with 10% v/v fetal calf serum, 2 mmol/L L-glutamine, streptomycin (100 μg/mL) and penicillin (100 IU/mL) in a humidified atmosphere containing 5% CO_2 at 37℃. One day before the experiments, cells were seeded on 96-well microtitre plates (Nunc, Denmark) at 2×10^5 cells/mL.

Depending on the groups, different concentrations of cadmium (0.5-1-5-10 μg/mL) and midkine (250, 500, 1000, 2500, 5000 pg/mL) were added to medium for 48 h. For evaluation of the effects of midkine during cadmium toxicity; cadmium was used at a dosage of 5 μg/mL. $n = 6$, for every experimental group.

LDH and caspase-3 levels were evaluated from cadmium and/or midkine treated cells at the 48th h. MTT was measured at the 2nd, 24th and 48th h. Midkine was measured from supernatants. After supernatants were removed cell surface was washed with sterile phosphate buffered saline (PBS) and cells were harvested with lysis solution and caspase-3 levels of groups were measured from cell lysates. LDH measurement was done from both of the supernatant and cell lysates.

Evaluation of cellular proliferation or death

MTT, a colorimetric assay based upon the ability of living cells to reduce MTT into formazan, was used for evaluation of the effects of dose and time dependent effects of cadmium and midkine on cellular death or proliferation (2nd, 24th, 48th h). Cell number % was calculated as ratio of cell number of effected group *vs* control group × 100 at the determined hour.

Biochemical determination of cell death

Hep3B cells were plated in 96 multiwell cell culture plates as 3×10^5 cells/mL. LDH is normally present in the cytosol of hepatocytes. In response to cell damage LDH is released from the cells. Therefore, to determine cell death, we measured secreted and intracellular LDH levels and calculated % released LDH at the 48th h for each group. To do this, the medium was collected to measure enzyme activities. The adherent cells were lysed. Both medium and cell lysates were used for quantitative determination of LDH activity (IU/L) which was performed with an automatic multianalyzer (Roche) using a kit (Roche). Released enzyme fractions for each sample were calculated as the ratio of enzyme present in the medium *vs* the sum of the levels of same enzyme in the supernatant and in the cells.

Measurement of apoptosis

Caspase-3 levels: The presence of apoptosis was determined by caspase-3 levels. Equal numbers of cells were used for caspase-3 level measurements. Cells were lysed with assay buffer (50 mmol/L HEPES, pH 7.4, 100 mmol/L NaCl, 0.1% CHAPS, 10 mmol/LM DTT, 2 mmol/L EDTA, 2 mmol/L EGTA, Triton X-100, 0.1%). Caspase-3 levels were measured by DEVD-R110 Fluorometric HTS Assay Kit from cell lysates. The fluorogenic substrate $(Ac\text{-}DEVD)_2$-R110 was used for this assay. It is completely hydrolyzed by the enzyme in two successive steps. Cleavage of the first DEVD peptide results in the monopeptide Ac-DEVD-R110 intermediate, which has absorption and emission wavelengths similar to those of R110 ($\lambda_{abs}/\lambda_{abs}$ = 496/520 nm), but has only about 10% the fluorescence of the latter. Hydrolysis of the second DEVD peptide releases the dye R110, leading to a substantial fluorescence increase.

Equal volumes of sample and caspase-3 detection buffer were added to assay plate, and then incubated at 37℃ for 1 h in an incubator. Results were read with a fluorometer at 470 nm excitation filter and 520 nm emission filters. R110 was used for generating a standard curve to calculate amount of substrate conversion.

Statistical analysis

Results of the experiments were analyzed by One Way ANOVA, followed by a multiple comparison test using SPSS 10.0. $P < 0.05$ was accepted as statistically significant. Results were given as mean ± SEM.

RESULTS

Cell proliferation and toxicity

We characterized the concentration-dependent cytotoxic effect of Cd on human hepatocyte cell line as a function of time. Cadmium exposure decreased living cell number depending on the dosage. Minimal cytotoxic (< 5%) effect was seen at the 0.5 μg/mL dosage. As shown in Figure 1,

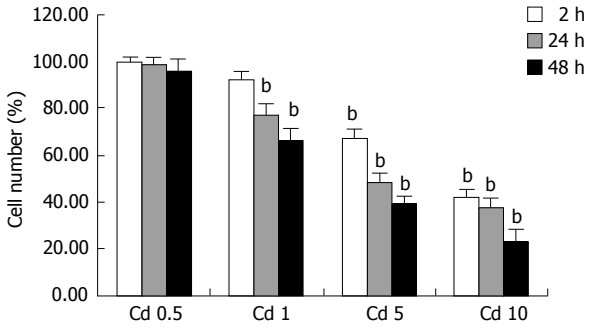

Figure 1 Cell death (%) was determined at 2nd, 24th and 48th h by the MTT assay. Cd exposure induced prominent cell death in Hep3B hepatocytes with dose and time dependent manner. Data are from 6 independent experiments for each condition. Data are presented as mean ± SEM. $^bP < 0.001$ *vs* control group.

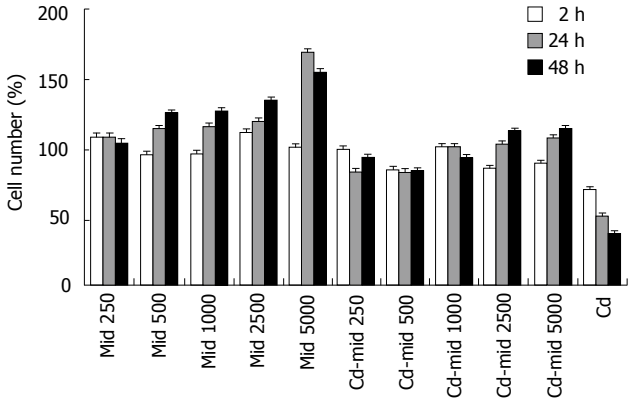

Figure 2 Cell number (%) was determined by MTT assay following 2nd, 24th and 48th h exposure to 250-5000 pg/mL and/or 5 μg/mL Cd. Midkine treatment increased cell proliferation in Hep3B hepatocytes with dose and time dependent manner. Data are presented as mean ± SEM.

cell exposure to 1 μg/mL Cd for up to 2 h only slightly affected cell viability as revealed by MTT measurements compared to control values estimated in untreated cells, but it becomes apparent at the 24th and 48th h. Cd exposure caused cellular damage in a dose and time dependent manner in the Hep3B cell line. Cytotoxicity was more prominent with higher dosages at the 24th and 48th h ($P < 0.001$, Figure 1). Regarding to these data, 5 μg/mL $CdCl_2$ concentration which with moderate-high toxic impact was chosen for subsequent experiments with different dosages of midkine.

Midkine treatment caused proliferation of Hep3B cells in a dose and time dependent manner compared to control group. The highest increase in cell number was at the 48th h and 5000 pg/mL midkine concentration ($P < 0.001$, Figure 2). Midkine treatment during Cd toxicity prevents cell death, even with the lowest dosages ($P < 0.001$, Figure 2).

Determination of apoptosis

Increased apoptosis was seen in Cd treated cells, which was confirmed with increased caspase-3 levels. Lowest dosage of Cd application did not increase caspase-3 levels compared to untreated cells. Activation of caspase-3 started at the 1 μg/mL Cd dosage ($P < 0.001$, Figure 3).

Midkine treatment decreased caspase-3 levels in the

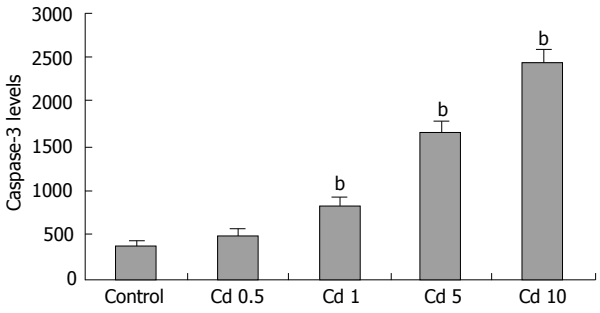

Figure 3 Caspase-3 levels were measured following a 48 h exposure to 0.5-10 μg/mL Cd. Data were given as mean ± SEM. $^bP < 0.001$ *vs* control group.

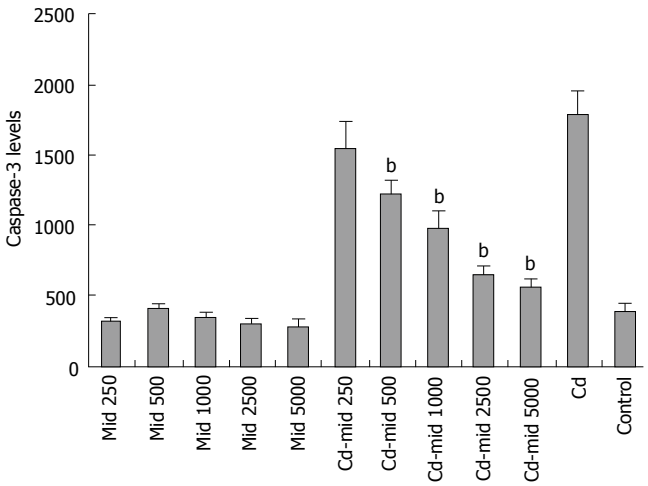

Figure 4 Caspase-3 levels were measured following a 48 h of exposure to 250-5000 pg/mL Midkine and/or 5 μg/mL Cd. Data are presented as mean ± SEM. $^bP < 0.001$ *vs* control group.

Hep3B cells. It prevents Cd induced apoptosis prominently starting from 500 pg/mL concentration of midkine application ($P < 0.001$, Figure 4).

Cytotoxic effects of Cd in the hepatocytes

Incubation of Hep3B cells with Cd resulted in cytotoxicity as assessed by LDH released into the incubation media. LDH release in the Hep3B cells to media started at the 1 μg/mL Cd dosage (Figure 5).

Midkine treatment at the same time with 5 μg/mL Cd exposure decreased LDH release in the Hep3B cells (Figure 6).

Midkine secretion

Measurable basal midkine secretion was found in the Hep3B cells under normal conditions. Cd treatment induced midkine secretion in the Hep3B cells in a dose dependent manner (Figure 7).

DISCUSSION

Acute/chronic Cd exposure mostly results in hepatotoxicity, where it is a good model to study toxic substance-induced liver damage[2]. Midkine family has strong anti-apoptotic function so they are obviously considered non specific (i.e., for Cd) mechanisms of defence[10]. Intense midkine expression has also been found in increased various human tumors and level of midkine expression correlates

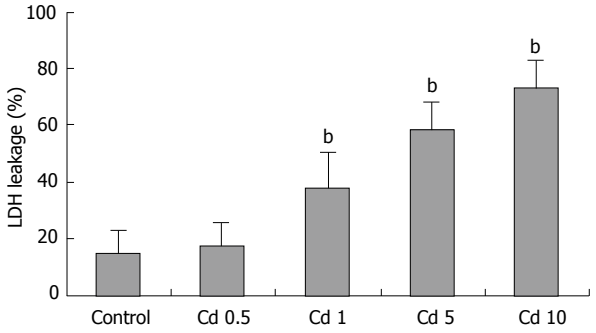

Figure 5 Cd induced cytotoxicity at the 48th h of experiment determined by % LDH released to medium. Starting from the 1 μg/mL dosage Cd treatment caused prominent LDH release from hepatocytes at the end of 48th h ($P < 0.001$). Data are presented as mean ± SEM. $^bP < 0.001$ *vs* control group.

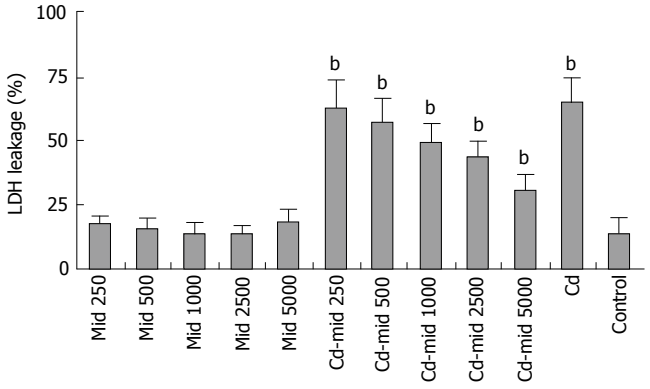

Figure 6 Effects of 48 h midkine (250-5000 pg/mL) and/or 5 μg/mL Cd treatment on the LDH leakage in the Hep3B cells. Data are presented as mean ± SEM. $^bP < 0.001$ *vs* control group.

negatively with the patients' prognosis[14,15]. Furthermore, midkine accumulation is noted in senile plaques in the brains of Alzheimer's disease patients[16]. Midkine is expressed around the damaged neuronal site after cerebral infarction[17], suggesting a role for midkine in tissue repair.

The results of the present study supports the idea that Cd exposure causes cytotoxicity and apoptosis in the Hep3B cells. In both time and dose-response studies, LDH leakage, which is very important parameter to detect hepatocellular integrity, was greater in Cd treated cells. These effects were more prominent at the 48th h. During Cd exposure, activation of caspase-3 was detected in Hep3B cells, suggesting a caspase-dependent pathway is involved in Cd toxicity. Cd can upregulate the expression of a number of genes that produce products that can detoxify Cd and/or repair Cd induced lesions. Our studies showed that midkine is one of them. The induction pathways or receptors of midkine expressed by Cd exposure is still unclear. Midkine is multifunctional heparin-binding growth factor and cytokine and has anti-apoptotic and cell-protecting activities[8]. Untreated Hep3B cells have also a basal midkine secretion. In our study, midkine treatment decreased apoptosis and increased cellular proliferation in a dose and time dependent manner. It has cytoprotective, anti-apoptotic effects against Cd toxicity in Hep3B cells. It seems that midkine is produced endogenously and released in to medium as a defense mechanism

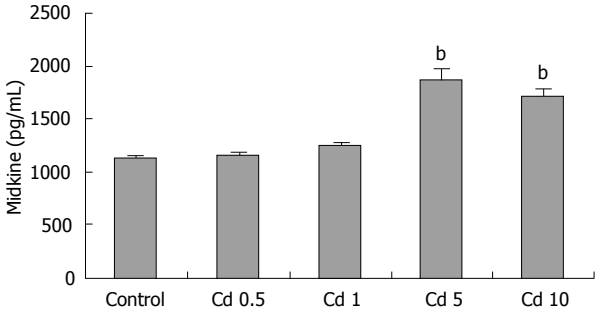

Figure 7 Effects of 0.5-10 μg/mL Cd treatment on midkine secretion in the Hep3B cells. With 0.5 and 1 μg/mL Cd exposure we obtained similar midkine secretion as untreated cells. Midkine secretion was highest as a response to 5 μg/mL Cd treatment dosage. Data are presented as mean ± SEM. $^bP < 0.001$ *vs* control group.

of Hep3B cells against Cd toxicity. Among midkine receptors, receptor-type protein tyrosine phophatase z (PTP z) has been studied extensively. Midkine stimulates phosphorylation of specific members of the JAK/STAT pathway, namely JAK1, JAK2, and STAT1α [18,19]. In addition, low density lipoprotein receptor-related protein (LRP) has also been identified as a receptor[20]. The midkine receptor is considered to be a molecular complex containing these proteins. The downstream signaling systems of these receptors include ERK, which participates in the reduction of necrotic and apoptotic cell death[21]. Internalization of midkine in to cell and nuclear targeting is important for its antiapoptotic function[22]. Activation of these receptors and intracellular pathways might take part in cytoprotective effects of midkine during Cd toxicity. Human and experimental studies have shown that apoptosis plays a role in hepatocyte death in alcoholic liver disease and nonalcoholic steatohepatitis and apoptosis levels correlate with the severity of the liver disease[23-26]. LDL receptor-related protein (LRP) is another midkine receptor. LRP is important for lipid and lipoprotein uptake to cells[27]. Lipid profiles of steatohepatitis patients were found disturbed[28]. It was shown that midkine takes part in the inflammatory and repair processes after partial hepatectomy. They suggested that midkine is beneficial for liver regeneration[29]. ERK, JNK signal pathways disturbed during Cd toxicity are activated by midkine[18,19,22,30]. Beneficial effects of exogenous midkine to minimize Cd induced damage would provide a new perspective for innovation in the treatment of Cd intoxications and in NonAlcoholic Fatty Liver Disease (disease near exclusively characterized by apoptotic process), in Drug Induced Liver Injury and in the combined form, illnesses far long more evident than Cd intoxication in the every day practice of gastroenterologists and hospitals. But further acute and chronic *in vitro* and *in vivo* studies are needed to evaluate which intracellular pathway(s) is activated during these processes.

COMMENTS

Background

Acute/chronic Cadmium (Cd) exposure mostly results in hepatotoxicity, where it is a good model to study toxic substance-induced liver damage. Midkine is expressed around the damaged tissues after ischemic damage and suggesting a role for midkine in tissue repair. Its expression has been found in tumors and level

of midkine expression correlates negatively with the patients' prognosis. Midkine is cytoprotective and has anti-apoptotic effect.

Research frontiers

Beneficial effects of exogenous midkine to minimize Cd induced damage would provide a new perspective for innovation in the treatment of Cd intoxications and other liver diseases.

Innovations and breakthroughs

Cd is well known environmental toxic substance which mainly damages liver. In this study we showed that Cd treatment induces midkine secretion from hepatocytes. Midkine might have protective role during Cd toxicity.

Applications

These finding may be used in the different liver diseases such as alcoholic, toxic and non- alcoholic liver disease models.

Peer review

In this experimental *in vitro* study, the authors showed that midkine secretion from Hep3B cells during Cd exposure protects liver cells from Cd induced cellular damage. Midkine has anti-apoptotic and cytoprotective role during Cd toxicity. Midkine may be a promising therapeutic agent in different toxic hepatic diseases.

Abstract

AIM: To investigate the effects of fibrin sealant on hemostasis and liver regeneration and intra-abdominal adhesions in an experimental liver injury.

METHODS: Thirty-six Wistar rats were randomly divided into primary suture group (n = 15), fibrin sealant group (n = 15) and control group (n = 6). A wedge resection was performed on the left lobe of the liver. In primary suture group, liver was sutured using polypropylene material, while fibrin glue was administrated on the liver surface in fibrin sealant group.

RESULTS: More intra-abdominal adhesions were observed in the primary suture group compared to the fibrin sealant group on 3rd (2.50 ± 0.5 *vs* 0.25 ± 0.5, P = 0.015), 10th (2.75 ± 0.5 *vs* 0.50 ± 0.6, P = 0.06) and 20th (1.75 ± 0.5 *vs* 0.70 ± 0.5, P = 0.015) postoperative days. Histopathological scores were better in the fibrin sealant group in comparison with the primary suture group on 3rd (8.75 ± 0.5 *vs* 6.75 ± 0.5, P = 0.006), 10th (7.50 ± 1.0 *vs* 5.5 ± 0.6, P = 0.021) and 20th (6.40 ± 1.7 *vs* 3.20 ± 1.6, P = 0.025) postoperative days.

CONCLUSION: Out data suggest that fibrin sealant is preferred over primary suture in appropriate cases including liver trauma since it causes less intra-abdominal adhesions while allowing shorter hemostasis time as assessed in experimental liver trauma.

INTRODUCTION

Liver injuries occur as a result of blunt and penetrating traumas and rarely due to some iatrogenic reasons. In blunt abdominal traumas, liver turns out to be the organ that mostly gets injured, with mortality rates varying from 10% to 15%. Eighty percent of the liver injuries are formed subsequent to penetrating wounds caused by fire guns or piercing, incisive tools. Acute bleedings and operative complications cause an increase in mortality and morbidity rates[1]. Fibrin glue has been used in a wide selection of surgical fields, such as thorax surgery[2-4], and otolaryngology[5], and neurosurgery[6], and cardiovascular surgery[7]. Besides this, in general surgery application of fibrin glue has been made for treatment[8,9] of anal fistulas and repair of inguinal hernia. Fibrin sealant can be used as a safe and appropriate treatment technique in liver injuries. However, its effects on liver regeneration and development of intra-abdominal adhesions yet remain unclear. In this experimental study, the early and late effects of the reparation techniques employing primary sutures and fibrin glues on an experimental trauma model are evaluated.

MATERIALS AND METHODS

The study was performed at the animal laboratory of Ministry of Health Ankara Training and Research Hospital, after obtaining an approval from the Ethics Committee. For the purposes of the study, 36 male albino Wistar rats were selected from ages varying between 18 to 20 wk and an average body weight of 160 g. Animals were fed standard rodent food and water. They were left hungry for 24 h during both the pre- and post-operative periods. Animals did not receive antibiotic prophylaxis. The experimental study was conducted under semi-sterile conditions.

Rats were randomly divided into three groups: (1) Primary suture group consisting of 15 rats; (2) fibrin sealant group consisting of 15 rats; and (3) control group (which was used only for bleeding time measurements) consisting of 6 rats. Anesthesia was induced with 75 mg/kg ketamin HCl and 5 mg/kg xylazine HCl (Rompun®)

Table 1 Findings obtained from experimental groups

Subgroup	Primary suture			FIbrin sealant			Control
	A	B	C	A	B	C	
Adhesion score	2.50 ± 0.5	2.75 ± 0.5	1.75 ± 0.5	0.25 ± 0.5 ($P < 0.015$)	0.50 ± 0.6 ($P < 0.06$)	0.70 ± 0.5 ($P < 0.015$)	-
Histopathologic score	8.75 ± 0.5	7.50 ± 1.0	6.40 ± 1.7	6.75 ± 0.5 ($P < 0.006$)	5.50 ± 0.6 ($P < 0.021$)	3.20 ± 1.6 ($P < 0.025$)	-
Bleeding time(s)		113 ± 78			59 ± 37 ([a]$P < 0.001$)		125.7 ± 74

A: Postoperative d 3; B: Postoperative d 10; C: Postoperative d 20. [a]Mann-Whitney *U* test, according to the control group.

im. Then the abdominal wall was shaved off all the hair and the skin was cleaned using Betadine® solution. The abdomen was then entered with a 3-cm median incision to resect a triangular piece with a side length of 1 cm from the inferior edge of the left liver lobe (approximately 4% of the overall liver weight). In the primary suture group, horizontal matrix sutures (6/0 polypropylene) were applied to repair the liver injury. In the fibrin sealant group, the liver surface was coated with fibrin sealant (Tissel Kit®, 2.0 mL, Baxter AG). The fibrin sealant kit contains proteins and thrombin, properly cooled and dried, as well as a $CaCl_2$ and aprotinin solution. Mixing these substances results in two components: a covering and a thrombin solution. After the administration of primary suture and fibrin sealant, both test groups underwent chronometric measurements to determine the bleeding times. Blood samples (1 mL) were taken from the inferior vena cava to detect AST, ALT and ALP values. Five rats from each of the two test groups were sacrificed by administration of ether anesthesia at high doses on 3rd, 10th and 20th postoperative days. Laparotomy was performed by an U-shaped incision curved to upwards. Development of intra-abdominal adhesions was then assessed in animals for qualitative aspects, which were defined formerly as the following phases: Phase 1: Avascular, transparent, thin adhesion; Phase 2: Partly vascular, medium thick adhesion distinguishable with blunt dissection; Phase 3: Vascular, barely thick adhesion distinguishable with sharp dissection[10]. Samples were taken from the recovering liver region.

Light microscopy was employed for the evaluation and scoring of hepatic regeneration based on the following criteria: 1 = necrosis, 2 = hemorrhage, 3 = cytoplasmic vacuolization, 4 = multinuclear large cells, 5 = fibro-vascular structures, 6 = inflammatory exudates. Scores ranging from 0 to 3 were interpreted as the following: 0 = absence of any of these parameters, 1 = slight levels, 2 = medium levels, and 3 = high levels attained by values for the same, which were processed for calculating the total histopathologic regeneration score[11]. Points calculated at high levels indicated that the regeneration had an immature character. Total histopathologic regeneration scores were calculated for each group. AST, ALT and ALP values were assessed as the liver enzymes indicating cellular damage.

Mann-Whitney *U* and Chi-square tests were used for statistical analyses when appropriate.

RESULTS

The mean bleeding times were 125.7 ± 74 s, 113 ± 78 s and 59 ± 37 s in the control group, primary suture group and fibrin sealant group, respectively, indicating that the bleeding time was significantly shorter in the fibrin sealant group as compared to the control group and primary suture group ($P = 0.001$). However, no significant difference ($P = 0.069$) in bleeding time was found between the control group and primary suture group. Results of the test groups are shown in Table 1.

In the primary suture group, tearing on the liver surface and bleeding were observed during the suturing procedure; abscess formation was noted on suture lines over the liver in one rat on d 3, in an another rat on d 10 and in two other rats on d 20 postoperatively. At the 10th and 20th postoperative days, wound regions could not be observed clearly due to intensive adhesions between the liver and the great omentum.

A second administration of fibrin sealant was required in two rats of the fibrin sealant group due to the separation of the wound surfaces on d 3. In this group, the sites of hepatic resection were proven to be indistinguishable from the normal parenchyma on the 20th postoperative day; and there was no abscess development in the any rat liver throughout the postoperative study period; few adhesions were observed between the liver and the omentum. Although the AST, ALT and ALP levels were found to be lower in fibrin sealant group on the 3rd, 10th and 20th as compared to the primary suture group, but the difference could not reach statistical significance.

Significantly more intra-abdominal adhesions were observed in the primary suture group compared to the fibrin sealant group on 3rd ($P = 0.015$), 10th ($P = 0.006$) and 20th ($P = 0.015$) postoperative days.

The mean histopathological regeneration scores indicated a significantly more wound immaturity in the primary suture group than in the fibrin sealant group on the 3rd ($P = 0.006$), 10th ($P = 0.021$) and 20th ($P = 0.025$) postoperative days. In the liver regeneration areas of necrosis and hemorrhage appeared to be less in the fibrin sealant group on the 3rd postoperative day ($P = 0.014$ and $P = 0.003$, respectively) as compared to the primary suture group. Cytoplasmic vacuolization was found to be significantly higher in primary suture group on the 20th postoperative day ($P = 0.014$) as compared to the primary suture group.

DISCUSSION

Deep hepatic sutures are known to prove inefficient in

stopping bleeding from the portal veins and branches of hepatic arteries as well as the posterior hepatic vein[12]. Recent studies tend to concentrate on investigating the risk of formation of intra-hepatic hematoma and abscess as well as the development of areas of necrosis dependent on parenchymal ischemia[12]. In the present study, the parenchymal suture group required a significantly longer duration for hemostasis (113 ± 78 s) than the fibrin sealant group (59 ± 37 s). We prefer using polypropylene sutures, a synthetic non-absorbable material known to have a more inert composition and pose lesser risk for infections. In some previous studies, it has been demonstrated that the thrombus generated after the administration of fibrin sealant may have less potential for the occurrence of the infection[13].

In the present study, the fibrin sealant provided shorter hemostasis times following the application. It was hard to re-find the operation area in fibrin sealant administered rats even on the 3rd postoperative day. In two rats, however, an extra fibrin sealant application was required to ensure the merging of the two surfaces, yet neither of these rats indicated any signs of secondary bleeding on surfaces of injured livers. Jacob *et al*[14] have recently reported that fibrin sealants are beneficial even in cases with prolonged hemostasis in rats with liver injuries. They demonstrated that fibrin impregnated collagens-enhanced survival compared to primary sutures, fibrin sealant was absorbed completely on d 28. In another study[15] performed on dogs, an efficient hemostasis was obtained using fibrin sealant in both superficial and profound injuries, no signs of hematoma or secondary bleeding were encountered and the fibrin sealant was completely absorbed within 6 wk of application. Chonn *et al*[16] administered the fibrin sealant in addition to performing surgery using standard surgical techniques subsequent to a liver injury created by infliction of an external blast effect. However, most of subjects in the control group required perihepatic packing, in the fibrin sealant administered group none of the subjects revealed a need for perihepatic packing and re-laparatomy[16]. Similarly, another study demonstrated that fibrin glue eliminated the need for packing after severe liver injuries[17]. Holcomb *et al*[18] attempted to apply the dry fibrin sealing dressing composed of concentrated fibrinogen, thrombin and calcium on polyglyconate mesh on pigs with grade V experimental liver injury. They consequently reported that dry fibrin sealing dressing provided a simple but quick and efficient control over hemorrhage without change of efficacy with neither hypothermia nor coagulopathy[18]. Moreover, several experimental studies have advocated the effectiveness of the novel fibrin sealant[19-21].

In this study, the highest incidence of abscess formation (33%) was observed in the primary suture group postoperatively, while no abscess was observed in the fibrin sealant group. This can be explained by the features of this technique which does not allow occurrence of any ischemic or blind areas or hematoma formation, and the fibrin sealant generates a quick and permanent sealing on blood and lymphatic veins by stopping fibrin exudation. According to the Dulchavsky's study, autologous fibrin gel possesses bactericidal properties in contaminated hepatic injuries[22]. Likewise, in the Taha's experimental study, the number of occurrences of abscesses was less extensive in the fibrin adhesive group than the suture group[23].

Dulchavsky's study with fibrin gel has demonstrated a significant improvement in adhesion formation and intra-abdominal abscess rate as compared with suture hepatorrhaphy[22]. The grade of adhesions found between the liver and omentum was observed to be drastically lower in the fibrin sealant group, the reason of which was attributed to minimal tissue damage and non-existent ischemia in liver parenchyma ensured with this technique[22].

The results obtained in this study are in compliance with those of past studies showing completion of liver, spleen and renal regeneration on d 30 following fibrin sealant administration[11]. Wound healing appeared to be completed at a high extent based on the findings of macroscopic evaluations in this group on d 20. The histological findings obtained also showed that hepatic healing was at higher rates in the fibrin sealant group than in the other groups. Tovar *et al*[11] investigated the effects of fibrin sealant administration on hemostasis and hepatic healing after hepatectomy. Fibrin sealant administration technique provided a faster hemostasis, while the hepatic recovery in the same group revealed to be quicker compared to hot air coagulation and primary suture techniques[11]. The results of this study are in agreement with those obtained in our experimental study. Previous studies demonstrated that plasminogen activators had an important additive role in liver regeneration by their contribution on remodelling of the liver[24,25]. Contrary to the presence of aprotinin in the fibrin sealant kit which is known as an plasminogen inhibitor, no negative effect on hepatic healing was observed. Vice versa, hepatic healing was more rapid than the other group. We believe that further studies need to be performed on this particular issue.

Kohno *et al*[26] compared the efficiencies of microcrystal collagen dust versus the fibrin sealant following an elective hepatic resection in 62 patients. They encountered bile leakage in two patients, and secondary hemorrhage in one patient in the collagen group, while no such complications were observed in fibrin sealant administered group[26]. Even though the study of Figueras *et al*[27] could not justify the influence of fibrin sealant, many clinical studies are available in the literature showing the useful effects of fibrin sealant in prevention of bile leakage after hepatic resection[27-31].

In conclusion, fibrin sealant may be preferred over to primary suture in appropriate cases of liver trauma, due to the shorter bleeding time, faster regeneration and lesser intra-abdominal adhesions by its use. However, more studies focusing on the clarification of the effects of this product on liver regeneration are needed to check the validity of these results.

COMMENTS

Background

Liver injuries occur as a result of blunt and penetrating traumas and rarely due to some iatrogenic reasons. In blunt abdominal traumas, liver turns out to be the organ that mostly gets injured. Acute bleedings and operative complications cause an increase in rate of mortality and morbidity.

Research frontiers

Fibrin sealant can be used as a safe and appropriate treatment technique in

liver injuries. There were many clinical and experimental studies in the literature showing the useful effects of fibrin sealant in prevention of bile leakage and in shortening bleeding time after hepatic resection and liver injury. However, the effects on liver regeneration and development of intra-abdominal adhesions yet remain unclear.

Innovations and breakthroughs

In this experimental study, more intra-abdominal adhesions were observed in the primary suture group compared to the fibrin sealant group. Hepatic healing was faster and liver abscess was not observed in the fibrin sealant group postoperatively. Minimal tissue damage and non-existent ischemia in liver parenchyma ensured with application of this technique.

Applications

Fibrin sealant can be used clinically in appropriate cases including liver trauma or hepatic resection.

Terminology

The fibrin sealant kit contains proteins and thrombin, properly cooled and dried, as well as a calcium chloride and aprotinin solution. Mixing these substances and covering the tissue surface result a thrombin solution.

Peer review

In this experimental study, the authors revealed that fibrin sealant causes less intra-abdominal adhesions and faster hepatic healing while allowing shorter hemostasis time compared to the primary suture as assessed in experimental liver trauma. Therefore, fibrin sealant can be preferred over primary suture in appropriate cases, including liver trauma.

Abstract

AIM: To explore if C-reactive protein (CRP) levels might serve as a prognostic factor with respect to the clinical course of Crohn's disease and might be useful for classification.

METHODS: In this retrospective cohort study we enrolled 94 patients from the inflammatory bowel disease (IBD) database of the University Medical Centre Utrecht. CRP levels during relapse were correlated with the number of relapses per year. Severity of relapses was based on endoscopic reports and prednisone use. Furthermore, patients were categorized in a low or high CRP group based on their CRP response during relapse and demographic and clinical features were compared.

RESULTS: Overall, a positive correlation between CRP levels, number of relapses, and severity of relapse was found (respectively r_s = 0.31, P < 0.01 and r_s = 0.50, P < 0.001). Employing a cut-off level of 15 mg/L, the index CRP level was found to discriminate patients with respect to the number of relapses per year, as well as for severity of relapses (respectively 0.25 ± 0.16 *vs* 0.36 ± 0.24, P < 0.05 and 4.4 ± 1.2 *vs* 3.2 ± 1.1 on a 10-point visual analogue scale, P < 0.001 for the high CRP and low CRP groups respectively). In addition, the high CRP group showed more cumulative days of prednisone use per year (107 ± 95 *vs* 58 ± 48, P < 0.05), as well as a better response to infliximab (93 % *vs* 33 %, P = 0.06).

CONCLUSION: A higher CRP level during relapse seems to be associated with a more severe clinical course of disease.

INTRODUCTION

Crohn's disease (CD) is thought to result from an ongoing activation of the mucosal immune system leading to an inappropriate innate immune response to normal luminal factors in a genetically susceptible individual[1,2]. The clinical expression of CD is heterogeneous with a wide spectrum of patterns and different clinical courses. Classification of CD is, therefore, difficult[3]. In the Vienna Classification, distinct definitions to categorize patients with CD have been formulated[4]. This classification distinguishes between age (< or > 40 years), anatomical localization (terminal ileum, colon, ileocolon, upper gastrointestinal) and disease behaviour (non-stricturing/non-penetrating, stricturing and penetrating). However, it has been shown to be unreliable in predicting the course of the disease[5,6]. Currently, it is not known whether other tools, such as the recently developed Montreal classification will prove to be superior in this respect[7,8].

C-reactive protein (CRP), an acute phaseprotein produced by hepatocytes upon activation by proinflammatory cytokines such as IL-6, IL-1α and tumour necrosis factor-alpha (TNF-α) is widely used as a parameter of inflammatory activity in a variety of infectious and inflammatory diseases[9-11]. Moreover, it has been found to correlate with clinical parameters of disease activity in CD[12-18].

We hypothesized that a high serum CRP level during a relapse predisposes patients to a more severe course of the disease. In the present study, we studied retrospectively the putative association between the height of CRP levels during a relapse and the clinical course of disease in patients with CD.

MATERIALS AND METHODS

In this retrospective cohort study, 94 patients with CD were selected from the IBD database of the University Medical Centre Utrecht, comprising the records of all patients diagnosed with IBD in the period 1994-2005.

CD patients were eligible if they were 18 years of age or older, had experienced at least one well-documented relapse during which serum CRP values were determined, and from whom records over a period of at least 4 years of follow-up were available. Excluded were patients with other chronic inflammatory diseases, concomitant infections or other serious comorbidity.

Data were collected from electronic and clinical charts. The index CRP level used for analysis had to be measured during a relapse which was confirmed by (ileo) colonoscopy and/or a small bowel follow-through examination. The highest CRP level during this exacerbation, within the first 4 wk after the onset of symptoms, was taken as an index CRP level. Severity of the index exacerbation was assessed retrospectively by two independent, blinded reviewers based on the endoscopic reports and recorded on a 10-point visual analogue scale (VAS). The mean of both scores was used for analysis.

The total number of relapses during follow up was assessed. These relapses were defined as a period of inflammatory activity accompanied by progressive symptomatology which was confirmed by (ileo) colonoscopy and/or a small bowel follow-through examination and requiring hospitalization and/or initiation of treatment with steroids or other immunosuppressive drugs. Another primary endpoint was the use of prednisone, measured in number of days during follow up.

Furthermore, age at the time of the diagnosis of CD, duration of the disease, localization and behaviour of CD according to the Vienna Classification, the presence of granulomas in pathology specimens, smoking behaviour, surgical treatment and treatment with immunosuppressives other than prednisone (azathioprine, mesalazine, methotrexate, budesonide, cortisone enema's or infliximab) were noted.

Statistical analysis

Analysis was performed using SPSS for Windows, version 12.0. The correlation between the index CRP value and the primary outcome measures were calculated employing a bivariate correlation with a non-parametric distribution (Spearman's rho). Differences in the primary, as well as the secondary outcomes of the Low C-reactive protein subgroup (LCRP) and High C-reactive protein subgroup (HCRP) groups were calculated with the Mann Whitney *U* test to compare means (non-parametric distribution) and the chi-square test to compare the differences in distribution (non-parametric distribution).

All tests were 2-tailed analysed. Data are presented in mean ± SD or otherwise stated. A *P*-value of < 0.05 was considered statistically significant.

RESULTS

Correlation variables

For the whole group, a significant positive correlation between the index CRP level and the number of relapses per year was noted ($r_s = 0.31$, $P < 0.01$, Figure 1). Severity of relapses was correlated with the index CRP level as well ($r_s = 0.50$, $P < 0.001$). The severity was based on the mean score of both independent reviewers with an interobserver correlation of $r_s = 0.71$, $P < 0.001$. The correlation between the index CRP level and cumulative use of prednisone per year was small but significant, $r_s = 0.22$, $P < 0.05$.

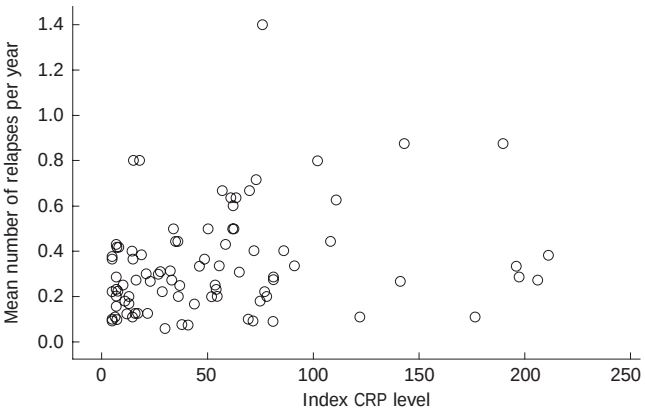

Figure 1 Correlation between the index CRP and the mean number of relapses per year. Spermann's rho = 0.31, $P < 0.01$.

Comparison of subgroups

Based on the index CRP levels two groups were created, the LCRP and HCRP group, with a cut-off level of 15 mg/L. Twenty-seven patients had a serum CRP level of ≤ 15 mg/L and 67 had a CRP level of > 15 mg/L. Baseline characteristics of the subgroups are given in Table 1. The baseline characteristics of the groups were similar. There were no differences between the two groups regarding gender distribution, mean age, age at the time of diagnosis, disease localization and disease behaviour according to the Vienna classification.

Table 2 shows the clinical findings, drug use, surgeries and related factors in the two groups. The numbers of relapses were respectively 0.25 ± 0.16 and 0.36 ± 0.24 per year in the LCRP and HCRP group ($P < 0.05$). The mean severity of the index exacerbation on a 10-point VAS was 4.4 ± 1.2 in the HCRP and 3.2 ± 1.1 in the LCRP group ($P < 0.001$). The number of courses of prednisone did not differ between the groups, but patients in the HCRP group were treated significantly longer with prednisone than LCRP-patients, 107 ± 95 *vs* 58 ± 48 d per year ($P < 0.05$).

There was no significant difference in the number of patients on infliximab in both groups, 20.9 % in the HCRP and 11.1% in the LCRP group, but the response rate was higher in the HCRP subgroup compared to the LCRP subgroup, respectively 92.8% *vs* 33.3%, $P = 0.06$.

In the follow-up of patients in the HCRP and LCRP groups, the percentages of azathioprine (77.6 *vs* 66.7), mesalazine (98.5 *vs* 100), budesonide (71.6 *vs* 63.0), cortisone enema's (43.3 *vs* 44.4) and methotrexate (4.5 *vs* 3.7) use did not differ significantly, nor did the total number of CD-related surgeries [1.7 (SD 0.1) *vs* 2.0 (SD 0.6) per patient], construction of stomas (22.4 % *vs* 22.2 %) or development of fistulas and/or abscesses (26.9 % *vs* 18.5%).

There were no significant differences between smokers and non-smokers. Patients with granulomas were significantly younger (38.4 ± 8.5 *vs* 45.4 ± 13.3 years, $P < 0.05$) and tended to be younger at the time

of diagnosis (24.2 ± 5.9 *vs* 29.7 ± 12.1 years, $P = 0.09$) compared with patients without granulomas. Other differences were not detected.

DISCUSSION

We hypothesized that the CRP response during a relapse of CD discriminates between phenotypic subsets of patients with an aggressive or more benign course of disease and predicts the response to drugs. We found a significant but relatively modest correlation between level of CRP during the index exacerbation and the number, as well as the severity of relapses per year. A significant, but rather small, correlation between CRP level and prednisone use was revealed. LCRP and HCRP groups were found to be comparable regarding baseline characteristics but the number and severity of relapses was significantly higher in HCRP patients. Furthermore, patients in the HCRP group appeared to respond better to infliximab infusions. The latter phenomenon is in line with literature. This apparently more aggressive disease behaviour in the HCRP patients was not reflected in a higher frequency of drug use other than prednisone. A possible explanation is the tertiary referral setting of this study, resulting in enrolment of relative severe cases of CD in most of whom immunomodulators were already prescribed.

Interestingly, we found the index CRP and severity of relapse based on endoscopic reports to be correlated. CRP levels are found to be weakly associated with clinical activity indices by several authors[14,19-21], although this has not been reported consistently[22]. Colombel *et al* reported a striking correlation of CRP levels with radiologic findings of perienteric inflammation[12]. Whether involvement of mesenteric adipocytes in the immune response results in an increased CRP level and, in the long run, the course of disease, is a matter of speculation. We could not confirm the data from Floren *et al*, who reported an exclusive ileal disease distribution in a group of CD patients with a CRP level below the level of 10 mg/L. In this study the LCRP group had a significant lower body mass index as well, while no differences were found in the frequency and distribution of CARD15 variants[23]. The association of colonic disease phenotype, cigarette smoking or the presence of granulomas with relapses as reported in other studies was not reproduced in the current study either[24-30].

Our study has its limitations. The severity of index relapses was scored retrospectively and the presence of relapses during the follow-up period was assumed if certain criteria were met in the charts. We tried to overcome these limitations by using blinded assessment of the index colonoscopies by two gastroenterologists and by defining strict criteria for relapse in the follow-up phase. The number of courses of prednisone had to be scored retrospectively as well, which only gives a global impression. In addition, we had to choose a cut-off level of CRP to create two groups. In literature, there is only one comparable study[23] in which 10 mg/L was used as the cut-off level. We found that a CRP level of 15 mg/L discriminated the two groups optimally.

In conclusion, this study showed that the level of CRP

during a relapse of CD can serve as a prognostic factor for the number and severity of relapses. Patients with a CRP level > 15 mg/L experienced more and more severe relapses, were treated more extensively with prednisone and responded better to infliximab therapy. However, we consider these differences too small to be of use in clinical decision making.

COMMENTS

Background

Crohn's disease (CD) may affect any part of the gastrointestinal tract and is characterized by a broad spectrum of clinical presentations and a variable disease course. Disease flares occur randomly and cannot be predicted reliably. The aim of the present study was to explore the value of C-reactive protein (CRP) as a prognostic factor with respect to the clinical course of CD.

Research frontiers

Early identification of CD patients with a propensity to an aggressive or more benign disease course could be of major clinical importance; this might guide the clinician in deciding what maintenance therapy should be prescribed and could even result in early initiation of aggressive induction therapy to avoid flares or complications. To date, a simple parameter, reliably predicting disease activity and flares is not available. From all laboratory markers, CRP seems to be the most promising candidate in this respect. Not all patients with confirmed disease activity, however, display raised CRP levels. We hypothesized that this group constitutes a distinct, benign phenotype, possibly requiring less intensive treatment.

Innovations and breakthroughs

A high CRP level during relapse is positively correlated with the severity and frequency of relapses. Furthermore, this was found to be associated with longer courses of steroids and a better response following infliximab administration.

Applications

These findings suggest that phenotypes can be identified using a biochemical parameter such as CRP, which predicts to a certain extent the course of disease and response to drugs. The differences found in this study, however, are too small to guide clinical decision making and the use of CRP in this setting should be seen as an additive tool.

Terminology

High CRP and low CRP responders are patients that respectively react with a high CRP level and a low CRP level during a relapse of Crohn's Disease.

Peer review

This is an important contribution to the literature of inflammatory bowel disease. The study is well conceived and the report is well written.

Abstract

AIM: To study the candidate tumor suppressor genes (TSG) on chromosome 4p by detecting the high frequency of loss of heterozygosity (LOH) in sporadic colorectal carcinoma in Chinese patients.

METHODS: Seven fluorescent labeled polymorphic microsatellite markers were analyzed in 83 cases of colorectal carcinoma and matched normal tissue DNA by PCR. PCR products were eletrophoresed on an ABI 377 DNA sequencer. Genescan 3.7 and Genotype 3.7 software were used for LOH scanning and analysis. The same procedure was performed by the other six microsatellite markers spanning D4S3013 locus to make further detailed deletion mapping. Comparison between LOH frequency and clinicopathological factors was performed by χ^2 test.

RESULTS: Data were collected from all informative loci. The average LOH frequency on 4p was 24.25%, and 42.3% and 35.62% on D4S405 and D4S3013 locus, respectively. Adjacent markers of D4S3013 displayed a low LOH frequency (< 30%) by detailed deletion mapping. Significant opposite difference was observed between LOH frequency and tumor diameter on D4S412 and D4S1546 locus (0% *vs* 16.67%, P = 0.041; 54.55% *vs* 11.11%, P = 0.034, respectively). On D4S403 locus, LOH was significantly associated with tumor gross pattern (11.11%, 0, 33.33%, P = 0.030). No relationship was detected on other loci compared with clinicopathological features.

CONCLUSION: By deletion mapping, two obvious high frequency LOH regions spanning D4S3013 (4p15.2) and D4S405 (4p14) locus are detected. Candidate TSG, which is involved in carcinogenesis and progression of sporadic colorectal carcinoma on chromosome 4p, may be located between D4S3017 and D4S2933 (about 1.7 cm).

INTRODUCTION

Colorectal cancer (CRC) constitutes the second most common neoplasm in Western countries and is the third leading cause of cancer-related death, the overall 5-year survival rate is approximately 45%[1]. Improvement in its prognosis can not be achieved without a better understanding of its etiology and tumor molecular biology. In recent years, the genetic basis of human tumors has been increasingly elucidated. As a model for both multistep and multipathway carcinogenesis, colorectal neoplastic progression provide paradigms of both oncogenes and tumor suppressor gene in epithelial tumors[2,3]. The latter changes predominate. In addition to the allelic loss on chromosome 5q, 17p and 18q, many other chromosome losses can be observed in colorectal carcinoma. Regions on chromosome 1q, 4p, 6p, 6q, 8p, 9p and 22q were lost in 25%-50% of the colorectal tumor cases studied previously[2].

Chromosome losses in colorectal tumor were first detected by cytogenesis, later, by probes of restriction fragment length polymorphisms (RFLP) and now by loss of heterozygosity (LOH) in analyzing allelic loss. The loss of tumor suppressor genes is believed to be one of the key steps to carcinogenesis of colorectal cancer[4]. The loss of one allelic at specific locus is caused by deletion mutation or loss of a chromosome from a chromosome pair[5]. When this occurs at a tumor suppressor gene locus where one of the allelics is already abnormal, it can result

in neoplastic transformation. The LOH analysis based on polymorphic microsatellite DNA has become an effective and powerful tool currently to find informative loci and candidate tumor suppressor genes[6,7]. Most investigations concentrated on defining the minimal regions of loss of specific chromosomes in various cancers in an effort to identify the putative tumor suppressor genes targeted by the loss[8].

In this study, we first analyzed the LOH events on chromosome 4p using seven microsatellite markers and made further refined deletion mapping analysis spanning D4S3013 locus in 83 sporadic colorectal carcinoma cases in an attempt to identify additional candidate tumor suppressor genes involved in colorectal tumorigenesis.

MATERIALS AND METHODS

Patient sample and DNA extraction

This study was based on consecutively collected tumors in 83 patients with colorectal cancer, including 40 males and 43 females, treated at the surgical department in Shanghai First People's Hospital, China. The patients' ages ranged from 31 to 84 years with a median of 66. The cancerous tissue and adjacent normal control tissue (> 10 cm) were freshly frozen. The tissues were cut into cubes of approximately 2 mm^3 and immediately frozen in liquid nitrogen. Each patient gave his or her informed consent for the use of his or her tissue in this study. DNA was extracted using standard methods with proteinase K digestion and phenol/chloroform purification[9]. All patients were confirmed by pathology and were staged by Duke's criteria.

Microsatellite markers and PCR

Initially, 83 cases of colorectal cancer were analyzed by PCR using seven microsatellite markers (Shanghai Biology Technology Company, China) which map to chromosome 4p. DNA samples were analyzed as matched normal and tumor pairs using primers of the following microsatellite loci (hereditary location/heterozygote): pter-D4S412 (4p16.3/76)-D4S2935 (4p16.1/62)-D4S1599 (4p16.1/81)-D4S303 (4p15.33/76)-D4S3013 (4p15.2/84)-D4S391 (4p15.2/85)-D4S405 (4p14/85). The average hereditary distance was 8.65 cm[10] (Figure 1A). As the D4S3013 locus showed high LOH frequency (35.62%), six additional microsatellite markers map to chromosome 4p15 were employed to further investigate LOH. The same DNA samples were then analyzed as matched pairs for the following microsatellite markers (location/heterozygote): pter-D4S2926 (4p15.32/80)-D4S1546 (4p 15.31 /77) -D4S3017 (4p 15.31/82)-D4S2933 (4p 15.31/60)-D4S2948 (4p 15.2 /81)-D4S1551 (4p 15.2/78). The average hereditary distance was restricted within 1.03 cm[10] (Figure 1B).

LOH result analysis

A portion of each PCR product (0.5 μL) was combined with 0.1 μL Genescan 500 size standard (PE Applied Biosystems Foster City, CA, USA) and 0.9 μL formamide loading buffer. After denaturation at 96℃ for 5 min, products were eletrophoresed on 5% polyacrylamide

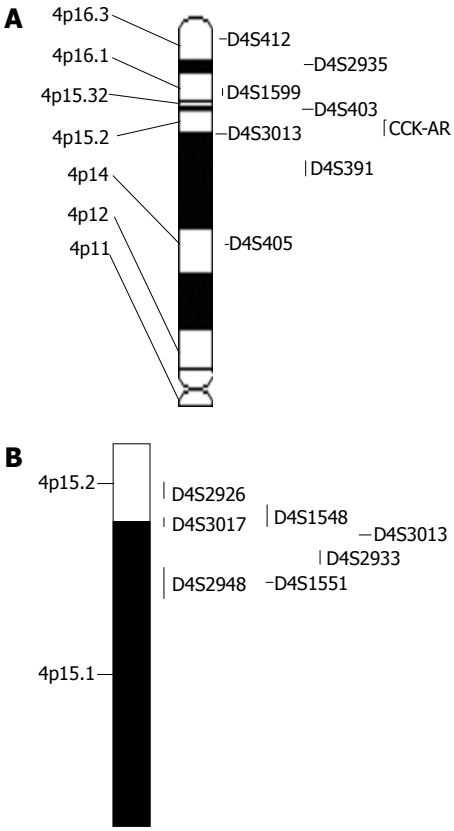

Figure 1 **A:** Microsatellite markers and candidate tumor suppressor genes on 4p (www.gdb.org); **B:** Microsatellite markers on D4S3013 (www.gdb.org).

gels using an ABI 377 DNA sequencer (PE Applied Biosystems Foster City, CA, USA) for 2.5 h. Genotype 3.7 software display individual gel lanes as electropherograms with a given size, height, and area for each detected fluorescent peak. Stringent criteria were used to score the samples. Alleles were defined as the two highest peaks within the expected size range. A ratio of T1:T2/N1:N2 of less than 0.67 or greater than 1.50 was scored as a loss of heterozygosity (Figure 2). Most amplified normal DNA produced two PCR products indicating heterozygosity. A single fragment amplified from normal DNA (homozygosity) and those PCR reactions, in which fragments were not clearly amplified, were scored as not informative. The LOH frequency of a locus is equal to the ratio of the number between allelic loss and informative cases. The average LOH frequency of chromosome 4p is the average value of each locus.

Statistical analysis

Comparisons between LOH and clinicopathological data were performed by χ^2 test. $P < 0.05$ was considered as statistically significant.

RESULTS

LOH analysis of colorectal cancer on 4p

Eighty-three colorectal cancers were analyzed for LOH at the seven marker loci spanning chromosome 4p. All loci got informative messengers. The average LOH frequency on 4p was 24.25%. Sixty-three samples (75.90%) showed

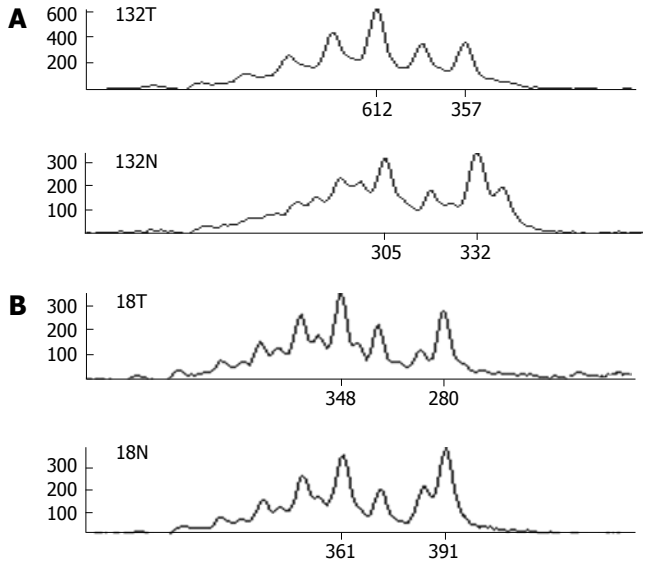

Figure 2 LOH Demonstration. **A:** Classic LOH peak: Allele ratio = (T1/T2)/(N1/N2) = (612/357)/(305/332) = 1.87 > 1.5; **B:** Heterozygosity retention: Allele ratio = (T1/T2)/(N1/N2) = (348/280)/(361/391) = 0.67 < 1.34 < 1.5. T: Tumor; N: Normal.

Table 1 LOH result and hereditary distance/location of chromosome 4p

Locus	Location	LOH cases	Normal cases	Informative rate	Distance (cM)	LOH rate (%)
D4S412	4p16.3	5	57	74.7	-	8.06
D4S2935	4p16.1	24	55	95.18	7.4	30.38
D4S1599	4p16.1	9	28	44.58	10.8	24.32
D4S403	4p15.33	3	34	44.58	5.1	8.1
D4S3013	4p15.2	26	47	86.9	7.7	35.62
D4S391	4p15.2	13	46	71.84	7.4	22.03
D4S405	4p14	22	30	62.65	13.4	42.3

at least one LOH event. Two distinct regions of frequent allelic loss at D4S3013 (4p15.2) and D4S405 (4p14) locus on chromosome were detected (Table 1). The LOH frequency was 35.62% and 42.3%, respectively. This suggested that putative tumor suppressor genes may be located near D4S3013 and D4S405 loci.

LOH deletion mapping results on 4p15 encompassing D4S3013

The chromosome region spanning D4S3013 locus on 4p15 was investigated using a saturation mapping strategy with another 6 microsatellite markers that are closely located within this region (Figure 2). To detect putative tumor suppressor genes easily, we limited average hereditary distance to 1.03 cm. Forty samples (48.19%) showed at least one LOH event. The average LOH frequency spanning D4S3013 was 24.2% (Table 2). We found that adjacent markers of D4S3013 displayed a low LOH frequency (< 30%), especially on D4S2933 locus, much less information was obtained because of more homozygosity.

Relationship between clinicopathological features and LOH on 4p

On D4S412 locus, none LOH was detected in patients with

Table 2 LOH result and hereditary distance/location of detailed deletion mapping spanning D4S3013

Locus	Location	LOH cases	Normal cases	Informative rate	Distance (cM)	LOH rate (%)
D4S2926	4p15.32	7	38	54.22	-	15.56
D4S1546	4p15.31	9	38	56.63	1.6	19.15
D4S3017	4p15.31	13	46	71.08	0.5	22.03
D4S3013	4p15.2	26	47	87.95	1.2	35.62
D4S2933	4p15.31	2	14	19.28	0.5	12.5
D4S2948	4p15.2	15	49	77.11	1.9	23.44
D4S1551	4p15.2	12	64	91.57	0.5	21.05

tumor larger than 5 cm in diameter (0/27), while in patients with tumor less than 5 cm in diameter, LOH frequency was 14.29% (5/35, $P = 0.041$). On the contrary, on D4S1546 locus, LOH frequency was 35.29% (6/17) in the former; and only 10% (3/30) in the latter locus ($P = 0.030$). Notably, on D4S403 locus, LOH was significantly associated with tumor gross pattern. In tumor of the massive, ulcerative and encroaching pattern, the LOH frequency was 10%, 0%, 33.33%, respectively ($P = 0.030$). No significant relationship was found between clinicopathological features and LOH on other loci (data not shown).

DISCUSSION

Inactivation of tumor suppressor genes appears to be one of the genetic mechanisms involved in the development of colorectal cancer[11,12]. Deletion of tumor suppressor genes occur frequently in human malignances. Such events can be detected using markers from the region of genome that include a tumor suppressor gene. Allelic deletions detected as LOH have been proved useful for mapping regions of DNA that contains tumor suppressor genes, i.e., LOH at specific chromosomal regions strongly suggests the existence of tumor suppressor genes at the relevant segment.

A great deal of evidence supported the presence of tumor suppressor genes in the short arm of chromosome 4. These include the reversion of the immortal phenotype by chromosome 4 transfer[13] and the frequent occurrence of losses in or near the 4p14-4p16 region in bladder cancer[14]. LOH has been observed at distal 4p in sporadic neuroblastoma with an incidence raging from 20% to 29%[15,16]. Using array comparative genomic hybridization, Hurst *et al*[17] reported the loss frequency of 4p to be 52% in bladder cancer. More importantly, Shirapurkar *et al*[18] observed the loss frequency of > 50% at 4p15.1-4p15.3 in malignant mesothelioma and lung carcinoma. LOH on 4p was 21% and > 30% in differentiated adenocarcinoma of stomach as well[19,20]. Head and neck squamous cell carcinoma, invasive cervical cancer and acinic cell carcinoma also showed a high allelic loss frequency[21-23].

In colorectal tumors, previous alletic typing[24], cytogenetic[25-27] and comparative genomic hybridization[28] studies have reported moderate losses(0%-30%) of chromosome 4. These data have not raised special interest in this chromosome as a candidate to harbor a tumor suppressor gene, therefore, colorectal cancer investigations

have not included a detailed analysis of loss in this chromosome. Choi *et al*[29] reported a LOH frequency of 24%-30% at just several loci on chromosome 4 in colorectal cancer. Later, Arribas *et al*[30,31], used AP-PCR method and suggested chromosome 4p14-4p16 may contain tumor suppressor gene, because LOH frequency on D4S2397 was as high as 35%. These reports indicate that 4p14-4p16 region displayed frequent loss in a couple of cancers, so 4p14-4p16 region is of important value for TSG screening.

D4S3013 locus region, 4p15.2, was concordant with several reports in other tumors before[14,16,20,21]. In this study, we investigated the LOH on 4p in 83 sporadic cases of colorectal cancer. The results showed putative tumor suppressor gene may harbor adjacent to D4S405 and D4S3013 locus. We made further detailed deletion mapping spanning D4S3013 locus, and found that the surrounding markers of D4S3013 displayed a low LOH frequency (< 30%). Therefore, we speculate that the candidate TSG may be located between D4S3017 and D4S2933, about 1.7 cm in hereditary distance.

We found several loci were significantly associated with clinicopathological features. On D4S412 locus, no LOH was detected in patients with tumor larger than 5 cm in diameter, while in patients with tumor less than 5 cm in diameter, the LOH frequency was 14.29% ($P = 0.041$). On the contrary, on D4S1546 locus, the LOH frequency showed opposite phenomenon. On D4S403 locus, LOH was significantly associated with tumor gross pattern. Similarly, Arribas *et al*[31] found solely at the D4S2397 locus was indicative of a shorter disease-free survival ($P = 0.027$). Choi *et al*[29] found 4p loss was significantly associated with early onset of colorectal cancer. The effect of 4p loss on the early-onset disease is unlikely to be the result of tumor aggressiveness, because 4p loss was not found to be correlated with cancer-related death. Nishizuka *et al*[20] found 4p LOH had an essentially similar frequency in early and advanced differentiated adenocarcinoma. The differential behavior of LOH at different markers suggested that distinct mechanisms and/or selection presses participate in the mutational event that affect this chromosomal region during the tumorigenic process.

Regarding allelic loss at 4p, cholecystokinin type A receptor (CCK-AR) gene maps near D4S2397[32,33] (Figure 1). Recent reports have suggested that cholecystokinin receptor may function as a tumor suppressor gene[34,35].

In summary, we investigated LOH on 4p in sporadic colorectal carcinoma in Chinese patients and detected two high deletion regions encompassing D4S3013 (4p15.2) and D4S405 (4p14). Candidate TSG, involved in sporadic colorectal carcinoma on chromosome 4p, may be located between D4S3017 and D4S2933 (about 1.7 cm). Further related gene screening and functional studies may contribute to the identification of the tumor suppressor gene in these regions.

COMMENTS

Background

Cancer arises from the accumulation of inherited polymorphism (i.e. SNPs) and mutation and/or sporadic somatic polymorphism (i.e. non-germline polymorphism) in cell cycle, DNA repair, and growth signaling genes. Neoplastic progression is generally characterized by the accumulation of multiple somatic-cell genetic alterations as the tumor progresses to advanced stages. The classic mechanism of tumor suppressor gene inactivation is described by two-hit modes in which one allele is mutated (or promoter hypermethylation or a small intragenic deletion) and the other allele is lost through a number of possible mechanisms, resulting in loss of heterozygosity at multiple loci. Loss of heterozygosity is the most common molecular genetic alteration observed in human cancers. In the model of colorectal tumorigenesis, mutational inactivation of tumor suppressor genes predominates.

Research frontiers

Most genome-wide scans for loss of heterozygosity (LOH) have been conducted at low resolution with a relatively small number of polymorphic markers. For example, an average of 120 microsatellites have been used to determine the allelotype of multiple different human neoplasms in a series of studies since 1995, and the highest density microsatellite allelotype was about 280 polymorphic markers before the year 2000. SNPs are the most common form of sequence variation in human genome, occurring approximately every 1200 base pairs (bps). High density mapping of genetic losses reveals potential tumor suppressor loci and might be useful for clinical classification of individual tumors. SNP array has been introduced recently for genome-wide screening of chromosome imbalance. Higher density SNP array can effectively detect small regions of chromosomal changes and provide more information regarding the boundaries of loss regions.

Innovations and breakthroughs

A great deal of evidence supported the presence of tumor suppressor genes in the short arm of chromosome 4. Much less studies have been reported in colorectal cancer. Previous allelotyping analysis of cancer by many groups was used with a relatively low density of markers. By deletion dense markers mapping, we detected two obvious high frequency LOH regions spanning D4S3013 and D4S405 locus in colorectal cancer. Candidate TSG, might be located between D4S3017 and D4S2933 (about 1.7 cm).

Applications

We used this method to detect some major allelic loss regions in genome-wide scans of LOH in patients with colorectal cancer.

Terminology

LOH is caused by a variety of genetic mechanisms, including physical deletion of chromosome non-disjunction and mitotic non-disjunction followed by republication of the remaining chromosomes, mitotic recombination and gene conversion. The mechanisms of LOH are remarkably chromosome-specific. Some chromosomes display a complete loss. However, more than half of the losses are associated with a only partial loss of a chromosome rather than a whole chromosome. LOH is also a common form of allelic imbalance and the detection of LOH has been used to identify genomic regions that harbor tumor suppressor genes and to characterize different tumor types, pathological stages and progression.

Peer review

This is a report that describes the LOH events in sporadic colorectal cancer in Chinese patients, further studies must benefit from this paper. The data presented is clear and concise in the text.

Abstract

AIM: To confirm whether insulin regulates resistin expression and secretion during differentiation of 3T3-L1 preadipocytes and the relationship of resistin with insulin resistance both *in vivo* and *in vitro*.

METHODS: Supernatant resistin was measured during differentiation of 3T3-L1 preadipocytes. L6 rat myoblasts and hepatoma cell line H4IIE were used to confirm the cellular function of resistin. Diet-induced obese rats were used as an insulin resistance model to study the relationship of resistin with insulin resistance.

RESULTS: Resistin expression and secretion were enhanced during differentiation 3T3-L1 preadipocytes. This cellular differentiation stimulated resistin expression and secretion, but was suppressed by insulin. Resistin also induced insulin resistance in H4IIE hepatocytes and L6 myoblasts. In diet-induced obese rats, serum resistin levels were negatively correlated with insulin sensitivity, but not with serum insulin.

CONCLUSION: Insulin can inhibit resistin expression and secretion *in vitro*, but insulin is not a major regulator of resistin *in vivo*. Fat tissue mass affects insulin sensitivity by altering the expression and secretion of resistin.

INTRODUCTION

Obesity is a worldwide health problem directly linked to several disease processes such as hypertension and type 2 diabetes mellitus[1]. Adipose tissue is not only an organ for passive energy reserve, but also an active endocrine organ secreting a wide range of hormones and other protein factors called adipokines[1,2]. Among the adipokines, resistin is involved in insulin sensitivity and glucose tolerance[3,4] while others are involved in hemostasis, inflammatory and stress responses, and energy balance[5,6].

Resistin, initially identified in screening for adipocyte-specific transcripts down-regulated by treatment with thiozolidinedione (TZDs), belongs to a novel family of cysteine-rich proteins, each with a unique tissue distribution[3, 4]. In rodents, resistin predominantly expressed in white adipose tissue[4] reduces insulin sensitivity in adipocytes and skeletal muscles by impairing insulin-mediated glucose transport and inducing the expression of suppressor of cytokine signaling 3 (SOCS3)[7-9], and regulates fasting blood glucose by increasing hepatic glucose release[10]. Therefore, resistin might provide a link between obesity and diabetes mellitus.

Initial studies on the regulation of resistin indicate that resistin expression is reduced by fasting and increases rapidly on refeeding[3]. Circulating resistin levels are elevated in genetically obese (ob/ob, db/db) mice, and obese is induced by a high-fat diet[3]. Insulin inhibits resistin mRNA expression in 3T3-L1 preadipocytes[11,12]. However, these data do not support a role of resistin in insulin resistance[11]. If resistin is mainly regulated by insulin, the major function of resistin is to induce insulin resistance, forming an insulin-resistin-insulin sensitivity positive feedback loop that cannot exist *in vivo*.

In the present study, resistin expression and secretion were elevated during 3T3-differentiation of L1

preadipocytes. This cellular differentiation-stimulated resistin expression and secretion were suppressed by insulin. Resistin also induced insulin resistance in H4IIE hepatocytes and L6 myoblasts. In diet-induced obese rats, serum resistin levels were negatively correlated with the insulin sensitivity index (ISI). No negative correlation was found between the levels of fasting serum insulin and resistin, suggesting that insulin is not the major regulator of resistin in rodents.

MATERIALS AND METHODS

Cell culture

3T3-L1 preadipocytes were cultured at 37℃ in an atmosphere containing 50 mL/L CO_2 and 950 mL/L air. The cells were maintained in growth medium consisting of Dulbecco's modified Eagle's medium (DMEM, Gibco BRL, USA), 45 mmol/L glucose, 10% heat-inactivated fetal bovine serum (FBS, Gibco BRL, USA), 2 mmol/L L-glutamine, and 50 U/mL penicillin and 50 ng/mL streptomycin (Sigma, USA). Induction of adipocytic differentiation of 3T3-L1 cells was performed as described elsewhere[13]. Briefly, 3T3-L1 cells were grown in DMEM supplemented with 10% FBS until confluence. Two days after complete confluence (d 0), cells were cultured in DMEM supplemented with 10% FBS and 0.5 mmol/L 1-methyl-3-isobutylxanthine (Sigma, USA), 0.25 μmol/L dexamethasone (Sigma, USA) and 100 nmol/L insulin (Sigma, USA) for 48 h. From d 2 to 4, the full medium was supplemented with 100 nmol/L insulin only. The cells were then switched back to DMEM containing only 10% FBS for the remaining days. Cultures were replenished every 2 d.

The rat hepatoma cell line H4IIE was cultured at 37℃ in an atmosphere containing 50 mL/L CO_2 and 950 mL/L air, and maintained in DMEM containing 1 g/L glucose and 10% FBS. The cells were incubated in serum-free DMEM (1 g/L glucose) overnight before assay. Glucose levels were adjusted to 4.5 g/L and H4IIE cells were treated with resistin (50 ng/mL) (Alexis, USA) for 2 h prior to insulin (100 nmol/L) stimulation for 2 h. Glycogen synthesis was then assayed as previously described[14].

L6 rat myoblasts were maintained in DMEM supplemented with 10% FBS and differentiated into myotubes by exposure to DMEM supplemented with 2% FBS. Myogenic differentiation to myotubes was confirmed morphologically and biochemically as previously described[15].

Resistin secretion

The supernatants of 3T3-L1 preadipocytes were collected on d 0, 4, 6, and 8 after differentiation and centrifuged to remove cells that might have detached from the culture flasks. The supernatants were kept at -20℃ until assayed for resistin content by enzyme immunoassay (ADL, USA).

RNA preparation and amplification by RT-PCR

Total RNA was isolated from cultured 3T3-L1 cells using the TRIZOL method (Invitrogen, USA). Single strand cDNA synthesis was performed. In brief, the reverse transcription mixture contained 1 μg total RNA, 0.5 μg of oligo d(T) primer, 4 μL of 5 × RT buffer, 0.5 mmol/L deoxynucleotides, 50 U of RNase inhibitor, and 200 U of reverse transcriptase (Promega, USA) in a total volume of 20 μL, the reaction was carried out at 42℃ for 1 h followed by heat inactivation at 95℃ for 5 min. The number of cycles and reaction temperatures used in the PCR assay were optimized to provide a linear relationship between the amount of input template and the amount of PCR product[16]. The primers used for amplification, together with their specific optimum cycling conditions, were as follows:

Mouse resistin (a 415 bp product): [sense primer: 5'-CAA ACAAGACTTCAACTCCC-3', antisense primer: 5'-ACA CACACCCTTCTCCACTA-3', annealing temperature (TA) 58℃, 33 cycles].

β-actin (a 240 bp product): [sense primer: 5'-TAA AGA CCTCTATGCCAACACAGT-3', antisense primer: 5'-CAC GATGGAGGGGCCGGACTCATC-3' annealing temperature (TA) 57℃, 25 cycles].

Glycogen detection

H4IIE cells were serum starved overnight in DMEM containing 0.2% FBS prior to resistin and/or insulin treatment in all experiments. Cells were lysed with 30% KOH and the vials were kept at 100℃ for 20 min. After addition of anhydrous ethanol, the vials were centrifuged at 4000 × *g* for 15 min with the supernatants discarded. Distilled water (0.5 mL) and 1 mL of 0.2% anthrone [0.2 g of anthrone in 100 mL of 98% H_2SO_4 (g/mL), prepared freshly within 1 h] were added, and the vials were placed into boiling water for 20 min. The optical density at 620 nm of the solution in vials was determined by photometry. This method could detect 1.6 μg of glucose per mL, which is equivalent to 1.44 μg of glycogen per mL[17].

2-Deoxyglucose uptake assay

Myotubes were serum starved overnight in DMEM containing 0.2% FBS prior to resistin and/or insulin (10 nmol/L 15 min) treatment in all experiments. Uptake of 2-deoxy-D-[3H] glucose (CIC, China) was assayed for 10 min as previously described[18]. Briefly, the cells were washed with ice-cold phosphate-buffered saline, and then 200 μL NaOH (1 mol/L) was added to each well. Aliquots of the cell lysate were transferred to the scintillation vials for radioactivity counting and the remainder were used for protein assay. Non-specific uptake was determined in the presence of cytochalasin B (10 μmol/L) and subtracted from all values.

Animals

Forty-eight weaned male Sprague-Dawley rats, supplied by the Animal Center of Jiangsu Province, were acclimated to 22℃ in a 12 h light/12 h dark cycle with free access to a standard chow diet for at least a week before grouping. High energy diet contained 10% milk powder, 10% glucose, 10% egg, 10% oil, and 60% standard feed[19]. Animals received this diet for 7 wk. Insulin sensitivity was defined by a value of ISI {ISI = Ln [1/(fasting plasma insulin*glucose)]}[20].

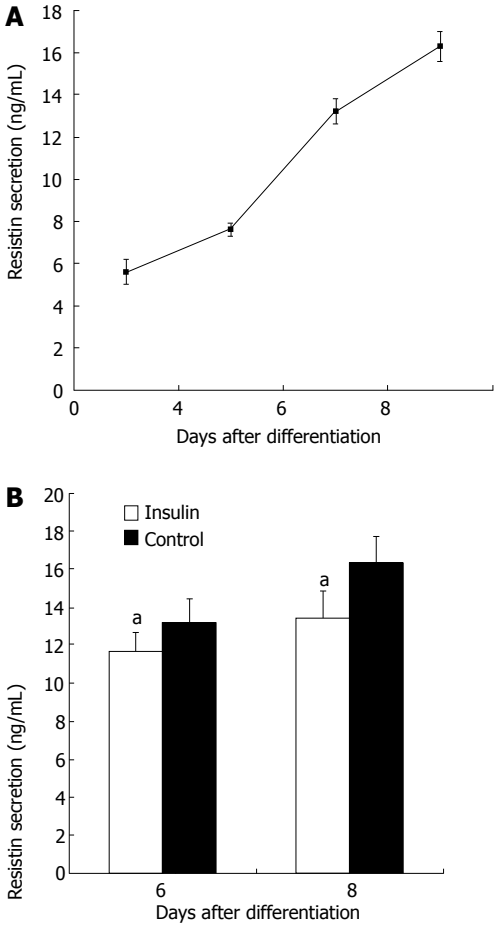

Figure 1 Increased resistin secretion (**A**) and insulin-inhibited resistin secretion (**B**) during 3T3-L1 preadipocyte differentiation. $^{a}P < 0.05$.

Statistical analysis

The data were presented as mean ± SE. Statistical analysis was undertaken using one-way ANOVA or the paired Student's *t*-test where appropriate. Serum resistin levels in diet-induced obese rats were compared with the insulin sensitivity index and levels using the Bivariate correlation. Differences between groups were considered statistically significant when $P < 0.05$.

RESULTS

Increased resistin secretion during 3T3-L1 preadipocyte differentiation inhibited by insulin

Resistin secretion was enhanced during 3T3-L1 preadipocyte differentiation ($P < 0.05$, Figure 1A). Resistin secrtion was about 3-fold higher in matured 3T3-L1 adipoctyes (d 8) than in 3T3-L1 preadipocyte (d 0) ($P < 0.05$). The effect of inslulin (100 nmol/L) on resistin secretion was then assessed in cultured 3T3-L1 adipocytes on d 6 and d 8. Six days after induction of differentiation, 100 nmol/L insulin reduced secretion of resistin by 13% ($P < 0.05$, Figure 1B). Eight days after induction of differentiation, 100 nmol/L insulin reduced secretion of resistin by 20% ($P < 0.05$, Figure 1B).

Upregulation of resistin mRNA level during 3T3-L1 preadipocyte differentiation inhibited by insulin

Resistin mRNA was not detectable in undifferentiated 3T3-L1 cells, but was evident by d 4 after the induction of differentiation into adipocytes (Figure 2A). Resistin mRNA was up-regulated during 3T3-L1 preadipocyte differentiation (Figure 2A), and 100 nmol/L insulin decreased resistin mRNA 6 and 8 d after differentiation (Figure 2B).

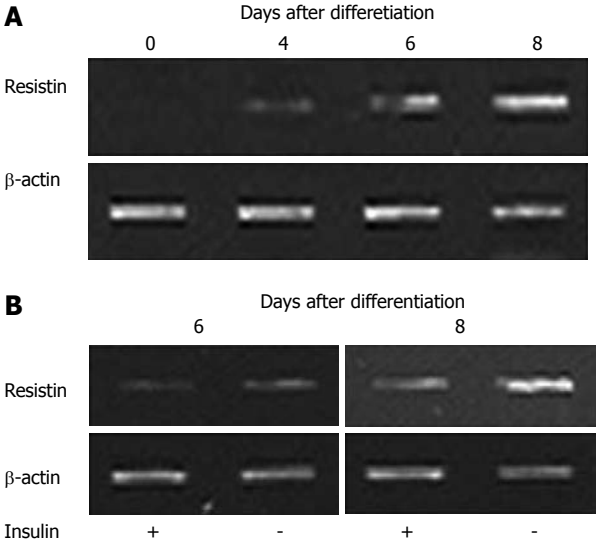

Figure 2 Up-regulation (**A**) and down-regulation (**B**) of resistin mRNA level by insulin during 3T3-L1 preadipocyte differentiation.

Induction of cellular insulin resistance by resistin

Since insulin could inhibit resistin expression and secretion *in vitro*, additional studies were initiated to determine whether resistin plays a role in insulin resistance. Hepatocytes and myotubes are two important targets of insulin[21]. Glycogen synthesis in insulin-stimulated hepatocytes is the most important marker of hepatocyte insulin sensitivity[22]. After treatment with resistin for 2 h, basal glycogen synthesis decreased about 15% and insulin-stimulated glycogen synthesis decreased about 25% in H4IIE cells ($P < 0.05$, Figure 3A). After treatment with resistin for 2 h, basal 2-deoxyglucose uptake decreased about 50% and insulin-stimulated 2-deoxyglucose uptake decreased about 60% in myotubes ($P < 0.05$, Figure 3B), suggesting that resistin could induce cellular insulin resistance, and both hepatocytes and myotubes are important targets of resistin.

Negative correlation of serum resistin with insulin sensitivity but not with serum insulin

Serum resistin levels correlated with rat ISI ($r = -0.662$, $P = 0.005$) in both control and diet-induced obese rats (Figure 4A). Resistin was positively correlated with insulin ($r = 0.592$, $P = 0.016$, Figure 4B), suggesting that insulin could not inhibit resistin secretion *in vivo*.

DISCUSSION

Obesity is associated with insulin resistance and type 2 diabetes, implying that adipose tissue plays a role in the development of such disorders[23]. Besides storing fat, adipose tissue is also an active regulation centre, providing signals to guide metabolism by secreting adipokines[1,2]. Resistin is a newly discovered adipokine that is believed

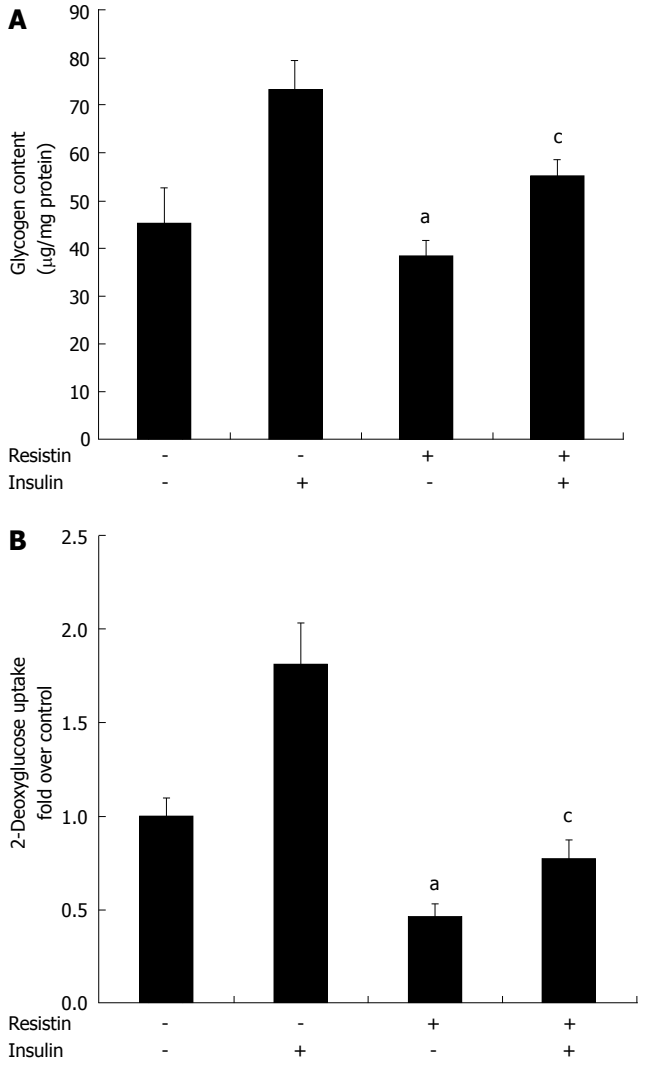

Figure 3 Cellular insulin resistance induced by resistin after treatment of serum-starved H4IIE hepatocytes with 50 ng/mL resistin (**A**) and 100 nmol/L resistin (**B**). $^{a}P < 0.05$ *vs* negative control, $^{c}P < 0.05$ *vs* positive control.

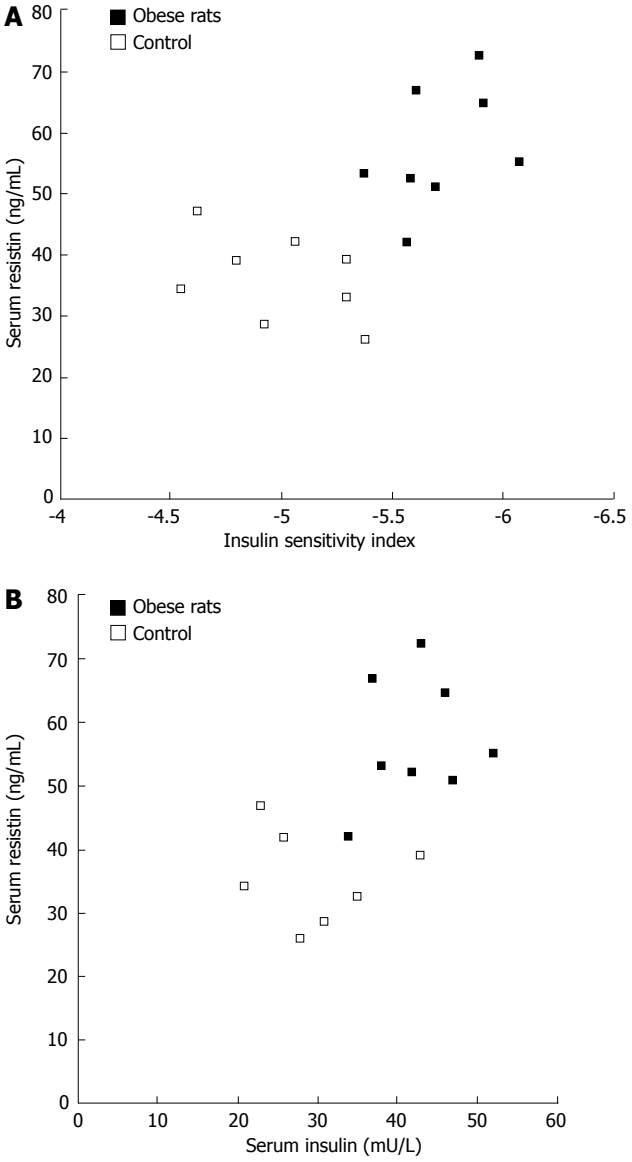

Figure 4 Correlation of serum resistin with rat insulin sensitivity index (**A**) and insulin levels (**B**).

to provide a link between obesity and diabetes[3,4]. Under conditions of insulin resistance and type 2 diabetes, fat tissue is subjected to increased levels of insulin, which may have a major impact on adipokine levels[24,25]. Studies have verified that circulating levels of insulin are correlated with specific adipokines in rodents and humans, with interleukin-6 and leptin levels showing a consistently positive association with insulin levels[24-26]. However, the association of resistin with insulin remains contradictory[27].

Resistin is one of the adipocytokines secreted by adipose tissue and has been shown to modulate both glucose and lipid metabolism *in vivo* and *in vitro*[3,4]. In L6 rat skeletal muscle cells, it has been shown that resistin does not alter insulin receptor signaling but affects insulin-stimulated glucose uptake, presumably by decreasing the intrinsic activity of cell surface glucose transporters[7,8]. In mature 3T3-L1 adipocytes, resistin reduces insulin-stimulated glucose uptake by activating SOCS3, which is an inhibitor of insulin signaling[9]. In addition, it was reported that resistin takes part in insulin resistance in resistin fat-specific transgenic rats by releasing free fatty acids (FFA) from adipose tissue[28].

In the present study, resistin expression and secretion were increased during 3T3-L1 preadipocyte differentiation and resistin mRNA was undetectable in undifferentiated 3T3-L1 cells but was evident by d 4 after the induction of differentiation into adipocytes. The highest expression of resistin mRNA was detected on d 8 after induction of differentiation. Insulin had a marked suppressive effect on resistin mRNA levels in 3T3-L1 adipocytes and inhibited resistin secretion 6 and 8 d after induction of differentiation, suggesting that resistin does not play a role in insulin resistance.

Then, we investigated whether resistin impairs insulin sensitivity *in vitro*, showing that resistin could induce cellular insulin resistance in hepatocytes and myotubes. That is a paradox, because resistin is not regulated by insulin but induces insulin resistance[11]. If both are correct, they will form a deadly insulin-resistin-insulin sensitivity positive feedback loop.

To confirm which one plays the primary role *in vivo*, we analyzed the relationship between serum resistin and

insulin and their sensitivity in diet-induced obese rats. Diet-induced insulin resistance is a relevant model for the most common form of insulin resistance in humans[29]. In our study, serum resistin strongly correlated with rat insulin sensitivity and resistin was positively correlated with insulin, suggesting that insulin could not inhibit resistin secretion *in vivo*. A number of factors can regulate resistin secretion, such as glucose, epinephrine, and somatropin[27,30]. Therefore, insulin may regulate resistin although it is not the major regulator.

In summary, insulin inhibits resistin secretion while resistin induces insulin resistance. Serum resistin correlates with rat insulin sensitivity, meaning that insulin is not the major regulator of resistin. Resistin may play a role in diet-induced insulin resistance by inducing insulin resistance in hepatocytes and myotubes.

COMMENTS

Background

Type 2 diabetes mellitus is closely associated with obesity. Resistin is a recently identified adipokine involved in insulin sensitivity and glucose tolerance. So the investigation of insulin and resistin interaction seems to be important.

Research frontiers

In this article, resistin biological function and interaction of resistin to insulin were studied. We also demonstrated the secretion levels of resistin *in vivo* and *in vitro*.

Innovations and breakthroughs

Resistin induces insulin resistance in hepatocytes, but insulin inhibits resistin secretion *in vitro*. Since serum resistin correlates with rat insulin sensitivity, insulin is not the major regulator of resistin and resistin may play a role in diet-induced insulin resistance by inducing insulin resistance in hepatocytes and myotubes.

Applications

Resistin is a newly identified hormone secreted by adipocytes. Resistin induces insulin resistance both *in vivo* and *in vitro*. This establishes a new field in the pathogenesis of type 2 diabetes.

Peer review

This paper discusses the regulatory mechanisms of resistin and insulin. The study is well designed and the paper is well written. The topic is of scientific value.

Abstract

AIM: To investigate the distribution pattern of lymphatic vessels and microvessels in sporadic colorectal carcinoma (SCRC) and their relationship to metastasis and prognosis.

METHODS: The lymphatic vessel density (LVD) and microvessel density (MVD) in tumor tissue obtained from 132 patients with primary SCRC, including 74 with metastases and 58 without metastases, were evaluated by immunohistochemistry using antibodies directed against D2-40 and von Willebrand factor (vWF).

RESULTS: (1) The lymphatic vessels and microvessels at central portions of SCRC often had a reticular architecture with numerous tiny and ill-defined lumina, while those at tumor borders had large and open lumina. The LVD and MVD were both obviously higher in colorectal cancer patients with metastases than in those without ($P < 0.001$). (2) For each one lymphatic vessel increased, there was a 1.45-fold increase in the risk of metastasis in SCRC. The specificity and sensitivity of LVD in predicting metastasis or non-metastasis in SCRC were 71.62% and 56.90%, respectively, and the corresponding LVD was 5. For each one microvessel increased, there was a 1.11-fold increase in the risk of metastasis in SCRC. The specificity and sensitivity of MVD were 66.22% and 51.72%, respectively. (3) Double labeling immunohistochemistry showed D2-40 immunoreactivity to be specific for lymphatic vessels. (4) Univariate analysis indicated that high LVD, high MVD, as well as co-accounting of high LVD and high MVD were associated with patient's poor disease-free survival ($P_{uni} < 0.05$); multivariate analysis indicated that co-accounting of LVD and MVD was an independent prognostic factor of colorectal cancer.

CONCLUSION: D2-40 is a new specific antibody for lymphatic endothelial cells. Lymphogenesis and angiogenesis are commonly seen in SCRC, especially at tumor borders. The detection of LVD and MVD at tumor borders may be useful in predicting metastasis and prognosis in patients with SCRC, and, in particular, co-accounting of LVD and MVD might be a useful prognostic factor in SCRC.

INTRODUCTION

Lymphangiogenesis (lymph vessel growth) and angiogenesis (blood vessel growth) are critical processes for tumor growth, invasion, and metastasis. Angiogenesis has established its role in the development and progression of a variety of malignancies, playing a crucial role in the dissemination of tumor cells[1,2]. However, lymphatic spread of cancer cells to lymph nodes is an important early event in the metastasis of carcinoma[3]. Previous studies have been limited by the lack of specific lymphatic endothelial makers that allow to discriminate between lymphatics and blood vessels. Recently, the monoclonal antibody D2-40, which is directed against the oncofetal membrane antigen M2A that has been identified in ovarian carcinoma cell lines and germ-cell tumors[4], was reported to be a specific marker for lymphatic endothelium in normal and neoplastic tissue[5,6].

In this study, using the antibody D2-40 and von Willebrand factor (vWF), we investigated the distribution patterns of microvessles and lymphatic vessels and calculated the lymphatic vessel density (LVD) and

microvessel density (MVD) in sporadic colorectal carcinoma (SCRC). Moreover, we analyzed their relationship with tumor metastasis and disease prognosis. By double labeling immunohistochemistry we were able to confirm D2-40 specificity.

MATERIALS AND METHODS

Patients and specimens

A total of 132 colorectal carcinoma samples were obtained from the archives of the Department of Pathology, Cancer Hospital, Fudan University, from July 2004 to May 2005. Samples were derived from patients who were solely surgically treated without prior chemo- or radiotherapy. There were 77 men (58.3%) and 55 women (41.7%) with a median age of 57 years (range, 22-82 years), 46 patients with colon and 86 patients with rectum tumors. 74 patients (56.1%) had histologically confirmed lymph node metastases, whereas the remaining 58 patients (43.9%) were found to have no clinical or histopathologic evidence of lymph node involvement. According to the current World Health Organization classification, tumors of 14 (10.6%) patients were well differentiated, that of 96 patients (72.7%) were moderately differentiated and that of 22 (16.7%) patients were poorly differentiated. Follow-up for this cohort was updated to September 2006. Complete data were available for 127 (96.2%) patients, with a median follow-up time of 22 mo (range, 2-26 mo). At the end of follow-up, 18 (14.17%) patients had died of disease and 9 (7.09%) had developed distant metastases. The study was approved by the local ethical committee in Cancer Hospital of Fudan University.

Immunohistochemistry

Tissues were fixed in 10% buffered formalin, processed, and stained with hematoxylin and eosin (H&E). H&E-stained slides of all samples were reviewed to confirm the diagnosis. One paraffin block with the bulk of tumor tissue was used for immunohistochemical studies. All slides showed the nonneoplastic colorectal tissue-carcinoma junction. Sections, 3 mm-thick, of formalin-fixed paraffin embedded tissues were cut and mounted on coated slides. The sections were deparaffinized in xylene and rehydrated in a descending ethanol series. Heat induced epitope retrieval techniques were used for antigen retrieval as follows: citrate buffer (pH 6.0) and a water bath at 95℃-98℃ for 30 min for D2-40, Tris-EDTA buffer (pH 8.0) and a water bath at 95℃-98℃ for 30 min for vWF. Sections were incubated for 10 min in 3% hydrogen peroxide to quench endogenous tissue peroxidase. The sections were immunostained with a monoclonal antibody (Clone D2-40, m3619; Dako Corp., Carpinteria, CA, USA) at a 1:100 dilution directed against D2-40 and a rabbit polyclonal antibody (A0082; Dako) at a dilution of 1:200 directed against vWF. Tissue sections were incubated with the primary antibody for 12 h at 4℃. After washing with phosphate-buffered saline, a Super picture secondary antibody (Zymed Lab Inc, CA, USA) and 3-3' diaminobenzidine detection kit (Dako) were used. A lymphangioma tissue sample served as a positive control and replacement of the primary antibody by PBS as a negative control. Thirty samples were picked randomly for double labeling immunohistochemistry (Histostain™-DS double labeling immunohistochemistry kit, Zymed). The sections were first subjected to D2-40 staining using BCIP/NBT as chromogenic agent, followed by a vWF staining using AEC as chromogenic agent.

Evaluation of immunostaining and vessels counting

Immunohistochemical reactions for D2-40 and vWF were interpreted independently by two authors (Y.G. and Z.GH.) using a two-headed microscope. After scanning the immunostained section at low magnification (× 100), five areas of carcinoma with the greatest number of distinctly highlighted intratumoral lymphatic/vascular foci (hot spots) were selected and vessels were counted in a representative high magnification (× 200) field in each of these five areas. Single immunoreactive endothelial cells, or endothelial cell clusters separate from other microvessels, were counted as individual microvessels. Endothelial staining in large vessels with tunica media, and non-specific staining of nonendothelial structures, were disregarded in microvessel counts. Mean visual microvessel density for D2-40 and vWF was calculated as the average of five counts[7]. In double labeling immunohistochemistry, lymphatic vessels were amethyst and blood vessels were bright red.

Statistical analysis

Mean differences in microvessel counts were compared with the use of "*t*" tests. The probability of differences between the high-vessel group and the low-vessel group in disease-free survival (DFS) was determined as a function of time by the use of Kaplan-Meier test, with significance probing by applying the log-rank test. We used multivariate regression analysis based on the Cox proportional hazard model to test the independence of these parameters to predict overall survival. Logistic regression analysis and ROC curve were used to determine specificity and sensitivity of LVD and MVD in assessment of metastasis in SCRC. Generally, P value < 0.05 was regarded as significant. For all statistical procedures, SPSS v12.0 and Stata v7.0 software were used.

RESULTS

Expression pattern of lymphatic vessels in SCRC and correlation of LVD with clinicopathologic parameters

A tissue sample of lymphangioma was chosen as a positive control for D2-40 staining. As shown in Figure 1A, endothelial cells in this sample were found to be positive. In SCRC samples, definite lymphatic vessels were stained by D2-40. Lymphatic vessels at central portions were rare, even absent in some case, and often had a reticular architecture with numerous tiny and ill-defined lumina (Figure 1B). The LVD was higher at tumor borders (10.32 ± 4.94) than at central portions and had large and open lumina (Figure 1C). The LVD was obviously higher in the CRC samples with metastases (12.08 ± 4.96) than in those without (8.26 ± 4.08) ($P < 0.001$). There was no significant correlation between

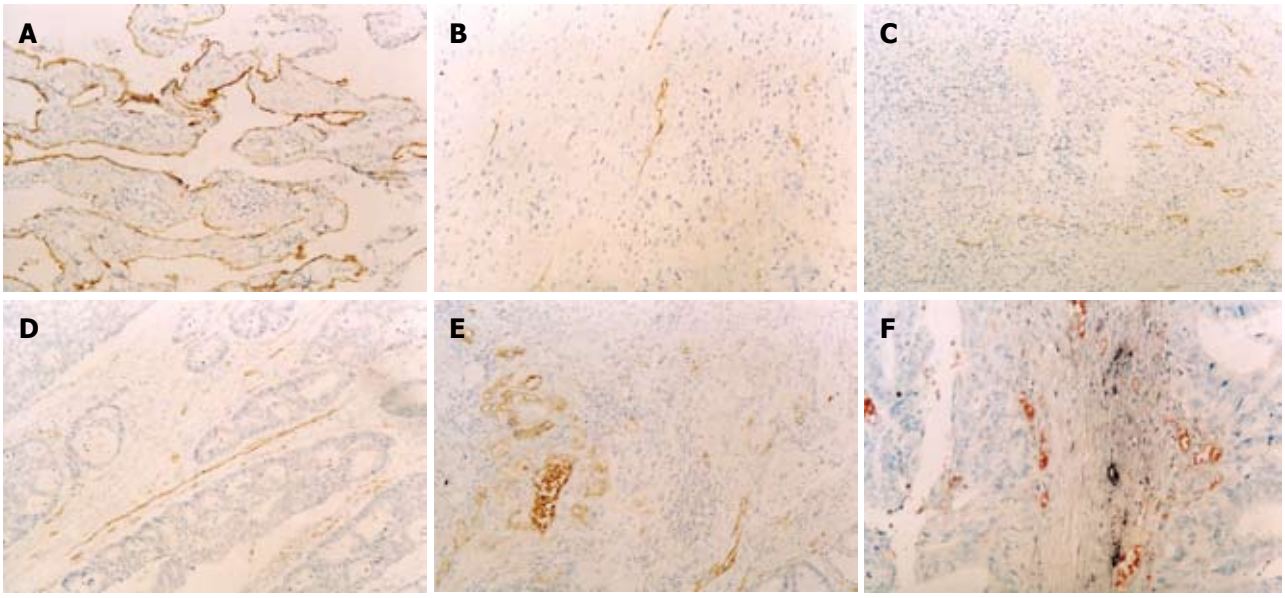

Figure 1 Immunohistochemical stainings of D2-40 (**A**, **B**, **C** × 100), vWF (**D**, **E** × 100) and double labeling immunohistochemistry (**F** × 200, red: Blood vessels labled by vWF; amethyst: Lymphatic vessels by D2-40). **A**: Lymphangioma (positive control); **B-F**: Colorectal carcinoma.

Table 1 Correlation of LVD/MVD with clinicopathologic parameters of SCRC

Clinico-pathologic features	*n*	LVD		MVD

LVD: Lymphatic vessel density; MVD: Microvessel density.

LVD with age, gender, tumor size, location, degree of differentiation, or invasive depth ($P > 0.05$) (Table 1).

Logistic regression analysis and ROC curve of LVD in SCRC

A logistic model was built with LVD as an independent and metastasis as dependent variable (Prob > chi2 = 0.0000, Pseudo R2-0.1176). According to the analysis for of the logistic model, we found an OR value of 1.45, meaning that for each lymphatic vessel there is an 1.45-fold increase in the risk of metastasis in SCRC. The specificity and sensitivity of LVD in predicting metastasis or non-metastasis in SCRC were 71.62% and 56.90%, respectively, and the corresponding LVD was 5 (Figure 2A).

Expression pattern of blood microvessels in SCRC and correlation of MVD with clinicopathologic parameters

There were abundant microvessels labeled by vWF in SCRC, with the similar distribution pattern to lymphatic vessels. The distribution feature and quantity of microvessels were different within one tumor sample. That is, microvessels at surrounding part of tumor were abundant (mean = 21.24 ± 11.98) and had large and open lumina (Figure 1D). But, microvessels at central portions were seldom and often had a reticular architecture with numerous tiny and ill-defined lumina (Figure 1E). The MVD was obviously higher in the colorectal carcinoma samples with metastasis (23.74 ± 12.02) than in those without (18.00 ± 9.44) ($P = 0.003$). There was no significant correlation between MVD with age, gender, tumor size, location, degree of differentiation, or invasive depth ($P > 0.05$) (Table 1).

The specificity of D2-40 for lymphatic vessels and vWF for microvessels was confirmed by double labeling immunohistochemistry. There was no cross-reaction between the two antibodies. Lymphatic vessels and microvessels distributed separately in tumor borders without obvious relationship (Figure 1F).

Logistic regression analysis and ROC curve of MVD in SCRC

A l-Logistic model with MVD as an independent and metastasis as the dependent variable could be established (Prob > chi2 = 0.0022, Pseudo R2 = 0.0519). According to this model, we found an OR of 1.11, meaning that for each microvessel there is an 1.11-fold increase in the risk of metastasis in SCRC. According to ROC curve analysis, the specificity and sensitivity of MVD in predicting metastasis or non-metastasis in SCRC were 71.62% and 56.90%, respectively (Figure 2B).

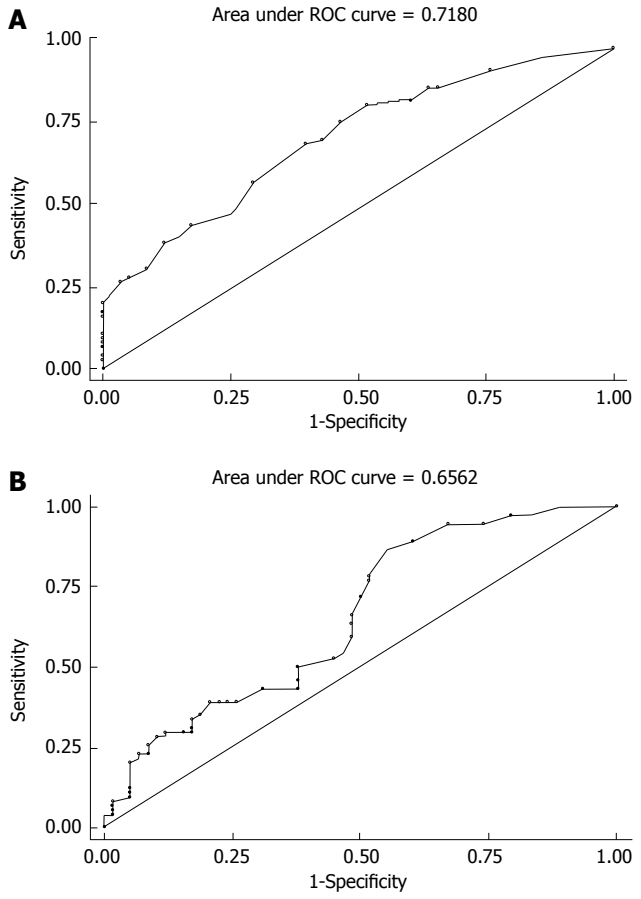

Figure 2 ROC curve of LVD (**A**) and MVD (**B**).

Univariate survival analysis

LVD = 5 was defined as demarcation value according to the ROC curve of LVD. LVD > 5 was high LVD group and LVD < 5 was low LVD group. The median of MVD (median = 9.33) was defined as demarcation value. MVD > 9.33 was high MVD group and MVD < 9.33 was low MVD group. LVD > 5 and MVD > 9.33 was co-high group. In univariate analysis with Kaplan-Meier for disease-free survival (DFS), high LVD (P = 0.0303), high MVD (P = 0.0196), co-high LVD and MVD (P < 0.0001) were associated with patient's poor DFS ($Puni$ < 0.05) (Figure 3).

Multivariate survival analysis

All factors were brought into a Cox regression model, including some clinico-pathologic parameters such as patients' age, gender, tumor size, location, degree of differentiation, invasive depth and metastasis, LVD, MVD, and co-accounting of LVD and MVD. Multivariate analysis indicated that besides metastasis (P = 0.004), gender (P = 0.012), and location (P = 0.028), co-accounting of LVD and MVD was an independent prognostic factor of colorectal carcinoma (P = 0.014).

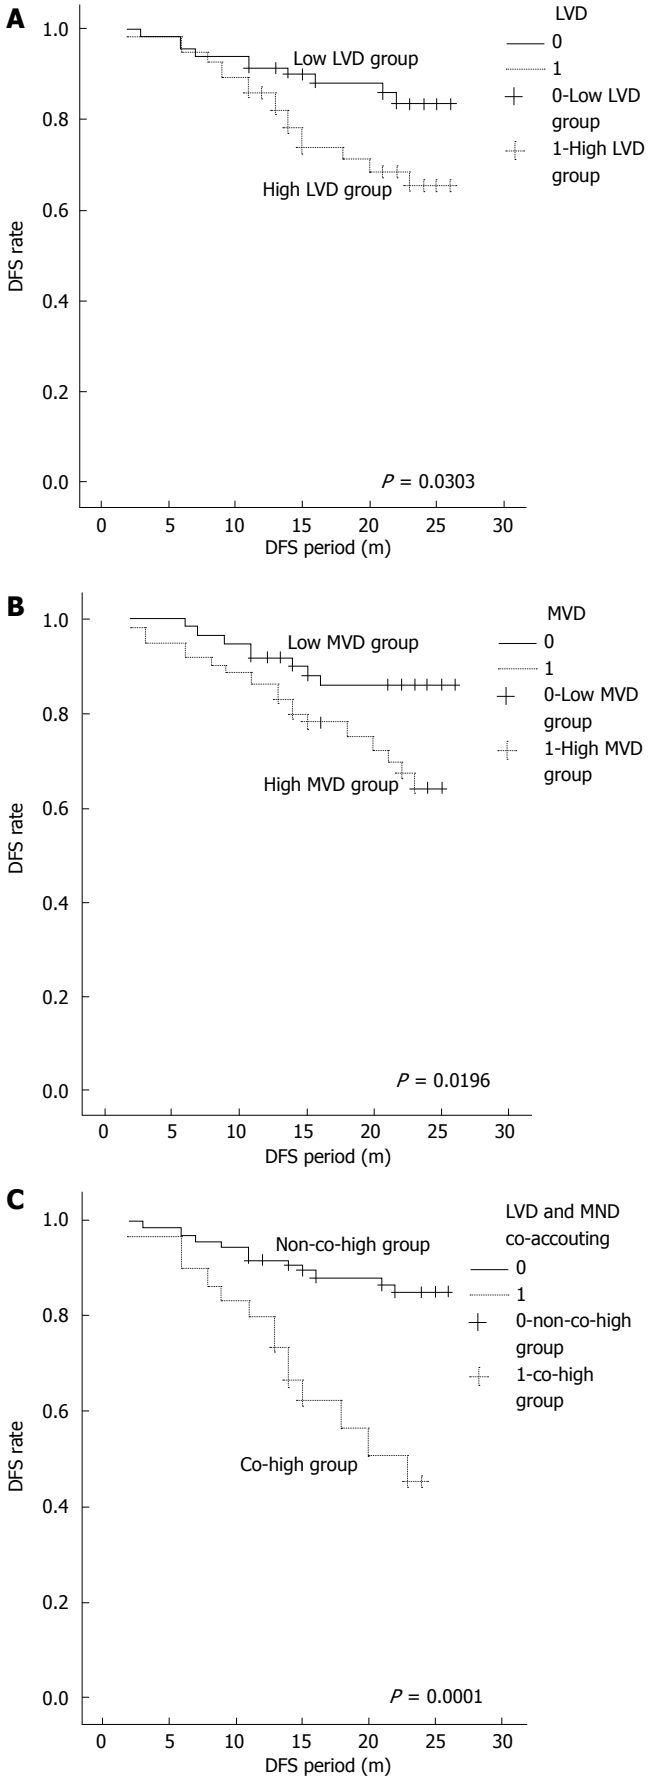

Figure 3 Survival curve of LVD (**A**), MVD (**B**) and co-accounting of LVD and MVD (**C**).

DISCUSSION

This study is one of the first attempts to quantify colorectal carcinoma lymphangiogenesis and angiogenesis in the same sample by microvessel density using the novel lymphatic marker D2-40 and vWF. We compared the distribution pattern and density of lymphatic vessels and

blood vessels, and related the results to clinicopathologic parameters and the outcome of colorectal carcinoma. Moreover, specificity of the two antibodies was confirmed by double labeling immunohistochemistry.

Significance of lymphangiogenesis in SCRC

The lymphatic system is the primary pathway of metastasis for most human cancers. Lymphangiogenesis refers to the development and proliferation of new lymphatics from host vessels. Recently, antibodies specific for lymphatic endothelium have become available, providing important new insights into the process of tumor-associated lymphangiogenesis and its possible clinical relevance. Many studies have reported that tumors are able not only to induce lymphangiogenesis, but also to enhance lymphatic metastasis[8,9].

There are some antibodies for lymphatic endothelium now, including VEGFR-3/flt4 (vascular endothelial growth factor receptor 3/fms-like tyrosine kinase 4)[10], LYVE-1 (lymphatic endothelial hyaluronan receptor)[11], Prox-1[12], CD31[13], and podoplanin[14]. VEGFR-3, the receptor for vascular endothelial growth factors (VEGFs) C and D, is expressed on lymphatic endothelium and may play a role in lymphangiogenesis[15,16]. But, some studies indicated that VEGFR-3 was also involved in blood vessel angiogenesis in the adult and it was not a specific antibody for lymphatic endothelium[17]. CD31 also stained both in blood vessel and in lymphatic vessel. But, the monoclonal antibody D2-40 is a highly selective marker of lymphatic endothelium in sections of both frozen and formalin-fixed paraffin-embedded normal and neoplastic tissues. In a direct comparison of D2-40 and CD31 on paraffin sections of a series of tumors derived from lymphatic endothelium (lymphangiomas) and blood vessel endothelium (hemangiomas), D2-40 stained all lymphagiomas (10/10) but no hemangiomas (0/10). Conversely, CD31 stained a fraction of lymphangiomas (5/10) but all hemangiomas (10/10)[13].

Pusztaszeri *et al*[18] found D2-40 to be a sensitive and relatively specific marker for lymphatic endothelium in all parenchymatous organs. It stained lymphatic endothelium only and it has been demonstrated to recognize tumor-associated lymphatic vessels in many tumors[19,20]. Lymphatic vessels stained by D2-40 in our study often had a defined lumen with thin walls lacking erythrocytes, which were all the features of lymphatic vessels. There was no cross-reaction between D2-40 for lymphatic vessels and vWF for microvessels in double labeling immunohistochemistry. D2-40 is specific for lymphatic vessels[21,22].

We also found lymphatic vessels to show a different distribution between tumor central portions and tumor borders in SCRC. Lymphatic vessels at central portions were seldom, even absent in some cases, but abundant at tumor borders. This phenomenon may be due to the inside pressure of the tumor. The LVD was obviously higher in the cases of colorectal carcinoma with metastasis than that in cases without, indicating that tumor cells might migrate from a primary site to lymph nodes through lymphatic vessels at the tumor borders. The increase of LVD was related to lymph nodes metastasis in SCRC. According to the logistic model and ROC curve analysis, we found an OR of 1.45, meaning that for each lymphatic vessel there is a 1.45-fold increase in the risk of metastasis in SCRC. The specificity and sensitivity of LVD in predicting metastasis or non-metastasis in SCRC were 71.62% and 56.90%, respectively, and the corresponding LVD was 5. The univariate analysis showed high LVD to be associated with patient's poor DFS. Thus, LVD was an important factor to predict metastasis and prognosis for the patients with SCRC. Lymphatic vessels were composed of a single, non-fenestrated endothelial layer with wide and irregular lumina. Endothelial cells, with scant cytoplasm were often overlapping. But there were infrequent interendothelial tight junctions and no basement membrane and encircling pericytes on them. The morphology of lymphatic vessels differed from that of blood microvessels consequently made it was easy for fluid, particles, and tumor cells to pass into the lymphatic vessels. The surface area between tumor cells and lymphatic endothelial cells increased with the enhancement of LVD, which promoted the migration of tumor cells to lymph nodes[2]. So lymphangiogenesis is associated with an increased incidence of lymph nodes metastasis, and it is possible that this step is essential to the metastatic process. Recently, some studies on gastric cancer[23] and breast cancer[24,25] demonstrated LVD to be correlated with lymph nodes metastasis.

Significance of angiogenesis in SCRC

Angiogenesis, the formation of new blood vessels from the endothelium of the existing vasculature, is fundamental in tumor growth, progression and metastasis, especially for colorectal carcinoma[26]. The complex network of tumor blood microvessels guarantees adequate supply of tumor cells with nutrients and oxygen and provides efficient drainage of metabolites. In addition to primary tumor growth, metastatic tumor growth depends upon neovascularization in at least two steps: First, malignant cells must exit from a primary tumor into the blood circulation after the tumor becomes neovascularized. Second, after arrival at distant organs, metastatic cells must again induce angiogenesis for a tumor to expand to a detectable size[27,28]. Zhao *et al*[29] suggests MVD as one of the important prognostic factors for gastric cancer patients by immunohistochemical staining of endothelial protein factor Ⅷ-related antigen. Romani *et al*[30] evaluated retrospectively the effect of CD105-assessed (a marker of neovascularization in solid malignancies) angiogenesis on the risk of developing metastatic disease in colorectal cancer. One hundred and twenty-five paraffin-embedded samples were analyzed by immunohistochemical methods using CD105 monoclonal antibody. The CD105-vessel count was found to be strongly correlated with the occurrence of metastatic disease. The median CD105-positive vessels in patients with and without metastatic disease were 24.7 and 13.2 vessels/mm^2, respectively ($P < 0.001$). For each one microvessel increase in the vessels count per 400 × field, there was a 1.42-fold increase in the risk of metastatic disease ($P < 0.001$). We found the distribution feature and quantity of microvessels were different within one tumor sample labeled by vWF, which is similar to the distribution pattern of lymphatic vessels.

That is, microvessels at surrounding part of tumor were abundant (mean = 21.24 ± 11.98) and had large and open lumina. In contrast, microvessels at central portions were less frequent and often had a reticular architecture with tiny and ill-defined lumina. The MVD was obviously higher in samples from colorectal carcinoma patients with metastasis than in those without. Our results indicated metastasis of SCRC to be associated with MVD. According to the logistic model, we found an OR of 1.11, meaning for each microvessel there is an estimated 1.11-fold higher risk of metastasis in SCRC. According to ROC curve analysis, the specificity and sensitivity of MVD in predicting metastasis or non-metastasis in SCRC were 71.62% and 56.90%, respectively. The univariate analysis showed high MVD to be associated with patient's poor DFS. The lymphatic system was the most common pathway of metastasis for SCRC, accounting 60%. And the second primary pathway was blood vessels. Compared with LVD, the specificity and sensitivity of MVD in predicting metastasis or non-metastasis was lower. But MVD still played a role in roughly predicting prognosis of patients with SCRC.

Lymphangiogenesis and angiogenesis are essential for metastasis of tumor cells. We evaluated the specificity (71.62% *vs* 66.22%) and sensitivity (56.90% *vs* 51.72%) of LVD and MVD in SCRC. The specificity and sensitivity of LVD was slightly higher than that of MVD. Thus, neither LVD nor MVD alone were sufficiently specific and sensitive to predict metastasis or prognosis. We thus combined LVD with MVD to co-account. Univariate analysis indicated that co-accounting of high LVD and high MVD were closely associated with patient's poor DFS and multivariate analysis indicated besides metastasis, gender and location, co-accounting of LVD and MVD to be independently predictive. Thus, evaluating lymphangiogenesis and angiogenesis are thought to be clinically important, particularly for the estimation of the metastatic risk and prognosis.

In summary, D2-40 is a new specific antibody for lymphatic endothelial cells. Lymphogenesis and angiogenesis are commonly seen in SCRC, especially at tumor borders. The detection of LVD and MVD at tumor borders may be useful in predicting metastasis and prognosis in patients with SCRC, and especially, the co-accounting of LVD and MVD might be used as a prognostic factor of SCRC.

We thank Jin-Biao Lu, Xiao-Mei Li and Teng-Fang Zhu for expert immunochemistry support. Special thanks to Yan-Yan Mao and Ji Zhu for technical assistance in statistical analysis.

COMMENTS

Background

More and more researchers focus on the importance of lymphogenesis in tumorigenesis and metastasis because of the development and update of new markers for lymphatic vessels. It is a common phenomenon that metastatic local lymph node in sporadic colorectal carcinoma (SCRC), but the relationship between the lymphogenesis and metastasis is not clear.

Research frontiers

D2-40 is a new specific marker for lymphatic endothelium in normal and neoplastic tissue. Recent studies demonstrated D2-40 to be probably useful for diagnosis of malignant mesothelioma and research on lymphatic spread of cancer cells.

Innovations and breakthroughs

We investigated the role of lymphogenesis and angiogenesis using D2-40 and their distribution patterns in Sporadic colorectal carcinoma (SCRC). Moreover, we assessed how to predict metastasis by the increase of Microvessel density (MVD) and Lymphatic vessel density (LVD) and determined specificity and sensitivity.

Applications

Our study found LVD and MVD to be related to prognosis of SCRC. We calculated the risk ratio in predicting metastasis in SCRC by statistical procedures. In the future, we will be able to give an estimate on the prognosis and the survival of patients with colorectal carcinoma by accounting LVD and MVD.

Terminology

SCRC: Sporadic colorectal carcinoma; LVD: Lymphatic vessel density; MVD: Microvessel density.

Peer review

The results of this paper are reliably to the conclusions. The innovative and significant points conform to the background, objectives, materials and methods, results and conclusions. There is no conflict of interest, nor ethics problems. This is significant research.

Abstract

AIM: To explore the expression of phosphatase and tensin homolog deleted on chromosome ten (PTEN) in liver of athymic mice with hepatocellular carcinoma (HCC) and the effect of Fuzheng Jiedu Decoction (FJD).

METHODS: Forty eight male BALB/c athymic mice models were built by Bel-7402 with an indirect method. After 24 h of postoperation, the 48 athymic mice were distributed randomly into 4 groups: A, B, C, D, each group had 12 athymic mice. Group A were treated by intragastric administration with FT207 (Tegafur) for 4 wk. Group B, C and D were treated by intragastric administration with FJD (complex prescription of Chinese crude drug) that had been delegated into 3 kinds of density as the low, middle, and high for 4 wk. At last, athymic mice were put to death, live time, volume of tumors, exponent of tumors and the tumor metastasis in livers were observed; and PTEN was detected in hepatic tissue, latero-cancer tissue and cancer tissue by immunohistochemistry.

RESULTS: Four weeks later, the total survival rate in treatment group (A + B + C) was 50% and higher than the control group (0%) treated by FT207, ($P < 0.01$). The survival rate in group A, B, C was higher than in group D, and except group A with D, there was significant differentces (Fisher's Exact Test $P = 0.05$ or 0.01). And no differences were observed between the treatment groups and the control group in volume of tumors and exponent of tumors ($P > 0.05$). Tumor metastasis in livers of the treatment group was less than the controls (Fisher's Exact Test, $P = 0.021$). The result of immunohistochemistry showed that the intensity of PTEN in latero-cancer tissue was the highest, and then the hepatic tissue, the lowest was cancer tissue (Kruskal-Wallis test, $\chi^2 = 60.67$, $P = 0.000$). It also showed that the intensity of PTEN in treatment groups (A, B, C) was higher than the control group (D) ($F = 5.90$, $P = 0.002$ in hepatic tissue and $F = 15.99$, $P = 0.000$ in latero-cancer tissue and $\chi^2 = 26.08$, $P = 0.000$ in cancer tissue), and group B is the highest in the treatment groups ($P < 0.05$, $r = 0.01$. respectively). However, there was no significant statistic difference between group A and group C ($P > 0.05$).

CONCLUSION: FJD can prolong the survival time and decrease tumor metastasis in livers of these experimental mice. Mechanisms of FJD healing HCC may partially be explained by enhancing the expression of PTEN in liver.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major cancer killers. Although surgical resection, liver transplantation and percutaneous ablation are considered as effective treatment for HCC[1-3], Traditional Chinese Medicine (TCM) has been widely used as combined therapies in treating the disease in China. According to the theory of TCM, the main mechanism of HCC

is deficiency of vital qi and exuberant pathogens, thus strengthening body resistance and disintoxication is the major method of treating HCC[4]. The previous study demonstrated that reduced expression levels of PTEN are involved in the pathogenesis of HCC. Moreover, decreased phosphatase and tensin homolog deleted on chromosome ten (PTEN) expression was correlated with tumor progression and poor prognosis in patients with HCC[5-7], whether TCM can down-regulate the expression of PTEN in HCC is still unknown. The aim of our study is to explore the effect of Fuzheng Jiedu Decoction (FJD), complex prescription of Chinese crude drug in treating BALB/c athymic mice with HCC, as well as the expression of PTEN. We proclaim that the animal study was acknowledged by the Ethical Committee of The First Affiliated Hospital of Sun Yat-Sen University committee in the materials and methods section. The results are reported as following.

MATERIALS AND METHODS

Study animals and environmental conditions

Forty eight BALB/c athymic male mice, 4-6 wk, were purchased from The Experimental Animal Center of Traditional Chinese Medicine university of Guangzhou. The animals were housed individually in cages and kept in a room maintained at a temperature of 23 with a relative humidity (RT) of 55 with a 12-h/12-h light/dark cycle. Solid rodent chow and tap water were given ad libitum.

Drugs and reagents

FJD (Application: 200710026976.6) consists of the following indegredients: Ezhu (Rhizoma Curcumae) 15 g, Banzhilian (Herba Scutellariae Darbatae) 30 g, *etc*. They were decocted routinely and then made into a final concentration of 2 g/mL which extracted and prepared by college of pharmacy of Traditional Chinese Medicine University of Guangzhou. The prepared herbal pieces were purchased from Guangzhou City Pharmacy Company and consistent with the requirement of Pharmacopoeia of the People's Republic of China[8]; FT207 parenteral solution (Tegafur parenteral solution), 5 mL/0.2 g per ramus, Shandongqilu production (production batch number 06020032); rabbit anti-human PTEN polyclonal antibody (production batch number 60182150), Power Vision™ Two-Step Histostaining Reagent (production batch number 125135), were bought from Beijing Zhongshan Jinqiao biotechnology limited company.

Preparation of animal model

The athymic mice with indirect orthotopic transplantation tumor models were established in accordance with the method by Dr. Zheng Jianhua[9]. The animals were inoculated Bel-7402 hepatoma carcinoma cell with concentration of 1 million cells/mL on their waist and back, until subcutaneous transplantation tumor grew to diameter 1 cm, then cut down the tumor. Remove necrotic tissue in the tumor and cut into pieces about 1 mm^3 in Hanks liquid. Anesthetize the athymic mice in abdominal cavity with Pentobarbital 45 mg/kg weight, transverse incise the left upper quadrant, expose liver, take 1 piece of tumor tissue, use bodkin pinhead (20° angle of slope, deep 3 mm) imbed the tumor tissue in deep part of hepatic lobes parenchyma of athymic mouse in *ex vivo* 40 min, compresse the incision to stop bleeding then close abdomen.

Grouping and the treatment of the animals

Athymic mice were raised in SPF condition in divided cages. After 24 h of postoperation, the 48 athymic mice were distributed randomly into 4 groups, every group has 12 mice. Low concentration group (A): drench the Ganaifang (0.25 g Chinese crude drug/mL, 0.2 mL/10 g weight) with the dose of 10 times human unit kilogram weight. Middle concentration group (B): drench the Ganaifang (0.5 g Chinese crude drug/mL, 0.2 mL/10 g weight) with the dose of 20 times human unit kilogram weight. High concentration group (C): drench the Ganaifang (1.0 g Chinese crude drug/mL, 0.2 mL/10 g weight) with the dose of 40 times human unit kilogram body weight. Chemotherapy group (D): drench the FT207 parenteral solution (Tegafur parenteral solution) (8 mg/mL, 0.2 mL/10 g weight) with the dose of 5 times human per day.

Record live time of each athymic mouse in the process of observation. When the treatment was ended, get blood from athymic mice eyeball, and put them to death, then dissect them, meanwhile record the tumor volume, tumor index number (the weight of the tumor/the weight of the mouse), fix the normal hepatic tissue, latero-cancer tissue and cancer tissue in 4% neutral formalin, sent to pathology laboratory to make paraffin imbedding microtome sections (4 mm thick serial sections) fixed in silicification glass.

Pathologic detection

Histologic detection: dying with the routine hematoxilin -eosine (HE).

Immunohistochemistry detection: 4 μm thick paraffin sections were baked at 65℃ until get deparaffinage and hydration; incubate in 3% Hydrogen Dioxide about 5-10 min to inactivate the endogenous peroxidase; microwave repairs the antigen; sealed by 10% normal goat serum; PTFN multiclone rabbit antibody (1:100) was incubated overnight at 4℃, washed by PBS 2 min for 3 times; dropwise goat anti-rabbit IgG antibody-HRP multimer, incubated about 30 min at 37℃, washed by PBS, 2 min × 3 times; DAB coloration; washed thoroughly by distilled water. In the same time, PBS was used as first-antibody and second-antibody in negative control.

Evalution of coloration result: using Bresalier[10] semiquantitative formula to judge coloration result. Selecting randomly 10 fields of vision from every section when enlarged 200 times, then we classified the cell coloration intensity into four categories: Negative, cell hasn't colored (0); Cell has colored buff (1); claybank (2); chocolatebrown (3). Count the number of field of vision of each intensity, and according to the formula calculate the average coloration intensity. IS (intensity score) = $\sum[(0 \times F0) + (1 \times F1) + (2 \times F2) + (3 \times F3)]$, $F = n/10$ (n = 0, 1, 2, 3 the number of field of vision of different score). Two people read the section two times with double

Table 1 Survival time in different groups

Group	*n*	Survival days mean ± SD	Survival rate (%) 3 wk	4 wk
A	12	23.67 ± 4.92	10/12 (83.3)	5/12 (41.7)
B	12	26.08 ± 2.31	12/12 (100)[a]	6/12 (50)[a]
C	12	25.92 ± 2.71	12/12 (100)[a]	7/12 (58.3)[b]
D	12	18.83 ± 2.29	7/12 (58.3)	0/12 (0)

[a]$P < 0.05$, [b]$P < 0.01$ *vs* group D.

Table 2 Volume and index of tumors (mean ± SD)

Group	*n*	Volume (mm^3)	Index
A	12	466.43 ± 645.66	0.0037 ± 0.0403
B	12	215.91 ± 275.23	0.0305 ± 0.0403
C	12	325.23 ± 464.30	0.0313 ± 0.0436
D	12	309.7 ± 309.72	0.0462 ± 0.0296

Table 3 Tumor metastasis in livers

Group	Rate of tumor metastasis in liver (%)
A + B + C	23/36 (63.9)[a]
A	7/12 (58.3)[c]

C	7/12(58.3)[c]
D	12/12(100)

[a]$P < 0.05$ *vs* group D; [c]$P < 0.05$ *vs* group D.

blind method, calculate IS for each time, and get the two times average as the result.

Statistical analysis

Using SPSS 14.0 statistic software, variance analysis and rank-sum test were used for measurement data; chi square test and rank-sum test were used for numeration data.

RESULTS

General situation

The dissection witness that achievement ratio of making model is 100%; at the end of the experiment, get 48 utility pathologic samples. Most tumors were enormous, some were accompanied multilesions in the liver and/or lung.

It was demonstrated that the model was stable and facility, consistent with dissection characteristic of human liver cancer.

Survival state

After 3 wk of drug intervention, the total survival rate in treatment group (A + B + C) was 94.4% and much higher than the chemotherapy group (58.3%) ($P = 0.007$, Fisher's Exact Test). Though the survival rate in group A was higher than that of group D, no differences were observed between them ($P > 0.05$). The survival rate in group Band C is higher than in group D, there was a significant difference ($P = 0.014$). 4 wk later, the total survival rate in treatment group (A + B + C) was 50% and much higher than the chemotherapy group (0%) ($P = 0.02$). Though the survival rate in group A was higher than that of group D, no difference were observed between them ($P > 0.05$). The survival rate in group B and C was higher than in group D, there was significant difference, ($P < 0.05$ or 0.01) (Table 1).

Table 4 Expression intensity of PTEN in the 3 kinds of tissue ($\alpha = 0.01$)

Kind of tissue	*n*	PTEN intensity median
Normal hepatic tissue	48	1.00
Latero-cancer tissue	48	1.31
Cancer tissue	48	0.23

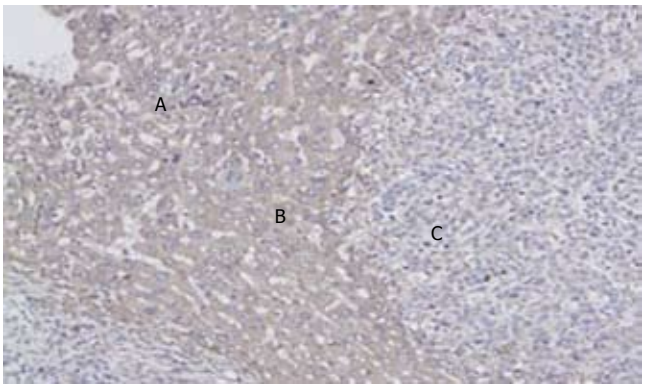

Figure 1 Intensity of PTEN: Latero-cancer tissue. A: > cancer tissue; B: > hepatic tissue; C: Two-Step, × 100.

Tumor state

No differences was observed between the group A, group B, group C and the group D in volume and index of tumors ($P > 0.05$) (Table 2).

The state of tumor metastasis in liver

After the transplantation tumors in liver of each mouse was taken out, then the remain liver were observe by microscope, if it existed hepatoma carcinoma cell, We diagnosed the liver had the metastases. Tumor metastasis in livers of group A and group C were both 58.3% (7/12) and much less than the group D 100% (12/12) $P = 0.037$. Tumor metastasis in livers of group A, group B and group C was 63.9% (23/36) and much less than the group D ($P = 0.021$), but there was no difference among group A, group B and group C (Table 3).

The expression intensity of PTEN in different tissues

Three groups were compared with each other applied Kruskal-Wallis test, $\chi^2 = 60.67$, $P = 0.000$. The result showed that the intensity of PTEN in latero-cancer tissue was the highest, and then the normal hepatic tissue, the lowest was cancer tissue (Table 4, Figures 1 and 2).

Interclass analyses positive expression intensity of PTEN in three kinds tissue

Tested by One-way ANOVA, LSD, Tamhane Test was used in normal hepatic tissue and latero-cancer tissue, and Mann-Whitney *U* in cancer tissue. in normal hepatic tissue

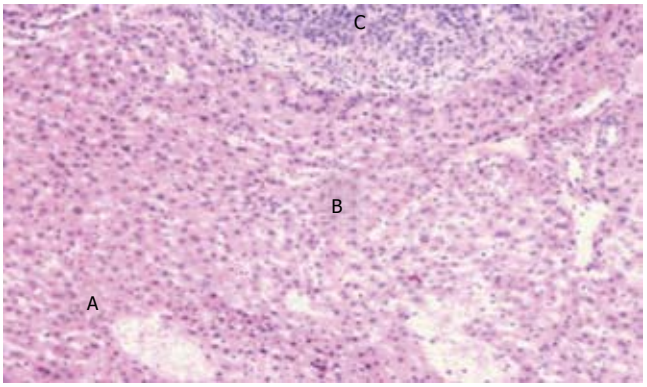

Figure 2 A: Hepatic tissue; B: Latero-cancer tissue; C: Cancer tissue, (HE, × 100).

(Test of Homogeneity of Variances, Levene Statistic = 2.18, $P = 0.104$; and One-way ANOVA Test, $F = 5.90$, $P = 0.002$), A > D, $P = 0.001$; B > D, $P = 0.031$; C > D, $P = 0.001$. It represented that the intensity of PTEN in Chinese crude drug group was higher than the Tegafur group. However, there was no significant statistic difference among Chinese crude drug group in difference concentrations ($P > 0.05$). In latero-cancer tissue, (Test of Homogeneity of Variances, Levene Statistic = 3.09, $P = 0.037$; and One-way ANOVA Test, $F = 15.99$, $P = 0.000$), A < B, $P = 0.170$; A > C, $P = 0.091$; B > C, $P = 0.017$; C > D, $P = 0.028$, it showed that expression intensity of PTEN under the intervention of Chinese crude drug was higher than that of Tegafur, the expression intensity of PTEN in medium dose group was the highest ($P = 0.05$). In cancer tissue, A < B, U = 30.5, $P = 0.016$; A > C, U = 44, $P = 0.104$; A > D, U = 24, $P = 0.005$; C > D, U = 18, $P = 0.002$; B < C, U = 9.5, $P = 0.000$; B > D, U = 4, $P = 0.000$. It represents that the intensity of PTEN in medium dose group was highest among the 3 kinds of tissue. In cancer tissue, A < B, $P = 0.014$; A > C, $P = 0.114$; A > D, $P = 0.005$; C > D, $P = 0.001$; B > D, $P = 0.000$, It also represented that the intensity of PTEN in medium dose group was highest ($P < 0.001$). However, there was no significant statistic difference between medium dose group and low group, low dose group and high dose group ($P > 0.05$) (Table 5).

Table 5 Expression intensity of PTEN of 3 kinds of tissue of the 4 groups (mean ± SD)

Group	*n*	Normal hepatic tissue	Latero-cancer tissue	Cancer tissue (median)
A	12	1.05 ± 0.34	1.42 ± 0.24	0.36
B	12	0.90 ± 0.31	1.75 ± 0.42	0.86
C	12	1.06 ± 0.18	1.27 ± 0.21	0.20
D	12	0.59 ± 0.48	0.64 ± 0.61	0.05

DISCUSSION

PTEN/MMAC1 (mutated in multiple advanced cancer 1) or TEP1 (TGF-regulated and epithelial cell-riched phosphatase1), located in human chromosome band 10q23[11], was recently identified together as tumor suppressor gene by three America research teams. As the first discovered dual-specific phosphatase, it may suppress tumor cell growth, regulate tumor cell invasion and metastasis through inhibiting many signal pathways of cell proliferation[12-15].

FT-207/tegafur, which belongs to the Second-generation fluoropyrimidine drugs, is metabolized to 5-fluorouracil through certain hepatic metabolizing enzymes and the cytochrome P450 (CYP450) system. Its anticancer mechanism is the same with that of 5-FU[16]. The advantage of Tegafur is highly fat-soluble, rapid gastrointestinal absorption, much longer half-life, as well as suitable for oral administration, its side effects is only one seventh that of 5-FU, while the efficacy index is twice higher. As the representative of the Second-generation 5-FU, Tegafur is used to treat several types tumors of alimentary canal as a routine chemotherapy drugs[17-19].

TCM includes primary hepatic carcinoma in the category of diseases such as: liver mass, abdominal mass, ZhengJia, tympanites, jaundice, *etc.* The etiological factors are concerned with yin-yang disbalance caused by the reception humid heat, long-term eating and drinking without temperance, being addicted to drink, internal injury caused by excess of seven emotions. When the vital qi gets deficient, evil factor easily invades the body and are stagnated in the liver cause the depression of liver-QI, activities of qi is stagnated and the blood circulation is blocked; Phlegm knobbing stagnant blood leads to the formation of abdominal mass, finally resulting in the formation of liver cancer[20,21]. The primary pathogenesis of liver cancer lies in the qi-stagnancy and blood stasis, the stagnation of humid heat, the discord of the spleen and the liver, as well as the weakness of vital qi[22]. At the early stage, this disease manifests itself in the unimpaired vital-qi, the type is most likely be sthenia syndrome or syndrome of blood stasis; at the middle stage, vital vital-qi is impaired, and asthenia and sthenia complicated with each other; at the advanced stage, the main syndrome is asthenia syndrome. Thus, the main treatment of TCM for liver cancer lies in strengthening body resistance and eliminating pathogen; the former is the mian way, the later is the assistant way[23,24]. Correlated investigation confirmed that the therapy of invigorating the spleen and regulating the qi could inhibit or delay the tumorous growth and metastasis, strengthen body's immunity, prolong the life span, and was more effective than the therapy of promoting blood flow and dissolving the stagnated blood and of[25,26], what's more, different therapeutic methods of TCM can in different degree regulate the transcription of some important oncogenes which play an important role in the process of occurrence and development of the liver cancer[27], thereby have some antitumous effect. Therefore, TCM becomes one of important combined therapies for cancer in China. In dealing with tumor, Chinese crude drugs have such advantages as following: guidance of wholism, strengthening the internal anticancer mechanism, mild toxicity, without pain, easily be accepted, it can relieve the symptoms, improve patient's function, lighten the toxicity and side effect meanwhile enhance effectiveness of the radiotherapy or chemotherapy, and accelerate recovery from operation, further more, can inhibit tumor growth, control or delay its recurrence, improve life quality, prolong

survival time. During to the traditionary chemotherapy wih the characteristic of being exist without tumor impacts the patient's exist quality, while people pay close attention to TCM wirh the characteristic of being exist with tumor.

FJD (Appl.: 200710026976.6) has been widely used to treat the hepatocellular carcinoma for years in our department. According to the special pathogenesis of middle and advanced hepatocellular carcinoma, the decoction can smooth the liver and strengthen the spleen, meanwhile can strengthen the body resistance, remove toxin and treat Biaol and Ben. So the decoction has the effect of strengthening the spleen and replenishing qi, diminishing stagnation by detoxification, relieving the depressed liver qi and regulating the blood. Previous research showed that this decoction had a certain anticancer effect on liver cancer cell lines *in vitro*[28] and in clinic[29]. In this study, we found that each TCM groups had distinct superiority in prolonging the live time and raising the survival rate of athymic mouse bearing cancer compared with the chemotherapy group. At the same time, middle and high concentration groups were more effective in prolonging the live time than that in low concentration group, which indicated TCM groups in prolonging the live time had dose-effect relationship. However, the TCM groups and the chemotherapy group has the similar effect in shortening tumor. Moreover, each group of the medicinal herbs were better than chemotherapy group chemotherapy group in inhibiting tumor diffusion and reducing tumor metastasis in liver. Compared with chemotherapy group, every TCM groups could reduce the number of tumor metastasis in liver, there was no difference between TCM groups and chemotherapy group in tumor metastasis rate in liver, which might relate with the insufficient the number of the sample. As mentioned previously, FJD could inhibit tumor metastasis and prolong the live time, the antitumous effect of FJD might through certain way to inhibiting tumor diffusion and metastasis other than shorten tumor, thus slowed down pathogenetic condition progressing, and prolonged the live time[30].

What on earth is the mechanism of the anticancer treatment by the Chinese herbs that strengthen the body resistance and remove toxic substances? Our research showed that the low, middle and high concentrations of the Chinese herbs could obviously increase expression of PTEN on the athymic mice bearing tumor respectively, compared with chemotherapy by ft207, which indicated the antitumous mechanism of medicinal herbs in this study. Interestingly, we found the expression of the PTEN in adjacent cancerous tissues of athymic mice bearing tumor was higher than that of the normal tissues, we inferred that this phenomenon might be a protection of the body itself to prevent cancer cell from further developing by high expression of PTEN in adjacent cancerous tissues under stressful condition. Therefore, the expression density of PTEN closely relates with the occurrence and development of liver cancer. Our study showed that FJD can provocate the expression of PTEN, and high expression of the PTEN in adjacent cancerous tissues seem to explain the reason why the intrahepatic metastasis rate in TCM groups is lower than that of chemotherapy group. The comparison among the TCM groups indicated that middle concentration achieved the best curative effect, low and high groups ranked secondly, this result illustrates that it is necessary for us to pay more attention to the dosage of medicinal herbs in clinic practice, because only the moderate dosage may acquire the best therapeutic effect. However, the best concentration of the FJD in treating HCC needs to be studied furtherly.

However, a control group of mice which were inoculated HCCs in the liver and were not given FZDJT and tegafur had been allocated. It's a pity that due to the too much cellular necrosis in pathological section we cannot get the result of immunohistochemistry. Next time we should do better.

In conclusion, our study showed that FJD can prolong the survival time and decrease tumor metastasis in livers of these experimental mice. Mechanisms of FJD healing HCC may partially be explained by enhancing the expression of PTEN in liver.

COMMENTS

Background

Traditional Chinese Medicine (TCM) which is useful to improve life quality, prolong survival time has been widely used as combined therapies in treating hepatocellular carcinoma (HCC). The primary pathogenesis of liver cancer lies in the qi-stagnancy and blood stasis, the stagnation of humid heat, the discord of the spleen and the liver, as well as the weakness of vital qi. Fuzheng Jiedu Decoction (FJD) (Appl.: 200710026976.6) has been widely used to treat the hepatocellular carcinoma for years. Previous research showed that this decoction had a certain antitumous effect on liver cancer cell lines *in vitro* and in clinic.

Research frontiers

TCM has been widely used as combined therapies in treating HCC in China. The novelty and innovation of the research consist in researching the mechanism of treatment of FJD to the hepatocellular carcinoma with mole-biological method. Mechanisms of FJD healing HCC may partially be explained by enhancing the expression of PTEN in liver.

Innovations and breakthroughs

TCM has been widely used as combined therapies in treating HCC, whether it can down-regulate the expression of PTEN in HCC is still unknown. The aim of our study is to explore the effect of FJD, complex prescription of Chinese crude drug in treating BALB/c athymic mice with HCC, as well as the expression of PTEN.

Applications

The mechanism of treatment of FJD to the hepatocellular carcinoma may partially be explained by enhancing the expression of PTEN tumor suppressor gene. We also found that different concentration of FJD had different effect in prolonging survival time and decreasing metastatic tumour. This study was indicated that FJD can be used as one of combined therapies in treating HCC and which was the best concentration of FJD.

Terminology

PTEN: Phosphatase and tensin homolog deleted on chromosome ten. FJD: Fuzheng Jiedu Decoction. FT207: Tegafur. TCM :Traditional Chinese Medicine.

Peer review

This is a good study in which the main objective is to explore the expression of PTEN in liver of athymic mice with HCC and the effect of FJD. PTEN was recently identified together as tumor suppressor gene. FJD can prolong the survival time and decrease Tumor metastasis in livers of these experimental mice. Mechanisms of FJD healing HCC may partially be explained by enhancing the expression of PTEN in liver.

Abstract

AIM: To investigate the therapeutic effects of the combined use of rosiglitazone and aminosalicylate on mild or moderately active ulcerative colitis (UC).

METHODS: According to the national guideline for diagnosis and treatment of inflammatory bowel disease (IBD) in China, patients with mild or moderately active UC in our hospital were selected from July to November, 2004. Patients with infectious colitis, amoebiasis, or cardiac, renal or hepatic failure and those who had received corticosteroid or immunosuppressant treatment within the last month were excluded. Following a quasi-randomization principle, patients were allocated alternatively into the treatment group (TG) with rosiglitazone 4 mg/d plus 5-ASA 2 g/d daily or the control group (CG) with 5-ASA 2 g/d alone, respectively, for 4 wk. Clinical changes were evaluated by Mayo scoring system and histological changes by Truelove-Richards' grading system at initial and final point of treatment.

RESULTS: Forty-two patients completed the trial, 21 each in TG and CG. The Mayo scores in TG at initial and final points were 5.87 (range: 4.29-7.43) and 1.86 (range: 1.03-2.69) and those in CG were 6.05 (range: 4.97-7.13) and 2.57 (range: 1.92-3.22) respectively. The decrements of Mayo scores were 4.01 in TG and 3.48 in CG, with a remission rate of 71.4% in TG and 57.1% in CG, respectively. Along with the improvement of disease activity index (DAI), the histological grade improvement was more significant in TG than in CG ($P < 0.05$).

CONCLUSION: Combined treatment with rosiglitazone and 5-ASA achieved better therapeutic effect than 5-ASA alone without any side effects. Rosiglitazone can alleviate colonic inflammation which hopefully becomes a novel agent for UC treatment.

INTRODUCTION

Ulcerative colitis (UC) is chronic intestinal inflammation with uneven relapsing course. Most patients need to take daily medications lifelong. The conventional therapies for UC include 5-aminosalicylate (5-ASA), glucocorticoid, and immunomodulator. 5-ASA and its derivatives were widely used to induce and maintain remission in patients with UC. But the general response rate was only 70%-80% and the relapse rate varied depending on the maintenance of the medications and other relapsing factors. It is necessary to search for special target of inflammatory cascades in UC so as to improve the therapeutic effects. With deeper understanding of its pathogenesis, more and more therapeutic targets have been found, and more and more novel clinical trials are directed to these targets with encouraging results. Peroxisome proliferators-activated receptor γ (PPAR-γ), highly expressed in the colon, is a subgroup of ligand-activated nuclear receptors responsible for the regulation of cellular events ranging from lipid homeostasis to cell differentiation and apoptosis. Recent studies showed its ligands can suppress the inflammatory response by inhibiting the activity of macrophages, cytokines production and NF-κB transcriptional activities. Thiazolidinediones (TZDs), such as rosiglitazon, are PPAR-γ synthetic ligands which have been used in type 2 diabetes mellitus for a long time. James *et al*[1] reported that refractory UC patients achieved clinical and endoscopic remissions using rosiglitazone, and concluded that it might represent a novel approach of UC therapy. However, it is an open-label trial with a small sample size and needs to be validated by expanded trials.

In this study we observed the therapeutic effects of combined use of rosiglitazone and 5-ASA in UC clinically and improvement pathologically.

MATERIALS AND METHODS

Design

Patients with mild or moderately active UC, who met with the criteria of suggested guidelines for the diagnosis and treatment of inflammatory bowel disease (IBD), were enrolled[2]. Patients with infectious colitis, acute or chronic cardiac, renal and hepatic failure and abnormal liver-associated chemistries were excluded. Patients who took glucocorticoid or immunomodulators, such as AZA, 6-MP, within the last month were also excluded. Included patients all provided informed consent. During the trial, the patients were not allowed to take traditional Chinese medicines (TCM), glucocorticoid and immunomodulator.

Assignment

The patients were assigned into treatment group (TG) or control group (CG), with even number allocated into TG and odd number into CG. Both groups took 5-ASA 2 g/d (500 mg granule, Beaufour Ipsen Pharmaceutical Co. Ltd), but rosiglitazone 4 mg/d (4 mg/tablet, GlaxoSmithKline Pharmaceutical Co. Ltd.) was added to the treatment group for 4 wk.

Follow-up

The patients were assessed from 0 to the 4th wk and interviewed by phone every week and returned for a visit at the 2nd wk, and received the colonoscopic examination and colonic mucosal sampling at initial and final points. The evaluation of disease activity was performed at 0 and the 4th wk according to the Mayo indices[3] (also called Sutherland index, Table 1).

Table 1 Mayo DAI indices

Stool frequency	
0	Normal number of stools for this patient
1	1 to 2 more stools than normal
2	3 to 4 more stools than normal
3	5 or more stools than normal
Rectal bleeding	
0	No blood seen
1	Streaks of blood with stool less than half the time
2	Obvious blood with stool most of the time
3	Blood alone passed
Findings of endoscope	
0	Normal or inactive disease
1	Mild disease (erythema, decreased vascular pattern, mild friability)
2	Moderate disease (marked erythema, absent vascular pattern, friability, erosions)
3	Severe disease (spontaneous bleeding, ulceration)
Physician's global assessment	
0	Normal
1	Mild disease
2	Moderate disease
3	Severe disease

Definition of outcome

Patients with a final DAI score of $\leqslant 2$ were defined to achieve clinical remission and patients with a final score $\geqslant 3$ but reduction in the DAI of $\geqslant 2$ were defined to achieve partial remission.

Safety analysis

All patients were included in the safety analysis. The adverse events and concomitant medication were carefully documented. Safety evaluations included vital signs, patients' symptoms, physical examination, hematology, serum biochemistry, fecal routine, and urinalysis. All the patients received these tests at the initial and the final points of the study.

Histopathology

At least 2 colon samples were taken from each patient at initial and final points of the trial through colonoscopy. Tissues were fixed in 10% buffered neutral formalin and embedded in paraffin. Four μm sections were stained with the hematoxylin and eosin (HE stain) for histological evaluation. Tissue slides were blindly assessed by experienced pathologists based on the Truelove-Richards histological grading system[4] as follows: 0 = no polymorphs, 1 = small number of polymorphs in the lamina propria with minimal infiltration of crypts, 2 = prominent polymorphs in the lamina propria with infiltration of > 50% of crypts, 3 = florid polymorph infiltrate with crypt abscesses, and 4 = florid acute inflammation with ulceration.

Immunohistochemistry

Labeled streptavidin-biotin (LsAB) methods were used for PPAR-γ and NF-κB p65 detection. Paraffin-embedded colonic tissue samples were dewaxed in xylene for 5 min twice, rehydrated in a series of ethanol (100%-70%) for 3 min each followed by rehydration in PBS for 30 min. After rehydration, the endogenous peroxidase was blocked with 0.3% hydrogen peroxide followed by antigen retrieval by autoclaving sections in citrate buffer pH 6.0 (10 mmol/L Na citrate). After antigen retrieval, the sections were stained using the above-mentioned kit according to manufacturer's recommendations, but with the following modifications. Sections were incubated with the primary antibody at 37℃ for 2 h. The following antibodies were used at the indicated dilutions: PPAR-γ (E-8: sc-7273, Santa Cruz, Santa Cruz, CA USA) 1:100 and NF-κB p65 (Boshide Bio Corp, Wuhan, China) 1:200. Each section had its own control using the secondary antibody only. Preimmune serum was initially used to ensure specificity of the signal with each of the antibodies. The lipoma resection sample was used as the positive control and the substitute monoclonal antibody of PPAR-γ with PBS as the blank control.

Statistical analysis

Statistical analysis was performed with the SPSS 10.0 software. The *t* test of the sample mean value of the designed group was used to examine the Mayo scores and positive cell numbers in the immunohistochemistry. The rank sum test was adopted for the histological grading. A P value < 0.05 was considered statistically significant.

RESULTS

Patient characteristics

We enrolled 42 patients with mild and moderately active UC into our trial and 21 patients each in TG and CG.

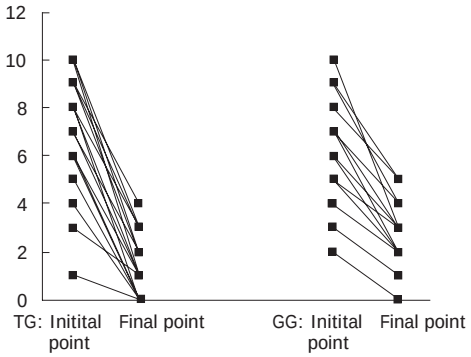

Figure 1 Mayo scores of TG and CG at initial and final points.

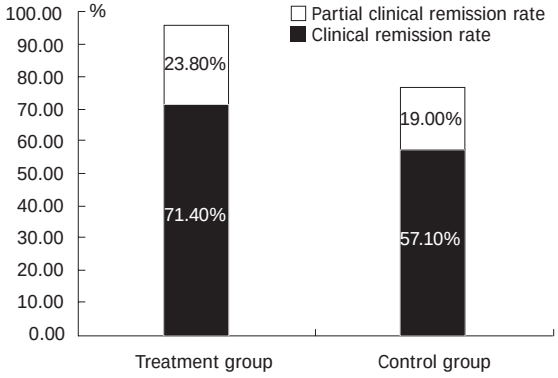

Figure 2 The clinical remission rate of TG *vs* CG.

The pre-study characteristics of patients are summarized in Table 2. The age ranged from 16 to 57 years (average, 38.8 ± 10.4 years) in TG and from 14 to 60 years (average, 37.1 ± 8.01 years) in CG, respectively. The extent of disease in TG was 8 proctitis (38.1%), 12 proctosigmoiditis (57.1%), and 1 left-side colitis (4.8%) and 9 (42.9%), 11 (52.4%), 1 (4.7%) in CG respectively. All patients received 5-ASA agents before enrolled into this study. The statistical analysis on the age, sex, location, type, and disease activity suggested similar baseline characteristics in the two groups ($P > 0.05$).

DAI scores at initial and final points

The Mayo score changes in each patient from 0 to the end of 4 wk were figured as below (Figure 1): the DAI in TG at initial and final points were 5.87 (range, 4.29-7.43) and 1.86 (range, 1.03-2.69), respectively, and those in CG were 6.05 (range, 4.97-7.13) and 2.57 (range, 1.92-3.22) respectively, (Table 3). There was a significant difference between the two groups and the therapeutic effect of TG was better than CG ($P < 0.05$).

According to the definition of outcome from the guideline, the clinical remission was achieved in 15 patients in TG (remission rate, 71.4%) and 12 patients in CG (remission rate, 57.1%), the partial remission was achieved in 5 patients (23.8%) and 4 patients (19.0%) in TG and CG respectively (Figure 2).

Histological grade at initial and final points

According to Truelove and Richards's histological grading system, the histological sections by H&E staining were graded in Table 4. The grade Ⅱ and Ⅲ of histology was found at the initial point (80.95%) and grade Ⅰ (57.14%) at the final points in TG, respectively, as compared with 33% grade Ⅰ at the final point in CG.

Immunohistochemistrical positive percentages at initial and final points

The positive percentage of PPAR-γ at initial and final points were 26.20%, 47.76% in TG and 24.90%, 39.24% in CG, respectively. The positive percentage of NF-κB were 58.09%, 21.19% and 58.00%, 27.00%, accordingly (Table 5). The relation between histological grade and immunohistochemistrical positive percentages was showed on Table 6.

Table 2 Clinical characteristics of ulcerative colitis

		TG (n = 21)	CG (n = 21)
Age (yr)		38.8 ± 10.4	37.1 ± 8.01
Sex	Male (%)	16 (76.2)	15 (71.4)
	Female (%)	5 (23.8)	6 (28.6)
Location	Rectum (%)	8 (38.1)	9 (42.9)
	Rectosigmoid (%)	12 (57.1)	11 (52.4)
	Left colon (%)	1 (4.8)	1 (4.7)
Type	Chronic relapse (%)	13 (61.9)	12 (57.1)
	Chronic persistence (%)	8 (38.1)	9 (42.9)
Severity	Mild (%)	5 (23.8)	6 (28.6)
	Moderate (%)	16 (76.2)	15 (71.4)

Table 3 Mayo scores of TG and CG at initial and final points

Mayo scores	Initial point	Final point
TG (n = 21)[a]	5.87 (4.29-7.43)	1.86 (1.03-2.69)
CG (n = 21)	6.05 (4.97-7.13)	2.57 (1.92-3.22)

[a]$P < 0.05$ *vs* CG.

Table 4 Histological grade of TG and CG

Grade	TG (n = 21)		CG (n = 21)	
	Initial point	Final point	Initial point	Final point
Ⅰ[a]	4	12	5	8
Ⅱ[c]	10	6	12	11
Ⅲ[e]	7	3	4	2
Ⅳ	0	0	0	0

[a]$P < 0.05$, TG *vs* CG; [c]$P < 0.05$, TG *vs* CG; [e]$P < 0.05$, TG *vs* CG.

Table 5 Positive percentages of PPAR-γ and NF-κB in TG and CG

	TG (n = 21)		CG (n = 21)	
	Initial point	Final point	Initial point	Final point
PPAR-γ[a] (%)	26.2	47.76	24.9	39.24
	(22.98-29.49)	(43.42-50.09)	(21.49-28.32)	(35.81-42.67)
NF-κB[c] (%)	58.09	21.19	58	27
	(54.51-61.68)	(19.13-23.25)	(53.21-61.02)	(21.08-32.92)

Table 6 Histological grade and PPAR-γ and NF-κB expression

		Expression positivity (100%)			
		Ⅰ	Ⅱ	Ⅲ	Ⅳ
Initial points	*n*	4	10	7	0
	NF-κB	46.09-51.91	52.11-56.89	61.35-70.65	0
	PPAR-γ	31.57-39.93	24.54-29.06	16.30-20.55	0
Final points	*n*	12	6	3	0
	NF-κB	21.55-26.62	18.93-20.07	8.42-20.92	0
	PPAR-γ	37.20-44.97	49.82-56.51	55.50-69.84	0

Safety among treatment group and control group

During the observation period, no adverse events and abnormalities in the blood biochemical test were found in the patients. No jaundice or edema was found either.

DISCUSSION

As it is known, except for open-label trial by James *et al*[1], there are few clinical trials about rosiglitazone as adjunctive agent for UC conventional therapy. In this trail, treatment group showed a greater decrease in DAI and higher clinical remission rate than control group. Our results showed similar effects as those of James and his colleagues and the adjunctive effect of rosiglitazone on the UC therapy. However, we investigated the effects of rosiglitazone in mild and moderately active UC, but James did in refractory UC.

The PPAR-γ, highly expressed on adipo-tissue and colons, can regulate gene transcription of lipoprotein, cell differentiation, inflammation and immune response. PPAR-γ plays a key role not only in adipocyte differentiation, insulin sensitivity and nonalcoholic fatty liver[6-10], but also in innate and adaptive immunity[11-13]. Activation of PPAR-γ can promote macrophage desensitization, thus attenuating the oxidative burst[14]. Arnold and Konig[15] observed that PPAR γ ligands inhibited dose-dependently the release of TNF-α, GM-CSF, IL-1α, IL-6, IL-8 and CCL5 from RSV-infected A549 cells while diminishing the cellular amount of mRNA of IL-6, IL-8 and CCL5 and binding activity of the transcription factors NF-κB and AP-1, respectively. Belvisi *et al*[16] also outlined the anti-inflammatory effects of PPAR-γ ligands. Pan *et al*[17] revealed this anti-inflammation effect on human gallbladder epithelial cells as well. PPAR-γ ligands can prevent intestinal inflammation by blocking the activation of NF-κB, down-regulate the production of ICAM-1 and TNF-α in intestinal epitheliums, suppress expressions of TNF-α and IL-1β, *etc.*

Dubuquoy *et al*[5] found that expression of PPAR-γ in colon mucosa was decreased in active UC and was negatively related with UC severity. PPAR-γ was regarded as a new therapeutic target in IBD, especially in UC[18]. Christel *et al*[19] even found that the intestinal anti-inflammatory effect of 5-ASA depends on the PPAR-γ in chemically induced colitis in mice heterozygous at the PPAR-γ locus. These results strongly suggested a reasonable combination of these two agents for the therapeutic purpose on UC.

There are two kinds of PPAR-γ ligands, one is natural ligands such as prostaglandins J2, the other is synthetic ligands including TZDs. TZDs (e.g. rosiglitazone and pioglitazone) can reduce the productions of several pro-inflammatory cytokines and ameliorate the intestinal inflammation. Adachi M *et al*[20] reported that PPAR-γ in colonic epithelial cells plays an anti-inflammatory role and protects against experimental IBD. Marina Sánchez-Hidalgo *et al*[21] draws a similar conclusion. Sasaki *et al*[22] reported that troglitazone significantly reduced the TNF-α mediated induction of endothelial MAdCAM-1 in a dose-dependent manner; it also lowered the VCAM-1, ICAM-1 and E-selectin expression and significantly reduced α4β7-integrin dependent lymphocyte adhesion. Bassaganya *et al*[23] found that activation of PPAR-γ can inhibit the activation of NF-κB and ameliorate experimental colitis. NF-κB controls the transcription of a large cohort of genes, its dysregulated activation is linked to various biological disorders including inflammatory, and immune disorders[24]. In IBD, NF-κB plays an important role and is a target of various anti-inflammatory drugs. The ability of TZDs to ameliorate the experimental colitis is closely related to inhibition of NF-κB activation[19]. Another unpublished study of ours also investigated colonic mucosal expressions of PPAR-γ and NF-κB in the oxalzolone-induced experimental colitis, and found that the PPAR-γ ligand could increase the expression of PPAR-γ and inhibit the activation of NF-κB in colonic epithelium, ameliorating the colon inflammation in experimental colitis. Lawrence *et al*[25] showed that PPAR-γ ligands could provide anti-inflammatory protection by maintaining the cytokine balance and shifting transcriptional regulation of T cells away from Th1 and towards Th2 predominance in acute DSS colitis. Lytle *et al*[26] found that rosiglitazone could slow down the onset of spontaneous IBD in IL-10 (-/-) mice. Sánchez-Hidalgo *et al*[27] also reported that rosiglitazone for TNBS colitis can correct mucosal lesions, and significantly lower the ulceration index, myeloperoxidase (MPO), and the levels of TNF-α. Meanwhile, it increased prostaglandin (PG) E_2 production and returned PG D_2 to basal levels and reduced COX-2 and NF-κB proteins expression. Pedersen *et al*[28] reported that PPAR-γ mRNA and adipophilin expressions (a marker of PPAR activation) were markedly lower in colonic epithelium cells (CEC) from the patients with active UC and were clearly associated with the inhibition of PPAR-γ function and the stimulation with rosiglitazone fully restored PPAR-γ activation in CEC. Zhang YQ *et al*[29] reported that rosiglitazone enhances apoptosis of HT-29 cells by activating PPAR-γ. Li *et al*[30] reported troglitazone can not inhibit cell proliferation, and induce apoptosis in HepG2 cells, but down-regulate the expression of COX-2 mRNA and protein.

Our study showed the therapeutic effects of rosiglitazone on human UC, but it is required to demonstrate whether the therapeutic effects of rosiglitazone or other PPAR-γ ligands depend on PPAR-γ NF-κB signal pathway or on other inflammatory pathway, such as P38 MAPK, or toll-like receptor. A larger sample size clinical trail is also needed to confirm the effects of rosiglitazone on human UC.

Rosiglitazone has few adverse effects except for an ALT increase and exacerbation of cardiac failure induced

by the body fluid retention. In our study, we excluded the patients with hepatic, cardiac failure and closely observed related clinical and chemical changes. No adverse events were found in our study, including 4 patients who took rosiglitazone for 12 wk. Based on the above observation, we conclude that TZDs, ligands of PPAR-γ can be used in the UC as an adjunctive agent efficiently and safely.

COMMENTS

Background

The peroxisome proliferators activated receptor γ (PPAR-γ) is highly expressed in the colon and play a crucial role in intestinal inflammation. Regulation of colon inflammation by PPAR-γ has been well demonstrated in experimental colitis. Recently, rosiglitazone achieved quite well therapeutic effects in refractory ulcerative colitis (UC) patients in the study of James D. This result suggested that PPAR-γ is a hopefully novel target for UC treatment in the future.

Research frontiers

The hotspots in this field of studies include mechanism of PPAR-γ in intestinal inflammation and finding its high-affinity ligands.

Innovations and breakthroughs

An open-label trial of rosiglitazone for UC by James D *et al* was a first research of clinical application of thiazolidinediones (TZDs); however, their study merely focused on refractory UC. We mainly studied the patients with active UC and explored the mechanisms of PPAR-γ ligands.

Applications

PPAR-γ has multiple functions in the immune system and in some major inflammatory diseases such as atherosclerosis, inflammatory bowel disease and rheumatoid arthritis. If the ligands of PPAR-γ can be utilized for UC treatment, it will provide another therapeutic target and improve the effects of UC treatment.

Terminology

PPAR-γ is a member of nuclear receptors family, proved to be a key transcription factor of adipocyte differentiation, lipid and glucose homeostasis and an important target in type 2 diabetes and metabolic syndrome. Besides its role in metabolic tissues, it appears to be expressed in several other cells, including immune cells such as macrophages, dendritic cells, eosinophils, T cells and B cells. It was pointed to a role in the immune system and its new aspect was revealed and developed in parallel: its potential anti-inflammatory activity. DAI is an abbreviation of disease activity index and widely used to evaluate the conditions and therapeutic effect for UC. There are several DAI systems; however, Mayo system is widely accepted.

Peer review

The authors aim to investigate the therapeutic effects of rosiglitazone on mild or moderately active ulcerative colitis and explore the relation between PPAR-γ and intestinal inflammation and NF-κB. Their results revealed the ligand of PPAR-γ can alleviate the inflammation of UC and this effect may be related with depression of NF-κB by PPAR-γ activation. Rosiglitazone can alleviate colonic inflammation and hopefully become a novel agent for the treatment of UC. PPAR-γ may be another therapeutic target of UC in the future.

Abstract

AIM: To compare the ligase detection reaction (LDR) and real-time PCR for detection of low abundant YMDD mutants in patients with chronic hepatitis B infection.

METHODS: Mixtures of plasmids and serum samples from 52 chronic hepatitis B patients with low abundant lamivudine-resistant mutations were tested with LDR and real-time PCR. Time required and reagent cost for both assays were evaluated.

RESULTS: Real-time PCR detected 100, 50, 10, 1 and 0.1% of YIDD plasmid, whereas LDR detected 100, 50, 10, 1, 0.1, and 0.01% of YIDD plasmid, in mixtures with YMDD plasmid of 10^6 copies/mL. Among the 52 clinical serum samples, completely concordant results were obtained for all samples by both assays, and 39 YIDD, 9 YVDD, and 4 YIDD/YVDD were detected. Cost and time required for LDR and real-time PCR are 60/80 CNY (8/10.7 US dollars) and 4.5/2.5 h, respectively.

CONCLUSION: LDR and real-time PCR are both sensitive and inexpensive methods for monitoring low abundant YMDD mutants during lamivudine therapy in patients with chronic hepatitis B. LDR is more sensitive and less expensive, while real-time PCR is more rapid.

INTRODUCTION

Lamivudine is an effective antiviral agent for treatment of patients with chronic hepatitis B and advanced liver diseases[1]. However, long-term lamivudine monotherapy leads to emergence of lamivudine-resistant hepatitis B virus (HBV) mutants in some patients chronically infected with HBV[1,2]. The incidence is 16%-32% in the first year and increases to 38%, 57%, and 67% after 2, 3, and 4 years, respectively[3-6]. Resistance is associated with mutations in the highly conserved tyrosine-methionine-aspartate-aspartate (YMDD) motif of the reverse transcriptase, which is part of the catalytic site of the HBV polymerase[7]. Viological breakthrough and alanine transaminase (ALT) elevation have been shown to occur 2-28 wk and 12-31 wk after the emergence of YMDD mutants, respectively[8-10]. Initially, YMDD mutants consist of minor populations. They gradually replace the wild-type virus, reaching a 100% lamivudine-resistant variant population, and this replacement occurs in parallel with the increase in HBV DNA load[10]. Sensitive methods for early detection of lamivudine-resistant mutants will be helpful for physicians to make clinical decisions in treatment of patients with HBV infection.

Several technologies have been developed for the detection of lamivudine-resistant mutants[11]. Although nucleotide sequencing of PCR products is widely used to detect lamivudine resistance, it is expensive and laborious, and can detect only mutant viruses representing at least 50% of the total virus population[8]. Inno-LiPA, pyrosequencing, real-time PCR, and ligase detection reaction (LDR) are able to detect low abundant YMDD mutants in the wild-type HBV[8,12-15]. However, only few studies have compared these methods.

We have previously compared real-time PCR and pyrosequencing for detection of YMDD mutants in patients with chronic hepatitis B[16]. In the present study, we compared LDR and real-time PCR for detection of low abundant YMDD mutants in mixed plasmids and clinical

samples from lamivudine treated patients with chronic hepatitis B.

MATERIALS AND METHODS

Plasmids and controls

Plasmids and controls were prepared as previously described[14,16]. In brief, three previously identified serum samples containing HBV with YMDD, YVDD and YIDD sequences were used as template and amplified by PCR. PCR products were cloned using pGEM-T systems (Promega, Madison, Wisconsin, USA), and clones were sequenced using ABI 3100 sequencer (Applied Biosystems, Foster, California, USA).

Patients and samples

Serum samples were collected from 196 patients with chronic HBV infection. All patients were treated with lamivudine for three months to three years and serum HBV-DNA levels were above 1.0×10^4 copies/mL by real-time PCR. Among these samples, 52 samples with YMDD mutants below 50% of total HBV population (determined by real-time PCR[14]) were selected for comparison of LDR and real-time PCR. All these 52 samples were found to contain only the YMDD variant by sequencing of PCR products, but found to contain YVDD or YIDD variants with real-time PCR or LDR.

Extraction and quantitation of HBV DNA

HBV DNA was extracted from serum samples using the HBV DNA extraction reagents (Fosun Diagnostics, Shanghai, China) according to the manufacturer's instructions. Serum HBV DNA levels were measured on ABI 7300 real-time PCR system (Applied Biosystems, Foster, California, USA) with quantitative real-time PCR reagents (Fosun Diagnostics, Shanghai, China), which was approved by the State Food and Drug Administration of China for *in vitro* diagnostic use.

Sequencing of PCR products

HBV DNA samples were prepared for sequencing by amplification with PCR as described by Allen *et al*[7]. HBV DNA extracted from serum samples was amplified by PCR. PCR products were purified with QIAquick PCR purification kits (Qiagen, Chatsworth, California, USA) and were eluted from the column with 80 μL of distilled deionized water. The DNA quality and concentration were determined by absorbance measurements at 260 and 280 nm and by gel electrophoresis on a 2.5% agarose gel. All sequencing reactions were performed on ABI 3130 DNA sequencer (Applied Biosystems, Foster, California, USA).

Ligase detection reaction

LDR was carried out as described by Xiao *et al*[15]. In brief, for one type of mutant (YIDD or YVDD), one common probe and two discriminating probes for mutant and wild-type YMDD were used in LDR, which was carried out in 20 μL of buffer, 1 pmol of each probe, and 5 μL of sample DNA. The reaction mixture was incubated at 94℃ for 2 min, before adding 15 U of thermostable Taq DNA ligase (New England Biolabs, USA), followed by 20 cycles of 30 s at 94℃ and 4 min at 65℃. Two PCR reactions were performed with the product of the LDR as template for 30 cycles at 94℃ for 30 s, 60℃ for 30 s, and 72℃ for 45 s. The PCR products were separated by agarose gel electrophoresis and visualized with ethidium bromide staining.

Real-time PCR

Real-time PCR for detection of YMDD mutants was performed as previously described[14,16]. In brief, parallel reaction C, V and I were used to detect total HBV, YVDD and YIDD variants, respectively. The amplification was performed on ABI 7300 PCR system (Applied Biosystems, Foster, CA, USA) by incubating the reaction mixture (50 μL) at 50 degree for two minutes, followed by 5 min at 95 degree, 40 cycles of PCR amplification (94 degree for 20 s and 53 degree for 30 s). The reaction system was provided and optimized by Fosun Diagnostics (Fosun Diagnostics, Shanghai, China). The percentage of mutants in total virus was calculated by the following equations[14]:

(1) ΔCt = Ct of control - Ct of mutants

(2) Ratio of mutants to total virus = $2^{\otimes X\tau}$

Mixing experiments

Mixing experiments were carried out as previously described[16]. In brief, mutant plasmid containing YIDD sequence and wild-type plasmid were mixed at a final concentration of 10^6 copies/mL, and the percentage of the YIDD plasmid in the mixture was 100%, 50%, 10%, 1%, 0.1%, and 0.01%, respectively. The mixtures were analyzed by LDR and real-time PCR respectively. For real-time PCR, each mixture was analyzed five times, and the mean Ct value of the five runs was used to determine the ratio of mutant to total viruses. For LDR assay, each mixture was analyzed only once.

Time study

Two skilled technicians were selected to perform the assays. Time required for each assay was measured by direct observation during the procedures performed by the technicians, including the process of DNA extraction, amplification, detection, and analysis.

Cost analysis

Cost for each assay was estimated based on the prices of reagents in China. The cost of instruments and labors was not included.

RESULTS

Detection of mixed plasmids

Mixtures of plasmids contained YIDD and YMDD at different ratios were detected by LDR and real-time PCR, respectively. LDR detected YIDD, YIDD/YMDD in the mixtures containing 100%, 50%, 10%, 1%, 0.1% and 0.01% YIDD plasmid. Real-time PCR detected YIDD in the mixture containing 100% YIDD plasmid and YIDD/YMDD in the mixtures containing 50%, 10%, 1% and 0.1% YIDD plasmids, but detected only YMDD in the mixture

Table 1 Results of LDR and real-time PCR for detection of mixed plasmids containing YIDD and YMDD at a final concentration of 10^6 copies/mL

YIDD plasmid in the mixture	LDR	Real-time PCR
100% (10^6 copies/mL)	YIDD	YIDD
50% (5×10^5 copies/mL)	YIDD/YMDD	YIDD/YMDD
10% (10^5 copies/mL)	YIDD/YMDD	YIDD/YMDD
1% (10^4 copies/mL)	YIDD/YMDD	YIDD/YMDD
0.1% (1000 copies/mL)	YIDD/YMDD	YIDD/YMDD
0.01% (100 copies/mL)	YIDD/YMDD	YMDD

containing 0.01% YIDD plasmid (Table 1). It means that real-time PCR and LDR are able to detect 1000 and 100 copies/mL of mutant virus in the background of wild type viruses, respectively. The results of real-time PCR were consistent with our previous study with mixtures of YVDD and YMDD plasmids[16].

Comparison of LDR and real-time PCR for detection of clinical samples with low abundant YMDD mutants

We tested clinical serum samples from 52 lamivudine treated patients with chronic hepatitis B who had low abundant YMDD mutants. All the samples were detected as YMDD virus by sequencing the PCR products. The results obtained by LDR and real-time PCR were consistent (Table 2). Both methods detected 39 YIDD, 9 YVDD, and 4 YIDD/YVDD. The percentages of mutants in the virus population obtained by real-time PCR ranged from 4% to 40%. The percentage of the four YIDD/YVDD mixed mutants was 10%/20%, 30%/20%, 40%/10%, and 20%/30%, respectively.

Time required

In this study, we used 96-well PCR equipment and all the 52 samples were dealt with in a run. The total assay time for LDR and real-time PCR was 4.5 and 2.5 h, respectively.

Cost

The cost per test for each assay was calculated based on the prices of the reagents in China. Primers and probe were synthesized in TaKaRa Biotech (TaKaRa, Dalian, China). Real-time PCR mixtures were from Fosun Diagnostics (Fosun Diagnostics, Shanghai, China). The total reagent cost per test for LDR and real-time PCR was 60 and 80 CNY (8 and 10.7 US dollars), respectively. Although the cost of labors is similar in the same region, the cost of equipment used for LDR assay is much lower than that for PCR assay (5000 US dollars *vs* 60 000 US dollars).

DISCUSSION

Lamivudine has revolutionized the treatment of chronic hepatitis B. Lamivudine-resistant mutations in the YMDD motif of polymerase gene were detected in lamivudine treated and untreated patients with chronic hepatitis B[14,17-19]. Clinical breakthrough was observed 2 wk-7 mo after the emergence of YMDD mutations[8-10], causing considerable morbidity and mortality in those patients[20-24].

Table 2 Comparison of results obtained by LDR and real-time PCR for 52 clinical samples

Types	No. of samples (%)	
	LDR	Real-time PCR
YMDD	0 (0)	0 (0)
YIDD	39 (75)	39 (75)
YVDD	9 (17)	9 (17)
YIDD + YVDD	4 (8)	4 (8)

Lamivudine-resistant mutants are frequently preexisting variants in HBV-infected patients and are selected during lamivudine therapy. These resistant variants initially represent a minority of the quasispecies and gradually replace the wild-type YMDD variants[10]. Detection of low abundant lamivudine-resistant mutants in the background of wild-type HBV as early as possible is helpful for virological follow-up and diagnosis of resistance in the clinical setting.

To date, many assays have been used for detection of lamivudine-resistant mutants in patients with hepatitis B[11]. The differences in sensitivity, specificity, cost, and time required do exist in these methods. Real-time PCR is able to quantitatively detect a small portion of resistant mutants in HBV populations and LDR is a newly developed method for detection of low abundant mutants in the background of wild-type HBV. In the present study, we compared LDR and real-time PCR for detection of low abundant YMDD mutations in lamivudine treated patients. The results obtained by the two methods were completely concordant in all samples, and 39 YIDD, 9 YVDD, and 4 YIDD/YVDD variants were detected. The percentages of mutants in the virus population obtained by real-time PCR ranged from 4% to 40%. In the mixing experiment, LDR was able to detect as low as 0.01% (100 copies/mL) of YIDD plasmid, while real-time PCR only detected 0.1% (1000 copies/mL) of YIDD plasmid in the background of YMDD plasmid. This may be due to LDR employing two kinds of amplification cycles, 20 cycles of LDR and 30 cycles of PCR, in the testing process. These results suggest that LDR is more sensitive than real-time PCR. In addition, the cost of LDR is slightly lower than that of real-time PCR. However, real-time PCR is much more rapid and requires less manual work than LDR. Both methods are sensitive and inexpensive compared to other methods for detection of YMDD mutation[16]. Another advantage of the real-time PCR method is that it is able to calculate the ratio of mutants to total virus in samples[14]. This will be useful in the clinical studies on the dynamics of resistant mutants during lamivudine therapy.

Several antiviral agents, such as adefovir and entecavir, can provide effective therapies in patients with lamivudine-resistant HBV[25-27]. Pegylated interferon also induces sustained responses in a portion of lamivudine-resistant patients[28-30]. Monitoring low abundant YMDD mutation during lamivudine therapy by sensitive and inexpensive methods will be helpful for physicians to make better clinical decisions as early as possible in management of chronic hepatitis B.

In conclusion, both LDR and real-time PCR are sensitive and inexpensive methods for monitoring low abundant YMDD mutations during lamivudine therapy in patients with chronic hepatitis B. LDR is more sensitive and less expensive, while real-time PCR is more rapid.

COMMENTS

Background

Many assays have been used for detection of lamivudine-resistant mutants in patients with hepatitis B. The differences in sensitivity, specificity, and cost do exist in these methods. However, only a few studies have compared these methods.

Research frontier

Lamivudine-resistant variants initially represent a minority of the viruses and gradually replace the wild-type YMDD variants. Methods for detection of low abundant lamivudine-resistant mutants in the background of wild-type hepatitis B virus (HBV) as early as possible are helpful for diagnosis of resistance in the clinical setting.

Related publications

Shi *et al* and Xiao *et al* developed real-time PCR and LDR assays for detection of minority lamivudine-resistant mutants in patients with hepatitis B. However, they did not compare the clinical performance between the two methods.

Innovations and breakthroughs

This article compared LDR and real-time PCR for detection of low abundant YMDD mutations in lamivudine treated patients. Both assays are sensitive and inexpensive for monitoring low abundant YMDD mutations during lamivudine therapy in patients with chronic hepatitis B. LDR is more sensitive and less expensive, while real-time PCR is more rapid.

Applications

Both LDR and real-time PCR are suitable for early detection of lamivudine-resistant mutations in patients treated with lamivudine.

Terminology

Ligase detection reaction (LDR) detects nucleotide sequence by annealing and subsequent ligation of two oligonucleotides (probe and detector). Ligation of the probe and detector occurs only when the two bases on either side of the ligation site are complementary to the template. LDR is usually coupled with PCR for detection of low abundant point mutations.

Peer review

This study is of importance for the early detection of lamivudine-resistant HBV mutants in patients with chronic HBV infection. The experiments appear to be conducted very carefully and by an experienced team of investigators.

Abstract

Bouveret's syndrome, defined as gastric outlet obstruction due to a large gallstone, is still one of the most dramatic biliary gallstone complications. Although new radiological and endoscopic techniques have made pre-surgical diagnosis possible in most cases and the death rate has dropped dramatically, "one-stage surgery" (biliary surgery carried out at the same time as the removal of the gut obstruction) should be still considered as the gold standard for the treatment of gallstone ileus. In this case, partial gastric outlet obstruction resulted in an atypical and insidious clinical presentation that allowed us to perform the conventional one-stage laparatomic procedure that completely solved the problem, thus avoiding any further complications.

INTRODUCTION

Gallstones are completely asymptomatic in the majority of patients (60%-80%)[1]. When they become symptomatic, biliary colic is usually the first manifestation to be encountered. Patients with mild symptoms have a higher risk of developing both common and less frequent complications[2].

Biliary fistula is a rare complication (3%-5%) that is frequently preceded by an episode of acute cholecystitis[3,4]. Biliary fistula is mostly encountered in the duodenum although it can occur anywhere in the gastrointestinal (GI) tract[5]. Finally, just 7%-10% of biliary fistulae cause gallstone ileus, an intestinal obstruction caused by a stone that has migrated through the fistula and stopped anywhere in the GI tract[6]. The terminal ileum and ileocecal valve are the most common locations[7], whereas gastric outlet obstruction from an impacted gallstone named "Bouveret's syndrome", is a very rare complication (1/10 000 cholelithisiasis)[8].

To our knowledge, this is the first case of incomplete gastric outlet obstruction manifested as a "waxing and waning" syndrome for a period of over 20 mo before diagnosis was defined.

CASE REPORT

A 79-year old woman was referred to our hospital when a recent oesophagogastroduodenoscopy (OGDS) revealed the presence of a foreign body with its maximum diameter > 4 cm, partially obstructing the gastric lumen, firmly attached to the antral greater curvature region where a fistula was partially explorative. The procedure was performed to investigate the patient's two-year old dyspepsia. This mild symptom alternated every two months with bouts of colic pain associated with self-

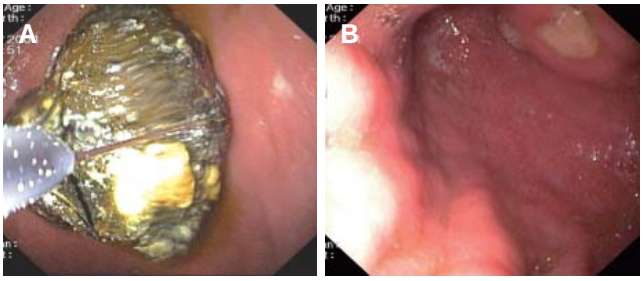

Figure 1 Oesophagogastroduodenoscopy confirming the presence of a foreign body looking like a biliary stone (**A**) and a 15 mm-wide ulcer (**B**).

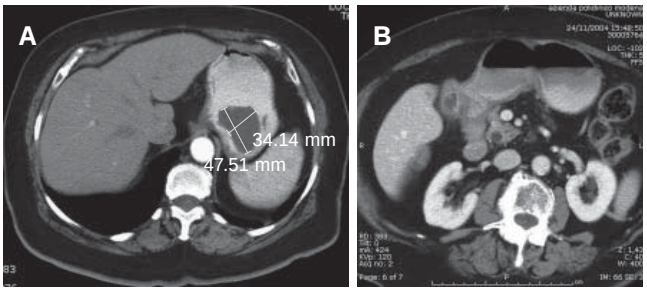

Figure 2 Computerised tomography revealing the density of foreign body typical of ectopic biliary stone (**A**) and the oedematous wall of the gastric antrum (**B**).

limited vomiting lasting 2 d.

The patient reported an earlier negative colonoscopy, performed due to the migration of gastric foreign body through a gastro-colic fistula. His symptoms occurred after two days of acute abdominal pain associated with vomiting due to acute gastroenteritis. An abdominal ultrasound scan (US) revealed cholelithiasis.

The patient was admitted to our ward in good general clinical conditions. Blood tests were completely normal apart from ferrittin, which was twice the normal range.

An abdominal computerised tomography scan (CT) and another OGDS were then performed. Endoscopic examination confirmed the presence of the foreign body, looking like a biliary stone (Figure 1A). Simple endoscopic lithotomy was not possible as the stone was too large, and an attempt at mechanical fragmentation of the stone was unsuccessful. The foreign body appeared to be firmly attached to the gastric wall, and a 15 mm wide ulcer was visible where the opening of the fistula has been previously described (Figure 1B). The CT revealed that the foreign body had a density typical of an ectopic biliary stone (Figure 2A) and the oedematous wall of the gastric antrum could not be separated from the thickened wall of the gallbladder fundus (Figure 2B).

Further air-fluid level was present in the gallbladder (Balthazar and Schester sign) and the intra- and extrahepatic bile ducts were slightly stretched. Lastly, a magnetic resonance cholangio-pancreatography (MRCP) was performed in the hope of observing the fistula. The procedure was negative (Figure 3). All of these data suggest that a multidisciplinary consultation was needed to decide the most appropriate management for this particular clinical setting.

We eventually opted to attempt "one-stage surgery".

Figure 3 Magnetic resonance cholangiopancreato-graphy showing no fistula.

Figure 4 One-stage surgery with dissection of omental-cholecystic adhesions.

Figure 5 A large ectopic stone extracted.

After dissection of many omental-cholecystic adhesions, retrograde cholecystectomy was performed successfully (Figure 4). Finally, a gastrostomy was performed on the anterior gastric wall and a large ectopic stone was extracted (Figure 5).

The post-surgical course was regular and during six-month follow-up the patients' general condition was excellent. The patient was completely asymptomatic with normal biliary tree on the US scan.

DISCUSSION

Like any other gallstone ileus, "Bouveret's syndrome" defined as gastric outlet obstruction caused by a large gallstone occluding the pyloro-duodenal region following a biliogastric or bilioduodenal fistula, primarily affects the geriatric population, with a medium age of 65-75 years and a female predominance (3-16:1)[9-11]. For these reasons, up to 80%-90% of patients have concomitant medical

illnesses (CIC, IRC, diabetes) and the management of such patients should be guided by their general clinical status[4].

The long period of approximately twenty months between the onset and diagnosis of the disease, can be attributed to the patients' carelessness, and the alternating gravity of symptoms combined with the patient's good general health can justify the decision to perform one-stage surgery.

In our case, the particular position of the gallstone led the patient to an insidious clinical setting that urged us to opt for "one-stage surgery" (namely, biliary surgery carried out at the same time as the removal of the intestinal obstruction), which should be still considered as the gold standard for the treatment of gallstone ileus[12]. In fact, it is the only procedure to solve the problem and avoid recurrences and other complications of gallstone disease[13].

In any case, over the past two decades, technological progress has probably made lithotomy or lithotripsy a more conservative approach to reducing patients' risks and has thus been suggested for older patients in poor medical conditions. In our patient, simple endoscopic lithotomy or lithotripsy was not indicated as the stone was excessively large (4 cm) and the inflammatory aspects of the gastric antrum required surgical treatment in order to close the fistula. An attempt at endoscopic mechanical fragmentation of the stone was unsuccessful.

The so-called "two stage surgery" consists of postponing biliary surgery (cholecystectomy and fistula repair) to a later stage with the presence of residual symptomatic stone in asymptomatic subjects[12,24].

Although no patients deny prompt relief from an intestinal obstruction[4], in the case of Bouveret's syndrome, an endoscopic approach represents a reliable alternative to gastro/duodenothomy[15,16]. Preoperative aetiological diagnosis is now possible in most patients and in this case, endoscopic lithotomy and lithotripsy (where possible) represent the first-line approach to treatment as the death rate associated with surgery is still 19%-24%[17,18].

Nevertheless, surgery remains the main procedure in particular situations such as stone impaction in the fistula[19], stone compression of the duodenal wall[20], GI haemorrhage[21] and improper stone manipulation[18,22-25].

In our case, the medical history and endoscopic findings suggested an unusual chronic situation to which the only possible solution was surgery. We, therefore, performed a complete radiological study to better define the anatomy of the lesion before the surgical procedure, including abdominal CT and MRCP of the biliary tree. The first combines the qualities of US and plain X-rays in defining Rigler's diagnostic triad (intestinal obstruction, pneumobilia and ectopic stone)[4,26]. It, therefore, represents the single best imaging technique for the diagnosis of gallstone ileus and Bouveret's syndrome[26]. It may also be helpful in assessing gallbladder wall thickness (signs of acute or chronic cholecystitis), content (air, residual gallstones) and biliary fistula[5,26].

MRCP has recently been proposed as a useful tool for differentiating between fluid and gallstones and also for observing the fistula when sufficient fluid is present[27].

In our case, all the investigations suggested a complicated clinical situation in which an incomplete pyloric occlusion developed following the migration of a large stone through a cholecystogastric fistula, probably due to a poorly-interpreted and treated episode of acute cholecystitis in a case of undiagnosed chronic cholecystitis.

In conclusion, the clinical picture and anatomy of the lesions suggest that a conventional one-stage laparatomic procedure can completely solve the problem, simultaneously avoiding recurrence and other gallstone disease complications.

Abstract

A 36-year-old woman was admitted to our department for close examination of a liver tumor that was found during a medical checkup. Abdominal US, CT and MRI showed a tumor in segment 7 (S7) of the liver. Although imaging suggested hepatocellular carcinoma, laboratory tests showed no abnormality in liver function, hepatitis virus markers were negative, and tumor markers including protein induced by vitamin K absence or antagonist Ⅱ (PIVKA-Ⅱ), α-fetoprotein (AFP), carbohydrate antigen 19-9 (CA19-9), and carcinoembryonic antigen (CEA) were all within normal ranges. Upon aspiration biopsy of the liver, the histopathological diagnosis was moderately differentiated hepatocellular carcinoma. Therefore, right hepatectomy was performed. Although a part of the tumor was necrotic, about 60% of the viable part showed a clear-cell variant. Consequently, it was diagnosed as clear-cell hepatocellular carcinoma. It was noted that the background liver tissue was normal. This case is worthy of reporting because development of clear-cell hepatocellular carcinoma in the normal liver of a middle-aged woman is rarely seen.

INTRODUCTION

Hepatocellular carcinoma often develops against a background of chronic viral hepatitis including hepatitis B virus (HBV) and hepatitis C virus (HCV), autoimmune hepatic diseases including autoimmune hepatitis and primary biliary cirrhosis, alcoholic liver injury, and non-alcoholic steatohepatitis (NASH). We report a case of hepatic cancer in which no abnormality existed in liver function, hepatitis virus markers were negative, and the background liver was normal, and which was histopathologically clear-cell carcinoma, in which clear cells accounted for about 60% of the tissue. This patient presented with no background of carcinogenic risk factors, such as viral hepatitis, and showed rare histopathology.

CASE REPORT

A 36-year-old woman had a medical checkup on October 17, 2005. A tumor was found in S7 of the liver by abdominal US. She was referred and admitted to our department on November 28, 2005 for close examination and treatment. She had a history of alcohol consumption of 1 L beer per day for 15 years. Her family had no history of hepatic disease. On admission, her conjunctivas were not jaundiced, and heart and respiratory sounds were normal. The liver, spleen and tumor were not palpable.

Laboratory tests on admission showed no abnormality such as inflammation or abnormal liver function for peripheral blood and biochemical tests. Hepatitis B surface antigen (HBsAg), hepatitis B core antibody (HBcAb) and HCV antibody (HCVAb) were negative. All tumor markers tested showed normal values: specifically, 16 mAu/mL for PIVKA-Ⅱ (criterion, < 40), 6.2 ng/mL for AFP (criterion, ≤ 10.0), 20.2 U/mL for CA19-9 (criterion, ≤ 37), and 0.9 ng/mL for CEA (criterion, ≤ 5.0). Anti-nuclear and anti-mitochondrial antibodies were negative.

Abdominal US and CT showed a tumor of about 60 mm diameter in S7 of the liver. The lesion was visible on early phase imaging. However, there was also a part that was not visible in the image. It was apparent as a low-density area in the portal phase image (Figure 1A and B). Abdominal MRI showed that the T1-weighted image revealed a well-defined low-intensity area in S7, with a high-intensity part inside. The tumor was depicted as a

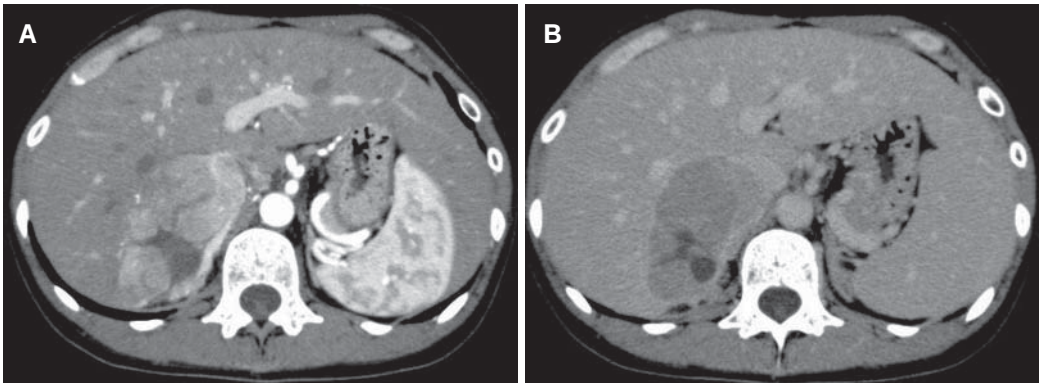

Figure 1 **A**: Dynamic enhanced CT showed a nodular lesion in the liver that was enhanced in the early image. However, the interior of the mass showed a low-density area; **B**: In the subsequent late phase, the lesion revealed washout of contrast enhancement.

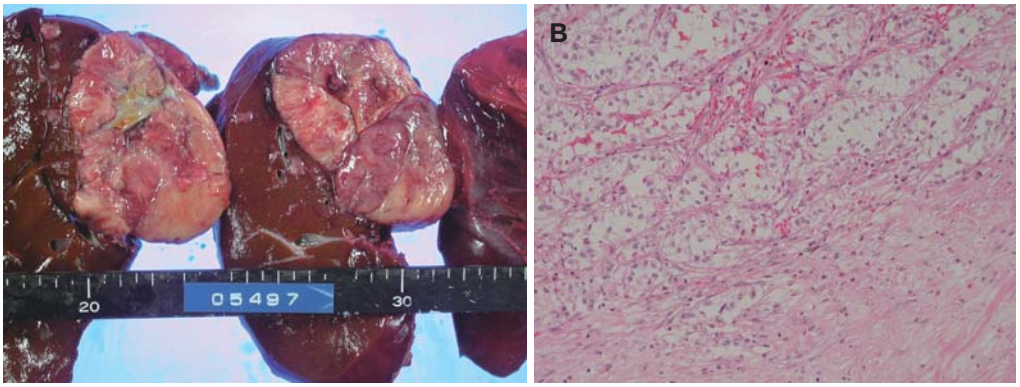

Figure 2 **A**: The tumor had a fibrous capsule. Its cut surface was whitish, and tumorous tissue had a necrotic part at the center; **B**: Histological examination showed sheet-like growth of clear, atypical cells (HE, × 40).

high-intensity area in the T2-weighted image. Angiography showed that increased tumor vascularity was observed from the right hepatic artery and the inferior phrenic artery to the tumor area. A slight tumor stain was visible in the tumor area in S7 of the liver. Although the imaging results suggested hepatocellular carcinoma, all hepatitis virus and tumor markers were negative, and non-cancerous tissues had no signs of chronic disease.

Consequently, aspiration biopsy of the liver was carried out for definitive diagnosis. Based on histopathology, the patient was diagnosed with moderately differentiated hepatocellular carcinoma, trabecular type, and right hepatectomy was performed on December 27, 2005. A 60-mm tumor was located in the posterior segment of the right hepatic lobe; the tumor was partly adherent to the caudal portion of the adrenal gland. The tumor had a fibrous capsule. Its cut surface was whitish, and tumorous tissue had a necrotic part at the center (Figure 2A). Histopathology showed the border between the tumor and the non-cancerous part formed a fibrous capsule. Approximately 60% of the tumor showed sheet-like growth of clear, atypical cells (Figure 2B). Other areas of the tumor were composed of moderately-differentiated HCC with a trabecular growth pattern. The tumor center was occupied by necrotic tissue.

DISCUSSION

Hepatocellular carcinoma often develops against a background of chronic liver disease. Specifically, 77.4% and 62.6% of cases in Japan are associated with chronic hepatitis and liver cirrhosis, respectively. Among cases with histopathological diagnosis, only 7.6% have normal liver as the background, as in this present case[1]. Furthermore, HBV- or HCV-antigen-positive liver cirrhosis accounts for about 80% of cases of liver cirrhosis; other causes include primary biliary cirrhosis, autoimmune hepatitis, alcoholic cirrhosis, NASH, and Budd-Chiari syndrome[2]. In the present case, although the patient had a history of alcohol consumption, there was no sign of alcoholic fibrosis in non-cancerous tissues. For that reason, it was presumed pathologically that the hepatocellular carcinoma developed from the normal liver. Liver cancer is considered to be comparatively rare in young persons, and patients < 35 years old account for 0.6% of the cases diagnosed with clinical hepatocellular carcinoma[1]. Moreover, according to data from 1994 to 1995 by the Follow-up Committee, Liver Cancer Study Group of Japan in 1998, 60 cases of liver cancer in young patients aged < 35 years old consisted of 12 HCVAb-positive (20%), 34 HBsAg-positive (57%), three positive cases each (5%) for HCVAb and HBsAg, and 11 virus-marker-negative cases (18%), which indicates that HBsAg is often positive among younger patients with liver cancer[3]. Although virus markers were negative in our case, reports also exist of occult HBV infection, in which serum HBV marker was negative, but HBV existed in the serum and liver tissue[4], and comparatively frequent incorporation of HBV in hepatocellular carcinoma developed in normal liver[5-7]. Therefore, involvement of viruses in this case is not implausible.

Clear-cell hepatocellular carcinoma is not frequent and has been reported to account for 7.5%-12.5% of all liver cancer cases[8,9]. The existence of clear cells, as well as fatty changes, is characteristic of well-differentiated hepatocellular carcinoma in the early stage; its frequency is presumed to

be decreased along with enlargement of the cancer[10]. In a large hepatocellular carcinoma, as that presented in this case, it has been reported that clear-cell hepatocellular carcinoma occurs at a frequency of 0.9%-8.8%[11]. The mechanism of development of clear cells is presumed to involve metabolic disorders and abnormalities of sugar metabolism for reasons including decreased portal blood flow and underdeveloped tumor arteries in the early stage of cancer[10,12]. Histopa-thologically, it is important to distinguish clear-cell hepatocellular carcinoma from liver metastases from other organs, especially renal cell carcinoma, and it can be distinguished by immunostaining[13]. As for the present case, the possibility of malignant tumors derived from other organs was clinically eliminated, and immunostaining of excised samples excluded liver metastasis from renal cancer. On the other hand, fibrolamellar hepatocellular carcinoma and epithelioid hemangioendothelioma are malignant liver tumors that are often seen in young persons without background liver diseases. However, the present case did not have the same histopathology as those diseases. Prognosis of clear-cell hepatocellular carcinoma has been reported to be better than[8,14], the same as, or worse than[9,12] that of common hepatocellular carcinoma. Further careful follow-up observations are needed in the future.

Abstract

Oncogenesis of anaplastic carcinoma of the pancreas is a subject of controversy, because it shows sarcomatous nature with extremely poor prognosis. We herein report an unusual case of anaplastic carcinoma occurring with a recurrent mucinous cystic neoplasm in a 38-year-old female. A 10-cm retroperitoneal cystic mass was pointed out in the first pregnancy and a probable diagnosis of mucinous cystic neoplasm was made in October 2000. She refused surgery first and delivered her baby uneventfully. During her second pregnancy in 2002, however, she presented hematemesis and underwent urgent distal pancreatectomy, splenectomy and partial resection of the gastric wall where the tumor perforated. A diagnosis of borderline-type mucinous cystic neoplasm with ovarian-like stroma was made. Nine months later, CT visualized a recurrent cystic tumor near the pancreatic stump, which was subsequently resected. Pathology revealed that the tumor was composed of two different components of borderline-type mucinous cystic neoplasm and anaplastic carcinoma. The latter was intensely positive for vimentin, CD68, p53 and focally for cytokeratin, suggesting both sarcomatous and carcinomatous differentiation. She survived four years after the second surgery without tumor recurrence. Although the origin of anaplastic carcinoma has not been determined yet, it should be remembered that anaplastic carcinoma can occur in association with mucinous cystic neoplasm of more benign histology.

http://dx.doi.org/10.3748/wjg.14.132

INTRODUCTION

Anaplastic carcinomas of the pancreas are rare, representing only 0.5%-7% of all non-endocrine malignances in this organ[1,2]. The origin of the tumor is considered pancreatic ductal cells because they are accompanied with areas of adenocarcinomas in most cases[2]. However, they also contain mesenchymal components such as spindle-shaped cells and osteoclastoid giant cells, reminiscent of having sarcomatous differentiation. The prognosis of pancreatic anaplastic carcinoma is extremely poor. The combination of immature adenocarcinoma and sarcoma components may portend an adverse clinical course.

Mucinous cystic neoplasms of the pancreas, on the contrary, have an indolent clinical course and a much better prognosis than anaplastic carcinoma if respectable[3]. Mucinous cystic neoplasms occur predominantly in women and often have an ovarian-like stroma that contains spindle cells commonly observed in the ovary. The association of anaplastic carcinoma with mucinous cystic neoplasm has rarely been reported to date.

We report an unusual case of pancreatic anaplastic carcinoma coexistent with recurrent mucinous cystic neoplasm in a 38-year-old female, who previously underwent distal pancreatectomy for a borderline-type mucinous cystic neoplasm during her second pregnancy.

CASE REPORT

A 38-year-old female patient with no previous medical history was introduced to our hospital in October 2000, for further examination of a retroperitoneal cystic tumor that was disclosed incidentally by routine ultrasonography (US) in the first trimester of her first pregnancy. She was completely asymptomatic. Magnetic resonance imaging (MRI) and US showed a large multiloculated cystic tumor with a thick capsule at the tail of the pancreas. It measured 10 cm in diameter and displaced the stomach

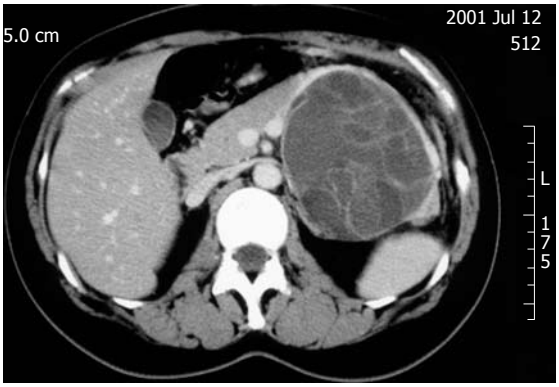

Figure 1 CT after the first delivery showing a 10 cm × 10 cm multi-loculated cystic tumor at the tail of the pancreas.

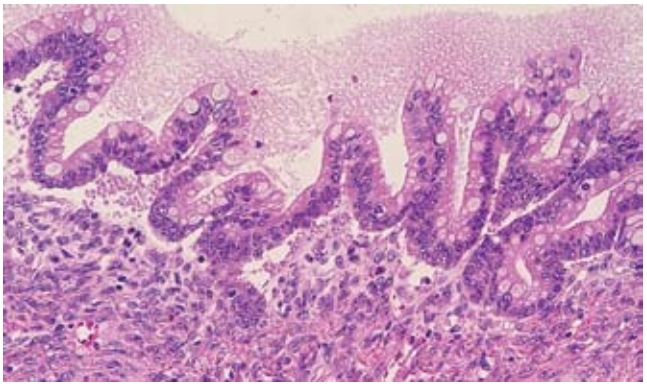

Figure 2 Consistent pathology of the primary tumor with a borderline-type mucinous cystic neoplasm (HE staining, original magnification, × 100).

anteriorly. A probable diagnosis of a mucinous cystic neoplasm was made. We recommended her to receive resection of this potentially malignant tumor soon, but she decided to postpone operation until delivery. She delivered a healthy baby in July 2001. Computed tomography (CT) showed a multiloculated cystic tumor (Figure 1), which seemed similar in size of that at the initial diagnosis. She hesitated to receive surgery and was lost to medical follow-up.

In September 2002, she presented repetitive vomiting and hematemesis, when she noticed her second pregnancy. In November, She presented hematemesis and tarry stool again. MRI and US showed marked enlargement of the cystic tumor. Because of progressive anemia, she underwent urgent operation in the second trimester. At laparotomy, a dense adhesion between the tumor and posterior wall of the stomach was noted, so that an en-block resection was accomplished by distal pancreatectomy, splenectomy and a partial resection of the stomach. The postoperative course was uneventful and she delivered her second baby in April 2003.

In August 2003, a routine medical checkup by US disclosed a 3 cm tumor near the pancreatic stump. The tumor showed both cystic and solid appearances with capsule enhancement. The second operation was performed under the diagnosis of local recurrence of the mucinous cystic neoplasm. At laparotomy, the tumor was located between the pancreatic stump, posterior wall of the stomach and the left adrenal, which was removed en-block by additional partial pancreatectomy, partial gastrectomy, and left adrenalectomy.

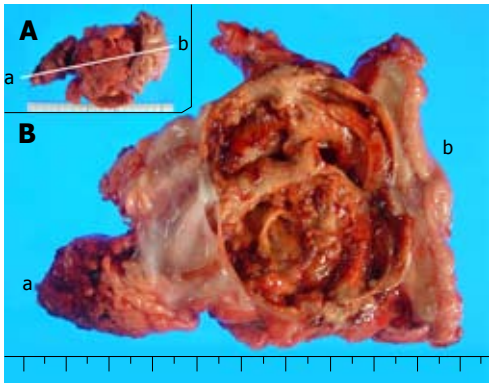

Figure 3 Cut surface of the recurrent tumor. **A:** Location of the cystic tumor between the pancreatic stump (a) and posterior wall of the stomach (b); **B:** Cut surface of the specimen revealing the tumor composed of two different components.

The patient was still alive and well four years after the resection. CT revealed no local and distant tumor recurrences at the latest follow-up.

Pathological findings

The tail of the pancreas resected at the first operation contained a multiloculated cystic tumor, measuring 14 cm × 14 cm, filled with about one liter of straw-yellow mucinous fluid. The cyst was uniformly lined with smooth inner surface with a thickened capsule of 5-10 mm width. At the cut surface of the maximal dimension, ten blocks were sampled for microscopic examination. The histological diagnosis was a mucinous cystic neoplasm, borderline type (Figure 2). The tumor had an ovarian-like stroma which was immunohistochemically positive for a progesterone receptor. None of the lymph nodes was involved, nor was the pancreatic cut margin. At the site of perforation to the stomach, no neoplastic change was identified in the gastric wall.

The recurrent tumor was entirely cystic and contained brown, dirty mucus. The tumor was located between the pancreatic stump and posterior wall of the stomach. Macroscopically, it was composed of two different parts. At the pancreatic side, the inner surface was white and smooth, resembling that of the previously resected primary tumor, while at the gastric side, it showed a tan-brown, irregular one. There was no transition area between the two parts (Figure 3). Pathology of the part near the pancreatic stump was a borderline-type mucinous cystic neoplasm. The part at the gastric side, on the other hand, contained an anaplastic carcinoma with osteoclastoid giant cells, atypical spindle-shaped cells and round cells, showing sarcomatous changes (Figure 4). The immunohistochemical the features of anaplastic carcinoma are summarized in Table 1. The recurrent tumor was also positive for progesterone receptor. All components of the anaplastic carcinoma were intensely positive for vimentin. Leukocyte common antigen and CD68 were positive in spindle-shaped cells and giant cells, while cytokeratin was positive in cytoplasm of the obviously epithelial component and

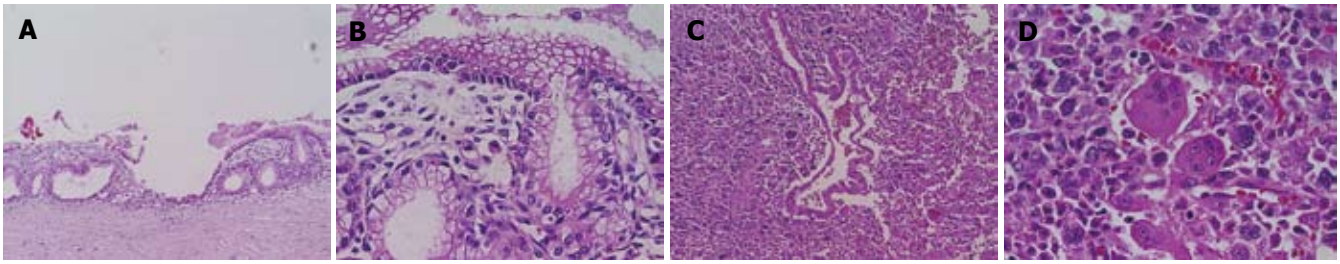

Figure 4 Pathology of the recurrent tumor at the pancreatic side (as pointed by a in Figure 3) revealing a borderline-type mucinous cystic neoplasm (HE, **A**: x 100, **B**: × 400) and at the gastric side (as pointed by b in Figure 3) an anaplastic carcinoma with giant cells, atypical spindle cells and round cells (**C**: × 100, **D**: × 400).

focally in some of the spindle-shaped cells. P53 was also positive throughout of anaplastic carcinoma.

DISCUSSION

Anaplastic carcinomas associated with mucinous cystic neoplasms are very uncommon. Only several cases have been reported to date (Table 2)[3-12]. Some underwent

ND: Not described; MCN: Mucinous cystic neoplasm. [1]Later re-analyzed genetically and reported by van den Berg W[11].

resection of the cystic tumor at the onset, while others were treated with cystenterostomy first. Because of co-existent adenocarcinomas in the areas of anaplastic cancer, most of the tumors were thought to be of epithelial origin. However, the pathogenesis of these neoplasms, particularly those with epithelial and mesenchymal components, remains a subject of controversy.

In our case, the entire anaplastic carcinoma was intensely immunohistochemical positive for vimentin, an intermediate fragment associated with mesenchymal cells. Areas of spindle-shaped cells and giant cells were also positive for leukocyte common antigen and CD60. These facts suggest the sarcomatous nature of the anaplastic carcinoma[12]. In addition to the positive vimentin, areas of the carcinoma were positive for cytokeratin. The co-expression of cytokeratin and vimentin in the cells with the same hisotological character seemed unusual, but it was reported that vimentin becomes positive when the tumor cells are in a proliferative state[13,14]. Immunohistochemical study alone cannot determine the origin of anaplastic carcinoma in the mucinous cystic neoplasms. Van den Berg *et al*[11] analyzed genetically three cases of anaplastic carcinoma related to mucinous cystic neoplasms, and disclosed that the sarcomatous and carcinomatous components are different phenotypically but genetically uniclone.

It was reported that malignant fibrous histiocytoma coexists with mucinous cystic adenoma[10], suggesting that sarcomas can occur from a relatively benign epithelial histology of mucinous cystic neoplasms. Indeed, the origin of sarcomas and carcinomas in mucinous cystic neoplasm is still unknown, but the theory that both sarcomas and carcinomas are originated from primitive mesenchymal stem cells with totipotential properties in the mucinous cystic neoplasm, might be another acceptable hypothesis for the histogenesis of anaplastic carcinoma.

Another interesting feature of this case is that the tumor experienced pregnancy twice. To the best of our knowledge, there are no reports on the relation of the progression of mucinous cystic neoplasm with pregnancy. Ovarian-like stroma exists exclusively in female patients with mucinous cystic neoplasms, which often are immunohistologically positive for progesterone and/or estrogen receptors. In our case, both the primary and recurrent tumors were positive for progesterone receptors. It is unknown whether physiological changes in blood concentration of these hormones promote the progression of the tumor. In our patient, the tumor size was stable during the first pregnancy, but rapidly enlarged in the second trimeseter of the second pregnancy. Increased mucious production might induce the enlargement of the tumor and subsequent rupture.

Our patient was still alive without any sign of recurrence four years after the second operation. However, close monitoring on tumor recurrence should be required because anaplastic carcinoma reportedly has a dismal prognosis.

ACKNOWLEDGMENTS

The authors thank Professor S Yagihashi, Department of Pathology, Hirosaki University, for his great contribution to reviewing the pathological specimens.

Abstract

Inflammatory myofibroblastic tumor (IMT) of the stomach in adults is extremely rare, with unpredictable prognosis. We present a 55-year-old woman with a gastric IMT. She experienced sudden abdominal pain 4 d previously. Physical examination showed mild abdominal tenderness in the hypogastrium, but no palpable abnormal abdominal mass. Abdominal CT showed a mass of approximately 8 cm in the gastrocolic ligament. On laparoscopic exploration, unexpected hemoperitoneum of approximately 1.5 L of blood was found, and an exophytic gastric mass of approximately 10 cm, appeared from the anterior wall of the gastric body along the greater curvature. Laparoscopy further showed that non-clotting blood in the abdominal cavity seemed to be from the gastric tumor. After conversion to open surgery for more precise evaluation of the cause of hemoperitoneum and the large friable tumor, gastric wedge resection, including the tumor, was conducted. The final diagnosis was consistent with IMT that originated from the gastric wall.

INTRODUCTION

Inflammatory myofibroblastic tumor (IMT) is a rare neoplasm. The perspective of this distinctive disease has changed over time from a reactive, inflammatory process to a neoplasm of intermediate biologic potential[1,2]. Even though IMT has recently been known to span the entire age range and can arise from any site in the body[1], gastric IMT in an adult is, nevertheless, still very rare. We present a case of gastric IMT in an adult and a review of the literature.

CASE REPORT

A 55-year-old woman presented with acute-onset, sharp abdominal pain. The pain had developed 4 d prior to referral to our department from a local hospital for further evaluation of abdominal pain. On admission, her vital signs were normal. She denied other gastrointestinal symptoms and signs such as nausea, vomiting, abnormal bowel habits, melena or hematochezia, except for sharp abdominal pain. She also denied weight loss, fever, or other systemic symptoms. She had no medical or family history. Physical examination showed mild abdominal tenderness in the hypogastrium, but no palpable abnormal abdominal mass. Her laboratory findings, including tumor markers, were unremarkable, except for a normocytic, normochromic anemia: hemoglobin, 9.86 g/dL; hematocrit, 28.6%; mean corpuscular volume, 100.4 fL; and elevated erythrocyte sedimentation rate, 54 mm/h. The chest and abdominal X-ray films revealed no abnormal findings. Abdominal CT demonstrated a mass of approximately 8 cm in the gastrocolic ligament or gastric wall (Figure 1), and abdominal MRI showed a heterogeneous mass of approximately 8 cm in the gastrocolic ligament or gastric wall (Figure 2).

Endoscopic examination, including colonoscopy, showed no luminal or mucosal lesion and no remarkable

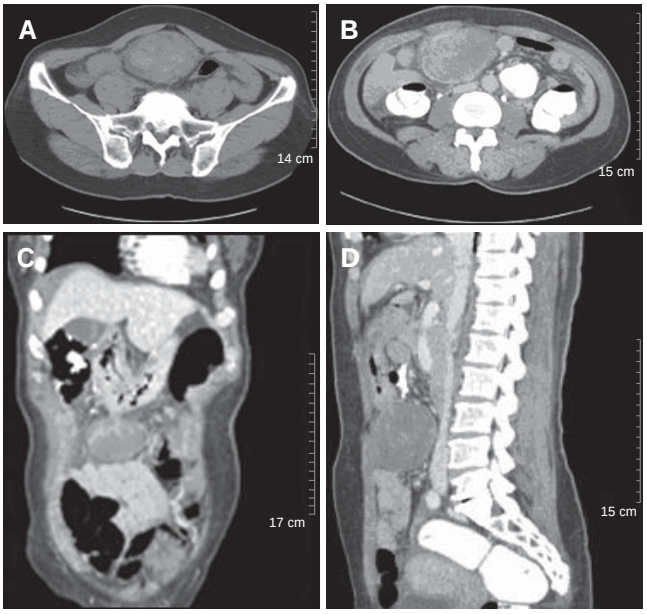

Figure 1 Abdominal CT revealed a large solid mass at the gastrocolic ligament or the gastric wall, which showed heterogeneous density on an non-enhanced image (**A**). The 8 cm mass showed internally enhanced vessels on the arterial phase of CT and delayed peripheral enhancement of the mass on the venous phase (**B**-**D**).

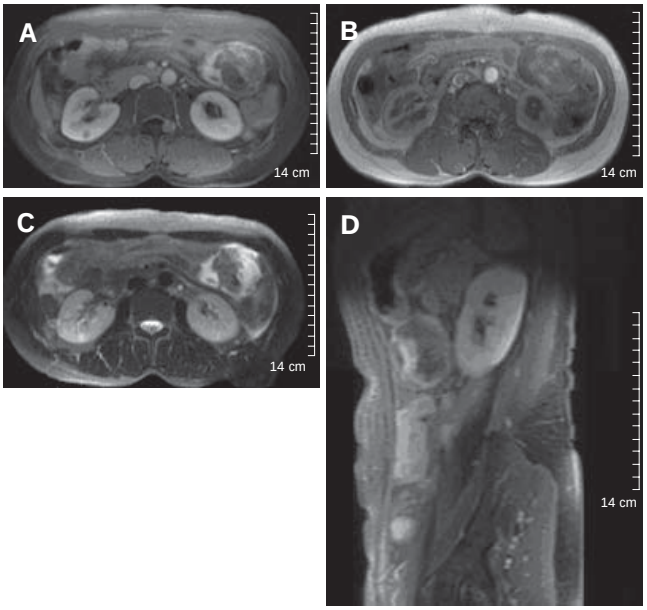

Figure 2 Contrast-enhanced MRI of the abdomen showed a mass of approximately 8 cm, seen at the left upper quadrant of the abdomen. The margin of the mass was lobulating, and it was attached to the greater curvature of the stomach. It contained a peripheral enhanced solid portion and a central non-enhancing portion (**A**). Signal intensity of the central non-enhancing portion was low on T1WI (**B**) and T2WI (**C** and **D**), which suggested internal hemorrhage within the tumor.

findings, except chronic atrophic gastritis with *Helicobacter* infection. Routine gynecological evaluation was unremarkable. After the work up for the intra-abdominal mass, her abdominal pain completely subsided at the time of operation.

The patient underwent laparoscopic exploration. Unexpected hemoperitoneum of approximately 1.5 L of non-clotting blood was found. An exophytic gastric mass from the anterior wall of the gastric body along the greater curvature appeared, similar in appearance to the spleen or a hematoma, approximately 10 cm in size (Figure 3). Laparoscopic diagnosis was massive intra-abdominal hemorrhage from the gastric tumor or ectopic spleen. Since further evaluation of the precise cause of hemoperitoneum was needed, and because it would have been difficult to remove the large friable tumor from the abdominal cavity, even after a safe laparoscopic resection we decided to convert to open surgery.

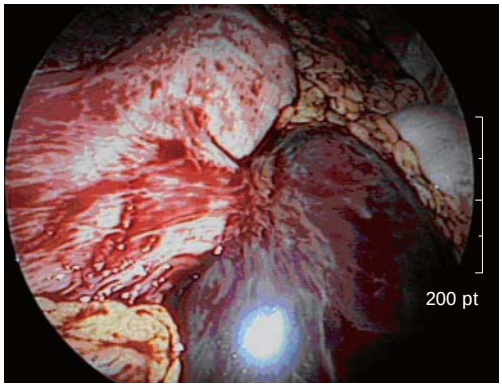

Figure 3 Laparoscopic view of the exophytic gastric mass with a large amount of intra-abdominal non-clotting hemorrhage.

After evacuation of blood, the abdominal cavity was thoroughly explored for any other source of bleeding, but none was found; the permeated or ruptured exophytic gastric mass was the cause of hemoperitoneum, because preoperative imaging studies, including gynecologic evaluation during admission, showed no evidence of intra-abdominal fluid, and also no other identified focus of bleeding upon surgical exploration. The tumor showed a dark reddish pedunculated mass with a stalk that originated from the gastric wall, but there was no blood vessel directly into the tumor. During dissection, we could not find any tear or rupture on the exophytic tumor. Gastric wedge resection, including the tumor and greater omentum, was conducted.

Grossly, the external surface of a well-encapsulated lump of soft solid tumor was smooth and glistening, but there was no gastric mucosal lesion (Figure 4A). The tumor measured 8.5 cm × 7.1 cm × 3.6 cm and weighed 88.1 g, and its stalk measured 2.0 cm × 1.2 cm × 1.9 cm. On serial sectioning, the cut surface was characterized by several amorphous fragments of parenchymal tissue, which were separated by the cystic spaces (Figure 4B). Histologically, the tumor was composed of round and spindle-shaped myofibroblastic cells, diffusely scattered inflammatory cells, and many vascular structures (Figure 5A). The mitotic count was 1/10 high power fields (HPF). The tumor cells showed positive immunoreactivity for vimentin (Figure 5B), while being negative for c-kit, CD34, desmin, smooth muscle actin (SMA), S-100, anaplastic lymphoma kinase (ALK), β-catenin, and CD31. Ki-67 labeling index was approximately 10%. Lymph nodes found along the gastroepiploic vessels in the omentum were all negative for tumor. The final pathologic diagnosis was consistent with IMT that originated from the gastric wall.

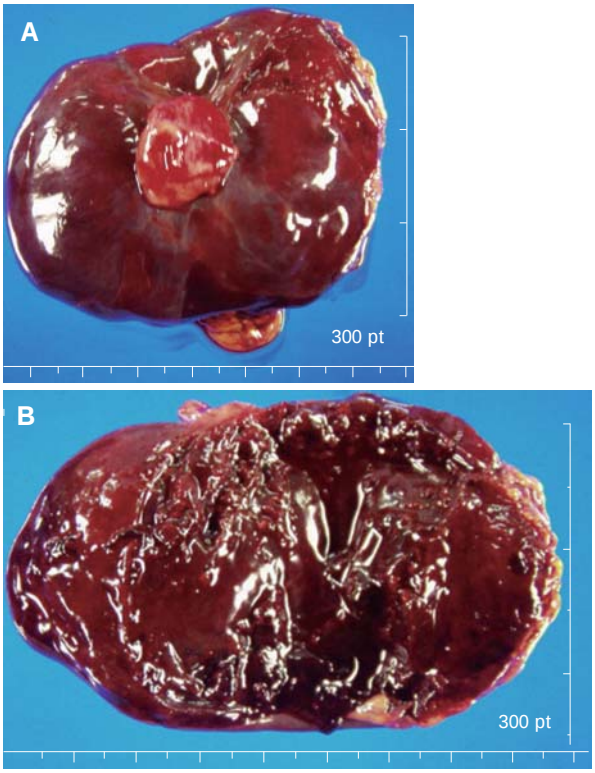

Figure 4 The external surface of a well-encapsulated lump of soft solid tumor, weighing 88.1 g, was smooth and glistening, but showed no gastric mucosal lesion (**A**). Cross-sectional surface of the tumor was characterized by several amorphous fragments of parenchymal tissue, which were separated by the cystic spaces (**B**).

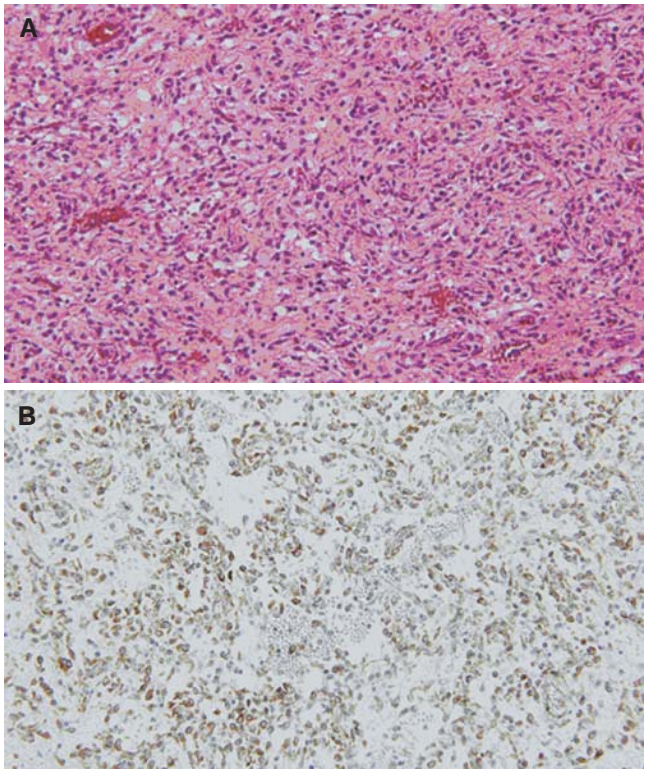

Figure 5 **A**: The tumor was composed of round and spindle-shaped myofibroblastic cells. Diffusely scattered inflammatory cells and many vascular structures are seen (HE, × 400); **B**: The tumor cells showed positive immunoreactivity for vimentin (× 400).

The patient had an uneventful postoperative course and has been followed up, including positron emission tomography, for any recurrence.

DISCUSSION

IMT is a rare, distinctive disease. Various terms such as inflammatory pseudotumor, plasma cell granuloma, inflammatory myofibroblastoma, and inflammatory myofibrohistioblastic proliferation have previously been used to describe the disease[3], which indicates that the exact nature of IMT is not yet fully understood. It has been debated whether IMT is a tumor or inflammation, and also whether it is benign or malignant[1]. However, recent studies on cytogenetic abnormalities, such as rearrangements of the ALK gene on chromosome 2p23[4,5], clonal chromosome abnormalities[6-8], and DNA aneuploidy[9], and the role of oncogenic viruses[10,11] in the pathogenesis of IMT suggest that it is a true neoplasm. According to the current classification of the World Health Organization[12], IMT is a neoplasm with a tendency for local recurrence and a very low rate of metastasis, and is histopathologically composed of myofibroblastic spindle cells, with inflammatory cell infiltrate of plasma cells, lymphocytes and eosinophils.

It was once accepted that IMT is primarily a disease of children and young adults and commonly occurs in the lungs[13,14]. However, a recent study by Coffin *et al* has shown that IMT may span the entire age range and can occur in any site of the body[1]. Nevertheless, gastric IMT in adults is still a very rare disease. Only four case reports of gastric IMT in adults exist in the English literature: Kim *et al* have reported a gastric IMT with peritoneal dissemination in a young adult[15]; Al-Taie *et al* have reported a rapidly growing inflammatory tumor after triple therapy for benign gastric ulcer[16]; Leon *et al* have experienced an IMT of the gastric remnant in a 50-year-old woman with a prior gastrectomy[3]; and Kojimahara *et al* have described a large, poorly demarcated, elevated IMT with infiltrative proliferation of spindle cells over the full thickness of the gastric wall in a 19-year-old woman[17].

This is believed to be the first case report of an exophytic gastric IMT that spontaneously bled into the peritoneal cavity and developed into hemoperitoneum. The present case can be compared with other intra-abdominal IMTs that present with an abdominal mass and related compressive symptoms, such as abdominal pain and vomiting[3,15-18].

Most IMTs require surgery to obtain definite diagnosis and cure. Complete resection is the preferred option, because incomplete excision has been shown to be a risk factor for recurrence[13]. As evident in this case, microrupture of the solid tumor might be another risk factor for early recurrence.

The main difficulty in the management of IMT lies in the unpredictable postoperative course. There are no definitive clinical, histopathological, or genetic features to predict recurrence or metastasis. Recently, reactivity of ALK has been reported to be a favorable prognostic indicator[1]. Differentiation between aggressive and non-

aggressive forms of IMT remains to be further clarified.

We reported a case of gastric IMT that spontaneously bled into the peritoneal cavity during admission. The patient is currently undergoing careful follow-up, because it is not clear whether gastric IMT is benign.

Abstract

Persistent hyperinsulinemic hypoglycemia is caused most commonly by an insulinoma in adults or by nesidioblastosis in neonates. In adults, nesidioblastosis is a rare disorder characterized by diffuse or disseminated proliferation of islet cells. We recently encountered a case of nesidioblastosis in an adult. A 71-year-old man was admitted due to intermittent general weakness, abdominal pain, and mild dyspnea. The patient underwent a subtotal gastrectomy for a gastric adenocarcinoma two years ago. After 5 d of admission, the patient showed symptoms of cold sweating, chilling, and hypotension 30 min after eating. Thereafter, he frequently showed similar symptoms accounting for hypoglycemia regardless of food consumption. Laboratory findings revealed a low fasting blood glucose level (25 mg/dL), and a high insulin level (47 μIU/mL). Selective intra-arterial calcium stimulation with hepatic venous sampling (ASVS) was performed to localize a mass and revealed an increased insulin level about four-fold that of the normal fasting level at 60 s in the splenic artery, which suggested the presence of an insulinoma in the tail of pancreas. A distal pancreatectomy was performed. Neither intraoperative exploration nor a frozen biopsy specimen detected any mass-forming lesion. On the histological examination, many of the islets were enlarged and irregularly shaped in all specimens, the arrangement of which was a lobulated islet pattern. Cytologically, a considerable subpopulation of endocrine cells showed enlarged and hyperchromatic nuclei. By immunohistochemistry, the cells were identified as β-cells. These clinical, radiological, microscopic and immuno-histochemical findings are consistent with diffuse nesidioblastosis in adults.

Key words: Hyperinsulinemic hypoglycemia; Nesidioblastosis; Adult

INTRODUCTION

Nesidioblastosis is a term originally conceived by Laidlaw[1] who described the neoformation of the islets of Langerhans from the pancreatic ductal epithelium. This disease is a rare disorder of infants characterized by persistent hypoglycemia as a result of hypersecretion of insulin from β-cell hyperplasia of the pancreas[2]. First described in neonates, it is widely recognized as the primary cause of persistent hyperinsulinemic hypoglycemia in infants[3]. However, in adults, hyperinsulinemic hypoglycemia is caused mostly by an insulinoma, and onset nesidioblastosis in adults represents 0.5%-5% of cases of organic hyperinsulinemia[4,5]. Since the first reported series of onset nesidioblastosis in adults by Harness *et al* in 1981[6], limited cases have been reported to date[7-9].

We report herein a very rare case of hyperinsulinemic hypoglycemia of an elderly man, which was negative in a localizing test for mass and positive in a selective arterial calcium infusion (SACI) test. He was found to have nesidioblastosis during a partial pancreatectomy.

CASE REPORT

A 71-year-old man was admitted to our hospital due to intermittent general weakness, abdominal pain, and mild dyspnea. The patient underwent a subtotal gastrectomy for a gastric adenocarcinoma 2 years ago. He had no history of diabetes mellitus or hypoglycemia. The patient had discomfort of the abdomen accompanying general weakness several months ago. After 5 d of admission, the patient showed abrupt symptoms of cold sweating, chilling, and hypotension 30 min after eating. These symptoms were relieved after intravascular administration of 50% glucose. Thereafter, the patient frequently showed similar symptoms accounting for hypoglycemia regardless of food consumption.

Laboratory findings determined when the symptoms were present revealed a low fasting blood glucose level (25-48 mg/dL), and a high insulin level (38-47 μIU/mL). A

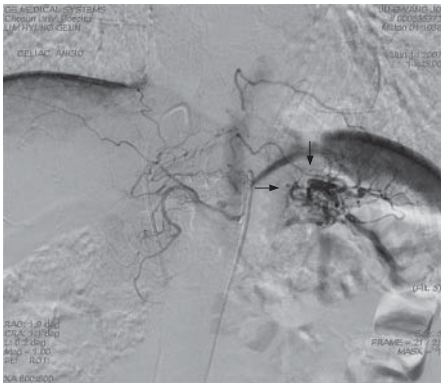

Figure 1 Celiac angiography showing a hypervascular mass-like lesion in the pancreatic tail area (arrows).

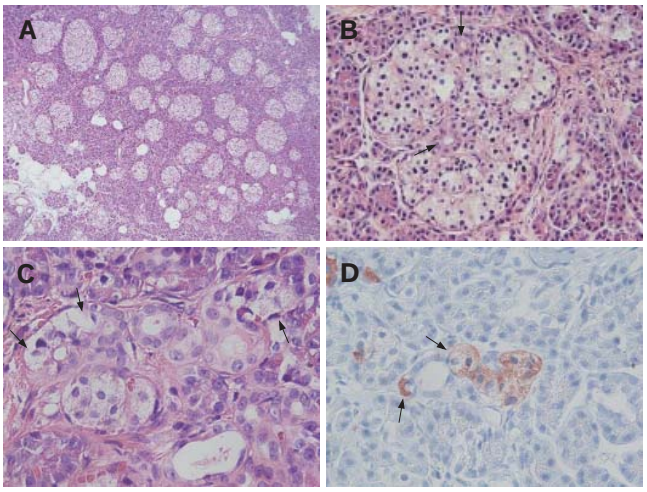

Figure 2 Irregularly sized-dysplastic islets scattering randomly throughout the pancreas (**A**), islets in intimate association with ducts forming a so-called ductulo-insular complex (arrows indicate ductules within the islet) (**B**), islet cells (arrows) budding off the duct epithelium (**C**), insulin-positive islet cells (arrows) budding off the duct epithelium (immunohistochemical stain for insulin) (**D**).

72-h fasting glucose study failed because of the occurrence of hypoglycemic shock 4 h after commencement of the test.

Endocrine examinations to exclude other causes of hypoglycemia, such as hypopituitarism and adrenal insufficiency, were within the normal range. The above-described symptoms and the results of serological tests were consistent with those of insulin-producing lesions including an insulinoma. However, imaging studies including computed tomography and a sonogram of the abdomen failed to detect a mass except for a highly vascularized area in pancreatic tail (Figure 1). To exclude any possible occult insulinoma, selective intra-arterial calcium stimulation with hepatic venous sampling (ASVS) was performed. After calcium gluconate (0.05 mg/kg body weight) was injected into the splenic, hepatic, gastroduodenal, and superior mesenteric arteries, blood samples were collected from the right hepatic vein every 30 s for 120 s. A selective arterial calcium injection test (SACI) to the left splenic artery increased the insulin level of about 4-fold over the pre-stimulated level. In contrast to the left splenic artery, no significant increment was induced by the SACI to the hepatic, gastroduodenal, and

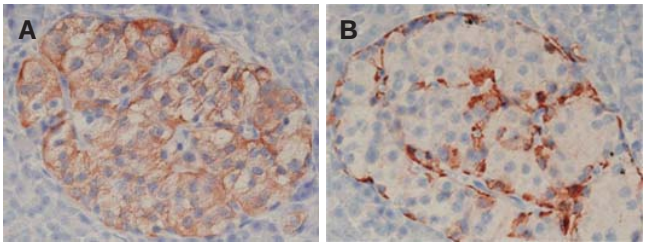

Figure 3 An immunohistochemical study showing increased insulin producing β-cells (**A**), glucagon producing α-cells (**B**).

superior mesenteric arteries, suggesting the presence of an insulinoma in the tail of pancreas. Under the assumptive diagnosis of an insulinoma of pancreatic tail based on the ASVS test, a distal pancreatectomy was performed. Neither intraoperative exploration nor a frozen biopsy specimen detected any mass-forming lesion. Grossly, the resected pancreas appeared normal, and there was no mass lesion in serial section specimens.

In a histopathological study, a number of dysplastic islets were randomly scattered throughout the pancreatic parenchyma, and their contour and size were markedly variable as compared to the normal pancreatic parenchyma. Ductuloinsular complexes and insulin-positive cells budding off the duct epithelium were also observed (Figure 2). Focally, the distribution of islets was densely crowded. In the majority of islets, multiple β-cells with enlarged and hyperchromatic nuclei and abundant clear cytoplasm were identified (Figures 2 and 3). Immunohistochemically, the number of insulin-secreting β-cells was increased, and the number of glucagon-secreting α-cells was decreased (Figure 3). These clinical, radiological, histopathological, and immunohistochemical findings were consistent with those of nesidioblastosis.

In the post-operative course, the glucose and insulin levels in the patient were well controlled and uneventful for two weeks after surgery. However, beyond that time, the patient repeatedly showed hyperinsulinemic hypoglycemia with no response to medication.

DISCUSSION

Nesidioblastosis is the name given to the presence of islets in intimate association with ducts, formation of so-called ductulo-insular complexes[10,11]. In adults, an insulinoma accounts for most cases of hyperinsulinemic hypoglycemia[4,12]. Nesidioblastosis has mainly been described in neonates[3]. Since Harness *et al*[6] first described nesidioblastosis in adults, it has only been reported in association with other diseases, such as Zollinger-Ellison syndrome, multiple endocrine adenomatosis, β-cell adenomatosis, Lindau's disease, cystic fibrosis, insulinomas, pancreatic transplantation, orbital lymphoma with hypopituitarism and adrenal insufficiency, familial adenomatous polyposis, hypergastrinemia, and pancreatic polypeptidemia[7].

The morphological criteria[13,14] for establishing its diagnosis are the presence of differently-sized islets often with somewhat irregular outline, and irregularly sized and poorly defined endocrine cell clusters scattered in the acinar parenchyma and often intimately connected with

small or large ducts (ductuloinsular complexes). Another feature is a distinct islet cell hypertrophy with nuclear enlargement, often resulting in the presence of giant and bizarre nuclei. As seen by immunohistochemistry and electron microscopy, these cells are found to be insulin-producing cells. The histopathological findings in the present case were compatible with these criteria. Nesidioblastosis is classified into focal and diffuse types characterized by different clinical outcomes[15]. Focal nesidioblastosis exhibits nodular hyperplasia of islet-like cell clusters, including ductuloinsular complexes and hypertrophied insulin cells with giant nuclei. In contrast, diffuse nesidioblastosis involves the entire pancreas with irregularly sized islets[10].

Sporadic hyperinsulinemic hypoglycemia is the main clinical feature of nesidioblastosis. The present patient had frequently hypoglycemic episodes mostly in the afternoon and night, independent of food consumption. It should be noted that a gastrectomy may evoke hypoglycemia, which is sometimes severe enough to cause loss of consciousness as a neurologlycopenic symptom[16]. However, postprandial hypoglycemia following a gastrectomy usually occurs 1.5 to 3 h after food digestion[17]. The present case did not show characteristic postprandial hypoglycemia and the hypoglycemic symptoms improved during the two weeks after surgery, suggesting that this kind of hypoglycemia results from nesidioblastosis rather than from gastrectomy. Additionally, it is assumed that past history of a gastrectomy may have partly aggravated the hypoglycemia in addition to the effect of nesidioblastosis.

When clinical examinations including ASVS suggest nesidioblastosis, a partial pancreatectomy is usually performed. Even if a frozen biopsy confirms the diagnosis of nesidioblastosis, the extent of pancreatic resection remains questionable. A distal pancreatectomy which can control the symptoms of the majority of patients, is well tolerated, and does not induce endocrine or exocrine insufficiency. Recovery after a partial pancreatectomy can remove enough abnormal proliferative tissue to achieve normoglycemia[4,18]. However, some investigators recommend an initial near-total pancreatectomy. Such extensive resections lead to an increased risk of post-surgical diabetes and pancreatic insufficiency. It seems that the best recommendation is a 70%-80% pancreatectomy, administration of diazoxide when hypoglycemia persists post-operatively, and a more extensive resection when previous measures fail[19-21].

In summary, we report here a case of nesidioblastosis of a patient having a history of a subtotal gastrectomy based on a diagnosis of a gastric adenocarcinoma. ASVS can detect a hyperinsulinemic lesion of the distal pancreas. However, sporadic hypoglycemia may occur after surgery, and is refractory to medication. Further study is needed to improve its treatment.

Abstract

The authors describe a rare case in which blunt abdominal trauma resulted in mesenteric injury with delayed double ischemic ileal stenosis. Abdominal computed tomography demonstrated stenotic ileal loop with mural thickening. At surgery, a double stenotic bowel loop was found adjacent to a healed defect in the mesentery. Histological examination of the two resected segments showed fibrotic and ischemic lesions within the mesentery. Ischemic intestinal stenosis from mesenteric injury should be considered in the differential diagnosis in patients suffering from intestinal occlusion with a history of blunt abdominal trauma.

INTRODUCTION

In the current treatment of blunt abdominal trauma, conservative management and observation with computed tomography (CT) have become the standard of care for the non-life threatening abdominal lesions. Ischemic intestinal stenosis has been described as a delayed rare complication of mesenteric blunt abdominal trauma. The authors present herein a case of post-traumatic mesenteric injury proved by histological examination, and with double bowel stenosis on CT scan and enteroclysis.

CASE REPORT

A 35-year-old female was admitted after an automobile accident with sudden deceleration. She drove the car and carried the safety belt. The admission check-up showed a cranial trauma and multiple fractures, in particular of the two inferior limbs. She underwent contrast enhanced abdominal CT which showed moderate fluid in the peritoneal cavity attributed to recent bleeding, but no free air, and no parenchymatous, visceral or vascular lesions. She was transferred to the traumatologic unit for surgical osteosynthesis, after which she underwent revalidation treatment.

Six weeks later, she returned to the emergency department with abdominal pain. Altogether, she suffered from four painful abdominal crises with vomiting, described as acute, periumbilical cramps, spontaneously resoluting, compatible with subocclusion or König syndrome.

Abdominal CT showed two ileal loops with a thickened wall and narrowed lumen (Figure 1) adjacent to a mesenteric haziness and minimal fluid in the Douglas. There was no sign of absolute obstruction. An enteroclysis confirmed two intestinal stenosis with rigid ileal loops, one proximal and the other distal (Figure 2).

The patient underwent laparotomy. Two ileal lesions were observed, one located at 180 cm from Treitz's angle, the second one at 60 cm from the Bauhin's valve. Both were scarred ischemic post-traumatic lesions located in front of a mesenteric injury, with thickened ileal wall and narrowed lumen (Figure 3). The two stenosed ileal segments were resected and a latero-lateral anastomosis was performed. Recovery was uneventful. Pathological examination showed mucosal ulceration of the gut located in front of a mesenteric tear (Figure 4), and degenerative infiltration of the mesenteric small vessels, arterioles and veins (Figure 5).

DISCUSSION

Some patients with traumatic intestinal lesion such as perforation or hemorrhage from disruption of mesenteric vessels or parenchymatous tears require immediate surgical intervention. Small and large bowel mesenteric injuries are found in approximately 13.5 % of all patients undergoing

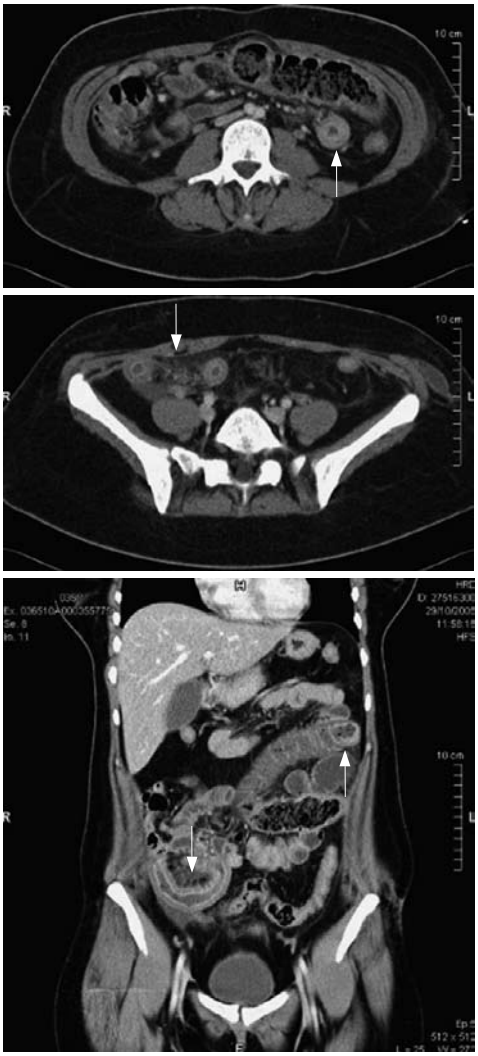

Figure 1 **A**: Transversal abdominal computed tomography, demonstrating two thickened bowel loops with mesenteric haziness (arrows); **B**: Frontal abdominal computed tomography, demonstrating two thickened bowel loops with mesenteric haziness (arrows).

laparotomy after blunt abdominal trauma[1,2]. In this setting, small bowel injuries are more frequent than colonic injuries, probably due to the factors, including location and lack of redundancy, which prevents formation of closed loops[3]. Contrast enhanced CT should be performed early in patients with blunt abdominal trauma because most significant bowel and mesenteric injuries, as well as associated injuries to other abdominal viscera, may be

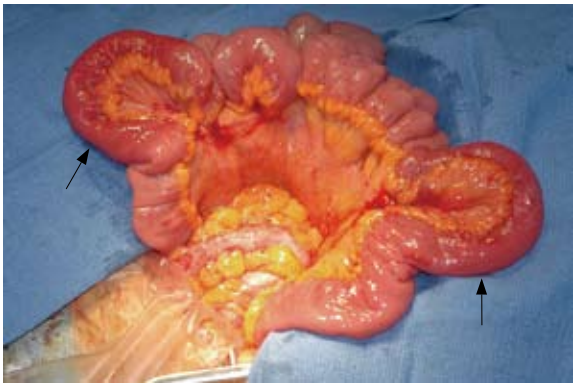

Figure 3 Preoperative picture showing two thickened, fibrotic small bowel segments (arrows) in front of a scarred mesenteric tear.

Figure 4 Inflammation with mucosal ulceration.

reliably identified. The presence of a moderate to large volume of intra-peritoneal fluid without visible solid organ injury can be an important sign of mesenteric or bowel injury[1], similar to this patient.

On the other hand, mesenteric injury may not cause clinical manifestations[4]. Patients with blunt abdominal trauma are often managed without surgical intervention if there is no sign of bowel perforation or hypovolemic shock. As a result, mesenteric injuries might remain undiagnosed after blunt abdominal trauma.

Small bowel obstruction following blunt abdominal trauma is rare. Three possible causes have been suggested: small bowel perforation[5], localized bowel ischemia[1,4] and mesenteric injury[6]. Mesenteric vascular injury may induce chronic ischemia of the corresponding segment of small bowel, inducing secondary thickening of the bowel wall and intestinal occlusion[1,6]. Post-traumatic bowel lesions may also be found in the colon, mainly on the left

side, specifically the sigmoid colon[7]. The case described herein and its pathological report, further support the mesenteric injury theory of post-traumatic bowel strictures. Most published reports of post-traumatic bowel stenosis described one stricture of the small bowel[8]. The patient reported herein suffered from a double localisation of small bowel lesions, both treated by resection and anastomosis.

Under this particular circumstance, enteroclysis may demonstrate the localization of the stricture, showing a narrowed, rigid loop[9,10]. Abdominal CT may show a bowel wall thickening and a concentric narrowed intestinal lumen, or signs of small bowel obstruction with changed calibre of loops[1]. Although angiography may further demonstrate mesenteric vessel occlusion and provide additional information concerning mesenteric injury[9,11], the authors consider that abdominal CT may provide sufficient information to confirm the clinical suspicion of post-traumatic small bowel stricture and to indicate the need for surgical exploration. Laparotomy with resection of the stenosed segment and primary anastomosis is the appropriate treatment. Early recognition and intervention may prevent prolonged morbidity[10,12].

In summary, a rare case of intestinal occlusion secondary to double small bowel stricture due to abdominal blunt trauma and mesenteric injury was described. This diagnosis should be considered in all patients presenting with abdominal pain some weeks after blunt abdominal trauma.

Abstract

We report a 31-year-old woman with Crohn's disease complicated by multiple stenoses and internal fistulas clinically misdiagnosed as small bowell endometriosis, due to the patient's perimenstrual symptoms of mechanical subileus for 3 years; at first monthly, but later continuous, and gradually increasing in severity. We performed an exploratory laparotomy for small bowel obstruction, and found multiple ileal strictures and internal enteric fistulas. Because intraoperative findings were thought to indicate Crohn's disease, a right hemicolectomy and partial distal ileum resection were performed for obstructive Crohn's ileitis. Histopathology of the resected specimen revealed Crohn's disease without endometrial tissue. The patient made an uneventful recovery from this procedure and was discharged home 10 d post-operatively. The differential diagnosis of Crohn's diease with intestinal endometriosis may be difficult pre-operatively. The two entities share many overlapping clinical, radiological and pathological features. Nevertheless, when it is difficult to identify the cause of intestinal obstruction in a woman of child-bearing age with cyclical symptoms suggestive of small bowel endometriosis, Crohn's disease should be included in the differential diagnosis.

INTRODUCTION

Endometriosis is a condition of unknown etiology in which proliferation of endometrial tissue occurs at extrauterine sites, including ovaries, fallopian tubes, peritoneum, and gastrointestinal tract[1]. It usually occurs between 30 and 40 years of age and remains active in some patients well into the postmenopausal period[2]. Four to 17% of menstruating women develop endometriosis[3]. Involvement of the intestine with endometrial implants complicates pelvic endometriosis in 17%-37% of cases[4]. Small bowel endometriosis may not be accompanied by pelvic endometriosis[5]. The most commonly affected gastrointestinal sites are the rectosigmoid colon, appendix, and ileum[6]. When the disease involves the small bowel, it usually has a benign course, but in rare circumstances, it may present as acute abdomen[7]. Invasive bowel endometriosis can present as bowel obstruction in an acute, chronic, or intermittent manner[8]. The major cause of obstruction is stricture formation and adhesions, which occasionally mimic Crohn's ileitis or a malignancy in their clinical presentation[9-12].

We report a case of Crohn's disease complicated by multiple strictures and internal fistulas clinically misdiagnosed as small bowell endometriosis, due to the patient's perimenstrual symptoms of mechanical subileus, which required surgical intervention with right hemicolectomy and partial distal ileum resection. To the best of our knowledge, this is the first reported case of complicated Crohn's disease clinically mimicking ileal endometriosis. Moreover, we have been unable to find in the medical literature any report of this particular presentation of complicated Crohn's ileitis.

CASE REPORT

A 31-year-old woman was admitted to our hospital with perimenstrual lower and mid-abdominal pain irradiating to the back and lower abdominal fullness for 3 years, at first monthly, but later continuous, and gradually increasing in severity. She had a history of low-grade fever with chills, which occured monthly during her menstrual periods. The abdominal pain was crampy and associated with

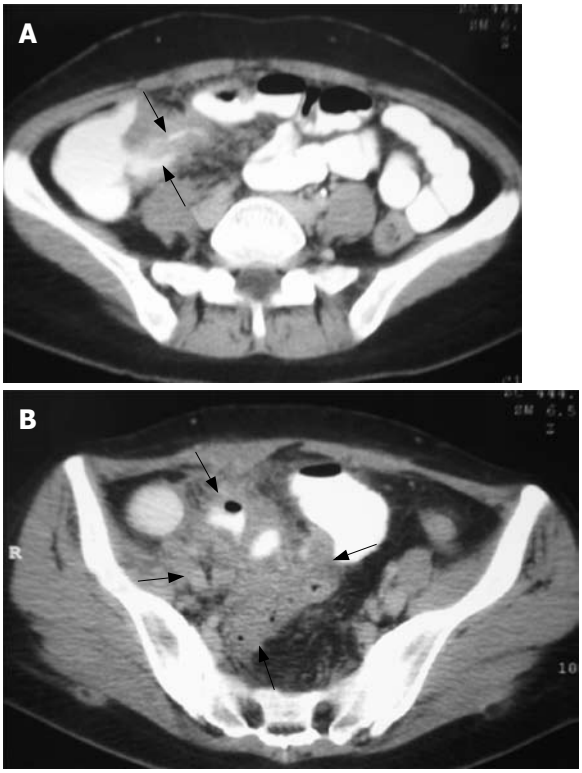

Figure 1 Contrast-enhanced scan showing the mural thickening of terminal ileum (arrows) (**A**), and a complex, predominantly inflammatory mass of large size (6.4 cm × 6.1 cm) (arrows) (**B**).

borborygmi, anorexia, nausea and vomiting, without hematemesis or coffee-ground emesis. The patient had lost 10 kg in weight over the previous 6 mo, and was having two to three semiformed stools per day. She also gave a history of moderate dysmenorrhea and menorrhagia, but no dyspareunia. Her only medication was an oral contraceptive. She denied any history of smoking, alcohol consumption, or illicit drug use. The patient had no history of sexually transmitted disease. She had delivered a healthy baby. There was no family history of inflammatory bowel disease or endometriosis.

Despite no pathological evidence, her gynecologist at a women's health clinic had diagnosed her with small bowel endometriosis, based on interviews and her clinical course. Since only oral contraceptive therapy was started, the symptoms due to mechanical subileus had gradually improved. Although he had no pathological evidence, lack of response to oral contraceptive therapy had encouraged him to perform an exploratory laparotomy 1 mo before she was admitted to our institution for further evaluation and management. At Pfannenstiel transverse laparotomy, extensive adhesion formation and inflammation around the cecum, terminal ileum, sigmoid colon, uterus and the right adnexa were found. The gynecologist was only able to perform an incisional biopsy from the highly inflamed areas. Biopsy results showed only chronic inflammatory infiltrate and granulation tissue. The patient was then referred to us to identify the underlying pathology.

A physical examination on admission revealed a thin and wasted woman weighing 48 kg. The patient was hypotensive with a blood pressure of 95/65 mm Hg and a heart rate of 108 beats/min. The patient's temperature was 37.5℃. The abdomen was soft and distended with right-lower-quadrant tenderness to palpation and fullness. A Pfannenstiel scar was present, but there was no scar tenderness. There was no hepatosplenomegaly or lymphoadenopathy. She demonstrated no arthralgia. Skin rash and erythema nodosum were not found. Rectal examination was unremarkable. There was no perianal fistula. A pelvic examination revealed cervical motion tenderness and right adnexal tenderness. Results of laboratory studies on admission showed: white blood cell count, 28 000/mm^3 with 85.7% neutrophils; hemoglobin, 8.3 g/dL; hematocrit, 24.3%; erytrocyte sedimentation rate, 72 mm/h; C-reactive protein, 26.2 mg/dL; albumin, 3.2 mg/dL; β-human chorionic gonadotropin (β-hCG), 0.1 mIU/mL; carcinoembryonic antigen (CEA), 0.58 ng/mL; and cancer antigen (CA)125, 13.71 U/mL. Urinalysis was in the normal range. Stool studies for ova, parasites, cultures including *Yersinia enterocolitica* and acid-fast bacilli and *Clostridium difficile* toxin were negative. A plain abdominal roentgenogram was consistent with partial small bowel obstruction. Abdominal ultrasonography demonstrated the presence of an inflammatory mass surrounding the terminal ileum and/or appendix, wall thickening and absence of peristalsis in the small intestine, with a small amount of ascites. Abdominopelvic CT scanning was performed with oral and intravenous contrast enhancement. There was a narrowing of the terminal ileum and bowel-wall thickening (Figure 1A). Adjacent to the terminal ileum in the right lower quadrant, a complex predominantly inflammatory mass of large size (6.4 cm × 6.1 cm) was present (Figure 1B). The mass was surrounded by fat stranding, with obliteration of the adjacent psoas muscle fat planes. The appendix was not identified separately from the mass. Colonoscopy with random biopsies from the colon and rectum was unremarkable.

A presumptive diagnosis of mechanical small bowel obstruction was made. The patient was initially treated conservatively with nasogastric suction, intravenous fluids and medication, and responded to this treatment. However, after ingesting a small amount of food she again complained of abdominal pain, and plain radiography once more showed mechanical small bowel obstruction. After improvement with conservative measures and obtaining adequate informed consent, an exploratory laparotomy was performed. At surgery, the proximal small bowel was dilated and the colon was collapsed. There was a small amount of free fluid in the abdomen. No macroscopic evidence of endometriosis was noted at laparatomy. Multiple stenotic ileal loops, adhering firmly to each other, were wrapped as a mass lesion around the cecum, ascending colon, sigmoid colon, right adnexa and uterus. The adhesions were released, and ileal loops were freed from adjacent organs by meticulous sharp dissection. The serosa overlying these areas was congested and hyperemic. The right ureter was completely exposed. Four strictures were noted in the distal 40 cm of the terminal ileum, and three internal fistulas were detected between the terminal ileum and the cecum, between the terminal ileum and the adjacent loop of small bowel, and between the two loops of ileum (Figure 2A and B). The macroscopic appearance

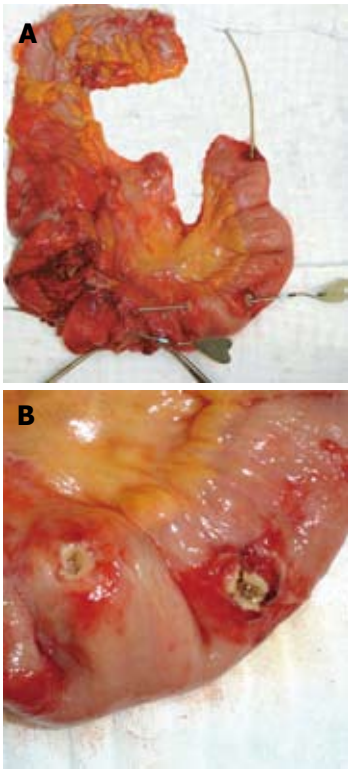

Figure 2 Gross appearance of the resected specimen showing Crohn's ileitis with multiple fistulas probed with instruments (**A**), and ileal segment with two adjacent openings of an internal enteric fistula after separation of adhesions (**B**).

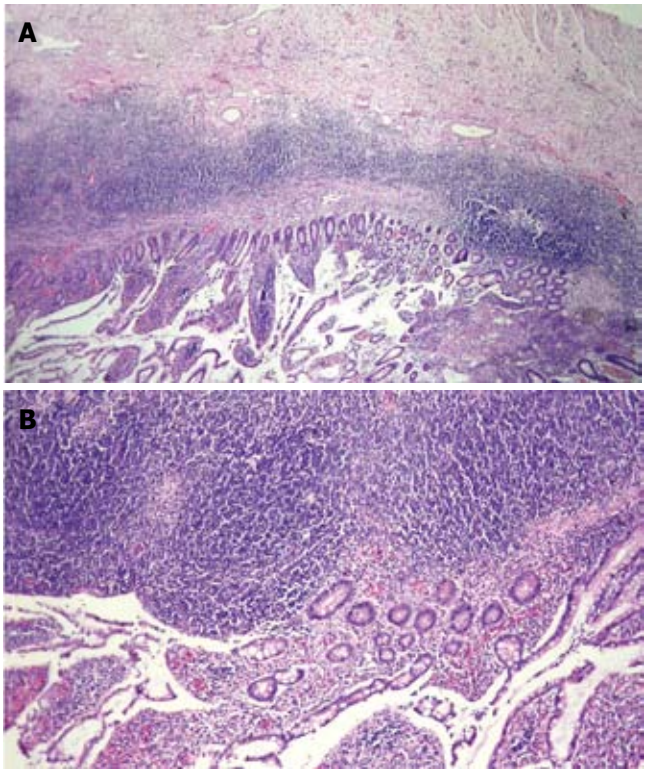

Figure 3 Microscopic examination of the resected specimen revealed transmural inflammatory cell infiltration with crypt distortion (**A**), and transmural lymphoid aggregates (**B**) (HE, **A** × 10, **B** × 20).

was thought to indicate Crohn's disease, but in view of the close relationship of the ovaries, tubes and uterus, an immediate gynecological opinion was obtained. The on-call gynecology registrar did not consider the appearance to be due to primary gynecological pathology, and therefore, a right hemicolectomy and partial distal ileum resection was performed with an end-to-end ileocolonic anastomosis.

On opening the specimen, there was severe narrowing of the terminal ileum and bowel-wall thickening characteristic of Crohn's disease. Ulceration measuring 3 cm in diameter, with an irregular margin, was detected at the level of ileocecal valve. Multiple ulcerations, which ranged in sized from 0.5 cm to 2.5 cm in diameter, were also observed on the oral side of the terminal ileum and adjacent loops of small intestine. The mucosa was edematous, pale and marked with deep linear ulcers, and the bowel wall was thickened. Histological examination of the resected terminal ileum revealed marked ulcers and fissures, with transmural inflammatory cell infiltration (Figure 3A), lymphoid aggregates (Figure 3B), and fibrosis. No endometrial tissue was noted in any segment of the resected specimen. The patient made an uneventful recovery from this procedure and was discharged home 10 d post-operatively. Ileocolic resection led to rapid resolution of the symptoms. She has been asymptomatic for over 1 year after her surgery.

DISCUSSION

Endometrosis is a common condition that occurs most frequently in the pelvis, in association with the ovaries, tubes and pelvic peritoneum, with related gynecological symptoms. The incidence of intestinal endometriosis varies between 3% and 37% of all cases of endometriosis, affecting the rectosigmoid colon in 50%-90%, rectovaginal septum in 10%-20%, cecum in 2%-5%, appendix in 3%-18% and small intestine in 2%-16%[13-17]. Small intestinal involvement is nearly always confined to the terminal ileum, which can be explained by its proximity to the tubes and ovaries. However, the correct diagnosis is often delayed because intestinal endometriosis may masquerade clinically as regional enteritis, ulcerative colitis, appendicitis, ischemic enteritis or colitis, diverticulitis, acute self-limited colitis, irritable bowel syndrome, ileocolonic intussusception, or a neoplasm such as colonic or small bowel cancer[18]. Therefore, many cases of bowel endometriosis have been clinically diagnosed based on interviews and response to hormone therapy.

This case demonstrated multiple strictures and internal fistulas that are frequently observed in complicated Crohn's disease by intestinal contrast, abdominal CT, or at surgery, but we could not make an accurate preoperative diagnosis. There were probably several major reasons for this misdiagnosis. First, our patient presented symptoms of mechanical subileus including intermittent abdominal pain, nausea, vomiting and weight loss, which occured monthly during her menstrual periods. Second, she lacked extraintestinal manifestations associated with Crohn's disease, including stomatitis, aphthous ulcer, colitic arthritis, pericholangitis, erythema nodosum, pyoderma gangrenosum, episcleritis, uveitis, nephrolithiasis, and hydronephrosis. Third, a histopathological diagnosis of the endoscopic biopsy specimen was reported to be negative for inflammatory bowel disease.

Endometriosis of the intestinal tract is a common

disorder that, when symptomatic, may be difficult to diagnose accurately. Intestinal endometriosis has a predilection for the terminal ileum, leads to obstruction, and affects women of reproductive age. Crohn's ileitis must be considered in the differential diagnosis of enteric endometriosis, as with our patient. Other conditions that may cause difficulty in young women with apparent terminal ileal disease include nodular terminal hyperplasia, *Yersinia* enterocolitis, tuberculous enteritis, lymphogranuloma, small bowel lymphoma, carcinoid tumors of the terminal ileum, primary adenocarcinoma of the small intestine, and Behcet's disease[9,10]. Many of these conditions will be diagnosed only with laparotomy.

The distinction of ileal endometriosis from Crohn's disease may be difficult pre-operatively. Indeed, there is a similarity between the two entities in terms of clinical presentation, symptomatology, radiological appearances, surgical and pathological findings. The nature of presentation is mainly dependent on the region of bowel affected for both ileal endometriosis and Crohn's disease. The ileum is the third most affected area, after the rectosigmoid colon and appendix, which is found to be involved in up to 7% of patients with intestinal endometriosis[19]. It usually involves the distal ileum and is limited to the serosa. More extensive and deeper involvement may produce intestinal obstruction by stenosis, kinking or adhesions. Fibrosis may cause puckering and kinking of the mucosa, which results in intestinal bleeding[20]. The presentation of ileal involvement may be an incidental mass found on barium enema or CT, or as a lead point for ileal intussusception. However, Crohn's disease almost invariably affects the gastrointestinal tract. Crohn's ileitis, affecting the ileum only, accounts for 30% of cases. There are three categories of disease presentation in Crohn's disease: stricturing, penetrating, and inflammatory (non-stricturing, non-penetrating disease)[21]. The clinical presentation of our patient with evidence of small bowel obstruction, multiple ileal strictures and internal fistulas at laparotomy suggested Crohn's ileitis, probably due to a combination of inflammatory mass in the right lower quadrant, proximal bowel distention, narrowing of the terminal ileum and bowel-wall thickening.

Endometriosis may present with a wide variety of symptoms that are more commonly associated with other diseases. Gastrointestinal endometriosis is suggested by dysmenorrhea, menorrhagia or perimenstrual symptoms. Intestinal involvement is usually only serosal, not associated with any intestinal symptoms, and only coincidentally noted at the time of open surgery or laparoscopy for gynecological symptoms. Frank intestinal symptoms are usually associated with intestinal obstruction[22]. While intestinal symptoms may occur during or be exacerbated by the menses, this association may not always be present. The symptoms coincide with menstruation in only 18%-40% of the cases in some series[23]. A recurring crampy lower or mid-abdominal pain is the most common presenting symptom for both enteric endometriosis and Crohn's disease. Moreover, right-sided or right-lower-quadrant abdominal pain often precipitates laparotomy or laparoscopy, possibly for the suspicion of appendicitis. Other symptoms that may occur in ileal endometriosis as well as Crohn's disease include diarrhea, constipation, nausea, vomiting, fever, anorexia, and weight loss. We initially considered ileal involvement by gastrointestinal endometriosis because of a history of the relationship between menstruation and presenting symptoms, and also previous surgery for misdiagnosis of enteric endometriosis in our patient.

Small bowel endometriosis is capable of producing both acute and chronic symptoms that can present a diagnostic and therapeutic challenge to the surgeon. Imaging studies may not provide an accurate diagnosis. The radiologic appearances of ileal endometriosis may be so similar to ileal Crohn's disease that a differential diagnosis is not possible. Plain abdominal X-ray or barium enema may be helpful. Contrast studies may demonstrate extrinsic bowel compression, abdominal mass, and bowel stenosis or angulation[24]. Typically, it appears as a long filling defect with tapering margins. Non-invasive radiological diagnostic aids are provided by CT or ultrasonography. Abdominal ultrasonography demonstrates the size, shape and location of lesions, but unequivocal diagnosis is rarely possible. In our patient, ultrasonography demonstrated the presence of an inflammatory mass in the right lower quadrant, and also wall thickening and the absence of peristalsis in the small intestine, with a small amount of ascites. CT is useful for evaluating the small bowel with enteroclysis protocols. The findings of enteric endometriosis on CT include one or more focal masses on the bowel wall or a lesion compressing the colon. Abdominal CT is especially useful when looking for intra-abdominal complications of Crohn's disease, such as abscesses, small bowel obstruction, or fistulas[25]. When thin-section abdominopelvic images with multidetector CT were obtained from our patient, there was a narrowing of the terminal ileum and bowel-wall thickening. It was not certain whether this was due to extrinsic compression or a primary intestinal lesion. Adjacent to the terminal ileum in the right lower quadrant, a complex, predominantly inflammatory mass was also detected on CT. Nevertheless, multiple stenotic ileal segments and small intestinal fistulas associated with Crohn's disease were not seen on CT slices, possibly due to extensive adhesion formation and inflammation. Therefore, we were not able to exclude enteric endometriosis according to the presented radiological findings pre-operatively.

Crohn's disease usually has a distinctive appearance operatively which is not to be confused with the findings in endometriosis, even if multiple site ileal endometriotic deposits are present[26]. Furthermore, in both diseases the surgical intention is limited resection of obstructing lesions, so there is no conflict of interest. An even more difficult, but more important operative distinction is malignant disease, and clearly this is relevant for cecal and ileal lesions, such as colonic or small bowel cancer. At operation, intestinal endometriosis appears as tumors having a glistening gray color on cross section[19]. In our patient, multiple stenotic ileal loops, which adhered firmly to each other, were wrapped as an inflammatory mass around the adjacent organs. The serosa overlying these areas was congested and hyperemic. Multiple ileal strictures

and internal enteric fistulas were detected at laparotomy. Intraoperative findings were thought to indicate Crohn's disease, hence a right hemicolectomy and partial distal ileum resection was the treatment of choice for obstructive Crohn's ileitis.

Both small bowel endometriosis and Crohn's disease are characterized grossly by patchy involvement of the small intestine with intervening, uninvolved skip areas of intestine. Moreover, both conditions may be transmural processes with marked chronic inflammatory changes resulting in the formation of strictures, adhesions, mucosal thickening, mural fibrosis, bowel angulation, stenosis, fibrosis and obstruction. Although transmural involvement by Crohn's disease is the result of chronic insult, strictures and masses in endometriosis result largely from profound smooth muscle hypertrophy around endometriotic foci present in the muscularis propria[27]. Other manifestations of Crohn's disease, such as perianal abscesses or fistulas, and inflammatory pseudotumors involving the cecum, terminal ileum and appendix, have been described in intestinal endometriosis[15]. In rare cases, endometriosis may cause deep fissures and even fistulous tracts, further mimicking regional enteritis. In the presented case, severe mural thickening of terminal ileum, with variable luminal stenosis or stricture formation and entero-enteric fistulas, were gross abnormalities. An approximately 40-cm segment of distal ileum, ileocecal valve and cecum had four strictures and three internal enteric fistulas, with associated serosal adhesions.

Endometriosis may cause many of the histological changes that are associated with Crohn's disease. The endometriotic deposists consist of well-defined endometrial glands embedded in a dense cytogenic stroma[29]. Previous studies have observed chronic mucosal changes ranging from focally branching surface crypts, mildly hyperplastic surface epithelium overlying endometriotic foci, hemorrhagic mottling, ulceration, ulceration with inflammation, occasional neutrophils and eosinophils, or a non-specific inflammatory cell infiltrate, to focal glandular architectural abnormality with edema and siderophages[30]. Chronic inflammatory infiltrates composed of lymphocytes and plasma cells surround the deep crypts, and transmural lymphoid aggregates are also seen. Superimposed acute changes with crypt abscesses and surface ulceration may be noted. The changes are focal in most cases and are flanked by normal, unremarkable mucosa[27]. However, histopathological features used to reach the diagnosis of Crohn's disease in the present case included both gross and microscopic features such as a discontinuous, asymmetric distribution of the lesions, patchy inflammation, ulceration, fissuring, transmural distribution of the inflammatory infiltrate and lymphoid aggregates.

To the best of our knowledge, there have been no other case reports of Crohn's disease complicated by multiple ileal strictures and internal enteric fistulas clinically mimicking small bowel endometriosis. Involvement of the intestinal tract with endometriosis may mimic clinically and pathologically a wide spectrum of diseases including infectious etiology, ischemic enteritis/colitis, inflammatory bowel disease, and neoplasms. The differential diagnosis of Crohn's disease with intestinal endometriosis may be difficult pre-operatively. The two entities share many overlapping clinical, radiological, and pathological features. Nevertheless, when it is difficult to identify the cause of intestinal obstruction in a woman of child-bearing age with cyclical symptoms suggestive of small bowel endometriosis, Crohn's disease should be included in the differential diagnosis.

Abstract

We reported a case of huge gastric phytobezoar. The gastric phytobezoar was successfully removed through gastrotomy after two failed attempts in endoscopic fragmentation and removal. Disopyrobezoars could be treated either conservatively or surgically. Gastrotomy or laparoscopical management is recommended for the treatment of huge disopyrobezoars.

INTRODUCTION

Phytobezoars are common bezoars in the gastrointestinal tract, including stomach and small intestine[1], but huge disopyrobezoars are rarely seen clinically. We report a case of huge disopyrobezoar (18 cm × 7.5 cm × 7cm), a kind of phytobezoar caused by persimmon, and to present our experience while reviewing the literature.

CASE REPORT

A 47-year-old man presented with complaints of acute aggravated epigastric distention and pain for half a month after one year of persistent epigastric distention and acid regurgitation, which were uninfluenced by ingesting food. There were no obvious symptoms of gastrointestinal obstruction, e.g., nausea or vomiting. The patient had a long history of overindulgence of bitter persimmons from childhood without the history of gastric surgery.

On physical examination, a solid, movable ellipse mass could be palpated in the left epigastrium and the abdomen was soft. Gastroscopical examination showed a giant brown solid gastric bezoar of 15 cm × 7 cm in size (Figure 1), chronic superficial gastritis as well as two erosions at the corner of the stomach, which were pathologically proven to be chronic superficial active membraneous inflammation. Abdominal computerized tomography revealed a mass-like occupational lesion within the stomach (18 cm long and 7 cm in diameter) with air bubbles retained in its interstices and mottled appearance, compatible with the features of bezoars (Figure 2). The patient was then admitted to the department of gastroenterology of our hospital.

On the 3rd day after admission to hospital, endoscopy (*Fujinon EG 250 WR 5*, Fuji Photo Optical Company Ltd, Tokyo, Japan) was used to fragment the huge bezoar with a mouse-teeth clamp and snare, but it was unsuccessful to extract the bezoar despite the help of gastric lavage using sodium bicarbonate ($NaHCO_3$) because the bezoar was too hard and big. On the 4th d, another attempt of endoscopical fragmentation and extraction procedure also failed. On the 5th day, the patient was transferred to the department of general surgery for operation after two failed attempts in endoscopic fragmentation and removal of the gastric bezoar.

Gastrotomy was performed on the patient and a huge grey ellipse bezoar (18 cm × 7.5 cm × 7 cm) was removed from the gastric lumen (Figure 3). A piece of the bezoar obtained during endoscopy was analyzed by infrared spectroscopy, which revealed that 85% of them was composed of tannin and 10% was cellulose, therefore, the bezoar was considered as disopyrobezoar derived from bitter persimmon. The patient was discharged on the 7th postoperative day. During the 6-month follow-up, the patient did not complain of any discomfort and the two concomitant erosions healed uneventfully on medical therapy shown by another gastroscopy.

DISCUSSION

Bezoars are classified according to their composition into phytobezoar, trichobezoar (hair), lactobezoar (concentrated

Figure 3 Surgical specimen of gastric disopyrobezoar,18 cm long, 7.5 cm in diameter, with visible brownish persimmon remnants on its surface.

milk formulas), mixed medication bezoar and food bolus bezoar[2]. Phytobezoars are composed of indigestible cellulose, tannin and lignin derived from ingested vegetables and fruits[3].

A disopyrobezoar is a type of phytobezoar caused by persimmons, although it is an infrequent entity in clinic, and not rare in some countries[4]. Disopyrobezoars are generated by over-ingestion of unripe or astringent persimmons containing rich soluble tannin and shibuol especially in free stomach. In the presence of the dilute hydrochloric acid in the stomach, the tannin undergoes polymerization to a coagulum that includes cellulose, hemicellulose, and protein, which is the basis of the bezoar[5].

Disopyrobezoar formation is commonly associated with previous gastric surgery (truncal vagotomy plus pyloroplasty or subtotal gastrectomy plus gastroenterostomy), dental problems, poor mastication, and overindulgence of persimmon[4]. Gastric operations may reduce gastric motor activity and delay gastric emptying. Loss of pyloric function, gastric motility and hypoacidity plays an important role in the formation of disopyrobezoar[6]. Diabetes mellitus and hypothyroidism were also reported as predisposing factors of disopyrobezoar formation because they could delay gastric emptying[7]. Our patient had a long indulgence history of bitter persimmon intake, resulting in the formation of the huge disopyrobezoar.

Clinical manifestations vary with the location of disopyrobezoar from no symptom to acute abdominal syndrome, e.g., epigastric distention, abdominal pain and acid regurgitation. Gastric disopyrobezoars are sometimes associated with gastric ulcer formation. When located in small bowel, they often cause small bowel obstruction (SBO)[1,4], presenting with nausea, vomiting and abdominal distention. Major complications of disopyrobezoars include intestinal obstruction, gastric perforation, gastric ulcer and gastritis[5]. Abdominal pain (49%-100%), epigastric distress (80%), anorexia, vomiting and nausea (35%-78%), and SBO (94.73%) are the main clinical symptoms[8]. Feelings of fullness and dysphagia with weight loss and even gastrointestinal hemorrhage could also be seen[2]. When complicated with SBO, diminished peristaltic sounds, rebounding pain and tenderness, distention, vomiting and abdominal pain could be found clinically, elevated leukocyte count up to 28.000/mm^3 and fever could also be detected[5]. In this study, the patient presented epigastric distention, epigastric pain and acid regurgitation.

As for the radiographic diagnosis, about 50%-75% of the SBO cases could be diagnosed by plain abdominal radiography[9]. CT-scan could demonstrate a well-defined round mass which could be outlined by stomach or the bowel wall and present characteristic internal gas bubbles of bezoars[10]. Abdominal ultrasonography could suggest hyperechoic arclike surface and marked posterior acoustic shadow of the gastric bezoars within the lumen of stomach and small bowel, and barium study could demonstrate intraluminally filling defect as well as mottled appearance of the bezoar. Endoscopic investigations could almost show and confirm all of gastric bezoars[11].

The ultimate goal of the treatment of gastrointestinal disopyrobezoars is the removal of the lesion and prevention of recurrence. Disopyrobezoars can be treated by conservative modalities (gastric lavage, endoscopic

disruption, *etc*.) and conventional surgery as well as videolaparoscopic surgery[4,12]. But disopyrobezoars are often resistant to drug treatment because they are much harder than other kinds of phytobezoars, hence being usually removed endoscopically or surgically. Gastric lavage has been reported for the treatment of disopyrobezoars using $NaHCO_3$ which has a mucolytic effect, and penetration of CO_2 bubbles into the surface of bezoars could digest the fibres of concretion[6]; and most interestingly, a successful nasogastric Coca-Cola lavage treatment for gastric disopyrobezoars was reported[13].

The side effects of conservative treatment of bezoars are gastric ulcer, SBO, hyperosmolar natremia, hemorrhagic pulmonary edema, pharyngeal abscess, endotracheal tube obstruction, esophago-gastric iatrogenic injuries (including perforation, laceration, hematoma and ulceration), vocal cord damage and so on[11].

The first step of endoscopic procedure is to determine whether the pylorus appears anatomically normal and to verify the absence of duodenal stricture before fragmenting disopyrobezoars[4]. If a disopyrobezoar is not too large, it can be extracted by a basket or direct suction. If it is big and pylorus is normal, fragmentation can be performed with large polypectomy snare, electrosurgical knife, endoscopic laser destruction and electrohydraulic lithotripsy as well as extracorporeal shock wave lithotripsy[14]. Once the disopyrobezoar is fragmented, the patient can be treated by combined use of cellulase and metoclopramide, cellulase and papain, water jet and lavage with $NaHCO_3$ as well[4].

In conventional surgery, bezoar removal is commonly done by gastrotomy and/or enterotomy. If complicated with SBO, gastric perforation or gastric hemorrhage, the patients can be treated by gastric and/or intestinal resections. Our patient had a huge solid gastric disopyrobezoar that was extracted by gastrotomy after two failed attempts of bezoar removal by endoscopical fragmentation and dissolution by $NaHCO_3$ gastric lavage. Moreover, the laparoscopic approach may be the treatment of choice when surgery is indicated. When expertise is available, laparoscopy is safe and effective in the management of bezoar-induced SBO and yields superior postoperative outcomes when compared with conventional open approach[15].

In conclusion, disopyrobezoar is a kind of phytobezoar. Plain abdominal radiography, barium studies, ultrasonography, CT-scan and endoscopy are helpful in the diagnosis of disopyrobezoars, while endoscopy can confirm its diagnosis. Disopyrobezoars could be treated either conservatively or surgically. Gastrotomy or laparoscopical manipulation is recommended for the treatment of huge disopyrobezoars.

Abstract

Anatomical variations of the cystic duct often occur and may be encountered during cholecystectomy. Knowledge of the variable anatomy of the cystic duct and cysticohepatic junction is important to avoid significant ductal injury in biliary surgery. Here, we present two unusual cases with an anomalous cystic duct, namely, low lateral insertion and narrow-winding of the cystic duct. The first case was a 64-year-old man with cholelithiasis and chronic cholecystitis. During surgery, the entrance of the cystic duct was misidentified as being short and leading into the right hepatic duct. Further exploration showed multiple calculi in the right and common hepatic ducts. Cholecystectomy was completed, followed by T-tube drainage of the common and right hepatic ducts. Postoperative T-tube cholangiography demonstrated that the two T tubes were respectively located in the cystic and common hepatic duct. Six weeks later, the retained stones in the distal choledochus were extracted by cholangioscopy through the sinus tract of the T-tube. The second case was a 41-year-old woman, in which, preoperative endoscopic retrograde cholangiopancreatography (ERCP) revealed a long cystic duct, with a narrow and curved-in lumen. The patient underwent open cholecystectomy. Both patients were cured. The authors propose that preoperative ERCP or magnetic resonance cholangiopancreatography (MRCP), and intraoperative cholangiography or cholangioscopy constitute a useful and safe procedure for determining anatomical variations of the cystic duct.

INTRODUCTION

It is recognized that misidentification of normal anatomy, as well as the presence of anatomical variations, contributes to the occurrence of major postoperative complications, especially biliary injuries[1]. Such injuries can in turn cause significant morbidity and occasionally even mortality. Sound knowledge of the normal anatomy of the extrahepatic biliary tract, as well as the surgical implications[2], is thus essential to prevent these complications. Magnetic resonance cholangiopancreatography (MRCP) is a recently developed technique that allows non-invasive assessment of the biliary tree[3]. Anatomical variants of the cystic duct and cysticohepatic junction that may increase the risk of bile duct injury in biliary surgery are frequently identified with endoscopic retrograde cholangiopancreatography (ERCP), MRCP and percutaneous transhepatic cholangiography (PTC). We highlight two cases of anatomical variations of the cystic duct, in which the abnormality was found during surgery and subsequently confirmed by postoperative cholangiography and ERCP.

CASE REPORT

Case 1

A 64-year-old man was admitted for surgery, with features of acute cholecystitis: right upper quadrant pain, vomiting and fever. Examination revealed a temperature of 38℃ with tenderness in the right upper quadrant. He had previously been investigated for abdominal pain and had abdominal CT 4 years previously, which showed minimal intrahepatic ductal dilatation. Laboratory values showed a normal white cell count, total and direct biluribin was 24 μmol/L and 6 μmol/L respectively, alanine aminotransferase was 80 U/L, aspartate aminotransferase was 38 U/L, alkaline phosphatase was 301 U/L, and amylase was normal. Ultrasonography showed distension of the gallbladder with calculi and a thick wall associated with pericholecystic fluid. Cholelithiasis with chronic cholecystitis was diagnosed, and an open laparotomic cholecystectomy was planned. Upon laparatomy, the liver was normal and the gallbladder was thick-walled with minimal adhesion in Calot's triangle and surrounding

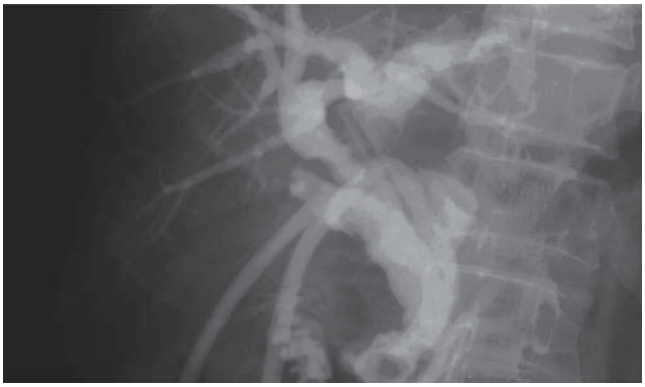

Figure 1 The cystic and left-right hepatic ducts were comparatively long, and the cystic duct opening was located in the distal choledochus with retained stones. Two T tubes were respectively located in the cystic duct and in the common hepatic duct.

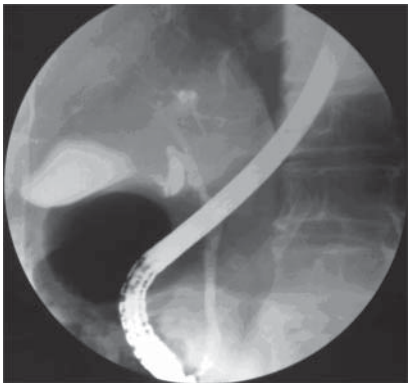

Figure 2 ERCP showing a narrow-winding cystic duct.

tissues. On separation, the entering of cystic was misidentified as being short and entering the right hepatic duct. The cystic duct was clipped and divided. The cystic artery was then identified, clipped and divided. Further exploration showed multiple calculi in the right and common hepatic ducts. Cholecystectomy was completed, followed by T-tube drainage of the common and right hepatic ducts (for postoperative confirmation and documentation). The surgical procedure was followed by abdominal pain, and T-tube cholangiography was requested on postoperative d 14. Cholangiography through a T-tube showed that the cystic and right hepatic ducts were comparatively long. Long cystic duct with low medial insertion into common bile duct was made (Figure 1). The entire bile duct was identified and found to be intact. Six weeks later, the retained stones was extracted by cholangioscopy through the sinus tract of the T-tube. The patient was successfully cured.

Case 2

A 41-year-old woman patient presented with 3-year discontinuous right upper quadrant pain that radiated into her back in keeping with biliary colic, sometimes accompanied with fever and nausea. The pain was aggravated with greasy food. In the course of the present illness, she had received medication for acid peptic disease and parasitic infestations, with no improvement. She had a similar history in the past. Physical examination revealed a soft, non-distended abdomen and no tenderness in the right upper quadrant, without peritoneal signs. Murphy's sign was negative. Her temperature was 37.5℃, and the rest of her vital signs were normal. Laboratory analysis of liver function was normal. US revealed no abnormalities. The patient was observed at rest with continuous gastrointestinal decompression and fluid infusion. Her symptoms improved significantly within 4 d of treatment. However, a few days later, she experienced right upper quadrant pain. ERCP was requested and revealed a long cystic duct with a narrow and in-curved lumen, which was well separated from the gallbladder. The rest of the entire biliary tract was normal without calculi (Figure 2). A narrow-winding cystic duct was created, followed by cholecystectomy. The surgical procedure was followed by an uneventful convalescence until discharge.

DISCUSSION

Anatomical variations of the cystic duct are usually of no clinical significance, occurring in 18%-23% of cases[4]. However, unrecognized variant anatomy can be a source of confusion on imaging studies. In addition, the cystic duct may be involved in a wide variety of both primary and secondary disease processes. The rate of injury varies in the medical literature from 0% to 1%[5]. The following are some of the cystic duct variations found: (1) the cystic and common hepatic duct are in parallel; (2) low confluence of the cystic duct[2]; (3) insertion of the cystic duct in the left and right hepatic ducts, and bifurcation of the left and right hepatic ducts[2]; (4) anterior, posterior spiral types of insertion of the cystic duct on the left side of the common hepatic duct; (5) parahepatic duct insertion into the cystic duct; (6) absent or short cystic duct (length < 5 mm); (7) cystic duct hypertrophy, with a diameter > 5 mm; (8) double cystic duct[6,7]; (9) right hepatic duct emptying into the cystic duct[8]; and (10) hepaticocystic duct[9], a very rare congenital abnormality in which the common hepatic duct enters the gallbladder. The left, right, and common hepatic ducts are all defective, with the cystic duct draining the entire biliary system into the duodenum.

Multiple modalities permit depiction of the normal anatomy, as well as disease processes of the cystic duct, including CT, PTC, ERCP, intraoperative cholangiography and MRCP. Although visualization of the dilated cystic duct is possible with US and CT, the normal-caliber cystic duct may be difficult to detect with these techniques[10]. In our first case, CT demonstrated minimal intrahepatic ductal dilatation, but failed to show low insertion of the cystic duct, as was revealed by surgery. In this case, the low insertion of the cystic duct was misdiagnosed as gallbladder and bile duct calculi. However, in the second case, ERCP showed a long cystic duct with a narrow and in-curved lumen. An anomalous cystic duct was diagnosed before surgery. Anatomical variation is readily identified at ERCP. In clinical practice, if the patient presents with intermittent non-colic right upper abdominal pain, and ultrasound, CT and endoscopy eliminate choledocholithiasis, tumor and peptic ulcer, then a narrow-winding cystic duct should

be considered. ERCP is extremely helpful in diagnosis. Recent studies have demonstrated that MRCP may provide a non-invasive alternative to ERCP and PTC in diagnosis of anomalous cystic ducts[11]. Taourel and colleagues[12] evaluated the accuracy of MRCP in the diagnosis of anatomic variants of the biliary tree in 171 patients. MRCP demonstrated a cystic duct in 126 patients (74%), including low cystic duct insertion in 11 (9%) and a parallel course of the cystic and hepatic ducts in 31 patients (25%). These findings suggest that accurate preoperative assessment is very useful in providing a surgical treatment plan in addition to confirming diagnosis. During cholecystectomy, to avoid biliary tree injury, it is important to identify the common hepatic-cystic duct junction. Misidentification of the cystic duct can lead to postoperative complications. In particular, attention should pay to low medial insertion of the cystic duct because this anatomical variant may lead to misdiagnosis on imaging, and thus affect therapeutic intervention, as was seen in our first case.

A limited literature review of bile duct variation has shown that the aim of most surgeons is to identify whether there are bile duct stones. With respect to the accidental discovery of bile duct variation, it is not the nature of the variation itself but rather the existence of the bile duct variation that is the most important factor in the prevention of bile duct injury. Most injuries to the cystic duct usually occur when it runs parallel to the common bile duct and is encased in a common sheath, so that separation between the ducts is not readily apparent at surgery. T-tube placement in the cystic duct remnant is usually of no consequence; however, there may be a difficulty if retained common duct stones are present, and stone removal *via* the T-tube is attempted. In such cases, access to the bile duct is *via* a tract that enters the cystic duct, and manipulation and extraction must occur *via* the cystic duct across the valves of Heister. Stone extraction is more difficult or may be impossible *via* this route[13]. Suspicion should be raised if the cystic duct is of an unusually large calibre. Intraoperative cholangiography should be used in case of doubt and, in unusual circumstances, cholangiography can be performed *via* the gallbladder to aid in the identification of the cystic duct as well as the common bile duct.

In conclusion, the cystic duct may be involved in a variety of anatomical variations. Diagnostic accuracy relies on a clear understanding of the normal anatomy and anatomical variants of the cystic duct, and imaging features of calculous disease.

Abstract

Acute liver failure (ALF) is relatively frequent during heat stroke (HS). This risk must be emphasized, because its incidence is higher than is usually thought. In a recent study by Weigand *et al*, two cases were reported in which liver failure was the leading symptom. We have confirmed their conclusion in a study of 25 cases of HS with ALF, compared with 25 other cases without ALF. Moreover, we observed that hypophosphatemia on admission could predict occurrence of ALF during HS. As for clinical and other biological parameters, phosphatemia should be monitored for at least 3 d in all cases of HS, even when it is thought to be mild.

LETTER TO THE EDITOR

We were particularly interested in the excellent study by Weigand *et al*[1], who reported two cases of acute liver failure (ALF) after heat stroke (HS), one during a half marathon [exertional heat stroke (EHS)], the other classical, due to excessive environmental heat, and complicated by multi-organ failure. In addition to severe rhabdomyolysis, each patient was characterized by marked elevation of liver enzymes. Liver injury and ALF are known complications of HS[2]: serum alanine aminotransferase (ALAT) level usually rises within 30 min after HS and peaks within 3-4 d. The risk of ALF during HS must be emphasized, because its incidence appears to be higher than is indicated in this study. Irreversible ALF is rare and may require liver transplantation[3].

We have already reported some of our clinical data[4,5], from a cohort of 50 male subjects (which now consists of 110 cases); all investigated after EHS were confirmed by clinical and biological data, study of muscle metabolism by magnetic resonance spectrophotometry, muscle biopsy for pharmacodynamic tests, and pathology. Twenty-five of these consecutive patients (aged 25 ± 4 years) with EHS and ALF were compared with 25 other EHS patients, who were age-matched but without ALF (ALAT 3563 ± 1313 *vs* 590 ± 742 IU/L; factor V 30% ± 12% *vs* 66% ± 20%; $P < 0.001$ for each). ALF was defined as ALAT > 10 times the upper limit, and coagulopathy (factor V lower than 50%).

Age, body mass index, physical fitness, background, climatic conditions, drug and alcohol intake, clinical manifestations and laboratory findings were analyzed with reference to their prognostic significance in ALF. A logistic regression model was used. In 22 of 25 patients, ALAT level returned to normal within 10 d, but three patients died of ALF. Univariate analysis found that poor fitness ($P = 0.02$), hygrometry > 86% ($P = 0.03$), creatininemia > 160 μmol/L ($P < 0.001$) and hypophosphatemia < 0.5 mmol/L ($P < 0.001$) were significant predictors of ALF. In multivariate analysis, on admission, hypophosphatemia < 0.5 mmol/L was the only independent predictive factor of ALF (RR 3.8, 95% CI 1.1-6.2).

In conclusion, ALF is not uncommon in EHS of which we assert, as Weigand *et al*[1], that this one is an underestimated cause.

This ALF is strongly associated with early hypophosphatemia, of which a value < 0.5 mmol/L is predictive. However, there is no evidence that hypophosphatemia by itself causes important liver dysfunction[6]. Massive liver cell necrosis results from thermal shock, circulatory disruption, endotoxinemia (heat sepsis), high blood concentration of cytokines and acute-phase proteins.

Therefore, in EHS, measurement of phosphatemia, ALAT and factor V should be systematic on admission, and 3-4 d later. Phosphorus supply, usual in an intensive care unit, has not been evaluated in this situation.

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or National Animal Welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, author contributions, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: An accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images with their size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with

a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation contents as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the author(s) name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), followed by publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) followed by book title, publication number, publication place: Publication Press, year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.
EDITORIAL and LETTERS TO THE EDITOR are free of charge.

[1]Passed away on October 20, 2007
[2]Passed away on June 11, 2007

Total of 1050 editorial members from 60 countries world wide have been active in peer review and editing

National Journal Award
2005

World Journal of Gastroenterology®

Weekly Established in October 1995

Volume 14 Number 2
January 14, 2008

Contents

EDITORIAL	165	Hygiene hypothesis in inflammatory bowel disease: A critical review of the literature *Koloski NA, Bret L, Radford-Smith G*
OBSERVER	174	The spirit of Henry Norman Bethune and gastroenterology *Freeman HJ*
REVIEW	176	Overwhelming postsplenectomy infection syndrome in adults - A clinically preventable disease *Okabayashi T, Hanazaki K*
	180	Adenoviral gene therapy in gastric cancer: A review *Khalighinejad N, Hariri H, Behnamfar O, Yousefi A, Momeni A*
TOPIC HIGHLIGHT	185	Non-alcoholic fatty liver disease and the metabolic syndrome: An update *Rector RS, Thyfault JP, Wei Y, Ibdah JA*
	193	Nonalcoholic fatty liver disease and mitochondrial dysfunction *Wei Y, Rector RS, Thyfault JP, Ibdah JA*
	200	Role of the JNK signal transduction pathway in inflammatory bowel disease *Roy PK, Rashid F, Bragg J, Ibdah JA*
ESOPHAGEAL CANCER	203	Methylation of TIMP3 in esophageal squamous cell carcinoma *Smith E, De Young NJ, Tian ZQ, Caruso M, Ruszkiewicz AR, Liu JF, Jamieson GG, Drew PA*
COLORECTAL CANCER	211	Clinical significance of type VI pit pattern subclassification in determining the depth of invasion of colorectal neoplasms *Kanao H, Tanaka S, Oka S, Kaneko I, Yoshida S, Arihiro K, Yoshihara M, Chayama K*
BASIC RESEARCH	218	Hepatic stellate cells may be potential effectors of platelet activating factor induced portal hypertension *Chen Y, Wang CP, Lu YY, Zhou L, Su SH, Jia HJ, Feng YY, Yang YP*
	224	Expression of thymidine kinase mediated by a novel non-viral delivery system under the control of vascular endothelial growth factor receptor 2 promoter selectively kills human umbilical vein endothelial cells *Wang Y, Xu HX, Lu MD, Tang Q*
CLINICAL RESEARCH	231	Clear cell colitis: A form of microscopic colitis in children *Józefczuk J, Wozniewicz BM*

Contents

World Journal of Gastroenterology
Volume 14 **Number** 2 **January** 14, 2008

RAPID COMMUNICATION

236 Elevated nitric oxide and 3',5' cyclic guanosine monophosphate levels in patients with alcoholic cirrhosis
Siqueira C, de Moura MC, Pedro AJ, Rocha P

243 Promoter polymorphism of transforming growth factor-β1 gene and ulcerative colitis
Tamizifar B, Lankarani KB, Naeimi S, Rismankar Zadeh M, Taghavi A, Ghaderi A

248 Prevalence and dietetic management of mild gastrointestinal disorders in milk-fed infants
Pina DI, Llach XB, Ariño-Armengol B, Iglesias VV

Abstract

The hygiene hypothesis is thought to be a significant contributor to the growing incidence of inflammatory bowel disease (IBD) around the world, although the evidence for specific factors that underlie the hygiene hypothesis in IBD is unclear. We aimed to systematically review the literature to determine which hygiene-related factors are associated with the development of IBD. Publications identified from a broad based MEDLINE and Current Contents search between 1966 and 2007 on key terms relevant to the 'hygiene hypothesis' and IBD including *H pylori* exposure, helminths, cold chain hypothesis, measles infection and vaccination, antibiotic use, breastfeeding, family size, sibship, urban upbringing, day care attendance and domestic hygiene were reviewed. The literature suggests that the hygiene hypothesis and its association with decreased microbial exposure in childhood probably plays an important role in the development of IBD, although the strength of the supporting data for each of the factors varies considerably. The most promising factors that may potentially be associated with development of IBD include *H pylori* exposure, helminths, breastfeeding and sibship. However, the vast majority of studies in this area are plagued by serious methodological shortcomings, particularly the reliance on retrospective recall of information making it difficult to truly ascertain the importance of a 'hygiene hypothesis' in IBD. The 'hygiene hypothesis' in IBD is an important area of research that may give clues to the aetiology of this disease. Directions for future research are recommended.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic inflammatory disorder of the gastrointestinal tract[1]. Crohn's disease and ulcerative colitis represent the two most common forms of the condition, with both associated with significant morbidity[2,3]. While the aetiology of IBD remains obscure, it is thought to be the result of a combination of genetic and environmental factors[4]. Although genetic factors including NOD2, IL-23R and ATG16 genes have been implicated in Crohn's disease (CD) and to a lesser degree in and ulcerative colitis (UC)[5,6], they do not account for the striking rise in the incidence of IBD seen over the course of the 20th century[7], raising a strong possibility for an environmental hypothesis in IBD. Only two environmental influences (smoking and appendectomy)[8,9], however, are well established risk factors for IBD, although many others (including oral contraceptives and diet)[10,11] have been proposed to be important in the condition but with inconsistent results[12]. One promising group of environmental factors that may be potentially associated with IBD are those related to the "hygiene hypothesis"[13], which is closely linked to decreased microbial exposure in childhood.

In this review we aim to critically review the evidence for a hygiene hypothesis in IBD by examining factors that are directly linked to microbial exposure, factors that modify the response to infection and proxy measures for microbial exposure. Understanding the role of environmental factors such as these is critical for the possible prevention of IBD in genetically predisposed individuals as well as potentially offering disease improvement to those already suffering with the disease.

THE HYGIENE HYPOTHESIS

The hygiene hypothesis as a potential explanation for IBD comes from observations that the rise in the incidence of IBD, both in developed and developing countries[14,15], has coincided with improvements in hygiene over the 20th century. These improvements in hygiene include access to clean water, a hot water tap, a smaller family size and

thus less crowding, non-contaminated food and hygiene products such as toothpaste[16,17]. There are suggestions however that the rise in allergic and autoimmune disorders[18] over the last century, particularly in developing countries may not be accurate. Based on data from the World Health Organisation it is evident that there is extremely poor coverage of even basic demographic information such as vital registration of deaths[19]. Moreover, so-called Third World economies cannot provide the necessary public infrastructure necessary for diagnosis and reporting of these types of conditions, thus raising doubts as to the importance of a hygiene hypothesis in these disorders.

Nonetheless, Strachan (1989) was the first to link the hygiene hypothesis to the rise in allergic diseases[13]. He reported an inverse relationship between family size and the development of atopic disorders. The hygiene hypothesis is based on the possibility that a child could be overprotected from exposure to common infectious agents in the environment owing to improved hygiene[20]. If the child then comes into contact with a pathogenic infectious agent later in life (delayed exposure), an inappropriate immunologic response is triggered that could lead to the development of an abnormal or ineffective inflammatory process and possibly even IBD.

MICROBIAL EXPOSURE

Improved hygiene is believed to result in a limited exposure to micro-organisms[21]. Such exposure is thought to be necessary in programming the immune system of the gut and mitigating its future inflammatory responses, perhaps even resulting in CD when the immune system is challenged[21]. The underlying premise is that early childhood infection helps to establish the immunological balance between pro-inflammatory Th1 and tolerance-inducing regulatory T cells, preventing the subsequent untoward responses to allergens, microbial or other antigenic stimuli[22]. Thus various childhood circumstances such as day care attendance, presence of siblings, and domestic hygiene-related factors can influence the probability of contracting a "viral infection" at a vulnerable time in immunological development.

We performed a broad based MEDLINE and Current Contents search between 1966 and 2007 on key terms relevant to the "hygiene hypothesis" and IBD including *H pylori* exposure, helminths, cold chain hypothesis, measles infection and vaccination, antibiotic use, breastfeeding, family size, sibship, urban upbringing, day care attendance and domestic hygiene were reviewed. The reference lists from all relevant studies located in this process were then used to trace other studies to provide systematic coverage of relevant studies in this area.

FACTORS DIRECTLY LINKED TO MICROBIAL EXPOSURE

H pylori exposure

Multiple studies since 1994 have found a significantly lower seroprevalence of *H pylori* in patients with IBD compared to both matched controls, and "disease" controls[23-25]. The prevalence of this bacterial infection is lower in CD compared to UC, in the majority of these studies. Potential confounders include the effect of salazopyrine, other 5-ASA compounds, and antibiotics on the carriage and eradication of *H pylori*[26,27]. However, neither salazopyrine nor the other 5-ASA drugs used in IBD reach the concentrations required in the corpus and antrum of the stomach to effect *H pylori* eradication. In addition, studies of IBD patients and disease control groups including patients with COPD[28], indicate that the *H pylori* rates in those individuals exposed to multiple antibiotics are in fact higher compared to those exposed to either no antibiotics or fewer courses.

This reciprocal relationship, similar to that seen between UC and appendectomy[9], has also been linked to subtle changes in disease natural history. Vare *et al*, investigating the relationship between *H pylori* and CD, found that seropositive patients presented at a significantly later age (40 years) compared to seronegative CD patients (30 years, $P < 0.001$)[29]. Modification of phenotype was also identified in a separate study in which seropositive non-smoking CD patients had significantly fewer relapses and a lower risk of bowel resection compared to seronegative non-smoking patients ($P < 0.01$ and $P < 0.05$, respectively)[30].

These observations support a protective role for *H pylori* in both the development and natural history of CD, and need further investigation to determine whether this organism is acting as a surrogate marker of childhood exposure, or may have a more direct and wide-ranging effect on gastrointestinal immune development.

Helminths and IBD

With greater urbanisation and other hygiene practices introduced over the last century has come the decreased acquisition of soil-borne helminths in infants. Helminths are thought to play an important immunoregulatory role in the intestinal flora and as such have been linked to the development of IBD[31]. Firstly helminthic infection is associated with a strong Th2 response, which opposes the Th1 response associated with autoimmune disease and CD[32-34]. Secondly, chronic infection with these organisms may generate a network of regulatory T (Treg) cells that secrete transforming growth factor (TGF)-B and interleukin (IL)-10[33,35]. These cytokines may not only regulate aggressive Th1 responses but also control heightened Th2 responses that contribute to chronic allergic diseases. While there is a wealth of data from animal models to support an immunological role for helminths[32-34] there are limited data to confirm these pathways in the human gut. Moreover helminths infection may bring other anti-colitis mechanisms into play, including increases in mucus and water secretion into the gut lumen[36,37], which may influence the interaction between gut bacteria, their products, and a diseased epithelium, as well as impacting on intestinal motility. Helminths may affect microbial ecology[38] and the neuroendocrine response[39], but none of these factors however have been assessed in human studies. While preliminary results

from human trials in IBD patients using *Trichiuris suis*, or pig whip worm, demonstrate clinical efficacy[40] and no significant allergic disease post infection[41]. Long-term data, particularly after repeated exposure however are urgently needed to confirm these results. Thus, helminths may offer a novel therapeutic avenue in IBD patients, but much more research is needed to fully understand the mechanism behind any potential human association.

Cold chain hypothesis

The cold chain hypothesis shows temporal and geographical coincidences between the development of the refrigerator and the outbreak of Crohn's disease[42]. It is also possible that external factors related to the cold chain hypothesis including machine maintenance procedures, food conservation habits and the availability of electricity may also explain these trends[42]. The potential link between the refrigeration of food and Crohn's disease is *via* exposure to psychrotrophic bacteria with pathogenic properties such as *Listeria monocytogenes*, *Yersinia enterocolitica*, *Clostridium botulinum* and *Bacillus cereus* which are bacteria that are capable of surviving or developing at low temperatures[43]. Some of these bacteria have been identified in CD lesions[44,45]. A recent study by Forbes and Kalantiz (2006) found that the average age of having a fridge was more than 4 years earlier in older IBD patients than in age-matched controls, a difference that was significant[46]. While a greater exposure of the gastrointestinal tract to psychrotrophic bacteria in the early years of life may be a contributory factor to the development of Crohn's disease it is not yet considered to be an independent risk factor for the disease.

Childhood infections

An infectious aetiology has been proposed for IBD based on studies finding a significantly higher frequency of infectious events e.g. gastroenteritis during the first 6 mo after birth especially among future cases of CD[47,48]. A questionnaire-based study examining both adults and children with IBD have reported an association between the incidence of gastroenteritis and diarrhoea in infancy and the later development of CD[49]. However, an international multicenter study found no difference in the frequency of gastroenteritis in patients with IBD versus control subjects[50]. While numerous infectious agents such as paramyxoviruses[51] and Mycobacterium paratuberculosis[52] have been implicated in CD without consistency[53], it is the measles virus that has received the most attention.

The evidence on whether the measles virus increases the risk of IBD has come from several sources. The first is based on the biological plausibility of a measles virus in IBD. It is hypothesized that the measles virus is able to persist within the mesenteric endothelium creating an inflammatory reaction characteristic of CD[54]. While several studies have identified the presence of the measles virus in tissue samples[55,56], this finding has not been confirmed in studies using more sensitive methods such as the polymerase chain reaction (PCR)[57,58].

Another group of studies have examined the association of *in utero* and perinatal measles exposure and the development of IBD. Ekbom *et al* (1996) reviewed the hospital charts from 25 000 deliveries at a Swedish hospital between 1940 and 1949[59]. They found 4 cases of measles infection during pregnancy and of these, three of the offspring had developed CD. This study however suffered from some important biases including the selection of a period of time when it was known that in two cases of measles in the mother were followed by CD in the offspring. Moreover the diagnoses of maternal measles was based on clinical criteria only and the retrospective design makes it impossible to determine whether it is the measles exposure or some other factor during pregnancy that led to the subsequent development of CD in these children. Moreover studies from Denmark[60] and the UK[61] have failed to detect any cases of IBD after exposure to measles virus *in utero*. A history of perinatal infection has been reported to increase the risk of developing CD by five times[62], although the risk for IBD from measles infection specifically is much lower at 1.5 and is not significant[63]. Moreover Haslam *et al* (2000) did not find an increased risk for Crohn's among children born in years with high measles incidence rates versus children born in other years[64].

In summary the evidence supporting an association between measles infection in terms of in situ detection of measles virus, in utero and perinatal exposure and ecological evidence is discordant, but does not appear to be a causative factor in this condition.

FACTORS MODIFYING THE RESPONSE TO INFECTION

Childhood vaccinations

Childhood vaccinations have the ability to alter the maturation of the intestinal and systemic immune system and as such have been implicated in IBD[65]. Thompson *et al*, 1995) were the first to raise the possibility of a link between measles vaccination and IBD[65]. In a cohort analysis of 3545 individuals in the U.K. they showed that individuals with a history of exposure to measles vaccination were 3 fold and 2.5 fold more likely to develop CD and UC, respectively, compared with unvaccinated controls. Methodological shortcomings such as selection of participants from different populations, differential loss to follow-up between the two cohorts, and different ascertainment of outcome by exposure category, however, all dampened the strength of their findings. Subsequent cohort studies were also unable to confirm these initial findings[66,67].

Further controversy was fuelled when Wakefield *et al* reported 8 out of 12 children with non-specific colitis had symptoms attributable by the parents to the measles, mumps and rubella (MMR) vaccination[68]. Several issues related to selection and recall bias, no control group and lack of a clear case definition raised concerns as to the validity of these claims. In response to public concern, a case control study from the Vaccine Safety Datalink Project was conducted to address the link between MMR and risk of IBD[69]. Cases were 142 patients with chart confirmed IBD born 1958 to 1989 who were compared

to 432 controls matched by birth year, gender and health maintenance organisation. There was no evidence that either monovalent measles vaccine or the combination of MMR vaccination was associated with risk of IBD. One study found a significantly increased risk for CD with increasing age, but this was based on three children vaccinated at 2 years or older[67].

Evidence from ecological studies has generally failed to find a link between the incidence of measles vaccination and IBD[70-72]. The incidence of CD has been reported to be increasing since the 1940's, twenty years before the introduction of the measles vaccine.

Although this is a controversial area of research, the findings from well-designed studies do not support a link between vaccines containing measles and the subsequent development of IBD.

Antibiotics and development of IBD

The critical relationship between the human gut and its microflora has been highlighted in the field of IBD, particularly with the development of molecular models of the disorder such as the IL-10 knockout mouse[73]. These models clearly indicate that IBD does not develop in a germ-free environment. The role of gut bacteria has been further underlined by recent genetic discoveries that point to disturbances in the recognition and handling of bacteria in CD[74].

Antibiotics can potentially influence and disturb this relationship, and therefore have been the subject of several case-control studies in IBD[50,75,76]. In addition, some authors have pointed to the temporal relationship between the introduction of antibiotics on a wide scale after the Second World War, and the significant increase in the incidence of IBD seen in the second half of the last century[77].

There are a limited number of studies that address the role of antibiotics in the aetiology of IBD. Two small early studies were both heavily influenced by recall bias and the potential for reverse causation[50,75]. These found a positive association between antibiotic use and CD. In view of the potential lead-in time between onset of symptoms and actual diagnosis of CD, it is perhaps not surprising then that there may be increased prescriptions for antibiotics given to CD patients in the 1-2 years prior to diagnosis. With this confounder in mind, Card *et al* analysed the General Practice Research database (GPRD) in the UK to pull out prospectively collected data on CD cases and controls[76]. This study assessed antibiotic usage, other medication use, and smoking status as well as addressing the above issue of lead-in time, by analysing data 2-5 years pre-diagnosis. The investigators found that 71% of 587 CD patients were prescribed antibiotics 2-5 years prior to diagnosis compared to 58% of 1460 controls (Adjusted OR 1.32 [1.05-1.65], $P < 0.001$). Although there was no obvious confounding by gender, age, or smoking status, there was a lack of specificity with respect to the type of antibiotic prescribed, and the finding of associations with other drug groups including those for neurological conditions and oral contraceptive pills. This indicated that the association with antibiotics may not be causal. However, the strong interaction between cases and use of tetracyclines, particularly in those subjects with no prior gastrointestinal symptoms nor gastrointestinal medications, was intriguing and may provide some guidance as to future studies in this area.

Breastfeeding

The role of infant feeding practices may play a role in the development of IBD by affecting the early exposure to dietary antigens. Some of the important differences between human breast milk and infant formula include immunoglobulins (IG's), lactoferrin, lysozyme, growth factors, allergic factors, carnitine and DHA & ARA. For example Lactoferrin is an iron-binding protein found in human milk but not in formulas. It limits the availability of iron to bacteria in the gut and alters which "healthy" bacteria will thrive in the gut. It has a direct antibiotic effect on bacteria such as *Staphylococcus spp.* and *E. coli*[78].

The majority of the evidence supports a protective effect of breastfeeding in UC and CD[79-81]. A recent study based on an Italian population of 819 IBD patients suggested lack of breastfeeding to be associated with an increased risk of both CD and UC[82]. These results were supported by paediatric studies in Canada and the United States that found paediatric CD patients were less likely to have been breastfed[83,84]. Gilat *et al* performed a 14-center, 9-country study looking at more than 400 IBD patients whose disease started prior to 20 years of age and who were younger than 25 years at the time of the study[50]. These investigators found no significant difference between patients and control subjects in the frequency of breastfeeding as well as consumption of cereal or refined sugar during infancy.

A major problem with studies in this area are their retrospective design and dependence on patient or maternal recall to complete questionnaires. Moreover no studies have examined the potential confounding effects on the development of IBD of environmental factors such as maternal exposure to endocrine disrupting chemicals and the subsequent levels in human breast milk[85]. Further prospective studies using larger sample sizes is necessary to strengthen the validity of these observations.

PROXY MEASURES OF MICROBIAL EXPOSURE

A range of factors including family size, sibship, birth order, urban upbringing, day care attendance and domestic hygiene such as presence of a hot water tap and flush toilets have been examined in IBD studies as a proxy marker of environmental exposures in early life. Table 1 summarises the methodologies of key studies in this area. It can be seen that there is a heavy reliance on adult case-control retrospective designed studies and while many variables have been studied; only a few are significantly consistent.

Family size/ sibship/ birth order

Family size can be used to indicate the level of over-crowding in a home, which has been associated with poor

Table 1 Key studies examining the association between IBD and proxy measures of the 'hygiene hypothesis'

Author	Sample	Study design	Variables examined
Gilat, 1987[50]	14 centres from 9 countries UC = 197; CD = 302 Diagnosis before 20 yr, all patients < 25 yr old Age-sex match controls	Case control Questionnaires	Siblings, birth order, breast feeding, infection, eczema, family history, vaccination, pregnancy factors
Rigas, 1993[84]	New York, USA Diagnosed between 1986-1990 CD = 68; UC = 39 Pediatric gastroenterology controls = 202	Case control Questionnaires	Sibship size, maternal age at birth, month of birth, breastfeeding, maternal smoking one more
Gent *et al*, 1994[92]	UK UC = 231; CD = 133 16-87 yr Age-sex matched controls from same general practice as cases	Case control Home interview	Housing in infancy, presence of a lavatory, hot water tap, separate bathroom
Duggan *et al*, 1998[93]	UK Consecutive weekly attendees at IBD clinics UC = 213, CD = 110 (aged over 15 yr) Aged-Sex match controls from hospital patients undergoing elective surgery	Case control Questionnaire	Previous surgery, childhood domestic circumstances before age 11 yr (heating, day care, toilets, fixed bathroom, bedroom sharing)
Sicilia *et al*, 2001[87]	Spain Gastroenterologists recruited incident cases of CD patients aged 10-79 yr = 103 Outpatient clinic patient controls matched for age, sex and urban/rural.	Case control Population based study Structured interview 95% response rate	Number of persons in home, number of bathrooms, availability of hot water
Montgomery *et al*, 2002[88]	Swedish inpatient register UC = 15 823; CD = 12 668 Controls from Swedish Census, Births & Deaths Register: age and location matched 79 546; 63 035, respectively	Case control Swedish Multi-generation register linking cases and controls with family history information	Siblings
Feeney *et al*, 2002[16]	UK (Grew up in UK) 16-45 yr CD = 139; UC = 137 attendees at Gastroenterology clinics	Case control General hospital Questionnaire	Hp seroprevalence, family, hot water tap, nursery attendance, indoor toilets, swimming pool use, number or cars, number of house moves, urban/rural location, pets
Hampe *et al*, 2003[89]	Germany Consecutive IBD patients identified from German Crohn's & Colitis association = 2351 Controls unaffected first degree relatives = 3364	Case controls Questionnaire	Availability of tap water, toilet, central heating, siblings and community size
Amre *et al*, 2006[22]	Canada Newly diagnosed CD < 20 yr old = 194 Orthopaedic patients controls matched for timing of diagnosis & area of residence	Hospital based Case control Structured questionnaires - mothers mostly answered for patients	Siblings, breastfeeding, day care, place of residency, hot water tap, toilets, number of inhabitants, number of rooms, availability of private bed, personal hygiene, pet ownership, infection, smoking history

hygiene and potential exposure to infection[86]. A small family size and thus a less propensity for exposure to infection has been associated with a lower risk for IBD[86]. Amre *et al* (2006) created a 'crowding index' which refers to the number of rooms in the home divided by the number of inhabitants living in the home and found the mean 'crowding index' to be lower in cases than controls and thus protective against CD[22]. No differences however were found between the numbers of people residing in the home during infancy (< 18 years) in IBD patients versus controls[87], although this study had limited power.

Siblings may influence the development of IBD by altering exposure patterns to microorganisms in early life by affecting acute manifestation of infection by influencing age of transmission and severity[88]. In a large Swedish case control study, Montgomery *et al* (2002) found having older siblings increased the risk for UC, even after controlling for multiple births, sex, maternal age, year of birth, region and socioeconomic class. This may be because older siblings risk exposing younger siblings to infection at a higher dose or at an earlier age. In contrast, having younger siblings was significantly associated with a decreased risk of CD. This effect was most pronounced when younger siblings were born within two years of the patient's birth. It is hypothesised that having younger siblings may prolong or re-expose the older sibling to the presence of micro-organisms, conferring some protective effect against CD through appropriate priming for mucosal immune function[88]. These findings however have not been replicated in smaller studies[22].

Birth order as a potential marker for the hygiene hypothesis in IBD has been examined in several studies with inconsistent results[50,89]. For example, Hampe *et al* (2003) found birth later in the sibling order was significantly associated with a lower risk for IBD (included patients with CD, UC and indeterminate colitis)[89]. This is because first-born children are usually exposed to infection later in life than younger siblings who come into contact with common viral and bacterial infection through older siblings. Rigas *et al* (1993) however did not find birth order to be significantly associated with either disease based on medical records[84].

Urban upbringing

It has been suggested that an urban upbringing represents a more "hygienic" childhood compared with a childhood spent on a farm or a rural location. Several studies report that a higher incidence of IBD in urban as opposed to rural areas[90,91]. Others however have failed to replicate this finding[16,87].

Day care attendance

Day care attendance in young children has the potential for exposing children to greater infections. Amre *et al* (2006) in a hospital- based case control study found day care attendance in the first 6 mo of life to be associated with an increased risk for CD[22]. Feeney *et al* (2002) however found no significant difference between IBD cases and controls in regards to pre-school attendance[16].

Domestic hygiene

Several domestic hygiene-related exposures have been investigated in relation to IBD. This is because good domestic hygiene may protect an individual from exposure to a full range of agents that programme the immune system in the gut during infancy, causing an inappropriate response, perhaps even CD, when exposure occurs at a later age[92]. Gent *et al* (1994) found CD to be 5 times more common in IBD patients whose first house had a hot water tap and a separate bathroom, but no association was reported for mains drainage or access to a flush toilet[92]. Moreover domestic hygiene variables were not associated with UC[93]. A similar finding was reported by Duggan *et al* (1998) who found availability of hot water before age 11 to be significantly associated with CD but not UC[93]. Others however have failed to find a significant association between availability of hot water, toilet facilities, bed sharing, source of drinking water and number of bathrooms and risk for CD[22,50,89] but some of these studies did not evaluate controls that were representative of the case population or had power problems[50]. Pet ownership[22] and animal exposure during childhood[94] have been associated with an increased risk for CD but are not consistent findings[16]. The frequent use of a swimming pool was significantly associated with CD, although the mechanisms behind the association remain unclear and could be more to do with socioeconomic status rather than hygiene related[16]. Most of the studies except one[50], however, rely on the retrospective collection of information *via* questionnaires making it difficult to rule out recall bias (Table 1).

SOCIOECONOMIC STATUS

Earlier studies cited socioeconomic status as an important factor in the development of IBD, in that a higher socioeconomic status was more prevalent in IBD patients versus controls[95,96]. A higher socioeconomic status may also confer less household crowding and better domestic hygiene (hot tap) and thus increase the risk for CD by limiting exposure to micro-organisms[86]. As hygiene practices have improved over the course of the 20th century, socioeconomic status has become less important in IBD. In a recent study by Bernstein *et al* (2001) no differences in socioeconomic status were found between IBD patients and controls[97].

FUTURE DIRECTIONS

Based on a systematic review of the literature it is evident that there is a strong need for future studies in this area to adopt a prospective design in a paediatric sample to avoid the pitfalls associated with retrospective studies such as recall bias. This is crucial as many factors proposed to be important in the hygiene hypothesis such as breastfeeding date back to birth and infancy. Population based studies are also important to overcome problems inherent with selection biases which may be present in the many patient based studies that dominate this area. The evidence suggests that it is also important to look at Crohn's disease and ulcerative colitis separately since exposure risks do not appear to be the same for both disorders. The need to establish and validate better markers for hygiene related factors is crucial as it is impossible to rule out the possibility that the relationship between IBD and a hygiene related factor such as sanitation for example is not an indirect effect that may serve as a mechanism for other yet unknown lifestyle factors. Future research should also be directed towards trying to understand the potential mechanisms underlying associations between hygiene related factors and IBD in the hope of providing clues to the aetiology of this disease.

CONCLUSION

IBD is a growing disease that is costly to the individual and society. The underlying premise of the hygiene hypothesis is that decreased microbial exposure in childhood may lead to the subsequent development of IBD appears to be plausible, although the strength of the evidence supporting this varies between many hygiene-related factors. Helminthic infection, *H pylori* exposure, antibiotic use, breastfeeding and sibship represent the most promising factors supporting the hygiene hypothesis in IBD, but carefully designed prospective evaluation is urgently needed.

From the Series Editor: A unique column, The Observer, will be initiated soon in *World Journal of Gastroenterology* (*WJG*). Professor Hugh James Freeman, a gastroenterologist from the Department of Medicine, University of British Columbia, Vancouver, has been appointed as a Series Editor for The Observer. Serving as a forum for both gastroenterologists and/or hepatologists worldwide, Professor Freeman will periodically invite experts in particular research fields to examine important progress made in both Gastroenterology and/or Hepatology. The Series will examine challenging issues faced at the fundamental level from the research laboratory to the bedside. The Observer is an invited editorial and will not accept independent uninvited submissions. For more information, please do not hesitate to contact Professor Freeman at hugfree@shaw.ca.

Abstract

Henry Norman Bethune was a physician and surgeon from Canada. He had a highly impressive medical career in Montreal but did his most important work in China where he cared for soldiers on the battlefield. He died in 1939 and was recognized as a hero, but only much later received recognition in Canada. He was a skilled doctor, both as a physician and as a surgeon. However, he was much more and will serve as an inspiration for this series. He was an innovator, an idealist and a perfectionist. It is hoped that this series will gather expert commentaries on a range of issues critical to the subspecialty from fundamental science to clinical care so that future directions can be defined.

INTRODUCTION

Developing this new editorial feature presents a challenge, but also an important opportunity. There is a broad range of critical issues that gastroenterologists must deal with on a daily basis. Some relate specifically to fundamental scientific aspects of our specialty as well as clinical elements of "cutting edge" patient investigation, treatment and ongoing care, particularly for chronic illnesses. Several subspecialty journals in gastroenterology, hepatology and nutrition already provide new and updated information, from time to time, on many of these issues. Although being informed about the past and present state of knowledge is very important, there is also an increased need to visualize, even speculate about future directions in all of these related fields. It is hoped that this column will help to share such insights through editorials from individual experts focused on specific areas of our discipline.

Other critical areas include the impact of industry and the role that different global or multinational corporations already have in our subspecialty, especially those involved in the production of new pharmaceuticals as well as biological agents. In addition, there are ongoing changes and developments in endoscopic technology and imaging devices that will continue to impact our highly procedure-driven specialty. Moreover, there are critical concerns related to manpower needs to screen for different forms of cancer. Finally, there are demanding needs in developing nations to provide optimal care in our subspecialty. This journal is unusual in its absence of advertising and will certainly provide a different setting for evaluation of many of these issues. Leading experts in the new frontiers of our rapidly expanding discipline will contribute updates in their field along with their insights. Candid editorial comments on the present state of knowledge, controversies, and, perhaps, their predictions related to the future will be encouraged.

BETHUNE

At McGill University in Montreal, it seemed customary during my student years for each new medical class to

become informed about the important efforts of many outstanding physicians that preceded our own experience. Like many other schools, their photographs and sculptures adorned the hallways of the medical school buildings. This feature of the curriculum probably had many purposes, including the development of a form of local pride for the contributions that these early faculty made to clinical and investigative medicine. Some, intimately linked to McGill University, seemed very impressive, including William Osler and Wilder Penfield. Many in my class, however, were most intrigued with the exploits of a rather curious Canadian physician, Henry Norman Bethune, who had a most amazing career ending with his final months in China. His life was first revealed to us in a low budget black-and-white film. Later, it appeared on an almost annual basis, witnessed by our own class, the result being that it seemed to become indelibly imprinted on our brains. Perhaps, in retrospect, this was done purposefully, before and during our initial clinical exposures and encounters on the wards where these ancestral giants had actually worked and toiled in previous times. We were being inspired.

Bethune was born in Gravenhurst, Ontario in 1890. He entered medical school at the University of Toronto, and then spent time as a stretcher bearer in a field ambulance unit for the Canadian Army in France in 1915. In the interim, his medical studies were temporarily interrupted, but eventually, he graduated in 1916. He was reported to have suffered a severe bout of pulmonary tuberculosis leading to surgical treatment using the technique of surgically-induced pneumothorax. This experience inspired his interest in surgery, particularly thoracic surgery.

He eventually came to Montreal and became a member of the McGill Teaching Faculty where he served on the surgical team at the Royal Victoria Hospital. There, he personally developed over a dozen new surgical instruments, including the Bethune Rib Shearer. Remembered by some for his intellect and surgical inventions, Bethune was also a realist, almost painfully so. In spite of a highly impressive career in Montreal, he became very disillusioned as many of his own patients, especially the poor, often re-developed tuberculosis after treatment. In large part, it seemed to Bethune to be due to their almost immediate return to their former poor living conditions after discharge from hospital. As a result, he developed a persisting passion for socialized medicine and, at this early stage in his career raised the issue of universal health care. As time has shown, however, he was a true revolutionary and, initially, was clearly not popular with his medical colleagues in Montreal. Indeed, in Canada, socialized medicine in its current form did not actually appear for almost another half century.

After visiting the Soviet Union, Bethune joined the Communist Party of Canada in 1935. During the Spanish Civil War in 1936, he worked on the Republican side against the Fascists, organizing the first mobile blood transfusion unit and treating battlefield injuries. In 1938, he joined the Chinese army of Mao Tse-Tung (Mao Ze-Dong) and the Communist Party during the Japanese invasion of China. There, he went to Yenan in 1938 and formed the first mobile army surgical hospital (MASH) unit that was carried on mules. Bethune performed numerous surgeries in the Taihang Mountains. He worked with tradesmen to develop new surgical instruments and trained physicians and nursing staff. Bethune died in November 1939 in Tanghsien (Tang xian County), Hopei, during the Sino-Japanese War, apparently of sepsis reported to have resulted from an accidental wound suffered during a surgical procedure without surgical gloves. In December 1939, Mao Tse-Tung (Mao Ze-Dong) wrote an essay entitled "*In Memory of Norman Bethune*" and concluded:

"...We must all learn the spirit of absolute selflessness from him. With this spirit everyone can be useful to the people. A man's ability may be great or small, but if he has this spirit, he is already noble-minded and pure, a man of moral integrity and above vulgar interests, a man who is of value to the people..."

Although Bethune became well known in China, recognition in Canada came only decades later, even after a medical school had been named in his honor, located in Jilin. In 1976, the Bethune Memorial House, a National Historic Site in Canada, was dedicated in Gravenhurst, Ontario. In 1990, a biographical film entitled "Bethune: The Making of a Hero", starring Donald Sutherland, was produced as a joint venture that included Telefilm Canada, the Canadian Broadcasting Corporation and China Film Co-production. During the same year, Canada and China each issued two national postage stamps, identical in design, to honor Bethune. In 1998, Bethune was inducted into the Canadian Medical Hall of Fame. In 2006, China Central Television developed a 20-part drama series directed by Yang Yang, entitled "Dr. Norman Bethune", reported to be the most expensive Chinese television series ever produced.

LOOKING FORWARD

This new editorial section, The Observer, will be dedicated to Henry Norman Bethune and his important contributions as a Chinese doctor. Bethune became a hero in China, not only because he was a very good physician and a skilled surgeon, but also because he was an innovator, an idealist and a perfectionist. These qualities seem especially important today in gastroenterology. It is sincerely hoped that this new journal column will be able to gather expert commentaries on a range of issues critical to the subspecialty from fundamental science to clinical care. Here, it is hoped that current specialty data can be deciphered and its future directions defined. The spirit of this man must be carried forward.

REVIEW

Overwhelming postsplenectomy infection syndrome in adults - A clinically preventable disease

Abstract

Overwhelming postsplenectomy infection (OPSI) syndrome is a rare condition, but is associated with high mortality. However, recognition and clinical management of OPSI is not well established. The prevalence of splenectomy increased recently because it was a clinically effective treatment for hepatitis C virus-associated thrombocytopenia before the introduction of the interferon/ribavirin combination therapy. We reviewed the literature characterizing the clinicopathological features of OPSI and assessed the most effective and feasible administration of the condition. A Medline search was performed using the keywords 'overwhelming', 'postsplenectomy infection', 'postsplenectomy sepsis', 'chronic liver disease', and/or 'splenectomy'. Additional articles were obtained from references within the papers identified by the Medline search. Durations between splenectomy and onset of OPSI ranged from less than 1 wk to more than 20 years. Autopsy showed that many patients with OPSI also had Waterhouse-Friderichsen syndrome. Although the mortality rate from OPSI has been reduced by appropriate vaccination and education, the precise pathogenesis and a suitable therapeutic strategy remain to be elucidated. Protein energy malnutrition (PEM) is commonly observed in cirrhotic patients. Since the immune response in patients with PEM is compromised, a more careful management for OPSI should therefore be applied for cirrhotic patients after splenectomy. In addition, strict long-term follow up of OPSI patients including informed consent will lead to a better prognosis.

INTRODUCTION

Splenectomized patients are a significant infection risk, because the spleen is the largest accumulation of lymphoid tissue in the body[1]. Overwhelming postsplenectomy infection (OPSI) is a serious fulminant process that carries a high mortality rate[2-4]. OPSI cases have been well documented, and more recently the syndrome was reviewed in the literature[1,5,6]. The pathogenesis and risk of developing fatal OPSI remain ill-defined, however, especially in the normal adult host.

Anti-hepatitis C virus (HCV) therapy with pegylated interferon has proven effective for virus clearance in recent years[7,8]. Prior to that, treatment of HCV-associated thrombocytopenia was an important and unresolved problem[9,10]. Splenectomy in patients with hepatitis C cirrhosis is now a safer prelude to antiviral treatment[11-14]. However, protein energy malnutrition (PEM) is a common manifestation in patients with liver cirrhosis, with incidences as high as 65%-90%[15-17], putting them at a higher risk of OPSI, because patients with PEM generally have a reduced immune response. This review describes the clinical features of OPSI and discusses management strategies for patients with OPSI, particularly those with chronic liver disease.

Symptoms of OPSI

King and Shumacker first described bacterial sepsis following splenectomy in infants and children in 1952[18]. It emerged subsequently that a comparable syndrome occurs in asplenic adults REF. Fulminant bacterial sepsis in asplenic patients will be termed OPSI in this review in keeping with common usage in the literature.

Aspecific and mild physical symptoms of postsplenectomy appear in the early stages of OPSI. These include fatigue, colored skin, body weight loss, abdominal pain, diarrhea, constipation, nausea, and headache (Table 1)[6,19]. Pneumonia and meningitis are frequent more severe concomitants. The clinical course may rapidly progress to coma and death within 24 to 48 h, due to the high incidence of shock, hypoglycemia, marked acidosis, electrolyte abnormalities, respiratory distress, and disseminated intravascular coagulation[20,21]. The mortality

rate is 50%-70% despite aggressive therapy that includes intravenous fluids, antibiotics, vasopressors, steroids, heparin, packed red blood cells, platelets, cryoprecipitates, and fresh frozen plasma[2,19,22-24]. The later clinical course frequently mirrors that of Waterhouse-Friderichsen syndrome (WFS), and bilateral adrenal hemorrhage may be found at autopsy[25,26]. The mechanism that connects splenectomy to WFS is unknown but the possible causes of OPSI include loss of splenic phagocytic function, decreasing serum immunoglobulin levels, suppression of lymphocyte sensitivity, or a change in the opsonin system[27,28].

Table 1 Clinical features of overwhelming postsplenectomy infection

Cryptic infection (no obvious focus)
Short, nonspecific prodrome
Massive bacteremia with encapsulated organism
Septic shock with disseminated intravascular coagulation
Marked virulence: 50% to 70% mortality
Death ensues in 24 to 48 h

Overwhelming postsplenectomy infection had been defined as septicemia and/or meningitis, usually fulminant but not necessarily fatal, and occurring at any time after removal of the spleen.

Risk factors

Splenectomized patients are at risk of life-threatening sepsis. Major factors for stratifying risk include the age at which splenectomy occurs, the subsequent time interval from splenectomy, the reason for splenectomy, and the overall immune status of the patient REF.

Infants do not acquire specific antibodies against encapsulated organisms until relatively late in the development of antibody responses. Although OPSI can occur at any age, children are therefore at greater risk of developing the condition, especially those under the age of 2 years[29,30]. However, estimates of the incidence and timing of OPSI vary widely in the literature, and some authors report the greatest risk of developing OPSI in the first two years after splenectomy[31]. Recent reports recommended that all asplenic patients should receive optimal advice and protection against OPSI regardless of the underlying etiology, based on evidence that the increased risk of severe sepsis after splenectomy is lifelong[32,33].

Splenectomy performed for a hematological disorder, including thalassemia, hereditary spherocytosis, auto-immune hemolysis, immune thrombocytopenic purpura, or lymphoma, appears to carry a higher risk than splenectomy performed as a result of trauma[34,35]. In addition, patients with hematological and autoimmune disorders, or lymphoma show impaired immunity, and patients undergoing treatment such as chemotherapy often show decreased serum immunoglobulin levels; both groups may therefore have an increased susceptibility for OPSI.

Hyposplenism occurs when splenic functions are reduced by disease or are absent congenitally or after splenectomy. Howell-Jolly bodies are small, round remnants of the original erythrocyte nucleus. Increased numbers of Howell-Jolly bodies in a peripheral blood smear, although not overly sensitive, can identify the degree of hyposplenism that presents a risk for developing OPSI[2,19,36].

Infecting organisms in OPSI

Outside the splenic circulation, polysaccharide antigens are poorly immunogenic in comparison with protein antigens. This contributes to polysaccharide-coated bacteria evading the immune response and subsequent phagocytosis[28]. Host defenses against bacteria are therefore critically dependent on humoral immunity and production of type-specific antibodies. While liver Kupffer cells clear most well-opsonized bacteria, encapsulated organisms resist antibody binding and are primarily removed by the spleen. Sepsis in asplenic patients can occur with any organism, be it bacteria, virus, fungus, or protozoan, however encapsulated organisms are frequently associated with sepsis in splenectomized patients. Encapsulated organisms such as *Streptococcus pneumoniae* are particularly resistant to phagocytosis, but is quickly overcome in the presence of even a small amount of type-specific antibody[24,37]. Without the spleen, prompt antibody production against a newly encountered antigen is impaired and bacteria proliferate rapidly. Therefore, the risk of invasive pneumococcal disease in patients without a spleen is 12-25 times greater than that in the population at large[38,39]. Invasive disease in the asplenic patient due to such encapsulated organisms as *Streptcoccus pneumoniae* (50%-90%), *Neisseria meningitides*, *Hemophilus influenzae*, and *Streptococcus pyogens* (25%) leads to uninhibited bacterial overgrowth[24,29,33,37].

Prevention of OPSI

Treatment of OPSI is generally aggressive due to the serious nature of the condition and associated mortality. Comprising intravenous fluids, antibiotics, vasopressors, steroids, heparin, packed red blood cells, platelets, cryoprecipitates, and fresh frozen plasma, it may fail to alter the course of this fulminant septic syndrome[25]. Therefore, prevention of OPSI is extremely important for immunocompromised patients who have undergone splenectomy.

Preventive strategies including vaccination and education are also important for splenectomized patients. Functionally or anatomically asplenic patients are at increased risk of infection from encapsulated organisms compared to the general population. Vaccines available for the most common organisms include the 23-valent pneumococcal polysaccharide vaccine, a 7-valent protein-conjugated pneumococcal vaccine, the *Hemophilus influenzae* type B vaccine, and the meningococcal vaccine[28]. The polysaccharide-based pneumococcal vaccine is recommended for all adults at increased risk of pneumococcal infection, and particularly the asplenic patients[40]. The Centers for Disease Control and Prevention in the US (revaccination every 6 years) and the British Committee for Standards in Haematology (revaccination every 5-10 years) recommended revaccination for the prevention of OPSI, at the same time emphasizing the rather frequent need for shorter intervals between revaccinations to keep antibody concentrations at a level sufficient by probability to confer protection[41,42]. Unfortunately, fatal pneumococcal sepsis has been

reported in asplenic, vaccinated patients. It remains advisable, nevertheless, to offer splenectomized patients protection due to their increased risk of developing severe disease and because the vaccine itself poses minimal risk. Jockovich[43] reported no OPSI among patients vaccinated before splenectomy; however, 10.4% of patients who did not receive vaccination developed OPSI. In addition, 5% of patients who were given vaccination after splenectomy developed OPSI. For elective splenectomy, the vaccine should be given at least 2 wk before surgery[43,44].

Finally, patient education represents a mandatory strategy for preventing OPSI. Studies have shown that from 11% to 50% of splenectomized patients remain unaware of their increased risk for serious infection or the appropriate health precautions that should be undertaken[45,46]. Patients should understand the potential severity of OPSI and the possibility of rapid progression. Physicians should inform any new healthcare professionals, including dentists, of asplenic status. In particular, the presence of increased Howell-Jolly bodies on a peripheral blood smear should be highlighted on the laboratory report to inform the patients' physicians of possible hyposplenism[2,19,36], This information and its significance should be in turn relayed to the patient. Moreover, advice for asplenic individuals to be issued with a form of medical alert, such as a card or a bracelet, has two purposes. First, it should provide a constant reminder to the individual of their condition and, second, knowledge of their state might be vital for medical attendants in the event of a medical emergency. This aspect of patient management needs increased attention as only one patient was found to hold such a card. The possibility that OPSI episodes in asplenic patients may have been avoided with improved knowledge cannot be excluded[5].

Future directions

HCV is a major public health problem and a leading cause of chronic liver disease. Various studies have suggested that 3%-20% of chronically infected patients will develop cirrhosis over a 20-year period, and are at significant risk of developing hepatocellular carcinoma[47]. Recent therapeutic trials in well-defined, selected populations revealed that combinations of interferons and ribavirin are more effective than monotherapy for HCV treatment. Moreover, trials of pegylated interferons yielded improved sustained virus response rates with similar toxicity profiles. As with all clinical decisions, selection of patients for HCV treatment requires an accurate assessment of therapeutic risk *vs* benefit, a determination that is complicated by exclusion from registration trials of persons with conditions that might increase risk and diminish benefit. Application of these principles to individual patients can be challenging, and the relative strength of recommendation of treatment varies accordingly. However, HCV is also a possible cause of chronic thrombocytopenia in these patients, by a mechanism that remains unclear. Moreover, treatment for HCV often leads to anemia, neutropenia, and thrombocytopenia. These conditions prevent safe application of treatment in patients with baseline pancytopenia, due to the cirrhosis-related hypersplenism[14]. The various treatments used, including steroids and intravenous immunoglobulin, have generally produced only transient responses[48,49]. Nevertheless, partial splenic embolization and laparoscopic splenectomy may enable anti-HCV therapy to be given. Recently, Hayashi *et al*[14] reported that splenectomy for severe thrombocytopenia with the intent to apply interferon therapy can be beneficial. It is therefore feasible that splenectomy prior to anti-HCV treatment for HCV-related chronic thrombocytopenia will occur more frequently in the near future. In addition, physicians should follow the occurrence of OPSI in these patients not only during the treatment for HCV clearance but also for the entire follow-up period.

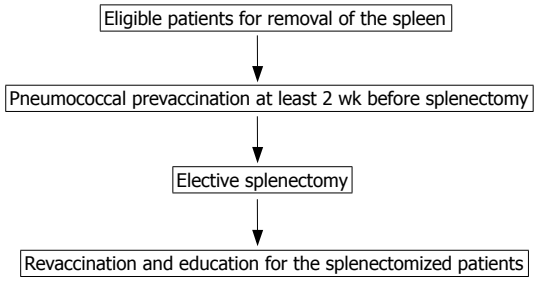

Figure 1 A proposed prevention strategy for splenectomized patients in management algorithm.

CONCLUSION

The spleen is crucial to the host response to infection by clearing polysaccharide-encapsulated bacteria. This response involves the clearing of pathogens from the bloodstream as well as the rapid production of specific antigens. Splenectomy results in an increased risk of septic complications associated with a high mortality rate, the most serious being the development of OPSI. Nonspecific symptoms, including nausea, vomiting, fever, and unconsciousness, followed by a rapid progression to coma and shock characterizes OPSI, and it is treated aggressively.

Eradication of HCV with the recently introduced therapy of pegylated interferon and ribavirin would be particularly beneficial in those with advanced liver fibrosis or cirrhosis. Splenectomy might be useful also to raise platelet counts so that pegylated interferon-based therapy can be performed safely in patients with cirrhosis due to HCV. Prevention strategies such as vaccination and education are also potentially important parts of the strategy for splenectomized HCV patients (Figure 1). Finally, reduction of the immune response in patients with chronic liver disease and/or PEM necessitates careful follow up of splenectomized patients with chronic liver disease to monitor the appearance of OPSI.

Abstract

Gastric cancer is one of the most common malignancies worldwide. With current therapeutic approaches the prognosis of gastric cancer is very poor, as gastric cancer accounts for the second most common cause of death in cancer related deaths. Gastric cancer like almost all other cancers has a molecular genetic basis which relies on disruption in normal cellular regulatory mechanisms regarding cell growth, apoptosis and cell division. Thus novel therapeutic approaches such as gene therapy promise to become the alternative choice of treatment in gastric cancer. In gene therapy, suicide genes, tumor suppressor genes and anti-angiogenesis genes among many others are introduced to cancer cells *via* vectors. Some of the vectors widely used in gene therapy are Adenoviral vectors. This review provides an update of the new developments in adenoviral cancer gene therapy including strategies for inducing apoptosis, inhibiting metastasis and targeting the cancer cells.

INTRODUCTION

Gastric cancer is one of the most common malignancies in the world with an estimated 934 000 cases reported globally in 2002[1], and the second most common cause of death from cancer. The prognosis of gastric cancer is poor with an estimated relative 5 years survival rate of less than 20%[2].

In Iran, 26.1% of cancers reported in 2002 in men and 11.1% of cancers in women were due to gastric cancer. Gastric cancer is the first leading cause of Cancer related death in Iranian men and the second in Iranian females. The incidence rates of gastric cancer in Iran are well above the world average; it is the fourth common cancer in the world however it is the most common malignancy in Iran[3]. Comparing gastric cancer rates with the data of 30 years ago, shows that the overall incidence of gastric cancer in Iran has gradually increased over the years[4]. This is in contrary to the global trend which has seen a steady decrease in the incidence and mortality rates for gastric cancer.

The current best approach for treating gastric cancer is complete surgical removal of the tumor with the adjacent lymph nodes however the efficacy of this therapeutic approach as well as hormone, radio and chemotherapy is very limited. Thus new therapeutic approaches are needed[5,6].

Gastric cancer is a genetic disease developing from a multi-step process[7]. Single or multiple mutations in genes related to growth control, apoptosis, invasion and metastasis form the molecular genetic basis of malignant transformation and tumor progression[8], so a better understanding of the molecular basis of tumor host interactions leads to significant progress in the development of new therapeutic agents. Based on this theory, cancers can be curable if the regulating mechanisms are reintroduced to the cancer cells; this can be achieved using gene therapy, which is an emerging alternative for treatment of cancers[9,10].

In gene therapy vectors are used to insert new genes into cells, or to switch off existing genes[11]. Some of the most efficient vectors used for gene therapy are viral vectors, as they naturally insert their genes into cells, they are well adopted and equipped for such a task. In recent years adenoviruses have been extensively used as vectors to deliver foreign genome into mammalian cells. Adenoviruses have certain features, which make them attractive vectors for gene transfer to target cells. Some of these characteristics include their ability to infect a broad range of cell types, including dividing as well as non-dividing cells, the ease with which adenovirus genome can be manipulated, and the ability to obtain high titers. To achieve an adenoviral vector, foreign cDNAs are inserted into the adenovirus genome, resulting in recombinant adenoviruses containing the gene of choice.

Cancer gene therapy has 3 essential goals: the first is

to suppress cancer growth and induce apoptosis in cancer cells, the second goal is to inhibit metastasis of malignancy to other sites and finally the effects of gene therapy must be limited to cancer cells. These goals can be achieved using some strategies, which we will further explain below[12-15].

TUMOR SUPPRESSOR GENES AND APOPTOSIS INDUCING GENES

As mentioned earlier, one of the ways for stopping cancer growth is to reintroduce the regulating mechanisms into cells, these mechanisms are supervised in the first place by tumor suppressor genes, so by inserting these genes into cells, tumor growth can be suppressed. Reintroduction of tumor suppressor genes also has the additional advantage of making targeted cells susceptible to chemotherapy[16].

The most famous tumor suppressor gene is P53, which is mutated in 60% of gastric cancers and in almost all other cancers[17]. Introduction of the p53 gene *via* a recombinant adenovirus has been shown to inhibit the growth of gastric cancer cells with mutated p53 *in vitro* and *in vivo*[18,19]. P53 not only regulates cell cycle and cell growth but it also has a crucial role in activating proapoptotic genes such as Bax, Apaf-1, Fas and PTEN thus not only limiting cancer growth but also inducing apoptosis in cancer cells (if the proapoptotic genes are not mutated themselves). Other tumor suppressor genes useful in gastric cancer include: P16 gene and Fhit[20-23].

There are two approaches for inducing apoptosis in cancer cell lines, the first is to introduce native proapoptotic genes into cancer cells, this has the additional advantage of minimum toxicity of novel gene for non cancer cells (which already have a copy of native proapoptotic genes). The second approach on the other hand is to introduce genes of non-mammalian enzymes into cancer cells, so that they can convert non toxic prodrugs into highly toxic substances that will kill the cell[24]. This approach has the advantage of bystander effect, which means not only the infected cell will be killed but it will release the highly toxic drug which will kill the adjacent cells as well[25].

Among genes introduced into cells to induce apoptosis, Bax is a good example, as it independently of cell's P53 activity can make the cell commit suicide; it also has the further advantage of sensitizing the malignant cells to conventional anti-tumor treatments[26]. Some other genes that can be used in inducing apoptosis in gastric cancer cells include genes, which are effective in Caspase 3 common pathway including Caspase 8[27,28].

Another method of killing cancer cells is to transfect them with genes of non-mammalian enzymes which can convert non toxic prodrugs into highly toxic agents, destroying the infected cell and nearby cells. The most widely used suicide gene/prodrug system is the herpes simplex virus (HSV) thymidine kinase (HSV-tk)/ ganciclovir (GCV) system that can convert the prodrug GCV into phosphorylated GCV. The phosphorylated GCV inhibits cellular DNA synthesis and leads to the killing of cancer cells *via* apoptotic and non-apoptotic mechanisms[29,30]. A similar approach involves the expression of recombinant *E. coli* cytosine deaminase (CD) in gastric cancer cells together with the administration of 5-fluorocytosine (5-FC). 5-FC is given orally and converted to 5-fluorouracil in the tumor cells expressing CD[31] (Table 1).

Table 1 A review of recent methods used in gastric cancer adenoviral gene therapy

Apoptosis inducers & tumor suppressors	
Gene	**Conclusion**
FasL	Infection of human gastric carcinoma cells (SGC-7901) with Ad-FasL showed increased expression of FASL, resulting in apoptosis[32].
HDAC inhibitor	Induces apoptosis in cancer cells expressing wild and pseudo-wild type p53 *via* activating the p53 through acetylation[35].
E2F-1	E2F -1 is a transcription factor that regulates cell cycle progression into S-phase. Combining E2F-1 overexpression with cyclin-dependent kinase inhibitors results in an enhanced apoptotic response, causing nearly complete gastric tumor cell death[33].
Bax	In a study, Ad/Bax made marked Bax protein expression and effective apoptosis in MKN-1, MKN-7, MKN-28 gastric cell lines[34].
p51 and p53	p51 (p73L/p63/p40/KET), a p53 homologue, binds to p53-responsive elements to upregulate some p53 target genes and has been suggested to share partially overlapping functions with p53. p53 is an apoptosis promoting gene which could be used to eliminate tumor growth in gastric cancer. Adenovirally transduced p51A cDNA into human gastric cancer cells promotes apoptosis just like p53[36].
Caspase 8	Adv-Caspase 8 can selectively induce apoptosis in detached carcinoma cells[37].

ANTI ANGIOGENESIS GENES

Angiogenesis is essential for tumors in order to grow and form metastases. It is a multi step process, which is initiated by release of growth factors from cells, these growth factors include growth factors such as the vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF) and hepatocyte growth factor (HGF)[38-40]. Inhibiting angiogenesis in tumors can in theory stop a tumor from functioning and growing, it is especially useful in limiting the dissemination of cancer[41-43]. Anti angiogenesis treatment do not need to specifically target cancer cells to inhibit metastasis as creating an anti angiogenesis environment around the cancer is equally effective. An example of anti angiogenesis genes is NK4, an HGF antagonist. It has been proved that transfecting gastric cancer cells with NK4 can stop the formation of Intra tumor vessels as well as peritoneal metastasis[44]. Another anti angiogenesis gene which can be introduced into cells using adenoviruses is soluble VEGF receptor (sFlt1) (Table 2).

TARGETED GENE THERAPY

One of the challenges of current gene therapy vector development, concerns targeting a therapeutic gene

Table 2 A review of recent methods used in gastric cancer adenoviral gene therapy

Metastasis inhibitors	
Gene	**Conclusion**
NK4	Peritoneal tumors in mice treated early with adenoviral mediated NK4 were significantly reduced. In another study Ad.CMV.NK4 resulted in efficient production and secretion of NK4 and significantly inhibited proliferation, migration and invasion of gastric cancer cells[45].
Flt-1	When administered intra peritoneally it markedly reduced the number of metastatic nodules larger than 1 mm in diameter on the peritoneal surface[46].
Caspase 8	In a study it was determined that Caspase 8 can augment anoikis in MKN-45 cells and suppress its peritoneal dissemination in nude mice with xenograft gastric cancer transplants and consequently increase survival, Caspase 8 has also proved to be useful in limiting metastasis in other carcinomas originating from epithelial tissues[37].

Table 3 A review of recent methods used in gastric cancer adenoviral gene therapy

Targeted gene therapy	
Method	**Conclusion**
HDAC inhibitor	Increase expression of the Coxackie adenovirus receptor and subsequent transfection efficiency of the adenovirus in cancer cells[35].
COX-2	COX-2 promoter shows the strongest cytocidal effect in gastric cancer cells when it is used in a conditionally replicating adenovirus (CRAD) context & with adenoviral vectors displaying 5/3 chimeric fibers[56].
EPCAM	It has been demonstrated that there is a marked difference in expression of the human epithelial cell adhesion molecule (EpCAM) between normal and (pre)malignant lesions of the stomach and esophagus. Based on this, using EpCAM to achieve gastric and esophageal adenocarcinoma selective gene transfer.may be a feasible choice for cancer-specific gene therapy[57]. In a study using EPCAM antibody adhered to adenovirus, transduction of normal gastric epithelium and liver tissue was reduced at least 10-fold in comparison with native adenovirus however tumor transduction levels remained the same[58].
Carcinoembryonic antigen (CEA)	A remarkable degree of targeted gene delivery to gastric cancer cells was obtained with Adv-FZ33 with the fully human anti-carcinoembryonic antigen (CEA) monoclonal antibody, C2-45[59-62].

to diseased cells with the aim of achieving sufficient gene expression in the affected tissue, while minimizing toxicity and expression in other tissues[47,48]. The use of recombinant adenoviruses as vectors for gene therapy is restricted by the widespread distribution of the coxsackie and adenovirus receptor (CAR), which allows infection of a range of tissues and precludes specific *in vivo* targeting[49-51].

Targeting can be achieved at the level of capsid binding or at later transduction events by the use of tissue-specific promoters. Targeting at the level of binding is preferred because even the interaction of cells with empty capsids leads to toxic effects. However a combination of both strategies has its obvious advantages.

Manipulating capsid binding can be achieved by direct genetic modifications of the capsid proteins, or it is possible to add ligands to the capsid *via* polymers like polyethylene glycol (PEG) and poly-[N-(2-hydroxypropyl) methacrylamide] (HPMA). Using these approaches, the native tropism of the virus is ablated either by the addition of polymer to fiber knob or the use of an anti fiber neutralizing antibody in the context of a bi-functional conjugate and creating targeted tropism by adding ligands. For example, for targeting ovarian cancer cells, it is possible to attach FGF to PEG bonded to viral capsid thus increasing specificity and also efficiency of transfection.

Targeting can also be achieved using tissue-specific promoters (TSP)[52-54], for example in alpha-fetoprotein (AFP)-producing gastric tumors, the adenovirus-mediated expression of HSV-tk by an AFP enhancer/promoter element selectively eliminates AFP positive, but not AFP-negative cell lines when treated with ganciclovir[55] (Table 3).

CONCLUSION

During the past 10 years, much has been learnt about molecular alterations in gastric cancer. Based on the understanding of the molecular mechanisms underlying gastric carcinogenesis, new therapeutic strategies targeted at the molecular defects in the tumor cells have been designed and many promising therapy results have been obtained from *in vitro* or *in vivo* studies. Among these approaches, Adenoviral gene therapy has proven to be the most promising however the efficiency of gene therapy for treatment of cancer in humans has remained low, this may be due to low rates of transduction and specificity. There may be many reasons for this, but it is widely agreed that this is mainly due to the relative resistance of cancer cells to introduce foreign material combined with low transgene expression *in vivo*. One of the most important issues affecting the possible clinical application of gene therapy is the need to ensure the highest possible safety levels developing protocols and targeting adenoviral vectors for gastric cell lines may yield the answer to this problem. Another prospect worth mentioning is the benefit of combining several approaches in order to achieve the highest possible therapeutic effect, examples of combined therapy approaches include combining Ad-p53 with HDAC inhibitor and sodium butyrate (SB), this has shown a significantly higher growth suppressive effect than single treatments of each. Another example shows combining NK4 with Cysplatin has enhanced inhibitory effect on peritoneal metastasis, suggesting that the combination of intra peritoneally chemotherapy with NK4 might be effective[63,64].

Recent studies have shed light on pathogenesis of gastric cancer, it has been long argued that *H Pylori* acts as a carcinogenic factor in inducing gastric adenocarcinoma, recent studies have supported this hypothesis, thus an area of future investigation in treatment of gastric cancer could involve *H Pylori* modification and also the intracellular

pathways altered by *H Pylori* in gastric mucosa. Although it has been reported that simple eradication of *H Pylori* without reversing the effects *H Pylori* has caused on gastric mucosa has limited efficacy in preventing gastric cancer, however there is a need for further investigation in this field[65-67].

Abstract

Sedentary lifestyle and poor dietary choices are leading to a weight gain epidemic in westernized countries, subsequently increasing the risk for developing the metabolic syndrome and nonalcoholic fatty liver disease (NAFLD). NAFLD is estimated to affect approximate 30% of the general US population and is considered the hepatic manifestation of the metabolic syndrome. Recent findings linking the components of the metabolic syndrome with NAFLD and the progression to nonalcoholic steatohepatitis (NASH) will be reviewed; in particular, the role of visceral adipose tissue, insulin resistance, and adipocytokines in the exacerbation of these conditions. While no therapy has been proven effective for treating NAFLD/NASH, common recommendations will be discussed.

INTRODUCTION

Sedentary lifestyles and poor dietary choices are contributing to a weight gain epidemic in westernized societies. Recent epidemiological studies suggest an increased risk of cardiovascular disease (CVD) and type Ⅱ diabetes in overweight and obese individuals. Unfortunately, incidence of the metabolic syndrome and nonalcoholic fatty liver disease (NAFLD), which can precede the development of CVD and type Ⅱ diabetes, are also increasing.

The metabolic syndrome, a cluster of metabolic abnormalities with abdominal adiposity and insulin resistance as its central components, affects approximately 25% of the American adult population[1] and is associated with an increased risk of CVD and type 2 diabetes[2]. NAFLD, hepatic steatosis not due to alcohol consumption, is the most common cause of chronic liver disease[3]. It is estimated that about 30% of the general US population has excessive fat accumulation in the liver[3], reaching levels as high as 75%-100% in obese and morbidly obese individuals[4].

The relationship between NAFLD and the metabolic syndrome is becoming increasingly recognized. Approximately 90% of patients with NAFLD have ⩾ 1 characteristic feature of metabolic syndrome and about 33% have the complete diagnosis[5], placing NAFLD as the hepatic representation of the metabolic syndrome[6,7]. In addition, presence of the metabolic syndrome predicts higher risk for the development of NAFLD in both men and women[8]. NAFLD encompasses a histological spectrum ranging from simple hepatic steatosis to nonalcoholic steatohepatitis (NASH), advanced fibrosis, and cirrhosis. The majority of individuals with NAFLD have no symptoms with a normal physical examination; however, about 2%-6% of adult Americans and 20% of those who are obese may develop steatosis with inflammation (NASH), fibrosis, and cirrhosis[9]. Furthermore, there appears to be a close link between the metabolic syndrome, low grade inflammation, and oxidative stress[10].

In this editorial, we will review the clinical links between the components of the metabolic syndrome with

the manifestations of NAFLD and the progression to nonalcoholic steatohepatitis (NASH). In addition, we will discuss the potential role of adipocytokines and oxidative stress in the exacerbation of these conditions. Further, we will briefly discuss commonly prescribed therapeutic treatments.

DIAGNOSIS AND PREVALENCE OF THE METABOLIC SYNDROME

Although an association between different metabolic abnormalities had been noted for several years, the metabolic syndrome was first publicly described in 1988 by Reaven[11]. Then called Syndrome X, the metabolic syndrome consisted of a cluster of metabolic abnormalities, including obesity (especially abdominal obesity), insulin resistance, impaired glucose metabolism, dyslipidemia, and elevated blood pressure[11]. The current definition of the metabolic syndrome varies depending on the position of different regulating bodies[12], and it is not within the scope of this review to delineate the best available definition.

The metabolic syndrome is estimated to affect about 25% of the American adult population[1], and the prevalence will continue to increase dramatically. Regardless of the precise definition, the hallmark features of the metabolic syndrome are impaired glucose tolerance/insulin resistance, hypertension, central adiposity, and dyslipidemia consisting of low high-density lipoprotein-cholesterol (HDL-C) and elevated plasma triglycerides (TG). It is largely believed that insulin resistance is the central feature in the development of the metabolic syndrome.

DIAGNOSIS AND PREVALENCE OF NAFLD

It is estimated that about 30% of the US adult population has NAFLD, approximately 16%-20% of non-obese individuals and as high as 76% and 100% prevalence in the obese and morbidly obese individuals, respectively[4]. Overall, NAFLD is estimated to affect over 90 million Americans. NAFLD is characterized by increased accumulation of triglycerides (TG) in hepatocytes (hepatic steatosis). The diagnosis of NAFLD requires that hepatic steatosis be $\geqslant$ 5% by weight in the absence of excess alcohol consumption (> 20 g/d)[13]. Most people with NAFLD, especially those with fatty liver but no inflammation, experience little to no problems from the condition. The diagnosis usually is first suspected in an overweight or obese person who is found to have mild elevations in specific liver enzymes measured in circulation including elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST), with ALT levels being greater than AST levels.

Currently, the liver biopsy is considered the "gold standard" for the direct measurement of hepatic fat and is the only reliable method for diagnosing fatty liver and/or NASH. However, the liver biopsy has limited applicability in epidemiological and clinical studies and is not routinely performed because of the invasiveness of the procedure. Several non-invasive methods are currently available, which include ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and ^{1}H-magnetic resonance spectroscopy (^{1}H-MRS). Each has its limitations and is only semi-quantitative, but is more easily employed for routine screening.

LINKING THE METABOLIC SYNDROME AND NAFLD

Hyperinsulinemia and insulin resistance play a major role in the pathogenesis of NAFLD[14]. Because insulin resistance is the key component of the metabolic syndrome (often referred to as the insulin resistance syndrome or pre-diabetes) and is also commonly found with obesity, and because these same factors are commonly associated with NAFLD, there is a plethora of accumulating evidence supporting an association between obesity, the metabolic syndrome, and NAFLD[6,7]. In fact, NAFLD is now considered to be the hepatic representation of the metabolic syndrome[14,15].

The metabolic syndrome, in part through glucose intolerance and insulin resistance, is strongly associated with steatosis, fibrosis, and cirrhosis of the liver in severely obese adults[16]. In addition, central fat distribution, fatty liver, and glucose intolerance are noted in mildly obese and in normal weight subjects[17,18]. Further, numerous studies have demonstrated that obesity, type 2 diabetes, dyslipidemia, hypertension, and insulin resistance are strongly associated with NAFLD[12,19-22]. NAFLD also is strongly associated with hepatic, adipose tissue, and whole body reductions in insulin sensitivity, increased rate of gluconeogenesis, impaired insulin response to suppress gluconeogenesis, and impaired fatty acid oxidation[23-25]. However, the question about whether hepatic insulin resistance is a cause or a consequence of hepatic steatosis is unresolved[26-28].

The metabolic syndrome predicts higher risk of NAFLD in men and women, independent of weight gain[8], and those individuals with the metabolic syndrome are less likely to experience regression of NAFLD[8]. In addition to insulin resistance, body mass index and waist circumference, indices of obesity and central adiposity, also are associated with the metabolic syndrome, insulin resistance, fibrosis, and steatohepatitis[29], and both liver fat and visceral adipose tissue stores are associated with metabolic risk[30]. Moreover, HDL-C concentrations are significantly reduced[24] and serum TG and cholesterol levels are elevated with NAFLD[24,30]. Collectively, it appears that insulin resistance is not the only contributing factor in the development of NAFLD, but rather, a combination of multiple stimuli.

IS THE METABOLIC SYNDROME MEDIATING THE PROGRESSION OF NAFLD?

Physical inactivity and poor nutritional choices are leading to a surge in obesity, insulin resistance, and metabolic syndrome in industrialized nations. Day and James[31] proposed the "two-hit hypothesis" to explain the presence of bland steatosis and the progression to inflammation

(NASH), fibrosis, and cirrhosis. Recent findings suggest that components of the metabolic syndrome are integrally involved in the pathogenesis of this two hit model.

The first "hit" is hepatic steatosis, NAFLD in its simplest form, develops from an imbalance in triglyceride formation *vs* turnover. We and others have shown that mitochondrial dysfunction (i.e. impaired mitochondrial β-oxidation) is a primary cause of hepatic steatosis (discussed in detail by Wei *et al* in this issue)[23,32,33]. Insulin resistance is a near essential requirement and is believed to influence the first "hit" of NAFLD in the following ways: (1) activate the secretion of harmful adipocytokines from adipocytes, (2) alter rates of hepatocyte TG synthesis and transport, (3) and finally increases lipolysis [hydrolysis of TG to free fatty acids (FFA)] rates in central adipose which are dumped into the portal vein where they are processed in the liver, exposing the liver to excessive FFA levels[12]. In addition to impaired mitochondrial function and conditions exacerbated by insulin resistance, elevated hepatic *de novo* lipogenesis and TG synthesis strongly contributes to hepatic steatosis. In fact, a recent study found that about 26% of hepatic TG accumulation in NAFLD patients could be accounted for by *de novo* lipogenesis[34].

Once hepatic steatosis is present, other factors, such as inflammation and oxidative stress, are thought to promote progression to NASH, fibrosis, and necrosis. The metabolic syndrome is linked to inflammation and oxidative stress[10], and it has been demonstrated that individuals with the metabolic syndrome have increased lipid peroxidation[35]. The second "hit" likely is comprised of a secondary insult, particularly by adipocytokines and reactive oxygen species, which activate stellate cells and increase fibrogenesis and lipid peroxidation. Hepatic inflammation and fibrosis are associated with the presence and severity of the metabolic syndrome[36]. Furthermore, the presence of steatohepatitis with fibrosis, confirmed with liver biopsy, is associated with increased waist circumference and body mass index[29]. Hyperglycemia and hypertriglyceridemia also are associated with NASH[37], and insulin resistance is more severe in individuals with NASH *vs* simple fatty liver[37]. If the insults are great enough and the patient develops cirrhosis, about 33% of these patients will die or develop morbid conditions[38].

THE METABOLIC SYNDROME AND COMMON LIVER MARKERS

Circulating concentrations of the liver transaminases, ALT, AST, and to less extent γ-glutamyltransferase (GGT) are commonly used as markers of NAFLD for many years. Elevated levels are considered a consequence of liver damage due to fatty acid infiltration and inflammatory stimuli, and recent findings indicate that serum levels of these enzymes are associated with multiple components of the metabolic syndrome.

Increases in ALT are positively associated with each component of the metabolic syndrome, increased TG, glucose, waist circumference, diastolic blood pressure, and reduced HDL-C levels[19]. In addition, insulin resistance, the prevalence of severe liver steatosis, and ALT values have been found to be significantly higher in subjects with the metabolic syndrome compared to those with less than three of the five clinical features considered for its diagnosis[39]. Recent data published from NHANES Ⅲ found significant association with increased ALT and insulin resistance, type Ⅱ diabetes, and the metabolic syndrome[40]. GGT, a less specific marker of liver function, is linked to obesity, hypertension, sedentary lifestyle, hyperinsulinemia, dyslipidemia, inflammation, and oxidative stress[41-45]. Furthermore, GGT concentrations have been found to be associated with hypertension in individuals with central adiposity[46], suggesting the potential for a pathogenic link among fatty liver disease, endothelial dysfunction, and cardiovascular risk.

ROLE OF ADIPOSE TISSUE, FREE FATTY ACIDS, AND ADIPOCYTOKINES

Adipose tissue

Adipose tissue is now recognized as not simply a storage depot for excess energy, but rather, an active endocrine organ that secretes a number of molecules termed, adipocytokines. A number of these adipocytokines have been linked to alterations in insulin sensitivity, including adiponectin, leptin, resistin, and tumor necrosis factor-α (TNFα). In addition, many of the same signaling molecules have been shown to be associated with suppressed hepatic insulin sensitivity[47,48], and it is thought that adipocytokines may contribute to the development of liver fibrosis.

Visceral adipose tissue is more biologically active than subcutaneous adipose tissue and is known to release greater quantities of adipocytokines. Visceral adipose tissue is a better predictor of altered liver function and insulin resistance than obesity defined by body mass index[49,50]. FFAs lipolyzed from visceral adipocytes are dumped directly into the portal vein where they circulate through the liver and with suppressed oxidative capacity seen in insulin resistance will overload hepatocytes with lipid and promote hepatic TG storage.

Free fatty acids

The liver represents a major site of glucose uptake and storage and the major site for insulin clearance. Under normal insulin sensitive conditions, insulin inhibits glycogenolysis and gluconeogenesis by the liver, suppressing glucose production. However, both the metabolic syndrome and NAFLD commonly lead to hepatic insulin resistance in which the most common feature is the inability of insulin to cease hepatic glucose production. Boden *et al*[51] demonstrated that hepatic insulin resistance could be induced in rats by infusing lipids during a euglycemic-hyperinsulinemic clamp, in part by elevating hepatic diacylglycerol concentrations and increasing the activation of protein kinase C, IKκB, and NF-κB. Moreover, free fatty acids (FFA) and lipid intermediate flux from adipocyte lipolysis or from excess dietary intake activate protein kinase C and phosphorylate serine residues on the insulin receptor and insulin receptor

substrates, impairing tyrosine phosphorylation and increasing hepatic insulin resistance which likely lead to elevated glucose production and persistent hyperglycemia.

The liver also responds to elevated FFA by increasing cholesteryl ester synthesis, production of very low density lipoproteins[52], and *de novo* TG synthesis, exacerbating dyslipidemia. In addition, elevated FFA also have toxic effects on the liver due to lipid peroxidation, resulting in fibrogenesis and progression to cirrhosis[53]. Furthermore, lipid-laden hepatocytes also can swell and this architectural distortion can influence hepatocyte health[54].

Leptin

The role of leptin and leptin resistance in NAFLD has been under recent investigation. Under normal, healthy conditions, leptin is thought to play a role in regulation of body weight. However, in human obesity, leptin concentrations are elevated but there is reduced responsiveness to available leptin presumably from reduced leptin receptor expression, resulting in leptin resistance either centrally or locally at the level of the liver. Leptin is thought to play a major role in hepatic TG accumulation[55], and hepatic steatosis is observed in ob/ob and db/db mice that have leptin and leptin receptor mutations, respectively. Elevated leptin levels are associated with increased serum ALT levels and could be involved in promoting hepatocellular injury[56]. However, leptin therapy has been shown to reverse insulin resistance and hepatic steatosis in individuals with lipodystrophy[57]. In addition, existing data from animal studies also support the role of leptin replacement in reducing TG synthesis and inducing β-oxidation[58]. Future studies should focus on leptin receptor expression and the bioavailability of leptin and associations with NAFLD and the metabolic syndrome.

Resistin

Resistin has recently been identified as a signaling molecule that is induced during adipogenesis and secreted by adipocytes, particularly visceral adipose tissue stores[48,59]. Resistin was identified on the basis of an adipocyte specific protein that played a role in insulin resistance. Little attention has been given to the role of resistin in the metabolic syndrome and NAFLD, but available findings targeting resistin appear promising. Resistin levels are increased in NAFLD patients and levels are related to the histological severity of the disease[60]. Resistin gene expression and protein secretion are markedly reduced by anti-diabetic thiazolidinediones (TZDs), and administration of anti-resistin antibody has been shown to improve blood glucose and insulin action in mice with diet-induced obesity[59]. In addition, weight loss interventions in humans have demonstrated significant reductions in circulating concentrations of resistin[48].

TNFα

Adipose tissue represents a site for significant macrophage accumulation, the major source of local TNFα expression[61]. TNFα is an adipocytokine with a well-known role in antagonizing the effects of adiponectin and contributing to insulin resistance[62]; however, recent observations suggest that it also is involved in the metabolic syndrome and progression of NAFLD. In particular, TNFα has been shown to play an important role in mouse models of obesity and insulin resistance, and there also appears to be a link between TNFα levels and liver mitochondrial dysfunction that contributes to NAFLD and NASH. TNFα is elevated in individuals with central adiposity and other components of the metabolic syndrome[63]. It is thought that overproduction of TNFα in liver plays a pathogenic role in NAFLD, as TNF mRNA and TNF receptor 1 mRNA levels are increased in patients with NASH[64]. Furthermore, TNFα alters apolipoprotein metabolism by suppressing apoE secretion and apoA1 expression in HepG2 cells[65] and rapidly down-regulates the anti-oxidative protein associated with high-density lipoprotein, paraxonase-1 (PON1)[66].

Adiponectin

Adiponectin is an adipocyte-specific secretory protein that is found in relatively high circulating levels (5-10 mg/L), but decreased concentrations predict the incidence of CVD, the metabolic syndrome, and NAFLD[67-71]. Adiponectin concentrations are decreased in patients with obesity, insulin resistance, type 2 diabetes, and NAFLD[69,72] and correlate negatively with hepatic fat content[28]. In addition, hyperinsulinemia down regulates adiponectin receptor expression[73], reducing overall biological activity. Adiponectin has antilipogenic effects that may protect non-adipocyte tissues like liver and muscle. Adiponectin stimulates mitochondrial β-oxidation by activating AMP-dependent protein kinase (AMPK)[74] and down regulates a key transcription factor in *de novo* fatty acid synthesis, sterol regulatory element binding protein 1-c (SREBP-1c)[75]. This, in turn, reduces malonyl-CoA levels and the inhibition on carnitine palmityl transferase-1, leading to increased fatty acid oxidation and reduced hepatic TG accumulation[76].

Adiponectin also displays anti-oxidative/inflammatory properties as it may antagonize the effects of inflammatory mediators like TNFα and attenuate the progression of NAFLD by reducing hepatic stellate cell proliferation and increases apoptosis[77]. Furthermore, administrations of recombinant adiponectin in ob/ob mice, a model of NASH, attenuates serum ALT levels and drastically reduces hepatic steatosis[78].

Regardless whether adipocytokines are merely markers of the presence of NAFLD or are playing pivotal roles in the pathogenesis of the disease, existing evidence supports further study of adipocytokines as possible therapeutics for human NAFLD. It appears that alterations in adipocytokines secretion are exacerbating insulin resistance in skeletal muscle and liver and promoting hepatic steatosis and the development of NASH.

THERAPIES OF NAFLD AND THE METABOLIC SYNDROME

With no proven treatment for NAFLD/NASH, the focus of previous investigations has been on the treatment of components of the metabolic syndrome (obesity, hypertension, dyslipidemia, and diabetes). This strategy has

been met with some success and available therapies appear to slow NAFLD development and progression.

Pharmacological interventions

The strong relationship between insulin resistance and NAFLD suggests that insulin sensitizing therapies (TZDs and metformin) might be beneficial in the prevention or improvement in NAFLD. TZDs and metformin are oral glucose-lowering medications used to treat type 2 diabetes that enhance insulin sensitivity and signaling. TZDs bind to the peroxisome proliferator-activated receptors (PPARs) and improve insulin sensitivity, in part, by facilitating enhanced TG storage by adipocytes, suppressing the ectopic storage of lipids into liver and skeletal muscle. In addition, TZDs appear to have anti-inflammatory properties, inhibiting adipocyte gene expression and reduce circulating levels of TNFα and resistin[79], and increase adiponectin concentrations[80]. However, it should be noted that a common side effect of TZDs in clinical trials is weight gain.

Metformin is the drug of choice for treating obesity and type Ⅱ diabetes, and additional findings support its use for treating NAFLD, although the precise mechanism(s) of action are not known. It is known, however, that metformin targets and activates AMPK[81], which has multiple beneficial effects. Administration of metformin reduces hepatic gluconeogenesis, decreases absorption of glucose from the gastrointestinal tract, and increases insulin sensitivity. It also has been shown to reduce hepatic lipogenesis, increase fatty acid oxidation, and reduce serum ALT levels, steatosis, and inflammation in the ob/ob mouse model of NAFLD[82]. Furthermore, metformin use in non-diabetic NAFLD patients has been shown to reduce liver fat by 50% and decrease liver inflammation and necrosis[83].

Lipid lowering agents also can lower risks of the metabolic syndrome and NAFLD. It is well known that statins combat dyslipidemia, a hallmark of the metabolic syndrome, by reducing serum TG and increasing HDL-C levels; however, statins also have been shown recently to improve liver enzymes and hepatic inflammation (reviewed in[84]). Fibrate administration also has been met with marginal success. Furthermore, the angiotensin system is known to play a role in hypertension, and it is thought to be involved in the pathogenesis of hepatic fibrosis and insulin resistance. Although only preliminary evidence exists, treatment with the angiotensin Ⅱ receptor antagonist losartan beneficially improved blood markers of hepatic fibrosis and serum ALT levels[85]. Large, randomized control trials are lacking, but future studies are warranted.

Lifestyle modifications

Lifestyle modifications targeted at increasing physical activity and reducing energy intake are recommended by health care providers for optimal health and are the most common prescribed therapy for individuals diagnosed with NAFLD. In addition, recent cross-sectional studies in humans provide evidence that increased habitual physical activity[86] and cardiorespiratory fitness[87] are inversely associated with NAFLD. However, there are relatively few prospective studies that have examined the effects of aerobic training on the development and prevention of hepatic steatosis in humans or animal models.

Managing body weight is likely the best overall method in the treatment of conditions in both the metabolic syndrome and NAFLD. Since insulin resistance and obesity play a central role in NAFLD, weight loss is the mainstay of treatment. The weight loss program should be centered on the caloric restriction rather than alteration of dietary contents, with a prescription of both aerobic and resistance training exercise. Initial goals from the patient should be a 10% reduction in body weight by the combination of exercise training and energy restriction. This should be targeted over a 6 mo period, and it is important that individuals continue exercising to maintain the lost weight and for overall cardiometabolic health.

Weight loss by energy restriction significantly reduces hepatic TG content, rates of endogenous glucose production, and increases insulin suppression of endogenous glucose production in type 2 diabetics[88]. Surgical weight loss has been reported to reduce prevalence of the metabolic syndrome, liver steatosis, inflammation, and fibrosis[89]. However, these findings are not universal and it has been suggested that rapid weight loss may in fact, significantly increase hepatic steatosis, presumably from increased FFA flux from elevated rates of lipolysis. Exercise training in combination with energy restriction significantly reduces fatty liver and serum ALT concentrations in obese individuals with NAFLD[90]. Furthermore, weight loss (10%) by diet and exercise significantly elevates adiponectin concentrations[72]. Moreover, we recently have shown that weight loss by diet and exercise significantly reduces circulating leptin concentrations[91] and improves insulin sensitivity and lipid peroxidation in overweight and obese adults with components of the metabolic syndrome[92].

CONCLUSION

Most experts consider NAFLD to be the hepatic manifestation of the metabolic syndrome. The progression from hepatic steatosis to steatohepatitis may worsen insulin resistance and dyslipidemia, or the worsening of peripheral factors may mediate alterations in the liver. Regardless of the initiating pathophysiological event(s), recent findings emphasize the important links between NAFLD and the metabolic syndrome. Future investigations targeting the components of the metabolic syndrome as they exacerbate conditions of NAFLD are warranted. Furthermore, weight loss and insulin-modulating pharmacologic agents are the most effective treatment thus far, but combination therapies of lifestyle modifications and pharmacological agents could prove to be more effective than the individual prescription of specific drugs.

Abstract

Nonalcoholic fatty liver disease (NAFLD) includes hepatic steatosis, nonalcoholic steatohepatitis (NASH), fibrosis, and cirrhosis. NAFLD is the most common liver disorder in the United States and worldwide. Due to the rapid rise of the metabolic syndrome, the prevalence of NAFLD has recently dramatically increased and will continue to increase. NAFLD has also the potential to progress to hepatocellular carcinoma (HCC) or liver failure. NAFLD is strongly linked to caloric overconsumption, physical inactivity, insulin resistance and genetic factors. Although significant progress in understanding the pathogenesis of NAFLD has been achieved in years, the primary metabolic abnormalities leading to lipid accumulation within hepatocytes has remained poorly understood. Mitochondria are critical metabolic organelles serving as "cellular power plants". Accumulating evidence indicate that hepatic mitochondrial dysfunction is crucial to the pathogenesis of NAFLD. This review is focused on the significant role of mitochondria in the development of NAFLD.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) encompasses a disease spectrum ranging from simple hepatic steatosis to steatohepatitis (NASH), fibrosis, and cirrhosis. NAFLD has a very high prevalence in the US and worldwide[1]. It is becoming the leading cause for referral to liver clinics in most areas. In the US, it occurs in about 20%-35% of the population in over 60 million of the general adult population. Further, NAFLD occurs in about 2.6% of children and up to 53% of obese children are diagnosed with NAFLD[2,3]. The prevalence of NAFLD will likely continue to rise. Obesity, hyperglycemia, type 2 diabetes and hypertriglyceridemia are most important risk factors. Genetic factors undoubtedly predispose to NAFLD, as supported by higher prevalence of steatosis in Hispanics than Caucasians and African-Americans[4]. NAFLD has the potential to progress to hepatocellular carcinoma (HCC) or liver failure, both events that ultimately lead to early death.

DEFINITION AND CHARACTERISTICS OF NAFLD

NAFLD is defined as an excess of fat in the liver in which at least 5% of hepatocytes display lipid droplets[5] that exceed 5%-10% of liver weight[6,7] in patients who do not consume significant amounts of alcohol (140 g ethanol/week for men and 70 g ethanol/week) for women[8]. However, this definition is still controversial, because there is only 1.7% ± 0.2% of liver fat content in some healthy men[9] and liver fatty accumulation is absent in hepatic cirrhosis[10]. Morphologically, hepatic steatosis manifests as accumulation of macrovesicular or microvesicular intracytoplasmic fat droplets in hepatocytes. In macrovesicular steatosis, a large single fat vacuole fills the cytoplasm of hepatocytes and displaces the nucleus to the periphery, causing a characteristic signet ring appearance. In microvesicular steatosis, numerous small lipid droplets occupy the cytoplasm of hepatocytes and do not displace the nucleus to the periphery. Hepatic steatosis can be reversible or progress to NASH depending on the cessation or persistence of the underlying provocative cause, respectively. NASH represents steatosis, inflammation, fibrosis, ballooning hepatocytes, apoptotic cells and Mallory's hyaline. The inflammatory extent varies considerably and does not always correlate with the degree of steatosis. Infiltrating inflammatory

cells consist of lymphocytes and polymorphonuclear leukocytes. Apoptotic ballooned and Mallory hyaline hepatocytes may indicate the onset of NASH. Liver cell death and inflammation activate stellate cells leading to the development of hepatic fibrosis that often commences in zone 3 and manifests as perisinusoidal, perivenular (around terminal hepatic veins), and pericellular fibrosis. Hepatic steatosis, inflammation and aggressive fibrogenesis as well as sustained hepatocellular proliferation contribute to the development of liver cirrhosis.

DIAGNOSIS OF NAFLD

The majority of patients with NAFLD are asymptomatic or may complain of fatigue, exercise intolerance, or unspecific, vague abdominal pain in the right upper quadrant[5]. Physical examination can be unremarkable, although a palpable enlarged liver is frequent. Liver tests usually show minor nonspecific abnormalities. Alanine aminotransferases and gamma-glutamyl transpeptidase levels are elevated in most cases, but may be normal in some patients with advanced NASH and hepatic cirrhosis[11]. Imaging techniques including ultrasonography and magnetic resonance imaging are useful to detect degrees of steatosis, but can not distinguish inflammatory activity and fibrosis. Liver biopsy is still the gold standard for the diagnosis of NASH and fibrotic severity[12-14] which can be used to evaluate the degree of steatosis, inflammation, and fibrosis and also can help exclude other causes of liver disease[15].

PATHOGENESIS OF NAFLD

A currently favored hypothesis is that "two hits" are required for a subject to develop NASH[16]. The first hit leads to hepatic steatosis, and the second to hepatocyte injury and inflammation. However, the primary metabolic abnormalities leading to lipid accumulation within hepatocytes has remained poorly understood. Accumulating evidence indicates that mitochondrial dysfunction plays a central role in the pathogenesis of NAFLD, and that NAFLD is a mitochondrial disease[17].

Liver and metabolism

The liver, as a super metabolic achiever in the body, plays a critical role in metabolism of carbohydrate, protein and fat to maintain blood glucose and energy homeostasis.

Hepatic mitochondria: Mitochondria serve as the cellular powerhouse that generates ATP or heat by using substrates derived from fat and glucose. Hepatocytes are normally rich in mitochondria and each hepatocyte contains about 800 mitochondria occupying about 18% of the entire liver cell volume. Mitochondria play an important role in hepatocyte metabolism, being the primary site for the oxidation of fatty acids and oxidative phosphorylation. A mitochondrion contains inner and outer membranes composed of phospholipid bilayers and proteins. The outer mitochondrial membrane contains numerous integral proteins called porins, which contain a relatively large internal channel that is permeable to all molecules of 5000 daltons or less. Larger molecules can only traverse the outer membrane by active transport through mitochondrial membrane transport proteins. Unlike the outer membrane, the inner membrane does not contain porins, and is highly impermeable; almost all ions and molecules require special membrane transporters to enter or exit the matrix. The inner mitochondrial membrane contains proteins with four types of functions: the oxidation reactions of the respiratory chain; ATP synthase; specific transport proteins that regulate the passage of metabolites into and out of the matrix; protein import machinery. The matrix contains a highly concentrated mixture of hundreds of enzymes. Of the enzymes, the major functions include oxidation of pyruvate and fatty acids, and the citric acid cycle. The mitochondrial respiratory chain (MRC) is extremely important for energy generation and it consists of multiple polypeptides. Most of the respiratory chain polypeptides are encoded by nuclear DNA, but some are encoded by mitochondrial DNA (mtDNA). mtDNA is a circular double-stranded molecule located in the mitochondrial matrix. mtDNA is extremely sensitive to oxidative damage due to its proximity to the inner membrane, the absence of protective histones, and the incomplete DNA repair mechanisms in mitochondria. Therefore, any factors that affect mitochondrial integrate will cause reduced mitochondrial function.

Hepatic free fatty acids sources: (a) dietary triglycerides (TG) as chylomicron particles from the intestine; (b) *de novo* synthesis in the liver; (c) Free fatty acids (FFA). influx into the liver from lipolysis of adipose tissue; (d) diminished export of lipids from the liver; and (e) reduced oxidation of fatty acids. Imbalance of these metabolic steps will increased TG accumulation within the cytoplasm of hepatocytes.

Hepatic mitochondrial fatty acid oxidation: Fatty acid oxidation (FAO) is the major source of energy for skeletal muscle and the heart, while the liver oxidizes fatty acids primarily under the conditions of prolonged fasting, during illness, and during periods of increased physical activity. FAO also plays an essential role in the intermediary metabolism of the liver. The oxidation of fatty acids in the liver fuels the synthesis of ketone bodies, 3-hydroxy butyrate and acetoacetate, which are utilized as alternative sources of energy by extrahepatic organs, like the brain when blood glucose levels are low. FAO occurs in three subcellular organelles, β-oxidation in mitochondria and peroxisomes, and ω-oxidation in the endoplasmic reticulum[18,19]. Mitochondrial β-oxidation is the dominant oxidative pathway for the disposal of fatty acids under normal physiologic conditions and is primarily involved in the oxidation of short-chain ($< C_8$), medium-chain (C_8-C_{12}), and long-chain (C_{12}-C_{20}) fatty acids. Short-chain and medium-chain FFAs freely enter the mitochondria, while long-chain FFAs entry into the mitochondria is regulated by the activity of the enzyme carnitine palmitoyl transferase I (CPT- I). Glycolysis generates pyruvate, which is transformed by mitochondria into acetyl-CoA, an intermediate that goes through the citric acid cycle for the production of reducing agents and ATP. However, when glucose and energy levels are

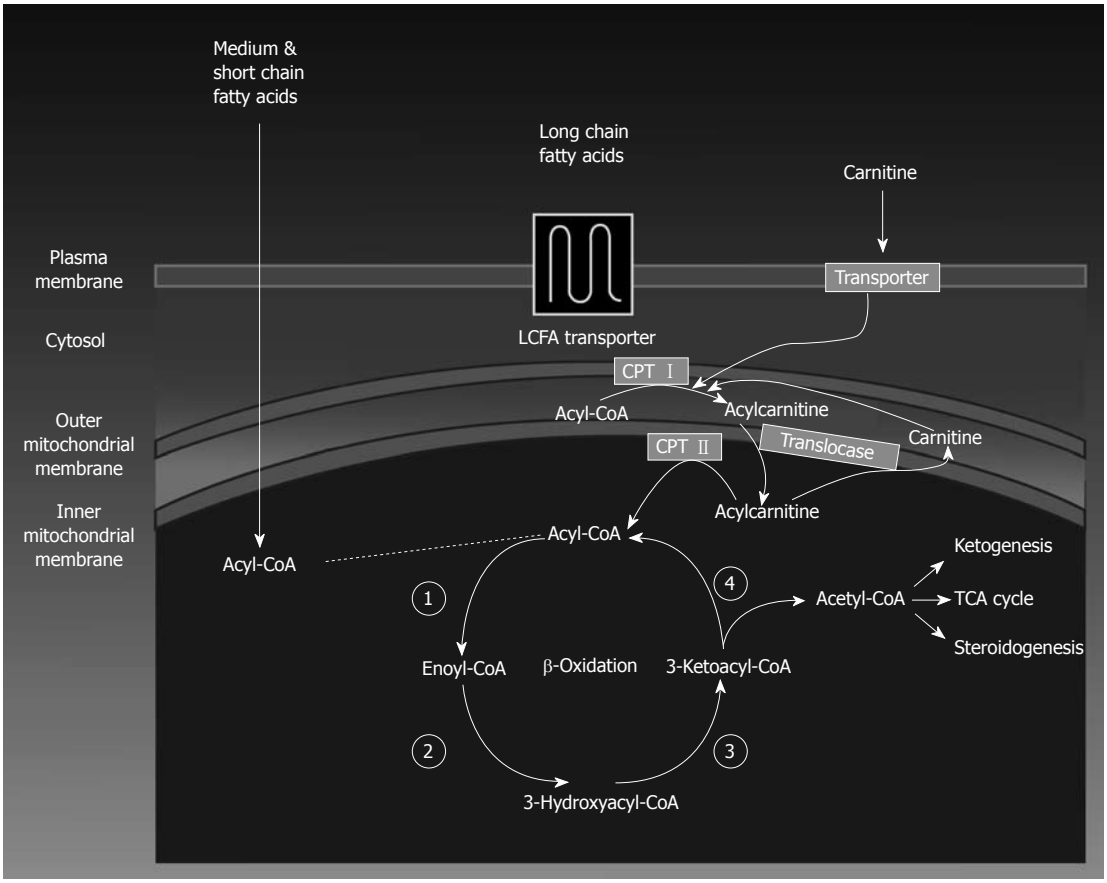

Figure 1 An illustration of mitochondrial fatty acid β-oxidation. LCFA: long-chain fatty acid; TCA: tricarboxylic acid.

elevated, acetyl-CoA is converted to citrate which can leak out of the mitochondrial matrix into the cytosol through the tricarboxylate carrier. In the cytosol, citrate regenerates acetyl-CoA which is converted to malonyl-CoA by acetyl-CoA carboxylase. Malonyl-CoA plays important roles in both hepatic fatty acid oxidation and lipid synthesis. Malonyl-CoA is the initial component for fatty acid synthesis. High malonyl-CoA levels also actively inhibit CPT- I enzyme activity thus robustly decreasing fatty acid oxidation by reducing the rate of fatty acid entry into the mitochondria. Thus, periods of caloric overconsumption, and excessive energy supply, increase malonyl-CoA levels which promotes hepatic fatty acid synthesis (storage) and suppresses fatty acid oxidation (catabolism). Conversely, in the fasting state, hepatic malonyl-CoA levels are low, allowing extensive mitochondrial import of long-chain FFAs and high rates of β-oxidation. Figure 1 depicts the pathway for mitochondrial fatty acid oxidation. During β-oxidation in mitochondria, FFAs undergo a dehydrogenation, then hydration, followed by a second dehydrogenation, and finally thiolysis, releasing one 2-carbon acetyl-CoA molecule and a shortened fatty acid (Figure 1). The cycle is repeated to split the fatty acid into acetyl-CoA subunits. The acetyl-CoA units enter the citric acid cycle to produce reducing agents which can be converted to ATP in the electron transport chain. Under fasting conditions, acetyl-CoA moieties can be converted into ketone bodies (acetoacetate and β-hydroxybutyrate), which are released by the liver to be oxidized in peripheral tissues by the tricarboxylic acid cycle.

MITOCHONDRIAL DYSFUNCTION IN NAFLD

Although the mechanisms responsible for fatty liver are still not fully elucidated, decreased capacity to oxidize fatty acids, increased delivery and transport of FFAs into the liver, and augmented hepatic fatty acid synthesis are likely to play a significant role in the pathogenesis of NAFLD. We and others have shown that mitochondrial abnormalities are closely related to the pathogenesis of NAFLD which raised the possibility that NAFLD is a mitochondrial disease[17,20-22]. The mitochondrial abnormalities associated with NAFLD include ultrastructural lesions, depletion of mitochondrial DNA (mtDNA), decreased activity of respiratory chain complexes, and impaired mitochondrial β-oxidation. Abnormal morphologic changes in liver mitochondria have been observed in patients and animal models with NASH[18,20-24]. Electronic microscopy revealed that mitochondria in NAFLD are big and swelled, scarce in number, and that the mitochondrial matrix has paracrystalline inclusions and hypodensity. Figure 2 shows an example of the ultrastructural changes in the mitochondrial in a mouse model with a fatty acid oxidation defect and hepatic steatosis that we have generated and reported earlier[22]. We have also found similar mitochondrial lesions in other rodent models that develop hepatic steatosis/NASH (data not shown). These same mitochondrial lesions are found in liver biopsy specimens from patients treated with 4,4'-diethylaminoethoxyhe xestrol, a drug that inhibits mitochondrial respiratory

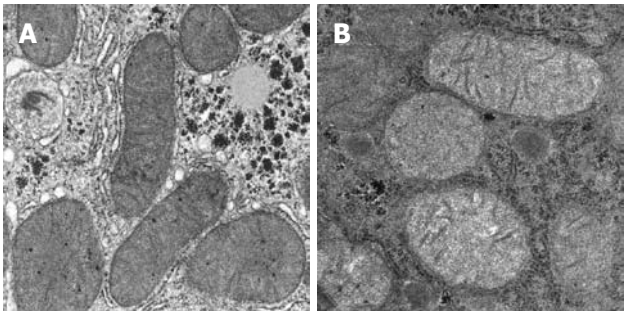

Figure 2 Representative electron micrograph of hepatocytes from control wild-type mice (MTPa$^{+/+}$) (**A**) and mice heterozygous for a mitochondrial trifunctional protein defect (MTPa$^{+/-}$) (**B**) at 11 700 × magnification. The MTPa$^{+/-}$ mice develop hepatic steatosis (see Figure 3). The mitochondria from the MTPa$^{+/-}$ mice were swollen with hypodense matrix and disrupted cristae. Reproduced with permission from *Gastroenterology*. 2005; 128: 1381-1390.

chain (MRC) activity and mitochondrial β-oxidation[25]. Prolonged treatment with this agent is associated with hepatic steatosis and steatohepatitis that is histologically indistinguishable from NAFLD in humans[25]. The ultrastructural mitochondrial defects in patients with NAFLD may be indicative of defective mitochondrial functions, e.g. reduced MRC activity[26] and impaired ATP synthesis[27]. NAFLD is often found in patients with insulin resistance, obesity and type 2 diabetes, the same metabolic conditions in which there is decreased oxygen consumption and ATP production, reduced total mtDNA and mtDNA transcription factor A, and reduced content of respiratory proteins in the fat, muscle and liver[28]. Many genes encoding mitochondrial proteins in skeletal muscle and fat are negatively correlated with body mass[29-33]. mtDNA depletion in hepatocytes impairs mitochondrial function and causes hepatic steatosis and other liver injury[34,35]. Patients with NASH have decreased expression of mtDNA-encoded polypeptides[36] and low activity of complexes Ⅰ, Ⅲ, Ⅳ and Ⅴ[26]. Mice with genetic deletion of NEIL1 DNA glycosylate have increased mtDNA damage and deletions and develop fatty liver disease[37].

Multiple enzymes are involved in mitochondrial β-oxidation and deficiency of these enzymes may lead to the development of hepatic steatosis, e.g. mice with disrupted medium-chain and very-long-chain acyl-CoA dehydrogenase genes manifest defects in fatty acid oxidation that likely lead to the witnessed micro- and macrovascular hepatic steatosis found in these mice. Mitochondrial trifunctional protein (MTP) is a heterotrimeric protein that consists of four α-subunits and four β-subunits and catalyzes long-chain fatty acid oxidation. MTP defects in humans are recessively inherited, and children with defects of any of the three enzymatic activities exhibit mostly microvesicular hepatic steatosis. We have generated a mouse model for a null mutation causing complete MTP deficiency and demonstrated that homozygous mice develop hepatic steatosis immediately after birth[38]. In subsequent report, we have documented that aging mice heterozygous for the MTP defect also become insulin resistant and develop hepatic steatosis as shown in Figure 3[22]. Further, the activity of mitochondrial respiratory chain complex is decreased in liver tissue of patients and animal models with NAFLD[26,39].

A number of mechanisms can be considered to explain the mitochondrial dysfunction found in NAFLD patients and animal models. Possible mechanisms include (a) excessive reactive oxygen species (ROS) production, (b) increased TNF-α expression, and (c) altered PGC-1 expression.

Reactive oxygen species

MRC dysfunction can directly lead to the production of ROS. If electron flow is interrupted at any point in the respiratory chain, the preceding respiratory intermediates can transfer electrons to molecular oxygen to produce superoxide anions and hydrogen peroxide[40,41]. Malondialdehyde and 4-hydroxynonenal, two byproducts of lipid peroxidation, can inhibit mitochondrial cytochrome *c* oxidase by forming adducts with this enzyme. ROS-induced depletion in mtDNA can severely lower mitochondrial number and function leading to steatosis and liver lesions[34]. Such depletion can impair the synthesis of complexes Ⅰ, Ⅲ, Ⅳ and Ⅴ of the MRC, because mtDNA encodes for 13 of the MRC polypeptides. Evidence of oxidative stress has been found in patients with NASH[21]. Decreased activity of the MRC in ob/ob mice is in part attributable to the oxidative stress, because treatment of ob/ob mice with antioxidant MnTBAP, a mimic of manganese superoxide dismutase, improved the activity of several complexes of the MRC. Surprisingly, activity of complex Ⅱ, which polypeptides are only encoded by nuclear DNA, decreased even more in ob/ob mice treated with MnTBAP. Furthermore, liver histology improved markedly in mice treated with MnTBAP. MRC complexes' activity was reduced by 30% to 50% versus control activity. These complexes' activity was inversely correlated to blood TNF-α levels, body mass index, and HOMA index[26].

TNF-α

Another important factor to consider in the pathogenesis of mitochondrial dysfunction is TNF-α. High blood TNF-α levels have been found in patients with NASH[26,42,43]. In ob/ob mice TNF-α concentrations in liver tissue were some 20-fold higher than in normal mice[39]. The likely sources of the hepatic TNF-α are hepatocytes and Kupffer cells[44]. TNF-α induces mitochondrial swelling with a lighter matrix and a loss of septa. In addition, TNF-α induced swelling of the mitochondria causes a bursting of the mitochondrial membrane leading to an interference between MRC complexes Ⅰ and Ⅲ[45,46]. Anti-TNF-α treatment in ob/ob mice improve complex Ⅰ, Ⅱ, Ⅲ and Ⅴ activity, β-oxidation activity, and liver histology[39].

PGC-1

Nuclear receptors are pleiotropic regulators of glycolytic and oxidative metabolism[47]. Mitochondrial activity is transcriptionally controlled, in part, by the nuclear receptors and the peroxisome proliferator-activated

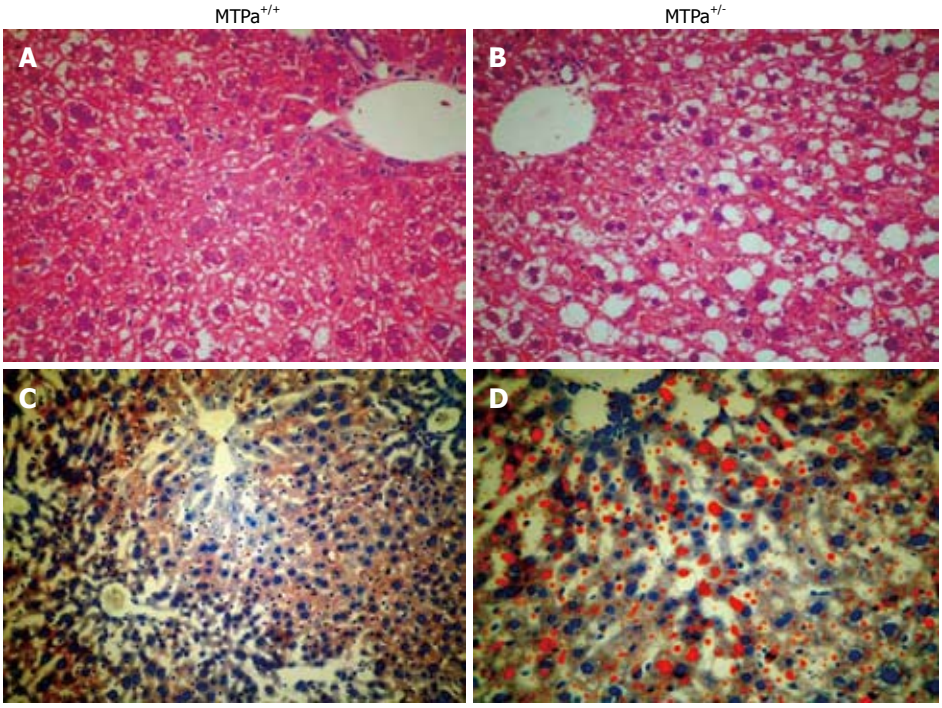

Figure 3 Representative liver sections obtained from control wild-type mice ($MTPa^{+/+}$) (**A** and **C**) and mice with a defect in mitochondrial trifunctional protein ($MTPa^{+/-}$) (**B** and **D**) littermates stained with hematoxylin-eosin (**A** and **B**) and oil red O (**C** and **D**) (20 ×). receptor-γ coactivator 1 (PGC-1)-related protein family such as PGC-1α and PGC-1β[48,49]. PGC-1α and PGC-1β are preferentially expressed in tissues with high oxidative capacity such as heart, skeletal muscle and brown adipose tissue, where they serve critical roles in the regulation of mitochondrial functional capacity and cellular energy metabolism[50-53] PGC-1α potently induces the expression of genes implicated in energy homeostasis in almost every cell type through known mitochondrial regulators such as the estrogen-related receptors (ERRs), peroxisome proliferator-activated receptor δ, or nuclear respiratory factor (NRF-1, 2)[48,49,54,55]. Overexpression of PGC-1α in skeletal muscle cells results in an increased energy expenditure, mitochondrial biogenesis[52,53], whereas loss of PGC-1α results in reduced muscle performance, cardiac defects, and other metabolic and behavioral defects[56,57]. Liver expresses low levels of PGC-1α and PGC-1β at normal condition, however, their expression is upregulated at fasting[58-60]. PGC-1α and PGC-1β activate hepatic fatty oxidation by inducing expression of PPARα[59,60]. Hepatocytes from PGC-1α deficient mice have diminished FAO activity and mitochondrial respiration rates[49].

CONCLUSION

Genetic, environmental and nutritional factors are involved in the pathogenesis of NAFLD, which is nowadays a major public health problem. In the absence of proven pharmacological therapy of NAFLD, it is critical to explore its pathogenesis and novel therapeutic pathways. In this Editorial, we have reviewed evidence that implicates mitochondrial dysfunction as a primary mechanism for development of NAFLD. Mitochondrial dysfunction may not only cause fat accumulation, but also may lead to the generation of ROS and cytokine production contributing to progression of NAFLD by inducing hepatic inflammation and fibrosis.

Abstract

The c-Jun NH2-terminal Kinase (JNK) pathway represents one sub-group of the mitogen-activated protein (MAP) kinases which plays an important role in various inflammatory diseases states, including inflammatory bowel disease (IBD). Significant progress towards understanding the function of the JNK signaling pathway has been achieved during the past few years. Blockade of the JNK pathway with JNK inhibitors in animal models of IBD lead to resolution of intestinal inflammation. Current data suggest specific JNK inhibitors hold promise as novel therapies in IBD.

INTRODUCTION

Although our understanding of the pathogenesis of inflammatory bowel disorders (IBD), especially Crohn's disease (CD) and ulcerative colitis (UC) has greatly improved, the specific causes are still not known. Cytokines such as TNF-α, IL-1 and IFN-γ play an important role in the pathogenesis of IBD[1,2]. Elucidating the mechanisms of cytokine induced inflammation in IBD could lead to novel therapies. Recent studies have focused on the identification of intracellular signaling pathways and transcription factors through which cytokines mediate their effects. Mitogen-activated protein kinases (MAPKs) are components of the signaling cascades where diverse extracellular stimuli converge to initiate inflammatory cellular responses. MAPKs are made of three subgroups-p42/44 extracellular signaling kinase (ERK), Jun-N-terminal Kinase (JNK), and p38 MAP Kinase[3]. Recent studies have highlighted the importance of the JNK pathway in IBD. This review will focus on the role of the JNK signaling pathway in IBD.

THE JNK-MAPK PATHWAY

The mammalian JNK were initially called stress activated protein kinase (SAPK) because they were activated by a variety of environmental stresses[3,4]. Later, the JNK pathway was also discovered to respond to cytokines, such as TNF-α and IL-1, and growth factors. JNK is a multi-factorial kinase involved in several physiological and pathological processes. Specific stimuli trigger the activation of MAP3Ks, which then phosphorylate and activate the MAP2K isoforms MKK4 and MKK7, which in turn phosphorylate and activate JNK[5]. JNK was discovered to phosphorylate c-Jun at the NH2-terminal Ser63 and 73 residues, and thus termed JNK. However, several recent studies have shown that JNK can phosphorylate a variety of substrates, including additional transcription factors and some non-nuclear proteins[3,6]. In addition to c-Jun, JNK can phosphorylate transcription factors such as JunB, JunD, c-fos, ATF2 and ATF3. These transcription factors along with c-Jun, make up the Activator Protein-1 transcription factor (AP-1), which regulates the expression of several stress-responsive genes. The JNK class of enzymes comprises of three main types: JNK1, JNK2, and JNK3[4,7]. The first two are ubiquitous, whereas the third is restricted to the brain, heart and testis. Differential splicing and exon usage results in multiple isoforms of JNK1, 2 and 3 genes. Each JNK is expressed as a short form (46 kDa) and long form (54 kDa)[3]. The alternative forms of each JNK1, 2, and 3 appear to differ in their ability of bind and phosphorylate different substrate proteins. Targeted gene disruption of each JNK has also defined differential functions for JNK1, JNK2 and JNK3 in many different cell types[7]. Deletion of JNK1 or JNK2 resulted in defective T cell differentiation and activation[8].

ROLE OF JNK IN IBD

The JNK pathway is considered to be a potentially relevant target for therapy inflammatory disease states. JNK regulates the maturation and activity of T cells and synthesis of pro-inflammatory cytokines such as interleukin-2 (IL-2), IL-6 and TNF-α. Several recent studies have demonstrated the importance of JNK pathway in chronic inflammatory disorders involving the expression of specific proteases and cytokines. For example, JNK pathway appears to be involved in the expression of TNF-α in rheumatoid arthritis[9]. JNK inhibitors such as SP600125 protected mice from joint damage in rheumatoid arthritis animal models[9]. Additionally, the JNK pathway also plays a role in artherosclerosis[10,11]. These findings led to the investigation of the role of JNK pathway in intestinal inflammation.

JNK activation in human intestine in patients with IBD was shown in 4 studies[12,13]. Increased activation of JNK along with ERK and p38 MAPK in human colonic tissue from 27 patients with moderate to severe CD or UC was first shown by Waetzig et al. Hommes *et al* also noted increased activation of p38 and JNK in their study involving 12 patients. Mistsuyama *et al* subsequently confirmed these findings in their recent study. They examined whether JNK phosphorylation was greater in sites of active inflammation compared to normal intestine in patients with IBD. Both ELISA and immunostaining demonstrated that JNK was highly activated in colonic tissue with active disease. Phospho-JNK was present in the intestinal cells, macrophages and lymphocytes, localized pre-dominantly in the nucleus. These findings validated the results from *in-vitro* cell culture studies[14]. Interestingly, increased JNK activation has also been shown in steroid-resistant patients[15]. The significance of this finding is currently unclear. The detection of enhanced activation of JNK in intestinal tissue in patients with IBD may serve as a diagnostic tool for early recognition of steroid unresponsiveness. Role of the different isoforms of JNK in IBD was investigated in a recent study[16]. Deletion of either JNK1 or JNK2 did not prevent the development of colitis in animals. However, deletion of JNK2 was associated with deterioration of disease activity. Further studies examining the role of different isoforms of JNK in IBD are needed.

The role of JNK inhibitors as potential therapies for IBD has been studied in both animal models of IBD and in humans. There are at least 40 different small-molecule JNK inhibitors that have either published or patented[3]. These inhibitors either affect JNK signaling pathway indirectly (e.g. CEP 1347) or block the catalytic domain of JNK (e.g. SP 600125). Unfortunately, most of these compounds only have a moderate specificity for JNK and may also interfere with other signaling pathways. Peptide inhibitors of JNK pathway, which have a higher specificity for their targets, are currently being developed. However, one of the major obstacles with peptide drugs is their rapid degradation and difficulty with delivery across cell membranes. These obstacles have been reportedly overcome by a recently described cell-permeable peptide that contains the JNK-binding domain of human c-Jun. Two studies assessed the effect of JNK inhibitor, SP 600125, on dextran sodium sulphate (DSS) colitis animal model[12,17]. SP 600125 is a reversible ATP-competitive inhibitor of protein kinases. It targets all the three different isoforms of JNK. At higher concentrations, it inhibits other protein kinases upstream of JNK (namely MKK3, and MKK6). One study evaluated SP 600125 in a rat model (Sprague-Dawley rats) of DSS colitis while the other used a mice model (C57BL/6) of DSS colitis. Both studies demonstrated the activation of JNK pathway in inflamed intestinal tissue in DSS induced colitis. JNK inhibition showed a marked protective effect against experimental colonic injury in animals. Specifically, treatment with SP600125 led to attenuation of weight loss and macroscopic damage. A beneficial effect was also noted on the histological severity of colitis. Destruction of the epithelial layer and glandular architecture, inflammatory infiltrates in the lamina propria, and edema of the submucosa in the colon was less severe in the SP600125 treated animals. Treatment with SP 600125 also resulted in a significant reduction in the levels of TNF-α, IL-6 and IFN-γ. Additionally, SP 600125 inhibited cytokine production by activated CD3/CD28 mesenteric lymphocytes[17]. One major limitation of these studies is that a more specific inhibitor of JNK was not investigated. Animal studies utilizing a peptide inhibitor or SiRNA against the JNK pathway are needed. Human studies have also suggested similar benefits of JNK blockade to those seen in animals. CNI-1493, a guanylhydrazone that inhibits the phosphorylation of both JNK and p38 MAP kinase, was studied in an open- label pilot study in 12 patients with moderate to severe Crohn's disease. Two different doses of CNI-1493 (8 or 25 mg/m^2) were given intravenously once daily for 12 d. A significant change in CDAI from baseline was noted at wk 2 and persisted up to wk 16. CRP levels decreased significantly during the first weeks of treatment. Endoscopic improvement was observed in all but one patient. Five patients had active fistulizing CD, and closure of the fistula was observed in 4 patients. A steroid sparing effect was seen in 89% of patients maintained on steroids. Additionally, CD-related arthralgia/arthritis resolved in all patients. Although the small sample size in this study precludes any significant conclusions, this study suggests CNI-1493 has significant therapeutic potential in CD. Further studies using JNK specific inhibitors in IBD are currently needed.

CONCLUSION

The JNK pathway plays an important role in various inflammatory disorders. Recent data suggest that JNK activation plays an important role in the intestinal inflammation in patients with IBD. However, the role of the different JNK isoforms in IBD has not been elucidated. Additionally, the mechanism by which JNK activation leads to intestinal inflammation is unclear and deserves further study. Cross talk of JNK pathway with other signaling pathways also needs to be investigated. Recent studies suggest a role for JNK blockade in IBD therapy. However, JNK inhibitors which could also inhibit other kinases were used. Studies using JNK specific inhibitors (e.g. peptide inhibitors) are needed. To increase

the likelihood of success, it may be important to develop isoform-specific JNK inhibitors, as they are likely to have increased efficacy and specificity resulting in fewer potential side effects.

Abstract

AIM: To measure the frequency of DNA methylation of the tissue inhibitor of metalloproteinase 3 (TIMP3) promoter and relate this to any change of gene expression in esophageal squamous cell carcinoma in patients from a region of high incidence in China.

METHODS: Cancer cell lines were treated with or without the demethylating reagent 5-aza-2′-deoxycytidine. Methylation of the TIMP3 promoter was assessed in three regions by melt curve analysis and its expression was assessed by real-time RT-PCR. Tumors and proximal resection margins were obtained from 64 patients with esophageal squamous cell carcinoma from a region of high incidence in China. Methylation was assessed by melt curve analysis and expression by immunohistochemistry.

RESULTS: Methylation in one of the three promoter regions assessed correlated with gene silencing in esophageal cell lines. A degree of methylation of TIMP3 was found in only four esophageal squamous cell carcinomas, and partial loss of TIMP3 protein expression in just one.

CONCLUSION: Methylation and loss of expression of TIMP3 occurs infrequently in esophageal squamous cell carcinoma in a region of high incidence in China.

INTRODUCTION

Tumor invasion, metastasis and angiogenesis require proteolysis and remodeling of basement membranes and extracellular matrix (ECM) by enzymes such as matrix metalloproteinases (MMPs). The MMPs can degrade all components of the ECM, which makes regulation of these enzymes important in the development and dissemination of cancer. Many factors, including inflammatory cytokines, growth factors, hormones, and cell-cell and cell-matrix interactions can alter the transcription of the MMP genes[1], while enzymes can be specifically inhibited by TIMPs, which bind covalently to the active site of the enzyme. Altered expression of MMPs is associated with a poor prognosis in a range of solid tumors[2].

TIMP3, which binds to the ECM, is a multifunctional secreted protein with properties not just limited to the inhibition of MMPs. These roles of TIMP3 in cancer progression are highlighted in reports that its vector-mediated expression in cancer cells reduces metastasis[3], induces apoptosis, augments drug sensitivity in prostate cancer cell lines[4], and inhibits tumor growth in lung cancer cells in an *in vivo* model[5].

A reduction in TIMP3 expression has been reported to correlate with poor outcome in a number of cancers. DNA methylation of gene promoters is one method of silencing transcription, and TIMP3 methylation has been noted in a wide range of tumors. Reports indicate that the reduced expression of TIMP3 is a common occurrence in esophageal adenocarcinoma (EAC), is associated with methylation of the promoter, and correlates with poor outcome[6,7]. TIMP3 is also frequently methylated in Barrett's esophagus (BE), and has been investigated as a prognostic indicator for progression to EAC[8,9]. In contrast to the many studies of EAC, there is a study of esophageal squamous cell carcinoma (ESCC) in a cohort of patients

from Japan that has shown a decrease in TIMP3 protein expression, as measured by immunohistochemistry (IHC), which correlates with invasive activity and metastasis[10]. However, the mechanism responsible for the reduction of this expression has not been investigated. This study aimed to measure the frequency of methylation of TIMP3 in ESCC in patients from a region of high incidence in China, and to determine if this correlated with a reduction of TIMP3 expression.

MATERIALS AND METHODS

Patient samples

Primary tumors and, when available, non-cancerous proximal resection margins from 64 consecutive patients undergoing resection for ESSC at the Department of Thoracic Surgery, Fourth Hospital, Hebei Medical University, China were preserved in RNAlater (Ambion, Austin, TX, USA). Patient gender, age at the time of operation, and tumor stage, differentiation and volume were recorded (Table 1). Survival data were available for 45 patients. The study complied with all appropriate institutional guidelines.

Table 1 Characteristics of patients with ESCC

Variable	*n*

Demethylation of cell lines with 5-aza-2'-deoxycytidine (aza-dC)

Demethylation studies of TIMP3 were performed on nine cancer cell lines, OE19, OE21, OE33, TE7, DU145, LNCAP, T47D, ZR75.1, and KCL22. The cell lines were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum at 37℃ in 5% CO_2. Cells were seeded into flasks and cultured for 24 h before they were treated with 0 or 1 μmol/L aza-dC (Sigma-Aldrich, Sydney, NSW, Australia). To determine the length of time required for the cells to undergo at least two divisions in the presence of aza-dC, selected cell lines were labeled with PKH-26 (Sigma-Aldrich), as described previously[11]. Cell lines were treated for either 72 or 96 (OE19) h with 0 or 1 μmol/L aza-dC. The medium was then replaced with fresh medium not containing aza-dC, and the cells incubated for a further 24 h before harvesting.

Preparation of bisulfite-modified DNA

Genomic DNA was isolated from normal donor lymphocytes, cultured cells, and RNAlater-stabilized tissues as previously described[11]. DNA (2 μg) was bisulfite-modified as previously described[11], except that bisulfite-modified DNA was purified using an UltraClean PCR Clean-up DNA Purification Kit (MO BIO Laboratories, Carlsbad, CA, USA), and resuspended in 100 μL ultra pure water (Fisher Biotec Australia, Wembley, WA, Australia).

Methylation analysis of the TIMP3 promoter

Bisulfite-modified DNA was amplified using primers that amplified three overlapping regions designated R1, R2 and R3 (Figure 1). The primer sets did not discriminate between methylated and unmethylated sequences. The primers and PCR conditions were specific for bisulfite-modified DNA, and did not amplify unmodified DNA. All methylation-analysis PCRs were performed using the QuantiTect SYBR Green PCR Kit (Qiagen, Hilden, Germany) in a final volume of 15 μL, containing 1 μL bisulfite-modified DNA and a final concentration of 0.5 μmol/L forward and reverse primers (GeneWorks, Therbarton, SA, Australia) (Table 2). Bisulfite-modified lymphocyte and CpG methylase-treated lymphocyte DNA were included in each PCR run, and served as unmethylated and methylated controls, respectively. Reactions were incubated in a Rotor-Gene 3000 (RG-3000) (Corbett Life Science, Sydney, NSW, Australia) at 95℃ for 15 min, then 45 cycles of 95℃ for 30 s and 55℃ for 60 s, and a final extension of 72℃ for 4 min. Methylation was determined by analyzing the melt curve of the PCR product at the end of the amplification cycle. The temperature was ramped from 60 to 95℃, rising 0.5 or 1℃ at each step, waiting 30 s on the first step, then 5 s for each step thereafter. The dF/dT was determined for each PCR product using the RG-3000 application software v6 (Corbett Life Science). The dF/dT curves of the samples were compared to those of the unmethylated and methylated controls. A sample was considered methylated when there was a shift in its dF/dT curve away from that of the unmethylated control. The degree of methylation was graded as -, +, ++, +++ according to the degree of the shift to the right, as assessed by two independent observers.

Expression of TIMP3 mRNA in cell lines by quantitative real-time RT-PCR

Cell line RNA was isolated using an RNeasy kit with on-column DNase I digestion (Qiagen). The cDNA was synthesized from 2 μg RNA using SuperScript Ⅱ (Invitrogen, Mount Waverly, Vic, Australia). Quantitative real-time RT-PCR (qRT-PCR) was performed using the QuantiTect SYBR Green PCR Kit in a final volume of 10 μL, containing 1 μL cDNA and a final concentration of 0.5 μmol/L forward and reverse primers (Table 2). Triplicate reactions were incubated in an RG-3000 at 95℃ for 15 min, then 45 cycles of 95℃ for 30 s and 60℃ for

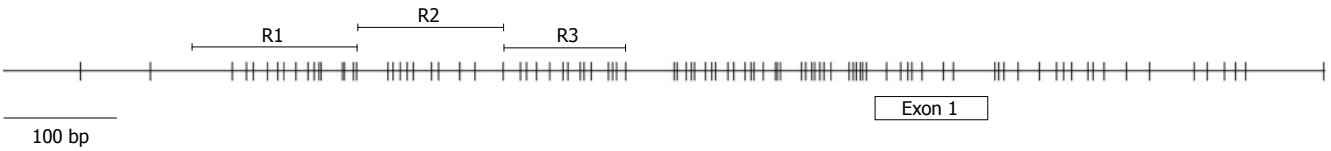

Figure 1 Schematic representation of the TIMP3 promoter. The schematic was generated by downloading the TIMP3 CpG island genetic element from http://genome.ucsc.edu/, using the Human March 2006 Freeze. The relative location of TIMP3 exon 1 is indicated. Each vertical line represents the location of a CpG. The three overlapping regions (R1, R2 and R3) amplified for methylation analysis are shown.

60 s, and a final extension of 72℃ for 4 min. The PCR products were electrophoresed on 1.5% (w/v) agarose gels and stained with ethidium bromide to confirm expected product sizes. The expression of TIMP3 was normalized to that of porphobilinogen deaminase (PBGD)[11].

Analysis of TIMP3 expression in ESCC by immunohistochemistry

Primary tumors and non-cancerous proximal resection margins preserved in RNAlater were fixed in formalin and embedded in paraffin using routine histopathology protocols. Sections (4 μm) of the formalin-fixed paraffin-embedded tissue were mounted on to polylysine-coated slides, de-waxed and rehydrated. Antigen retrieval was performed by heating the sections for 5 min in 10 mmol/L citrate buffer (pH 6) in a microwave pressure cooker. After cooling to below 30℃, sections were immunostained at room temperature using a Dako Autostainer Plus (Dako, Glostrup, Denmark). Sections were incubated for 60 min with a 1:750 dilution of mouse anti-human TIMP3 monoclonal antibody (Chemicon International, Temecula, CA, USA), and then with the MACH 4 Universal HRP Polymer (Biocare Medical, Concord, CA, USA). Visualization was performed with liquid 3, 3-diaminobenzidine (Dako) as the chromogen. Sections were counterstained with Meyer's hematoxylin.

Statistical analysis

Statistical comparison of the expression of TIMP3 mRNA following treatment with and without aza-dC for each cell line was performed using unpaired *t* tests. All statistical analysis was performed using InStat version 3.0a (GraphPad Software, San Diego, CA, USA).

RESULTS

Expression and methylation of TIMP3 in cell lines

The expression of TIMP3 mRNA was measured by qRT-PCR in cell lines without (0 μmol/L) and with (1 μmol/L) aza-dC demethylation treatment (Figure 2). Without aza-dC treatment, no TIMP3 expression was detected in

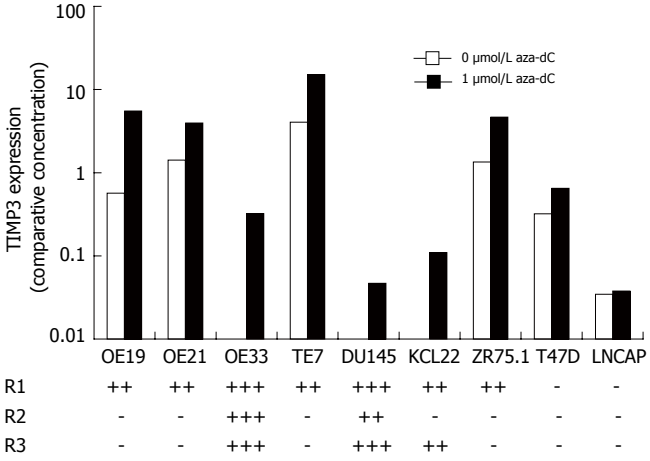

Figure 2 Expression and methylation of TIMP3 in cancer cell lines. The level of TIMP3 mRNA in cell lines treated with either 0 or 1 μmol/L aza-dC was determined by qRT-PCR and normalized using PBGD. Methylation was determined by melt curve analysis in three overlapping regions R1, R2 and R3, and is summarized.

OE33, DU145 and KCL22 cells, but was detected in all other cell lines tested. A significant increase in expression was induced by aza-dC in all cell lines except LNCAP.

The methylation in three overlapping regions of the TIMP3 CpG island (Figure 1) was evaluated by melt curve analysis and is summarized in Figure 2. Methylation in R1 was observed in OE19, OE21, OE33, TE7, DU145, KCL22, and ZR75.1 cells. Methylation in R2 was observed in OE33 and DU145 cells. Methylation in R3 was observed in OE33, DU145 and KCL22, the cell lines that did not express TIMP3 prior to treatment with aza-dC. Treatment with aza-dC caused a reduction in methylation in all regions in which methylation was observed (Figure 3). These data suggested that in the cell lines evaluated in this study, methylation in R3 was the one associated with transcriptional silencing of TIMP3 expression.

Expression and methylation of TIMP3 in ESCC

Methylation of the TIMP3 CpG island was evaluated in

Table 3 TIMP3 methylation and expression in methylated ESCC samples

Patient	M/F	Age	Tumor			Methylation			Expression
			Volume (cm^3)	Differentiation	Stage	R1	R2	R3	
28	F	65	60	Moderate	T3N1M1	++	-	-	Strong heterogeneous
41	M	65	30	Moderate	T3N0M0	++	-	++	Strong heterogeneous
44	M	66	18	Moderate	T3N0M0	++	-	++	Strong heterogeneous
75	F	72	27	Moderate	T3N1M0	++	+	++	Focal loss

tissues resected from patients with ESCC. Methylation was not detected in R1, R2 or R3 in the cancer-free proximal resection margins from these patients. However, methylation was detected in tumors from 4/64 (6%) patients. In the four tumors in which methylation was detected, low levels of methylation were present in R1 but not R2 or R3 in one patient, in R1 and R3 but not R2 in two patients, and in all three regions in one patient (Figure 4). TIMP3 protein expression was assessed in patient tissues by IHC. Strong heterogeneous cytoplasmic expression of TIMP3 was limited to the basal layers of the squamous mucosa (Figure 5A). All ESCCs that were unmethylated in all three regions analyzed displayed strong heterogeneous cytoplasmic staining of TIMP3 in cancer cells (Figure 5B and C). A significant loss of TIMP3 staining was not observed in the ESCCs that were methylated in either R1 or R1 and R3. By contrast, focal loss of TIMP3 staining was observed in the tumor that was methylated in all three regions (Figure 5D). TIMP3 methylation or loss of expression was not associated with patient age, gender, tumor volume, differentiation or stage (Table 3), or survival.

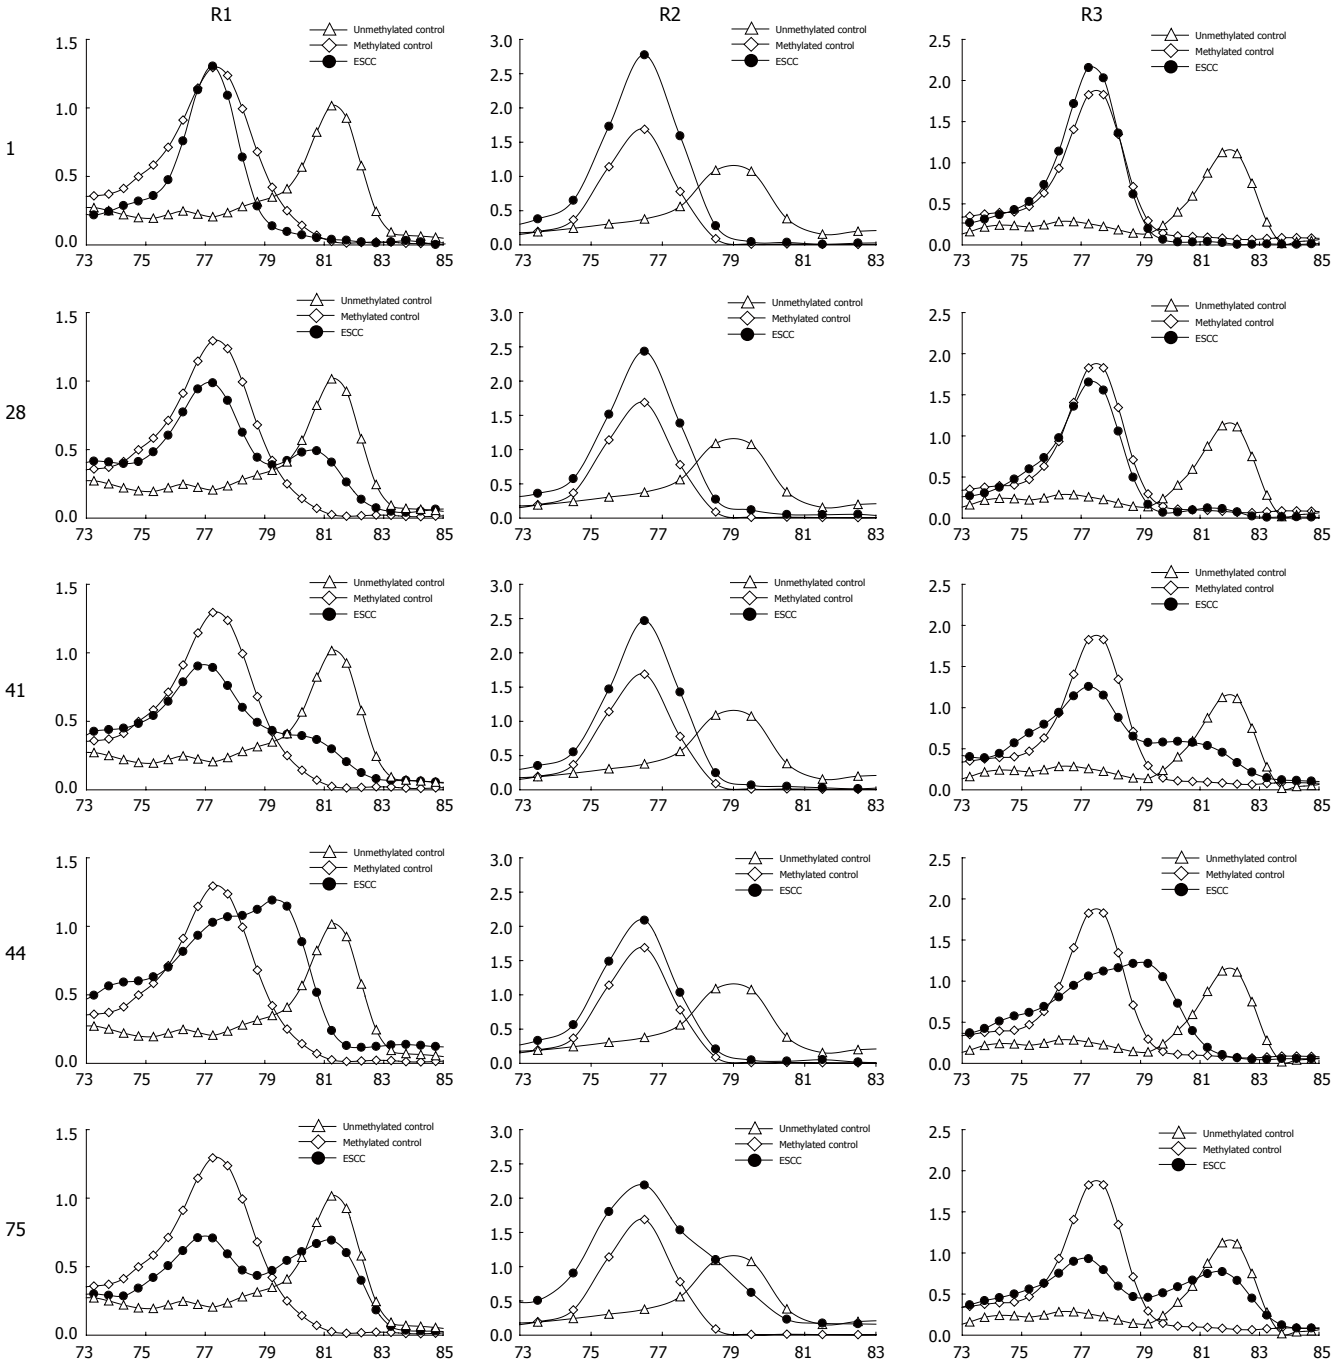

Figure 4 Methylation of TIMP3 in ESCC samples. The X axis is temperature, the Y axis is fluorescence dF/dT.

DISCUSSION

TIMP3, as an inhibitor of the proteolytic activity of MMPs, is believed to reduce tumor invasiveness and metastasis. Down-regulation of TIMP3 expression occurs in a number of cancers and has been linked to a poor outcome. One possible mechanism for the reduction in TIMP3 expression is DNA methylation of its promoter region. We first determined which region of the promoter CpG was associated with gene silencing by measuring gene expression and methylation in three overlapping regions of the TIMP3 CpG island in nine cancer cell lines. We found that methylation in only one of these regions appeared to be important in gene silencing. We then measured methylation and expression of TIMP3 in ESCC specimens resected from 64 patients from an area of China that has a very high incidence of this disease. Methylation was present in any of these three regions in just four of the 64 ESCC samples examined. Significant focal loss of TIMP3 protein expression was only observed in the tumor of one patient with ESCC, which was methylated in all three regions.

TIMP3 not only inhibits MMPs but also inhibits tumor growth and angiogenesis[12,13], and induces apoptosis in cancer cells[4,14]. Clinical studies have reported a reduction in TIMP3 expression that correlates with clinical

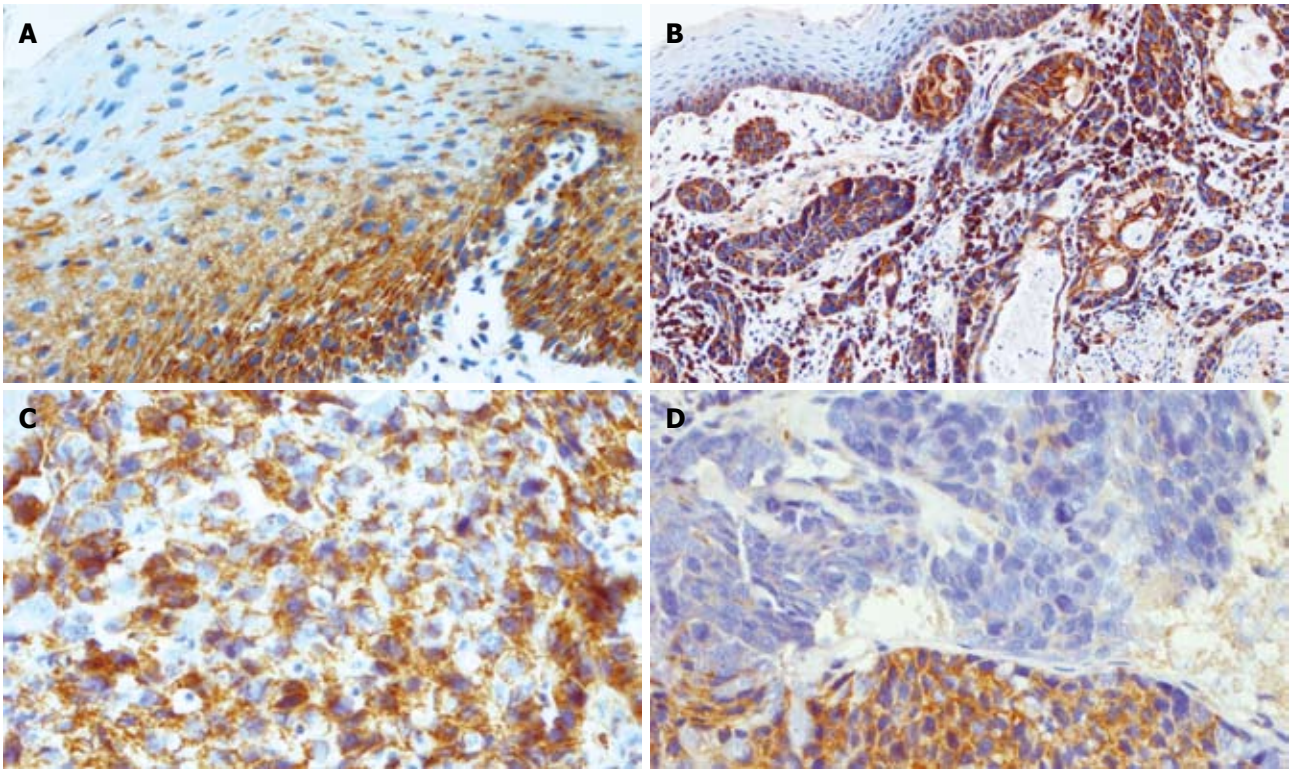

Figure 5 Expression of TIMP3 in esophageal tissues. **A**: Strong heterogeneous cytoplasmic expression of TIMP3 was limited to the basal layers in normal squamous mucosa; **B**: TIMP3 expression in unmethylated ESCC underlying normal squamous mucosa; **C**: Unmethylated ESCC showing strong heterogeneous staining; **D**: Methylated ESCC showing the region of reduced expression.

parameters in a number of cancers, including colon[15], lung[16,17] and breast[18,19] cancer and choriocarcinoma[20]. Methylation of the TIMP3 promoter is associated with silencing of transcription and has been noted in tumors of the thyroid[21,22], lung[16,17], bladder[23,24], stomach[25,26], uterus[27,28], bone[29], breast[30], liver[31] and colon[32,33].

Several studies have suggested that there is regional variation in TIMP3 expression within a tumor. Powe *et al* reported that TIMP3 mRNA expression decreases at the invasive edge of poorly differentiated colon carcinoma, and suggested that a regional loss of TIMP3 may contribute to increased invasiveness[34]. In normal esophagus, TIMP3 expression is restricted to the cytoplasm of basal, parabasal and stromal cells. Darnton *et al*[6] reported that TIMP3 protein expression was observed in all of 79 EACs examined, but staining intensity varied throughout the tumor. Whilst superficial areas of the tumors were always intensely stained, reduced expression was observed in central regions and variable expression, from pale to intense, was observed at the invading edges. Reduced TIMP3 expression was more often observed in an advanced tumor stage and was associated with reduced patient survival, but not lymph node positivity or tumor differentiation. TIMP3 mRNA and methylation were detected in 16/16 and 19/21 primary EACs, respectively, but correlation with reduced staining was not reported[6].

Most interest in methylation in cancer has focused on regions with relatively high densities of CpG islands, which are associated with gene promoter regions. It is common for methylation to vary between different regions of a particular CpG island when comparing DNA isolated from different cell lines or from different human tissues. For some genes, methylation of particular regions of the CpG island appears to be more important as a cause of silencing than methylation of other regions. Using established cancer cell lines, we analyzed three overlapping regions of the CpG island and correlated the methylation in each with expression, to determine if some regions of the island were more important than others in regulating gene expression.

The first detailed analysis of DNA methylation of the CpG island at the TIMP3 promoter was performed by Bachman *et al*[35]. They have demonstrated methylation in R1 in colon cancer cell lines, irrespective of whether or not these cells expressed TIMP3 mRNA. Their data are consistent with our findings in cell lines, and together, these findings suggest that methylation in this region by itself is not sufficient for transcriptional silencing. Bachman *et al* have observed dense methylation in R2 and R3 in cell lines that do not express TIMP3, and less methylation in these two regions in cell lines that do express the TIMP3 transcript. Significantly, our results demonstrated that in cell lines, complete silencing of TIMP3 transcription was only observed when there was significant methylation in R3, and that this complete silencing occurred even though there was no detectable methylation in R2.

A consistent characteristic of methylation of the TIMP3 CpG island that we observed was that methylation in R2 only occurred when there was methylation in R3, which in turn only occurred when there was methylation in R1. These findings indicate that aberrant methylation in the TIMP3 CpG island is progressive, beginning in

R1, before progressing to R3 and then R2. Progressive methylation has been observed in the p16 CpG island of primary human mammary epithelial cells escaping from growth arrest[36]. Regional methylation within a CpG island that is sufficient to silence transcription has also been reported for other genes, including MGMT[37] and MT3[11].

More than 90% of esophageal cancers are either adenocarcinomas or squamous cell carcinomas. In EAC, a number of reports have indicated that reduced expression of TIMP3 is common, and is associated with methylation and poor outcome. Darnton *et al* reported methylation of TIMP3 in 90% of EAC and 72% of BE patients, and that reduced expression of TIMP3 protein in EAC is associated with increased tumor invasiveness and reduced patient survival[6]. By contrast, Brock *et al*[38] reported that only 19% of EAC tissues showed TIMP3 methylation, and that this by itself was not a prognostic indicator. Eads *et al* reported TIMP3 methylation in 86% of EAC, and in 78% of dysplastic BE patients, and low methylation in 33% of metaplastic BE patients[7]. Clement *et al* found that TIMP3 was methylated in 65% of EAC patients, and that a significantly higher percentage of patients with BE who progressed to EAC had methylated TIMP3 than those who did not progress, which suggests its value as a prognostic indicator in BE[8]. Schulman *et al*, however, reported TIMP3 methylation in 56% of EAC and 59% of BE tissues, and concluded that hypermethylation of TIMP3 is not an independent risk factor for progression from BE to EAC[9].

In contrast to the many studies of TIMP3 in EAC, there is only one in ESCC. Miyazaki *et al*[10] reported that in 90 patients who underwent surgery for ESCC at Gunma University Hospital (Japan), TIMP3 protein expression was always observed in cells in the shallow areas of the tumor, but was not expressed by cells at the invasive front of the same tumor. The percentage of cells with reduced TIMP3 expression at the invasive front varied between patients; in 33% of patients, 80% of the cells expressed TIMP3; in 30% of patients, 30%-80% of the cells expressed TIMP3; and in 37% of patients, < 30% of the cells expressed TIMP3. The patients that had the greatest percentage of cells with reduced expression had significantly reduced postoperative survival, increased depth of invasion, more metastatic lymph nodes, and higher disease stage. However, they did not analyze methylation of TIMP3. The low frequency of methylation that we observed in ESCC was not due to our methods, as we have found methylation in 88% (22/25) of EAC patients (unpublished observations); this is consistent with other reports of this cancer[7-9]. There is no obvious explanation for the discrepancy between our results in this Chinese cohort and the Japanese study. The disease may be biologically different, perhaps due to lifestyle, environmental or genetic differences. Further studies are required to investigate this issue.

We found that methylation of the TIMP3 CpG island was detectable in only 4% (4/64) of ESCC patients from a region in China that has a high incidence of this disease. The number of patients with methylation in R3, which we showed in cell lines correlated with transcriptional silencing, was 3/64. We found a loss of TIMP3 expression by immunohistochemistry in only one patient, and then this was only a focal loss. There is no obvious explanation for the presence of TIMP3 protein in patients with R3 methylation. Our results clearly showed that the loss of expression or methylation of TIMP3 is uncommon in ESCC from this region of China.

ACKNOWLEDGMENTS

We thank Dr. Yutaka Shimada for the generous gift of several of the cell lines used in this study.

COMMENTS

Background

Increased knowledge of the underlying biology of the cancer may lead to improvements in diagnosis and treatment. TIMP3 inhibits matrix metalloproteinases (MMPs), which can inhibit tumor growth and metastasis. There is one report suggesting that TIMP3 is reduced in esophageal squamous cell carcinoma (ESCC). We measured the frequency of methylation of TIMP3 in ESCC in patients from a region of high incidence in China, and determined if this correlated with a reduction of TIMP3 expression.

Research frontiers

Methylation which silences genes is generally found in regions with relatively high densities of CpG, known as CpG islands, which are associated with gene promoter regions. Measuring methylation in these critical regions of DNA may assist in diagnosis or prognosis in cancer.

Innovations and breakthroughs

We defined the region of the TIMP3 CpG island which is associated with the silencing of the gene. We found that reduction in expression of TIMP3 is uncommon in ESCC from a region of high incidence in China, and correspondingly methylation was infrequent as well.

Terminology

MMPs: enzymes which break down and reshape the molecules which surround a cell and hold it in its place. Methylation of DNA: one way to silence a gene. Gene promoter: the part of the DNA where the cell begins to make gene product.

Peer review

This is an excellent and well written contribution.

Abstract

AIM: To clarify whether subclassification of the type VI pit pattern on the basis of magnifying colonoscopy findings is useful in determining the type and depth of invasion of colorectal neoplasms.

METHODS: We retrospectively analyzed 272 colorectal neoplasms (117 dysplasias and 155 submucosal invasive carcinomas; 228 patients) with a type V pit pattern [type VI, *n* = 202; type VN, *n* = 70 (Kudo and Tsuruta classification system)]. We divided lesions with a type VI pit pattern into two subclasses, mildly irregular lesions and severely irregular lesions, according to the prominent and detailed magnifying colonoscopy findings. We examined the relation between these two subclasses and histology/invasion depth.

RESULTS: One hundred and four lesions (51.5%) were judged to be mildly irregular, and 98 lesions (48.5%) were judged to be severely irregular. Ninety-seven (93.3%) mildly irregular lesions showed dysplasias or submucosal invasion of less than 1000 μm (SM < 1000 μm). Fifty-five (56.1%) severely irregular lesions showed submucosal invasion equal to or deeper than 1000 μm (SM ⩾ 1000 μm). Mild irregularity was found significantly more often in dysplasias or lesions with SM < 1000 μm than in lesions with SM ⩾ 1000 μm ($P < 0.01$).

CONCLUSION: Subclassification of the type VI pit pattern is useful for identifying dysplasias or lesions with SM < 1000 μm.

INTRODUCTION

Pit pattern classification (Figure 1) of colorectal lesions, initially proposed by Kudo[1] and modified by Kudo and Tsuruta[2], is reported to be related to the histologic characteristics of the lesions[3-9]. Magnifying colonoscopy is used for differential diagnosis between non-neoplastic and neoplastic lesions[5,9-16] and for assessing the depth of invasion of early colorectal carcinoma[9,17-21].

Several studies have suggested that there is little risk of lymph node metastasis from early colorectal carcinoma that involves the superficial layer of the submucosa, less than 1000 μm from the muscularis mucosae[9,17,22-24]. Recently, the Japanese Society for Cancer of the Colon and Rectum proposed the following new criteria for curative histopathologic conditions after complete endoscopic mucosal resection (EMR) of submucosal carcinoma: (1) a submucosal invasion depth of less than 1000 μm (SM < 1000 μm), (2) well to moderately differentiated adenocarcinoma including the invasive portion, and (3) no vessel involvement[22,24]. In accordance with these proposed criteria, it has become important to distinguish submucosal invasion equal to or deeper than 1000 μm (SM ⩾ 1000 μm) from SM < 1000 μm prior to treatment of submucosal carcinoma, to reduce the number of needless surgical resections.

Many studies have shown that the type VN pit pattern is an indicator of massive submucosal invasion of colorectal neoplasm[9]. However, colorectal neoplasms with a type VI pit pattern include various lesions, such as dysplasia and submucosal carcinoma, with either SM < 1000 μm

or SM ⩾ 1000 μm[9]. Thus, it is difficult to decide upon a therapeutic strategy for colorectal neoplasm on the basis of the current type VI pit pattern classification. In this study, we assessed the clinical usefulness of type VI pit pattern subclassification in determining the histology/invasion depth of colorectal neoplasms.

MATERIALS AND METHODS

We analyzed 272 colorectal neoplasms with a type V pit pattern (type VI, n = 202; type VN, n = 70). The colorectal neoplasms comprised 117 dysplasias and 155 submucosal invasive carcinomas, 129 of which were deeper than 1000 μm, resected endoscopically or surgically from 228 patients at Hiroshima University Hospital during the period January 1999 through March 2005. All lesions in this study were analyzed by five colonoscopists who were well trained in magnifying colonoscopy and blinded to the pathology findings, retrospectively.

To evaluate pit patterns, we used a magnifying colonoscope (EC-410CM, EC-450ZM, EC-450ZH or EC-450ZW, Fujinon Toshiba, Omiya, Japan; or CF-240Z or CF-H260AZI, Olympus, Tokyo, Japan) with zoom functions ranging from × 17 to × 126. When a lesion was detected by standard colonoscopic observation, the surface mucus was washed away with lukewarm water, and indigo carmine dye was spread over the lesion. This dye enhances the colonoscopic appearance because it is retained within the pits and grooves of the mucosal surface. For more precise assessment, crystal violet stain was applied to the margins of the pits, rendering each pit pattern clearly visible in all cases. The type V pit pattern was classified as one of two subtypes according to the Kudo and Tsuruta classification system[1,2] (Figure 1): type VI, irregularly arranged and similar to type IIIL, IIIS, or IV patterns in size; and type VN, an area of obvious non-structure (as per the Hakone consensus meeting in April 2004)[9,25].

Each resected neoplasm was fixed routinely with 10% buffered formalin and embedded in paraffin, after which the entire tumor was cut into serial 2- to 3-mm thick slices. Microscopic examination of hematoxylin and eosin-stained sections was performed by one pathologist unaware of other features of the case. Dysplasia was defined according to the Vienna criteria[26]. According to previously proposed measuring methods[22,24], the depth of submucosal invasion was determined using a micrometer under a microscope, and taken as the distance from the muscularis mucosae to the point of the deepest invasion (tumor apex).

We first analyzed the relation between the type V pit pattern subtype (VI or VN) and histology/invasion depth. We then examined the relation between SM ⩾ 1000 μm and histology/invasion depth and the following five detailed magnifying colonoscopy findings: (1) irregularity of the pit margins, (2) staining characteristics of the areas between pits, (3) area diameter of the type VI pit pattern (< 5 mm or ⩾ 5 mm), (4) density of the pits, and (5) width of the intervening membrane between the pits (Figure 2).

We divided the lesions with a type VI pit pattern into two subclasses (mildly irregular lesions and severely irregular lesions) according to the prominent and detailed magnifying colonoscopy findings of the first analysis. Mildly irregular lesions were defined as lesions with one or no significant magnifying colonoscopy findings, and severely irregular lesions were defined as lesions with two or more significant magnifying colonoscopy findings. This was done to diagnose SM ⩾ 1000 μm on the basis of cluster analysis[27,28]. Using these data, we examined the relation between the type VI pit pattern subclassifications and histology/invasion depth, the status of the muscularis mucosae, and the presence of desmoplastic reactions at the surface of the lesion (Figure 3). The muscularis mucosae were classified as detected, partially disappeared, or disappeared, as reported previously[29]. Desmoplastic reaction of the submucosal layer was classified as absent (-), mild to moderate (+), or severe (++), as reported previously[18,30].

The associations of dysplasia, SM < 1000 μm, and SM ⩾ 1000 μm with the type V pit pattern subtypes, detailed magnifying colonoscopy findings, and the type VI lesion subclasses, were analyzed by chi-square test. $P < 0.05$ was accepted as statistically significant. In addition, to identify predictors of SM ⩾ 1000 μm, we performed multivariate logistic regression analysis. All statistical analyses were performed using JMP statistical software, version 5.0.1 J (SAS Institute Inc, Cary, NC).

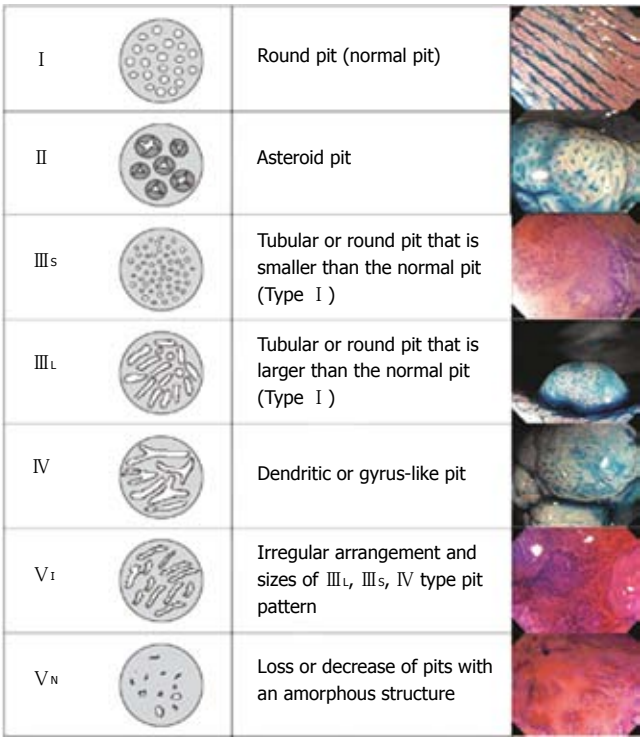

Figure 1 Classification of pit patterns of colorectal lesions.

RESULTS

Histology/invasion depth of colorectal neoplasm in relation to type V pit pattern subtypes

Dysplasia, SM < 1000 μm and SM ⩾ 1000 μm were found

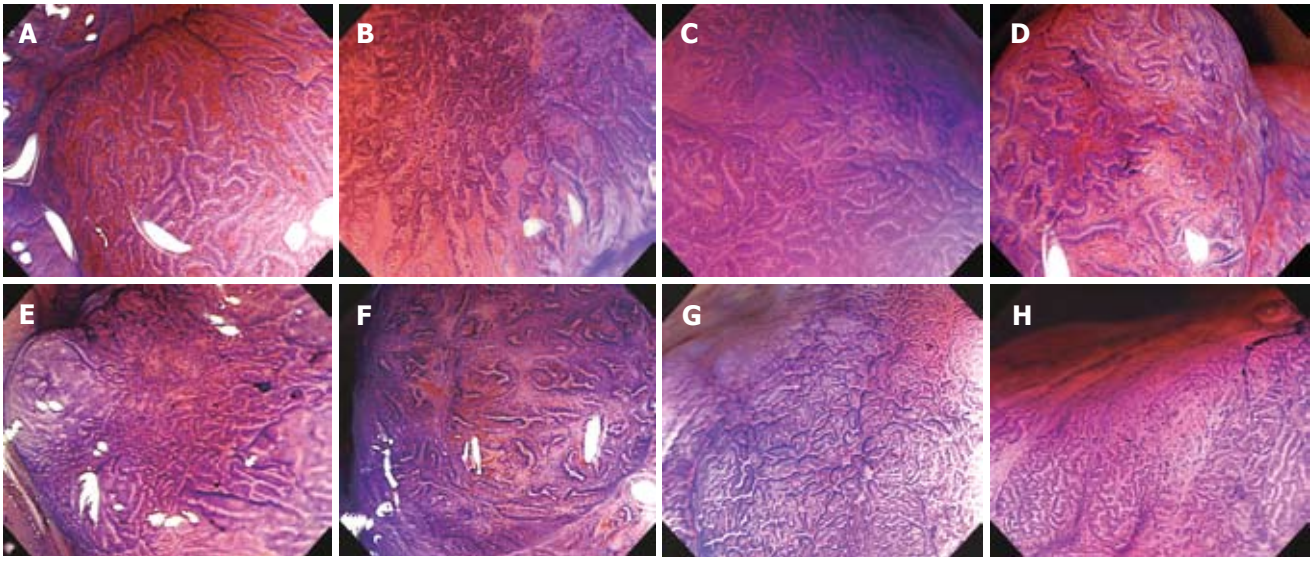

Figure 2 Magnifying features of colorectal neoplasm (crystal violet): **A**: Regular pit margins; **B**: Irregular pit margins; **C**: Clear staining characteristics of the areas between pits; **D**: Unclear staining characteristics of the areas between pits; **E**: High residual pit density; **F**: Low residual pit density; **G**: Narrow intervening membrane between pits; **H**: Wide intervening membrane between pits.

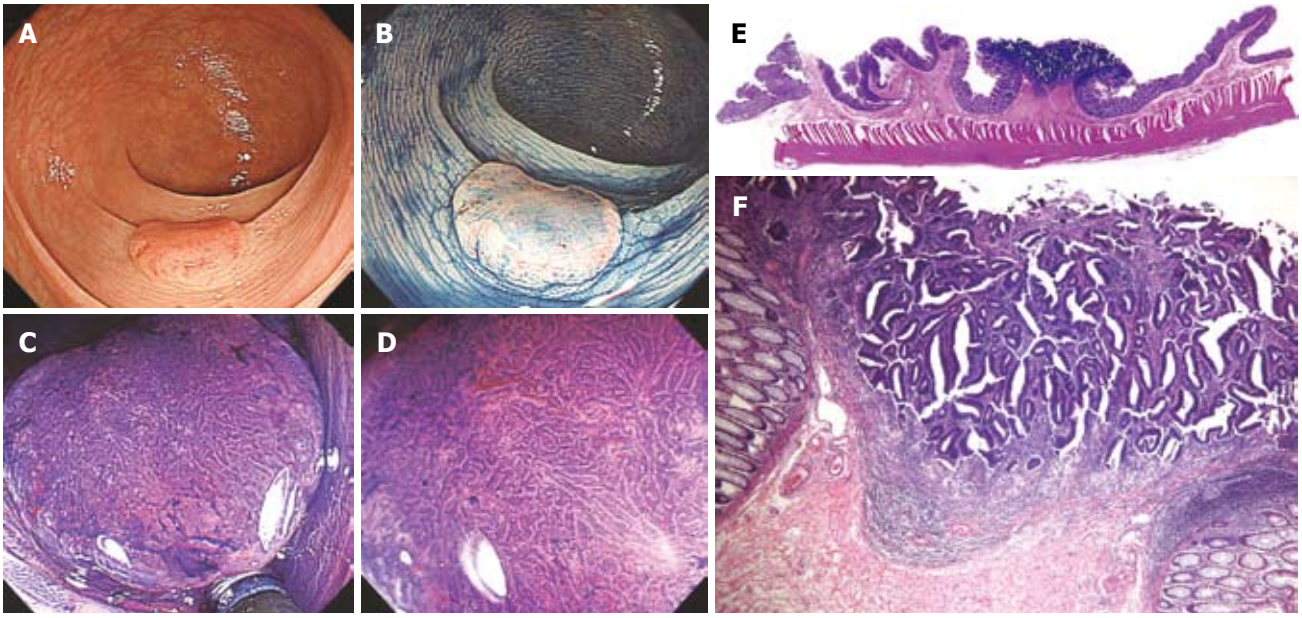

Figure 3 Type Ⅱa + 10Ⅱc lesion, 12 mm in diameter. **A**: Standard colonoscopic view; **B**: Standard colonoscopic view with indigo carmine spraying; **C**, **D**: Magnifying colonoscopic picture with crystal violet staining reveals type V_I pit pattern. Irregular pit margins, unclear staining characteristics of the areas between pits, > 5 mm area of type V_I pit pattern, high residual pit density, and narrow intervening membrane between pits is revealed; **E**: Cross-section (hematoxylin-eosin, × 8) of a surgically resected specimen showing submucosal invasion (1800 μm); **F**: Low-power view (hematoxylin-eosin, × 40) of type V_I pit pattern. Muscularis mucosae have disappeared. Desmoplastic reactions are mild to moderate. In this case, lymph node metastasis was not detected.

in association with 57.9% (117/202), 11.4% (23/202), and 30.7% (62/202) of the neoplasms with type V_I pit patterns, respectively (Table 1). Dysplasia, SM < 1000 μm, and SM ≥ 1000 μm were found in association with 0% (0/70), 4.3% (3/70), and 95.7% (67/70) of the neoplasms with type V_N pit patterns, respectively. The type V_N pit pattern was found significantly more often in lesions with SM ≥ 1000 than in dysplasias or lesions with SM < 1000 μm ($P < 0.01$). Sensitivity and specificity of the type V_N pit pattern for a diagnosis of SM ≥ 1000 were 51.9% (67/129) and 97.9% (140/143), respectively.

Histology/invasion depth of colorectal neoplasm with a type V_I pit pattern in relation to detailed magnifying colonoscopy findings

SM ≥ 1000 μm was found in association with 58.2% (46/79) of the lesions with irregular pit margins, 57.5% (50/87) of the lesions with unclear staining characteristics of the areas between pits, 41.3% (57/138) of the lesions with a type V_I pit pattern area ≥ 5 mm in diameter, 26.6% (29/109) of the lesions with high residual pit density, and 31.9% (44/138) of the lesions with a wide intervening membrane between pits (Table 2). SM ≥ 1000 μm was

Table 1 Histology/invasion depth of colorectal neoplasm in relation to type V pit pattern subtypes, *n* (%)

Type V pit pattern subtypes		Histology/invasion depth		
		Dysplasia	SM < 1000 μm	1000 μm ≤ SM
V_I	202 (100)	117 (57.9)	23 (11.4)	62 (30.7)
V_N[1]	70 (100)	0 (0)	3 (4.3)	67 (95.7)

[1]Dysplasia. SM < 1000 μm *vs* SM ≥ 1000 μm, $P < 0.01$. SM: Submucosa.

Table 2 Histology/invasion depth of colorectal neoplasm with type V_I pit pattern in relation to detailed magnifying colonoscopy findings, *n* (%)

Magnifying colonoscopy finding		Histology/invasion depth		
		Dysplasia	SM < 1000 μm	1000 μm ≤ SM
Irregular pit margins[1]	79 (100)	23 (29.1)	10 (12.7)	46 (58.2)
Unclear staining characteristics of the area between pits[1]	87 (100)	21 (24.1)	16 (18.4)	50 (57.5)
Area diameter of type V_I pit pattern ≥ 5 mm[1]	138 (100)	65 (47.1)	16 (11.6)	57 (41.3)
High residual pit density	109 (100)	64 (58.7)	16 (14.7)	29 (26.6)
Wide intervening membrane between pits	138 (100)	81 (58.7)	13 (9.4)	44 (31.9)

[1]Dysplasia. SM < 1000 μm *vs* SM ≥ 1000 μm, $P < 0.01$. SM: Submucosa.

found significantly more often in association with irregular pit margins, unclear staining characteristics of the areas between pits, and a type V_I pit pattern area ≥ 5 mm in diameter than in association with regular pit margins, clear staining characteristics of the areas between pits, and a type V_I pit pattern area < 5 mm in diameter.

Results of multivariate logistic regression analysis for predictors of SM ≥ 1000 μm

In multivariate logistic regression analysis, unclear staining characteristics of the areas between pits, irregular pit margins, and a V_I pit pattern area diameter of ≥ 5 mm were shown to be significant predictors of SM ≥ 1000 μm (Table 3). High residual pit density and a wide intervening membrane between pits were not significant.

Histology/invasion depth of colorectal neoplasm in relation to type V_I pit pattern subclassifications

One hundred and four lesions (51.5%) were judged to be mildly irregular, and 98 lesions (48.5%) were judged to be severely irregular (Table 4). Ninety-seven (93.3%) mildly irregular lesions showed dysplasias or SM < 1000 μm. Fifty-five (56.1%) severely irregular lesions showed SM ≥ 1000 μm. Mild irregularity was found significantly more often in dysplasias or in lesions with SM < 1000 μm than in lesions with SM ≥ 1000 ($P < 0.01$). Sensitivity and specificity of mild irregularity for dysplasias or SM < 1000 μm were 69.3% (97/140) and 88.7% (55/62), respectively.

Table 3 Results of multivariate logistic regression analysis for predictors of submucosal invasion deeper than 1000 μm (*n* = 202)

Magnifying colonoscopy finding	Odds ratio (*P* value)	Relevant finding
Unclear staining characteristics of the areas between pits	6.24 (< 0.0001)	Clear staining characteristics of the areas between pits
Irregular pit margins	4.89 (< 0.0001)	Regular pit margins
Area diameter of type V_I pit pattern ≥ 5 mm	4.14 (0.0132)	Area diameter of type V_I pit pattern < 5 mm
High residual pit density	1.51 (0.3335)	Low residual pit density
Wide intervening membrane between pits	1.02 (0.9740)	Narrow intervening membrane between pits

Table 4 Histology/invasion depth of colorectal neoplasm in relation to type V_I pit pattern subclassifications, *n* (%)

Type V_I pit pattern subclassification		Histology/invasion depth		
		Dysplasia	SM < 1000 μm	1000 μm ≤ SM
Mildly irregular[1]	104 (100)	89 (85.6)	8 (7.7)	7 (6.7)
Severely irregular	98 (100)	28 (28.6)	15 (15.3)	55 (56.1)

[1]Dysplasia. SM < 1000 μm *vs* SM ≥ 1000 μm, $P < 0.01$. SM: Submucosa.

Table 5 Status of muscularis mucosae in relation to type V pit patterns, *n* (%)

Type V pit pattern		Status of muscularis mucosae		
		Detected	Partially disappeared	Disappeared
V_I				
Mildly irregular[1]	104 (100)	97 (93.2)	6 (5.8)	1 (1.0)
Severely irregular[a]	98 (100)	38 (38.8)	31 (31.6)	29 (29.6)
V_N[b]	67 (100)		8 (11.9)	59 (88.1)

[1]Detected *vs* partially disappeared, disappeared, [b]$P < 0.01$, [a]$P < 0.05$.

Status of the muscularis mucosae in relation to type V pit patterns

The muscularis mucosae was detected in 97 (93.2%) mildly irregular lesions (Table 5). Partial disappearance or disappearance of the muscularis mucosae was seen in 60 (61.2%) severely irregular lesions and 67 (100%) lesions with a type V_N pit pattern. Severe irregularity was found significantly more often in association with partial disappearance or disappearance of the muscularis mucosae than in association with detection of the muscularis mucosae ($P < 0.05$). The type V_N pit pattern was found significantly more often in association with partial disappearance or disappearance of the muscularis mucosae than in association with detection of the muscularis mucosae ($P < 0.01$).

Desmoplastic reactions at the surface of the lesion in relation to type V pit patterns

No desmoplastic reaction of the superficial layer was observed in 100 (96.2%) mildly irregular lesions (Table 6). Desmoplastic reactions (+)/(++) were observed in 50

(51.0%) severely irregular lesions and 67 (100%) lesions with a type VN pit pattern. The type VN pit pattern was found significantly more often in lesions with a desmoplastic reaction (+)/(++) than in lesions with desmoplastic reaction (-) ($P < 0.01$).

DISCUSSION

Endoscopic treatment, such as EMR, is both a therapeutic technique and an important diagnostic technique. Therefore, it is important to be able to identify lesions for which endoscopic resection would be curative to avoid meaningless endoscopic resection for lesions that should be treated surgically. Pit pattern classification is used clinically to help determine the best treatment for colorectal tumors[9]. Type Ⅰ and Ⅱ pit patterns predict nonneoplastic lesions, whereas type Ⅲ, Ⅳ, and Ⅴ pit patterns predict neoplastic lesions. Lesions with a type Ⅲ or Ⅳ pit pattern are almost always dysplasias and are thus indications for endoscopic resection. Almost all lesions with a type VN pit pattern show SM ⩾ 1000 μm. The reported accuracy of detection of massive submucosal invasion on the basis of the type VN pit pattern is 97%[23]. In our study, SM ⩾ 1000 μm was found in 95.7% of lesions with a type VN pit pattern. Therefore, surgical resection is indicated for such lesions. By contrast, lesions with a type VI pit pattern include dysplasia and various submucosal carcinomas; thus, it is difficult to decide upon a therapeutic strategy on the basis of the current pit pattern classification system. It is necessary to analyze the type VI pit pattern in detail to determine the appropriate therapeutic strategy. The present study revealed that irregular pit margins, unclear staining characteristics of the areas between pits, and a type VI pit pattern area diameter ⩾ 5 mm are significant predictors for submucosal invasion of colorectal neoplasms of 1000 μm or more.

Lesions that were subclassified as mildly irregular lesions were mainly dysplasias or lesions that showed SM < 1000 μm (93.3%). Therefore, endoscopic resection is indicated for mildly irregular lesions. On the contrary, lesions that were classified as severely irregular lesions included not only dysplasias or lesions with SM < 1000 μm (43.9%), but also lesions with SM ⩾ 1000 μm (56.1%). For severely irregular lesions, the therapeutic strategy should be determined on the basis of standard endoscopic findings in conjunction with those of other modalities, such as contrast enema radiography or endoscopic ultrasonography[29,31,32]. New diagnostic modalities, such as narrow band imaging, are expected to provide more information about the invasion depth of colorectal carcinomas[33-36].

Our results revealed that there is a significant histologic difference between mildly irregular lesions and severely irregular lesions. The degree of disappearance of the muscularis mucosae increased as the pit patterns changed from VI with mildly irregularity to VI with severely irregularity to VN. If we could determine the status of the muscularis mucosae by magnifying colonoscopy, the pit pattern would be helpful in determining the depth of submucosal invasion depth by endoscopic ultrasonography. The muscularis mucosae had disappeared in all lesions with a type VN pit pattern; thus, we can measure the invasion depth from the surface of a lesion of this type to the deepest portion[29]. It has been reported that desmoplastic reactions are related to massive submucosal invasion[18]. In the present study, the incidence of desmoplastic reactions increased as the pit patterns changed from VI with mildly irregularity to VI with severely irregularity to VN. There were no desmoplastic reactions in mildly irregular lesions. These results indicate that changes in the appearance of the pits are caused by the process of submucosal infiltration of the colorectal neoplasm. Although the mechanism underlying this process is not clear, it is possible that irregular pit margins and unclear staining characteristics of the areas between pits may involve several molecular markers. We reported previously that the proliferation, infiltration and lymph node metastasis of submucosal colorectal carcinoma are significantly related to the expression of markers such as Ki-67, E-cadherins, MUC1, cathepsin D and MMP-7 at the deepest portion[37-43]. We also reported previously that MUC1 expression at the superficial layer may be related to colorectal tumors with a type V pit pattern[42]. However, there are few reports pertaining to the relation between the expression of specific molecular markers and morphogenesis of the type VI pit pattern. There may be a relation between the expression of molecular markers and detailed magnifying colonoscopy features of the type VI pit pattern. Further investigation will clarify the relation between molecular morphogenesis at the lesion surface and type VI pit pattern subclassifications.

We conclude that type VI pit pattern subclassification is useful for identifying dysplasias or lesions with SM < 1000 μm. Subclassifications can be applied to decisions about whether endoscopic treatment is indicated for colorectal neoplasms. However, we cannot identify lesions with SM ⩾ 1000 μm on the basis of type VI pit pattern subclassifications.

Table 6 Desmoplastic reaction at the lesion surface in relation to type V pit pattern, *n* (%)

Type V pit pattern		Desmoplastic reaction		
		Absent (-)	Mild to moderate (+)	Severe (++)
VI				
Mildly irregular	104 (100)	100 (96.2)	4 (3.8)	
Severely irregular	98 (100)	48 (49.0)	29 (29.6)	21 (21.4)
VN[b]	67 (100)		16 (23.9)	51 (76.1)

[b]$P < 0.01$ (-) *vs* (+), (++).

COMMENTS

Background

Colorectal neoplasms with a type VI pit pattern include various lesions, such as dysplasias and submucosal carcinomas, with either SM < 1000 μm or SM ⩾ 1000 μm. Thus, it is difficult to decide upon a therapeutic strategy for colorectal neoplasm on the basis of the current type VI pit pattern classification.

Research frontiers

In this study, we assessed the clinical usefulness of type VI pit pattern subclassification in determining the histology/invasion depth of colorectal neoplasms. There has been little study on type VI pit pattern subclassification.

Innovations and breakthroughs

Type V_I pit pattern subclassification is useful for identifying dysplasias or lesions with SM < 1000 μm.

Applications

Subclassifications can be applied to deciding whether endoscopic treatment is indicated for colorectal neoplasms.

Terminology

Type V_I pit pattern subclassification: We divided the lesions with a type V_I pit pattern into two subclasses (mildly irregular lesions and severely irregular lesions) according to the prominent detailed magnifying colonoscopy findings of the first analysis. Mildly irregular lesions were defined as lesions with one or no significant magnifying colonoscopy findings, and severely irregular lesions were defined as lesions with two or more significant magnifying colonoscopy findings.

Peer review

The authors retrospectively investigated whether subclassification of the type V_I pit pattern on the basis of magnifying colonoscopy findings was useful in determining the type and depth of invasion of colorectal neoplasm. They concluded that subclassification of the type V_I pit pattern is useful for identifying dysplasias or lesions with SM < 1000 μm.

Abstract

AIM: To establish and validate the mutation testing for identification and characterization of hereditary non-polyposis colorectal cancer (HNPCC) in suspected Chinese patients.

METHODS: Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. Genomic DNA was extracted after informed consent was obtained. The coding region of hMSH2 and hMLH1 genes was detected by polymerase chain reaction (PCR) and denaturing high-performance liquid chromatography (DHPLC). Mutations identified in the proband by DHPLC were directly sequenced using a 377 DNA sequencer, analyzed with a basic local alignment tool (BLAST), and tested in the corresponding family members by direct DNA sequencing.

RESULTS: Mutations were identified in two Chinese HNPCC kindreds. One was the missense mutation of hMSH2 c.1808A→G resulting in Asp 603 Gly identified in the proband of the fifth HNPCC (HNPCC5) kindred. In the HNP5 kindred, three family members were found to have this mutation and two of them had colorectal cancer. The other mutation of hMLH1 c.1882A→G was identified in the HNP2 kindred's proband, which might be the nonsense mutation analyzed by BLAST.

CONCLUSION: Pedigree investigation and mutation testing of hMSH2 and hMLH1 are the practical methods to identify high-risk HNPCC patients in China.

INTRODUCTION

Hereditary non-polyposis colorectal cancer (HNPCC) syndrome is characterized by autosome-dominantly inherited predisposition to early colorectal carcinoma and extracolonic epithelia-derived tumors most often located in the gastrointestinal and urogenital tracts[1]. The mean age of HNPCC and sporadic colorectal cancer (CRC) patients at diagnosis is 42 years and 65 years, respectively. HNPCC, accounting for approximately 5%-15% of all CRCs, is categorized as Lynch I or Lynch Ⅱ syndrome (according to revised Amsterdam criteria)[2]. Germline mutations of the mismatch repair (MMR) genes identified in HNPCC kindreds, including *MSH2*, *MLH1*, *MSH6*, *PMS1* (promotion of mutS homology 1), *PMS2*, and *MLH3*, have been proved as the major cause for HNPCC by linkage analysis. Mutations in two of these MMR genes, *MSH2* and *MLH1*, account for the majority of the kindreds with HNPCC[3]. Thus, pedigree investigation and MMR gene testing, as the basis for efficient prevention and treatment of HNPCC, are most often used in early diagnosis of at-risk family members and in confirmation of the diagnosis of HNPCC.

CRC is the third life-threatening cancer in China. However, HNPCC pedigree and its predisposition gene have not been extensively studied. We have established a CRC database since 1994 and the follow-up rate is above 90%. We have recently paid attention to hereditary colorectal cancer in South China and found that about 3% of CRC patients have multiple CRCs to which the young are vulnerable[4,5]. Thus, we collected those CRC families and finally obtained eleven independent Chinese kindreds with HNPCC by deep pedigree investigation until January,

2004. Five of them fulfilled the classical Amsterdam criteria. To identify high-risk populations with HNPCC, we tested hMSH2 and hMLH1 mutations in these classical kindreds.

MATERIALS AND METHODS

Patients

The clinical diagnosis of classical HNPCC was established and verified at the Department of Gastrointestinopan creatic surgery, the First Affiliated Hospital of the Sun Yat-Sen University[2]. Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. The study was approved by the Ethical Committee of Sun Yat-Sen University.

DNA isolation

Peripheral blood samples were collected from both patients and their family members in each Chinese kindred after informed consent was obtained for genetic analysis. DNA was extracted directly from leukocytes following the standard procedures.

All exons of *MLH1* and *MSH2* were amplified for mutation testing. Samples used were amplified in 20 mL reaction volume containing approximately 100 ng DNA in 50 mmol/L KCl, 10 mmol/L Tris-HCl, 1.5 mmol/L $MgCl_2$, 200 mmol/L each dNTP, 0.01% gelatin, 1 U Taq-polymerase, and 20-40 pmol each primer. The PCR amplification conditions were as follows: denaturation at 95℃ for 5 min, followed by 30 cycles of denaturation at 95℃ for 30 s, annealing at fragment-specific annealing temperature for 1 min, extension at 72℃ for 1 min, and a final extension at 72℃ for 7 min. The primers, annealing temperature, and size of the PCR products for each of the investigated hMLH1 and hMSH2 exons are described elsewhere[6-8]. The primers were synthesized by Shanghai Bio-Chemical Corporation.

DHPLC analysis

The amplified PCR fragments were screened for sequence variants by denaturing high pressure liquid chromatography (DHPLC) on a WAVE DNA fragment analysis system (Transgenomic, San Jose, CA, USA). The running conditions for each amplicon (available upon request) were determined by the Wavemaker 3.4.4 software (Transgenomic, San Jose, CA, USA) based on the DNA sequence. Five mL of each PCR product (containing 50-100 ng of DNA) was denaturated at 95℃ for 3 min and then gradually reannealed by decreasing the sample temperature from 95℃ to 65℃ over 30 min. PCR products were then separated at a flow rate of 0.9 mL/min with a linear acetonitrile gradient. Generally, analysis took approximately 10 min including column regeneration and re-equilibration to starting conditions. The column mobile phase consisted of a mixture of 0.1 mol/L triethylamine acetate (pH 7.0) with (buffer B) or without (buffer A) 25% acetonitrile. Samples displaying variant elution peaks in each run were chosen for sequence analysis. For some amplicons displaying variations in elution profiles of control samples, all samples were sequenced.

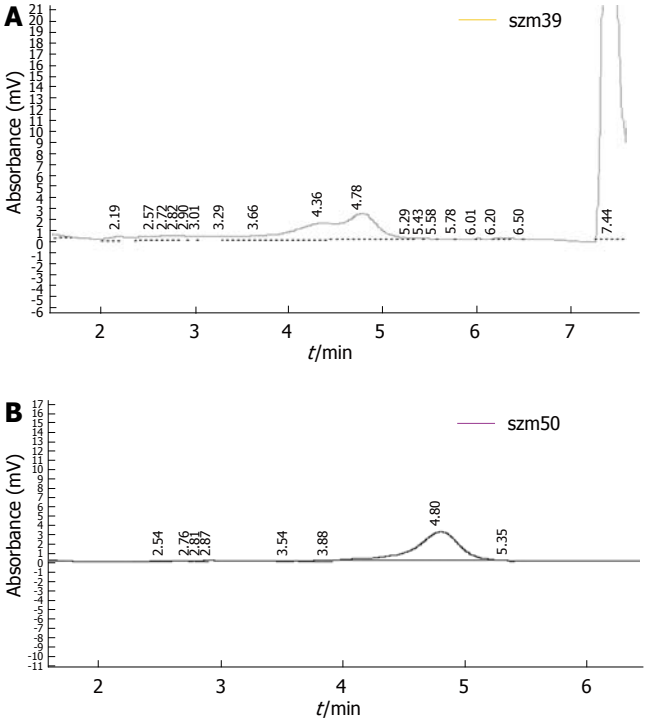

Figure 1 DHPLC showing variant elution peaks (**A**) and normal elution peaks (**B**) in exon 12 of hMSH2 gene.

DNA sequencing

DHPLC variants were confirmed by direct sequencing of independently amplified PCR products of the amplicons, in both sense and antisense direction, using the same primers. Sequencing was performed with Big Dye™ terminator cycle sequencing ready reaction kit (Applied Biosystems, Inc., Foster City, CA) on an ABI Prism™ 377 DNA sequencer following the standard conditions recommended by the manufacturer. Sequences obtained were aligned and compared to published wild-type sequences by Sequencher 3.1.1 analysis software.

Mutations identified in the kindred's proband were tested among their family members by direct DNA sequencing.

RESULTS

Among the 5 probands of the five Chinese HNPCC kindreds, 180 PCR products were screened by DHPLC. Two PCR products found with variant elution peaks by DHPLC were identified to have mutations. One was hMSH2 c.1808A→G resulting in Asp 603 Gly identified in the HNP5 kindred's proband and tested among the family members (Figures 1-3). The other was hMLH1 c.1882A →G identified in the HNP2 kindred's proband (Figures 4 and 5), which was not tested among the family members, because it might be the nonsense mutation analyzed by BLAST.

As shown in Figure 3, in the HNPCC5 kindred, there were four colorectal carcinoma patients in two successive generations, and three of these were diagnosed before the age of 45 years. The proband developed endometrial carcinoma at the age of 61 years, bladder carcinoma at the age of 66 years and colorectal carcinoma at the age of 72

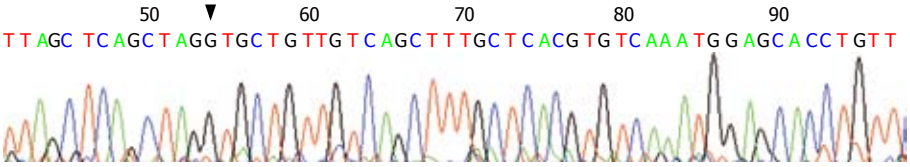

Figure 2 HPLC variants confirmed by direct sequencing displaying a single nucleotide substitution of c.1808A→G in exon 12 of hMSH2 gene.

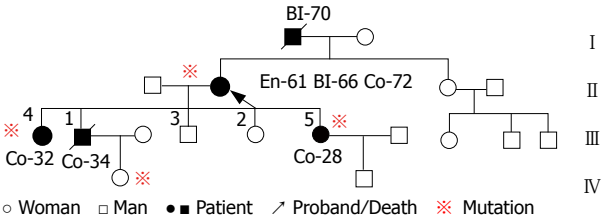

Figure 3 Pedigree tree of HNPCC 5 kindred. Co: Colon; Bl: Bladder; En: Endometrium.

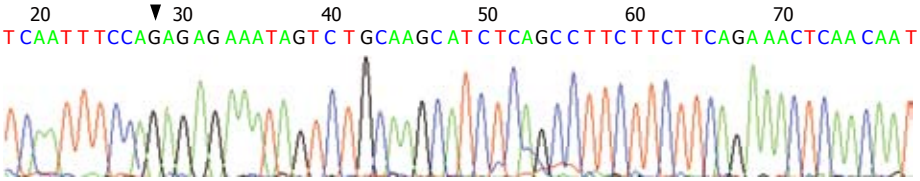

Figure 4 DHPLC variants confirmed by direct sequencing revealing a single nucleotide substitution of c.1882A→G in exon 16 of hMLH1 gene.

years, while his father developed bladder carcinoma at the age of 70 years. In addition, patient Ⅲ-1 had colorectal carcinoma at the age of 34 years and died of synchronous hepatic metastasis.

In the HNP5 kindred, each PCR product from nine proband's family members was tested by direct DNA sequencing. Only three of them were found to have the missense mutation in hMSH2 at position A1808G. The missense mutation sequence variant was found in exon 12 of hMSH2 gene. It was a single nucleotide substitution of c.1808A→G (Figure 2), which resulted in Asp 603 Gly of hMSH2 (NCBI Ref. Seq. NM 000251 and NP 000242 for mRNA and protein, respectively). Proband and patient Ⅲ-4 and -5 had this mutation and developed colorectal carcinoma. Patient Ⅲ-1's daughter had no colorectal disease even though she had this mutation, and was still under follow-up. No mutation was found in the others.

DISCUSSION

CRC is one of the most common cancers and its clinical selection criteria for cancer families were first established in Amsterdam in 1990 by the International Collaborative Group on HNPCC and modified in 1999[2]. Detection of constitutional mutations in genes associated with predisposition to cancer is practical in molecular diagnosis. Data suggest that molecular testing is much more efficient, if analyses are focused on a limited number of alterations[9-13]. Detection of germline mutation carriers is an efficient method to define high-risk CRC patients. Identification of germline mutations of either hMSH2 or hMLH1 could be performed in 50%-70% of families meeting the Amsterdam criteria for HNPCC, whereas the families not complying with these criteria show a much lower frequency of the MMR gene mutations[14-17]. Thus, hMSH2 or hMLH1 gene testing is most often used in early diagnosis of at-risk family members with HNPCC.

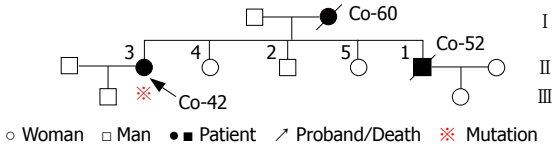

Figure 5 Pedigree tree of HNPCC 2 kindred. Co: Colon.

To identify a population-specific panel of mutations, it is crucial to describe them in all ethnic groups.

Even though CRC is common in China, few studies on HNPCC pedigree and its predisposition gene are available[4,17]. In our study, HNPCC kindreds were collected and hMSH2 and hMLH1 gene mutations were tested in order to find high-risk CRC populations. Two mutations were found among the five Chinese HNPCC kindreds. In the 5HNPCC kindreds, missense mutation was found in four members, three of them developed colorectal carcinoma. Although it has not been confirmed as a germline mutation yet, it may be an important factor for CRC development. Thus, the patient Ⅲ-1's daughter with this mutation should be closely followed up.

Approximately 20% of patients with colorectal cancer have a genetic component and HNPCC is the most common autosome dominant hereditary syndrome predisposing to colorectal cancer[18,19]. Various methods have been described to screen for HNPCC and directly test for mismatch repair gene mutations[20-27]. For patients with available tumor specimens, MSI and IHC are widely performed. Ruszkiewicz *et al*[28] reported that immunohistochemistry is an alternative method for assessment of MSI status, which is fast and relatively inexpensive compared with MSI testing. Some reports[26,29,30] suggest that detection of MSI and IHC for hMSH2/hMLH1 proteins is a reliable pre-screening test for hMLH1/hMSH2 germline mutations in families suspected of having HNPCC. Because China is a developing country with a large population and the incidence rate of CRC

increases, a screening protocol specific for the Chinese population is necessary to detect the high-risk populations with HNPCC. hMSH2 and hMLH1 gene mutation testing is a practical method for detecting HNPCC in Chinese population. Meanwhile, further research should be performed in Chinese HNPCC kindreds with germline mutations.

COMMENTS

Background

Approximately 20% of colorectal cancer patients have a genetic component and hereditary non-polyposis colorectal cancer (HNPCC) is the most common autosome dominant hereditary syndrome predisposing to colorectal cancer. Various methods have been described to screen for HNPCC and directly test for mismatch repair gene mutations. Even though CRC is common in China, few studies on HNPCC pedigree and its predisposition gene are available.

Research frontiers

Data suggest that molecular testing is much more efficient when analyses are focused on a limited number of alterations. Detection of germline mutation carriers is an efficient method to define high-risk CRC patients. Germline mutations of either hMSH2 or hMLH1 can be identified in 50%-70% of families meeting the Amsterdam criteria for HNPCC. Thus, hMSH2 or hMLH1 gene testing is most often used in early diagnosis of at-risk family members with HNPCC.

Innovations and breakthroughs

Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. Mutations were identified in two Chinese HNPCC kindreds. One was the missense mutation of hMSH2 c.1808A→G resulting in Asp 603 Gly, the other was the mutation of hMLH1 c.1882A→G .

Applications

Molecular pathological tests should be performed in order to identify individuals and at-risk family members with HNPCC. Close follow-up and intensive surveillance should be performed.

Terminology

Denaturing high-performance liquid chromatography (DHPLC) is a method for separating DNA duplexes that differ in the identity of one or more base pairs. The method is believed to be most efficient at the site of mutation. Basic local alignment search tool (BLAST) is powerful to compare novel sequences with previously characterized genes. Both functional and evolutionary information can be obtained from well designed queries and alignments. BLAST 2.0 can rapidly search for nucleotide and protein in their databases.

Peer review

The results of this clinical study indicate that mutation testing for hMSH2 and hMLH1 by PCR and direct sequencing is a preferable method to identify high-risk HNPCC patients.

Abstract

AIM: To investigate the killing efficiency of a recombinant plasmid containing a thymidine kinase (TK) domain insert driven by the vascular endothelial growth factor receptor 2 (VEGFR2) promoter (KDR) on vascular endothelial cells.

METHODS: The KDR-TK fragment was extracted from pBluescript Ⅱ KDR-TK plasmid by enzymatic digestion with *Xho*I and *Sal*I. The enhanced green fluorescence protein (EGFP) carrier was extracted from pEGFP by the same procedure. The KDR-TK was inserted into the pEGFP carrier to construct pEGFP-KDR-TK. Using ultrasound irradiation and microbubble, pEGFP-KDR-TK was transferred into human umbilical vein endothelial cells (HUVECs). The transient infection rate was estimated by green fluorescent protein (GFP) expression. Transfected HUVECs, non-transfected HUVECs, and HepG2 cells were cultured in the presence of different concentrations of ganciclovir (GCV), and the killing efficacy of HSV-TK/GCV was analyzed by 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazolium bromide (MTT) assay.

RESULTS: The recombinant pEGFP-KDR-TK was successfully constructed by inserting the KDR-TK fragment into the pEGFP carrier. Transfected HUVECs showed cytoplasmic green fluorescence, and the transient transfection rate was about 20.3%. Pools of G418-resistant cells exhibited a higher sensitivity to the prodrug/GCV compared to non-transfected HUVECs or non-transfected HepG2 cells, respectively.

CONCLUSION: KDR promoter and the suicide gene/prodrug system mediated by diagnostic ultrasound combined with microbubble can significantly kill HUVECs. Such therapy may present a novel and attractive approach to target gene therapy on tumor vessels.

INTRODUCTION

Angiogenesis coincides with increased tumor cell entry into the blood circulation and thus facilitates metastasis. Previous reports revealed that targeting angiogenesis represents a new strategy for antitumor therapy[1].

Vascular endothelial growth factor-A (VEGF-A) is the major player in tumor angiogenesis, which activates two tyrosine kinase receptors VEGFR1 (Flt-1) and VEGFR2 (KDR in humans/Flk-1 in mice). KDR was found to be overexpressed on activated endothelial cells of newly formed vessels and strongly associated with invasion and metastasis in human malignant diseases[2].

Gene therapy has made significant progress in tumor therapy[3]. The effectiveness of suicide gene strategy directed against cancer cells has been shown for various tumor cell types[4]. Among several suicide gene prodrug combinations, the herpes simplex virus-thymidine kinase (HSV-TK) gene is a prototype. However, non-selective, ubiquitous expression of suicide genes may

cause unexpected adverse effects such as bone marrow suppression[5,6]. Thus, prerequisite for achieving effective and safe gene therapy against cancer is the induction of a strong, tumor vascular-selective expression of suicide genes. The success of gene therapy largely depends on the development of a gene delivery vector that is safe, easy-performed, and efficient. Ultrasound exposure in combination with microbubble is a new non-viral delivery system that might improve transfection efficiency. Nie *et al*[7] have shown that a combination of microbubble contrast agents and ultrasound irradiation might be a beneficial and much easier way for non-viral gene therapy.

In the present study, we established a KDR promoter to drive TK gene expression in human umbilical vein endothelial cells (HUVECs). Transfection was achieved by diagnostic ultrasound combined with a microbubble contrast agent. Our purpose was to analyze the cytotoxic effect of TK/ganciclovir (GCV) under the control of the KDR promoter on HUVECs.

MATERIALS AND METHODS

Cell isolation and culture

Primary HUVECs were isolated using the modified "irrigative digestion" technique as described by Jaffe *et al*[8]. Briefly, a transfusion silica gel tube was inserted into one end of new born aseptic umbilical cords after abdominal delivery from healthy pregnant women who had normal routine urinalysis and blood tests (women with any complications of pregnancy or viral infections were excluded) to flush the bloodstain remaining in the cavity repeatedly with PBS, and then 15-20 mL collagenase Ⅱ (Sigma, St. Louis, MO, USA) was injected into the vein cavity and retained 10-12 min for digestion. The collection of umbilical vein was flushed with PBS and the endothelial cells were collected and centrifuged at 1000 rpm for 8 min. Cells were resuspended and seeded in human endothelial-serum free medium (SFM) (Gibco, California, USA) supplemented with 100 mL/L fetal bovine serum (FBS, Gibco), 2 ng/mL vascular endothelial cell growth factor (Sigma), 90 μg/mL heparin (Sigma), 100 U/mL penicillin, and 50 μg/mL streptomycin. Culture medium was changed after 24 h and then every three days (3 mL) till the cells became a confluent monolayer. The primary cells were allowed to grow for 3 passages (1:2 split). Viability was assessed by trypan blue dye exclusion staining (Sangong Biological Engineering technology, Shanghai, China). HUVECs were identified by staining with rabbit anti-human von Willebrand factor (Boshide Company, Wuhan, China), as well as by performing the acetylated low-density lipoprotein color reagent test (DiI-Ac-LDL) (Molecular Probes, Novato, Canada, Europe BV). Experiments were performed on cultures with a viability > 95%. The human hepatoma cell line HepG2 was obtained from Laboratory of Surgery of our institution and cultured in Dulbecco's modified Eagle medium (Sigma) supplemented with 10% FBS. The level of KDR expression in HUVEC and HepG2 cells was determined immunohistochemically.

Preparation of plasmid DNA

The pBluescript Ⅱ KDR-TK plasmid, which contains Herpes simplex virus thymidine kinase (HSV-TK) and the restriction sites for *Xho*I and *Sal*I and which is driven by the KDR promoter, was kindly provided by Dr Li Baojin. The 2.2-kb KDR-TK fragment was extracted from pBluescript Ⅱ KDR-TK by a double digestion with *Xho*I and *Sal*I (Takara Biotechnology Co.,Ltd, Dalian, China) and identified by electrophoresis and DNA sequencing. The pEGFP 4.7 kb carrier was released from EGFP plasmid DNA (donated by Doctor Zhang Ge, Laboratory of Molecular Medicine, Sun Yat-Sen University, China) containing the restriction sites for *Xho*I and *Sal*I using the same technique. The KDR-TK was inserted into the same clone location of the pEGFP vector with T4 ligase (Takara) to construct a plasmid termed pEGFP-KDR-TK. Restriction enzyme digestion and DNA sequencing (Bioasia Biotech Ltd, Shanghai, China) were used to confirm correct construction. The plasmid EGFP-KDR-TK was propagated in *E. coli* strain DH5α and purified using a large-scale plasmid DNA purification kit (Plasmid Maxi Kit; Qiagen, Hilden, Germany). The purity of EGFP-KDR-TK plasmid DNA was assessed by ultraviolet spectrophotometry.

Preparation of microbubble contrast agent

The ultrasound contrast agent SonoVueTM (Bracco SpA, Milan, Italy) that was used in this study consists of 59 mg of sulfur hexafluoride gas (SF6) and 25 mg of a freeze-dried white powder. Reconstitution of the material with 5 mL saline, yielded phospholipidstabilized microbubbles filled with sulfur hexafluoride with a diameter of less than 8 μm (mean, 2.5 μm)[9].

Gene transfer into cells with microbubble-enhanced ultrasound irradiation

HUVECs were seeded in 24-well plates at a density of 1.5×10^5 cells/well together with 15.0 μg of pEGFP-KDR-TK (50 μg/mL) in a total volume of approximately 300 μL and incubated for 20 min at 37℃. The 24-well plates were randomly divided into three groups with 8 samples in each group: group A, sham-exposure to ultrasound without addition of SonoVue; group B, exposure to ultrasound without addition of SonoVue, and group C, exposure to ultrasound with the addition of 2% SonoVue (600 μg/well). The ultrasound machine used was HP-Viewpoint 2500 scanner (Phillips Medical System, Bothell, MA, USA). An E94K213 transcranial vector transducer probe (12 mm in diameter) was placed on a polyester film (thickness, 6 μm) that covered the 24-well plate with 10 mm thickened contact gel between the probe and the polyester film, and the cells were exposed to 1.9 MHz continuous ultrasound for 5 min at an 80.0 mW/cm^2 output intensity (Figure 1). Five minutes after the first exposure, another 3 min exposure was performed under the same conditions. Cell viability was tested immediately after exposure by trypan blue dye exclusion staining. Cells were then incubated in SFM, 10% FBS, and 2 ng/mL vascular endothelial cell growth factor in 5% CO_2 at 37℃ for 48 h. Transfection efficiency was determined by fluorescence microscopy (Leica, Danaher Corporation, Wetzlar, Germany).

Subsequently, the cells were incubated for another 4 h

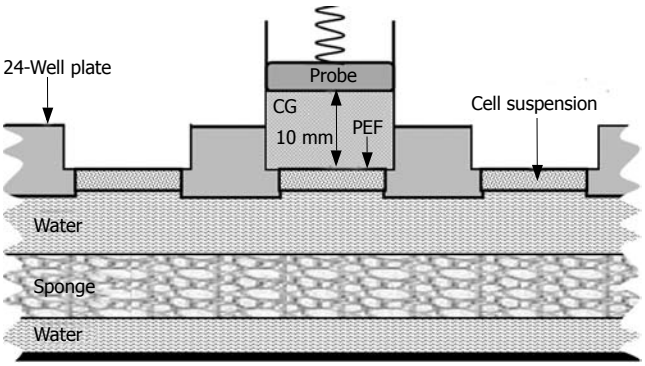

Figure 1 Schematic diagram of gene transfection. Transducer with contact gel (CG) was placed on the cell suspension covered with a 6-μm poly-ester film (PEF) under 1.9 MHz continuous ultrasound with a 80.0 mW/cm^2 output intensity. The 24-well plate was kept in a water bath at 37℃, and a sponge mat was placed in the water bath.

before they were subjected to selection with 600 μg/mL G418 (Gibco). At that time point when most of the cells in group A had died, G418 concentration was decreased to 200 μg/mL to maintain filtrate efficacy. After around three weeks of selection, a stable G418-resistant cell pool has formed as visualized by fluorescence microscopy. Cell colonies named KDR-TK/VEC were transferred with filter paper dipped trypsin to anther 24-well plate and cultured in an humidified atmosphere with 5% CO_2 at 37℃ for 3 d for subsequent experiments.

Sensitivity of cells to prodrug

KDR-TK /VEC, HUVEC, and HepG2 cells in logarithm growth term were detached by amylopsin (Sigma), the number of viable cells was determined by trypan blue dye exclusion, and viable cells were seeded in 96-well plates at a density of 2×10^3 cells/well. One day later, the cells were treated with 500 μL of fresh medium in the absence or presence of varying concentrations of GCV (0, 1, 10, 50, or 100 μg/mL). After incubation for 3 d, the sensitivity of cells to GCV was assessed using conventional 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazolium bromide (MTT) assay[10]. The percentage of suppressive cells was calculated with the following formula:

Relative suppressive rate = (1 - average OD570 of experiment/OD570 of control) × 100%.

Statistical analysis

Data were expressed as mean ± SD. The statistical significance of the data was compared by using two paired Student *t* test. ANOVA was used to analyze the differences among the different groups. Results were considered significant at $P < 0.05$.

RESULTS

Identification of HUVEC and KDR expression in cell lines

The average amounts of the endothelial cells isolated from umbilical cords using modified "irrigative digestion" technique were 1×10^6 cells. Light microscopic studies found that after 5 d in culture, HUVECs grew in confluent monolayer without a definable whirling pattern. The cells

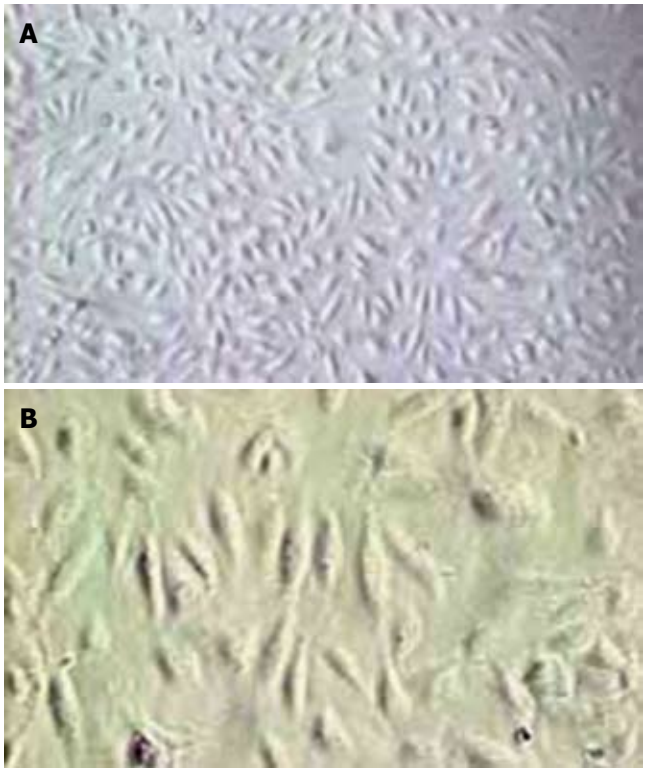

Figure 2 Photomicrographs show cultured human endothelial cells on d 7. The cells appeared to be a monolayer of very flat, polygonal-shaped cells. **A**: × 100; **B**: × 200.

were homogenous, closely opposed, large, and polygonal with an oval centrally coated nucleus and indistinct cell border (Figure 2). Factor Ⅷ is an important plasma marker of endothelium damage/dysfunction, which can also be detected in death or dysfunctional endothelial cells. The positive dye was brown in cytoplasm of HUVEC stained with the factor Ⅷ related antigen (Figure 3A). Compared with the factor Ⅷ, DiI-Ac-LDL can be taken up only by the living endothelial cells. The living HUVECs incubated with DiI-Ac-LDL are found to be red fluorescence under the fluorescent photomicroscope (Figure 3B), while the dead cells are uncolored. In the present study, the DiI-Ac-LDL stain revealed that more than 95% HUVEC were alive. To estimate the selectivity of the strategy using the KDR promoter, it is necessary to identify KDR-positive and KDR-negative cell lines. As shown in Figure 4, immunohistochemical analysis revealed KDR expression in HUVECs but not in HepG2.

Identification of recombinant plasmids

The positive clone of recombinant pEGFP-KDR-TK, which contains the neomycin resistance gene and the independent KDR promoters controlling the expression of TK, was identified by restriction endonuclease cleavage and sequencing. DNA sequencing and electrophoresis showed correct KDR-TK insertion into the pEGFP carrier (Figure 5).

Transfection of HUVECs with pEGFP-KDR-TK

The transient transfection rate was assessed by fluorescence microscopy 48 h after transfection. Fluorescent microscopy

The cells were stained brown (× 400); **B**: Shows positive-stained cells *in vitro* treated with DiI-Ac-LDL. More than 95% HUVECs are found to be red fluorescence (× 400).

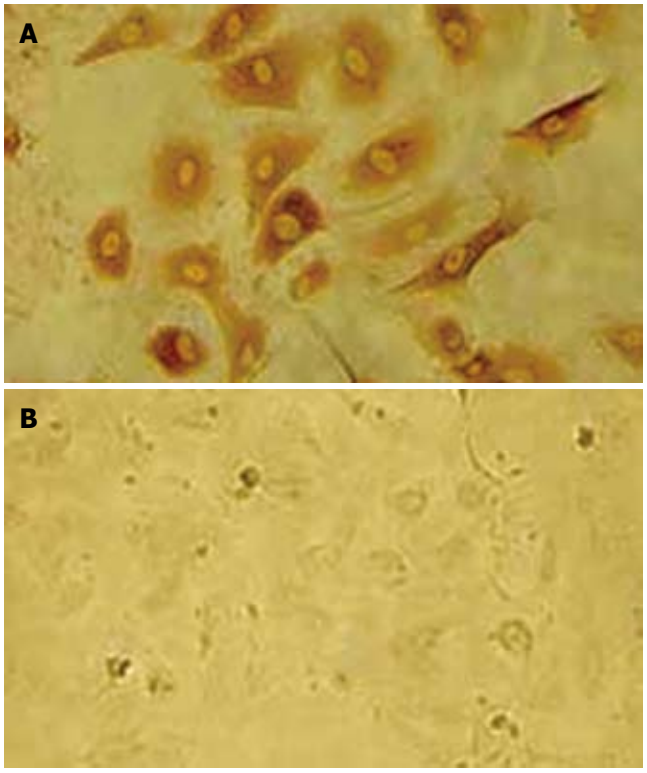

Figure 4 Immunofluorescence study (× 400) of cultured human endothelial cells. **A**: Shows positive-stained human endothelial cells with KDR receptor; **B**: Shows negative-stained human hepatoma cells without KDR receptor.

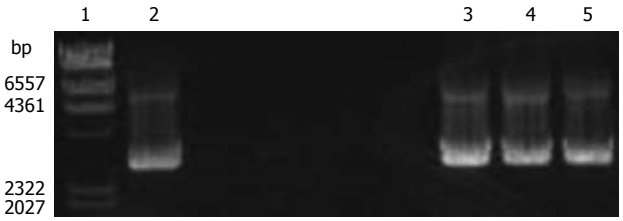

Figure 5 Identification of recombinant pEGFP-KDR-TK by restriction enzyme digestion (*Sal*Ⅰ/*Xho*Ⅰ) and electrophoresis. Lane 1: DNA markers (λDNA/*Hind*Ⅲ); Lane 2-5: pEGFP-KDR-TK was digested with *Sal*Ⅰ/ *Xho*Ⅰ.

revealed that the cells in group A had no obvious coloration (Figure 6A). Fluorescent staining was observed in few cells (1.7%) in group B (stimulated by ultrasound only, Figure 6B), whereas the HUVECs transfected by the pEGFP-KDR-TK in group C (stimulated by both SonoVue and ultrasound exposure) showed clear green fluorescence within 20.3% HUVECs indicating EGFP expression (Figure 6C and D). EGFP and TK were co-expressed in HUVECs by microbubble-enhanced ultrasound irradiation, followed by selection of permanent transfectants in the presence of G418. The G418-resistant cells were named KDR-TK/VEC.

Cell survival rate

The percentage of surviving cells was examined by trypan blue dye exclusion after ultrasound exposure. The cell survival rates were 94.0% ± 1.1% in the group A, 93.5% ± 0.9% in the group A and 90.2% ± 0.9% in group B (Figure 7).

Sensitivity of genetically modified cells to GCV

We selected GCV as a prodrug and examined the sensitivity of KDR-TK/VEC, HUVEC, and HepG2 to GCV. As shown in Figure 8, HepG2 cells were found to be resistant to GCV, and the value of IC 50, defined as the dose required for 50% cytotoxicity, was > 100 μg/mL (the highest concentration tested). HUVECs exhibited a higher sensitivity to GCV in comparison to HepG2, when the concentration tested was above 50 μg/mL, the IC 50 value for HUVECs was still more than 100 μg/mL. Conversely, KDR-TK/VEC cells were susceptible to GCV in a dose-dependent manner and exhibited approximately 75% suppression at a GCV concentration of 100 μg/mL, with the IC 50 value being approximately 10 μg/mL. KDR-TK/VEC cells also showed significantly higher sensitivity to GCV compared to non-transfected HUVECs, resulting in 2 to 5-fold higher suppression to GCV.

DISCUSSION

Acquired drug resistance is a major problem in cancer therapy. Many deaths from cancer may follow the development of resistance to chemotherapy. The emergence of resistance depends in part on the genetic instability, heterogeneity, and high mutational rate of tumor cells[1]. In contrast, endothelial cells have relative genomic stability. Therefore, antiangiogenic therapy targeting tumoral endothelial cells may avoid the problem

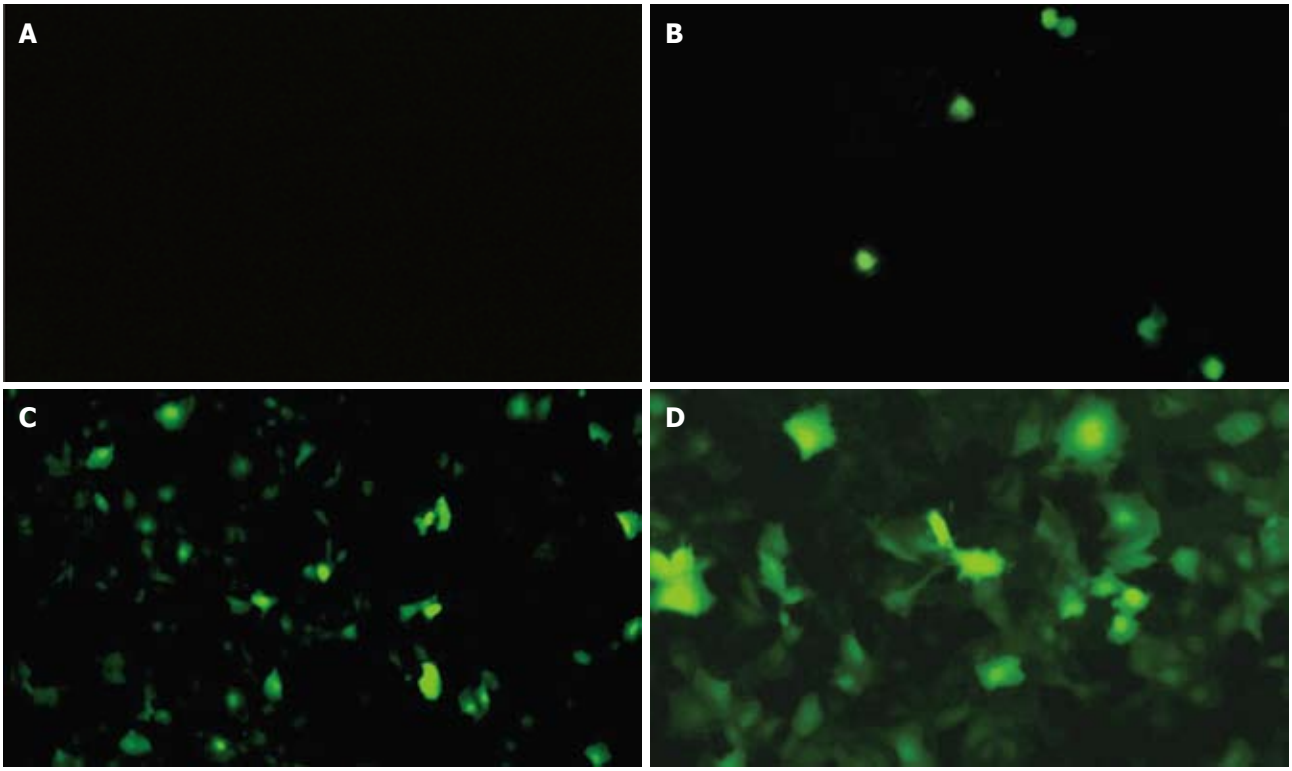

Figure 6 Fluorescent microscopy showed EGFP expression 48 h after pEGFP-KDR-TK transfection. **A**: Shows no obvious EGFP expression in cells without microbubbles and ultrasound (× 200); **B**: 1.7% cells exposed to ultrasound only shows EGFP expression (× 200); **C, D**: Significant increase in EGFP expression in HUVECs exposed to both the ultrasound and SonoVue (**C**: × 200, **D**: × 400). About 20.3% HUVECs had EGFP expression.

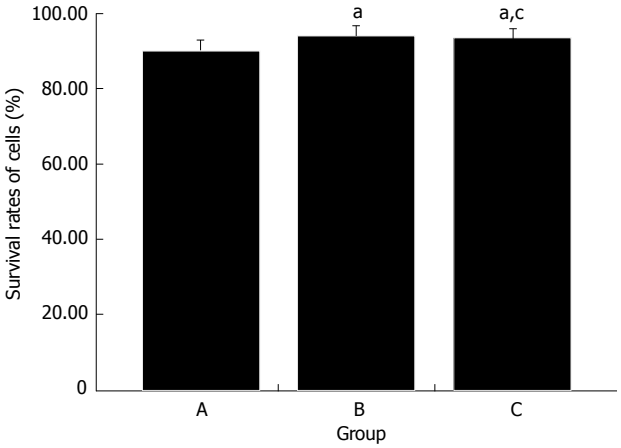

Figure 7 HUVECs survival rate examined by trypan blue dye exclusion after transfection. Values are expressed as the average percentage of viable cells, $n = 5$ from 3 independent experiments. $^{a}P < 0.05$ *vs* group A; $^{c}P > 0.05$ *vs* group B.

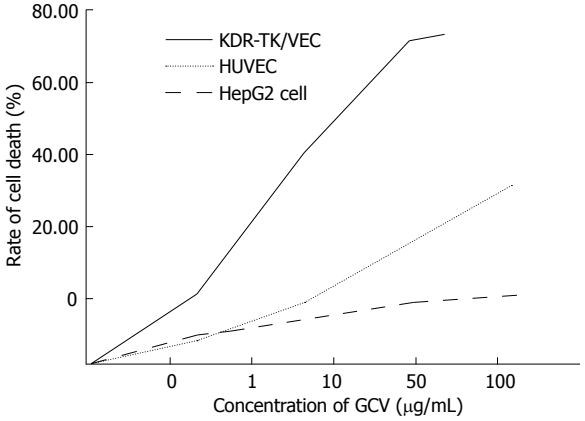

Figure 8 *In vitro* cytotoxic effect of GCV on KDR-TK transfected HUVECs (KDR-TK/VEC), non-transfected HUVECs, and HepG2 cells. KDR-TK/VECs, non-transfected HUVECs, and HepG2 cells were cultured with various concentrations of GCV for 3 d and viability was estimated by MTT assay.

of drug resistance. In addition, the growth and persistence of solid tumors and their metastases are angiogenesis dependent[11], thus angiogenesis provides a target for therapeutic approaches to solid tumor, and the inhibition of angiogenesis is very promising.

Most angiogenic inhibitors are biologically active peptides. It is difficult to express proteins persistently and stably *in vivo*, and the complexity and time requirement for protein purification make their clinical application infeasible[12]. Gene therapy is an attractive means of delivering these antiangiogenic agents to tumor site, and targeting the tumor vessels could avoid potential side effects. Although several previous studies have shown the effectiveness of TK targeting in endothelium as antiangiogenic strategy, few of them have reported with suicide gene therapy by targeting TK in the vasculature and not in the human tumor cells[13,14]. Ozalki *et al* have shown that vWF2 promoter combined with HSV-TK suicide gene can exert an endothelial-preferential killing effect on the transduced HUVECs *in vitro*[15]. Von Willebrand factor (vWF) is a blood glycoprotein which is excreted by endothelium and megakarcytes, and the elevation of vWF

is not only found in cancer, but also in other cardiovascular diseases[16]. Consequently, tumor vessels are not accessible targets for antiangiogenic gene therapy, when the vWF2 promoter and HSV-TK/prodrug are administrated systemically. Compared with vWF, KDR has a major role in tumor angiogenesis, and in adulthood, KDR appears mostly restricted to vascular endothelial/lymph endothelial cells[2]. Because of the overexpression of KDR in tumors vasculature, KDR-promoter did not yield high TK protein expression in normal vasculature, whereas in endothelial cells within tumors. Dancer and colleagues indicated that expression of TK driven by an endothelial-specific promoter can cause significant decrease in microvessel density and inhibit tumor growth[17].

The suicide gene used in this study has been widely used in gene therapy of animal tumors, and it encodes an enzyme that can effectively phosphorylate the antiviral nucleoside analogue ganciclovir (GCV) to its monophosphase form, which is further phosphorylated by cellular kinases to DNA polymerase inhibitors[18]. Apoptosis has been demonstrated as the major mechanism of cell death caused by the HSV-TK/GCV system in different cells[19,20]. The present study demonstrated that KDR promoter and the suicide gene/prodrug system showed a targeted killing effect on transfected HUVECs. The sensitivity of KDR-TK-transfected HUVECs to GCV was found to be about 2 to 5-fold higher when compared to non-transfected HUVEC and HepG2 cells.

Viral delivery systems have been developed as highly efficient carriers for gene delivery to a variety of tissues. However, viral gene carriers have some major disadvantages such as possible immune response, severe inflammation reactions, the risk for insertional mutagenesis, and interference with expression of cellular genes[21,22]. Recently, ultrasound together with microbubble has been recognized as a useful means for controlled delivery of drugs. Although the mechanism of enhanced transfection efficiency by ultrasound is not yet fully understood, cavitation is an important event that increase capillary permeability and produce transient nanopores in cell membranes. SonoVue as well as other microbubble can be rapidly destroyed by the sonication, and the threshold of cavitation decreases after addition of microbubbles. In this study, we demonstrate that widely used diagnostic ultrasound and microbubble-based ultrasound contrast agent can also be applied for the delivery of DNA. The expression of EGFP in HUVECs was just 1.7% in the group only treated with ultrasound, whereas the expression rate significantly increased to 20.3% ($P < 0.001$) when treated with ultrasound and SonoVue. In contrast, therapeutic or high-intensity focused ultrasound has been used for most of the described ultrasound-facilitated gene delivery and gene transfection experiments[23-25]. An advantage of using diagnostic ultrasound instead of therapeutic ultrasound allows visualization of the site of interest and microbubble possible by using conventional ultrasound imaging systems. In this study, more than 90% of the cells treated with ultrasound and SonoVue were viable. Though the longer exposure time used in our experiment, the cell viability in this study is also higher than that using therapeutic ultrasound[26]. Although the transient transfection rate of KDR-TK in this study is relatively low compared with other studies using viral vectors, we believe this disadvantage can be offset by lower acoustic frequency, higher ultrasound output, or longer exposure time.

Our observation also suggested that non-transfected HUVECs have more sensitivity to GCV, compared with non-transfected HepG2 cells. The mechanism was not yet understood; we speculated that the lower sensitivity to GCV of non-transfected HepG2 cells might partly involve the deficiency of TK in tumor cells[27].

In summary, our study revealed that, on the basis of the KDR-mediated invasion, TK/GCV can accomplish a selective killing effect on HUVECs *in vitro*. KDR promoter and the suicide gene/prodrug system mediated by diagnostic ultrasound combined with microbubble may present a novel and attractive approach for gene therapy to target tumor vessels.

COMMENTS

Background

Tumor angiogenesis plays a critical role in the development and progression of the solid tumor. Targeting angiogenesis represents a new strategy for antitumor therapies. Ultrasound exposure in combination with microbubble is a new non-viral delivery system.

Research frontiers

Gene therapy to target tumor vessels can cause a significant decrease in microvessel density and inhibit tumor growth. Just as therapeutic ultrasound, diagnostic ultrasound in conjunction with microbubbles can also be a useful gene delivery system.

Innovations and breakthroughs

Diagnostic ultrasound-facilitated gene delivery on targeting the vascular endothelial cells has not been used. This study established a specific promoter in order to target gene expression in human umbilical vein endothelial cells and demonstrated that diagnostic ultrasound combined with microbubble can be a useful gene delivery system.

Applications

This study showed KDR promoter and the suicide gene/prodrug system mediated by diagnostic ultrasound can significantly kill human umbilical vein endothelial cells. This may present a novel and attractive approach to target gene therapy on tumor vessel.

Terminology

Microbubble: microscopically gas bubbles encapsulated by an elastic shell, can be used in diagnostic and therapeutic applications.

Peer review

This study is well-designed and very interesting, and the manuscript is well-written.

Abstract

AIM: To describe a new clinical and pathological subtype of microscopic colitis in children.

METHODS: A selected group of children with abdominal pain, constipation and/or diarrhoea showing discrete or no macroscopic abnormalities on endoscopy was described.

RESULTS: Multiple biopsies of colon showed large mononuclear clear cells in lamina propria of mucous membrane provided that good quality histological sections were performed and observed under a higher magnification. Otherwise, they could be misinterpreted as artefacts. Their presence in routine histology might suggest a systemic storage disease (Whipple's disease), and neuronal intestine dysplasia. Using immunohistochemical staining and electron microscopy we confirmed their origin from CD68 positive mononuclear macrophages.

CONCLUSION: The presence of large clear cells is a constant microscopic feature. Failure of transient large bowel stationary macrophages plays a role in the pathogenesis of this benign microscopic clear cell colitis, sometimes coexisting with allergy.

INTRODUCTION

Microscopic colitis constitutes a group of diseases with unknown aetiology and causes neither destruction nor rebuilding of large bowel mucosa. Microscopic colitis is rarely recognized in children[1,2] and may be misinterpreted as inflammatory bowel disease[3]. Various forms of microscopic colitis have been identified in adults[4-11], including lymphocytic, collagenous, multinucleated giant cells. No description of microscopic colitis with the presence of giant mononuclear clear cells in lamina propria in children is available. Several staining methods can be used to identify the phenotype of these cells. This is probably not a new disease but it is frequently overlooked due to routine use of low magnifications and poor quality of histological staining for paraffin-embedded materials. The presence of large amounts of these cells in our series of biopsies is characteristic in children with chronic abdominal pain, diarrhoea or constipation. In three cases, the preliminary diagnosis was Whipple's disease, neuronal dysplasia and even Gaucher disease. Definitive diagnosis of clear cell colitis (CCC) was made by immunohistochemistry methods and electron microscopy. A higher diagnostic profile is possible for identification of various forms of microscopic colitis.

Clinical, endoscopic and morphological analyses of CCC were described in series of large bowel biopsies. Characteristic giant mononuclear clear cells were found in sections by routine hematoxylin and eosin staining. Magnifications larger than 200 × must be used and high quality paraffin histology sections must be obtained to detect the cells. Otherwise, CCC may be overlooked. Using immunocytochemical and electron microscopic procedure, these clear cells were identified as activated macrophages which were CD68 positive and contained multiple vacuoles with characteristic amorphic homogenous lipid like material. The cells were found only in various parts of large intestine but not in small intestine or gastric or duodenal mucosa. Ten-year observation of patients in whom repeated biopsies were performed, allowed us to conclude that CCC is a form of microscopic colitis with chronic persistent benign course and persistent constant histological pattern. During the last 3 years, 20 patients underwent a prolonged (6-mo to a 1-year) therapy with probiotics. Clinical symptoms improved and the number of clear cells decreased in microscopic examinations. In 6 cases the cells disappeared

completely from mucous membranes. The remaining patients received a continuous long-term follow-up.

MATERIALS AND METHODS

Patients

Clinical and morphological study on CCC involved 81 children aged between 17 mo and 17 years selected out of 5000 large bowel biopsies taken from children who underwent treatment in paediatric centres between 1994 and 2005. The group included 63% boys and 18% girls. The majority of patients (68%) were inhabitants of urban areas, whilst the rest (32%) lived in the countryside. Colon dysfunction was the reason for diagnostic investigation. The majority of patients reported recurring abdominal pain, diarrhoea, constipation, and poor appetite. Their stools were of various consistency and contained mucus. Each child had at least two endoscopic examinations of the final part of the alimentary tract (23 had rectoscopy and 58 had colonoscopy).

Clinical, laboratory and endoscopic evaluations were performed carefully. Clinical diagnosis was established based on the number of stools per week, the presence of mucus, general comfort of a child, intensity of stomach aches, the presence of fever, ESR, haemoglobin concentration, state of nutrition and the presence of parenteral manifestations. Evaluating the rate for changes in endoscopic image, we took into consideration vascular drawing, granulation of mucous membrane.

Bacteriology and virology

The presence of intestinal pathogens (Salmonella, Shigella, Campylobacter, Escherichia coli, Yersinia, Clostridium difficile) and Giardia infection was verified. Diagnostic research for the presence of enteroviruses was performed in the Center of Virology of the National Institute of Hygiene on the Hep-2 and RD cell lines supplied by the WHO. The presence of retrovirus was checked in order to obtain a full virological evaluation. Tests of the latex reaction with Slidex Rota-kit 2 set and ELISA serological examination (using the DAKO rabbit anti-rotavirus (Human) reactants recommended by the WHO) were performed.

Morphological examination

During colonoscopy 3 specimens were collected from each of the 58 patients. Colonoscopy was performed 2 times and a total number of 248 biopsies were examined. A comparison of long-term changes occurring in the course of CCC was possible. Rectoscopy was performed 3 times in 23 cases. A total number of 317 biopsies were collected. Paraffin-embedded specimens were cut into serial sections which were stained with hematoxyllin and eosin. In 81 cases, 162 immunological staining procedures were performed with 16 monoclonal antibodies (to CD3, CD4, CD22, CD34, CD31, CD68, PCNA, Ki67, chromogranin, synaptophysin, neurofilament, actin, p53, GFAP, IL-beta, TNF alpha) and 4 histological staining procedures were performed for mucicarmin, PAS, PAS diastase. A total of 2916 staining procedures were reviewed (Table 1). The phenotypes of clear cells were identified.

Table 1 Expression of immunocytochemical markers in the CCC of the colon submucosa including some histological staining

Marker	Clear cells
CD3 (T cell)	Negative
CD4 (T cell)	Negative
CD22 (B cell)	Negative
CD34 (precursor cell)	Negative
CD31 (Endothelial)	Negative
CD68 (Macrophages)	+++ Strongly positive
PCNA-proliferation antigen	Negative[2]
Ki67 mitotic activity	Negative[1]
Chromogranin	Negative
Synaptophysin	Negative
Naurofilament	Negative
Actin	Negative
P53 mutations	Negative
GFAP glial marker	Negative
TNF alpha	Negative
IL2	Negative
Mucicarmin	Negative
PAS	Strong positive
PAS diastase	Digested
Osmium tetraoxide	Positive

[1]1-3 per crypt; [2]Positive in the cryptic epithelium.

In 10 cases, examination under an electron microscope (Jeol 100CX) was also performed. Preparations of intestinal mucosal biopsies were fixed in 4% glutaraldehyde in cacodylate buffer and then in OsO_4, followed by a typical Epon procedure. Ultra-thin sections were counterstained with lead citrate and uranyl acetate.

RESULTS

Clinical observation

The incidence of CCC as a form of microscopic colitis (MC) was 2% in children with abdominal pain, diarrhoea and constipation. ESR < 100 mm and MHC/hemoglobin concentration > 8.5 g/dL were found in all children. During the 10 years of observation, no clinical or endoscopic changes in IBD were noticed. Before analysis, children did not take any medicines or drugs that could caused pathological changes in mucous membrane of the large intestine. No treatment was administered. In some cases, a pre-treatment with salazopyrine for a few months did not result in regression of endoscopic or histological changes. Clinical symptoms were improved when probiotics was administered in 20 patients. Clear cells disappeared on mucosal membranes in the second biopsy from 6 patients. The remaining patients remained on treatment with Saccharomyces boulardi.

The dominant symptoms in both girls and boys included recurrent abdominal pain, stiff and (or) loose stools, even diarrhoeal stools with mucus additive. Some patients were admitted to gastroenterology hospital departments mainly because of suspected IBD. Some showed atopic skin inflammation and (or) recurring upper respiratory system inflammation. Five children with bronchial asthma were treated. Laboratory peripheral blood and urine tests and microbiologically parasitological stool tests did not reveal any pathological changes.

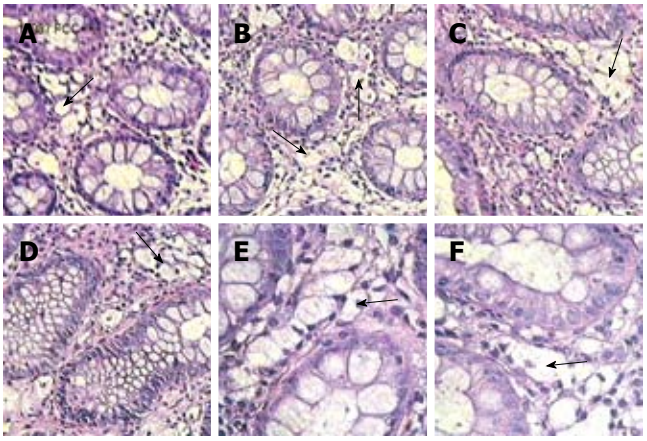

Figure 1 Microscopic features of CCC (**A-F**) (HE, × 320).

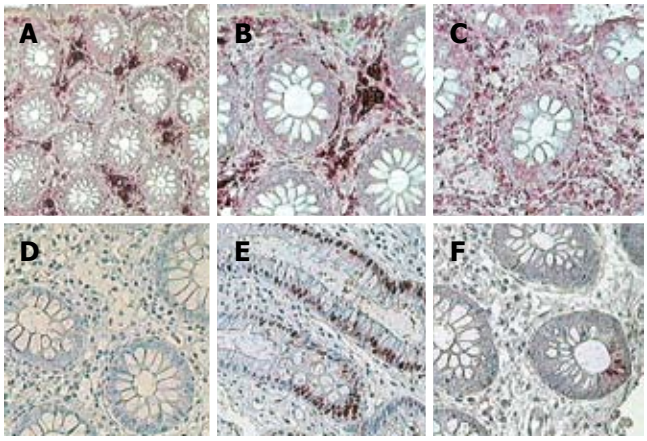

Figure 2 Immunocytochemistry of CCC using monoclonal antibodies and APPAP method showing positive expression of mononuclear phagocytic cell line (**A** and **B**), negative T3 and T4 lymphocytes (**C**), negative neurofilament (**D**), Normal PCNA expression in cryptal epithelium (**E**), and normal mitotic activity of positive CD67 (**F**) (× 320).

Abdominal pain occurred in all cases. The pain was mild or moderate. Less than 18 stools per week were counted in 7 children, 18-35 stools in 59 cases and 36-60 stools per week in the remaining 15 cases, constipation in 19 cases. A subjective evaluation of general feeling of children was good. Parenteral symptoms were noted in 19 out of 81 children, mainly upper respiratory tract infection. Forty-three children had ESR less than 40 mm, 20 had 50-100 mm ESR after 1 h. Haemoglobin concentration was above 10 g/dL in all cases. The state of nutrition (Cole and Stanfield) was over 85% in 27 cases, 80%-85% in 46 cases and under 80% in 8 cases. Bacteriological and virological examination of stools gave negative results.

Endoscopic examination

Endoscopic examinations were done with a stiff rectoscope. Eighty-two percent of the patients had also a supplementary colonoscopy. Macroscopically, all patients appeared to have normal mucosa or granulated mucosa, with sharply outlined vascularization and a thin layer of mucus in the rectum and sigmoid colon. In children with CCC undergoing colonoscopy, characteristic fine granulation and increased sharpness of vascular outline in the descending and transverse colon were found and changes in the ascending colon were also observed in 6 children. Susceptibility to bleeding was increased in 9 children. Three to six biopsies were taken during each endoscopic examination of the large intestine, observation was repeated 3 times during the 5-10 years. One specimen was collected at each rectoscopy during the 5-10 years of observation. In the consecutive rectoscopic and endoscopic examinations, the mucosal pattern of CCC was not changed. Persisting granulation and increased sharpness of the vascular pattern were revealed. Endoscopic examination of the upper part of alimentary tract gave normal results.

Histology

Microscopic images of routinely HE-stained sections were analysed. There were large clear cells in the lamina propria of mucosa, appearing either separately or in groups (Figure 1). The cells occupied the entire lamina propria from the covering epithelium to the basis of cryptal glands and the level of muscularis mucosa. Distribution of the clear cells allowed identification of 3 degrees of clear cell density: grade 1-single cells at various levels of lamina propria, grade 2-the presence of aggregates of 3-10 cells, grade 3-clear cells uniformly distributed in lamina propria. The presence of clear cells in patients was permanently observed during the 5-10 years. Clear cells showed a positive reaction with neutral mucopolisacharides in the PAS method with periodic acid and the Shiff's reagent (PAS- positive reaction), and negative reaction after digestion with diastase. Staining with mucicarmine was negative. No intraepithelial lymphocytosis was noted and the base membrane was normal. About 243 serial sections stained with HE were reviewed microscopically.

Immunocytochemistry

Clear cells presented a strong positive expression in the reaction with the CD68 antibody (Figure 2A-F, Table 1). Sixteen immunocytochemical reactions were performed 3 times in 81 patients during the period of observation in order to identify the phenotype of large clear cells.

Electron microscopy

In contrast to primary metabolic diseases, electron microscopic examination of clear cells revealed the presence of single nuclei with nucleoli and multiple secondary phagosomes with accumulation of homogenous osmophilic materials (Figure 3). Other structures of the large intestine mucosa were normal. The material for electron microscopic analysis was taken from 10 patients with CCC confirmed previously by histological examination.

DISCUSSION

Microscopic colitis is the term suggested by some authors for abdominal pain, alternating chronic diarrhoea and constipation and endoscopic image close to normal[4-8]. A characteristic microscopic picture of adults is in the form of collagenous and lymphocytic colitis[9-11]. The cause for microscopic colitis is unknown. Several concepts are

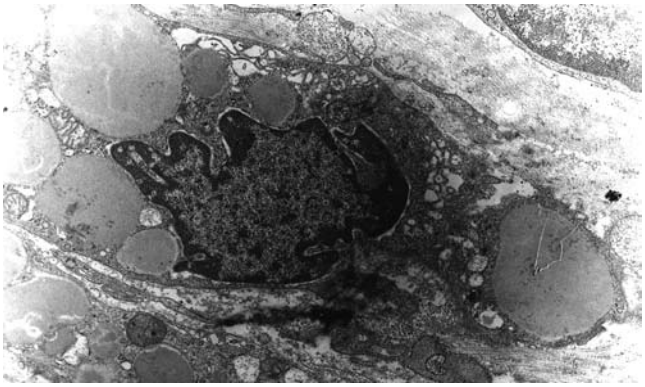

Figure 3 Electron microscopy of clear cells. Giant clear macrophages contain multiple vesicles varying in size filled with homogenous osmiophylic materials (secondary phagosomes) without any structural components in their cytoplasm (OsO_4 staining, × 24 000).

published, including abuse of medications[12], increased concentration of antigens and cytokine expression[13], auto-antibodies in blood[14], prostaglandin level[15]. MC may overlap with indeterminate inflammatory bowel disease[16], but in contrast to CCC, TNF alpha expression may be positive in silent inflammatory bowel disease[17].

CCC in children as a form of microscopic colitis is characterized by the presence of various large mononuclear clear cells in lamina propria. The cells are easily recognized when high magnification microscopy is used and section staining of microscopic slides is good. CCC does not manifest as destruction or reconstruction of glands. In the present study, basic membrane was not damaged, no lymphocytic or calagenous colitis or other forms of microscopic colitis described elsewhere were observed. Clear cells are mononuclear in contrast to other microscopic colitis, where there are giant multinucleated cells[18]. Clear cells described here are different from other muciphages[19]. On the other hand, Hamrock[20] has reported clear cells in patients with AIDS. The cells look like Whipple cells but they can be overloaded with inclusion material (Mycobacterium). Some authors suggested that rectal biopsy should be performed in cases of irritable bowel disease since they may be classified as MC[21].

Differential diagnosis should also consider neuronal dysplasia[22] of intestine, in which large, bright ganglion cells can be very similar to the giant clear cells in CCC. The reaction with neurofilaments, synaptophisine or (and) chromogranine is helpful. Some authors suggest that Salmonella typhimurium type can mobilize phagocytosis in macrophages of the large intestine but we have not found bacterial or viral particles in the phagosomes of clear cells. Different macrophages described in Erdheim-Chester disease exhibit neoplastic characteristics[23]. Possible persistent changes (e.g. after the rotaviral diarrhoea) and the presence of enteroviruses in clear foamy cells can be ruled out on the ground of electron microscopy and negative results of blood and stool test.

Xanthelasma of rectum containing sialomucin, is a different disease rather than CCC. However, patients with similar symptoms suffer from diarrhoea, constipation or haemorrhages. The presence of these symptoms is a result of mechanical injuries of mucosa in the course of chronic constipation. In contrast to muciphages, clear cells were negative for mucicarmine staining in our study.

The mononuclear phagocytic system consists of macrophages widely distributed in the body as circulating or stationary cells. Macrophages of large bowel mucosa belong to stationary cells and have various functions. In some special unknown conditions, they can transform into large clear cells and exhibit transient malfunction with accumulation of lipid material. It should be emphasized that one third of our patients had allergic extra intestinal manifestations. Finally, application of probiotics (Saccharomyces bulardi) has a beneficial effect in children with CCC. Confirmation of this finding requires further long-term observation.

COMMENTS

Background

Clear cell colitis (CCC) is a description of a new form of microscopic colitis in children. This is a benign disease recognized in some children showing symptoms of recurrent alternate diarrhoea and constipation. Patents are directed by physicians to gastroenterology units of district hospitals. Endoscopic examination shows normal or minor changes which do not constitute a qualification for further therapy. Pathologists using usually low magnifications can overlook the presence of large clear cells in lamina propria, and describe mucosa as normal. The lesions are seldom found in academic gastroenterological centers, where selected patients with more serious symptoms are ordered.

Research frontiers

Detection of giant clear cells is very important if no other lesions in large intestine musosa or other organs are found. Otherwise, false diagnosis of primary metabolic disease or neuronal displasia can be made. Before application of immunocytochemical tests, electron microscopy is useful in differential diagnosis, even microscopic examinations of conjunctiva and liver are recommended.

Innovations and breakthroughs

The reason why giant clear cells are aggregated is not clear. The presence of so called muciphages, described previously as a phenomenon in adults can be excluded on the basis of negative mucicarmine staining and different electron microscopic pictures.

Applications

As the children included in the study showed symptoms of allergy, and even asthma, selective activation of lipid and protein storing macrophages is considered to be associated with mucosa auto-immunological response, probably under influence of antigenemia occurring in children suffering from constipation. It should be emphasized that the presence of giant macrophages is chronic and the clinical course is stable. In the present paper, no therapy was needed at the end of a long term clinical and morphological observation period. During the last two years, some improvement was achieved after application of probiotics. Usage of probiotics (among others of Lactobacilus casei) in all children is the aim in future studies.

Terminology

Clear cell colitis is a form of microscopic colitis in children with accumulation of giant clear cells.

Peer review

This manuscript appears to be reasonably well written. The authors described a new form of CCC in children and presented evidence to support their contention.

Abstract

AIM: To evaluate whether serum levels of nitric oxide ($NO^{\bullet}$) and plasma levels of cyclic guanosine monophosphate (cGMP) and total glutathione (GSH) are altered in patients with alcoholic cirrhosis and to examine their correlation with the severity of liver disease.

METHODS: Twenty-six patients with alcoholic liver cirrhosis were studied. Serum levels of $NO^{\bullet}$ and plasma levels of cGMP and GSH were measured in 7 patients with compensated alcoholic cirrhosis (Child-Pugh A) and 19 patients with advanced cirrhosis (Child-Pugh B and C). The model for end-stage liver disease (MELD) score was evaluated. Sixteen healthy volunteers served as controls. Liver enzymes and creatinine levels were also tested.

RESULTS: $NO^{\bullet}$ and cGMP levels were higher in patients with Child-Pugh B and C cirrhosis than in Child-Pugh A cirrhosis or controls ($NO^{\bullet}$: 21.70 ± 8.07 *vs* 11.70 ± 2.74; 21.70 ± 8.07 *vs* 7.26 ± 2.47 μmol/L, respectively; $P < 0.001$) and (cGMP: 20.12 ± 6.62 *vs* 10.14 ± 2.78; 20.12 ± 6.62 *vs* 4.95 ± 1.21 pmol/L, respectively; $P < 0.001$). Total glutathione levels were lower in patients with Child-Pugh B and C cirrhosis than in patients with Child-Pugh A cirrhosis or controls (16.04 ± 6.06 *vs* 23.01 ± 4.38 or 16.04 ± 6.06 *vs* 66.57 ± 26.23 μmol/L, respectively; $P < 0.001$). There was a significant correlation between $NO^{\bullet}$ and cGMP levels in all patients with alcoholic cirrhosis. A significant negative correlation between reduced glutathione/glutathione disulfide and the MELD score was found in all cirrhotic patients.

CONCLUSION: Our results suggest a role for oxidative stress in alcoholic liver cirrhosis, which is more significant in decompensated patients with higher levels of $NO^{\bullet}$ and cGMP and lower GSH levels than in compensated and control patients. Altered mediator levels in decompensated patients may influence the hemodynamic changes in and progression of liver disease.

INTRODUCTION

Increased production of free radicals has been implicated in several conditions, such as liver damage and fibrosis[1]. Free radicals can damage cellular macromolecules and, therefore, may participate in hepatocellular injury when produced in excess. Endotoxins or cytokines induce macrophages, neutrophils and vascular smooth muscle cells to express a calcium-independent isoform of nitric oxide synthase (NOS). Nitric oxide ($NO^{\bullet}$) is a messenger molecule that functions as a vasodilator and accounts for the biological activity of endothelium-derived relaxing factor (EDRF)[2-4]. The three isoforms of nitric oxide synthase (NOS), the enzyme responsible for the generation of $NO^{\bullet}$, are all found in the liver[4].

Production of $NO^{\bullet}$ activates the soluble guanylate cyclase (sGC) the enzyme with a prosthetic heme group by binding to the ferrous heme iron (Fe^{2+}), resulting in the formation of cyclic guanosine 3'-5' monophosphate (cGMP) from guanosine 5' triphosphate (GTP). This process occurs in both endothelial and vascular smooth muscle cells[5,6]. The increase in concentrations of the second messenger cGMP is stimulated by activation of dependent protein-kinase G (pKG) and confers signalling capacity to the free radical *via* $NO^{\bullet}$-sGC-cGMP-PKG pathway, which in turns leads to the relaxation or dilation of vascular smooth muscle cells (VSMCs), and, subsequently, to inflammation and tissue damage mediated by reactive oxygen species (ROS; for example, $O_2^{\bullet}$ and $OH^{\bullet}$).

$NO^{\bullet}$ promotes tissue toxicity when it reacts with the superoxide anion radical ($O_2^{\bullet}$), which leads to formation of peroxinitrite anion ($ONOO^-$) and hydroxyl radical ($OH^{\bullet}$)[6-9] ($NO^{\bullet} + O_2^{\bullet} \rightarrow ONOO^- + OH^{\bullet}$). Both of these products $OH^{\bullet}$ and $ONOO^-$ are aggressive free radicals and powerful oxidants that can cause membrane lipid peroxidation[5-7,10]. Antioxidants are substances that help to reduce the severity of oxidant stress either by contributing to the formation of a less active radical or by quenching the reaction of $NO^{\bullet}$ which produce peroxinitrite anion and hydroxyl radical. Glutathione (GSH) and its related enzymes are protective effects against oxidative damage[11]. One consequence of GSH depletion, as seen during redox stress, would be enhanced peroxinitrite formation. Glutathione may also be involved in the detoxification of peroxinitrite. Both $O_2^{\bullet}$ and $OH^{\bullet}$ increase production of ROS and GSH depletion, which leads to the abnormal breakdown of fat molecules (that is, lipid peroxidation). This complex process results in the formation of toxic compounds and may contribute to the pathogenesis of alcoholic liver injury.

The aim of this study was to investigate whether serum levels of $NO^{\bullet}$ and 3',5'cyclic guanosine monophosphate (cGMP), and plasma levels of thiol-reduced glutathione (GSHr) and glutathione disulfide (GSSG), are altered in patients with alcoholic liver cirrhosis, and to assess their possible correlation with the severity of liver disease, measured by the Child-Pugh and MELD scores.

MATERIALS AND METHODS

Patients

This study was performed in 26 patients with alcoholic cirrhosis (19 men and 7 women, mean age 56.00 ± 12 years) admitted to the Liver Unit and Division of Gastroenterology, Santa Maria Hospital for evaluation. All patients had a history of alcoholic consumption greater than 80 g/d for at least 5 years. The diagnosis of liver cirrhosis was based on clinical, biochemical and ultrasonographic findings or histological criteria. The patients were classified as having compensated (n = 7) or decompensated liver cirrhosis (n = 19). According to the Child-Pugh scores, all compensated patients belonged to class A. The decompensated group consisted of 8 patients in class C and 11 patients in class B with a Child-Pugh score above 8. At the time of the study no Child A patients showed clinical features of decompensated liver cirrhosis (ascites, edema, encephalopathy or recent portal hypertension associated gastrointestinal bleeding). All patients graded Child-Pugh B-C had moderate to severe ascites without evidence of infection. The main clinical and laboratory findings are shown in Table 1. There was no evidence of hepatocellular carcinoma, cardiac, renal or respiratory failure in the patients studied, and none of them were administered vasoactive drugs or antioxidants during the study.

The control group consisted of 16 healthy subjects (10 men and 6 women, mean age 38 ± 18 years) with normal laboratory findings. Informed consent to participate in the study was obtained from each patient.

Methods

Peripheral venous blood from fasted healthy volunteers and fasted cirrhotic patients was collected in separate tubes, one containing the anticoagulant ethylenediamine tetraacetic disodium (Na_2EDTA) and the other without serum anticoagulant. The blood was allowed to clot for 30 min at 25℃, centrifuged at 2000 × g for 15 min at room temperature, and the serum was then separated and aliquoted into tubes for storage. To obtain plasma samples, the blood was centrifuged immediately at 2000 × g for 10 min at 4℃, and then aliquoted into tubes. The tubes were then stored frozen at -80℃ until they were used to study different biomarkers.

Analytical procedures

Determination of NOx levels: The level of serum $NO^{\bullet}$ was obtained indirectly by measuring the levels of its metabolites nitrate (NO_3^-) and nitrite (NO_2^-). The levels of the final products of $NO^{\bullet}$ oxidation (NO_3^- and NO_2^-) were assessed using the Griess reaction. NO_3^- was enzymatically converted into NO_2^- in the presence of reduced nicotinamide adenine dinucleotide phosphate (NADPH), flavine adenine dinucleotide (FAD) and nitrate reductase. Nitrite reacts with Griess reagent (1 g/L sulphanilamide 0.1 g/L N-(1-naphtyl)-ethylenediamine and 5 g/L phosphoric acid) to give a red-violet diazo dye. The determination of these two elements (NO_3^- and NO_2^-) was measured in triplicate in a microplate reader on the basis of absorbance in the visible range at 540 nm. The concentrations of NO_2^- were determined from a calibration curve obtained using standard NO_2^- solutions. The mean values of the measurements were taken as the final result. The limit of detection of the method is 0.28 μmol/L for nitrate and 0.32 μmol/L for nitrite.

Determination of cGMP: The plasma concentration of cGMP was determined in duplicate by radioimmunoassay (RIA) using a commercial kit according to the manufacturer's protocol (IBL Hamburg, Germany).

Determination of GSHt, GSSG and GSHr: For 1 mL of plasma was used (50 μL of 5% sulphosalicylic acid) to prevent spontaneous oxidation of GSH. After centrifugation at 2000 × g for 10 min, 100 μL of the supernatant was removed for assay of GSH.

The sulfhydryl group of GSH reacts with Ellman's reagent, 5,5'-dithio-bis-(2-nitrobenzoic acid) (DTNB) to produce yellow 5-thio-2-nitrobenzoic acid (TNB). The mixed disulfide, GS-TNB (between GSH and TNB) is subsequently reduced by glutathione reductase and the reduced form of β-nicotinamide adenine dinucleotide phosphate (NADPH), releasing a second TNB molecule and recycling the GSH. The rate of TNB production is directly proportional to this recycling reaction, which, in turn, is directly proportional to the concentration of GSH in the sample. GSH is easily oxidized to GSSG by glutathione reductase (GR), according to the following formula:

$GSSG + NAD(P)H \rightarrow GSH + NADP^+$.

Table 1 Laboratory findings in the patients with alcoholic cirrhosis

Table 2 Levels of $NO^{\bullet}$, cGMP, GSHt, GSSG, GSHr, MELD and GSHr/GSSG among the controls and patients with alcoholic liver cirrhosis (Child-Pugh A, B and C) studied

Biomarkers	Controls (n = 16)	Child-Pugh A (n = 7)	Child-Pugh B and C (n = 19)	P values
NO_3^- μmol/L	4.16 ± 1.36; (4.21)	6.73 ± 1.32; (6.89)	12.23 ± 4.29; (11.79)	$^b P < 0.001$; $^a P < 0.05$
NO_2^- μmol/L	3.10 ± 1.27; (2.90)	4.97 ± 1.5; (5.76)	9.46 ± 3.93; (7.80)	$^b P < 0.001$; $^a P < 0.05$
$NO^{\bullet}$ (NO_3^- + NO_2^-) μmol/L	7.26 ± 2.47; (7.31)	11.70 ± 2.74; (12.72)	21.70 ± 8.07; (18.22)	$^b P < 0.001$; $^a P < 0.05$
cGMP pmol/L	4.95 ± 1.21; (5.39)	10.14 ± 2.78; (9.0)	20.12 ± 6.62; (21.00)	$^b P < 0.001$; $^a P < 0.05$
GSHt μmol/L	66.57 ± 26.23; (59.88)	23.01 ± 4.38; (22.82)	16.04 ± 6.06; (14.30)	$^b P < 0.001$; $^a P < 0.05$
GSSG μmol/L	18.57 ± 6.39; (18.57)	9.43 ± 2.3; (9.65)	9.47 ± 4.17; (8.13)	$^b P < 0.001$; $^a P < 0.05$
GSHr μmol/L	47.78 ± 23.63; (45.19)	13.58 ± 3.7; (13.88)	6.54 ± 3.31; (6.02)	$^b P < 0.001$; $^a P < 0.05$
GSHr/GSSG	2.68 ± 1.16; (2.95)	1.52 ± 0.63; (1.50)	0.81 ± 0.42; (0.58)	$^b P < 0.001$; $^a P < 0.05$
MELD	6-8	8.29 ± 2.75; (8.00)	20.17 ± 8.45; (20.00).	$^b P = 0.001$; $^a P < 0.05$

Data were analysed by one-way analysis of variance (ANOVA) $^bP < 0.001$ between groups of each biomarker and Student-Newman-Keuls post-hoc test was used for comparison of difference of means between each parameter $^aP < 0.05$. $NO^{\bullet}$: Nitric oxide; cGMP: Cyclic guanosine monophosphate; GSHt: Total glutathione; GSSG: Glutathione disulfide; GSHr: Thiol-reduced glutathione; MELD: Model for end-stage liver disease; GSHr/GSSG: Thiol-reduced glutathione to glutathione disulfide ratio.

The concentrations of GSHr and GSSG in plasma were determined from a calibration curve using standard GSHr and GSSG solutions. Both GSHr and GSSG were measured in duplicate in a microplate reader on the basis of absorbance in the visible range at 405 nm.

Total GSHt is equivalent to the sum of GSSG and GSHr.

MELD score: The model for end-stage liver disease (MELD) score was calculated from the following equation:

$9.57 \times \log_e$ (creatinine mg/dL) + $3.78 \times \log_e$ (bilirubine mg/dL) + $11.2 \times \log_e$ (INR) + 6.43.

The maximal creatinine level considered in the MELD score is 4.0 mg/dL[12].

Statistical analysis

Statistical analyses were performed using the SPSS 12.0 statistical package (SPSS Inc., Chicago). All results are expressed as means ± SD, median values and ranges. Data were analysed by one-way analysis of variance in addition to the Student-Newman-Keuls post-hoc test. Coefficient correlations were evaluated using the linear regression analysis or Pearson correlation. Statistical significance was established at $P < 0.05$.

RESULTS

The baseline laboratory characteristics of the 26 patients with alcoholic liver cirrhosis (classified as Child-Pugh A, B and C) are shown in Table 1. The concentrations of serum $NO^{\bullet}$ and the different plasma biomarkers in the cirrhotic patients and controls are shown in Table 2. There were statistically significant differences between the 4 groups. The minimum $NO^{\bullet}$ level obtained in the control group was 3.19 μmol/L.

Patients with decompensated liver cirrhosis (Child-Pugh B and C) exhibited significantly higher serum concentrations of $NO^{\bullet}$ than both patients with compensated liver cirrhosis (Child-Pugh A) and controls (Figure 1). There was a significant difference in serum $NO^{\bullet}$ concentrations between control subjects and compensated liver cirrhotic patients. The concentrations of plasma cGMP in patients with decompensated cirrhosis were higher than in those in compensated cirrhosis, and this difference was statistically significant ($P < 0.001$). The concentrations of plasma cGMP in patients with compensated liver cirrhosis were higher when compared with those with the controls and this difference was statistically significant ($P < 0.001$) (Figure 2). Significant correlations between $NO^{\bullet}$ and cGMP levels ($r = 0.866$, $P < 0.001$), between $NO^{\bullet}$ levels and MELD scores ($r = 0.627$,

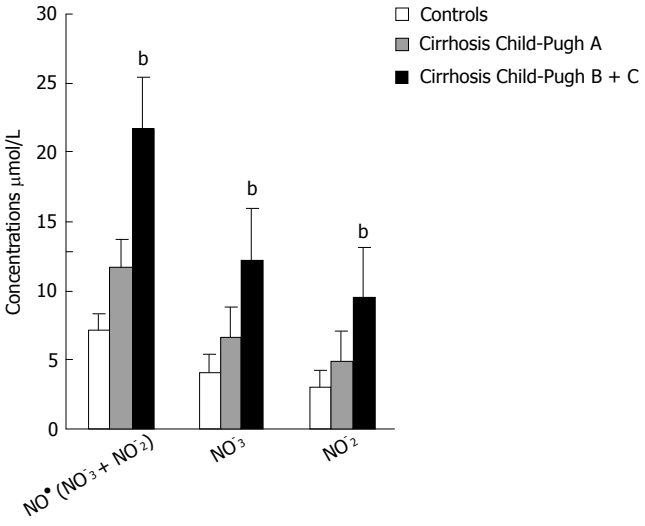

Figure 1 Serum concentrations of nitric oxide NO• (NO_3^- + NO_2^-), nitrates (NO_3^-) and nitrites (NO_2^-), in patients with alcoholic liver cirrhosis classed as Child-Pugh A, B or C, and controls. Data are expressed as means ± SD of triplicate determinations. $^bP < 0.01$ between controls and patients with Child-Pugh A, B or C cirrhosis.

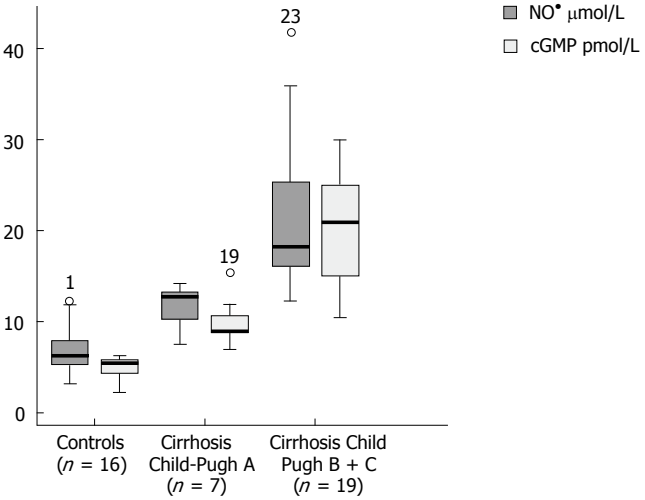

Figure 2 Boxes show the interquartile ranges. Vertical lines show 80% of the values (10^{th}-90^{th} percentiles). The bold horizontal line represents the median. $^bP < 0.01$ between controls and cirrhosis Child-Pugh A, and between controls and cirrhosis Child-Pugh B and C.

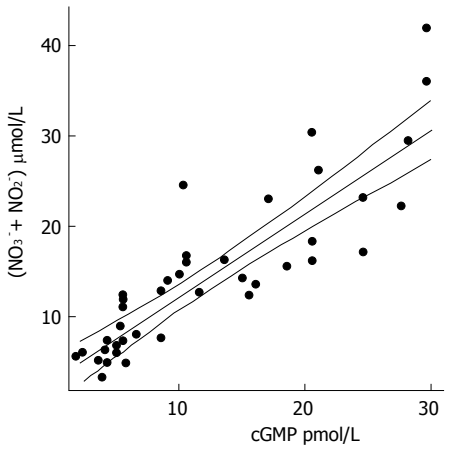

Figure 3 A significant positive correlation between the levels of NO• and cGMP was observed among the 26 patients with alcoholic liver cirrhosis, classed as Child-Pugh A, B and C. Linear regression with 95.00% mean prediction interval, $^bP < 0.01$; NO_3^- + NO_2^- μmol/L = 2.81 + 0.93; *R*-Square = 0.75.

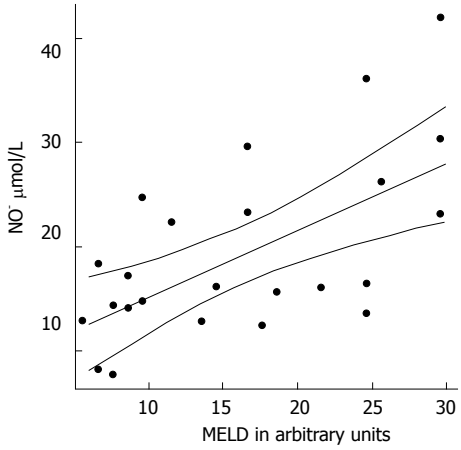

Figure 4 Correlation between NO• levels and MELD scores. Linear regression with 95.00% mean prediction interval, NO• μmol/L = 8.76 + 0.64; $^bP < 0.01$; *R*-Square = 0.39.

$P < 0.01$) and between cGMP levels and MELD scores ($r = 0.452$, $P < 0.05$) were observed among the 26 alcoholic liver cirrhotic patients (Figures 3-5).

Decreases in the plasma levels of GSHt, GSSG and GSHr were observed in all alcoholic liver cirrhotic patients, when compared with controls (Table 2). This decrease in GSHr levels was most prominent in decompensated liver cirrhotic patients. Figure 6 shows the plasma levels of the biomarkers of oxidative stress (GSHr, GSSG and GSHr/GSSG) in controls and in plasma of cirrhotic patients Child-Pugh classes A, B and C. There was a markedly reduced ratio GSHr/GSSG in patients with Child-Pugh B and C cirrhosis compared with patients with Child-Pugh A cirrhosis or controls ($P < 0.001$). The GSHr levels were higher in the controls than in the cirrhotic patients stratified according to Child-Pugh score.

The GSSG levels were higher in patients with Child-Pugh B and C cirrhosis than in those with Child-Pugh A cirrhosis or controls. The ratio between GSHr/GSSG was lower in patients with Child-Pugh B and C cirrhosis than in those with Child-Pugh A.

No correlation between NO• and cGMP levels and creatinine levels was found in patients with decompensated cirrhosis.

The MELD scores were determined in the 26 patients with alcoholic cirrhosis (Table 2). These was higher in the decompensated patients than in the compensated cirrhotic patients ($P < 0.001$). The GSHr/GSSG ratios were lower in cirrhotic patients belonging to Child-Pugh class B and C compared with those in Child-Pugh class A. Significant negative correlations between the MELD score and the GSHr/GSSG ratio ($r = -0.693$, $P < 0.001$) and between NO• level and the GSHr/GSSG ratio ($r = -0.558$, $P < 0.01$) were found in all of the alcoholic cirrhotic patients, as shown in Figures 7 and 8.

DISCUSSION

There is firm evidence of enhanced oxidative stress

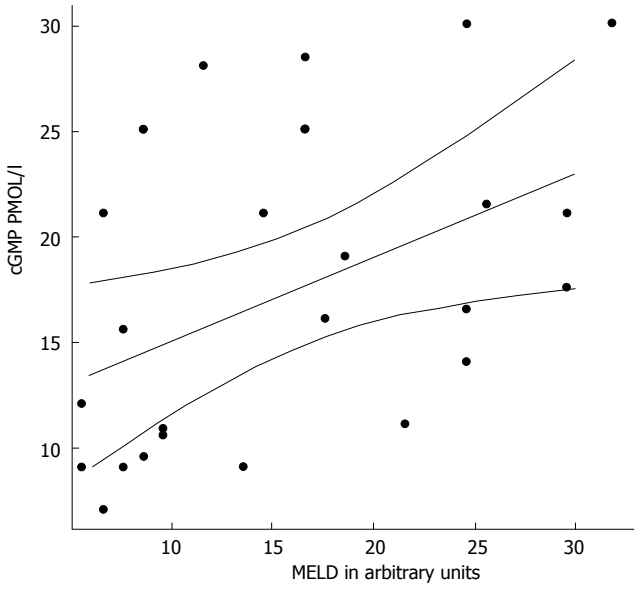

Figure 5 Correlation between cGMP levels and MELD scores. Linear regression with 95.00% mean prediction interval, $^{b}P < 0.01$; cGMP pmol/L = 11.05 + 0.40; *R*-Square = 0.20.

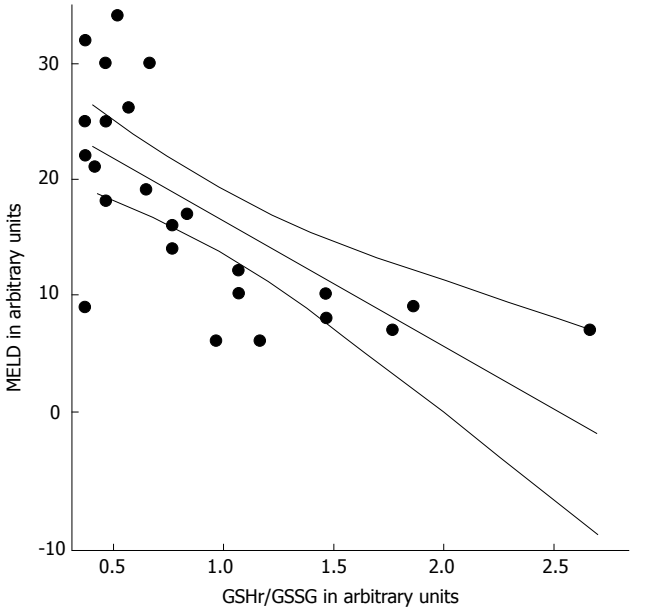

Figure 7 The MELD score increases progressively from Child-Pugh class A to C. A significant negative correlation between MELD scores and GSHr/GSSG ratios was observed. Linear regression with 95.00% mean prediction interval, $^{b}P < 0.01$; MELD in arbitrary units = 27.08 + -10.74; *R*-Square = 0.48.

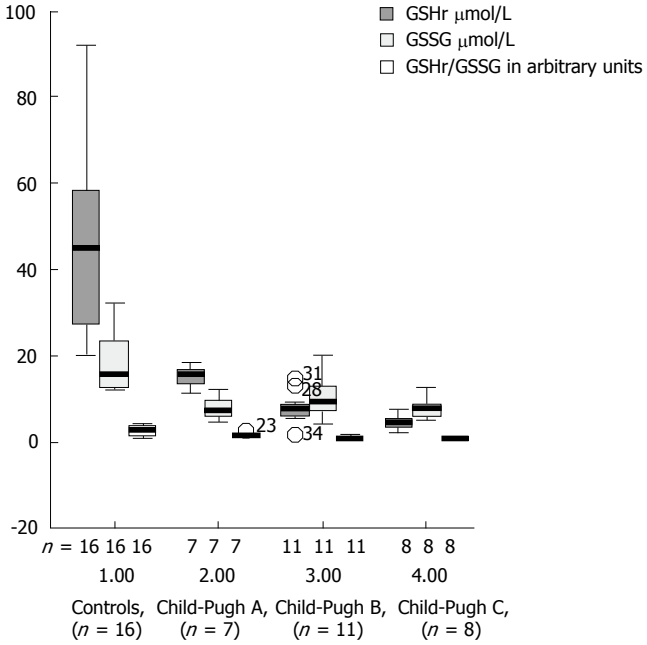

Figure 6 Boxes show the interquartile ranges. Vertical lines show 80% of the values (10^{th}-90^{th} percentiles). The bold horizontal line represents the median. $^{b}P < 0.01$ between controls and patients with Child-Pugh A cirrhosis or between patients with Child-Pugh B cirrhosis or between Child-Pugh C cirrhosis.

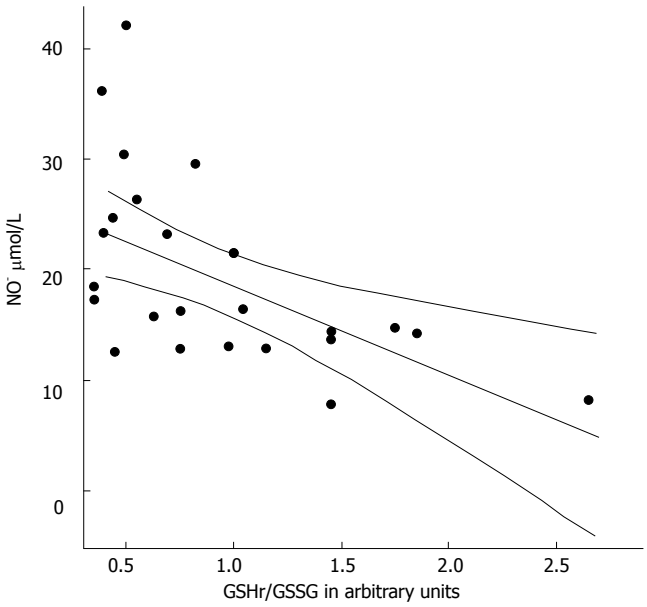

Figure 8 Correlation between NO· levels and GSHr/GSSG ratios. Linear regression with 95.00% mean prediction interval, $^{b}P < 0.01$; NO· μmol/L = 26.52 + -7.99; *R*-Square = 0.31.

in patients with alcoholic liver disease. Studies have shown increased plasma and tissue levels of markers of lipid peroxidation[13-16], and reduced hepatic and plasma antioxidant content[17-20].

In the liver, as in many other organs, NO· has many actions and cellular sources[4,5,16-21]. Determination of the levels of the NO· radical itself is hampered by its radical nature and very short half-life (in the range of seconds). Because NO· activates soluble guanylate cyclase to produce cyclic guanosine 3',5' monophosphate (cGMP) and stable nitric oxide metabolites, we measured the levels of its metabolites, NO_3^- and NO_2^-, in serum, and the levels of cGMP in plasma. The intracellular concentrations of ROS are tightly regulated by multiple defence mechanisms involving ROS-scavenging enzymes and anti-oxidant molecules, which include glutathione and GSH dependent enzymes. We also measured the levels of glutathione in its thiol-reduced (GSHr) and glutathione disulfide (GSSG) forms to better understand the defence mechanisms involving GSH operating in alcoholic cirrhotic patients[22-24].

The data of this study indicate that serum concentrations

of the NO• metabolites NO_3^- and NO_2^-, and those of plasma cGMP, an intracellular second messenger[25] of nitric oxide, in patients with alcoholic cirrhosis, were higher than those in healthy controls. The NO• and cGMP levels were higher in patients with decompensated liver cirrhosis (Child-Pugh B and C) than in those with compensated liver cirrhosis (Child-Pugh A) ($P < 0.001$). Our results also show a decrease in GSHt levels in alcoholic cirrhotic patients compared with healthy controls.

Associations were found between the levels of the biomarkers NO• and cGMP, as well as between the levels of each biomarker and MELD scores ($P < 0.01$). Significant negative correlations were observed between NO• levels and GSHr/GSSG ratios, and between MELD scores and GSHr/GSSG ratios, in the 26 alcoholic cirrhotic patients belonging to all three Child-Pugh classes ($P < 0.01$). The increased concentrations of GSSG in plasma provide a sensitive index of whole-body oxidative stress[26]. A deficiency of hepatic GSH and increased toxic free radical species may contribute to the progression of liver disease[17,18].

One of the more common free radicals produced in response to the ingestion of ethanol is oxygen in a deformed toxic state. These radicals, known as reactive oxygen species, include oxygen radicals and substances closely related to oxygen radical reactions. They can play a role in the development of alcoholic hepatitis by altering the redox state, damaging cell constituents in the liver and causing severe injury[27].

NO• can interact with ROS to form other reactive nitrogen species (RNS). These reactive nitrogen species secondarily promote important reactions such as nitrosation (production of nitrosamines), oxidation (mediating lipid peroxidation, DNA strand breaks and hydroxylation) or nitration (production of nitrotyrosines and nitroguanosines), leading to impaired cellular functions and enhanced inflammatory reactions[28]. On the other hand, ROS stimulates stellate cell activation and fibrogenesis[20,22,27]. Thus, oxidative stress seems to contribute to the pathogenesis of alcoholic liver injury and the progression of alcohol-induced liver disease to alcoholic cirrhosis[22,23].

Patients with advanced liver disease tend to develop a hyperdynamic circulation, which complicates cirrhosis. There is vast experimental evidence for enhanced NO• overproduction and associated cGMP formation in cases of portal hypertension. Moreover, several clinical studies have evaluated NO• synthesis and serum levels in various cirrhotic conditions[29-32]. Our study, including only alcoholic patients of different Child classes, strengthens previous investigations and adds further information with respect to the second messenger cGMP and its relationship with the redox state of GSH.

NO• or nitrite/nitrate measurements can be affected by creatinine levels, as demonstrated recently in acute decompensated cirrhotic patients[32]. In our clinical population, patients with Child C cirrhosis had elevated creatinine values compared to those with Child A cirrhosis, and this could also influence the results. A positive correlation was found between creatinine levels and NO• and cGMP mediators in all three Child-Pugh classes ($P < 0.01$, $P < 0.05$), but no correlation between these mediators and creatinine was found in either decompensated or compensated cirrhotic patients. However, we found an inverse relationship between GSHr/GSSG ratios and creatinine levels, only in decompensated cirrhotic patients ($P < 0.01$). The elevated mediator levels could also be caused by portal hypertension and hyperdynamic circulation where NO• is elevated and, therefore, have no relation to intrahepatic oxidative stress. Recent studies by Lluch *et al*[29] suggest that the serum concentration of asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide synthase is elevated in patients with alcoholic cirrhosis. This finding may offer an alternative compensatory mechanism to counteract the excessive visceral vasodilatation caused by excess production of NO• in patient with advanced liver disease.

In summary, our study shows that patients with decompensated alcoholic cirrhosis have higher levels of NO• and cGMP than compensated patients, and that there is a positive correlation between the clinical score of the disease (Child-Pugh classes and MELD scores) and the abnormalities observed. Our findings suggest that NO• and cGMP may contribute to progressive liver disease in these patients and influence the hemodynamic abnormalities. Our findings emphasize the need for further investigations correlating the serum levels of NO•, cGMP or GSH seen in decompensated cirrhotic patients with their clinical outcomes (for example, survival, variceal bleeding, renal failure and septic complications) to develop prognostic parameters and delineate new therapeutic strategies.

COMMENTS

Background

Alcohol accounts for 40%-50% of all deaths due to cirrhosis and remains the most common cause of liver-related mortality. Important pathophysiologic events that mediate alcohol-induced liver injury include increased oxidative stress, hepatocyte apoptosis and necrosis and deposition of collagen, with ensuing fibrosis.

Research frontiers

The correlation of mediators of oxidative stress with the severity of disease in patients with alcoholic liver injury has been studied intensively in recent years, mainly in patients with alcoholic hepatitis. We investigated patients with alcoholic cirrhosis and measured the levels of mediators of oxidative stress (namely, NO• and cGMP), antioxidant defences [thiol-reduced glutathione (GSHr) and glutathione disulfide (GSSG)] and correlated these levels with clinical liver disease severity.

Innovations

In contrast to previous studies, we measured the levels of not only NO•, but also cGMP (an intracellular second messenger of NO•) and correlated these with mediators of antioxidant defence. We found that the levels of nitric oxide metabolites and cGMP were high in alcoholic cirrhotic patients, particularly in those that were decompensated. There was a positive correlation between the clinical score of the disease (Child-Pugh classes and MELD scores) and the oxidative stress abnormalities observed.

Applications

Our findings suggest that NO• and cGMP may contribute to progressive liver disease in these patients. Further investigations correlating the serum levels of NO•, cGMP or GSHr seen in decompensated cirrhotic patients with their clinical outcomes (for example, survival, variceal bleeding, renal failure and septic complications) are needed to develop better prognostic parameters and delineate new therapeutic strategies.

Peer review

The authors measured nitric oxide metabolites in the serum and cGMP, GSH, and GSSG in the plasma with alcoholic cirrhosis patients. They found that nitric oxide metabolites and cGMP levels were high in alcoholic cirrhosis patients, particularly in decompensated alcoholic cirrhosis. Moreover, they found a significant negative correlation between GSH/GSSG ratio and MELD score in all cirrhotic patients.

Abstract

AIM: To elucidate the possible difference in two promoter polymorphisms of the transforming growth factor-β1 (TGF-β1) gene (-800G > A, -509C > T) between ulcerative colitis (UC) patients and normal subjects.

METHODS: A total of 155 patients with established ulcerative colitis and 139 normal subjects were selected as controls. Two single nucleotide polymorphisms within the promoter region of TGF-β1 gene (-509C > T and -800G > A) were genotyped using PCR-RFLP.

RESULTS: There was a statistically significant difference in genotype and allele frequency distributions between UC patients and controls for the -800G > A polymorphism of the TGF-β1 gene ($P < 0.05$). The frequency of the TGF-β1 gene polymorphism at position -800 showed that the AA genotype and the allele A frequencies significantly differed between the patients and healthy controls ($P < 0.05$). At position -509, there was no statically significant difference in genotype and allele frequency between the patients and control subjects.

CONCLUSION: The results of our study indicate that there is a significant difference in both allele and genotype frequency at position -800G > A of TGF-β1 gene promoter between Iranian patients with UC and normal subjects.

INTRODUCTION

Transforming growth factor-β1 is a cytokine produced by both immune and non immune cells, and it exhibits a broad range of functions. TGF-β1 controls the differentiation, proliferation, and state of activation of all immune cells, wound healing, angiogenesis and is implicated in immune abnormalities linked to cancer, autoimmunity, opportunistic infections, and fibrotic complications[1-5]. It has chemotactic properties and may stimulate cells to produce cytokines such as IL-1, IL6, and TNF-α at the sites of inflammation[1,6]. It is interesting that TGF-β1 plays an important role in promoting and activating extracellular matrix and bone remodeling. Paradoxically it is also involved in several immune suppressive mechanisms particularly as an inhibitor of intestinal epithelial proliferation[7-9]. It is proposed that the TGF-β1 production is under genetic control[7,10]. In the human TGF-β1 gene, which is located on chromosome 19q13 [11-15], eight polymorphisms are presently known. Three of them are localized in the promoter region at positions -988C > A, -800G > A and -509C > T from the first transcribed nucleotide[13].

Polymorphism of TGF-β1 has been investigated in several diseases. For instance, our own investigation indicates that polymorphism of this cytokine is not associated with the repeated spontaneous abortion[16,17]. Polymorphism of TGF-β1 and the risk of hepatocellular carcinoma have been investigated in patients with chronic hepatitis B virus infection[18,19]. In patients with liver cirrhosis, an association has been found between codon 10 and morphology of hepatocellular carcinoma in Korean population[20].

Inflammatory bowel disease is thought to result from inappropriate and ongoing activation of the mucosal immune system due to the presence of normal luminal flora. This aberrant response is most likely facilitated by defects in both the barrier function of the intestinal epithelium and the mucosal immune system[21,22]. As only two previous studies are available on the association of the -509 C > T TGF-β1 polymorphism with inflammatory

bowel disease, especially Crohn's disease[23,24], we investigated whether these two polymorphisms (-509, -800) are associated in south Iranian patients with established UC.

MATERIALS AND METHODS

Subjects

The subjects in this study were comprised of 155 unrelated patients with UC (69 males and 86 females, aged 23-51 years, mean 36.4 years) attending the Department of Gastroenterology, Namazi and Saadi Academic Hospitals of Shiraz Medical University. Disease duration was at least 2 years. Patients were asked about acute phases of the disease after diagnosis. Every patient chart was revisited to complete all available information. A total of 139 age- and sex- matched health volunteers with no history of chronic bloody diarrhea and abdominal pain (50 males, 89 females) served as controls (aged 18-61 years, mean 35.5 years). Diagnosis of UC was established on the basis of conventional endoscopic and histological criteria. Since UC is a dynamic disease and patients can fluctuate into a different phenotype during the course of the disease, we analyzed the clinical records of our patients at two time points: when patients visited the hospital and for the first time he/she was followed up (mean time after diagnosis of 1.5 years). All patients were sub-classified according to gender, age of onset, localization of the disease, need for steroid therapy, and emergent surgical treatment. In UC patients, the localization of gut involvement was defined as proctitis, left-sided (up to the splenic flexure) or pancolitis (beyond the splenic flexure).

DNA extraction and TGF-β1 genotyping

Venous blood was collected into EDTA-coated tubes. DNA was extracted from whole blood using the salting-out method. The following primers (MOLBIOL, Germany) were used for amplification of promoter regions -509 and -800. The sequences of PCR primers for the -509C/T and -800G/A polymorphisms are 5'-CAGTAAATGTATGGGGTCGCAG-3' (forward) and 5'-GGTGTCAGTGGGAGGAGGG-3' (reverse), and 5'-ACAGTTGGCACGGGCTTTCG-3' (forward) and 5'-TCAACACCCTGCGACCCCAT-3' (reverse) respectively. The PCR product sizes from these primers were 153 bp and 388 bp, respectively. PCR was performed in a total volume of 20 μL containing 100 ng genomic DNA, 20 pmol/L of each primer, 0.2 mmol/L dNTPs, 20 mmol/L Tris-HCl (pH 8.8), 10 mmol/L $MgCl_2$, and 1 unit of Taq polymerase (New England BioLabs Ipswich, MA). The PCR cycle conditions consisted of an initial denaturation at 94℃ for 3 min followed by 35 cycles at 94℃ for 60 s, at 61℃ for 60 s, at 72℃ for 60 s for -509 C/T, and at 94℃ for 45 s, at 61℃ for 45 s, at 72℃ for 45 s for -800G/A, and a final elongation at 72℃ for 5 min.

Genotyping was performed by restriction fragment length polymorphism (RFLP) analysis. The following restriction enzymes (Fermantes, Lithuania) were used for the digestion of amplified PCR products. For digestion of PCR products containing positions -800, *Nmu*CI and -509, *Eco811* was applied. The digested PCR products were resolved on 2% agarose gel and stained with ethidium bromide for visualization under UV light.

Table 1 Distribution of TGF-β1 genotype and alleles in UC patients and controls

TGF-β1 genotype and alleles	UC patients *n* = 155 (%)	Controls *n* = 139 (%)	*P* value
Genotype -800			
GG	125 (80.6)	104 (74.8)	< 0.05
GA	29 (18.8)	27 (19.4)	
AA	1 (0.6)	8 (5.8)	
Allele frequency			
G	279 (90)	235 (84.5)	< 0.05
A	31 (10)	43 (15.5)	
Genotype-509			
CC	57 (36.8)	56 (40.3)	
CT	65 (41.9)	63 (45.3)	0.3
TT	33 (21.3)	20 (14.4)	
Allele frequency			
C	179 (57.75)	175 (62.9)	0.19
T	131 (42.25)	103 (37.1)	

Statistical analysis

Allele frequencies at each polymorphic site were calculated by allele counting method. Deviation of the genotype counts from the Hardy-Weinberg equilibrium was tested using χ^2 test with 1 degree of freedom. Differences in the allele frequencies and genotype distributions between the patients with UC and the controls were analyzed by χ^2 or Fisher's exact tests when necessary.

RESULTS

Position -800 (G/A)

In this investigation, the change at position -800G > A of the TGF-β1 gene was studied using PCR-RFLP in 155 cases of UC and 139 normal Iranian subjects. At this position, homozygote GG was found in 125 (80.6%) UC patients and 104 (74.8%) normal subjects, heterozygote GA was observed in 29 (18.8%) UC patients and 27 (19.4%) normal subjects, while homozygote AA was demonstrated in only one of the patients, homozygote AA was shown in eight normal individuals. There was a statistically significant difference in genotype and allele frequency distributions between UC patients and controls for the -800G > A polymorphism of the TGF-β1 gene ($P < 0.05$) (Table 1). A typical genotyping at this position is represented in Figure 1A.

Position -509 (G/A)

In addition, the genotype at position -509C > T of the TGF-β1 gene was studied in the same study groups. At this position, homozygote CC was found in 57 (36.8%) UC patients and 56 (40.3%) normal subjects, heterozygote CT was observed in 65 (41.9%) UC patients and 63 (45.3%) normal subjects, homozygote TT was demonstrated in 33 (21.3%) UC patients and 20 (14.4%) normal subjects. There was no statistically significant difference in genotype distribution and allele frequency at this position between

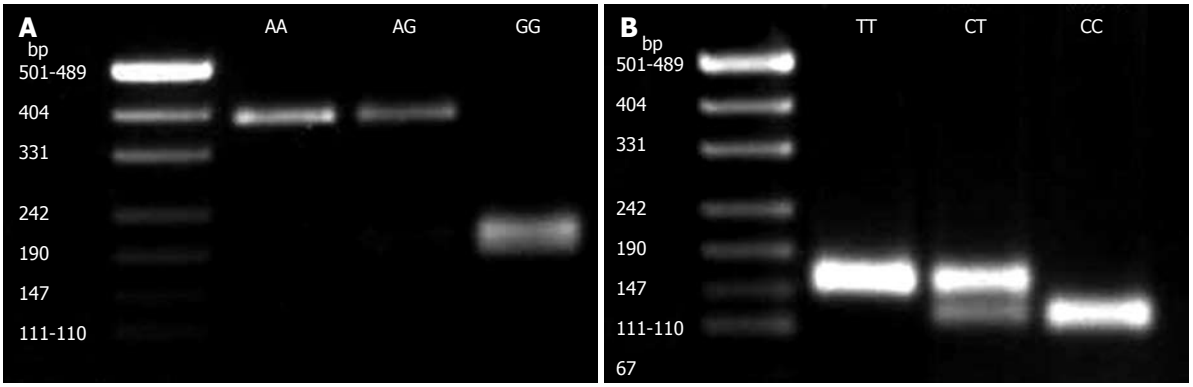

Figure 1 **A**: PCR-RFLP genotyping at position -800 (G/A). PCR product (388 bp) was digested with NmuCI restriction enzyme. From left to right: Lane 1: DNA size marker; lane 2: Homozygote AA; lane 3: Heterozygote AG; lane 4: Homozygote GG; **B**: PCR-RFLP genotyping at position −509 (C/T). PCR product (153 bp) was digested with Eco811 restriction enzyme. Lane 1: DNA size marker; lane 2: Homozygote TT; lane 3: Heterozygote CT; lane 4: Homozygote CC.

UC patients and controls. The distribution of TGF-β1 genotype and allele frequency in UC patients and controls are summarized in Table 1. A typical genotyping at position -509C > T is represented in Figure 1B. A Hardy-Weinberg equilibrium test was performed for the two polymorphisms.

Relation between other factors and polymorphisms

In our study, no significant relation was found between the two polymorphisms and factors such as gender, age of onset, cumulative dose of steroids, need for steroid therapy, localization of the disease, and need for emergent surgical treatment.

DISCUSSION

TGF-β1 is an immunoregulatory and immunosuppressive cytokine. Its role and function have been extensively investigated in inflammatory type of diseases[14]. It has been known that TGF-β1 has various biological and immunological functions, such as decreasing expression of MHC-Ⅱ, reducing synthesis of TH1/TH2 cytokine and suppressing the activation of both T and B lymphocytes. Plasma levels of TGF-β1 have been detected in several inflammatory and malignant diseases and the consensus is that the synthesis of this immunosuppressive cytokine is under the control of genetic factors[3,6,11]. TGF-β1 gene is located on chromosome 19 and contains 7 exons.

Several polymorphisms have been reported in TGF-β1 gene at positions -988, -800 and -509 located in the gene promoter[13-21]. Garcia-Gonzalez and co-workers showed that codon 10 and 25 TGF-β1 polymorphisms in Dutch IBD patients and healthy controls do not participate in defining the susceptibility to and tile nature of the clinical course in IBD[24]. Polonikov AV *et al*[28] reported that TGF-β1 gene polymorphism plays a role in the pathogenesis of gastric ulcer disease. Su Zg and colleagues[16] reported that allele A at position -800 and allele T at position -509 of TGF-β1 gene are increased in Chinese population with chronic obstructive pulmonary disease. Schulte CM[23] showed that IBD susceptibility is not associated with genetic variations in TGF-β1 promoter polymorphism.

In addition to the reports on genetic variations in TGF-β1 polymorphism in IBD, several studies showed that serum level of TGF-β1[17] and mRNA expression[18] are significantly increased in IBD patients.

In the present study, the genotype distribution and allele frequencies of polymorphisms at position -509C > T were not significantly different between UC patients and controls, which is consistent with the previous reports[24,30]. However, at position -800G > A both allele and genotype frequencies were significantly different between UC patients and controls. It has been reported that -800G > A substitution is thought to disrupt a consensus half-site for binding to the nuclear transcription factor (CRE-binding protein), consequently contributing to a lower production of total TGF-β1 in the circulation[7,26].

In our study, AA genotype was reduced in patients with IBD compared with controls. A similar finding was seen in UC patients and controls when the frequency of allele A was analyzed. These findings indicate that individuals bearing allele A and genotype AA are less susceptible to IBD than those lacking allele A and genotype AA.

To the best of our knowledge, polymorphism at position -800 of TGF-β1 gene promoter has not yet been reported in IBD patients. However, both plasma level of TGF-β1 and mRNA expression should be further studied and compared in IBD patients carrying genotype AA at this position.

There are a number of other polymorphisms with known influence on different TGF-β1 expressions[3,4]. To study the role of TGF-β1 haplotype in the pathogenesis of IBD, analysis of other known TGF-β1 gene polymorphisms will strength our current observation.

In conclusion, there is no significant difference in TGF-β1 polymorphisms at position -509 C > T and allele A is significantly associated with genotype AA at position -800 of the promoter region between southern Iranian UC patients and healthy individuals.

COMMENTS

Background

Inflammatory bowel disease (IBD) is a common disorder in our population with an increasing incidence but no clear cut etiology. Cytokines and their receptors,

immunogenetics and host -related factors are all involved in the disease susceptibility. TGF-β1 is produced by regulatory T lymphocytes with a profound suppressive effect on the induction phase of immune response. Plasma levels of TGF-β1 and its local synthesis, in addition to the contribution of genes encoding TGF-β1 have widely been investigated in IBD patients with no convincing and solid ground so far.

Research frontiers

Investigation of cytokine gene polymorphism in health and disease conditions has provided valuable information on the incidence of autoimmune diseases in different ethnics. Current data on TGF-β1 gene polymorphism in IBD are controversial due to the heterogeneity in clinical presentations of the disease and different methods. There is no evidence that TGF-β1 gene polymorphism is associated with IBD in European Caucasian population. Here we report the impact of allele A and genotype AA at -800 of TGF-β1 promoter region and susceptibility to Iranian patients with IBD.

Publications

Schults *et al* and Garcia Gonzalez reported that polymorphism at promoter region has no association with IBD in European individuals. Our data give another view on the significance of polymorphism of TGF-β1 promoter region in IBD patients.

Innovations and breakthroughs

Our findings provide a window for investigation on the mRNA and local secretion of TGF-β1 in IBD patients carrying allele A and genotype AA of TGF-β1 at position -800 of promoter region.

Application

By extending this investigation in a larger sample size within other ethnic groups or in a broader study in a format of meta-analysis, a genetic marker for screening of individual susceptible to IBD can be expected.

Peer review

This is a very interesting and original paper that merits to be fully published without any substantial modifications.It is also in good english written.

Abstract

AIM: To assess the prevalence of mild gastrointestinal disorders in milk-fed infants in paediatric practice, and to evaluate the effectiveness and satisfaction with dietetic treatment.

METHODS: A cross-sectional epidemiological study was first carried out. A total of 285 paediatricians included 3487 children seen during a period of one week. In a second phase an observational, prospective and multicentre study was conducted and 2069 milk-fed infants with mild gastrointestinal disorders (colic, constipation, regurgitation and diarrhoea) were included. There was a baseline visit (start of treatment) and a final visit four weeks later. The effectiveness of the various Novalac formulas, as well as the satisfaction of the parents/tutors and paediatricians with the dietetic treatment were assessed at the final visit.

RESULTS: The prevalence of mild gastrointestinal disorders was 27.8% of all paediatrician consultations (9.2%, 7.8%, 6.1% and 4.6% in relation to colic, constipation, regurgitation and diarrhoea, respectively). The several Novalac adapted milk formulas resolved 88.4% of the mild gastrointestinal disorders. Depending on the type of disorder, differences in response rate were observed. The highest effectiveness was recorded with respect to diarrhoea (92.6%), followed by constipation (91.6%), colic (87.6%) and regurgitation (81%). Overall, 91% of the paediatricians and 88.8% of the parents/tutors were satisfied or very satisfied with the Novalac adapted milk formulas.

CONCLUSION: Mild gastrointestinal disorders show a high prevalence in paediatric practice. The Novalac adapted milk formulas have been shown to be effective in treating mild gastrointestinal disorders in milk-fed infants in the context of routine clinical practice.

INTRODUCTION

Human milk is a complete and complex species-specific food that provides all the nutrients needed for the growth of infants born to term during the first 4-6 mo of life. There is total agreement that maternal milk is the feeding method of choice for infants. However, at present, 25% of our population does not breastfeed, while 50% of women do so for only a reduced period of time (3-4 mo). In the event of contraindication or refusal to breastfeed, artificial nursing measures must be adopted. In many of these cases the infant may suffer mild gastrointestinal disorders (MGDs) during the period of lactation[1] including colic[2], regurgitation[3], diarrhoea[4] and constipation[5]. These symptoms cause discomfort for the infant and are a source of concern for parents. Acute diarrhoea cannot be considered a dysfunction as such; however, since it can be treated by dietetic measures, it has been included among these MGDs.

Interest among paediatricians to solve these disorders and improve knowledge of their physiopathology has led the infant food industry to develop specific formulas for these conditions. In many cases, dietetic adjustments are the first link in the treatment chain. At present, a broad range of artificial formulas have been developed[6] for feeding "healthy" infants. These formulas can partially or completely replace human milk, covering the normal nutritional requirements of the infant. In the case of infants with MGDs, adapted formulas have been developed[7,8] in which some of the nutrients have been specifically modified with the purpose of minimizing or resolving the digestive disorder while ensuring optimum infant growth. These formulas are manufactured according to the recommendations of the European Society for

Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)[9-11], the European Commission[12,13], and the Royal Decrees of the Spanish Ministry of Health[14,15].

The present study investigates the prevalence of MGDs in Spanish infants under four months of age and seen in paediatric practice. An evaluation is also made of the effectiveness of the specifically elaborated formulas belonging to the Novalac line of products (United Pharmaceuticals, France; Chiesi España S. A, Spain) [Novalac Anti-Colic (low lactose, adapted formula), Novalac Anti-Regurgitation (thickened with starch and enriched amylopectins), Novalac Anti-Diarrhoea (lactose-free and with adapted concentration of electrolytes), or Novalac Anti-Constipation (adapted concentration of magnesium and lactose)], in relation to the number of avoided episodes of colic, regurgitation, diarrhoea and constipation among infants exclusively fed with artificial milk formulas. Lastly, satisfaction with the Novalac line of products among both parents/tutors and paediatricians, was evaluated along with its relation to resolution or reduction of the symptoms associated with MGDs.

MATERIALS AND METHODS

Study design and patients

The present study comprises of two sub-studies. The first sub-study is a cross-sectional data-collecting study involving a 7-d period to estimate the prevalence of infants less than four months of age with MGDs such as colic, constipation, regurgitation and diarrhoea, among the global infant population seen in paediatric practice for any reason. The second sub-study in turn corresponds to a prospective longitudinal survey of the effectiveness of dietetic treatment with the Novalac range of formulas specifically developed for such MGDs.

A total of 285 paediatricians throughout Spain (except Ceuta and Melilla) participated in the study, under real-world conditions of clinical practice. Representation of the nursing infant population by Spanish Autonomous Communities was maintained. To investigate the prevalence of infants with MGDs in paediatric practice, each investigator included all infants less than four months of age seen in the clinic for any reason, during a period of one week. The infants of the cross-sectional study presenting MGDs with artificial milk formulas, and who according to medical criterion could be fed with the Novalac range of formulas, were enrolled in the longitudinal study. During one week, each investigator consecutively included 10 infants that met the selection criteria. This period was prolonged for two weeks until the full quota designated to each investigator was covered.

The selection criteria were: (1) infants up to four months of age fed with artificial milk formulas; (2) the presence of MGDs; (3) the possibility of feeding the infants with some product of the Novalac line of formulas; and (4) continuation of these formulas on an exclusive basis for at least 30 d (with no incorporation of other foods to the diet).

The cross-sectional study included 3487 infants to assess the prevalence of MGDs. The prospective study for evaluating the efficacy of the Novalac line of products involved 2069 patients with MGDs. The patients were visited on two occasions: at the time of inclusion and after four weeks. In the case of infants with diarrhoea, the final visit took place after 4-7 d. A total of 1441 infants completed follow-up.

Study variables

During the initial visit, data were collected relating to sociodemographic (age and sex) and clinical variables (gestational age, weight and height at birth and at the time of the visit, and the type and duration of the disorder). A questionnaire addressing the different symptoms and their intensity was designed for each disorder: (1) Constipation: number of stools/d, consistency, irritability, need for external help to defecate; (2) Regurgitations-vomiting: number/d, duration of the feedings, volume ingested; (3) Colic: excess gases, duration of crying, duration of bottle feeding; (4) Diarrhoea: number of stools and their characteristics.

The effectiveness of the dietetic treatment was evaluated on the final visit. Anthropometric data were collected (weight, height), along with the number of days to disappearance or improvement of the disorder, the evolution of symptoms, adverse events, and satisfaction of the parents/tutors and paediatricians with the treatment. Also documented was paediatrician contact after 15 d with the parents by telephone, to know the condition of the infant (in those cases where the paediatrician considered the call relevant).

The satisfaction of the parents/tutors and paediatrician with the Novalac formulas used for the MGDs was assessed on occasion of the final visit by means of a Likert-type scale with five possible answers (from very satisfied to very dissatisfied).

Statistical analysis

Duplicate data introduction was carried out, with validation of the database. Analysis of the prevalence of MGDs was based on a descriptive analysis of the sociodemographic and clinical characteristics of the study population. Continuous variables were reported as the mean and standard deviation (SD), while categorical variables were expressed as the number and percentage of infants per response category. The description of the characteristics of the infants was made for the total study sample, with stratification according to MGD presence.

A descriptive analysis was made of the number and percentage of infants seen in paediatric practice for MGDs, calculating the confidence interval (CI) of prevalence with a level of significance of 0.05. In order to assess variability in the Spanish setting, comparative studies were made of the prevalence of MGDs among the different regions in the country, based on the chi-square test.

Calculation was made of the number of days needed for disappearance or improvement of the disorder, along with the mean number (95% confidence interval) of days of MGD persistence.

A descriptive analysis was made of satisfaction as expressed by the parents/tutors and paediatricians. To this effect we used descriptive indicators such as the mean,

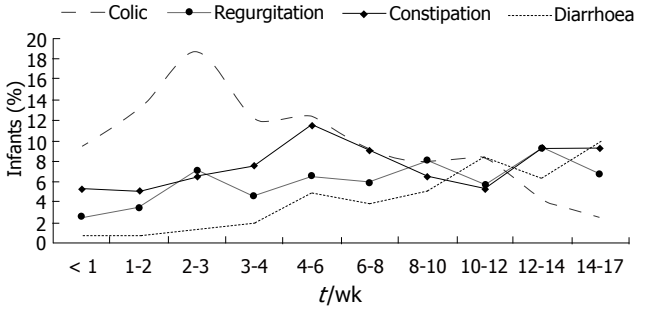

Figure 1 Percentage presentation of mild gastrointestinal disorders (MGDs) according to infant age and mean age at presentation.

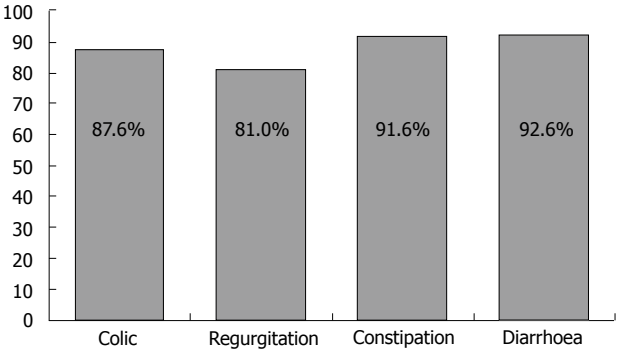

Figure 3 Percentage resolution of disorders with the Novalac formulas.

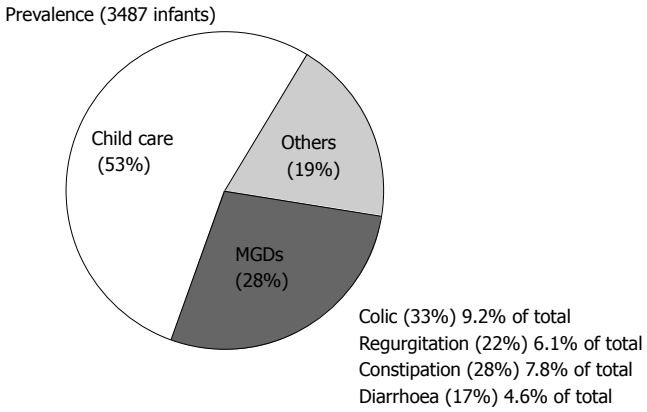

Figure 2 Prevalence of mild gastrointestinal disorders (MGDs) in paediatric practice.

standard deviation, median and percentiles 25 and 75. A study was made of the relationship between parent/tutor satisfaction with the Novalac line of products and their effectiveness, based on the Student t-test for independent data.

The SAS version 8.02 statistical package for Microsoft Windows was used throughout. In all the statistical tests a level of significance of $\alpha = 0.05$ was used.

RESULTS

The results of the cross-sectional study were obtained from the infant population included in the period of one week commented above, and involved 3487 infants. Boys predominated slightly over girls (52.2% *vs* 47.8%). Patient age at consultation was between under one week and 17 wk. Colic manifested at earlier ages (6.2 wk on average), followed by constipation (7.6 wk), regurgitation (8.6 wk) and diarrhoea (10.4 wk) (Figure 1). Gestational age was 39 wk on average (SD: 1.6 wk), with a mean body weight at birth of 3.2 (SD 0.5) kg and a height of 49.5 (SD: 2.3) cm.

The prevalence of MGDs was 27.8% (95% CI: 26.3-29.2); of these disorders, 9.2% (95% CI: 8.3-10.2) corresponded to colic, 7.8% (95% CI: 6.9-8.7) to constipation, 6.1% (95% CI: 5.3-6.9) to regurgitation -vomiting, and 4.6% (95% CI: 3.9-5.3) to diarrhoea. Only 0.6% of the infants presented with other digestive disorders (anorexia/hyporexia and eating disorders), while 19.0% (95% CI: 17.8-20.4) were diagnosed with some other non-digestive problem (upper airways infection, bronchitis and dermatitis). Of the study series, 52.6% consulted for aspects related to child care (Figure 2). The prevalence considering only the 27.8% of infants with MGDs was: colic 31.2% (95% CI: 30.3-36.2), constipation 29.2% (95% CI: 25.3-30.9), regurgitation 21.3% (95% CI: 19.5-24.7) and diarrhoea 18.3% (95% CI: 14.2-18.9).

The longitudinal study included 2069 infants with MGDs: 646 infants with colic, 441 with regurgitation, 604 with constipation and 378 with diarrhoea. The effectiveness of dietetic treatment for these disorders was evaluated among the 1441 infants that completed follow-up. Premature study termination among some infants was due to adverse events in 2.7% of cases, parent decision in 6.9%, loss to follow-up in 1.64%, protocol violations in 2.46%, and non-specified reasons in 16.62%.

Effectiveness in resolving the different disorders, after feeding with the specific Novalac formulas under conditions of routine clinical practice, is reported in Table 1 and Figure 3.

Colic was resolved among 87.6% of the infants after a median of 8 d - the proportion of infants with normal bottle feeding increasing from 33.9% at baseline to 69.2%. Likewise, a considerable reduction was observed in excess gases (from 82.9% at baseline to 25.8%). The duration of crying decreased in all infants.

Regurgitation was resolved in 81% of the infants after a median of 6 d of follow-up. The figure decreased from six regurgitations and/or vomiting episodes a day to only two, and the time required for bottle feeding decreased 53% - with an increase in the volume of daily ingestions in 61.9% of the infants.

A full 91.6% of the cases of constipation were resolved within 7 d. The number of daily stools among the infants with constipation increased from 0.6 (SD 0.7) stools/d to 1.7 (SD 0.8) stools/d. At the end of follow-up, the stools were found to be normal in 95.6% of the infants, while 89.6% presented no pain or discomfort, and 91.2% required no external help in defecating.

The infants with diarrhoea in turn, showed a decrease (mean [SD]) from 5.4 (1.8) to 2.2 (1) stools/d. Fever was absent in 98.5% of the cases, and 79.7% of the infants showed normal defecation at the end of treatment. A full 92.6% of the cases of diarrhoea were resolved within three days (Figure 4).

Development of all infants fed with the Novalac

Table 1 Description of clinical characteristics of patients at baseline and at the end of the study

		Baseline	30 d
Colic	Excess gases	82.90%	25.80%
	Duration of crying		
	< 1 h/d	12.10%	85.20%
	1-3 h/d	53.00%	13.30%
	> 3 h/d	34.80%	1.60%
Regurgitations	Regurgitation and/or vomiting per day [mean (SD)]	6.9 (4.5)	2.4 (1.8)
	Mean number of daily ingestions	6.0	5.6
	Duration of daily ingestions		
	Increases	-	24.50%
	Without change	-	22.40%
	Decreases	-	53.10%
	Volume of daily ingestion		
	Increases	-	61.90%
	Without change	-	18.70%
	Decreases	-	19.40%
Constipation	Type of stools		
	Normal	33.40%	95.60%
	Hard	66.60%	4.40%
	Presence of pain or discomfort		
	Yes	90.00%	10.40%
	No	10.00%	89.60%
	External help needed for defecation		
	Yes	76.10%	8.80%
	No	23.90%	91.20%
		Baseline	7 d
Diarrhoea	Presence of fever		
	Yes	21.40%	1.50%
	No	78.60%	98.50%
	Number of stools per day [mean (SD)]	5.4 (1.8)	2.2 (1)
	Type of stools		
	With mucus and/or blood	5.20%	1.10%
	Liquid	45.00%	4.80%
	Semiliquid	49.80%	14.40%
	Normaly	0.00%	79.70%

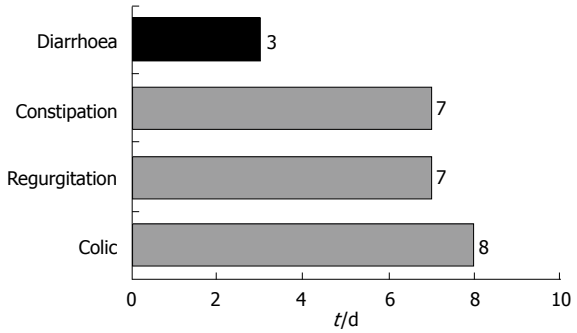

Figure 4 Mean days to resolution of mild gastrointestinal disorders (MGDs).

formulas was within the normal range.

Ninety-one percent (91%) of the paediatricians were satisfied or very satisfied with the dietetic regimen, though statistically significant differences were observed between groups ($P < 0.001$) - increased satisfaction being recorded among the paediatricians that treated diarrhoea and constipation versus those that treated colic and regurgitations. The greatest levels of satisfaction corresponded to the treatment of diarrhoea, with 95.9% of the paediatricians claiming to be satisfied, followed by constipation (92.8%), colic (88.5%) and regurgitation (87.8%).

As to parent satisfaction with the treatment ($P < 0.001$), 88.8% claimed to be satisfied with the course of the disorder - the specific figures being 93.7% in the case of diarrhoea, followed by constipation (90.0%), colic (88.1%) and regurgitation (83.3%).

Regarding the adverse events recorded during the study, only 3.9% of the infants receiving Novalac formulas suffered some adverse event. The most frequent affected the digestive tract (1.4%), including diarrhoea and constipation, and respiratory apparatus (0.7%) (e.g. bronchitis and bronchiolitis). Ten infants (0.5%) required hospital admission for different reasons: septicaemia ($n = 1$), dehydration ($n = 2$), vomiting ($n = 1$), hernia ($n = 1$) and bronchitis or bronchiolitis ($n = 2$).

DISCUSSION

Maternal breast milk is the usual food source for infants, though when breastfeeding is not possible, artificial lactation can be provided in the form of starting formulas, with the introduction of follow-up formulas 4-6 mo later, to ensure optimum nutritional development. During this period mild gastrointestinal disorders (MGDs) are not uncommon, and may be treated with dietetic measures.

This study for the first time provides information on the prevalence of these disorders in Spain, and on

the efficacy of dietetic treatment using the different formulas of the Novalac product range. The results of the prevalence study indicate that colic in infants is the MGD most often seen in paediatric clinics (9.2%), representing 33.3% of all MGDs.

Infant "colic" is an ill-defined term that is often used in reference to different situations found in paediatric practice[16]. Due to the lack of a clear definition, prevalence and treatment studies characteristically include heterogeneous groups of infants. These are usually healthy children that in the first four months of life develop paroxysmal crying without any apparent cause, and that gradually subsides. The underlying aetiology has not been clearly established, though the disorder has been related to alterations in motility[8], prostaglandin dysfunction, abnormal serotonin concentrations, and neuropeptide immaturity. Other authors more inclined to seek behavioural explanations tend to relate infant colic to alterations in the family environment, or even consider it a "normal" form of behaviour in infants with a more irritable temperament.

Human milk contains 7 g of lactose per 100 mL. However, in the first few weeks of life, infants present physiological or functional lactase insufficiency that limits absorption of these amounts. The non-hydrolyzed lactose reaches the colon, where it ferments to yield lactic acid, short-chain fatty acids, methane, carbon dioxide and hydrogen. This exerts a beneficial effect in that the stools become semiliquid as a result. However, is some cases such fermentation gives rise to excess gas[17-19], which favours the development of colic. In effect, different studies have related excess crying with excess intestinal gas[20].

The Novalac Anti-Colic formula offers an important reduction of the symptoms. Colic was resolved in 87% of the cases within one week, with a reduction in crying time, improvement in feeding continuity, and a reduction in the amount of intestinal gas.

In this study, constipation was the cause of consultation in 7.8% of the infants (representing 28% of all MGDs). A recent article published by Quinlan *et al*[21] studied the stool characteristics of 844 infants between 7-15 d old. Hard stools were recorded in 17% of the formula-fed infants, and in none of the breastfed infants. Breastfeeding entails a series of compensating physiological mechanisms that avoid constipation[22]. The Novalac Anti-Constipation formula bases its therapeutic efficacy partially on its high lactose content (8.1 mg/100 mL). The non-hydrolyzed lactose reaches the colon, where it is metabolized by the anaerobic flora, producing an osmotic laxative effect, since it attracts water into the intestinal lumen[17-19]. The magnesium contained in the formula (within the authorized maximum limits: 9.1 mg/100 mL) also enhances the laxative effect due to its osmotic action, and stimulates bowel motility by inducing cholecystokinin (CCK) secretion[23-25]. The efficacy of such treatment is reflected by an increase in the number of stools, and a reduction in the number of hard depositions, associated discomfort and the need for external help in defecation.

The next most prevalent MGD in the present study was regurgitation (22% of the total MGDs). Regurgitation and vomiting are the final manifestation of reflux. The aetiology of reflux in infants is of a multifactorial nature, and has not yet been fully elucidated. Postprandial reflux is accepted to be physiological, and occasionally occurs in almost all infants. However, in some cases the clinical picture is particularly manifest and can produce important discomfort for both the child and family. It is generally agreed that uncomplicated gastro-oesophageal reflux should not receive pharmacological treatment (antacids, prokinetic agents, H2 receptor blockers), though effective measures such as postural and dietetic management are recommended. In any case, the same authors that initially recommended such treatment have recently questioned it[26].

Milk thickening is a therapeutic practice that has been recommended for decades. Increased food viscosity and density reduces the reflux rate but does not modify the rest of parameters indicative of pathological gastro-oesophageal reflux. The products used as thickeners for the most part have been locust bean flour, pectin and cellulose. Cereal starch (rice and corn) has also been proposed, and offers the advantage of avoiding the possible adverse effects associated with the presence of galactomannans[27]. The Novalac Anti-Regurgitation formula contains a specially selected corn starch (having high amylopectin content) in a proportion of 1.9 g per 100 mL. It is pregelatinised and contributes to the increased viscosity in the stomach (on average 10 fold the viscosity in the feeding bottle). The presence of medium-chain fatty acids in turn favours a reduction in gastric emptying[28]. The efficacy of the treatment is reflected by the results obtained in the present study. In effect, the number of regurgitations/vomiting episodes decreased during the 7 d of treatment, and improvements were also seen in the rapidity of bottle ingestion, with a larger ingested volume.

Lastly, acute gastroenteritis represented 16.5% of the global MGDs in our study. Acute gastroenteritis, of a bacterial or viral origin, is characterized by alterations in the normal displacement of water and electrolytes within the intestinal lumen. When diarrhoea is caused by a virus (fundamentally rotavirus) transient lactase deficiency may also result. The duration of this deficiency is usually 7-15 d, though infants that are malnourished or suffer serious intestinal lesions may have persistent diarrhoea for up to 18-24 mo. In those cases in which deficient lactose absorption is suspected, lactose-free formulas are justified[29,30]. In most cases a single week of lactose exclusion suffices, after which the usual formula is reintroduced, while monitoring tolerance.

The most recent developments point to the advisability of introducing soluble fibre[31]. The use of amylase-resistant carbohydrates is an innovation that takes advantage of the functional properties of the colon - specifically, the metabolic activity of the anaerobic flora and the absorption capacity of the colon mucosa. The purported mechanism involves use by the colon mucosa of the short-chain fatty acids produced by bacterial metabolism of non-absorbed carbohydrates, to favour the absorption of water and electrolytes[32]. In the colon, many carbohydrates are fermented by the anaerobic flora, resulting in short-chain fatty acids: propionate, acetate and butyrate. In the mucosa, these fatty acids stimulate the absorption of water and electrolytes.

The Novalac Anti-Diarrhoea formula contains no lactose, and moreover incorporates a series of novelties. The presence of electrolytes within the accepted maximum range (31 mg of Na/100 mL, 83 mg of K/100 mL and 49 mg of Cl/100 mL) ensures an increased mineral supply for those patients who after discontinuing oral rehydration remain at risk of excessive losses. On the other hand, the presence of pectin (1.5 g per 100 mL) offers the advantage versus other fructo-oligosaccharides of being totally fermented in the colon, since it is a larger and more viscous molecule - thereby favouring short-chain fatty acid production.

The present study for the first time offers information on the prevalence of mild gastrointestinal disorders in Spanish infants under four months of age seen in paediatric clinical practice. Dietetic intervention with the Novalac formulas has been shown to be effective in resolving these disorders in the routine clinical setting - with a significant reduction in associated symptoms. A close relationship has been found between satisfaction among the parents/tutors and paediatricians and the effectiveness of the dietetic treatment provided. In turn, the low prevalence of treatment-related adverse events reflects the good tolerability of the formulas belonging to the Novalac range of products.

COMMENTS

Background

Different milk-feed infant formulae have appeared in the market during the last decades for the nutritional treatment of different entities such as colic, constipation, regurgitation and acute diarrhoea, called "mild gastrointestinal disorders" (MGD), There are few data about the prevalence or these MGD and its evolution after the intake of nutritional formulae.

Research frontiers

This study investigated the MGD prevalence, MGD physiopathology, International Committees and Scientific Societies position in front of new formulations composition, as well as clinical response with these new formulae.

Innovations and breakthroughs

In this article we have published, for the first time in our country, relevant data regarding the MGD prevalence and dietetic clinical response in a huge number of milk-fed infants (*n* = 2069). Among international publications one can find lots of information about recommendations of how these formulations have been made and its usages indications and efficacy, but never in a population as big as this.

Applications

This study allows the real acknowledgment about MGD prevalence, and also explains why new formulae composition have to be used and its clinical response. It also increases paediatricians possibility of use of these formulations, giving them confidence regarding clinical efficacy and nutritional safety.

Terminology

Mild gastrointestinal disorders: colic, constipation, regurgitation and acute diarrhoea.

Peer review

The authors are to be congratulated on an important and well presented study.

Received: April 23, 2007 Revised: October 24, 2007

Abstract

AIM: To evaluate the efficacy and safety of pegylated-interferon alpha-2a in hemodialysis patients with chronic hepatitis C.

METHODS: Thirty-six hemodialysis patients with chronic hepatitis C were enrolled in a controlled and prospective study. All patients were treatment naive, positive tested for anti-HCV antibodies, and positive tested for serum HCV-RNA. Twenty-two patients received 135 μg peglyated-interferon α-2a weekly for 48 wk (group A). The remaining patients were left untreated, eleven refused therapy, and three were not candidates for kidney transplantation and were allocated to the control group (group B). At the end of the treatment biochemical and virological response was evaluated, and 24 wk after completion of therapy sustained virological response (SVR) was assessed. Side effects were monitored.

RESULTS: Of 22 hemodialysis patients, 12 were male and 10 female, with a mean age of 35.2 ± 12.1 years. Virological end-of-treatment response was observed in 14 patients (82.4%) in group A and in one patient (7.1%) in group B (P = 0.001). Sustained virological response was observed in 11 patients (64.7%) in group A and in one patient in group B (7.1%). Biochemical response parameters normalized in 10/14 patients (71.4%) at the end of the treatment. ALT levels in group B were initially high in six patients and normalized in one of them (25%) at the end of the 48 wk. In five patients (22.7%) therapy had to be stopped at mo 4 due to complications of weakness, anemia, and bleeding.

CONCLUSION: SVR could be achieved in 64.7% of patients on hemodialysis with chronic hepatitis C by a treatment with peglyated-interferon α-2a. Group A had a significantly better efficacy compared to the control group B, but the side effects need to be concerned.

INTRODUCTION

Hemodialysis patients are at high risk of infection by hepatitis C virus (HCV) because the hemodialysis unit is a medical environment where exposure to blood is frequent. Therefore, the prevalence of HCV infection, from less than 5% to over 70% in some countries, is greater than the prevalence of HCV infection in the general population[1]. HCV infection is an important cause of morbidity and mortality among patients with end-stage renal disease (ESRD)[2]. HCV infection in patients on maintenance hemodialysis was reported in 10%-59% of patients, in comparison to 0.3%-1.5% observed in the general population[3]. The prevalence of HCV infection is 10%-20% in dialysis patients in developed countries[4,5] and much higher in less developed countries[6]. The prevalence of anti-HCV antibodies among dialysis patients was 40.3% in Turkey[7], 30% in India[8], and 43.9% in Saudi Arabia[9]. In United States of America in 2000, 8.4% of haemodialysis patients were anti-HCV positive[10].

The main mechanisms involved in nosocomial infection with HCV in haemodialysis patients are filter re-use, the use of contaminated haemodialysis machines, and contamination of medical staff's hands. It has been shown that the incidence of HCV infection in haemodialysis patients increases if the medical staff member does not change her/his gloves before injecting each patient and if hepatitis C patients undergo haemodialysis in the same room[11].

The eradication of HCV infection is thought to be valuable for patients with ESRD, especially those who are candidates for kidney transplantation[12]. To prevent the development of these complications and to make these patients suitable for transplantation, standard interferon-α

was used in various doses or regimes for the treatment of these patients[13].

The supplement of a polyethyleneglycol molecule to interferon produces a biologically active molecule with a longer half-life time and more favorable pharmacokinetics; these characteristics enable for a more appropriate once-weekly dosing. When pegylated-interferon α-2a (PEG-IFN) alone is given to chronic hepatitis C patients with normal renal function for 48 wk, the sustained virological response (SVR) rate is approximately twice that with standard interferon[14,15].

This study evaluated the tolerability and efficacy of PEG-IFN in patients with chronic hepatitis C. Therefore, we carried out a controlled prospective longitudinal study to assess the biochemical and the virological response at 48 wk of treatment with PEG-IFN and its tolerability in hemodialysis patients with chronic HCV infection.

MATERIALS AND METHODS

Study design and patients

The present controlled and prospective study was carried out in the Department of Infectious Diseases in Dicle University Hospital, and in one Private Dialysis Center in Diyarbakir, Turkey. In total, 58 among the 161 patients with total hemodialysis in this center were anti-HCV positive (36%). Of the 58 patients, 38 were HCV-RNA positive (65%). Two patients were excluded because they had decompensated liver disease (n = 1), coinfection with hepatitis B virus (n = 1), or because they were lost to follow-up. Thirty-six HCV-RNA positive patients were informed about the benefits and possible risks of PEG-IFN treatment. Fourteen patients were excluded from the study, eleven refused the therapy, and three were not candidates for kidney transplantation and were allocated to the control group (group B). The remaining 22 patients were allocated to the PEG-IFN treatment group (group A). All patients underwent chronic hemodialysis treatment for ESRD during the study period. Hemodialysis was carried out routinely 2-3 times weekly in the patient population. All patients were anti-HCV antibody positive and had detectable HCV-RNA by polymerase chain reaction for at least 6 mo. It has been reported that liver biopsy (histology) is not suggested in the patient with chronic hepatitis C and end-stage renal diseaese because of high bleeding risk.

Inclusion criteria

PEG-IFN therapy was performed in patients meeting the following inclusion criteria: (1) Age < 65 years; (2) absence of pregnancy and agreement to avoid pregnancy during therapy; (3) informed consent; (4) lack of autoimmune, thyroid, psychiatric, or malignant disorders; (5) negative HIV antibody test; and (6) thrombocyte count > 70 000/mm^3 and white blood cell count > 3000/mm^3.

Exclusion criteria

Patients meeting at least one of the following criteria were excluded: (1) Age < 18 or > 65 years; (2) presence of coinfection with HBV or HIV; (3) receiving immunosuppressive therapy or other treatments, namely antihistaminics, non-steroidal anti-inflammatory drugs, aciclovir, or amiodarone; (4) previous treatment for HCV infection; (5) alcohol consumption > 40 g/d; (6) active drug addiction; (7) evidence of hepatocellular carcinoma (α-fetoprotein > 100 ng/mL); (8) hemophilia; or (9) contraindication to interferon therapy.

Study protocol

Patients (group A) enrolled in the study received 135 μg PEG-IFN (40 kDa) (PEGASYS; F. Hoffmann-La Roche, Basel, Switzerland) weekly for 48 wk at the end of dialysis session. All treated patients were evaluated at the end of wk 12 of treatment. The antiviral treatment was continued if the patient had at least a 2-log decline from baseline HCV-RNA level. Patients were followed up and evaluated for 24 wk after completion of treatment. Therapy was monitored weekly by complete blood count and liver function tests (alanine aminotransferase [ALT; U/L], aspartate aminotransferase [AST; U/L]) for 3 mo, then monthly. HCV-RNA testing was carried out before treatment and then every 3 mo. Anti-HCV antibody was measured by a third generation commercial ELISA (Innotest HCV Ab IV; Innogenetics NV, Ghent, Belgium). Liver biopsy was not performed in hemodialysis patients. Serum HCV-RNA was quantified using a reverse transcriptase-polymerase chain reaction assay (Amplicor HCV ver. 2.0; Roche Diagnostic Systems, Branchburg, NJ) with a dynamic range being between 600 and 500 000 IU/mL. All samples were blindly tested in duplicate.

Virological and biochemical response criteria

In group A virological early response (virological EAR), virological end-of-treatment response (virological EOR), and sustained virological response (SVR) were defined as negative HCV-RNA by PCR at 12 and 48 wk of the therapy, and 6 mo after completion of therapy, respectively. In the treatment group, biochemical early response (biochemical EAR), biochemical end-of-treatment response (biochemical EOR), and sustained biochemical response (biochemical SR) were defined as the normalization of serum ALT activity at wk 12 and 48 and 6 mo after completion of therapy, respectively. Although group B patients did not receive PEG-IFN, biochemical and virological recovery at 12, 48, and 72 wk after the beginning of the study were categorized as early response (EAR), end-of-treatment response (EOR), and sustained response (SR), too.

Statistical analysis

Student's t test was used to compare mean values between groups, and the χ^2 test and Fisher's exact test were performed to analyze qualitative data. Parametric data are expressed as mean ± SD. A value of $P < 0.05$ was considered statistically significant. Statistical analysis was performed by using SPSS version 10.0 (SPSS Inc; Chicago, IL).

RESULTS

Enrollment started in November 2004 and the study was finished in July 2006. Seventeen of 22 patients finished therapy. The mean serum viral load before treatment was

Table 1 Demographic and clinical features of study patients

Variables	Group A (n = 22)	Group-B (n = 14)	P
Age (yr)	35.2 ± 12.1	37.1 ± 14.6	0.629
Male (%)	12 (54.5)	10 (71.4)	0.448
BMI (kg/m^2)	25.6 ± 3.3	26.1 ± 3.9	0.78
ALT (IU/L)-Range	59.2 ± 22.4-(33-109)	44.8 ± 20.9-(21-71)	0.489
Viral load (x 10^5 copy/mL)	7.9 ± 4.8	8.1 ± 4.5	0.89
Genotype 1b (%)	86.4	92.9	0.56
HD duration (mo)	52.4 ± 24.7	49.8 ± 21.1	0.95

Table 2 Virological response rates

	Group A (n = 22)	Group-B (n = 14)	P
Early response			
Virological (%)	82.4	0	< 0.001
End-of-treatment response			
Virological (%)	82.4	0	< 0.001
Sustained response			
Virological (%)	64.7	0	< 0.001

2.4 × 10^5 copy/mL. At the beginning of therapy, ALT levels were found to be elevated in fourteen patients (63.6%). In nine of these patients, ALT activity decreased to normal levels within 12 wk of treatment (biochemical EAR 64.3%). At the end of the treatment, four patients still had high ALT levels (biochemical EOR 71.4%). In this group, the mean serum ALT activity at initiation was 59.2 ± 22.4 IU/L (range, 33-109 IU/L). This significantly decreased to 29.9 ± 13.7 IU/L and 21.8 ± 10.9 IU/L at wk 12 (P = 0.017) and at the end of the treatment (P = 0.001), respectively. At the beginning of the study, ALT levels were high in six patients in group B. One of the patients' levels became normal at 12 wk resulting in a biochemical EOR of 16.7%. In the control group, the mean ALT level was 44.8 ± 20.9 IU/L at the beginning. This value declined to 33.8 ± 21.7 IU/L at wk 12 (P = 0.786) and 33.1 ± 18.9 IU/L at wk 48 (P = 0.760).

The mean pretreatment serum HCV-RNA levels were 7.9 ± 4.8 × 10^5 copy/mL and 8.1 ± 4.5 × 10^5 copy/mL in group A and group B, respectively (Table 1).

The viral load was statistically similar between the groups (P = 0.890). All patients treated with PEG-IFN showed at least a 2-log decline from baseline HCV-RNA level. But HCV-RNA became undetectable in 82.4% of the patients at wk 12 of therapy. Virological EOR and SVR occurred in 82.4% and 64.7% of the patients (Table 2). Virological EOR and SVR 0% of the control group.

Therapy with PEG-IFN was associated with a higher rate of virological response than the control group (P < 0.001). All of the subjects had genotype 1. In the treatment group, three patients had genosubtype 1a and 19 had genosubtype 1b. In group B one subject had genotype 1a, and 13 had genotype 1b. There was no significant difference between the groups with respect to genotype distribution (P = 0.560).

Most adverse events were mild to moderate in severity, and all adverse events were typical of those previously reported for PEG-IFN. The drug was suitably tolerated by patients. Flu-like syndrome, throbocytopenia, leucopenia, and anemia were the most frequent side-effects and were experienced in nine patients (53%). These side-effects included flu-like syndrome in eight (47%), fatigue in six (35%), anemia in four (23.5%), thrombocytopenia in three (17.6%), and leucopenia in three of them (17.6%). We had to stop the treatment in five patients (22.7%) in fourth month at the begin of the treatment due to complications (two of anemia, two of weakness, one of gastrointestinal bleeding). The side-effects led to discontinuation of the treatment in five patients. Seventeen of 22 patients finished the treatment in spite of side-effects due to PEG-IFN. No patient had a serious infection during the treatment period.

DISCUSSION

In patients with normal renal function, pegylation increases the size of the molecule, delays its clearance, and enhances the therapeutic effect of standard IFN. It is possible to hypothesize that, in patients with renal failure; the clearance of PEG-IFN would be even more delayed, resulting in higher serum levels of the drug and in a longer half-life time.

The results of this study confirm the efficacy and safety of PEG-IFN therapy in hemodialysis patients with chronic hepatitis C. Treatment for 48 wk with PEG-IFN resulted in sustained virologic responses in 64.7% of patients. HCV infection increases the risk of death in patients on chronic hemodialysis, along with hepatocellular carcinoma and liver cirrhosis[16]. Many controlled and uncontrolled trials have focused on the treatment of chronic hepatitis C patients on chronic haemodialysis with IFN therapy[17], because treatment with PEG-IFN is rarely recommended.

Fabrizi *et al* have found a mean SVR of 37% in chronic hepatitis C patients on dialysis after IFN therapy. Sustained biochemical and virological response rates in patients under classical IFN therapy were reported as 0%-67% and 15.8%-64%, respectively[6]. Sporea *et al* have found, in treatment of these patients with standard IFN the sustained biochemical response of 46.1% and sustained virological response of 38.4% respectively 6 mo after interferon treatment[17]. The promising results at the standard IFN therapy in chronic haemodialysis patients with chronic hepatitis C, have shown that viral clearance occurs in 27%-64% of patients after 12 mo of treatment with standard IFN[18,19].

Patients with end-stage renal disease and chronic hepatitis C might have severe chronic hepatitis despite normal serum liver enzyme activity[20]. In our study, serum ALT levels were normal in 36.4% of the patients at the beginning of the study. Similarly, Perez *et al* reported normal ALT levels in 49% of patients at the beginning of treatment[20]. In the treatment group in our study, serum ALT levels became normal in 71.4% of the patients by the end of the therapy, whereas 16.7% of the patients in the control group had a biochemical response of end of therapy. In contrast, the side-effects of IFN treatment are very important for the patients with ESRD. In several situations, the IFN treatment could not be continued in those patients. Liver biopsy was avoided because of the risk of bleeding in these patients[21].

Recently, a pharmacokinetic study was carried out with

PEG-IFN in subjects with various degrees of stable renal failure who were not yet dialysis dependent. Adsorption and distribution of PEG-IFN were similar in subjects with stable chronic renal impairment versus individuals with normal renal function[22]. The dose of 135 μg of PEG-IFN in patients with ESRD gave similar serum concentrations to a dose of 180 μg in patients with normal renal function. On the trials of PEG-IFN in patients with end-stage renal disease have been designed using weekly doses of 135 μg (as opposed to 180 μg)[7].

HCV genotype 1 is very common in Turkey. Similarly, all of the patients in the present study had genotype 1. Although the response to IFN treatment is not excellent in genotype 1, our results were outstanding[23]. Most of the patients in our study were infected with genotype 1b (86.4% group A, 92.9% group B).

Recently, Kokoglu *et al* reported the results of a controlled study in which PEG-IFN 135 μg/wk for 48 wk was used in hemodialysis patients with HCV infection. They found 83.4% virological EOR and 71.4% biochemical EOR[7]. Sporea *et al* reported on a 50% SVR in hemodialysis patients receiving PEG-IFN 180 μg/wk[24]. In another study, virological response was 40% with PEG-IFN. The difference in virological response could be related to the duration of treatment in the last study (24 wk) and the molecular weight of PEG-IFN (17 kDa)[25]. We found in our study 82.4% virological EOR and 71.4% biochemical EOR.

PEG-IFNs are likely to become a valuable addition for HCV therapy in ESRD when combined with reduced ribavirin doses. However, the pharmacokinetics and tolerability of PEG-IFN and ribavirin combination therapy need to be studied in prospective studies[26]. To date, PEG-IFN and ribavirin combination therapy is the treatment of choice for patients with HCV infection. Ribavirin is metabolized by the kidneys and its clearance reduces in patients with ESRD. High ribavirin serum levels markedly increase the risk of hemolytic anemia and the use of ribavirin in uremic patients, who are often already anemic, could cause severe and life-threatening anemia. Thus, a combination therapy with ribavirin is not an option for treatment of chronic HCV infection in hemodialysis patients[27].

We found in the present study 64.7% SVR and we can expect that in these subjects the use of PEG-IFN would lead to a higher rate of SVR than that observed with standard IFN, probably with a higher rate of adverse effects[11]. PEG-IFN therapy had a successful efficacy in the present study but tolerability was not perfectly. We had to stop the treatment in five patients (22.7%) due to complications (two of anemia, two of weakness, one of gastrointestinal bleeding).

In conclusion, the results of the present study show PEG-IFN (40 kDa) administered at a dose of 135 μg weekly for 48 mo was efficacious but not perfectly tolerable in dialysis patients with HCV infection.

COMMENTS

Background

Our study showed that PEG-IFN (40 kDa) administered at a dose of 135 μg weekly for 48 mo was efficacious but not perfectly tolerable in dialysis patients with chronic hepatitis C.

Research frontiers

The present study was carried out in South-east Anatolien/Diyarbakir, Turkey, in hemodialysis patients with chronic hepatitis C.

Pegylated-interferon α 2a treatment for chronic hepatitis C in patients on chronic hemodialysis. *World J Gastroenterol*. 2006 Jul 14; 12(26): 4191-4194.

Innovations and breakthroughs

Many studies published that PEG-IFN treatment is efficacious and tolerable in hemodialysis patients with chronic hepatitis C. In our study we found similar efficacy, but this treatment was not perfectly tolerable in dialysis patients with HCV infection.

Peer review

Ayaz *et al* investigated the effects of PEG-IFN for treatment of HCV infection in hemodialysis patients. Eleven of 17 patients had a SVR at wk 24 after end-of-treatment. In 5 patients treatment had to be stopped because of side effects. The currently available data on this topic are scarce and therefore this is an important study which should be published.

Abstract

AIM: To assess the role of echo-Doppler ultrasonography in postprandial hyperemia in cirrhotic patients by comparing the results with the hepatic vein catheterization technique.

METHODS: Patients with cirrhosis, admitted to the portal hemodynamic laboratory were included into the study. After an overnight fast, echo-Doppler ultrasonography (basal and 30 min after a standard meal) and hemodynamic studies by hepatic vein catheterization (basal, 15 min and 30 min after a standard meal) were performed. Ensure Plus (Abbot Laboratories, North Chicago, IL) was used as the standard liquid meal. Correlation analysis of the echo-Doppler and hepatic vein catheterization measurements were done for the basal and postprandial periods.

RESULTS: Eleven patients with cirrhosis (5 Child A, 4 Child B, 2 Child C) were enrolled into the study. After the standard meal, 8 of the 11 patients showed postprandial hyperemia with increase in portal blood flow, portal blood velocity and hepatic venous pressure gradient. Hepatic venous pressure gradient in the postprandial period correlated positively with postprandial portal blood velocity (r = 0.8, P < 0.05) and correlated inversely with postprandial superior mesenteric artery pulsatility index (r = -1, P < 0.01).

CONCLUSION: Postprandial hyperemia can be efficiently measured by echo-Doppler ultrasonography and the results are comparable to those obtained with the hemodynamic studies.

INTRODUCTION

It is well known that portal pressure increases during the postprandial period. It is caused by an augmentation of blood flow into the splanchnic area, a phenomenon known as "postprandial hyperemia"[1,2]. In portal hypertensive patients, postprandial hyperemia may increase the variceal wall tension and trigger acute variceal bleeding. Therefore, an assessment of postprandial hyperemia (PPH) in cirrhotic patients may provide a better understanding of the pathophysiology of variceal bleeding, and consequently impact our treatment strategy.

Hepatic venous pressure gradient measurement by hepatic vein catheterization is the gold standard technique for the assessment of portal pressure changes in postprandial period in patients with cirrhosis[3]. However, this procedure is costly, is uncomfortable for the patients and is not available in every hepatology unit. By contrast, echo-Doppler ultrasonography (USG) is inexpensive, easy for the patients and is available in most hospitals. Sabba *et al* studied the sensitivity of echo-Doppler USG in detecting hemodynamic changes caused by postprandial hyperemia in an observer-blinded study. They found that echo-Doppler USG was highly sensitive for the evaluation of postprandial hyperemia[4]. Additionally, several studies have been done to investigate the effects of different drugs on postprandial hyperemia by using echo-Doppler USG[5-8]. However, to the best of our knowledge, there is no study which compares the hepatic venous catheterization with echo-Doppler USG in the assessment of PPH in patients

with cirrhosis. Therefore, the aim of present study was to investigate the sensitivity of echo-Doppler USG in the assessment of PPH by comparing results with the gold standard test, hepatic vein catheterization.

MATERIALS AND METHODS

Patients

All cirrhotic patients who were admitted to the portal hemodynamic laboratory of Marmara University School of Medicine, Department of Gastroenterology from November 2003 to March 2004, for the hemodynamic measurements before initiation of primary or secondary variceal bleeding prophylaxis were evaluated for the enrollment into the study. The exclusion criteria were age less than 18 or greater than 80 years, presence of hepatocellular carcinoma, coronary heart disease, hypertension, diabetes mellitus, portal vein thrombosis, refractory ascites, chronic lung disease, hepatic encephalopathy, hepatorenal syndrome and refusal to participate in the study.

The study was approved by the ethical committee of Marmara University School of Medicine and all patients gave written informed consent prior to participating in the study.

Study design

Diuretics and beta-blocker drugs were stopped 3 d before the study. After an overnight fast, baseline echo-Doppler (ATL, Ultramark 8 echo-Doppler duplex system) study was performed and the systolic (SBP), diastolic blood pressure (DBP) and heart rate (HR) were obtained. After these procedures, the patients were prepared for hepatic vein catheterization to obtain baseline hemodynamic measurements. Right hepatic vein catheterization was performed percutaneously through the jugular vein and the pressures were recorded in both the wedged and free position, using a balloon catheter (Medi Tech, Cooper Scientific Corp, Watertown, MA). The wedged position was controlled by the absence of reflux after the injection of 2 mL of contrast medium. Pressures were measured by a strain gauge transducer previously calibrated, and the findings were recorded on paper. Each pressure reading was recorded twice and the mean of the two values was used for the final result.

After the baseline measurements were obtained, a standard mixed liquid meal was given which consisted of 237 mL, of balanced dietary supplement (Ensure Plus, Abbot Laboratories, North Chicago, IL), containing 355 kcal as 14.7 g protein, 53.3 g carbohydrate and 32 g lipid. The meal was consumed over a period of 10 min. The mixed liquid meal was chosen because of ease of consumption, and standard formula and calorie intake. Hemodynamic measurements were repeated at 15, 30 and 60 min after the meal. At 30th min after the meal, echo-Doppler USG measurements were repeated simultaneously with the hemodynamic study. Because of technical difficulties (transport of the patients to the Doppler room), echo-Doppler USG could not be performed at the 15th and 60th min of postprandial period.

Parameters

Mean arterial pressure (MAP) = (systolic + diastolic × 2)/3.

Hemodynamic studies

Hepatic venous pressure gradient (HVPG) = Wedge hepatic venous pressure (WHVP) - Free hepatic venous pressure (FHVP).

Echo-Doppler USG

Portal Blood Flow (PBF) = Portal vein cross-sectional area (A) mm^2 × Portal blood velocity (PBV) cm/s.

An area was obtained from the cross-section of the vessel visualized by B-mode after defining the major and minor diameters of the vessel. Velocity measurements were performed in quiet suspended inspiration and averaged over a few seconds. These measurements were obtained from the longitudinal section of the vessel by positioning the sample volume cursor over the vessel at a known angle of insonation, defined as an angle between the Doppler beam and the long axis of the vessel. The Doppler sample volume probe was positioned over the middle of the vessel and was manipulated to cover about 90% of the vessel section in order to detect the maximum Doppler frequency shift, related to the maximum velocity (4).

According to the Doppler equation:

$$\Delta f = \frac{2 \text{ foV max cos Q}}{c}$$

c: speed of the sound in the tissue

Q: angle between the ultrasound beam and the director of the blood flow (angle of insonation)

$$Vm = 0.57 \times Vmax$$

Additionally, pulsatility index (PI) for the superior mesenteric artery (SMA) was measured according to the formula:

PI = Vmax - Vmin/Vmean

To decrease the inter-observer variability, all measurements were repeated 3 times by 2 different investigators and the mean value was used for statistical analysis.

Statistical analysis

Baseline results for the measurements are given as mean ± SE of absolute values. The values over time (Basal, 15 and 30 min after the test meal) were compared by ANOVA and the Student's *t* test. Spearman correlation tests were done between the measurements of echo-Doppler USG and hemodynamic studies.

RESULTS

One hundred patients attending the hepatology outpatient clinic of the Marmara University Hospital were screened. However, only 11 patients were included in the study; the remainder were excluded due to factors such as clinical status, high Child-Pugh score, hematologic parameters, patients not providing informed consent and other exclusion criteria. The characteristics of the 11 patients are shown in Table 1. Eight out of the 11 patients showed postprandial hyperemia as judged by

Echo-Doppler measurements				
PBF (L/min)	1.5 ± 0.9		2.4 ± 1.1	< 0.05
PBV (cm/s)	23.5 ± 11.6		32.9 ± 12.3	< 0.01
SMA-V (cm/s)	120.2 ± 23.3		158.1 ± 59.9	< 0.05
SMA-PI	2.8 ± 0.5		1.7 ± 0.2	< 0.05
Systemic measurements				
MAP (mmHg)	85 ± 12.9		80 ± 9.6	< 0.05
Pulse Rate (min)	89.70 ± 21.2		85.3 ±13.3	< 0.05

[b]$P < 0.01$ postprandial 15 min *vs* basal hepatic venous pressure gradient (HVPG); [a]ANOVA statistics of basal, 15 min and 30 min measurements of hepatic vein catheterization; [d]$P < 0.01$ postprandial 15 min HVPG *vs* basal HVPG. FHVP: Free hepatic venous pressure; WHVP: Wedge hepatic venous pressure; PBF: Portal Blood Flow; PBV: Portal blood velocity; SMA: Superior Mesenteric Artery; PI: Pulsatility index; V: Velocity; MAP: Mean arterial pressure.

both echo-Doppler and hemodynamic studies, shown in Table 2. The maximum postprandial hyperemia was obtained at the 15 min. measurement by hepatic vein catheterization. Three patients did not show any increase in the hemodynamic or echo-Doppler parameters during the postprandial period (data not shown).

When compared with the baseline parameters, there was a statistically significant difference in WHVP, HVPG, PBF, PBV, SMA-V, SAMA-PI, MAP and pulse rate at the 15th and 30th min of the postprandial period, with the portal vein velocity showing the highest increase ($P < 0.01$) (Table 2).

Spearman correlation tests were performed in order to evaluate the correlation between the echo-Doppler and hemodynamic parameters. Postprandial PBV showed a positive correlation with post-prandial HVPG values ($r = 0.8$, $P < 0.05$) (Figure 1), whereas SMA-PI showed an inverse correlation with the HVPG ($r = -1$, $P < 0.01$) (Figure 2). The percent increase in the echo-Doppler and hemodynamic measurements did not show any correlation between the echo-Doppler and hemodynamic tests.

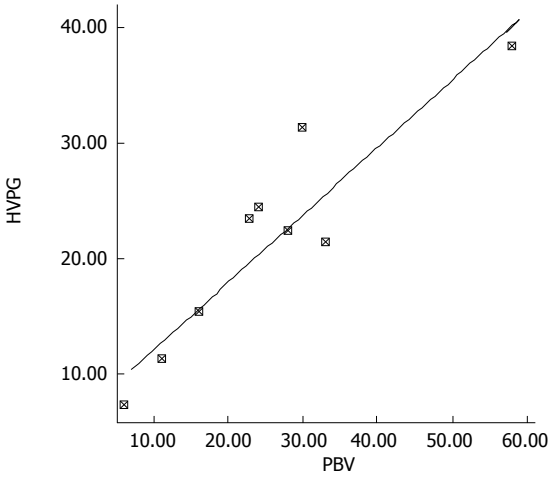

Figure 1 Positive correlation between the portal blood velocity (PBV) and hepatic venous pressure gradient (HVPG) ($r = 0.8$, $P < 0.05$).

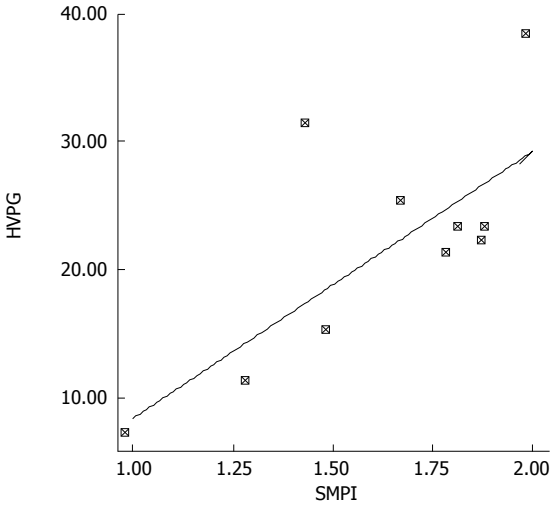

Figure 2 Inverse correlation between the superior mesenteric artery pulsatility index (SMA-PI) and hepatic venous pressure gradient (HVPG) ($r = -1$, $P < 0.01$).

DISCUSSION

The development of a non-invasive test for monitoring portal hemodynamics has been the subject of debate ever since the importance of portal pressure in cirrhotic patients was established. The increase in portal pressure in the postprandial period may initiate variceal bleeding in cirrhotic patients[9]. Therefore, it is important to identify patients who experience increased postprandial hyperemic response, and treat these patients appropriately. Echo-Doppler ultrasonography is a non-invasive test which is widely used to determine portal blood flow[4,7,8,10] In an observer-blinded study, it was shown that echo-

Doppler USG is highly sensitive in detecting postprandial hemodynamic changes[4]. Since hepatic venous pressure gradient measurement is the gold standard for the evaluation of portal hemodynamic changes, the aim of the present study was to compare the results obtained with this technique with echo-Doppler ultrasonography.

We observed that patients who showed postprandial increase in HVPG also demonstrated an increase in the parameters by echo-Doppler ultrasonography. Initially, we did not find any correlation between the basal measurements obtained by echo-Doppler and hemodynamic studies. However, postprandial portal blood flow increased significantly in patients who showed significant postprandial HVPG increase. Moreover, correlation analysis showed a strong correlation between postprandial PBV and hepatic venous pressure gradient (Figure 1). The SMA index showed a negative correlation with the HVPG (Figure 2). However, we did not find any correlation between portal blood flow and hemodynamic measurements. Portal blood velocity and SMA-PI are both velocity measurements which were obtained by direct measurements. However, measurement of portal blood flow requires assessment of cross sectional portal vein area which depends on the position of the probe as well as that of the patient, which may result in marked variability of portal blood flow readings. It is difficult to explain the lack of correlation in the basal measurements obtained by echo-Doppler and hemodynamic studies, although there was a good correlation during the postprandial period. This may be due to individual differences in the basal parameters obtained by echo-Doppler studies, which is why the echo-Doppler studies cannot replace the gold standard hemodynamic studies in the primary and secondary prophylaxis of variceal bleeding.

Hepatic venous pressure gradient measurement is the gold standard for the evaluation of portal hemodynamics. To the best of our knowledge, the present study is the only one which has compared hepatic vein catheter and echo-Doppler measurements. Assessment of patients with significant increase in postprandial portal pressure allows the use of several treatment options. It was recently observed that administration of low dose isosorbide mononitrate attenuates postprandial hyperemia[10]. By contrast, propranolol is ineffective in blunting postprandial hyperemia but has some effect in reducing postprandial portal blood flow[11]. Somatostatin analogs have a favorable effect in reducing postprandial hyperemia in cirrhotic patients[12-14]. Most of these studies are performed by echo-Doppler measurement[8,12,13].

Another unexpected finding in the present study was the absence of postprandial hyperemia in 3 patients (data not shown). These 3 patients showed more collateral vessels in the splanchnic area on echo-Doppler studies, compared to the other patients. In a recent study, it was shown that the extent of collateral circulation influences postprandial increase in portal pressure in patients with cirrhosis[15]. Other factors such as circadian rhythm, posture, age and gender did not have any effect in patients who failed to show a significant increase in postprandial pressure[16-20]. We believe that an increase in collateral circulation prevents postprandial rise in portal pressure despite increased blood flow in the splanchnic area.

In conclusion, if properly performed, echo-Doppler ultrasonography is a good test to measure postprandial portal hemodynamics. Future studies are needed to assess the usefulness of echo-Doppler measurements in primary and secondary prophylaxis of variceal bleeding.

COMMENTS

Background

Echo-Doppler USG is widely used for evaluation of the mechanisms of postprandial hyperemia in healthy people and cirrhotic patients, although the findings have not been validated.

Research frontiers

This is the first study which investigated the validity of echo-Doppler USG in postprandial hyperemia by comparing the results with the gold standard test, hepatic vein catheterization.

Innovations and breakthroughs

Postprandial pressure and portal blood flow were evaluated in eleven patients enrolled from a cohort of cirrhotic patients, by hepatic vein catheterization and echo-Doppler USG at 15 min and 30 min after a standard liquid meal. Although, basal parameters did not show any correlation, hepatic venous pressure gradient and portal blood velocity showed a positive corelation in postprandial measurements.

Applications

Although there were some limitations in the present study, it can be stated that the evaluation of postprandial hemodynamic alterations can be performed safely by echo-Doppler USG, and the measurements obtained by echo-Doppler study reflect accurately the postprandial parameters in cirrhotic patients.

Peer review

This is an experimental work conducted in humans, comparing hepatic vein catheterization with echodoppler measurement of post prandial hyperemia in cirrhotics. The authors conclude that the increased portal pressure observed in the post prandial period can be reliably measured by echo-doppler. The work is novel and may be clinically relevant.

Abstract

AIM: To examine the association between obesity and gastropharyngeal reflux disease (GPRD) as well as gastroesophageal reflux disease (GERD)

METHODS: We conducted a cross-sectional study of consecutive patients undergoing ambulatory 24-h dual-probe pH monitoring from July 2003 to December 2006. The association between body mass index (BMI) and parameters about gastroesophageal or gastropharyngeal reflux was examined in univariate and multivariate analyses.

RESULTS: A total of 769 patients (307 men and 462 women; mean age 50.7 years) were finally enrolled. Most variables showing gastroesophageal reflux was higher in the obese patients than the patients with normal BMI. There was no difference in all the variables showing gastropharyngeal reflux according to the BMI. After adjustment for age, sex, alcohol intake and smoking, obese patients demonstrated an about 2-fold increase in risk of GERD compared with patients with normal BMI (OR, 1.9; 95 CI, 1.3-2.9), but overweight patients did not demonstrate increased risk of GERD (OR, 1.2; 95 CI, 0.8-1.7). Both obese patients and overweight patients did not demonstrated increased risk of GPRD compared with patients with normal BMI (OR, 1.1; 95 CI, 0.8-1.7; and OR, 0.9; 95 CI, 0.6-1.3, respectively).

CONCLUSION: Obesity is not associated with GPRD reflux while it is associated with GERD.

INTRODUCTION

The worldwide prevalence of being overweight and obesity has been increasing at an alarming rate over the last decade, indiscriminately affecting populations of both higher and lower middle income countries[1]. The rise in obesity coincides with rising prevalence of gastroesophageal reflux disease[2,3], and gastroesophageal reflux disease is a common disorder that has been linked to obesity.

Obesity is a postulated risk factor for gastroesophageal reflux disease, although individual studies have conflicting results[4-8]. Some studies suggest that an increased body mass index (BMI) is associated with increased esophageal acid exposure[9] and with an increased risk of hospitalization for esophagitis[10]. In contrast, other studies, including one of the largest population-based studies to date, have found no association between BMI and gastroesophageal reflux disease[11-13]. Potential explanations for the disparate results include a true lack of an association between BMI and gastroesophageal reflux disease, differences in definitions or methodology, dissimilar study populations, or a lack of power to detect an effect in some studies. Additionally, many studies assessing the relationship between gastroesophageal reflux disease and obesity are symptom-based and lack objective tests to confirm this association.

Gastropharyngeal reflux, also called laryngopharyngeal reflux, is a term used to describe esophageal acid reflux into the laryngeal and pharyngeal areas. It causes extraesophageal manifestations (e.g., chronic cough, hoarseness, asthma, globus sensation, chronic sinusitis, or other pulmonary or otorhinolaryngologic diseases). Currently, the best way to demonstrate gastropharyngeal reflux is ambulatory 24-h dual probe pH monitoring[14]. Up to present, there are few reports on the association between BMI and gastropharyngeal reflux disease[15].

Therefore, we conducted this cross-sectional study to

examine the association of BMI and gastropharyngeal reflux disease as well as gastroesophageal reflux disease by using the ambulatory 24-h dual probe pH monitoring.

MATERIALS AND METHODS

Study design

We conducted a cross-sectional study of consecutive patients who underwent ambulatory 24-h dual-probe pH monitoring from July 2003 to December 2006 at the motility laboratory in Pusan National University Hospital (Busan, Korea). The indications for ambulatory 24-h dual-probe pH monitoring were globus sensation (sensation of a lump, something sticking in the throat), hoarseness, chronic cough, halitosis, throat clearing and laryngeal pathology such as vocal polyp. We did not enroll patients who had history of gastric surgery, were diagnosed as scleroderma or achalasia, or were on anti-reflux medications at the time of the study.

This study was reviewed and approved by the Institutional Review Board at Pusan National University Hospital.

Evaluation of body mass index

Body mass index (BMI) was calculated as body weight (kg) divided by the square of standing height (m). The BMI was categorized into 3 levels according to the WHO for the Western Pacific region[16]: normal weight-BMI < 23 kg/m^2, overweight-BMI $\geqslant$ 23 kg/m^2 and $\leqslant$ 25 kg/m^2, obese-BMI > 25 kg/m^2.

Esophageal manometry

All antisecretory and prokinetic medications were discontinued at least 7 d before testing. Esophageal manometry was performed, after an overnight fast, using an eight-lumen catheter (Synetics Medical Co., Stockholm, Sweden) with side holes 3, 4, 5, 6, 8, 13, 18, and 23 cm from the catheter tip and a water-perfused, low-compliance perfusion system (Synetics Medical Co., Stockholm, Sweden), according to a standard protocol. Briefly, the manometry protocol included the following: first, a station pull-through was performed through the lower esophageal sphincter (LES) to determine the end-expiratory resting pressure, LES length, and location relative to the nares. Then the catheter was positioned with the most-distal side-hole 2 cm below the upper margin of the LES. Ten 5-mL water swallows were given to evaluate peristalsis; only esophageal body contractions measured at 3, 8, and 13 cm above the LES were recorded for data analysis. Then the catheter was pulled through the upper esophageal sphincter (UES) in the same manner (station pull-through) to determine the resting UES pressure, length, and location relative to the nares. Esophageal manometric abnormalities were classified as achalasia, diffuse esophageal spasm, nutcracker esophagus, isolated hypertensive LES, ineffective esophageal motility, or nonspecific esophageal motility disorder[17].

Ambulatory 24-h dual-probe pH monitoring

Ambulatory 24-h dual-probe pH monitoring was performed immediately after esophageal manometry, with using a single-use monocrystalline antimony dual-site pH probe (Zinetics 24, Medtronic Inc., Minneapolis, USA) with electrodes placed at the tip and 15 cm proximal to the tip. A cutaneous reference electrode placed on the upper chest was also used. All the electrodes were calibrated in buffer solutions of pH 7 initially and then pH 1. The pH catheter was introduced transnasally into the stomach and withdrawn back into the esophagus until the electrodes were 5 cm above the proximal margin of the LES. The subjects were encouraged to eat regular meals with restriction for intake of drink or food with a pH below 4. All the subjects recorded their meal times (start and end), body position (supine and upright), and any symptoms in a diary. The data was collected using a portable data logger (Digitrapper Mark Ⅲ, Synetics Medical Co., Stockholm, Sweden) with a sampling rate of 4 s, and was transferred to a computer for analysis using "Polygram for Windows release" 2.04 (Synetics Medical Co., Stockholm, Sweden). For both sites, a decrease in pH below 4, which was not induced by eating or drinking, was considered the beginning of a reflux episode, and the following rise to pH above 4 was considered the end of such an episode. To be accepted as a gastropharyngeal reflux event, the decrease at the proximal probe had to be abrupt and simultaneous with the decrease in the esophagus, or to be preceded by a decrease in pH of a similar or larger magnitude in the distal probe. Thus, acid episodes induced by oral intake, aero-digestive tract residue and secretions, proximal probe movement, or loss of mucosal contact in which the proximal pH decline may precede the esophageal pH drop were not included as gastropharyngeal reflux episodes.

The variables assessed for gastroesophageal reflux in the distal probe were the total percentage of time the pH was < 4, the percentage of time the pH was < 4 in the supine and upright positions, the number of episodes the pH was < 4, the number of episodes the pH was < 4 for $\geqslant$ 5 min, the duration of the longest episode the pH was < 4 and the DeMeester composite score[18].

The variables assessed for gastropharyngeal reflux in the proximal probe were the total percentage of time the pH was < 4, the percentage of time the pH was < 4 in the supine and upright positions, and the number of episodes the pH was < 4.

For the diagnosis of gastroesophageal reflux disease (GERD) in the distal probe, two different aspects were analyzed[19,20]: (1) total reflux time: the total proportion of the recorded time with pH < 4; a value of > 4 was considered abnormal; (2) number of reflux episodes: the total number of pH episodes with pH < 4 during the recording; a value of > 35 episodes was considered abnormal.

For the diagnosis of gastropharyngeal reflux disease (GPRD) in the proximal probe, we considered more than 0.1 for the total, 0.2 for the upright, and 0 for the supine time of pH < 4 to be pathological. For the number of reflux episodes, more than 4 reflux episodes were considered pathological[21,22].

Assessment by endoscopy

The presence or absence of reflux esophagitis,

Hiatal Hernia	15/291 (5.2)	19/204 (9.3)	12/166 (7.2)	0.199
Endoscopically suspected esophageal metaplasia	18/291 (6.2)	18/204 (8.8)	16/166 (9.6)	0.348

[1]Other indications were halitosis, throat clearing and laryngeal pathology such as vocal polyp; [2]Los Angeles classification grade.

endoscopically suspected esophageal metaplasia and hiatal hernia were determined by two endoscopists (G.H. Kim, G.A. Song), who were blind to the information of the ambulatory 24-h pH monitoring.

Reflux esophagitis

If esophagitis was present, it was graded according to the Los Angeles classification[23].

Hiatal hernia

Hiatal hernia was defined as a circular extension of the gastric mucosa above the diaphragmatic hiatus greater than 2 cm in the axial length.

Endoscopically suspected esophageal metaplasia (ESEM)

The presence or absence of ESEM[24] was examined in the lower portion of the esophagus, including the esophagogastric junction, during inflation of the esophagus before inserting the endoscope into the stomach. The esophagogastric junction was defined as the oral side end of the fold, which exists continuously from the gastric lumen[25], as well as the end of the anal side of the fine longitudinal vessel, because the veins in the lower part of the esophagus were distributed uniformly, running parallel and longitudinally in the lamina propria[26,27]. The squamo-columnar junction was defined by a clear change in the color of the mucosa. ESEM was defined as the area between the squamo-columnar junction and the esophagogastric junction.

Statistical analysis

Data were expressed as mean ± SE unless otherwise noted. The differences in gender, alcohol intake, smoking, indication for pH monitoring, reflux esophagitis, hiatal hernia, ESEM, manometric diagnosis, GERD and GPRD according to the BMI were assessed using the χ^2 test. The one-way ANOVA was used to assess statistical significance for age, parameters of esophageal manometry and parameters of ambulatory pH monitoring according to the BMI and post-hoc analysis was performed using the Tukey's HSD. Multiple logistic regression analyses were used to examine association of the two primary outcomes (GERD, GPRD) with the main predictor variable, BMI. GERD and GPRD was adjusted for age, sex, alcohol intake and smoking. For all models, the number of covariates examined was determined by the number of outcome events with 10 events required for one covariate[28]. Patients with normal BMI constituted the reference group in comparisons between BMI levels. Odds ratios (ORs) and their 95 confidence intervals (CIs) were used to assess the association between BMI and GERD or GPRD, defined by ambulatory pH monitoring. A $P < 0.05$ was considered statistically significant. Statistical calculations were performed using the SPSS version 12.0 for Windows software (SPSS Inc., Chicago, IL, USA).

RESULTS

A total of 769 patients were enrolled in the study: 307 men and 462 women, and their mean age was 50.7 years. Of them, 661 patients underwent the upper endoscopy. Obese patients were more likely to be older and alcohol drinker. There was no difference in the hiatal hernia and ESEM according to the BMI. Reflux esophagitis was higher in the obese patients than the patients with normal BMI and the overweight patients ($P < 0.05$) (Table 1).

There was no difference in the proximal esophageal amplitude, LES pressure and LES length according to the BMI. But the distal esophageal amplitude was higher in the obese patients than the patients with normal BMI and the overweight patients ($P < 0.05$). There was no significant difference in esophageal motility abnormalities according to the BMI (Table 2).

There was no difference in all the variables showing gastropharyngeal reflux in the proximal probe according to the BMI. The total and upright time of pH below 4, the number of reflux episodes, and the DeMeester composite score was higher in the obese patients than the patients with normal BMI ($P < 0.05$) (Table 3).

Table 2 Results of esophageal manometry according to the body mass index (mean ± SE)

	Body mass index (kg/m^2)			*P* value
	< 23 (*n* = 344)	23-25 (*n* = 231)	> 25 (*n* = 194)

Absent	143 (41.6)	103 (44.6)	69 (35.6)	
Present	201 (58.4)	128 (55.4)	125 (64.4)	

The frequency of GERD defined by the ambulatory pH monitoring was higher in obese patients, not in overweight patients than in the patients with normal BMI. There was no significant difference in the frequency of GPRD defined by the ambulatory pH monitoring according to the BMI (Table 4).

After adjustment for age, sex, alcohol intake and smoking, obese patients demonstrated an about 2-fold increase in risk of GERD defined by the ambulatory pH monitoring compared with patients with normal BMI (OR, 1.9; 95 CI, 1.3-2.9), but overweight patients did not demonstrate increased risk of GERD (OR, 1.2; 95 CI, 0.8-1.7). Both obese patients and overweight patients did not demonstrated increased risk of GPRD defined by the ambulatory pH monitoring compared with patients with normal BMI (OR, 1.1; 95 CI, 0.8-1.7; and OR, 0.9; 95 CI, 0.6-1.3, respectively) (Table 5).

DISCUSSION

In present study, we evaluated GERD and GPRD by objective mean (ambulatory 24-h dual-probe pH monitoring) in a large group of 769 patients. Obese patients demonstrated an about 2-fold increase in risk

Table 5 Multivariable analysis: unadjusted and adjusted analyses for relationships of the body mass index with gastroesophageal reflux disease and gastropharyngeal reflux disease, defined by ambulatory pH monitoring

	Body mass index (kg/m^2)		
	< 23	23-25	> 25
Gastroesophageal reflux disease			
Unadjusted OR (95 CI)	1	1.3 (0.9-1.8)	2.0 (1.4-2.8)
Adjusted OR (95 CI)[1]	1	1.2 (0.8-1.7)	1.9 (1.3-2.9)
Gastropharyngeal reflux disease			
Unadjusted OR (95 CI)	1	0.9 (0.6-1.2)	1.3 (0.9-1.9)
Adjusted OR (95 CI)[1]	1	0.9 (0.6-1.3)	1.1 (0.8-1.7)

[1]Adjusted for age, sex, alcohol intake and smoking.

of GERD defined by the ambulatory pH monitoring compared with patients with normal BMI, but overweight patients did not demonstrate increased risk of GERD. Also, most variables showing gastroesophageal reflux was higher in the obese patients than in the patients with normal BMI, but not in overweight patients than in the patients with normal BMI. These results were in accord with the previous report that all measures of esophageal acid exposure were observed only for obesity, but not for overweight when compared to normal BMI[29]. In addition, we analyzed the endoscopic findings according to the BMI. Reflux esophagitis was higher in the obese patients than in the patients with normal BMI and the overweight patients.

The mechanism by which obesity promotes GERD remains unclear. One potential mechanism is related to mechanical factors whereby an increase in abdominal fat leads to an increase in intragastric pressure[9,30,31], and increased frequency of transient lower esophageal sphincter relaxation[32]. Obese patients may have an increased risk for hiatal hernia, which has a role in initiating and promoting gastroesophageal reflux[33,34]. On the other reports[35,36], there was not statistically significant association between BMI and hiatal hernia, similar to our results.

We also assessed the degree of gastropharyngeal reflux according to the BMI. There was no difference in all the variables showing gastropharyngeal reflux in the proximal probe according to the BMI. Also, obese patients did not demonstrated increased risk of GPRD defined by the ambulatory pH monitoring compared with patients with normal BMI. These results were consistent with the only previous report[15] about the association of BMI and GPRD. In that report, the authors showed that obesity was not associated with the pharyngeal reflux events but had a significant association with esophageal reflux events. But they simply compared the mean pharyngeal and esophageal reflux numbers between 195 non-obese patients and 90 obese patients. Even though we demonstrated the similar result that GPRD was not associated with BMI, we included much more patents, categorized them into 3 levels (normal, overweight, obesity) and performed the multiple logistic regression analysis after adjustment for age, sex, alcohol intake and smoking. Also, our results were consistent with a prospective study[37] that obesity was not risk factors for the occurrence of extraesophageal disorders after multivariate analysis, although the presence of extraesophageal disorders was assessed by only a questionnaire.

The prevalence of esophageal motility abnormalities according to the BMI is not yet unknown. In present study, there was no significant difference in esophageal motility abnormalities according to the BMI. Hong *et al*[38] showed the increased distal esophageal amplitude in 33 of morbidly obese patients and they suggested that this might be due to the presence of a high intraabdominal-thoracic pressure gradient in morbidly obese patients. This would cause a functional outflow obstruction of the esophagus, creating a high-pressure zone within the esophagus. In response to this chronic high-pressure zone, the distal esophagus would have to produce high amplitude contractions for passage of oral contents into the stomach. Similarly, in present study, the distal esophageal amplitude was higher in the obese patients than in the patients with normal BMI and the overweight patients. There was no difference in the LES pressure and LES length according to the BMI, which is consistent with previous reports[9,39].

Much more controversy exits about the location of the proximal probe. The recording of the pH in the hypopharynx is technically difficult. Acid exposure in the hypopharynx can easily be missed because of the relatively large space within the hypopharynx[21]. On the contrary, placement of the proximal probe in or below the upper esophageal sphincter allows a more permanent contact with the mucosa during the 24-h period resulting in fewer artifacts[21,22]. We used the dual-site pH probe with electrodes placed at the tip and 15 cm proximal to the tip, and we could not choose the exact location of proximal probe. But in most cases (72.7, 559/769), the proximal probe was located in the upper esophageal sphincter. So, for the diagnosis of GPRD, we used the criteria proposed by Smit *et al*[21,22].

There were some limitations in this study. First, ambulatory pH monitoring can be subjected to measurement errors related to placement of the probe and instrument calibration. However, all procedures were conducted using a similar technique with single-use pH probe. Another limitation is the absence of systematic collection of GERD symptoms. Because our main focus was to examine objective evidence of GERD (i.e., ambulatory pH monitoring) according to the BMI, we did not administer structure questionnaire. Nevertheless, this study had several advantages including the prospective design including the measurement of weight, height, alcohol intake and smoking, the consecutive enrollment to reduce the impact of selection bias and the large sample size. In addition, numerous patients (661/769) underwent the upper endoscopy and we could analyze the endoscopic findings according to the BMI.

Why is obesity not associated with GPRD despite of the association with GERD? First, acid refluxed into esophagus is usually cleared by gravity and peristaltic contractions. In obese patients, the esophageal peristaltic contraction is not impaired compared with patients with normal BMI. On the contrary, the distal esophageal amplitude is increased. This fact would play some role in preventing the refluxed acid extending to the upper level. Second, the amount of acid refluxed into esophagus is

increased in obese patients, so it is easily assumed that the amount of acid refluxed into the upper level would be increased by a secondary phenomenon. The refluxed acid is neutralized by esophageal submucosal secretions and swallowed salivary secretions, so it becomes non-acid reflux material. Therefore, even though this non-acid refluxate would reach to the upper level, the proximal pH probe cannot detect it. To solve this problem, a prospective study using a combined multichannel intraluminal impedance and pH measurement which is able to detect both acid and non-acid reflux, as well as the proximal extent of the refluxate, will be needed.

In summary, this is the largest study to evaluate GERD and GRPD simultaneously according to the BMI by using the ambulatory 24-h dual-probe pH monitoring. Obesity is associated with GERD but is not associated with GPRD. Further studies using a combined multichannel intraluminal impedance and pH measurement will be needed.

COMMENTS

Background

Obesity is a postulated risk factor for gastroesophageal reflux disease, although individual studies have conflicting results. Some studies suggest that an increased body mass index (BMI) is associated with increased esophageal acid exposure and with an increased risk of hospitalization for esophagitis. In contrast, other studies have found no association between BMI and gastroesophageal reflux disease. Gastropharyngeal reflux is a term used to describe esophageal acid reflux into the laryngeal and pharyngeal areas. It causes extraesophageal manifestations such as chronic cough, hoarseness, asthma, globus sensation, chronic sinusitis, or other otorhinolaryngologic diseases. This study was to examine the association of BMI and gastropharyngeal reflux disease as well as gastroesophageal reflux disease.

Research frontiers

The research front in this area is focused on the association of BMI and gastropharyngeal reflux disease as well as gastroesophageal reflux disease. There have been many debates about the association of obesity with gastroesophageal reflux disease. Up to present, there are few reports on the association between BMI and gastropharyngeal reflux disease. This study has examined the association of BMI and gastropharyngeal reflux disease as well as gastroesophageal reflux disease by using the ambulatory 24-h dual-probe pH monitoring. Obesity was associated with increased risk of gastroesophageal reflux disease but was not associated with increased risk of gastropharyngeal reflux disease.

Innovations and breakthroughs

There are few reports on the association between BMI and gastropharyngeal reflux disease. Most previous studies about the association of obesity with gastroesophageal reflux disease are symptom-based and lack objective tests such as ambulatory 24-h pH monitoring. This study is the largest study to evaluate gastroesophageal reflux disease and gastropharyngeal reflux disease simultaneously according to the BMI by using the ambulatory 24-h dual-probe pH monitoring.

Applications

Obesity is associated with GERD but is not associated with GPRD. Further studies using a combined multichannel intraluminal impedance and pH measurement will be needed.

Terminology

Esophageal acid reflux into the laryngeal and pharyngeal areas causes extraesophageal manifestations such as chronic cough, hoarseness, asthma, globus sensation, chronic sinusitis, or other otorhinolaryngologic diseases. This condition is called as gastropharyngeal reflux disease.

Peer review

This manuscript describes a well-designed GPRD. The classification of obesity is much higher in the United States and Europe, so this may be an issue that warrants attention. Nonetheless, this is important research.

Abstract

AIM: To determine the indicated referrals to a tertiary centre for patients with anorectal symptoms, the effect of the advised treatment and the discomfort of the tests.

METHODS: In a retrospective study, patients referred for anorectal function evaluation (AFE) between May 2004 and October 2006 were sent a questionnaire, as were the doctors who referred them. AFE consisted of anal manometry, rectal compliance measurement and anal endosonography. An indicated referral was defined as needing AFE to establish a diagnosis with clinical consequence (fecal incontinence without diarrhea, 3rd degree anal sphincter rupture, congenital anorectal disorder, inflammatory bowel disease with anorectal complaints and preoperative in patients for re-anastomosis or enterostoma, anal fissure, fistula or constipation). Anal ultrasound is always indicated in patients with fistula, anal manometry and rectal compliance when impaired continence reserve is suspected. The therapeutic effect was noted as improvement, no improvement but reassurance, and deterioration.

RESULTS: From the 216 patients referred, 167 (78%) returned the questionnaire. The referrals were indicated in 65%. Of these, 80% followed the proposed advice. Improvement was achieved in 35% and a reassurance in 57% of the patients, no difference existed between patient groups. On a VAS scale (1 to 10) symptoms improved from 4.0 to 7.2. Most patients reported no or little discomfort with AFE.

CONCLUSION: Referral for AFE was indicated in 65%. Beneficial effect was seen in 92%: 35% improved and 57% was reassured. Advice was followed in 80%. Better instruction about indication for AFE referral is warranted.

INTRODUCTION

Anorectal function evaluation (AFE) consists of several tests. Institutions differ in their selection of tests[1]. At our tertiary centre, anal manometry, rectal compliance measurement and anorectal endosonography are performed as part of our standard procedure[2]. Defecography and colon transit time are performed on strict indications. Neurophysiological tests of the pelvic floor are performed only for research purposes. Anal manometry establishes anal pressures while rectal compliance measures sensitivity and the volume of the rectum. Anal endosonography visualizes possible defects or atrophy of the anal sphincter complex. AFE is often requested in patients with anorectal symptoms including fecal incontinence, anal soiling, fistulas, anorectal tumours, anal pain, constipation *etc*. AFE is available in a limited number of hospitals, mainly academic centres and some large peripheral clinics.

A clinical referral (no research purposes) is indicated when disease can be demonstrated or excluded on the basic of AFE and when it has further therapeutical consequences. Which patients benefit most from anorectal function tests (by reduction of symptoms or reassurance) is unclear. Literature concerning this issue is scarce. Most studies that mention anorectal function tests in relation to anorectal pathology limit themselves to pre- and post-treatment results. Therefore, it often remains unclear whether AFE leads to relevant findings or subsequent change of therapy[1-10]. A large multi-centre Dutch study referred to the value of AFE for outcome of physiotherapy in patients with fecal incontinence[1]. One conclusion was that AFE had no predictive value for outcome of physiotherapy. Further, referral for AFE largely depended on availability of these tests in the referring hospital.

The aim of this study was to determine the indicated referrals to our tertiary center for patients with anorectal symptoms, the effect of the advice on their complaints and the perceived discomfort for the patients during AFE.

MATERIALS AND METHODS

Patients

All patients who were first clinical referrals for AFE between May 2004 and October 2006 were selected from our database. The database contained the complete medical history and extensive data of anorectal symptoms and anorectal test results. Deceased patients were excluded. All patients were sent a questionnaire. Additional data about follow-up in the outpatient clinic, hospital admittance, diagnostic and therapeutic procedures performed in our hospital could be retrieved from the (electronic) patient hospital files.

The Medical Ethical Commission of the VU University Medical Centre granted permission.

The referring doctors

The doctors who referred patients in the study period were also sent a questionnaire.

Anorectal function evaluation (AFE)

This consisted of anal manometry, rectal compliance measurement and anorectal endosonography according to our methods previously described elsewhere[11].

Indicated referral

A referral is indicated when disease can be demonstrated or excluded on the basic of AFE and when it has further therapeutical consequences. These are patients with fecal incontinence without diarrhea, 3rd degree sphincter rupture with or without fecal incontinence, congenital disorders, patients with inflammatory bowel disease with anorectal complaints and preoperative in patients for re-anastomosis or enterostoma, anal fissure or constipation. In patients with fistula, an ultrasound is always indicated but anal manometry and rectal compliance measurement only on indication regarding fecal incontinence. Test results in all these patients influence management. In patients with constipation, AFE was considered indicated in suspected Hirschsprungs' disease and surgery. AFE was not considered indicated in patients with fissures treated conservatively, soiling (defined as anal discharge without overt fecal incontinence), anal pain and hemorrhoids, since results do not change management.

Questionnaires

The questionnaire for patients[2] contained questions about the actual received therapy and changes in their symptoms by the received treatment, stated in a Visual Analogue Score (VAS) (score 1-10, 1 = very bad, 10 = very good) and also stated as (1) improved, (2) no change but reassurance or acceptance of situation without further need for seeking other medical advice and (3) worse and/or no reassurance. Discomfort and pain during the examination was scored with VAS (score 1-10, 1 = very uncomfortable/painful, 10 = no discomfort/pain).

The questionnaire for the referring doctor[2] consisted of questions about implementing the advice (yes, no), the quality of the advice (good, neutral, poor) and the willingness to refer again (yes, no).

Treatment advice strategy

The patients with symptoms of fecal incontinence were divided into five diagnostic subtypes: incontinence due to a sphincter defect, neurogenic incontinence, combined incontinence (sphincter defect and neurogenic), incontinence due to small rectal capacity and incontinence due to diarrhea. Patients with incontinence due to diarrhea were advised to have the cause of their diarrhea treated by the referring doctor.

All patients with fecal incontinence were prescribed fibres and physiotherapy. When unsuccessful additional therapy was advised depending of the cause. Patients with a sphincter defect > 25% were offered a sphincter repair. In patients with a small rectal compliance an enterostoma was proposed (< 60 mL) or strongly recommended (between 60 and 100 mL)[12].

Patients with a known 3rd degree sphincter rupture and as a result fecal incontinence were advised as other patients with fecal incontinence and the strong advice for a cesarean section with a next childbirth. If they were not incontinent, depending on the size of the rupture, the possibility of a cesarean section for next childbirth was discussed.

Advising re-anastomosis or enterostoma depended on the total impression of the anorectal function measured with anal pressures, rectal compliance and sphincter defects or atrophy.

In patients with a fistula the extension of the fistula tract(s) with anal ultrasound determined the type of surgery in our hospital (fistulotomy in simple and curettage with mucosal advancement plasty in complicated fistulas).

Patients where AFE was not indicated also received an advice. In patients with constipation a fibre-enriched diet, additional fibres and laxatives were advised. When unsuccessful and not previously attempted, pelvic floor physiotherapy was advised. When constipation coexisted with complaints of prolapse, a defecography was advised. When surgery was considered (rectocele correction or colectomy) besides an AFE, also a colon transit time was performed. Patients with fissures were treated conservatively; when treatment failed they were referred to the surgeon and AFE was indicated. Hemorrhoids and mucosal prolapse were treated with rubber band ligation. A hemorrhoidectomy was advised only in refractory cases. Local causes of anal pain were treated according to their causes. When no local abnormalities were seen in patients with anal pain, fibres and referral to the anaesthesiologist was advised.

Statistical analysis

The results were described as mean with standard deviation. The χ^2 test for independence and for trend, the Kruskal-Wallis test and the Wilcoxon matched-pair test were used when appropriate (GraphPad InStat Software, San Diego, Ca, USA).

RESULTS

Response questionnaires

There were 216 first referrals for AFE, 181 (84%) females, mean age 51 years, (SD 15, range 15-82). Two patients had died. A total of 167 patients [137 females (82%), mean age 51 years, SD 15, range 16-82] returned an adequate (almost all questions answered) questionnaire (78%).

Indicated referrals

Table 1 shows the indicated referrals. Of the 167 referrals, 109 (65%) were indicated. The most frequent referral was fecal incontinence, from which 93% was indicated (7% had diarrhea).

Non-indicated referrals

Two of the 31 patients with constipation had signs of anismus during physical examination and anal manometry. Of the five patients with soiling, four had a mucosal prolapse and/or hemorrhoids. The fifth patient had an anal fissure on inspection, not previously found. In two patients with anal pain a fissure was found, one treated conservatively and one eventually much later with surgery. AFE revealed no abnormalities in all patients besides high rest pressure in the patients with fissures. AFE did not influence therapeutic advice.

Effect of treatment

Symptoms improved in 54 patients (35%). In 88 patients (57%) symptoms were unchanged but patients were reassured. Despite treatment, 12 patients (8%) deteriorated. The whole group improved one point on the VAS scale (5.1-6.1) ($P < 0.0001$), for those improved (35%) this was even 3.2 points (4.0-7.2). Both indicated and non indicated referred patients improved equally.

The causes of fecal incontinence were: sphincter defect (14), neurogenic (37), combined incontinence (10), incontinence due to diarrhea (5) and incontinence due to small rectal capacity (< 100 mL) (5). Within these groups, the largest improvement was seen in the combined incontinence group (1.8 point) ($P = 0.01$). Patients with a small rectal capacity had no improvement at all.

The actual therapies received by the patients according to the reason for referral are mentioned in Table 2. Some patients received several therapies. The most frequent advice was medication, mainly fibres.

Of all referred patients, only 17% were operated. No difference between effectiveness of conservative and surgical treatment could be observed on patient symptoms ($P = 0.09$).

AFE induced little stress, indicated by an average pain score of 7 (SD 2.7) and a discomfort score of 7.2 (SD 2.8). Two patients with fistulas experienced the examination as unpleasant and painful due to the hydrogen peroxide injection in their fistula tract during anal ultrasound. Thirty five females (26%) preferred to be examined by a female doctor while the remaining 102 (75%) had no preference. Twenty six males (93%) had no preference and the remaining two (7%) preferred a male and a female doctor, respectively ($P < 0.0001$). Dutch ethnic minorities did not influence these data.

Table 1 Indicated referrals in the main groups of patients

	All *n* (% of referrals)	Indicated *n* (% of that group)
Incontinence	71 (43)	66 (93)[1]
Constipation	31 (19)	6 (19)[2]
3rd sphincter rupture	21 (13)	21 (100)
Pain	9 (5)	0 (0)
Re-anastomosis/enterostoma	8 (5)	8 (100)
Soiling	5 (3)	0 (0)
IBD	4 (2)	4 (100)
Hemorrhoids	3 (2)	0 (0)
Anal atresia	2 (1)	2 (100)
Fistulas	2 (1)	2 (100)
Fissure	1 (1)	0 (0)
Other	9 (5)	0 (0)
Total	167 (100)	109 (65[3])

[1]Five patients with diarrhea not indicated; [2]Only patients suspected of Hirschsprung/surgery indicated, IBD-inflammatory bowel disease; [3]Percentage of all referrals.

Questionnaires referring doctors

Of the 214 questionnaires, 102 (48%) responses were obtained. The advice was nearly always implemented (96%). The quality of the advice was considered good in 76% and neutral in 24%. All doctors except one (98%) were willing to refer again.

Agreement between proposed and followed advice.

The proposed and followed therapies are shown in Table 3. Therapies could also be a combination of medication, physiotherapy or surgery. Dietary advice was always followed (100%), while surgical advice was generally followed (89%). Less accepted advice included medication (71%) and physiotherapy (73%) ($P = 0.005$, 99% CI).

DISCUSSION

The 78% response to the questionnaires of the patients was good. In our previous study we reported a similar result[2]. Only 65% of the referrals were indicated. In 35% the diagnosis could have been established by clinical examination or added nothing. This is a signal that more communication and education is warranted, especially in times with restrictions and limited resources. However, many of the referred patients suffered from chronic symptoms, bringing both patient and doctor to despair. The possibility of referring the patients to another centre may come as a welcome alternative. The symptoms of the whole group improved an average of one point from 5.1 to 6.1 on a ten-point scale. Actual improvement took place in 35% of the referred patients; they improved an average of 3.2 points. The moderate improvement might be explained by the fact that it concerned patients with chronic disorders, already treated conservatively for a long time. Success was not related to a specific symptom, diagnosis or treatment, only the five patients with fecal incontinence due to small rectal capacity did not improve. Deterioration in 8% of the patients was mainly due to the fluctuating course of the chronic complaints combined with their reluctance to follow the advice. In 80% of patients, advice was followed. Medication and

Total	162 (100)	7 (100)	76 (100)	44 (100)	31 (100)	40 (100)

physiotherapy were the least applied therapies (Table 3). Some disagreement between advised and followed therapy could be explained by the fact that patients considered fibres a diet instead of medication. Physiotherapy was advised in 44 patients (26%) and effectuated in 32 (73%). Ten years ago this was only respectively 18% and 67%[2]. Increasing interest in pelvic floor disorders and special training for physiotherapists has certainly contributed to the change in attitude towards physiotherapy[1,13]. Although therapeutic advice was given after AFE, actual improvement in symptoms is not necessarily caused by AFE. A placebo effect due to the referral to a specialized centre and the knowledge present in a 3rd referral centre may play a role. This is comparable with biofeedback studies for fecal incontinence, were the added value of the biofeedback was very difficult to separate from the received specialized care and treatment[13,14].

The examination was generally well tolerated, except in two patients with fistulas who reported the examination as painful. This was caused by local injection of hydrogen peroxide into the external fistula opening in order to visualize the fistula tract. It was remarkable that ten years ago only 13% of the females[2] and now 26% of the females preferred a female doctor. The larger number of referred Dutch ethnic minorities could not explain this.

Although the questionnaire was retrospective and has not been officially validated (we had used it before[2]), it has proven to be very useful. Questions about for instance surgery or 3-6 mo of physiotherapy could not easily be misunderstood. In patients treated in our own hospital follow up data were also obtained from the (electronic) patient files and no discrepancies were found with the answers provided by these patients.

Our treatment advice strategy is derived from clinical practice and the literature. In patients with fecal incontinence, regulating defecation and thickening of the fecal mass has proven to be effective and should always be tried first[15-17]. Biofeedback aimed at improving rectal sensation, recto-anal coordination and training external anal sphincter contraction is the next step and has a success rate varying from 40%-85% and is closely related to patient motivation[18]. Diarrhea should be properly diagnosed and treated before referring the patient for AFE since this overwhelming factor makes it impossible to establish the (possible) importance of anorectal causes. A rectal capacity between 60 and 100 mL will lead to fecal incontinence in 50% and < 60 mL in 100% of patients[12]; they will often need an enterostoma. Patients with fecal incontinence with a significant sphincter defect (> 25%) without severe neuropathy leading to atrophy can be identified as suitable candidates for a sphincter repair[1,19-21].

In our group of incontinent patients, only 12 (18%) ultimately underwent sphincter repair. Two patients were later referred for sacral neuromodulation elsewhere and eleven patients[22] were treated with SECCA® (radio frequent energy application to the external sphincter[23,24]).

Women who experienced a 3rd degree sphincter rupture are indicated for AFE, even without complaints. There in always some damage to the external anal sphincter and appropriate advice concerning defecation regulation, physiotherapy and possible future cesarean section can be discussed.

Most patients with constipation were referred for assessment of anismus/hyper tonic pelvic floor or rectocele. Generally AFE is not needed in these patients. Both anismus and a rectocele can be diagnosed by proper rectal examination[6,25,26]. When prolapse complaints dominate a defecography is indicated to demonstrate a possible enterocele as this can be corrected surgically. In patients with constipation, correction is not indicated in accidentally found intussusception since the obstructed defection will not improve[26-29]. AFE is indicated when (partial) colectomy is considered to be informed about the continence reserve. For patients with fistulas anal endosonography demonstrates the fistula tracts and anal manometry will establish the continence reserve[21,30-33]. In patients with soiling (anal secretion), medical history, good physical and rectal examination and an additional proctoscopy have proven be sufficient to establish a diagnosis[10], without the need for AFE, as was shown again in our patients. For patients with pain, AFE does not contribute[34]. Suspected discrete abnormalities e.g. an occult abscess, could not be demonstrated in our study as well. Sometimes a fissure is found in these patients, diagnosed on the basis of the medical history and rectal examination. In patients with a fissure, high pressures are usually found using manometry, but this does not alter therapy[35]. Only in those who where conservative measures have failed and will undergo surgery AFE seems indicated. In patients with haemorrhoids, anal manometry can also reveal high pressures and anal endosonography can demonstrate a thickened mucosa; however, these findings have no influence on therapy[36,37]. AFE is indicated in patients with an enterostoma when re-anastomosis is considered. In some rare disorders like anal atresia AFE can also be indicated to document anorectal problems and help choose a specific therapy.

In conclusion, feferral for AFE was indicated in 65%, communication and education to colleagues seems warranted. Indications are fecal incontinence without diarrhea, 3rd degree sphincter rupture, pre-operative for stoma or re-anastomosis, fistula, fissures or constipation. Anal ultrasound is always indicated in patients with fistula, anal manometry and rectal compliance when impaired continence reserve is suspected. Generally, in patients with constipation and soiling the medical history, physical examination and additional proctoscopy is sufficient and AFE is not necessary.

In 80% of patients, advice was followed. After AFE 92% benefited (35% of the patients improved and 57% was reassured). AFE is well tolerated. Women preferred a female doctor in 26% of cases.

COMMENTS

Background

Anorectal disorders like fecal incontinence, peri-anal fistula, pre-operative decisions for stoma are distressing and isolating conditions, with a large impact on quality of life. With restricted resources it is important to make a good selection of referrals for anorectal function evaluation, those patients who benefit most. In this study we established the indicated referrals our tertiary referral centre for patients with anorectal symptoms, the effect of the advised treatment and the discomfort of the tests.

Research frontiers

A clinical referral is indicated when disease can be demonstrated or excluded on the basic of anorectal function evaluation and when it has further therapeutical consequences. Which patients benefit the most from anorectal function tests (by reduction of symptoms or reassurance) is unclear.

Innovations and breakthroughs

Most studies mention anorectal function tests in relation to anorectal pathology and limit themselves to pre- and post-treatment results. Therefore it often remains unclear whether anorectal function evaluation leads to relevant findings or subsequent change of therapy. Literature concerning this issue is scarce. The aim of our study was to determine the indicated referrals to our tertiary center for patients with anorectal symptoms, the effect of advice on their complaints and the perceived discomfort for the patients during anorectal function evaluation.

Applications

It is very important to understand the usefulness of the anorectal function evaluation to provide referrals of those patients, which could benefit the most. Indications for anorectal function evaluation are fecal incontinence without diarrhea, 3rd degree sphincter rupture, pre-operative for stoma or re-anastomosis, fistula, fissures or constipation. Anal ultrasound is always indicated in patients with fistula, anal manometry. Rectal compliance is indicated when impaired continence reserve is suspected. Generally, in patients with constipation and soiling the medical history, physical examination and additional proctoscopy is sufficient and anorectal function evaluation is not necessary.

Terminology

Anorectal function evaluation consists of several tests: (1) anal manometry: establishes anal pressures; (2) rectal compliance: measures sensitivity and the volume of the rectum; (3) anal endosonography: visualizes possible defects or atrophy of the anal sphincter complex.

Peer review

The manuscript presents referral patterns for anal function investigation. Although the study has all limitations of a retrospective study, the authors provide valuable information from their experience as tertiary care center for patients with anorectal symptoms.

RAPID COMMUNICATION

Changing spectrum of Budd-Chiari syndrome in India with special reference to non-surgical treatment

Abstract

AIM: To evaluate patterns of obstruction, etiological spectrum and non-surgical treatment in patients with Budd-Chiari syndrome in India.

METHODS: Forty-nine consecutive cases of Budd-Chiari syndrome (BCS) were prospectively evaluated. All patients with refractory ascites or deteriorating liver function were, depending on morphology of inferior vena cava (IVC) and/or hepatic vein (HV) obstruction, triaged for radiological intervention, in addition to anticoagulation therapy. Asymptomatic patients, patients with diuretic-responsive ascites and stable liver function, and patients unwilling for surgical intervention were treated symptomatically with anticoagulation.

RESULTS: Mean duration of symptoms was 41.5 ± 11.2 (range = 1-240) mo. HV thrombosis (HVT) was present in 29 (59.1%), IVC thrombosis in eight (16.3%), membranous obstruction of IVC in two (4%) and both IVC-HV thrombosis in 10 (20.4%) cases. Of 35 cases tested for hypercoagulability, 27 (77.1%) were positive for one or more hypercoagulable states. Radiological intervention was technically successful in 37/38 (97.3%): IVC stenting in seven (18.9%), IVC balloon angioplasty in two (5.4%), combined IVC-HV stenting in two (5.4%), HV stenting in 11 (29.7%), transjugular intrahepatic portosystemic shunt (TIPS) in 13 (35.1%) and combined TIPS-IVC stenting in two (5.4%). Complications encountered in follow-up: death in five, re-stenosis of the stent in five (17.1%), hepatic encephalopathy in two and hepatocellular carcinoma in one patient. Of nine patients treated medically, two showed complete resolution of HVT.

CONCLUSION: In our series, HVT was the predominant cause of BCS. In the last five years with the availability of sophisticated tests for hypercoagulability, etiologies were defined in 85.7% of cases. Non-surgical management was successful in most cases.

INTRODUCTION

Budd-Chiari syndrome (BCS) refers to hepatic venous outflow tract obstruction (HVOTO) starting from the level of small hepatic veins (HV) through large HV and inferior vena cava (IVC) to the junction of the IVC and right atrium[1-3]. This includes both hepatic vein thrombosis and IVC thrombosis or obliterative hepatocavopathy[4,5].

Clinical studies on BCS in India date back to the 1970s[6-10]; following which, there are many case reports and case studies from India, concentrating on clinical spectrum, on underlying etiology, on diagnostic modalities and/or on various treatment strategies[11-47]. In contrast to the western world, in the Indian series, there is a striking predominance of IVC obstruction (mainly from membrane or web) or combined IVC-HV obstruction rather than HV obstruction alone[12-15]. Tumors, pregnancy, oral contraceptive pills (OCP) and infections were proposed as predominant underlying etiologies, hypercoagulable states were uncommon, and idiopathic cases were the most common[9,12-21,42]. In the series of cases during the last 10 years, various hypercoagulable states are being increasingly described as etiologies of BCS[24-26,28-30,46,47].

Obstruction of the IVC, either thrombotic or non-thrombotic, was considered to be a major cause of BCS in Asia[5]. Two-thirds of IVC obstruction cases leading to BCS are due to membranous obstruction[11]. Datta *et al*[6] reported 40 cases of membranous obstruction of IVC (MOVC) while Victor *et al*[11] reported 17 cases

of membranous obstruction. Though MOVC and membranous obstruction of HV was initially thought to be congenital, Okuda demonstrated these lesions to be an after-effect of thrombosis in the IVC or HV which were organised over a period of time[5]. Similar cases of have been reported from Nepal[53]. Originally, it was perceived that MOVC and membranous obstruction of HV are important causes of BCS which is different from the West. Over the years, many prothrombotic states leading to BCS have been described in India[28,47]. In an elegant review, Valla has described the level of HVOTO, the nature of obstructive lesions, presentation, course of disease and causes that are comparable in Indian and western literature[4]. A few differences in etiologies were noticed between India and the West i.e. peripartum occurrence of BCS was common in India while oral contraceptive use was commonly implicated in the West.

The majority of patients with BCS present with a chronic course, while only a small number of patients present with acute or fulminant forms[6-22]. BCS is mostly encountered in the adult population and considered uncommon in children; when seen in children, the clinical presentation is similar[13]. Anti-thrombotic drugs and anticoagulants form the mainstay in the treatment of acute and chronic BCS. Percutaneous balloon angioplasty for membranous obstruction of the IVC and hepatic vein has also been used successfully in the treatment of BCS. Although TIPS has gained popularity in the treatment of BCS, it has rarely been performed in India, with only one case being reported[41]. Furthermore, there are only a few reports on the use of covered TIPS in BCS. In this report, we evaluated patterns of obstruction, aetiological spectrum and non-surgical treatment of BCS in patients.

MATERIALS AND METHODS

In last seven years (during the study period of 1999 to 2005), all the consecutive cases of BCS were prospectively evaluated. Diagnosis of BCS was based on angiographic evidence of HVOTO (i.e. obstruction of IVC and/or HV) and/or histological evidence of BCS (sinusoidal dilation with centrilobular congestion with variable amount of pericentral hepatocyte necrosis and pericentral fibrosis).

The protocol for evaluation of BCS in our unit is shown in Figure 1. BCS was suspected in the following situations: patients with ascites of high serum-ascitic fluid albumin gradient (> 1.1) and with low cell count (< 250 cells/cm^2); patients with ascites and/or back veins in the presence of hepatomegaly and/or right upper quadrant pain; patients with refractory ascites, patients with acute liver failure with hepatomegaly and/or ascites; patients with a known hypercoagulable state who showed evidence of liver involvement (on clinical examination, biochemistry or imaging); and patients with unexplained chronic liver disease (when work-up for alcoholic, drug-induced, viral, metabolic or autoimmune liver disease were negative). All such patients (suspected BCS) were subjected to ultrasonography of the abdomen and Doppler studies with special emphasis on IVC, HV and splanchnic venous system. If HVOTO was confirmed, patients were subjected to inferior vena cavogram and hepatic venogram

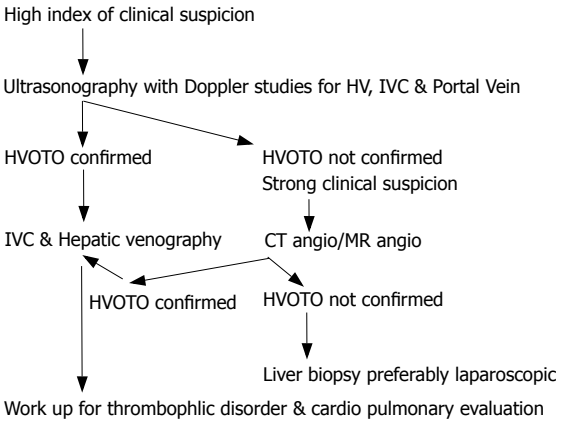

Figure 1 Evaluation of patients with Budd Chiari syndrome.

(*via* transfemoral, transjugular and/or transhepatic route) to define the site and morphology of the obstruction. However, if ultrasonography/Doppler was negative or ambiguous for HVOTO, computerised tomography (CT) angiography or magnetic resonance (MR) angiography (if CT angiography was contraindicated) was performed. If CT angiography or MR angiography showed HVOTO, these patients were subjected to catheter venography. If computerised tomography with angiography or magnetic resonance angiography was negative, these patients were subjected to liver biopsy (either *via* percutaneous or transjugular route depending on clinical status) to define BCS and rule out other diseases like veno-occlusive disease. All patients with suspected BCS were subjected to chest x-ray, electrocardiogram and 2-dimensional echo of the heart to rule out cardiac etiology. Liver histology was performed whenever possible to confirm the diagnosis and to define the presence of cirrhosis. Upper gastrointestinal endoscopy was performed in all cases of BCS to determine the presence of varices.

All the patients with BCS were subjected to tests available for hypercoagulable state before starting any treatment. In the initial two years of the study period, tests for protein C, protein S and antithrombin Ⅲ levels in addition to work-up for myeloproliferative disease and paroxysmal nocturnal haemoglobinuria (PNH) were performed. During the last five years of the study period, tests for protein C, protein S and antithrombin Ⅲ levels (corrections for liver dysfunction were done)[48], serum homocysteine levels, factor V Leiden, prothrombin gene 20210 and MTHFR gene mutations, lupus anticoagulant, anticardiolipin and antiphospholipid antibodies, tests for PNH (Sucrose lysis and Ham tests), complete blood counts and bone marrow histopathology/cytogenetic studies (whenever feasible) for myeloproliferative disorder were performed. Imaging (ultrasonography, computerised tomography and/or magnetic resonance imaging of abdomen), serological markers (including tumor markers and tests for amoebiasis or echinococcus) and/or histology were done to identify underlying etiology for BCS as and when required. All the female patients were subjected to a urine test for pregnancy and were questioned regarding use of oral contraceptive pills.

All patients with refractory ascites (RA) or deteriorating

Table 1 Clinical parameters in 49 patients with BCS

Clinical features	% of Patients
Ascites	86
Distended abdominal wall veins & back veins	28
Jaundice	20
Splenomegaly	20
Pedal edema	12
Upper GI bleeding	8
Infertility	6
Fever	8
Hepatic encephalopathy	4
Hydrothorax	6
Vericocity	4
Asymptomatic	6
Previous episode of thrombosis	8
Family history of thrombotic event	2
Previous antituberculous treatment	12
Mean duration of symptoms prior to diagnosis	41.5 + 11.2 mo (range 1-240 mo)
Types of presentations	
Asymptomatic	6
Fulminant	8
Acute	41
Chronic	42

Patients were classified as per definitions in reference number 4

Table 2 Laboratory parameters in 49 patients with BCS

Parameter	Value	Range
Sr. Bilirubin mg%	1.49 ± 1.2	0.2-5.6
Sr. ALT Iu/mL	53.4 ± 13.2	17-424
Sr. AST Iu/Ml	61.6 ± 15.6	16-724
Sr. AlkPO4 Iu/mL	159.6 ± 35	91-313
Sr. GGPT	109.6 ± 1.2	18-417
Sr. Albumin g/Dl	3.44 ± 1.2	1-4.8
Increase in prothrombin time	3.5 ± 1.1	1-10 s

All the patients were negative for serology of Hepatitis B, C & HIV.

liver function (presence of hepatic encephalopathy (HE) or jaundice, serum bilirubin > 2 mg/dL, serum albumin < 3 gm/dL and/or international standardised ratio of prothrombin time (INR) > 2), depending on morphology of IVC and/or HV obstruction, were triaged for either IVC stenting, HV stenting, TIPS or in combination: (1) For supra-hepatic IVC block with patent HV: IVC balloon angioplasty with self-expandable metallic stent (SEMS) placement; (2) For membranous obstruction of inferior vena cava (MOVC): IVC balloon angioplasty; (3) For juxta-hepatic IVC block with patent HV: IVC balloon angioplasty with SEMS placement; (4) For juxta-hepatic IVC block and short-segment HV block (< 3 cm) involving all three HV or two major HV: IVC balloon angioplasty with SEMS placement and HV balloon angioplasty with SEMS placement; (5) For juxta-hepatic IVC block and long-segment HV block (> 3 cm): IVC balloon angioplasty with SEMS followed by TIPS placement; (6) For short-segment HV block (< 3 cm) involving all three or two major HV: HV balloon angioplasty with SEMS placement; (7) For long-segment HV block (> 3 cm) involving all three or two major HV: TIPS placement. In addition to symptomatic therapy, all these patients were started on anticoagulation following radiological intervention with the aim of keeping INR 2-3. Asymptomatic patients, patients with diuretic-responsive ascites, patients with stable liver function or patients who were not willing to undergo radiological intervention were subjected to anticoagulation to keep INR 2-3 in addition to symptomatic therapy (including low-salt diet, diuretic therapy and/or beta-blockers as needed). Peritoneo-venous shunting was offered to patients with RA who were not candidates for any intervention.

Follow-up was done on the 3rd d, at the end of the 1st mo, every 3rd mo for the 1st year and every 6th mo thereafter. During each follow-up visit, clinical, biochemical and ultrasonography/Doppler evaluations were done. Patients with TIPS or SEMS dysfunction were managed by repeat radiological interventions.

For patients undergoing TIPS, the following outcome measures were used: (a) technical success: creation of a channel by stent between hepatic vein and portal vein to reduce the portosystemic pressure gradient (PPG) to less than 12 mmHg; (b) TIPS dysfunction: 50% decrease in portal vein blood flow velocity on Doppler, angiographic evidence of stent stenosis (> 50% reduction in diameter) or increase in PPG > 12 mmHg in presence of recurrent ascites/hepatic hydrothorax or gastrointestinal bleeding; and (c) primary patency: duration of continuous TIPS patency without re-intervention. Comparison between uncovered TIPS and covered TIPS was done using chi square test. Institutional review board permission was obtained.

RESULTS

During the study period, 49 patients (mean age = 34.3 ± 6.5 years; age range = 1-57 years; male:female ratio = 24:25) were included in the study. In our series there were only two children below the age of 18 years. One child at the age of one year presented with rapidly accumulating ascites, the other child at the age of 11 had refractory ascites for 5 mo.

Clinical presentation and biochemical features of these patients are shown in Tables 1 and 2.

Ultrasonography with Doppler studies was diagnostic in 80% of patients. The remaining 20% of patients required CT/MR angiography for diagnosis. Liver histology was done in 28 (57.1%) cases, of which 14 (50% of 28 cases) were cirrhotic.

Morphology of hepatic venous outflow tract obstruction was short segment hepatic vein thrombosis in 13 patients, long segment in 16 patients, supra hepatic IVC in three, juxta hepatic IVC in five, IVC plus short segment hepatic vein in six and long segment hepatic vein in four. Associated portal vein thrombosis was seen in two (4%) and superior mesenteric vein thrombosis was seen in one (2%) patient. Features of caudate lobe hypertrophy and extrinsic compression of IVC (on imaging and/or IHV) was seen in 30 (61.2%) cases. One MOVC case had past imaging (on CTA) evidence of IVCT, which was done to rule out intraabdominal malignancy as a cause of femoral vein thrombosis and was negative for the same. At that time, IVCT patient was asymptomatic. Four years later this patient presented with symptomatic MOVC and was found to have factor V Leiden mutation.

Etiological spectrum in 35 patients who had undergone

all tests for thrombophilia work up was Polycythmia vera 3 (8.5%), Protein C deficiency two (6%), Protein S deficiency one (3%), Hyper homocysteinemia two (6%), Anti thrombin Ⅲ deficiency three (9%), Anti cardiolipin antibodies five (14%), Factor V laden mutation four (11.4), Lupus anti-coagulant two (6%), PNH one (3%), Multiple abnormalities four (11%), Renal Cell Carcinoma one (3%), IVC leiomyoma one (3%), Acute myeloid leukemia one (3%), Idiopathic six (19%). None of the patients was pregnant or taking OCP.

Radiological interventions done in 38 patients were as follows: IVC stenting eight (20%), IVC balloon angiography two (5%), Combined IVC Hepatic Vein stenting two (5%), Hepatic vein stenting 11 (30%), TIPS 15 (40%), and IVC stenting with TIPS two (5%).

In one patient with supra-hepatic IVC block with refractory ascites and deteriorating liver function, attempted IVC stenting failed; he was then lost to follow-up. In the radiological intervention group, technical success was achieved in 97.3% (37/38 cases). One (2.7%) patient had a technical complication of post-TIPS (uncovered TIPS) peritoneal haemorrhage, to which the patient succumbed. Another patient (HV stenting) with acute myeloid leukemia succumbed within 1 mo of follow-up. Complete resolution of ascites or improvement in liver function was seen within 3 mo of follow-up in the remaining 35 cases. During further follow-up (mean period = 24.5 ± 12.5 mo, range = 3-84 mo) of these 35 cases, mortality was 8.5% (3/35 cases): causes of death were liver-related in one case [resistant HE (covered TIPS-related)] and non-liver related in two cases [one with intracranial bleeding (anticoagulation therapy related, one in IVC-HV stenting group) and one with metastatic renal cell carcinoma (one with IVC stenting)]. Details of other complications encountered during follow-up are as follows: (a) Episodes of HE responsive to medical treatment were seen in two post-TIPS (both covered TIPS) cases (5.7%). (b) Re-occlusion of stent was seen in six (17.1%) cases (one at 1-mo, two at 3-mo, two at 6-mo and one at 1-year follow-up) of which one had IVC stent, two had HV stent, two had uncovered TIPS and one had covered TIPS, radiological re-intervention (balloon dilatation) was possible in all cases. During further follow-up, in the event of stent occlusion, one patient with uncovered TIPS was offered covered TIPS and one patient with HV stent underwent balloon angioplasty again. (c) Hepatocellular carcinoma (HCC) was encountered at 2-year follow-up in one (2.8%) patient with MOVC, who had undergone IVC balloon angioplasty and was treated three times with trans-arterial chemo-embolisation during further five years follow-up. During follow-up of these 35 cases, only two patients (of HV stenting) were lost to follow-up after 6 mo.

On evaluating the patient subset with TIPS treatment, technical success was achieved in all 15 (100%) patients (five uncovered TIPS and 10 covered TIPS), procedural complication (uncovered TIPS) was seen in one (6.6%) patient, total mortality (one in uncovered TIPS and one in covered TIPS) was 13.3% (two patients), re-occlusion rate was 23% (one with covered and two with uncovered TIPS) in 13 survivors, primary patency rate at 6 mo for uncovered TIPS was 50% and for covered TIPS was 88.9%, and occurrence of new-onset HE was in 20% (3 patients of covered TIPS). There was a statistically significant difference ($P < 0.05$) in primary patency rate between covered and uncovered TIPS.

Eleven (22.4%) patients [all patients had stable liver functions, three cases were asymptomatic cases and three cases had RA; five patients with HVT (two short-segment and three long-segment) and six patients with IVCT-HVT (two long-segment HVT and four with short-segment HVT)] were treated with anticoagulation in addition to symptomatic therapy (mean duration of follow-up = 28.4 ± 10.8 mo, range = 1-74 mo). Two patients with RA, who were not willing to undergo radiological intervention, underwent placement of PVS. Of these, one patient had blockage of PV shunt and died of sepsis after five years; the other patient was all right at four years follow-up. Of the remaining nine cases, one patient with RA (unwilling to undergo any intervention) died of progressive liver failure after 3 mo; two patients (one at 6-mo and one at 1-year follow-up) with HVT showed complete resolution of ascites, normalisation of liver function tests and re-canalisation of HV on USG-D (repeat IHV was not done); three asymptomatic patients remained asymptomatic until 6-mo follow-up, but were lost to follow-up then; three patients were lost to follow-up after 1 mo.

Overall, in 42 cases who completed at least 6 mo of follow-up, mortality was seen in 4/42 cases (9.5%), and evidence of HCC in 1/42 (2.3%) cases.

DISCUSSION

Our study is distinct from previous Indian reports in many aspects. It showed predominance of HV thrombosis and identification of etiologies in more than three out of four of cases, the majority being hypercoagulable states. To the best of our knowledge, IVC leiomyoma and acute myeloid leukemia are being reported as etiologies for the first time in India. Also, cases showing transition from IVC thrombosis to MOVC and development of hepatocellular carcinoma in MOVC are well documented. For the first time in India, the experience of using covered TIPS in BCS is presented.

In our series, HV thrombosis represented the majority of cases (59.1%), which were followed in decreasing order by combined IVCT/ HV thrombosis (20.4%), IVC thrombosis (16.3%) and MOVC (4%). All previous Indian series, except two[29,32], describe the predominance of IVC up to 79.2%[7,9,11-13,15,30,39,40,42] or IVC-HV obstruction up to 57.7%[14,24,25,35]; HV involvement was described in 0%-32% of cases in these series[7,9,11-15,24,25,30,35,39,40,42]. Of the two distinct previous series, one (total 53 cases) showed similar frequency of HV (35.8%), IVC (33.9%) and combined IVC-HV involvement (30.1%)[29]; whereas the other series involving only chronic BCS showed predominance of HV (45.9%) followed by combined IVC-HV (29.7%) and IVC involvement (24.3%)[32]. In the western countries, hepatic vein thrombosis remains responsible for majority of BCS cases, IVC obstruction is rarely found. In Asian and African countries, more common is IVC involvement. In Japan, over span of last 30 years, there is change in the spectrum i.e. marked decrease in cases of IVC

obstruction[5,49-52]. Is similar trend is following in India or this is just reflection of selection bias at tertiary care centre? For definite answer, reports from all over the country will be needed in support.

Previously, MOVC was thought to be the predominant cause of IVC involvement (20.4%-58.6%) and of BCS in India[6,7,11-15,17,29,35,39], as well as in Asian countries[49,50,53]. In two recent Indian studies, MOVC was present in 0% and 17.2%, while IVC involvement was seen in 56.2% and 62% cases, respectively[24,40]. In our series, IVC involvement in the majority of cases was due to IVC thrombosis. Previously, MOVC and IVC thrombosis were considered to be idiopathic in origin by most Indian and Asian workers[5,6,11,13-15,17,35,49,50,53,54]; but this view has been challenged recently in a few reports[22,29,30,42,55-58]. In cases of IVC thrombosis in our study, the etiology was identified in 50%. In our series, one of two MOVC cases had a hypercoagulable state and in that case, we were able to demonstrate evolution of IVC thrombosis to MOVC. Transition from IVC thrombosis to MOVC is well described in worldwide literature[5,59,60]. The other patient with MOVC in our study developed hepatocellular carcinoma, without any other predisposing factors, such as: hepatitis B, hepatitis C or alcohol. Reports of hepatocellular carcinoma developing in MOVC are rare in Indian literature[7,12-15]. However, such an association is commonly described in most other countries[5,49,50,53,61-64].

In our study, with the application of all commercially available hypercoagulability tests, an underlying etiology could be defined in 85.7% of cases, the majority having a hypercoagulable state. This was in contrast to the initial study period (before 2001), during which few tests were performed, where etiology was evident only in 28.5% cases. None of our patients were pregnant, taking oral contraceptive pills, in a post-partum state, had abdominal trauma, abdominal surgery, amoebic liver abscess, pyogenic liver abscess, hydatid cyst, hepatic tuberculosis or filariasis; these were the predominant causes in the previous Indian studies[9,12-20,23,42]. Previous Indian series (before the year 2001) have shown identification of underlying etiology in 12%-50%, of which hypercoagulable states were uncommon[9,12-15,42]. In the last decade, there are many reports identifying one or another hypercoagulable state[21,22,24-28,46,47]. Recently, application of more tests has defined hypercoagulability in up to 59% of cases[29,30]. In addition to tests performed in our study, studying haemopoietic stem cell defects in bone marrow may further identify occult MPD, as previously shown in two Indian studies[26,46] and in many western studies[4,64]. As in our series, multiple co-existing etiologies have recently been described throughout the world[29,65]. Our work was in accordance with the majority of western reports, where identification of etiology is more than 75%[2], and at a few centres more than 90%[64-66]. Changes in the etiological spectrum probably represents the effect of availability and application of tests for hypercoagulability.

Renal cell carcinoma, which was present in three cases in our study, was rarely reported in the past[15]. Likewise, IVC leiomyoma and acute myeloid leukemia as underlying etiologies are described for the first time in Indian literature. Other malignancies described in the past include hepatocellular carcinoma, adrenal tumor, Wilm's tumor, cholangiocarcinoma and chronic lymphoid leukemia[9,13-15,39,42].

In a few examples, medical treatment only was shown to be effective in a subset of patients with stable liver function, diuretic-responsive ascites and asymptomatic presentation[2,67,68].

Few reports have shown the beneficial results of surgery in selected BCS patients with low operative mortality up to 5%, high long-term assisted patency rate of more than 90% and five-year survival rates more than 75%[2,69-72]. Poor results of surgery in patients with liver dysfunction; anatomical difficulties causing success rates as low as 30%; higher post-operative complications and mortality rates (more than 20%); high re-stenosis rates (around 30%) requiring surgical revisions in a minority (around 10%); and poor survival rates as low as 57% at five years have been described[1,3,4,70,73,74]. Surgical treatment has also failed to show a favorable effect in two multivariate analyses[68,75], but was successful in one other study[76]. In most Indian reports, while surgery for IVC involvement has shown fair results[34,36]; surgical treatments for HV occlusion have shown poor results[12,38]. These were the driving force in deciding not to offer surgical treatment to our patients.

Radiological interventions for both IVC and HV achieved technical success rates of more than 90% and long-term patency rates of more than 80%; also radiological re-interventions are usually successful[1,69,77-80]. In our series, radiological intervention protocols according to morphology of the obstruction yielded good results. Previous Indian series have shown the efficacy of balloon angioplasty of IVC with or without stent placement [11-13,37,39,40,43-45], with a re-stenosis rate ranging from 16.6% to 28.5%[11,39]. Balloon angioplasty of HV thrombosis has shown variable results throughout the world, restricting its use to short-segment HV thrombosis only[4,77]. In India, experience with HV balloon angioplasty is rare[12,37]. Patients with combined IVC-HV blockages, which are considered difficult to treat, were treated with balloon angioplasty followed by surgical portosystemic shunting in previous Indian studies, but post-operative complications and mortality were prominent[12]. In a recent study from China, a two-stage approach was recommended, the first stage being IVC stenting followed by another session of HV stenting[77]. In our work, we successfully performed balloon angioplasty with stent placement in IVC followed by either TIPS or HV balloon angioplasty with stent placement in a single session.

In the last decade, the use of TIPS in BCS is increasingly described in the world literature[81-94]. In cases with severe liver dysfunction requiring liver transplantation, TIPS used as an interim bridge to transplantation, can improve the situation dramatically[4]. In most studies, TIPS was used as rescue therapy in patients with failed or re-occluded radiological or surgical interventions or was used as a bridge to liver transplantation. Difficulty with TIPS may be associated splanchnic venous thrombosis, which can be successfully tackled by radiological interventions in the same session[89]. Technical success for TIPS ranges from 75% to 100% in various works[81,84,88,90,93]. The problem

of TIPS dysfunction (present in 40% to 75% if followed up for more than two years[80,82,84,90,91,93]) necessitates re-intervention in up to 70% of cases[1,87-89,91], giving a revision rate of 1.4 revisions per patient[91]. TIPS related complications occur in less than 20% of patients[91]. TIPS provided a survival rate of 85% at four years in one series and 74% at five years in another series[82,91]. Covered TIPS in BCS has shown lower TIPS dysfunction rate (33% *vs* 87% in uncovered group) and higher primary patency rate at 1-year (67% *vs* 19% in uncovered group) in one recent series comprising nine patients in a covered TIPS group[94]. Another series using covered TIPS in eight patients showed there was no need for revisions during almost one year of follow-up[91]. In our study, TIPS was used as a primary treatment in the subset of the patients with long-segment HV thrombosis with or without IVCT. During the study period (mean follow-up of more than two years), the technical success rate was 100%; procedural complication rate was 6.6% (post-TIPS peritoneal haemorrhage); total mortality rate was 13.3%, re-occlusion rate was 23%; primary patency rate for uncovered TIPS was 50% and for covered TIPS was 88.9%; and new-onset hepatic encephalopathy rate was 20%. All the re-occlusions were tackled radiologically. Our study, although with a small number of patients, showed promising results with TIPS as the primary therapy in BCS patients. Covered TIPS was better than uncovered TIPS in terms of long-term patency.

COMMENTS

Background

Budd-Chiari syndromes (BCS) has been commonly described in India. It was always considered that the spectrum of BCS in India is different from that of the west.

Research Frontiers

In this study we discussed the changing spectrum of BCS in India which is almost comparable to the west.

Innovation and Breakthroughs

Radiological interventions including TIPS with a covered stent has been useful in managing these patients with good long term efficacy.

Application

This study will help to improve the management of patients with BCS in India.

Terminology

BCS is an uncommon condition induced by thrombotic or nonthrombotic obstruction to hepatic venous outflow. It was first described by Budd in 1845 and Chiari later added the first pathologic description in 1899.

Peer review

It's an excellent overview of BCS in India, showing a change in the aetiology towards hypercoagulopathic diseases. They authors could as well demonstrate the effectiveness of TIPS, especially when using covered stents.

Abstract

AIM: To compare the performance of the Child-Pugh-Turcott (CPT) score to that of the model for end-stage liver disease (MELD) score in predicting survival of a retrospective cohort of 172 Black African patients with cirrhosis on a short and mid-term basis.

METHODS: Univariate and multivariate (Cox model) analyses were used to identify factors related to mortality. Relationship between the two scores was appreciated by calculating the correlation coefficient. The Kaplan Meier method and the log rank test were used to elaborate and compare survival respectively. The Areas Under the Curves were used to compare the performance between scores at 3, 6 and 12 mo.

RESULTS: The study population comprised 172 patients, of which 68.9% were male. The mean age of the patient was 47.5 ± 13 years. Hepatitis B virus infection was the cause of cirrhosis in 70% of the cases. The overall mortality was 31.4% over 11 years of follow up. Independent factors significantly associated with mortality were: CPT score (HR = 3.3, 95% CI [1.7-6.2]) (P < 0.001) (stage C *vs* stage A-B); Serum creatine (HR = 2.5, 95% CI [1.4-4.3]) (P = 0.001) (Serum creatine > 1.5 mg/dL versus serum creatine < 1.5 mg/dL); MELD score (HR = 2.9, 95% CI [1.63-5.21]) (P < 0.001) (MELD > 21 *vs* MELD < 21). The area under the curves (AUC) that predict survival was 0.72 and 0.75 at 3 mo (P = 0.68), 0.64 and 0.62 at 6 mo (P = 0.67), 0.69 and 0.64 at 12 mo (P = 0.38) respectively for the CPT score and the MELD score.

CONCLUSION: The CPT score displays the same prognostic significance as does the MELD score in black African patients with cirrhosis. Moreover, its handling appears less cumbersome in clinical practice as compared to the latter.

Attia KA, Ackoundou-N'guessan KC, N'dri-yoman AT, Mahassadi AK, Messou E, Bathaix YF, Kissi YH. Child-Pugh-Turcott versus Meld score for predicting survival in a retrospective cohort of black African cirrhotic patients. *World J Gastroenterol* 2008; 14(2): 286-291

http://www.wjgnet.com/1007-9327/14/286.asp

INTRODUCTION

The Child-Pugh-Turcotte (CPT) score has usually been used to assess the prognosis of patients with cirrhosis[1], since it is related to the severity of the liver disease.

The detrimental effect of renal failure on survival of patients with cirrhosis is widely acknowledged[2-6]. The prevalence of renal failure in cirrhotic patients varied between 7%-65%[7-9]. About 20% of the cirrhotic patients presenting with ascites were likely to display an acute pre-renal failure. This value has been reported to exceed 50% when end-stage liver disease is present[10].

The model for end-stage liver disease (MELD) score has recently been developed to better rationalize liver graft allocation. Indeed liver graft allocation has been so far performed according to the severity of the liver failure as determined by the CPT score plus the time spent on the waiting list. Since the first transplanted have almost been the first on the waiting list and knowing that they did not necessary display the most severe disease, such an approach has been subjected to debate[11-17]. The MELD score has been elaborated using three independent prognostic factors: creatine, International Normalized Ratio (INR) and bilirubin. In a study in 311 patients on the waiting list, the MELD score has been found adequate to predict mortality[12-20]. The MELD score has been thus far used in the USA for liver graft allocation in place of the CPT score.

Several studies have been performed to compare the performance of the two scores in predicting survival in patients with cirrhosis[21-33]. However such studies have yielded conflicting results[23, 24, 28, 30-33].

The aim of the present study was to compare the performance of the MELD score to that of the CPT score to predict survival in a retrospective cohort of 172 black African patients with cirrhosis.

MATERIALS AND METHODS

Type of study

A retrospective analysis of a cohort of black African patients with cirrhosis has been undertaken. Patients have been recruited from January 1, 1991 to December 31, 2001 (11 years) at the hepatology unit of the University hospital of Yopougon (Abidjan), one of the three tertiaries hospitals of the capital, admitting and hospitalising at least 650 patients a year for a total capacity of 20 beds.

Patients

In our daily practice, all the patients who were diagnosed as having cirrhosis were systematically hospitalised, because most of them were seen at a very late stage of the disease. Of 307 patients recruited over this study period, 135 have been excluded because of missing data. 172 patients have, therefore, been considered for analysis.

Methods

Data of the patients such as, age, gender, motives of admission, aetiology of cirrhosis, serum creatine, CPT score and the MELD score, date of first symptoms of decompensated cirrhosis, date of first admission, date of last visit for the patients lost to follow up or still alive, the date of death for deceased patients have been all collected using a standardized collection sheet.

Definitions

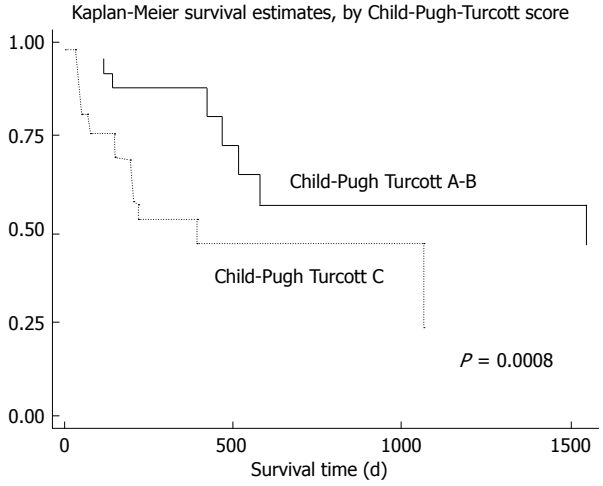
The CPT score has been widely described elsewhere. It has been elaborated by using five (5) parameters: hepatic encephalopathy, ascite, prothrombin in percentage, serum albumin in g/L and bilirubin in mg/L.

The MELD score: It has been elaborated by using the Malinchoc formula which comprises 3 parameters: INR, bilirubin (mg/dL) and creatine (mg/dL). This formula is as follow: [9.57 × Loge creatine (mg/dL) + 3.78 × Loge bilirubin (mg/dL) + 11.20 × Loge INR + 6.43].

Time of follow up: It corresponds to the time between the date of first admission for cirrhosis and the date of last visit or the date of death for deceased patients.

Time of survival: It corresponds to the time between the date of the first symptoms of decompensated cirrhosis as reported by the patient and the date of last visit for the patients lost to follow up or still alive or the date of death for the deceased patients.

Statistical analysis



By univariate analysis, relationship between mortality and the following parameters has been assessed: age, gender, aetiology of cirrhosis, serum creatine, CPT score and the MELD score. The Student t-test or the Mann-Whitney test was used for quantitative parameters and the chi square test or the Fischer exact test for qualitative parameters. A multivariate analysis has been performed using a Cox model in a forward selection manner. Two models have been elaborated subsequently: the first has included all the parameters used in the univariate analysis with the exception of serum creatine. The second model has included all the parameters used in the univariate analysis at the exception of the MELD score. Survival has been elaborated using the Kaplan Meier method. The log rank test has been used for comparison of survival between groups. Correlation between the two scores has been evaluated. The ROC curve has been used to compare performance between scores.

Table 1 Characteristics of the study population

Male (%)	120/172 (69.8)
Mean age (yr)	47.5 ± 13.54
Child-Pugh-Turcott score (%)	
A	20 (11.6)
B	54 (31.4)

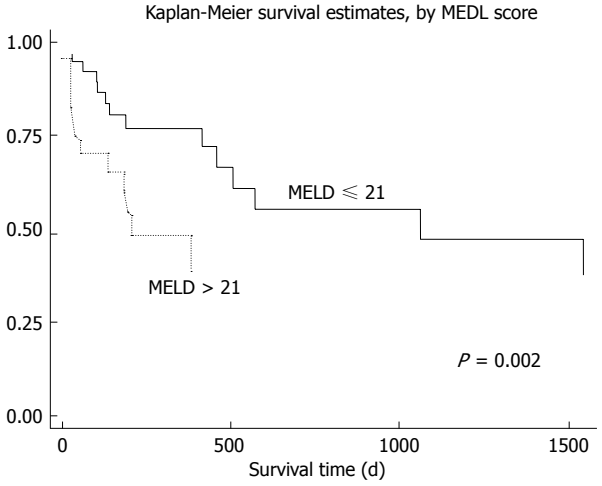
Etiology (%)	
Virus B	78 (45.3)
Virus C	17 (10)
Both alcohol and virus B or C	41 (23.8)
Unknown	36 (20.9)

RESULTS



The different motives of admission of patients with cirrhosis were: ascites and oedema of the lower limbs (68.6%), jaundice (25.2%), haemorrhage of the digestive tract (15.1%) and hepatic encephalopathy. The study population comprised 172 patients, of which 69.8% were male. The mean age of the patients was 47.5 ± 13.54 years. 57% of the patients were with a CPT score stage C, 23.3% had renal failure and the mean MELD score was 20.9 ± 10.87. Hepatitis B was the main cause of cirrhosis in 45.3% of the case (Table 1). Over the study period (11 years), 54 out of 172 patients (31.4%) have died, of which 22 during the first three months and 32 the first 6 mo. The median and the mean duration of follow up were 206 and 226.6 + 41.6 d, respectively. By univariate analysis, the following parameters have appeared to significantly influence mortality: age > 48 years old ($P < 0.023$); male gender ($P < 0.003$); CPT score stage C ($P < 0.016$); serum creatine > 1.5 mg/dL ($P < 0.001$) and MELD score over 21 ($P < 0.03$). Indeed, the mean CPT score has appeared significantly less elevated in living cirrhotics as compared to those who have died during the study period (10.2 ± 0.28 *vs* 11.3 ± 0.33, respectively; $P = 0.02$), as it was with the MELD score (19.4 ± 0.83 *vs* 24.2 ± 1.85, $P = 0.007$, respectively). Moreover mortality increased proportionally to the level

Probability of survival (95% CI):

	Child-Pugh-Turcott A-B (%)	Child-Pugh-Turcott C (%)
-3 mo	100	75.1 (64.5-82.9)
-6 mo	87.3 (73.9-94.1)	68.6 (57-77.7)
-12 mo	87.3 (73.9-94.1)	52.1 (38.8-63.9)
-24 mo	56.0 (35.9-72)	45.6 (31.4-58.8)

20	55.60	57.60	37.50	73.90
21[2]	48.20	69.50	41.20	74.60
22	44.00	69.50	40.00	73.20
23	44.40	76.30	46.20	75.00

[1]Optimal cutoff point for CPT (Child-Pugh-Turcott) score; [2]Optimal cutoff point for MELD (Model for End-stage Liver Disease) score.

of the CPT score (0% for stage A, 29.6% for stage B and 38,8% for stage C; $P = 0.001$), as it did with the MELD score (26.5% for MELD < 30, 42.9% for MELD between 30 and 40, 75% for MELD > 40; $P = 0.007$) (Table 2). By multivariate analysis, parameters such as CPT score stage C (HR=3.3 95% CI [1.7-6.2]) ($P < 0.001$); serum creatine > 1.5 mg/dL (HR = 2.5 95% CI [1.4-4.3]) ($P = 0.001$) and MELD score over 21 (HR = 2.9 95% CI [1.63-5.21]) ($P < 0.001$) have appeared to significantly influence mortality (Table 2). The overall survival at 3, 6 and 12 mo was 85.4% (95% CI: 78.5-90.1), 76.1% (95% CI: 67.7-82.6) and 67% (95% CI: 57.3-75), respectively. The median and the mean survival time were 142.6 and 318 + 45.1 d, respectively. When the CPT score was considered, survival at 1 year was just 52.1% for CPT score stage C as compared to CPT stage A-B which was over 85% (Figure 1). A MELD score over 21 was synonymous of 50% of survival at 1 year as compared to a MELD score less than 21 for which survival was about 80% (Figure 2). A cut off point of 10, corresponding to the very least value of the CPT score stage C, has been found optimal to predict sensitivity (74%), specificity (49.2%), positive predictive value (38.8%) and negative predictive value (78.4%). A cut off point of 21 for the MELD score has been found optimal to predict sensitivity (48.2%), specificity (69.5%), positive predictive value (41.9%) and negative predictive value (74.6%) (Table 3). However, when the performance of the two scores was

Table 4 Comparison between The Area Under the Curve (AUC) of the CPT score and the MELD score in predicting survival at 3, 6 mo

Survival	Pronostic score	AUC (95% CI)	*P*
At 3 mo	CPT	0.72 (0.64-0.80)	0.68
	MELD	0.75 (0.62-0.88)	
At 6 mo	CPT	0.64 (0.54-0.74)	0.67
	MELD	0.62 (0.49-0.74)

DISCUSSION

About 60% of our patients have displayed a CPT score stage C that amounts to severe liver disease. Hepatitis B has been the main cause of cirrhosis in our study population. The main factors that have appeared to influence mortality were a CPT score stage C (with an optimal cutoff point of 10), renal failure that was present in 1/4 of the patients, and a MELD score over 21. The performances of the two scores were comparable.

Renal failure occurring in the setting of cirrhosis has widely been reported to represent an independent risk factor for mortality[2-6]. However, the CPT[1] score that has been used so far to appreciate prognosis in patients with cirrhosis does not take into account the renal function. This has led, therefore, to the elaboration of the MELD score which formula encompasses serum creatine for the evaluation of survival in patients with cirrhosis[11]. The performance of the two scores has been compared in several studies with conflicting results: some studies[11,18,22,25-27,29] have showed superiority of the MELD score over the CPT score in predicting survival in patients on the transplantation waiting list or in patients awaiting Transjugular Intrahepatic Portosystemic Shunt (TIPS), or even in patients with acute alcoholic hepatitis, while others have found the two score to be comparable[13,14,18,20,21]. Indeed, in the study by Zhang *et al*[27], the area under the curve (AUC) was significantly more with the MELD score than the CPT score: 0.95, 0.85 and 0.83 for the MELD and 0.70, 0.66 and 0.61 for the CPT score ($P < 0.05$) at 3, 6 and 12 mo, respectively. In the study by Papatheodoridis *et al*[28] analysing a cohort of 102 decompensated cirrhotics, the AUC as determined by the MELD score was comparable to that of the CPT score in predicting survival at 3, 6, 12 mo: 0.79, 0.77, 0.78 and 0.79 for the MELD score and 0.73, 0.71, 0.68 and 0.70 for the CPT score. And a recent review by Cholongitas *et al*[31] has highlighted the lack of a clear cut superiority of the MELD score over the CPT score in predicting mortality of cirrhotic patients before and after liver transplantation.

The present study has showed that the two scores were also comparable as the AUC was: 0.75, 0.62, and 0.64 for the MELD score and 0.72, 0.64, 0.69 for the CPT score at 3, 6, and 12 mo, respectively. Moreover, the through value of the MELD score in our study confirms the fact that this value varies from one study to another as it was at 14, 17 and 18 in the Angermayr[24], Cestron[32] and Ferral[25] study, respectively. This could be attributed to the fact that most of our patients were admitted a very late stage of the disease, explaining an elevated mean and median MELD score. The retrospective nature of our study has led to the exclusion of many patients for missing data. Should these patients have been recruited, different findings as the one reported might have been found. However, the present findings could easily be extrapolated to any of our patients since the epidemiological profil of the 172 recruited patients represent the one currently encountered in our daily practice. Our study, which represents the only of its kind to be performed in black African patients with cirrhosis, appears to be of a great interest. Indeed, our population characteristics are quite different from what are currently reported in western countries since our patients are much younger with a diagnosis of cirrhosis made at a very late stage of the disease and hepatitis B being the main cause of cirrhosis. Moreover, the high prevalence of hepatitis B virus in an endemic country, like the Ivory Coast, is often responsible for contamination at birth and in infancy, leading to chronic hepatitis in 30%-50% (when contamination take place in infancy) to 90% (when contamination take place at birth) of the case[34-40]. In addition, the prognosis of our patients is further aggravated by the fact that most of them are diagnosed as having cirrhosis at a very late stage of the disease for different reasons; lack of insurance coverage, delay in hospital visit because of financial problems or cultural considerations. Consequently, few interventions could be offered to these patients as liver transplantation or endoscopic and/or radiological treatments are not currently available in our country. Inversely, Hepatitis C virus and alcohol remain the main causes of cirrhosis in western countries[40-42]. Contamination by hepatitis C virus occurs in adult age and chronic hepatitis related to alcohol represents a disease of adult patient.

Patients with cirrhosis are diagnosed at a very late

stage of the disease. Consequently, mortality is elevated. Renal and liver failures represent independent risk factors of mortality. In the present study, the performance of the MELD score has appeared comparable to that of the CPT score which remains the primary tool to assess patients in the daily practice. The improvement in the MELD score predicting survival ability over the CPT score may necessitate the incorporation in its determination of several others factors such as age, and population characteristics to allow the universal utilizability of this equation. The present study has indeed suggested the impact of the population characteristics on the MELD score level. The use of the CPT score in association with serum creatine as proposed by Angermayr[24] could also be currently performed in daily practice in order to also improve its predicting survival ability.

COMMENTS

Background

Renal failure occurring in the setting of cirrhosis is an independent risk factor of mortality. The Child-Pugh-Turcotte (CPT) score has usually been used to assess the prognosis of patients with cirrhosis. Formulas devoted to include the renal function in the determination of the CPT score have not gained wide acceptance. The Model for End-Stage Liver Disease (MELD) score which encompasses renal function and other factors known to influence mortality in cirrhotic patients has also been found adequate to predict mortality in patients awaiting liver transplantation. The MELD score has thus far been used in the USA for liver graft allocation instead of the CPT score.

Research frontiers

The superiority of one score over the other is subjected to debate as studies comparing the two scores have yielded conflicting results.

Innovations and breakthroughs

Studies performed so far were mostly in western populations, with few in Asian. The present study represents the first of its kind in black Africans. In Africa the main cause of cirrhosis is hepatitis B virus, inversely to hepatitis C and alcohol in western countries. Affecting patients are much younger. Cirrhosis is diagnosed at a very late stage and very little can be done to prolong life of the patients, explaining very high mortality related to it. No difference has been found between the performance of the two scores. However, the optimal cut-off point of the MELD score that is determined from our study appears much higher than any of what that has been published to date.

Applications

The improvement in the MELD score predicting survival ability may necessitate the incorporation in its formulation of several other factors including population characteristics to allow the universal applicability of this equation. Consequently, the setting up of an international collaborative study appears urgent than ever.

Terminology

Cirrhosis: End-stage liver disease. Renal failure: Kidney dysfunction amounting to serum creatine value more than 1.5 mg/dL. CPT score: Five parameters are used to calculate the CPT score. These are hepatic encephalopathy, ascites, and prothrombin in percentage, serum albumin in g/L and bilirubin in mg/L. Each parameter is affected a number going from 1 to 3 depending on its degree of impairment, so that the very least score amounts to 3 and the very most to 15. MELD score: The MELD score is determined through the following equation: [9.57 × Loge creatine (mg/dL) + 3.78 × Loge bilirubin (mg/dL) + 11.20 × Loge INR + 6.43]. Its value appears to vary from to one study to another, depending probably to the population characteristics. Optimal cut-off point: The value of the equation that yields the best sensitivity, specificity, positive predictive value and the negative predictive value.

Peer review

The authors conducted a retrospective study to compare the ability of the CPT and MELD scores to predict mortality in a cohort of black patients with cirrhosis. The key findings of the study are that the CPT and MELD scores had similar predictive ability. Based on the fact that the CPT is easier to compute than the MELD score, the authors recommend the CPT over the MELD score in blacks with cirrhosis. Although not entirely novel, the study does provide interesting and important findings.

Abstract

AIM: To investigate the effect of pituitary homeobox 1 (PITX1) expression in cases of human gastric cancer on cancer differentiation and progression, and carcinogenesis.

METHODS: Using polyclonal PITX1 antibodies, we studied the expression of PITX1 in normal gastric mucosa, atypical hyperplasia, intestinal metaplasia, and cancer tissue samples from 83 gastric cancer patients by immunohistochemistry. Moreover, semi-reverse transcription polymerase chain reaction (semi-RT-PCR) was performed to detect the mRNA level of PITX1 in three gastric cancer cell lines and a normal gastric epithelial cell line. Subsequently, somatic mutations of the PITX1 gene in 71 gastric cancer patients were analyzed by a combination of denaturing high performance liquid chromatography (DHPLC) and DNA sequencing.

RESULTS: Immunohistochemistry showed that PITX1 was strongly or moderately expressed in the parietal cells of normal gastric mucosa (100%), while 55 (66.3%) out of 83 samples of gastric cancers showed decreased PITX1 expression. Moreover, PITX1 expression was reduced in 20 out of 28 cases (71.5%) of intestinal metaplasia, but in only 1 out of 9 cases (11%) of atypical hyperplasia. More importantly, PITX1 expression was significantly associated with the differentiation, position and invasion depth of gastric cancers (r = -0.316, P < 0.01; r = 0.213, P < 0.05; r = -0.259, P < 0.05, respectively). Similarly, levels of PITX1 mRNA were significantly decreased in 2 gastric cancer cell lines, BGC-823 and SGC-7901, compared with the normal gastric epithelial cell line GES-1 (0.306 ± 0.060 *vs* 0.722 ± 0.102, P < 0.05; 0.356 ± 0.081 *vs* 0.722 ± 0.102, P < 0.05, respectively). Nevertheless, no somatic mutation of PITX1 gene was found in 71 samples of gastric cancer by DHPLC analysis followed by sequencing.

CONCLUSION: Down-regulation of PITX1 may be a frequent molecular event in gastric carcinogenesis. Aberrant levels of PITX1 expression may be closely correlated with the progression and differentiation of gastric cancer.

INTRODUCTION

Cancer develops as a result of multiple genetic and epigenetic alterations[1,2]. Functional imbalances between oncogenes and tumor suppressor genes have been identified in most cancers, including gastric cancer. Better knowledge of the changes in gene expression that occur during gastric carcinogenesis may lead to improvements in diagnosis, treatment and prevention[3]. Recently, PITX1, first identified as a *bicoid*-related transcription factor involved in proopiomelanocortin (POMC) gene expression[4], was reported to be a tumor suppressor in many parenchyma tumors.

The evidence that *PITX1* gene is a significant tumor suppressor gene in human cancer remains largely circumstantial, but is clearly worth further study. As little is known about the tumor-inhibitory roles of PITX1 in gastric cancer, we focused on the expression of PITX1 in gastric cancer tissues and gastric cancer cell lines; the

potential roles of PITX1 in cancer differentiation and carcinogenesis of the stomach will be discussed.

MATERIALS AND METHODS

Tissue materials

For immunohistochemical analysis, we used archival formalin-fixed, paraffin-embedded tissues from 83 patients with gastric cancer. The average age of patients was 61 ± 1.5 years and the male/female ratio was 63/20. Histological classification of gastric cancers was performed according to the general rules established by the Japanese Gastric Cancer Association and staging was performed according to the TNM classification of Malignant Tumors (5th edition) in 1997[5].

Tissues from 71 cases of gastric cancer were used for DNA mutation analysis. Tissue fragments were frozen and stored at -80℃ for DNA extraction. DNA was isolated using a standard proteinase K digestion and phenol-choloroform extraction procedure.

All of the above tissues were obtained from the patients who underwent surgery for gastric cancer at the First Affiliated Hospital of China Medical University between December 2001 and November 2004.

Cell lines and cell culture

Three human gastric cancer cell lines, including the poorly-differentiated MGC-803 and BGC-823 lines and the well-differentiated SGC-7901 line, as well as the normal gastric epithelial cell line GES-1, were cultured by the Research Center for Medical Genomics of China Medical University. Among the three gastric cell lines, SGC-7901 was originally obtained from metastatic lymph nodes of gastric cancer while the other two were obtained from gastric primary loci. All cell lines were grown in RPMI 1640 medium containing 10% heat-inactivated fetal calf serum at 37℃, in 99% humidity under 5% CO_2, subcultured every 3 d, and checked routinely to avoid microbial contamination. Those cells growing logarithmically were harvested for total RNA isolation and RT-PCR.

Immunohistochemistry

An S-P Kit (Zhongshan Golden Bridge Biotech Co., Ltd) was used for immunohistochemical analysis. In brief, paraffin sections were deparaffinized in xylene and gradually rehydrated in alcohol. Antigen retrieval was performed by microwave treatment in 0.01 mol/L sodium citrate buffer (pH = 6.0) for 15 min, cooled to room temperature for 1 h, and then washed with phosphate-buffered saline (PBS). After endogenous peroxidase activity was blocked by incubation with 3% methanol for 10 min and washed with PBS, sections were incubated with normal rabbit serum for 1 h to block non-specific staining. Subsequently, sections were treated with polyclonal PITX1 antibodies (Santa Cruz, CA, USA) diluted to 1:300 with PBS, overnight at 4℃ in a humidified chamber. Sections then were incubated with biotinylated anti-rabbit IgG for 10 min and then with peroxidase-labeled streptavidin for 10 min. Staining was completed with a 10-min incubation with 3,3'-diaminobenzidine. Sections were counterstained with 0.1% haematoxylin. Intracytoplasmic and/or intranuclear buffy granular staining in gastric mucous cells was regarded as positive. Ten visual fields were randomly selected from each section, and at least 100 cells were counted in each field.

Omission of primary antibodies acted as a negative control, while normal gastric tissue was regarded as a positive control. Immunohistochemical results were assessed as 'negative' if fewer than 50% of cancer cells were stained. When at least 50% of cancer cells were stained, immunostaining was considered to be 'positive'.

Semi-RT-PCR

Total RNA was isolated from the cell lines using Trizol (Invitrogen, CA, USA), and 1 μg of total RNA was converted to cDNA using a First Strand cDNA Synthesis Kit (Takara, Japan). Then, PCR reactions were performed in volumes of 20 μL. A 1 μL aliquot of the cDNA was used for PCR amplification with the primers 5'-ATGGA CGCCTTCAAGGGGGGC-3' (forward) and 5'-TGCA ACTGCTGGCTTGTGAAG-3' (reverse), resulting in a DNA product of 305 bp. PCR conditions were 95℃ for 1 min, 55℃ for 30 s and 72℃ for 45 s, for 30 cycles. Under the same PCR conditions, *glyceraldehyde-3-phosphate dehydrogenase* (*GAPDH*) transcripts (227 bp) were amplified as an external control for RT-PCR analysis from the same cDNA samples, using the following primer pair: 5'-GACC ACAGTCCATGCCATCAC-3' (forward) and 5'-GTCCAC CACCCTGTTGCTGTA-3' (reverse).

PCR products were separated by 1.5% agarose gel electrophoresis, stained with ethidium bromide, and visualized under UV light. Electrophoresis strips were analyzed by Fluor-S software. By calculating the ratio of the IDVs (integrated density value) for PITX1 transcripts to those for *GAPDH* transcripts, we compared the PITX1 mRNA levels between gastric cancer cell lines and the normal gastric epithelial cell line.

DHPLC analysis and DNA sequencing

DNA was amplified in a final reaction volume of 20 μL using 100 ng of genomic DNA, 10 × buffer, 1.5 mmol/L $MgCl_2$, 200 μmol/L dNTPs, 0.27 μmol/L (100 ng) primers and 1.25 units of rTaq polymerase (Takara, Japan).

In order to form the presumed heteroduplex, unpurified PCR products were pretreated by heating at 94℃ followed by cooling down to 25℃ at a rate of 0.03℃/s. DHPLC was carried out using the Transgenomic WAVEMAKE DNA fragment analysis system (Transgenomic, Ohama, USA). PCR products showing aberrant chromatograms on DHPLC were subjected to direct DNA sequencing.

Statistical analysis

The software SSPS for Windows version 11.5 was used for statistical analysis. Correlations between clinicopathological parameters and PITX1 expression were analyzed by χ^2-test, and comparisons of the mRNA levels in different cell lines were performed using *t*-tests. *P* values of less than 0.05 were considered to be statistically significant.

RESULTS

Expression of PITX1 protein in human gastric cancer samples

As shown in Table 1, all parietal cells (100%) of normal

Table 1 Comparison of the expression of PITX1 in normal tissue and tumor tissue from patients with gastric cancer

	PITX1		
	n	Negative (%)	Positive (%)
Normal tissue	83	0 (0)	100 (100)
Tumor tissue	83	55 (66.3)[b]	28 (33.7)[b]

[b]$P < 0.001$ *vs* normal tissue.

gastric mucosa showed strong or moderate PITX1 staining, while 55 (66.3%) out of 83 gastric cancer samples showed decreased staining for PITX1 ($P < 0.001$). In addition, the expression of PITX1 in intestinal metaplasia tissue samples was reduced in 20 out of 28 cases (71.5%), but in only 1 out of 9 (11%) cases of atypical hyperplasia.

The correlations between clinicopathologic parameters and PITX1 expression in 83 patients are shown in Table 2. PITX1 expression did not differ significantly by age, gender, size, clinical staging and lymph node metastasis. However, significant differences in PITX1 expression were found in tumors with different degrees of differentiation, position or depth of invasion. That is, reduced expression of PITX1 was significantly linked with tumors with poor differentiation, located in the upper and middle parts of the stomach, or with T3/T4 invasion depth ($P < 0.01$, $P < 0.05$, and $P < 0.05$ respectively). Representative results of PITX1 expression in gastric cancer samples are depicted in Figure 1.

Table 2 Relationship between the expression of PITX1 in gastric cancer and biological behavior

	PITX1		
	n	Negative (%)	Positive(%)
Gender			
Male	53	42 (66.7)	21 (33.3)
Female	20	13 (65.0)	7 (35.0)
Age (yr)			
< 60	32	22 (68.7)	10 (31.3)
⩾ 60	51	33 (64.7)	7 (35.3)

Well[1]	38	19 (50)	19 (50)
Poorly[2]	45	36 (80)[b]	9 (20)[b]
Lymph-node metastasis			
Yes	47	33 (70.2)	14 (29.8)
No	36	22 (61.1)	14 (38.9)

[a]$P < 0.05$ *vs* upper and middle part of stomach; [c]$P < 0.05$ *vs* gastric cancer in T1/T2; [b]$P < 0.01$ *vs* well differentiation type. [1]Well-differentiated tumors, for example, papillary adenocarcinoma and tubular adenocarcinoma. [2]Poorly-differentiated tumors, including undifferentiated tumors, signet-cell carcinoma and mucous adenocarcinoma.

Expression analysis of PITX1 mRNA in gastric cancer cell lines and human gastric cancer

RT-PCR was repeated 12 times to analyze the differences in PITX1 mRNA expression between the three gastric cancer cell lines and the normal GES-1 cell line (Figure 2). The average IDV ratios of the gastric cancer cell lines BGC-823 and SGC-7901 were significantly lower than that in the normal gastric cell line GES-1 ($P < 0.05$); there was no statistically significant decrease in IDV ratio in the MGC-803 cell line (Table 3).

PITX1 gene mutation analysis

All of the DHPLC chromatographies in coding area from 71 tumor tissues showed a normal single peak shape except that the deletion of a repeated sequence "gggcgc" in 3' UTR in one sample was found through DHPLC screening and sequencing.

DISCUSSION

Carcinogenesis refers to changes of multiple genes, and is closely related to the corresponding transcription factors (TFs) and their mutual regulation. As a family of TFs, homeobox genes not only play important roles in embryonic development and differentiation, but also control the differentiation and proliferation of mature tissues[6,7]. Class I human homeobox-containing genes (*HOX* genes) have been reported to act as a network of transcriptional regulators involved in the process of cell to cell communication during normal morphogenesis, the alteration of which may contribute to the evolution of cancer[8]. Moreover, a recent study concluded that *HOX* genes may play a critical role in the genesis and progression of gastric cancer[9].

PITX1 and PITX2 are members of the PITX (pituitary homeobox) family, a family of homeobox genes; they have been widely researched and contain a highly conserved homeodomain (HD) with a lysine residue at amino acid position 50, which is responsible for recognition of the TAA (T/G) CC motif in the promoter regions of several target genes[10]. Besides sharing similar DNA binding specificities, PITX1 and PITX2 are co-expressed in the stomodeum and have overlapping expression patterns in stomodeal derivatives[11-13]. Specifically, PITX1 is responsible for the morphology of muscles, tendons and the bones of hind limbs, and is involved in the development of anterior structures as well as pituitary and craniofacial morphogenesis[14,15].

Although PITX1 has essential roles in human development, the possible involvement of PITX1 in human cancer has been suspected since an elegant study by Gidekel *et al*[16] showed that a homeobox gene normally required for the differentiation of a particular tissue can play a causal role in the carcinogenesis of the same tissue if expressed at the wrong time, at the wrong levels, or in the wrong contexts. For instance, PITX1 was found in adrenocorticotropic hormone (ACTH or corticotrophin) -positive tumors as well as in ACTH-negative carcinoids[17]. Expression of PITX1 mRNA might be a potential biomarker of malignancy in patients with

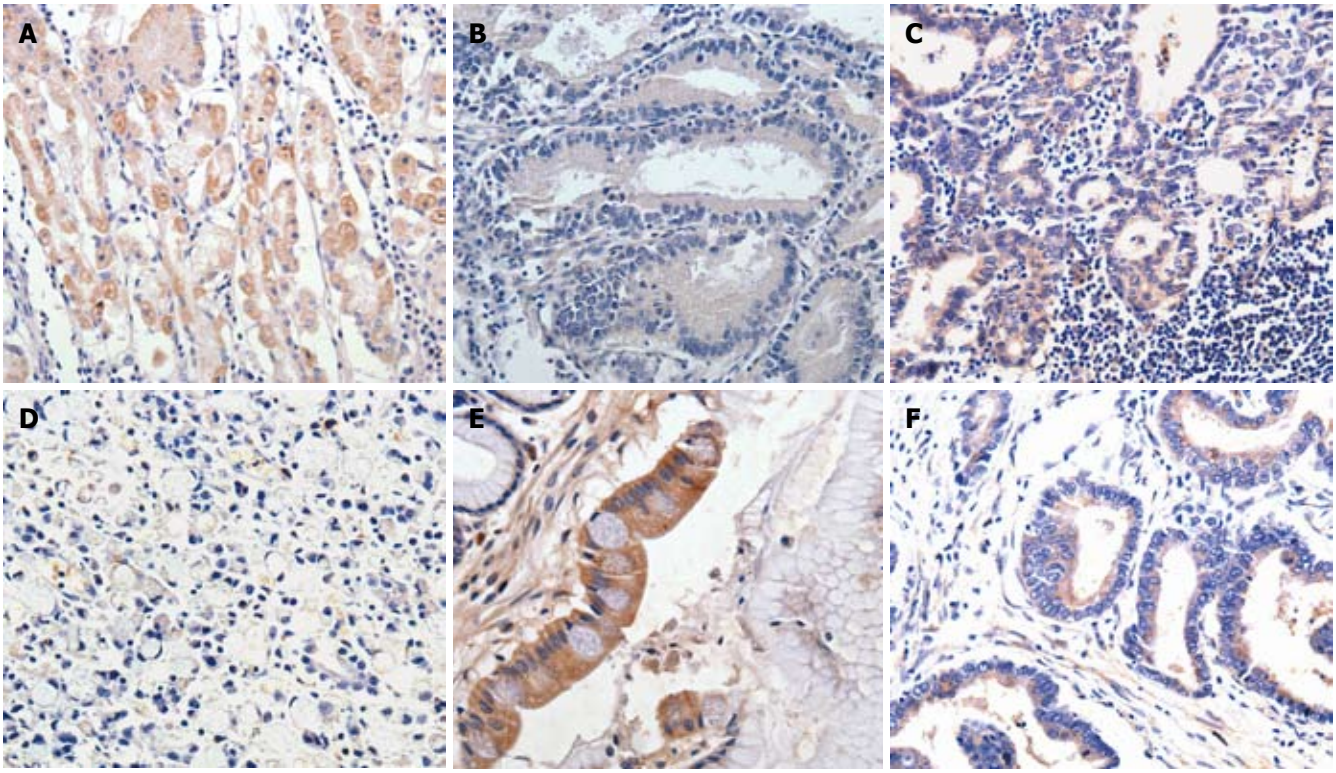

Figure 1 PITX1 expression in normal gastric mucosa and gastric cancer tissue samples (x 400). **A**: Normal gastric mucosa, PITX1 positive; **B**: Well-differentiated gastric carcinoma, PITX1 positive; **C**: Gastric carcinoma with lymph node metastasis, PITX1 positive; **D**: Signet-ring-cell carcinoma (poor-differentiated), PITX1 negative; **E**: Intestinal metaplasia, PITX1 negative; **F**: Atypical hyperplasia, PITX1 positive.

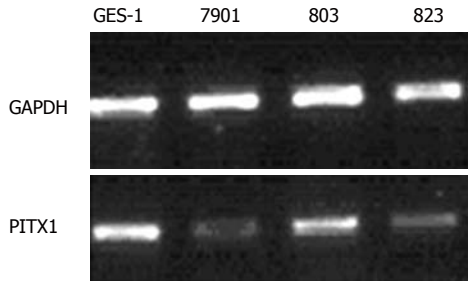

Figure 2 PITX1 expression in three cancer cell lines (SGC-7901, MGC-803 and BGC-823) and the normal gastric epithelial cell line GES-1 (GAPHD serves as the external control).

Table 3 Relationship between the expression of PITX1 in gastric cancer cell lines and the normal gastric cell line

	IDV
MGC-803	0.636 ± 0.092
BGC-823	0.306 ± 0.060[a]
SGC-7901	0.356 ± 0.081[a]
GES- 1	0.722 ± 0.102

[a]$P < 0.05$ *vs* GES-1 cell line.

Barrett's esophagus[18]. Moreover, PITX1 expression is also decreased in lung, prostate and bladder tumor tissues compared with normal control tissues[19-22].

Considering that the expression of the homeobox genes, such as *BARX1* and *PITX1*, is confined to the stomach mesenchyme during gastrointestinal development[23], we studied PITX1 expression in human gastric cancer tissues. In our study, PITX1 expression declined in 63.3% cases of gastric cancer, compared with adjacent normal tissues ($P < 0.001$). Together with former reports on the role of PITX1 in various cancers, our results hinted the negative regulation of PITX1 during carcinogenesis and the development of gastric cancer.

In addition, we found that PITX1 mRNA expression in gastric cancer cell lines was in accordance with its protein expression in immunohistochemistrical results, which agrees with the research of Chen *et al*[19] in lung cancer. Given the insufficient evidence of gastric cancer cell lines, a further study on PITX1 mRNA expression in gastric cancer tissues is necessary to confirm the results of immunohistochemistry and RT-PCR in cell lines.

The low expression of PITX1 suggested that *PITX1* may have a tumor suppressive function, inspiring us to examine its potential role in carcinogenesis. Kolfschoten *et al*[22], reported that *PITX1* regulates the RAS (rat sarcoma) signaling pathway and, therefore, tumorigenesis. As a transcriptional activator, PITX1 might activate RASAL1 to inhibit RAS activity, because PITX1 consensus binding sites, TAA(T/G)CC, were found in the 2 kb upstream promoter region of *RASAL1*, a member of the RAS-GAP family of genes (GTP-activating factors-negative regulators of RAS). Another novel explanation for *PITX1* tumorigenesis came from a study on the role of PITX1 in the transcription of the p53 tumor suppressor gene in human mammary carcinoma (MCF-7) cells, implying that p53 is a direct transcriptional target of PITX1[24].

It has been long recognized that the inactivation of tumor suppressor genes results from mutation, loss of heterozygosity (LOH), aberrant methylation and haploinsufficiency[25,26], among which aberrant promoter hypermethylation is well-known to participate in homeobox gene silencing[27,28]; however, PITX1 promoter hypermethylation has not been found in studies of lung cancer[19]. Therefore, we examined the *PITX1* gene for the presence of mutations in order to explore the mechanism of inactivation of this candidate tumor suppressor gene. We failed to find any mutation in the coding area of *PITX1*, although we did identify the deletion of a repeated sequence in 3'UTR of only one gastric cancer sample. Hence, the absence of detectable mutations or epigenetic silencing suggest that haploinsufficiency is behind the loss of *PITX1* expression[29]. Indeed, it was recently shown that the striking phenotype observed in patients with Rieger's syndrome resulted from decreased PITX2 expression due to deletion mutations in one allele of the gene[30]. As a close relative of PITX2, is PITX1 also subject to haploinsufficiency in gastric carcinogenesis? Further studies are required to investigate the mechanism of PITX1 down-regulation in gastric cancers.

Our study showed that the levels of PITX1 protein are decreased in gastric cancer tissues and that PITX1 mRNA levels are decreased in gastric cancer cell lines, suggesting that *PITX1* is a candidate tumor suppressor gene in gastric cancers, and that its expression is related to the differentiation, position and depth of invasion of gastric cancers.

Knowledge of transcription factors is crucial for understanding the molecular basis of neoplasia. PITX1, a pituitary transcription factor, mediates a plethora of embryonic functions, and its down-regulation in parenchyma tumors may be associated with carcinogenesis. Our study is the first time to explore the link between PITX1 and gastric cancer. Down-regulation of PITX1 both in gastric cancer and gastric cancer cell lines may be involved in the development of gastric cancer and may be a frequent molecular event in gastric carcinogenesis; thus, PITX1 represents a candidate tumor suppressor gene. Therefore, further study should investigate potential mechanisms for modulating PITX1 expression during carcinogenesis and the progression of gastric cancer.

COMMENTS

Background

Gastric cancer is one of the most common types of cancer worldwide. A more complete molecular genetic understanding of gastric cancer will allow the development of specific therapies. Recently, studies on tumor suppressor genes have been highly valued in gastric cancer research owing to their widespread involvement in diverse cellular activities.

Research frontiers

A family of homeobox genes, the PITX family, contains a highly-conserved homeodomain responsible for recognition of the TAA(T/G)CC motif in the promoter regions of several target genes. By virtue of its DNA-binding specificity, PITX1, an important member of this family, has been reported to be involved in many human cancers, such as Barrett's esophagus and lung cancer. The carcinogenic mechanism of PITX1 has been explored in terms of regulation of the RAS signaling pathway and direct activation of p53 transcription.

Innovations and breakthroughs

The study observed a change in the expression levels of PITX1 that parallels the progression of gastric carcinogenesis; we discussed the possible carcinogenic mechanisms used by PITX1 and its clinicopathological significance in gastric cancer. This is the first study to explore the link between PITX1 and gastric cancer.

Applications

The present study suggests that down-regulation of PITX1 may be a frequent molecular event in gastric carcinogenesis. However, the exact function and mechanism of PITX1 in gastric cancer remain to be elucidated.

Terminology

Homeobox genes contain a 180-base-pair segment (the homeobox) that encodes a protein domain (homeodomain) that is involved in binding to and, thus, regulating the expression of DNA; members of the Ras family of small G proteins have been implicated as key intermediates mediating signals from upstream tyrosine kinases to downstream cascades of serine/threonine kinases, which then activate the nuclear factors that control gene expression and protein synthesis.

Peer review

An excellent paper - well written, nicely researched. The results support the hypothesis but further research across multiple centers is needed to establish a positive correlation.

Abstract

AIM: To establish and validate the mutation testing for identification and characterization of hereditary non-polyposis colorectal cancer (HNPCC) in suspected Chinese patients.

METHODS: Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. Genomic DNA was extracted after informed consent was obtained. The coding region of hMSH2 and hMLH1 genes was detected by polymerase chain reaction (PCR) and denaturing high-performance liquid chromatography (DHPLC). Mutations identified in the proband by DHPLC were directly sequenced using a 377 DNA sequencer, analyzed with a basic local alignment tool (BLAST), and tested in the corresponding family members by direct DNA sequencing.

RESULTS: Mutations were identified in two Chinese HNPCC kindreds. One was the missense mutation of hMSH2 c.1808A→G resulting in Asp 603 Gly identified in the proband of the fifth HNPCC (HNPCC5) kindred. In the HNP5 kindred, three family members were found to have this mutation and two of them had colorectal cancer. The other mutation of hMLH1 c.1882A→G was identified in the HNP2 kindred's proband, which might be the nonsense mutation analyzed by BLAST.

CONCLUSION: Pedigree investigation and mutation testing of hMSH2 and hMLH1 are the practical methods to identify high-risk HNPCC patients in China.

INTRODUCTION

Hereditary non-polyposis colorectal cancer (HNPCC) syndrome is characterized by autosome-dominantly inherited predisposition to early colorectal carcinoma and extracolonic epithelia-derived tumors most often located in the gastrointestinal and urogenital tracts[1]. The mean age of HNPCC and sporadic colorectal cancer (CRC) patients at diagnosis is 42 years and 65 years, respectively. HNPCC, accounting for approximately 5%-15% of all CRCs, is categorized as Lynch I or Lynch Ⅱ syndrome (according to revised Amsterdam criteria)[2]. Germline mutations of the mismatch repair (MMR) genes identified in HNPCC kindreds, including *MSH2*, *MLH1*, *MSH6*, *PMS1* (promotion of mutS homology 1), *PMS2*, and *MLH3*, have been proved as the major cause for HNPCC by linkage analysis. Mutations in two of these MMR genes, *MSH2* and *MLH1*, account for the majority of the kindreds with HNPCC[3]. Thus, pedigree investigation and MMR gene testing, as the basis for efficient prevention and treatment of HNPCC, are most often used in early diagnosis of at-risk family members and in confirmation of the diagnosis of HNPCC.

CRC is the third life-threatening cancer in China. However, HNPCC pedigree and its predisposition gene have not been extensively studied. We have established a CRC database since 1994 and the follow-up rate is above 90%. We have recently paid attention to hereditary colorectal cancer in South China and found that about 3% of CRC patients have multiple CRCs to which the young are vulnerable[4,5]. Thus, we collected those CRC families and finally obtained eleven independent Chinese kindreds with HNPCC by deep pedigree investigation until January,

2004. Five of them fulfilled the classical Amsterdam criteria. To identify high-risk populations with HNPCC, we tested hMSH2 and hMLH1 mutations in these classical kindreds.

MATERIALS AND METHODS

Patients

The clinical diagnosis of classical HNPCC was established and verified at the Department of Gastrointestinopan creatic surgery, the First Affiliated Hospital of the Sun Yat-Sen University[2]. Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. The study was approved by the Ethical Committee of Sun Yat-Sen University.

DNA isolation

Peripheral blood samples were collected from both patients and their family members in each Chinese kindred after informed consent was obtained for genetic analysis. DNA was extracted directly from leukocytes following the standard procedures.

All exons of *MLH1* and *MSH2* were amplified for mutation testing. Samples used were amplified in 20 mL reaction volume containing approximately 100 ng DNA in 50 mmol/L KCl, 10 mmol/L Tris-HCl, 1.5 mmol/L $MgCl_2$, 200 mmol/L each dNTP, 0.01% gelatin, 1 U Taq-polymerase, and 20-40 pmol each primer. The PCR amplification conditions were as follows: denaturation at 95℃ for 5 min, followed by 30 cycles of denaturation at 95℃ for 30 s, annealing at fragment-specific annealing temperature for 1 min, extension at 72℃ for 1 min, and a final extension at 72℃ for 7 min. The primers, annealing temperature, and size of the PCR products for each of the investigated hMLH1 and hMSH2 exons are described elsewhere[6-8]. The primers were synthesized by Shanghai Bio-Chemical Corporation.

DHPLC analysis

The amplified PCR fragments were screened for sequence variants by denaturing high pressure liquid chromatography (DHPLC) on a WAVE DNA fragment analysis system (Transgenomic, San Jose, CA, USA). The running conditions for each amplicon (available upon request) were determined by the Wavemaker 3.4.4 software (Transgenomic, San Jose, CA, USA) based on the DNA sequence. Five mL of each PCR product (containing 50-100 ng of DNA) was denaturated at 95℃ for 3 min and then gradually reannealed by decreasing the sample temperature from 95℃ to 65℃ over 30 min. PCR products were then separated at a flow rate of 0.9 mL/min with a linear acetonitrile gradient. Generally, analysis took approximately 10 min including column regeneration and re-equilibration to starting conditions. The column mobile phase consisted of a mixture of 0.1 mol/L triethylamine acetate (pH 7.0) with (buffer B) or without (buffer A) 25% acetonitrile. Samples displaying variant elution peaks in each run were chosen for sequence analysis. For some amplicons displaying variations in elution profiles of control samples, all samples were sequenced.

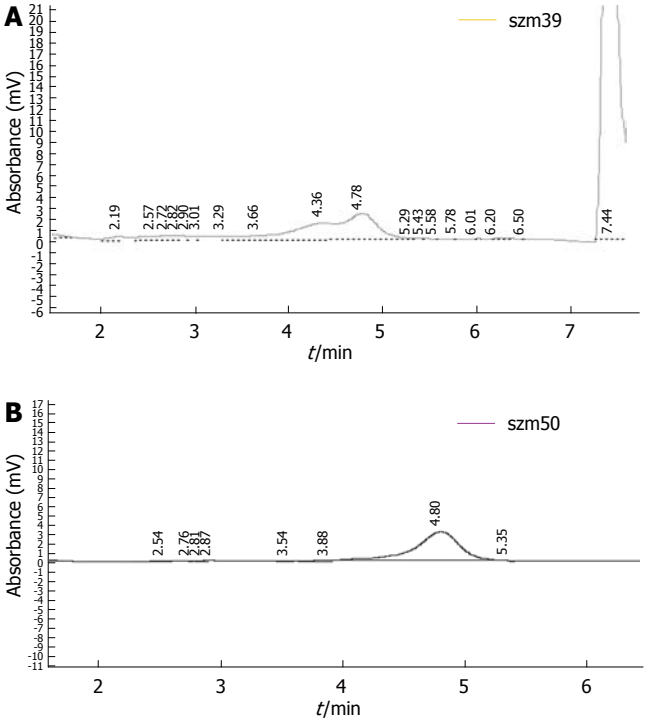

Figure 1 DHPLC showing variant elution peaks (**A**) and normal elution peaks (**B**) in exon 12 of hMSH2 gene.

DNA sequencing

DHPLC variants were confirmed by direct sequencing of independently amplified PCR products of the amplicons, in both sense and antisense direction, using the same primers. Sequencing was performed with Big Dye™ terminator cycle sequencing ready reaction kit (Applied Biosystems, Inc., Foster City, CA) on an ABI Prism™ 377 DNA sequencer following the standard conditions recommended by the manufacturer. Sequences obtained were aligned and compared to published wild-type sequences by Sequencher 3.1.1 analysis software.

Mutations identified in the kindred's proband were tested among their family members by direct DNA sequencing.

RESULTS

Among the 5 probands of the five Chinese HNPCC kindreds, 180 PCR products were screened by DHPLC. Two PCR products found with variant elution peaks by DHPLC were identified to have mutations. One was hMSH2 c.1808A→G resulting in Asp 603 Gly identified in the HNP5 kindred's proband and tested among the family members (Figures 1-3). The other was hMLH1 c.1882A →G identified in the HNP2 kindred's proband (Figures 4 and 5), which was not tested among the family members, because it might be the nonsense mutation analyzed by BLAST.

As shown in Figure 3, in the HNPCC5 kindred, there were four colorectal carcinoma patients in two successive generations, and three of these were diagnosed before the age of 45 years. The proband developed endometrial carcinoma at the age of 61 years, bladder carcinoma at the age of 66 years and colorectal carcinoma at the age of 72

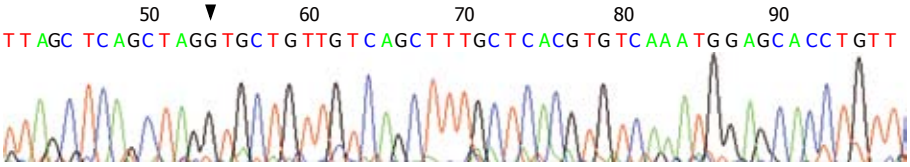

Figure 2 HPLC variants confirmed by direct sequencing displaying a single nucleotide substitution of c.1808A→G in exon 12 of hMSH2 gene.

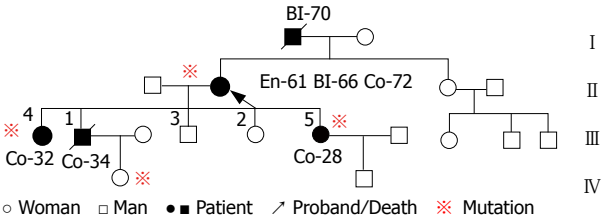

Figure 3 Pedigree tree of HNPCC 5 kindred. Co: Colon; Bl: Bladder; En: Endometrium.

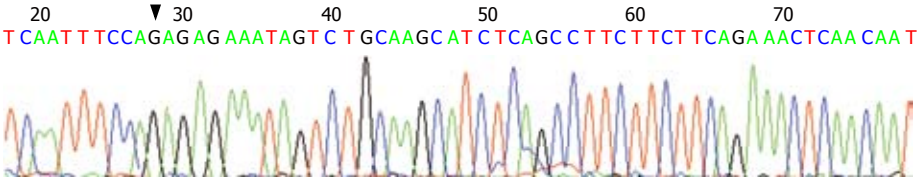

Figure 4 DHPLC variants confirmed by direct sequencing revealing a single nucleotide substitution of c.1882A→G in exon 16 of hMLH1 gene.

years, while his father developed bladder carcinoma at the age of 70 years. In addition, patient Ⅲ-1 had colorectal carcinoma at the age of 34 years and died of synchronous hepatic metastasis.

In the HNP5 kindred, each PCR product from nine proband's family members was tested by direct DNA sequencing. Only three of them were found to have the missense mutation in hMSH2 at position A1808G. The missense mutation sequence variant was found in exon 12 of hMSH2 gene. It was a single nucleotide substitution of c.1808A→G (Figure 2), which resulted in Asp 603 Gly of hMSH2 (NCBI Ref. Seq. NM 000251 and NP 000242 for mRNA and protein, respectively). Proband and patient Ⅲ-4 and -5 had this mutation and developed colorectal carcinoma. Patient Ⅲ-1's daughter had no colorectal disease even though she had this mutation, and was still under follow-up. No mutation was found in the others.

DISCUSSION

CRC is one of the most common cancers and its clinical selection criteria for cancer families were first established in Amsterdam in 1990 by the International Collaborative Group on HNPCC and modified in 1999[2]. Detection of constitutional mutations in genes associated with predisposition to cancer is practical in molecular diagnosis. Data suggest that molecular testing is much more efficient, if analyses are focused on a limited number of alterations[9-13]. Detection of germline mutation carriers is an efficient method to define high-risk CRC patients. Identification of germline mutations of either hMSH2 or hMLH1 could be performed in 50%-70% of families meeting the Amsterdam criteria for HNPCC, whereas the families not complying with these criteria show a much lower frequency of the MMR gene mutations[14-17]. Thus, hMSH2 or hMLH1 gene testing is most often used in early diagnosis of at-risk family members with HNPCC.

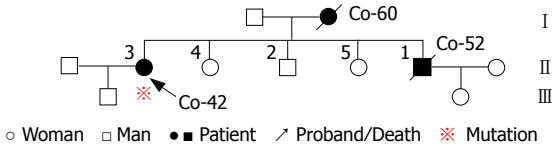

Figure 5 Pedigree tree of HNPCC 2 kindred. Co: Colon.

To identify a population-specific panel of mutations, it is crucial to describe them in all ethnic groups.

Even though CRC is common in China, few studies on HNPCC pedigree and its predisposition gene are available[4,17]. In our study, HNPCC kindreds were collected and hMSH2 and hMLH1 gene mutations were tested in order to find high-risk CRC populations. Two mutations were found among the five Chinese HNPCC kindreds. In the 5HNPCC kindreds, missense mutation was found in four members, three of them developed colorectal carcinoma. Although it has not been confirmed as a germline mutation yet, it may be an important factor for CRC development. Thus, the patient Ⅲ-1's daughter with this mutation should be closely followed up.

Approximately 20% of patients with colorectal cancer have a genetic component and HNPCC is the most common autosome dominant hereditary syndrome predisposing to colorectal cancer[18,19]. Various methods have been described to screen for HNPCC and directly test for mismatch repair gene mutations[20-27]. For patients with available tumor specimens, MSI and IHC are widely performed. Ruszkiewicz *et al*[28] reported that immunohistochemistry is an alternative method for assessment of MSI status, which is fast and relatively inexpensive compared with MSI testing. Some reports[26,29,30] suggest that detection of MSI and IHC for hMSH2/hMLH1 proteins is a reliable pre-screening test for hMLH1/hMSH2 germline mutations in families suspected of having HNPCC. Because China is a developing country with a large population and the incidence rate of CRC

increases, a screening protocol specific for the Chinese population is necessary to detect the high-risk populations with HNPCC. hMSH2 and hMLH1 gene mutation testing is a practical method for detecting HNPCC in Chinese population. Meanwhile, further research should be performed in Chinese HNPCC kindreds with germline mutations.

COMMENTS

Background

Approximately 20% of colorectal cancer patients have a genetic component and hereditary non-polyposis colorectal cancer (HNPCC) is the most common autosome dominant hereditary syndrome predisposing to colorectal cancer. Various methods have been described to screen for HNPCC and directly test for mismatch repair gene mutations. Even though CRC is common in China, few studies on HNPCC pedigree and its predisposition gene are available.

Research frontiers

Data suggest that molecular testing is much more efficient when analyses are focused on a limited number of alterations. Detection of germline mutation carriers is an efficient method to define high-risk CRC patients. Germline mutations of either hMSH2 or hMLH1 can be identified in 50%-70% of families meeting the Amsterdam criteria for HNPCC. Thus, hMSH2 or hMLH1 gene testing is most often used in early diagnosis of at-risk family members with HNPCC.

Innovations and breakthroughs

Five independent Chinese kindreds with HNPCC fulfilling the classical Amsterdam criteria were collected. Mutations were identified in two Chinese HNPCC kindreds. One was the missense mutation of hMSH2 c.1808A→G resulting in Asp 603 Gly, the other was the mutation of hMLH1 c.1882A→G .

Applications

Molecular pathological tests should be performed in order to identify individuals and at-risk family members with HNPCC. Close follow-up and intensive surveillance should be performed.

Terminology

Denaturing high-performance liquid chromatography (DHPLC) is a method for separating DNA duplexes that differ in the identity of one or more base pairs. The method is believed to be most efficient at the site of mutation. Basic local alignment search tool (BLAST) is powerful to compare novel sequences with previously characterized genes. Both functional and evolutionary information can be obtained from well designed queries and alignments. BLAST 2.0 can rapidly search for nucleotide and protein in their databases.

Peer review

The results of this clinical study indicate that mutation testing for hMSH2 and hMLH1 by PCR and direct sequencing is a preferable method to identify high-risk HNPCC patients.

Received: August 9, 2007 Revised: October 11, 2007

Abstract

AIM: To assess the clinical value of duodenal circular drainage for superior mesenteric artery syndrome (SMAS).

METHODS: Forty-seven cases of SMAS were treated with duodenal circular drainage from 1959 to 2001. Clinical data were analyzed retrospectively.

RESULTS: In this group, good effects were achieved in 39 cases treated with duodenal circular drainage after 2-15 years of follow-up. The other eight cases were first treated with anterior repositioning of the duodenum (two cases), duodenojejunostomy (five cases), subtotal gastrectomy and billroth Ⅱ gastrojejunostomy (one case), but vomiting was not relieved until duodenal circular drainage was performed again. A follow-up study of 8-10 years revealed satisfactory results in these eight patients.

CONCLUSION: In SMAS, if the reversed peristalsis is strong and continuous, and vomiting occurs frequently, the symptom can not be relieved even if the obstruction of duodenum is removed surgically. The key treatment is the relief of reversed peristalsis. The duodenal circular drainage can resolve the drainage direction of duodenal content, thus relieving the symptom of vomiting.

INTRODUCTION

The pathogenesis of superior mesenteric artery syndrome (SAMS) is so complicated[1-3] that there are different operations for treating SAMS[4-7], such as ligament of Treitz amputation, gastrojejunostomy, subtotal gastrectomy and Billroth Ⅱ gastrojejunostomy, duodenojejunostomy, anterior reposition of the duodenum, duodenal circular drainage operation, *etc*[8-10]. The last one of all these procedures is suitable for the patients who have failed in other operations or have stronger and continuous reversed peristalsis[11]. Among a total of 108 patients with SAMS who received operations, 47 patents were treated with duodenal circular drainage from 1959 to 2001 in the Second Affiliated Hospital of Harbin Medical University.

MATERIALS AND METHODS

Patients

This study included 28 men and 19 women, aged from 16 to 50 years (average 29), including 38 patients aged 16-35 years. The clinical course of the diseases lasted 2-11 years, averaging 3.5 years.

Clinical characteristics

The onset of SAMS was slow in all 47 patients. The symptoms were upper abdomen expanding, dull and bursting pain. The pain may present in upper abdomen, upper left or right of umbilicus and right hypochondrium, which was not relieved after body position change. The vomiting could be triggered by eating and drinking. Body position change (knee-chest position) did not make any difference. The vomit contained bill-stained material and no dejection smell. Six patients were misdiagnosed as having obstruction of pylorus (five patients were misdiagnosed by other hospitals) and 14 patients had ejecting vomiting. Three patients were misdiagnosed as having gastric cancer because of severe dehydration and disorder of electrolyte induced by a high frequency of vomiting.

All patients suffered from severe dehydration, disorder of electrolyte and loss of weight. The patients weighed from 45-53 kg in 28 men and 40-42 kg in 19 women. The patients' upper abdomen was distended and lower abdomen was plainness. There were no abdominal muscle guarding and obviously tenderness, but shaping of the stomach and succussion splash occasionally. There was no change of borhorygmus.

Laboratory examination

Obvious expansion in stomach, and descending and

Figure 1 Barium X ray study in duodenal circular drainage operation.

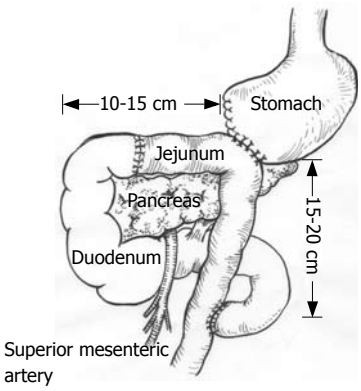

Figure 2 Duodenal circular drainage operation.

transverse portion of duodenum were found in all the patients in barium X-ray study. The barium was delayed in the ascending portion of duodenum which looked like pen trace (Figure 1). The reversed peristalsis of duodenum was much stronger than direct peristalsis. It looked like the movement of pendulum, and barium could reverse to stomach. If the patients were put in prone position, a smaller portion of barium could go through the obstructive site and enter into jejunum. Five patients had histories of peptic ulcer at the same time. Duodenum expanded obviously, reaching 7.5 cm-8 cm in diameter, in 26 patients with SMAS.

Duodenum air charge test in operation

A total of 108 SMAS patients received duodenum air charge test in operation. After interdiction duodenum with an elastic tourniquet, about 200-400 mL air was injected into the proximal duodenum. The diameter of duodenum expanded to 5.5 cm-6.0 cm was considered as light expansion, 6.5 cm-7.0 cm as moderate expansion, and 8 cm or broader as severe expansion. In our group, the duodenum expanded to 8 cm in 47 patients.

Operation

All the 47 patients received duodenal circular drainage operation finally. Two patients received anterior reposition of the duodenum and gastrojejunostomy and five patients underwent duodenojejunostomy before receiving this operation. Vomiting was not alleviated after these procedures in these patients, and they received duodenal circular drainage operation 3-6 mo after the first surgery. One patient suffered from duodenal partial obstruction after subtotal gastrectomy and Billroth Ⅱ gastrojejunostomy, which induced obstructive jaundice and suppurative cholangitis because the bilious and pancreatic liquid can not be drained easily. The reason was that when duodenal nub was closed, a bowel segment was formed between duodenal nub and the position compressed by the duodenum. The patient was cured after duodenal circular drainage operation two mo after the first operation.

Operational methods

Under epidural anesthesia or general anesthesia with tracheal intubation, midline incisions were made in upper abdomen in all patients. We performed duodenum air charge test first. If the duodenum was distended and widened obviously to 8 cm or wider, distal stomach should be resected, and if the patients had gastric ulcer, subtotal gastrectomy should be performed. Afterwards the jejunum should be cut off 10 cm-15 cm from ligament of Treitz (sometimes 20 cm according to blood vessel supply). Distal jejunum was drawn through mesentery of transverse colon and was retrocolically anastomosed end to end with duodenal cap. Half length stomach (about 5 cm) was anastomosed to jejunum end to side 10 cm-15 cm from the jejunum-duodenal cap anastomosis. Finally proximal jejunum was anastomosed with distal jejunum end to side 15 cm-20 cm below the gastrojejunoanastomosed stoma. The incision was stitched after washing of abdominal cavity (Figure 2).

RESULTS

All 47 received gastroenteric X-ray test (60-100 mL of 76% meglumine diatrizoate injection or 200 mL barium was taken orally). Contrast agent could pass the gastroenteroanastomosed stoma and jejunal-jejunostosed stoma successfully. No stricture of anastomotic stoma was found in our group. The contrast agent was refluxed to the end to end duodenal cap anastomosis in 6 patients. Meglumine diatrizoate injection (76%) was administered in 2 cases after 10 min. Barium was influxed to the jejunum, and some was refluxed to the end to end duodenal cap anastomosis, and partly refluxed to stomach. Six patients had bile refluxed gastritis 20-25 d after operation. The symptom disappeared after one month treatment with pectous bismuth and domperidone. The contrast agent was administered to the jejunum and no reflux was found in barium X-ray study in other patients. Reverse peristalsis disappeared in all patients finally.

All patients were released from symptoms in our group 10-15 d after operation. All patients had a good status in a follow-up study of 2-15 years. The ratio of follow-up was 100%, including 47 cases followed within two years. No abdominal expanding, pain and vomiting occurred. The weight increased by 8 kg in 25 patients, 5 kg in 15 patients and 7 kg in 3 patients. Gastroenteric barium X-ray studies showed no stricture in two anastomosed stomas and no contrast agent reflux was observed in these cases (Figure 3). Thirty-eight (80.9%) patients were followed in the third year and no abdominal pain or expanding and vomiting were found and appetite all became normal, with weights

Figure 3 Barium X ray study after duodenal circular drainage operation.

of 60-64 kg in male patients and 46-51 kg in female. In 21 patients who received ultrasonic examination, no obvious expansion was found in duodenum, the diameter of duodenum being 3 cm-5 cm. Eighteen (38.3%) patients have been followed up to the present. Eight patients had received other operations before the duodenal circular drainage operation. A follow-up study of 8-10 years revealed good effects in these patients. No abdominal pain, expansion, and vomiting were found in all the 18 patients and all with normal appetite. Gastroenteric barium X-ray study showed no stricture and ulcer in two anastomosed stomas and no contrast agent reflux was observed in these cases. The weight was 60-64 kg in male patients and 45-51 kg in female. No obvious expansion was found in duodenum in the 18 patients, the diameter of duodenum being 4-5 cm[12-14].

DISCUSSION

Theoretic basis and indications for duodenal circular drainage operation

The movements of duodenum are complicated and the most important movements are reversed peristalsis and direct peristalsis[15-18]. The direct peristalsis is greater than reversed peristalsis under normal circumstances. Complete or partial obstruction could be induced when the ascending portion of duodenum was compressed by superior mesenteric artery[19-22]. The reversed peristalsis is greater than the direct peristalsis, which is the most important reason inducing opening of pyloric duct[23,24]. The patients may suffer from frequent vomiting in such situation[25-27]. If reversed peristalsis exists continually and chronically, the reversed peristalsis will be hardly eliminated. Releasing from obstruction by operation can not alleviate clinical symptoms because the strongly reversed peristalsis still exists. Therefore, emphasis should laid on eliminating the reversed peristalsis to alleviate frequent vomiting. Duodenojejunostomy is commonly used but can not stop the vomiting while duodenal circular drainage operation can manage the drainage direction of duodenal contents. When duodenum takes peristalsis directly, the duodenal contents could only partly enter into jejunum through anastomosis of proximal and distal jejunum. When the strongly reversed peristalsis with the duodenal contents could come into jejunum completely through anastomosis of distal jejunum and duodenal cap, the vomiting is eliminated completely[28-30].

Indications for duodenal circular drainage are as follows: (a) the history of the disease is up to 2 years, especially 5 years; (b) frequent vomiting, no obvious abdominal pain but marked abdominal distention after eating. The pain may be alleviated after vomiting; (c) the vomiting can not be alleviated by changing body position (prostrate position after eating), it may result from chronic reversed peristalsis; (d) the descending and transverse portion of duodenum is markedly expanded and show strong and frequent reversed peristalsis in barium X-ray test, pyloric duct is opened, the stomach is expanded and atonic; (e) the cavity of duodenum was expanded to 8 cm or more in air charge test, and the pressure of duodenum is 15-17 cm H_2O; and (f) the patients are not cured after duodenojejunostomy and anterior reposition of the duodenum. Duodenal circular drainage should conform to the indications above. If the patients do not meet with these indications, duodenal circular drainage can induce disorder of duodenal function.

Assessment of duodenal circular drainage

Duodenal circular drainage can eliminate frequent vomiting induced by chronic reversed peristalsis in SMAS. The ulcer focus and most of gastric body can be resected (gastrojejunostomy similar to Billroth Ⅱ) if the patients suffer from the ulcer intercurrently. The operation also can eliminate blind end between anastomosis and obstructive site after duodenojejunostomy and can not induce blind loop syndrome. No ulcer or stricture of anastomosis occurred in our group.

There are still several disadvantages of duodenal circular drainage operation. The operation is complicated as compared with duodenojejunostomy, and the patients may suffer from more damages as a result of the operation; small stomach syndrome and anemia can be induced by resection of most gastric body; the mucous membrane of alimentary tract can not be nourished by gastrin after resection of gastric antrum; and bilious reflux gastritis may occur after resection of sphincter of pylorus. A few patients had bilious reflux gastritis in our group and recovered within one month.

COMMENTS

Background

Superior mesenteric artery syndrome (SMAS) is an uncommon disease which can result in postprandial epigastric pain, nausea, vomiting, anorexia and weight loss. The pathogenesis of SMAS is ascribed to compression of the third part of the duodenum in the angle between the aorta and the superior mesenteric artery. If conservative management fails, surgical options should be applied.

Research frontiers

Conservative therapy with nutritional supplementation is the initial treatment, and surgery is reserved for those who do not respond to medical therapy. The main character of the SMAS is that the reversed peristalsis is greater than the direct peristalsis, which is the most important reason inducing the symptoms. If reversed peristalsis exists continually and chronically, the reversed peristalsis will be hardly eliminated. Only releasing from obstruction by operation can not alleviate clinical symptoms because the strong reversed peristalsis still exists. Therefore, emphasis should be laid on eliminating reversed peristalsis to alleviate frequent vomiting.

Related publications

Surgical options include open or laparoscopic duodenojejunostomy or ligament of Treitz amputation, gastrojejunostomy, subtotal gastrectomy and Billroth Ⅱ gastrojejunostomy, duodenojejunostomy, anterior reposition of the duodenum, duodenal circular drainage operation, and so on. SMAS is associated with a wide range of predisposing conditions and surgical procedures, more studies are needed to better define the optimal treatment for this disease.

Innovations and breakthroughs

We and many other authors had performed other operations for SMAS. However, some patients showed bad results, especially those with stronger reversed peristalsis. So we designed the operation of duodenal circular drainage. In practice, the operation achieved good results in most patients, All patients showed good status during a follow-up study of 2-15 years.

Applications

Forty-seven cases of SMAS were treated with duodenal circular drainage operation from 1959 to 2001 and had good effects after 2-15 years of follow-up.

Terminology

Duodenal circular drainage: A kind of operation we designed to treat SMAS. The distal jejunum is retrocolically anastomosed with duodenal cap end to end. Half length stomach is anastomosed to jejunum end to side 10 cm-15 cm from the jejunum-duodenal cap anastomosis. Proximal jejunum was anastomosed with distal jejunum end to side 15 cm-20 cm below the gastrojejunoanastomosed stoma.

Peer review

The manuscript evaluates the clinical value of duodenal circular drainage operation for superior mesenteric artery syndrome. The method is simple and correct. Discussion is well organized and conclusions are valuable.

Abstract

AIM: To evaluate the arguments for and against the possible roles of *H pylori* in hepatocellular carcinoma (HCC).

METHODS: We performed a systematic review of all relevant studies published in the literature. A total of 103 clinical trials and reports were identified, but only 10 trials qualified under our selection criteria. A meta-analysis was carried out by a biostatistician according to the Cochrane Reviewers' Handbook recommended by The Cochrane Collaboration.

RESULTS: Nine case-control studies and one retrospective cross sectional study were included in the final analysis. Overall the prevalence of *H pylori* infection was 53.3% (129 of 242) in cases and 10.4% (29 of 280) in controls, and the summary odds ratio for the association of *H pylori* infection with the risk for HCC (using the fixed-effects model, which accounted for the homogeneity across the 10 studies) was determined to be 13.63 (95% CI, 7.90-23.49).

CONCLUSION: Our analysis showed a positive association between *H pylori* infection and the risk of HCC, with an indication of possible publication bias and possible confounders due to study designs that showed results of less pronounced associations.

INTRODUCTION

The profound impact of hepatocellular carcinoma (HCC) on human health is known worldwide[1]. Persistent hepatitis B virus (HBV) and hepatitis C virus (HCV) infections and aflatoxins are the main causes of HCC[2]. The real risk factors for HCC may be far more numerous than the known causes. The infectious agent *Helicobacter hepaticus* (*H hepaticus*), for example, first described by Ward *et al* in 1994, has recently received new attention for its role in causing chronic active hepatitis and associated liver tumors[3].

Since *H pylori* was first cultivated from a human gastric biopsy specimen in 1982, it has become apparent that *H pylori* infection is correlated with gastric cancer and mucosa-associated lymphoid tissue lymphoma. More recently, researchers have reported that *Helicobacter spp.* have been identified in liver tissue resected from patients with HCC[4]. Experimental infection by *Helicobacter hepaticus* in mice causes chronic hepatitis and HCC. It is highly noteworthy that *H pylori* was found in liver tissues resected from patients with HCC[5-7].

The question of whether *H pylori* could play a role in the development of HCC remains controversial. Many conflicting reports have been published to date; thus, we performed a systematic rev iew of all of the relevant studies published in the literature to evaluate the arguments for and against the possible roles of *H pylori* in HCC.

Rocha *et al*[15]	France, 2005	19/31	19/78	Non-cirrhotic chronic hepatitis C (*n* = 24), HCV Positive cirrhosis without HCC (*n* = 29), HCV Positive cirrhosis and HCC (*n* = 25)	NA	NA

2007), for the terms 'hepatocellular carcinoma' and '*H pylori*'. The reference lists of pertinent reviews and retrieved articles were also checked for the identification of additional studies. We also performed a full manual search from the bibliographies of selected papers. Studies were identified by two researchers, independently; the two lists were compared and discrepancies were resolved. We also contacted the authors of studies containing relevant information, who did not report the results necessary for this analysis. Unpublished data were also accepted if an abstract was available and further information was obtained from the author.

In the meta-analysis, the following inclusive selection criteria were set and reviewed by two independent investigators: (1) each trial is an independent case-controlled study; (2) the purpose of all studies and statistical methods is similar; (3) the numbers of cases, controls and positive rate of *helicobacter* (the presence of *H pylori* DNA sequences in human liver or other standard methods for definition of *H pylori* infection in the liver) are concrete; (4) the study groups have definite HCC by pathology, histology and operation; (5) only studies that selected HCC patients as cases and subjects with other liver diseases or normal liver tissue specimens as controls are included.

The following exclusive selection criteria were set: (1) incomplete raw data; (2) repetitive reports (if more than one version of the same study was retrieved, only the most recent is used); (3) the positive rate of *helicobacter* is not detected by the presence of *H pylori* DNA sequences or other standard methods for detection of *H pylori* infection in liver (that is, all subjects are tested for the presence in serum of IgG antibodies against *H pylori*).

A total of 103 clinical trials and reports were identified and only 10 trials[6-15] qualified on the basis of our selection criteria. The studies were independently evaluated by two researchers. Discrepancies in the evaluations of some studies were resolved by discussion between the reviewers. The main features of the trials included in the meta-analysis are shown in Table 1.

Data extraction and outcomes

Data extracted included year of publication, country of origin, number of cases and controls, characteristics of controls, age of participants, prevalence of *H pylori* infection in cases and controls, and reported odds ratios (OR). All available studies were reviewed by two investigators independently. Reference 18 is a retrospective cross-sectional study; the others are case-controlled studies.

Statistical analysis

The meta-analysis was carried out by a biostatistician (Chen AJ) according to the Cochrane Reviewers' Handbook recommended by The Cochrane Collaboration. First, a pooled OR was calculated using the fixed-effect model. The heterogeneity of the studies was examined using the DL Q statistic[16]. Because the results were homogeneous ($P = 0.07$), a fixed-effects model was employed using the DerSimonian and Laird (DL) methods. A pooled OR was presented as a standard plot with 95 percent confidence intervals (CI). Begg and Mazumdar's proposed adjusted rank correlation test[17] and Egger's linear regression approach[10] were used to measure publication bias, which was shown as a funnel plot (Figure 1). Fixed (Figure 2A) and random-effects models (Figure 2B) were also used to perform sensitivity-analysis to assess the reliability of meta-analysis. The statistical package RevMan version 5.0 (provided by The Cochrane Collaboration, Oxford, England) was used for statistical analyses.

RESULTS

Nine case-controlled studies and one retrospective cross-sectional study were were identified and reviewed, as shown in Table 1[6-15].

In the meta-analysis, the overall prevalence of *H pylori* infection was 53.3% (129 of 242) in cases and 10.4% (29 of 280) in controls, and a summary OR for the association of *H pylori* infection with the risk for hepatocellular carcinoma (using the fixed-effects model, which accounted for the homogeneity across the 10 studies) was determined to be 13.63 (95% CI, 7.90-23.49) (Figure 2A). Figure 2A shows the ORs and 95% CIs of each study, and the summary OR determined by meta-analysis. The proportion of the total variation in study estimates, because of heterogeneity, was 44.0% (heterogeneity test statistics χ^2 = 14.28, on 8 df, P = 0.07, I^2 = 44.0%). A random-effects model was also used to perform sensitivity-analysis to assess the reliability of meta-analysis, as shown in Figure 2B.

Graphical and statistical evaluation of publication bias

Publication bias was assessed for all pooled ORs with confidence intervals using Begg's test[17,18]. This bias is shown as a funnel plot in Figure 1.

The funnel plot method was used to assess the possible presence of publication bias[19,20]. It consists of plotting each study's OR on a logarithmic scale (horizontal axis) against its SE (vertical axis), with an informal visual examination of the funnel plot graph to check for funnel plot asymmetry as an indication of potential publication bias. Studies of smaller size normally have a wider distribution of results than larger studies, because of a higher degree of random variation, and the ORs scatter more widely at the bottom of such a graph, with the spread narrowing with increasing precision among larger studies. In the absence of a publication bias, the graph appears as a symmetrical inverted funnel, as the risk estimates should be symmetrically distributed around the midpoint value (that is, the summary OR). Publication bias may occur if smaller studies showing no significant results remain unpublished, leading to an asymmetrical appearance of the funnel plot with a gap at the bottom of the graph.

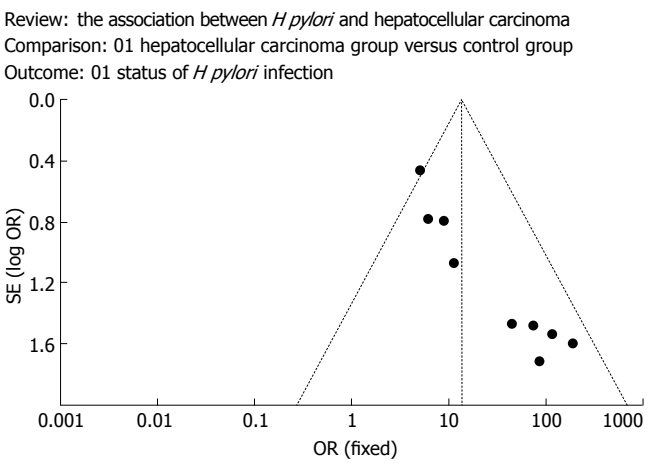

Figure 1 Funnel plot to explore publication bias. The graphical funnel plot of the 10 published studies appears to be asymmetrical.

DISCUSSION

H pylori infection is a classical model with which to study cancer development as a consequence of chronic inflammation. The estimated total of infection-attributed malignancies per year is 1.9 million cases or 17.8% of the global cancer burden[21]. Among the principal carcinogenic agents, *H pylori* is a leading factor, being responsible for 5.5% of all cancers. *H pylori* was classified as a type I carcinogen by the International Agency for Research on Cancer in 1994[22]. A striking finding indicated by Ward *et al* is that bacterial infection of the liver in healthy A/JCr male mice is capable of inducing a strong inflammatory change in the parenchyma (for example, hepatitis) leading to HCC.

We analyzed the published evidence investigating the association between *H pylori* infection and HCC. Studies concerning this possible association have been undertaken since the early 2000s. To our knowledge, this is the first published meta-analysis investigating this association. The summary OR for the association of evidence of *H pylori* infection and the risk for HCC was estimated to be 13.63 with a 95% CI from 7.90 to 23.49, with a confound of study design (lower for studies of prospective design and higher for retrospective case-controlled studies).

In our study, only publications in English or Chinese were used for evaluation. 'Meta-analytical' research on 29 meta-analyses investigating language bias has provided evidence that the OR estimated in meta-analyses from non-English publications are on average 0.8-fold (95% CI, 0.7-1.0) the OR estimates from English-written publications[23]. Therefore, even if we had not searched for non-English publications, this might have introduced only a small bias in the overall findings, which, in our opinion, would not have altered our main conclusions.

Several other points should be considered when interpreting the results of our study.

First, the positive rate of *helicobacter* of the most studies was detected by the presence of *H pylori* DNA sequences. Polymerase chain reaction (PCR) amplification using two sets of primers located in the 16S ribosomal DNA (rDNA) was used to detect the presence of bacteria, but this is not a 'gold standard' method for detecting *H pylori* infection in the liver. Histology with standard stains and culturing maybe more precise than 16S rDNA; however, false negatives are likely. Research in this area has been limited by the lack of a gold standard for the diagnosis of these organisms in the liver. Most published data to date have been based on molecular techniques that detect the DNA of *Helicobacter* species in liver tissues, rather than evidence of viable organisms in the liver.

Secondly, Reference 18 is a retrospective cross-sectional study, whereas the other studies are case-controlled studies. Such studies are generally lower in quality for use as prospective design studies and higher in quality as retrospective case-controlled studies. These observational studies are more prone to bias than randomized clinical trial (RCT) studies.

Third, in this analysis, graphical and statistical methods for testing and adjusting for a possible publication bias and a test for potential heterogeneity between studies were performed. A graphical funnel plot of the 10 published studies was asymmetrical, which may suggest the probable

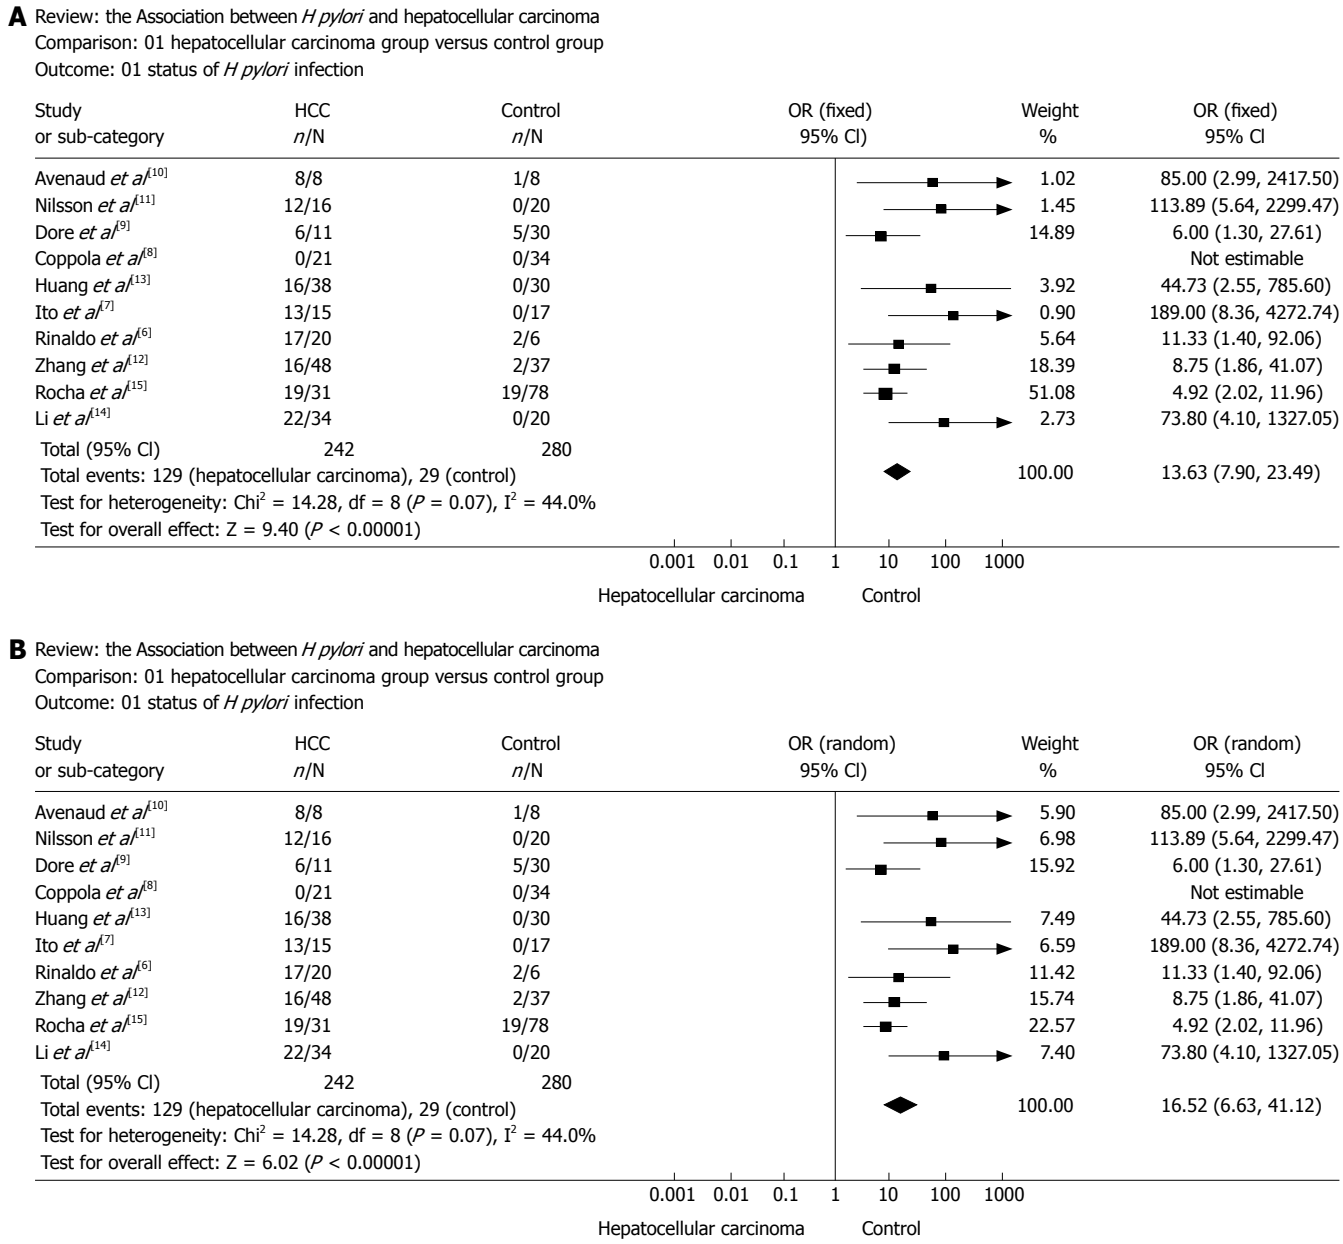

Figure 2 **A**: Forest plot of a meta-analysis of the association between *H pylori* and hepatocellular carcinoma risk (fixed-effects mode). It shows the ORs and 95% CI of each study, and the summary OR determined by meta-analysis. The proportion of total variation in study estimates, because of heterogeneity, was 44.0% (heterogeneity test statistics χ^2 = 14.28, on 8 df, P = 0.07, I^2 = 44.0%); **B**: Sensitivity-analysis: A Forest plot of a meta-analysis of the association between *H pylori* and hepatocellular carcinoma risk (random-effects mode).

existence of publication bias, although this may occur if some studies showing no significant results remained unpublished or if such negative studies are few.

Additionally, because the information used in our research was based on data from observational studies, the characteristics of each study population and the different methodologies of these studies should be taken into account when interpreting the results of our analysis. For example, different inclusion criteria for selection of the participants might have influenced the results of this research. Differences in the age distribution, different countries and different types of control groups (cirrhotic patients, patients with chronic viral hepatitis without or with cirrhosis, patients without primary liver carcinoma, patients with metastatic liver carcinoma, pericacinomatous tissues, benign tumors of the liver, liver external injuries, giant hemangiomas, macrosis hepatic cysts, and intrahepatic bile duct stones) could also be among the potential causes of variation in the studies' estimates.

Most studies did not control for the matching variables in the analysis, and the risk for HCC was not controlled for possible confounders such as HBV or HCV, except in Reference 18.

Only the articles of Dore *et al*[9] and Rocha *et al*[15] demonstrated the association of *Helicobacter* species with hepatitis C cirrhosis and HCC. These two studies included a large series of patients and examined both tumor and cirrhotic liver tissue samples from patients with HCV-positive HCC. *Helicobacter* DNA was found in a small percentage of liver biopsies from controls as well as from patients with chronic hepatitis C (4.2% and 3.5%, respectively). However, the prevalence of *Helicobacter*

species was high in patients with HCV-positive cirrhosis and in those with cirrhosis and HCC (68% and 61%, respectively). In nearly all cancer tissues, *Helicobacter* DNA was detected and identified as *Helicobacter* pullorum or *H pylori*-like organisms. The authors suggested a possible causal role of these bacteria in the progression of chronic hepatitis C and the development of HCC.

Furthermore, although we tried to maximize our efforts to identify all relevant published studies in peer-reviewed journals, it is possible that some escaped our attention.

There is some evidence to suggest that *Helicobacter* infection may be associated with an increased risk of extra-gastric malignancies[24]. The presence of *Helicobacter* species in liver tissues from patients with different liver diseases, including hepatic neoplasias, has been reported by numerous authors. The most intriguing hypothesis is that these bacteria might play a role in the development of HCC[25].

Despite its limitations, the present analysis has some implications: as relatively few studies are available in this field and current evidence remains limited, the necessity to conduct large studies with an adequate methodological quality, properly controlling for possible confounds in order to obtain valid results, should be emphasized; for example, tissue from unaffected liver metastatic carcinoma could be used as a suitable control.

In conclusion, our analysis showed a positive association between *H pylori* infection and the risk of HCC. We obtained from our meta-analysis a summary OR of 13.63 for the association of *H pylori* infection and HCC, with an indication of possible publication bias and confounds of study design, with less pronounced associations in prospective studies than in retrospective studies. Therefore, this risk increase should be interpreted with caution. Better designed and better controlled studies are needed to clarify the strength of this association and the possible causal role of *H pylori* infection in patients with HCC, and further prospective studies are required to prove this hypothesis. Given the importance of this potential association, further verification is warranted.

COMMENTS

Background

The real risk factors for hepatocellular carcinoma (HCC) may be far more than the known causes. A new infectious agent, *Helicobacter hepaticus* (*H hepaticus*), causing chronic active hepatitis and associated liver tumors, has been described by Ward *et al*. The question of whether *H pylori* could play a role in the development of HCC remains controversial. Many conflicting reports have been published to date, so we performed a systematic review of all of the relevant studies published in the literature to evaluate the arguments for and against the possible roles of *H pylori* in HCC.

Research frontiers

Since *H pylori* was first cultivated from human gastric biopsy specimens in 1982, it has become apparent that *H pylori* infection is correlated with gastric cancer and mucosa-associated lymphoid tissue lymphoma. More recently, researchers have reported that *Helicobacter spp*. were identified in liver tissue resected from patients with HCC. Experimental infection by *Helicobacter hepaticus* in mice causes chronic hepatitis and HCC. It is highly noteworthy that *H pylori* was found in liver tissue resected from patients with HCC.

Innovations and breakthroughs

To our knowledge, this is the first published meta-analysis investigating the association between *H pylori* and hepatocellular carcinoma risk.

Applications

Our analysis showed a positive association between *H pylori* infection and the risk of hepatocellular carcinoma, with an indication of possible publication bias and confound of study design, with less pronounced associations in prospective studies than in retrospective studies. Therefore, this risk increase should be interpreted with caution; better designed and better controlled studies are needed to clarify the strength of the association and the possible causal role of *H pylori* infection in hepatocellular carcinoma. Further prospective studies are requested to prove this hypothesis; given the importance of this potential association, further verification is warranted.

Terminology

Meta analysis: In statistics, a meta-analysis combines the result of several studies that address a set of related research hypotheses. *H pylori*: *H pylori* is a bacteria that can cause digestive illnesses, including gastritis and peptic ulcer disease. More recently, researchers have reported that *Helicobacter spp*. were identified in liver tissue resected from patients with hepatocellular carcinoma.

Peer review

Authors evaluated the arguments for and against the possible roles of *H pylori* in HCC through a systematic review of all relevant studies published in the literature. The analysis showed a positive association between *H pylori* infection and the risk of HCC.

RAPID COMMUNICATION

Small intestinal bacteria overgrowth decreases small intestinal motility in the NASH rats

Received: February 14, 2007 Revised: November 22, 2007

Abstract

AIM: To explore the relationship between small intestinal motility and small intestinal bacteria overgrowth (SIBO) in Nonalcoholic steatohepatitis (NASH), and to investigate the effect of SIBO on the pathogenesis of NASH in rats. The effect of cidomycin in alleviating severity of NASH is also studied.

METHODS: Forty eight rats were randomly divided into NASH group (n = 16), cidomycin group (n = 16) and control group (n = 16). Then each group were subdivided into small intestinal motility group (n = 8), bacteria group (n = 8) respectively. A semi-solid colored marker was used for monitoring small intestinal transit. The proximal small intestine was harvested under sterile condition and processed for quantitation for aerobes (*E. coli*) and anaerobes (Lactobacilli). Liver pathologic score was calculated to qualify the severity of hepatitis. Serum ALT, AST levels were detected to evaluate the severity of hepatitis.

RESULTS: Small intestinal transit was inhibited in NASH group (P < 0.01). Rats treated with cidomycin had higher small intestine transit rate than rats in NASH group (P < 0.01). High fat diet resulted in quantitative alterations in the aerobes (*E. coli*) but not in the anoerobics (Lactobacill). There was an increase in the number of *E. coli* in the proximal small intestinal flora in NASH group than in control group (1.70 ± 0.12 log10 (CFU/g) *vs* 1.28 ± 0.07 log10 (CFU/g), P < 0.01). TNF-α concentration was significantly higher in NASH group than in control group (1.13 ± 0.15 mmol/L *vs* 0.57 ± 0.09 mmol/L, P < 0.01). TNF-α concentration was lower in cidomycin group than in NASH group (0.63 ± 0.09 mmol/L *vs* 1.13 ± 0.15 mmol/L, P < 0.01). Treatment with cidomycin showed its effect by significantly lowering serum ALT, AST and TNF-α levels of NASH rats.

CONCLUSION: SIBO may decrease small intestinal movement in NASH rats. SIBO may be an important pathogenesis of Nash. And treatment with cidomycin by mouth can alleviate the severity of NASH.

INTRODUCTION

With much more prevalence of nonalcoholic fatty liver disease (NAFLD) than previously thought noticed, there has been an explosion on the research of pathogenesis of NAFLD. NAFLD may develop into cirrhosis of liver through NASH, in some cases, to hepatocellular carcinoma[1-5], Insulin resistance and peroxidative injury were thought to place an important role in the pathogenesis of NASH[6-12]. But there are still other mechanisms that can trigger and maintain NASH[13-18]. Small intestinal bacterial overgrowth has been reported to place a role in the pathogenesis of NASH, endotoxin and TNF-α being the possible mediator[19-21]. But contrary to this hypothesis, in another study, antibiotic treatment did not normalize aminotransferase levels in NASH patients[22]. Therefore more study is needed on the influence of SIBO on the pathogenesis of NASH and the curative effect of antibiotic on NASH. Alejandro S[22] found that prolonged Orocecal Transit Time (OCTT) in NAFLD patients coexist with SIBO. It is generally thought that prolonged OCTT is the cause of SIBO. But it is not clear if alteration of intestinal motility is a cause or a consequence of SIBO.

We established an NASH animal model by high fat diet to explore the relationship between intestinal motility and SIBO in NASH. The relationship between SIBO and NASH, and the curative effect of antibiotic on NASH were also studied.

MATERIALS AND METHODS

Materials

Forty eight male SD strain rats were used in this study.

Rats were housed individually in cages at constant room temperature in a 12-h light/dark cycle and had free access to laboratory feed and water. Semi-solid colored marker (carbon-ink 85%, gum acacia 10%, activated charcoal 5%) was made in our laboratory. Bacteria evaluation kit (API 20) was purchased from French Biomerieux CO. TNF-α kit was purchased from Technology Development Center of the General Hospital of PLA.

Establishment of animal mode

Forty eight SD rats were randomly divided into NASH group, cidomycin group and control group. Each group were subdivided into small intestinal motility group (n = 8) and bacteria group (n = 8) respectively. Rats in NASH group and cidomycin group were fed with high fat diet that was made by ordinary diet (88%) plus fat (10%) and cholesterol (2%) (supported by Qinglongshan Nursery) Rats in control group were fed with ordinary diet (supported by Qinglongshan Nursery). Furthermore, rats in cidomycin group were treated with cidomycin (12Mu ig qd) after eight weeks of high fat diet while those in the other two groups were treated with isotonic Na chloride (1 mL/d ig qd). At the end of the twelfth week, when the rats in NASH group and cidomycin group had received high fat diet for 12 wk, all the rats were killed, the serum levels of aminotransferase, TNF-α were tested and the histology of liver specimen was observed by H&E staining.

Measurement of small intestinal transit

Rats in small intestinal motility group was deprived of food for 24 h and water for 12 h prior to measurement of small intestinal transit. Then 1.0 mL semi-solid colored marker was administered into stomach by orogastric gavage. Twenty minutes later, the rat was killed, abdomen was opened and small intestine was dissected. The distance traveled by the marker was calculated. The small intestinal transit was represented by ratio of the distance traveled by the marker to the total length of the small intestine.

Histological evaluation

The liver pathologic score was calculated according to the lecture[23]: Inflammation in portal canal area was denoted by "P", inflammation inside lobules of liver by "L", piecemeal necrosis by "PN" and bridging necrosis by "BN". According to the severity of inflammation and necrosis, every item was scored from one to four. The total score of the liver inflammation was "P+L+2PN+2BN".

Measurement of small intestinal bacteria

Rats in the bacteria group was deprived of food for 24 h and water for 12 h prior to measurement of small intestinal bacteria. Then the rat was killed, the abdomen was opened and the proximal small intestine was harvested under sterile condition. A two-centimeter-long small intestine was dissected from the point about ten centimeters from pylorus, then rinsed with sterile saline thrice, and next, the leftover was sucked by sterile filter paper. After weighing, the leftover and 2 mL sterile saline were placed in a sterile glass homogenizer and homogenized. The homogenate was diluted with sterile saline at the ratio of 1:1, then, 100 μL dilution was plated on SS agar (*E. coli*) and MRS agar (Lactobacilli) respectively. The quantity of *E. coli* was determined after 24 h of aerobic cultivation at 37℃. While the quantity of Lactobacilli was determined after 48 h of anaerobic cultivation at 37℃. The number of Colony forming units (CFU) of bacteria was quantified. The quality of aseptic manipulation was evaluated by inoculating swab of abdominal cavity on sheep-blood agar. The serum TNF-α levels were detected, using radio-immunity method, in our laboratory.

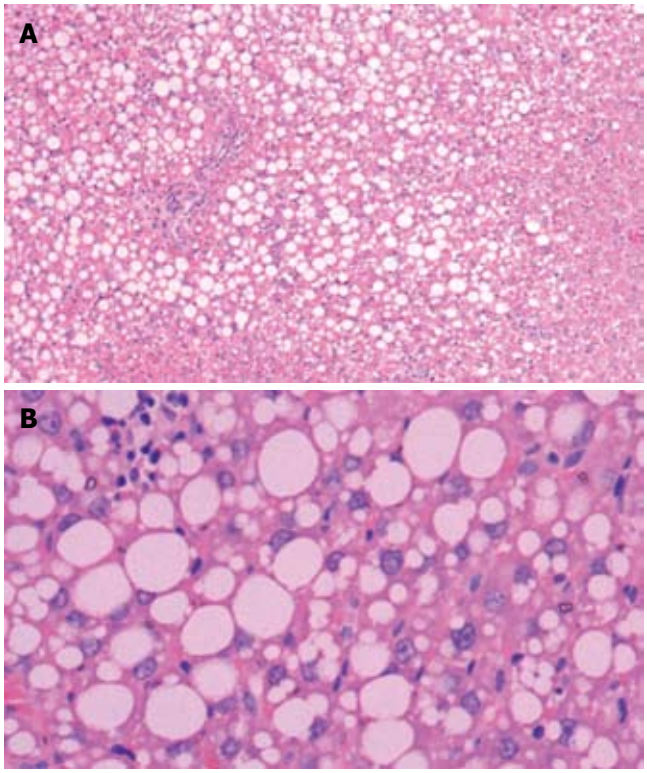

Figure 1 Pathological changes of liver after 12 wk of high fat diet. **A**: Fat drops in more than one thirds of liver cells (HE, × 40); **B**: Lymphocytes in hepatic steatosis background (HE, × 100).

Statistical analysis

Throughout this report, data were expressed as mean ± SD. Experimental results were analyzed by one-factor analysis of variance. $P < 0.05$ was considered statistically significant.

RESULTS

The weight of the model group rise *vs* controls was 455.38 ± 11.48g *vs* 395.38 ± 10.91 g, $P < 0.05$.

Pathologically a NASH model has been successfully made (Figure 1).

TNF-α, liver pathologic score, serum ALT and AST levels are higher in the NASH group than in the other two groups indicating a NASH model has been successfully made ($P < 0.01$, $P < 0.01$, $P < 0.05$). There are no statistical differences between the control group and the cidomycin group in serum TNF-α level. Liver pathologic score, serum ALT and AST levels are higher in cidomycin group than in control group ($P < 0.01$) (Table 1).

Table 1 The concentration of TNF-α, liver pathologic score, serum ALT and AST levels (mean ± SD)

	n	TNF-α (ng/mL)	ALT (U/L)	AST (U/L)	Liver pathologic score
Control group	8	0.57 ± 0.09[b]	39.73 ± 5.10	168.00 ± 16.41	1.00 ± 0.93
NASH group	8	1.13 ± 0.15	86.63 ± 20.91[d]	379.63 ± 61.73[d]	6.00 ± 1.20[d]
Cidomycin group	8	0.63 ± 0.09[b]	70.88 ± 11.93[a,d]	318.75 ± 52.62[a,d]	4.25 ± 1.58[a,d]

[b]$P < 0.01$ *vs* NASH group; [d]$P < 0.01$ *vs* control group; [a]$P < 0.05$ *vs* NASH group.

Table 2 Small intestinal bacteria, small intestinal transit rate (mean ± SD)

	n	*E. coli* [$\log_{10}$(CFU/g)]	*Lactobacilli* [$\log_{10}$(CFU/g)]	Small intestinal motility(fraction)
Control group	8	1.28 ± 0.07	1.67 ± 0.16	0.58 ± 0.06
NASH group	8	1.70 ± 0.12[b]	1.69 ± 0.16	0.39 ± 0.11[b]
Cidomycin group	8	1.17 ± 0.08[a,d]	1.81 ± 0.13	0.51 ± 0.07[d]

[b]$P < 0.01$ *vs* control group; [a]$P < 0.05$ *vs* control group; [d]$P < 0.01$ *vs* NASH group.

The number of *E. coli* in the proximal small intestinal flora are more in the NASH group than in the control group and cidomycin group ($P < 0.01$, $P < 0.01$). Small intestinal motility are weaker in NASH group than in control group and cidomycin group ($P < 0.01$, $P < 0.01$). The number of *E. coli* are less in cidomycin group than in control group ($P < 0.05$). There are no statistic difference in small intestinal motility between control group and cidomycin group. There are no statistical differences in the number of Lactobacilli between every two groups of the three (Table 2).

DISCUSSION

It was found that NASH coexist with SIBO[19,24]. In our study excessive multiplication of *E. coli* and increased serum level of aminopherase coexist in NASH rats, that was consistent with previous studies. We thought that SIBO is an important, though not the only, pathogenesis of NASH by the fact that antibacterial treatment can alleviate the severity of NASH. We also found the level of aminopherase went up and down with serum level of TNF-α. It strongly supported TNF-α to be an important mediator in the promotion of NASH by SIBO. In our study, rats treated with cidomycin had a serum level of aminopherase slightly higher than controls and a serum level of TNF-α similar to controls. The reason or this phenomenon might be that TNF-α is not the only mediator. Generally endotoxemia was thought to be a link between SIBO and elevated TNF-α level[19,20]. But Wigg A J[25] observed that serum levels of TNF-α and endotoxin were not parallel in NASH patients. Given the disadvantage of clinical trials to control experimental conditions, and the disadvantage of C^{14} breath test in identification of bacteria, animal experiments are necessary to find the link between SIBO and NASH. Our study found a significant increase in the number of *E. coli*, a widely known source of endotoxin, in the proximal small intestinal flora in NASH group. It might support endotoxin to be the promoter to TNF-α in NASH.

With respect to the causality between SIBO and small intestinal motility in NASH, ALEJANDRO-S[22] found that delayed intestinal transit coexist with SIBO in patients effected by NASH. We also observed that NASH rats suffered both delayed intestinal motility and an increase in intestinal E. coli. It is widely believed that delayed intestinal motility could cause SIBO. Leveau P *et al*[26] noticed a delay in intestinal transit time, appeared as an early event in acute pancreatitis, preceding intestinal bacterial overgrowth, and suggested that impairment in intestinal motility probably played a role in the development of bacterial overgrowth. Gangarosa[27] demonstrated that intestinal motility served as a normal cleansing mechanism of the intestine, and drugs that decreased this motility might facilitate replication of pathogens and their attachment to or invasion of the intestinal tissue. Nieuwenhuijs *et al*[28,29], clarified the role of the migrating motor complex (MMC) in the regulation of small intestinal microflora by the fact that the disruption of MMC with morphine promotes duodenal bacterial overgrowth. Since MMC can also coordinate with the movement of the pylorus, gut and cholecyst, the alteration of MMC necessarily has an influence on the secretion of bile (the inhibiter of gram-negative bacilli). MMC might influence intestinal bacteria *via* another mechanism. Grzesiuk *et al*[30], demonstrated that intestinal bacteria, particularly those adhering to intestinal epithelial cells, were exposed to electric fields and currents generated by the muscular activity of the small intestine and that the myoelectrical activity of the duodenum, through action on cell membrane, can affect cell division of intestinal bacteria.

Though it is generally believed that insulin resistance can explain the delay of small intestinal motility in NASH, and abnormality of intestinal bacteria may be caused by delayed intestinal motility, in our experiment, treatment with antibiotics improved the abnormality of small intestinal motility in NASH rats, indicating that small intestinal bacterial can also regulate intestinal motility in NASH rats. The interpretation may be founded on the influence microflora has on intestinal smooth muscle cell myoelectricity action. Huseby *et al*[31] demonstrated that after introduction of conventional intestinal microflora the interval between activity fronts of the MMC in proximal jejunum of germ-free rats was reduced. Sjogren *et al*[32] reported that bacterial adherence to the intestinal mucosa appeared to be important in eliciting the abnormal myoelectric responses. Different intestinal bacterial genus may have different influence on intestinal motility. *E. coli* adherence to intestinal mucosa delayed spike bursts[29], reduced the frequency and amplitude of the intestinal contractions and inhibit small intestinal transit[29]. while

Lactobacillus promoted regular spike burst activity, reduced the MMC period and accelerated small intestinal transit[29]. In our study the overgrowth of *E. coli* coexist with the reduction of small intestinal motility, and the elimination of *E. coli* could increase the small intestinal motility, strongly supporting *E. coli* to be an important mediator in the small intestinal motility in NASH rats. In our study Lactobacillus didn't change according to high fat diet or cidomycin treatment, indicating Lactobacillus may not be important in the pathogenesis of NASH.

The results of this study suggest that SIBO may be not only the result of but also a promoter to delayed intestinal motility in NASH. There might be a vicious circle between SIBO and delayed intestinal motility in NASH rats. SIBO can trigger NASH *via* TNF-α, and treatment with cidomycin orally can alleviate the severity of NASH.

COMMENTS

Background

While once considered a benign process, nonalcoholic steatohepatitis (NASH) has been found to lead to cirrhosis and, in some cases, to hepatocellular carcinoma. The mechanisms underlying disease development and progression are awaiting clarification; however the finding that not all patients with steatosis develop hepatic inflammation and hepatocellular damage has led to the hypothesis that different pathogenic factors lead firstly to hepatic steatosis and secondly to hepatic damage ("the second hit"). Insulin resistance and obesity-related inflammation, among other possible genetic, together with oxidative stress, microcirculation disturbance, malnutrition are thought to play a key role in the second stage. People also found that small intestinal bacteria overgrowth (SIBO) may also play a role in the process of NASH. Some people think the medium of TNF-α to be an endotoxin, but all people do not accept this.

Research frontiers

Great effort has been and is still being done to clarify all the possible mechanism in the development of NASH, The source and pathogenesis of mediators of inflammation in the process has been the hotspot. People also want to know if it can act as a target point in the treatment of NASH.

Innovations and breakthroughs

In this article the relationship between the small bowel moment and SIBO is studied. And the cidomycin was first studied for the treatment of NASH.

Applications

This article helps to understand the process of SIBO leading to NASH, and suggests that Cidomycin might be useful in the treatment of NASH. Since there might be a vicious circle between SIBO and delayed intestinal motility, the treatment of accelerator of intestinal motility might also be useful.

Terminology

NASH: A liver disease, which resembles alcoholic liver disease consists of steatosis plus inflammation, necrosis, and fibrosis while lack of history of drinking. SIBO: Small intestinal bacterial overgrowth.

Peer review

This article tries to study the relationship between SIBO and delayed intestinal motility in NASH rats and suggest that cidomycin might be effective in the treatment of NASH. But the conclusion needs further probation in future clinical study before clinical application.

Abstract

The combination of pegylated interferon (Peg-IFN) and ribavirin is the standard of care for chronic hepatitis C virus (HCV) infection treatment. In general, common side effects related to this combination therapy are mild and are very well tolerated. However, peripheral neuropathy including demyelinating polyneuropathy related to Peg-IFN is extremely rare. We present the first case of an acute inflammatory demyelinating polyneuropathy (AIDP) associated with Peg-IFN-α 2a (Pegasys) after 16 wk of a combination therapy with Pegasys and ribavirin in a 65-year-old woman with chronic HCV infection. She developed tingling, numbness, and weakness of her upper and lower extremities and was hospitalized for acute neurological deficits. Her clinical course, neurological findings, an electromyogram (EMG), nerve conductions studies (NCS), muscle biopsy, and a sural nerve biopsy were all consistent with AIDP likely related to Pegasys use. The patient recovered completely with the use of intravenous immunoglobulin (IVIG) including physical therapy and neurological rehabilitation. It is very important that gastroenterologists and/or hepatologists recognize this rare neurological complication related to Peg-IFN treatment very early, since it requires a prompt discontinuation of therapy including an immediate referral to a neurologist for the confirmation of diagnosis, management, and the prevention of long-term neurological deficits.

INTRODUCTION

The combination of Peg-IFN and ribavirin has been shown to be an effective treatment for chronic hepatitis C. Overall, the common side effects associated with these two drugs are well known. The common side effects of IFN include flu-like symptoms and psychiatric symptoms such as depression, suicidal ideation, irritability, nervousness, and insomnia[1-5]. Less common side effects include hematopoietic suppression, reversible hair loss, hearing loss, retinopathy, dermatitis, seizures, and the development or exacerbation of autoimmune diseases such as thyroid dysfunction, rheumatoid arthritis, sarcoidosis, systemic lupus erythematosus, vitiligo, type 1 diabetes, and myasthenia gravis[1-5]. Neurological complications, however, are rare. Only some publications reported on IFN-related peripheral neuropathy including sensory neuropathy[6,7]. In addition, rare neurological complications such as vasculitic neuropathy, autonomic neuropathy, Bell's palsy, and chronic inflammatory demyelinating neuropathy (CIDP) related to IFN use have also been documented in the literature[1,5,8,9]. Here we present the case of a severe AIDP that developed at wk 16 of Pegasys therapy.

CASE REPORT

A 65-year-old white female presented to liver clinic at the University of Chicago Medical Center for chronic hepatitis C treatment. The initial physical examination was unremarkable with the exception of spider angiomata in her neck and face, and bilateral palmer erythema. Initial liver profile included aspartate aminotransferase (AST) 56 (8-37) IU/mL, alanine aminotransferase (ALT) 67 (8-35) IU/mL,

total bilirubin 0.6 mg/dL, alkaline phosphatase 77 IU/mL, albumin 4.8 g/dL, and prothrombin time (PT) 13.1 s. Serum viral load was estimated to 2414896 IU/mL with a genotype 1a. A liver biopsy examination revealed a grade I and stage Ⅲ liver disease with a focal bridging fibrosis. The patient participated in a clinical trial for chronic hepatitis C and received Pegasys 180 μg subcutaneously per week and ribavirin 1000 mg/d in divided doses orally. HCV RNA levels decreased to 416 IU/mL after 12 wk of therapy, indicating an early viral response (EVR).

Approximately 13 wk after start of the treatment, the patient presented to the University of Chicago hospital with a 24 h onset of fever, chills, nausea, vomiting, headache, and fatigue. Her chest X-ray and CT scan of chest demonstrated a right upper lobe pneumonia. A cerebrospinal fluid (CSF) analysis revealed the presence of single WBC (monocyte), glucose levels of 74 mg/dL within the normal range, and a protein level of 15 mg/dL. However, her sputum culture grew pneumococci requiring treatment with vancomycin, ceftriaxone, and moxifloxacin for pneumonia. Pegasys and ribavirin treatment thus was temporarily discontinued. The patient was discharged home with oral moxifloxacin medication and recovered from pneumonia. However, shortly after discharge, the patient developed a macular rash on the anterior and posterior chest wall with an extension of rash into the anterior abdominal wall, which was attributed to the use of antibiotics. Two weeks after the onset of pneumonia (wk 15), the patient was restarted with Pegasys and ribavirin. Unfortunately, she reported tingling, numbness, and weakness of her lower extremities 3 wk later (wk 16). Her neurological symptoms progressed rapidly over the course of 1 wk to the point of losing the ability to ambulate, and she became wheelchair bound. In addition, the patient also complained of tingling and numbness in the upper extremities involving the fingers and wrists bilaterally. Pegasys and ribavirin were discontinued due to an acute onset of weakness of upper and lower extremities. The patient was hospitalized again. The neurological examination revealed normal cranial nerves with normal bulk of muscles and tone; but a weak muscle strength (4/5) in the upper extremities as well as in hips, knees, and ankle dorsiflexion and ankle plantarflexion bilaterally. Other muscle groups were even weaker (3/5) including ankles and toes. Tendon reflexes were diminished significantly. Sensory examination revealed decreased light touch, pinprick, and temperature sensation from the feet to mid-calves as well as hands except vibratory sense. A clinical diagnosis of acquired, acute demyelinating sensorimotor polyneuropathy was made. Other laboratory tests included a normal complete blood count, chemistry profile, erythrocyte sedimentation rate, and C-reactive protein. Antinuclear antibodies, rheumatoid factor, human immunodeficiency virus (HIV) test, anti-GM1 (ganglioside) antibodies, serum cryoglobulin level, Epstein-Barr virus serology, and cytomegalovirus serology were tested negative. A second CSF analysis was acellular again with protein (29 mg/dL) and glucose (60 mg/dL) levels within the normal range. In addition, myelin associated glycoprotein antibody was tested negative, and immunoglobulin A level was normal including negative immunoelectrophoresis for monoclonal antibodies in CSF.

Table 1 EMG/Nerve conduction studies

	Distal latency (m/s)	Conduction velocity (m/s)	Amplitude (uV (sensory) mV (motor))
Sensory			
Right sural	NR	NR	NR
Left sural	NR	NR	NR
Motor			
Right peroneal	8.9	27	0.6
Right tibial	9.5	27	1.4
Left tibial	7.9	30	1.1
Right ulnar	6	37	3.9
Right median	7.6	49	2.4
Left median	7.8	48	1.1
F wave	F-Latency		
Right tibial	Unclear		
Right ulnar	42.6		
Right median	54.8		
Left median	Unclear		

NR: No response obtainable.

An EMG, NCS, and Sural nerve biopsy were consistent with an AIDP (Table 1). The patient was treated with a course of IVIG at a dose of 0.4 g/kg per day. Unfortunately, she was only able to complete 4 d of treatment due to the development of a rash and leukopenia from IVIG. The patient was subsequently discharged for physical therapy and neurological rehabilitation where she had some improvement in her ability to write, to use utensils, and to ambulate with a walker.

Even though her neurological symptoms somewhat improved after a short course of IVIG, the patient developed bilateral foot drop, loss of finger grips, and a progressive weakness and numbness in both her hands and feet four weeks later. A neurological examination revealed decreased muscle bulks in the upper and lower extremities distally. Muscle strength was weaker (3/5) in finger abduction, plantar flexion and dorsiflexion bilaterally with bilateral foot drops. Tendon reflexes were 2/4 in the upper extremities but diminished significantly in the lower extremities, including absent reflexes at patella and achilles bilaterally. Remainders of motor examinations were normal. Sensory examination revealed normal sensation in the upper and lower extremities except absence of all modalities of sensation at her toes excluding sense of vibration and decreased pinprick sensation below the knees. Laboratory findings were again negative including anti- Sjogren's syndrome A (SSA) and Sjogren's syndrome B (SSB). Subsequently, a sural nerve biopsy and a gastrocnemius muscle biopsy were obtained and findings were consistent with an AIDP without showing any vasculitic features (Table 1). The patient was treated with 5 d of 2nd course of IVIG and the symptoms of weakness and bilateral legs numbness markedly improved over two months. Six months after the completion of the 2nd course of IVIG, the patient felt very well and neurological symptoms and signs resolved completely without having any residual neuromuscular deficits.

DISCUSSION

Peripheral neuropathy is a rare and uncommon side effect

seen in patients treated with IFN-α. In recent years, a variety of peripheral neuropathies have been reported in patients treated with IFN including sensory neuropathy, autonomic neuropathy, Bell's palsy, and more recently, CIDP[6-12]. As an example, one patient who received multiple cycles of IFN-α developed parasthesias of both legs and was diagnosed with sensorimotor polyneuropathy due to high cumulative effect of IFN-α[6]. IFN-α 2a has also been shown to have caused peripheral sensory neuropathy given for a period of twenty months[7]. In this case, when IFN-α 2a was discontinued for 4 wk, peripheral neuropathy resolved. However, upon reinitiating the IFN-α 2a, the peripheral neuropathy re-appeared suggesting IFN-related neuropathy. Furthermore, Lapinski *et al* reported a case of peripheral polyneuropathy in a patient who received Pegasys for 1 mo followed by pegylated IFN α-2b (Pegintron) for 3 mo that resulted in paresis of hands and legs leading to a CIDP confirmed by an EMG[9].

The more probable etiologies in our patient included infectious processes, toxins and/or drugs, and immune-mediated processes leading to demyelinating neuropathies[13]. Viral infections such as HIV and CMV have been described to cause demyelinating neuropathy[14,15]. HIV infection can lead to peripheral neuropathy that can rapidly progress to either acute or chronic demyelinating neuropathy due to macrophage-mediated immune attachment within the endoneurial parenchyma[16]. Since HIV test was negative in our patient this was not the cause of her neuropathy. A CMV infection in a patient with chronic HCV can present as an acute Guillain-Barre syndrome (GBS)[15]. It has been hypothesized that host immune system mistakenly attacks own nerve cells that expressed similar epitope as of HCV or CMV antigen. Our patient had multiple CSF analysis that failed to detect CMV DNA. Therefore, our patient also did not have CMV-related demyelinating neuropathy.

Toxins and/or drugs are also common etiologies for demyelinating neuropathies, which can be acute or chronic in nature. Common toxins/drugs are barbital, sulfonamides, phenytoin, nitrofurantoin, heavy metals, carbon monoxide, industrial poisons, and certain AIDS drugs (e.g., zalcitabine, didanosine)[13]. Our patient had no exposure to any of these above toxins or drugs other than Pegasys, ribavirin, and moxifloxacin. There are several reported cases of moxifloxacin induced peripheral sensory neuropathy including an evidence of a tendon rupture without showing demyelinating neuropathy[17]. Similarly, ribavirin also has not been associated with any type of reported neuropathy. But Pegasys including IFN-α has been implicated to cause immune mediated CIDP during chronic hepatitis C treatment[5,8] due to cytokine-induced apoptosis in the myelin-producing oligodendrocyte resulting in inhibition of central nervous system remyelination thus causing demyelinating neuropathy[5,18,19]. To the contrary, IFN-α has also been shown to be a successful treatment in patients with CIDP[8]. However, if a patient develops demyelinating neuropathy secondary to IFN use, it should be discontinued immediately since it may cause irreversible nerve damage due to inhibition of remyelination process. Two cases of CIDP have been described either with Pegasys or IFN-α use[5,8]. In both cases, parasthesia and muscle weakness developed 6 wk after therapy and lasted more than 8 wk suggesting CIDP. It has been shown that patients with CIDP respond to prednisone, plasma exchange, and IVIG[5,20,21]. The time course for our patient's symptoms was not long enough to meet the criteria for a CIDP. The criteria for CIDP usually include the clinical deterioration of neurological symptoms for a period of greater than 8 wk as opposed to AIDP and/or GBS, which usually has deterioration over a period of approximately 4 wk or less[21]. Furthermore, immune-mediated AIDP of GBS type has been reported after infection, post-vaccination, or surgery and also accounts for a significant portion of demyelinating polyneuropathies[13]. In our patient, there was an initial high suspicion for AIDP of GBS type due to a pneumonia prior to neurogical symptoms and signs. Her time course fit an acute demyelinating neuropathy given that it developed approximately 3 wk later. A typical presentation of GBS includes a significant motor weakness along with mild to moderate paresthesias. The muscle weakness typically starts in the distal muscles of the lower extremities and weakness ascends rapidly involving upper extremities. In addition, CSF analysis usually reveals an elevated protein level with normal white blood cell count. Even though our patient's presentation was suggestive of a GBS due to a preceding pneumonia, CSF analysis on multiple occasions revealed a normal CSF protein. Furthermore, our patient had significant painful paresthesias that are not commonly seen in GBS. Thus, the clinical course including normal CSF protein and painful paresthesias was not suggestive of a typical GBS, but rather suggestive of an acute immune mediated process related to Pegasys use as AIDP. The pathogenesis of AIDP related to Pegasys use is thought to be an acute immune-mediated progress similar to GBS. The precise and exact immune regulatory function of IFN-α including Peg-IFN is not well understood and it is likely similar to mechanism associated with IFN induced CIDP described above[5,18,19]. In addition, IFN-α has been reported to enhance *in vivo* and *in vitro* autoantibody production and may upregulate transcription of genes associated with class I major histocompatibility complex (MHC) antigens[22]. It is likely that the levels of proinflammatory cytokines may trigger autoimmune phenomena in immunologically predisposed individuals when IFN is administered. Therefore, the immune system mistakenly attacks the host's nerve tissue after recognizing a molecular epitope similar to a foreign antigen and may result in acute inflammatory neuropathy[23]. Immunomodulation with plasma exchange or IVIG usually shortens the disease process and provides the best outcome[23]. Our patient fit this clinical picture of an acute inflammatory neuropathy and showed a quick response to IVIG therapy.

One other possible immune-related process as the etiology of the demyelinating neuropathy would be IgM binding to Myelin-Associated Glycoprotein (MAG). Demyelinating polyneuropathy with monoclonal IgM is often associated with anti-MAG autoantibodies[24]. Our patient was negative for this antibody including negative immunoelectrophoresis suggesting this is not the case.

Vasculitic neuropathy, an autoimmune process may

also occur in association with chronic HCV infection. Generally, patients may develop a chronic symmetrical axonal sensorimotor peripheral polyneuropathy due to a necrotizing vasculitis[25]. Subsequent treatment with IFN-α can worsen vasculitic neuropathy[25]. In addition, there have been multiple reported cases of GBS associated with HCV related to cyroglobulinemia[26,27]. However, our patient had an undetectable cryoglobulin level on multiple occasions, which rules out a possibility of cryoglobulin induced demyelinating neuropathy.

In conclusion, the treatment of chronic HCV infection has come a long way in recent years. Physicians and other medical providers must be aware of possible side effects, including demyelinating neuropathy in patients who are treated with IFN and/or pegylated IFN in addition to HCV/cryoglobulin related neuropathy. As we learned from our case, Pegasys may cause neurological symptoms including AIDP. In addition, it is imperative on the part of the health care providers recognize AIDP very early for the diagnosis and treatment including the prevention of a long-term neurological complication by obtaining a neurology consultation.

Abstract

The literature illustrates the important issue of physician adherence to guidelines in their daily practice. In a quantitative study, we asked a random sample of 100 hospital gastroenterologists to evaluate their knowledge of guidelines and awareness of promoters. The degree to which guidelines were considered reliable was not related to the scientific evidence but was significantly associated with the promoter. The French Society of Gastroenterology was considered to be a more reliable promoter than national health agencies and pharmaceutical industries. Gastroenterologists become aware of guidelines mainly through their specialty society (62%). Specialty societies appear to be a more important source of information on guidelines for physicians. National health agencies should involve the specialty societies in the guideline development process to achieve changes in clinical practice.

TO THE EDITOR

Recently, Grassini *et al*[1] have shown that the percentage of inappropriate referrals for colonoscopy in an open-access endoscopy system is still high, despite the number of papers published on the issue and the definition of international guidelines. These results illustrate the important issue of physician adherence to guidelines in their daily practice.

In a study carried out in 2005, we showed how gastroenterologists judge and adhere to guidelines, based on who promotes them. Using a multiple-choice questionnaire, we asked a random sample of 100 hospital gastroenterologists to evaluate their knowledge of guidelines and awareness of promoters, and investigated how they became aware of the guidelines. The overall response rate was 71%. The degree to which guidelines were considered reliable was not related to the scientific evidence on which they were based (consensus conferences were considered more reliable compared to clinical practice guidelines 89.5% *vs* 77.6%, $P < 0.01$), but rather was significantly associated with the promoter. Specifically, the French Society of Gastroenterology was considered to be a more reliable promoter than national health agencies and pharmaceutical industries (67.4 *vs* 11.6 and 0.8%, $P < 0.001$).

Gastroenterologists become aware of guidelines mainly through their specialty society (62%), but also through congresses (31%), hospital colleagues (23%) and medical publications (14%). The main resources used for finding guidelines are the websites of specialty societies.

According to these results, peers and, in particular, specialty societies appear to be a more important source of information on guidelines for physicians. When previous studies have shown that the quality of some guidelines developed by specialty societies might be unsatisfactory, the authors have not criticized the specialty societies' influence for supporting guidelines[2,3]. Only the lack of explicit methodological criteria for production of guidelines was confirmed. Grol has recommended targeting each specific type of public for a best integration of the guidelines and an real impact in clinical practices[4]. Since many medical specialists (such as gastroenterologists, internists and primary care physicians) intervene in the field of gastroenterology, the target audience of the guidelines is very diverse and difficult to reach. National health agencies should integrate the specialty societies into the guideline development process to achieve change in clinical practice.

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008
Istanbul

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327/ CN 14-1219/R) is a weekly journal of with a circulation of more than 15707, published on the 7th, 14th, 21st and 28th of every month. *WJG* is a peer-reviewed journal. The number of overseas users with an independent IP address was 15600, representing 123 countries worldwide. Original research, reviews, comments, and case reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted elsewhere simultaneously.

Publication model

WJG is a journal with a so-called public beneficial publication model, which consists of an Open Access and the commercialized publication model (i.e. payment by the third party). This publication model has been proven very effective and produced fruitful outcome. By 21st December 2007, the number of visit hits to the *WJG* website has reached 21350084. *WJG* advocates the tenet that the research funding granted to scientists be used to serve scientists, by which high quality scientific articles can be published.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from the organization in which the author(s) works should be provided with the contributed article to warrant not give away any secret and if the contributed article is completed in cooperation by authors from different organizations, a letter of recommendation from each of the organizations should be provided to ensure not given away any secret.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained in the mailing process.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381901-600. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. font with ample margins. The preferred font is Book Antiqua. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, author contributions; disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analysed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend. Otherwise, article is rejected. Reviewers are acknowledged in the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou Univerisity, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, that reflect the content of the study.

Text

For articles of these sections, original articles, rapid communicatin and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. As require, figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. The examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is nessesary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to make out the high resolution-figures of E-version or the printed one.

Tables

Three-line tables should be numbered 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate that already contained in the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "Fom references [19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

DOI roots in the serial number indexed by CrossRef (http://www.crossref.org/guestquery/). DOIs are required for journal articles, conference papers and book titles but are optional for journal titles, volumes and issues and book chapters/entries and components. CrossRef is currently working on expanding the types of content it registers DOIs for to include theses and dissertations and database records. The author should supply the DOI for journal citation.

The accuracy of the information of the journal citations is very important. We will interlink all references with DOI in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Electronic journal (list all authors)

Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter and responses, to reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a CAF from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After the manuscript goes online, links to PDF edition of submitted manuscript, peer-reviewers' report and revised manuscript will be created. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors could benefit from the feedbacks and revise the manuscript according to the comments in real time.

Science news releases

Authors of accepted manuscripts are suggested to write science news to their articles as both following guidelines and samples, and the news will be released soon at EurekAlert/AAAS --http://www.eurekalert.org. The title for news is less than 90 characters. The summary for news is less than 75 words, and main body less than 500 words. The science news should be lawful, ethical, and tightly based on your original contents with attractive title and amusing pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Contents

EDITORIAL

329 What's new in inflammatory bowel disease in 2008?
Baumgart DC

TOPIC HIGHLIGHT

331 Primary sclerosing cholangitis, autoimmune hepatitis and overlap syndromes in inflammatory bowel disease
Saich R, Chapman R

338 Inflammatory bowel disease: Genetic and epidemiologic considerations
Cho JH

348 Epithelial restitution and wound healing in inflammatory bowel disease
Sturm A, Dignass AU

354 Treatment of inflammatory bowel disease: A review of medical therapy
Kozuch PL, Hanauer SB

378 Cancer in inflammatory bowel disease
Xie J, Itzkowitz SH

390 Immunopathogenesis of inflammatory bowel disease
Shih DQ, Targan SR

401 Role of the intestinal barrier in inflammatory bowel disease
Laukoetter MG, Nava P, Nusrat A

408 Recent trends in the surgical management of inflammatory bowel disease
Roses RE, Rombeau JL

413 Special issues in pediatric inflammatory bowel disease
Dubinsky M

GASTRIC CANCER

421 Correlation of integrin β3 mRNA and vascular endothelial growth factor protein expression profiles with the clinicopathological features and prognosis of gastric carcinoma
Li SG, Ye ZY, Zhao ZS, Tao HQ, Wang YY, Niu CY

COLORECTAL CANCER

428 Inhibition of signal transducer and activator of transcription 3 expression by RNA interference suppresses invasion through inducing anoikis in human colon cancer cells
Fan Y, Zhang YL, Wu Y, Zhang W, Wang YH, Cheng ZM, Li H

World Journal of Gastroenterology
Volume 14 **Number** 3 **January** 21, 2008

Contents

BASIC RESEARCH	435	Effect of Daxx on cholesterol accumulation in hepatic cells *Tuo QH, Liang L, Zhu BY, Cao X, Liao DF*
	441	Experimental study on operative methods of pancreaticojejunostomy with reference to anastomotic patency and postoperative pancreatic exocrine function *Bai MD, Rong LQ, Wang LC, Xu H, Fan RF, Wang P, Chen XP, Shi LB, Peng SY*
CLINICAL RESEARCH	448	Management of gastric fundal varices without gastro-renal shunt in 15 patients *Kameda N, Higuchi K, Shiba M, Kadouchi K, Machida H, Okazaki H, Tanigawa T, Watanabe T, Tominaga K, Fujiwara Y, Nakamura K, Arakawa T*
	454	Effectiveness and safety of herbal medicines in the treatment of irritable bowel syndrome: A systematic review *Shi J, Tong Y, Shen JG, Li HX*
RAPID COMMUNICATION	463	Enteral glutamine pretreatment does not decrease plasma endotoxin level induced by ischemia-reperfusion injury in rats *Demirkan A, Orazakunov E, Savaş B, Kuzu MA, Melli M*
	469	Single-center study comparing computed tomography colonography with conventional colonoscopy *Roberts-Thomson IC, Tucker GR, Hewett PJ, Cheung P, Sebben RA, Khoo EEW, Marker JD, Clapton WK*
	474	Impact of alanyl-glutamine dipeptide on severe acute pancreatitis in early stage *Xue P, Deng LH, Xia Q, Zhang ZD, Hu WM, Yang XN, Song B, Huang ZW*
	479	Comparison of real-time polymerase chain reaction with the COBAS Amplicor test for quantitation of hepatitis B virus DNA in serum samples *Shi M, Zhang Y, Zhu YH, Zhang J, Xu WJ*
CASE REPORT	484	Secondary aortoduodenal fistula *Geraci G, Pisello F, Li Volsi F, Facella T, Platia L, Modica G, Sciumè C*
LETTERS TO THE EDITOR	487	Natural Killer T cells and non-alcoholic fatty liver disease: Fat chews on the immune system *Kremer M, Hines IN*
APPENDIX	489	Meetings
	490	Instructions to authors

Abstract

Ulcerative colitis and Crohn's disease represent the two major forms of inflammatory bowel disease. In this highlight topic series of articles we cover the latest developments in genetics and epidemiology, intestinal physiology, mucosal immunology, mechanisms of epithelial cell injury and restitution, current medical therapy, modern surgical management, important extra-intestinal complications such as primary sclerosing cholangitis, cholangiocellular carcinoma and autoimmune hepatitis as well as endoscopic and molecular screening, detection and prevention of small bowel and colorectal cancer.

Baumgart DC. What's new in inflammatory bowel disease in 2008? *World J Gastroenterol* 2008; 14(3): 329-330 Available from: URL: http://www.wjgnet.com/1007-9327/14/329.asp DOI: http://dx.doi.org/10.3748/wjg.14.329

In this special issue of the *World Journal of Gastroenterology* we have put together a group of expert faculty from all over the world to cover inflammatory bowel disease as a highlight topic.

Ulcerative colitis and Crohn's disease represent the two major forms of inflammatory bowel disease. Crohn's disease was first observed by the German surgeon Wilhelm Fabry (aka Guilhelmus Fabricius Hildanus) in 1623, and was later described by and named after the New York physician Dr Burril B Crohn[1,2]. Ulcerative colitis (UC) was first described by the London physician Sir Samuel Wilks in 1859[3].

Much has been learned since these early days about the etiology and particularly the genetic predisposition for these two disorders. The first paper in our series reviews the current knowledge about the etiology of inflammatory bowel disease. While all genome wide scans in the past have identified increased susceptibility genes, the most recently discovered susceptibility allele (IL23R) protects from Crohn's disease. The first article in our series puts this discovery in genetics in perspective with disease mechanisms and other etiological factors and its potential impact on the development of novel therapeutic strategies[4].

The most widely accepted hypothesis for the cause of inflammatory bowel disease is a disturbed interaction of the host immune system with the commensal microflora and other luminal antigens. This interaction begins at the epithelial layer and extends below to a multitude of other immune cells of the mucosal interface. Ultimately, mature and activated antigen presenting cells, (i.e. dendritic cells) induce and probably perpetuate an imbalance of effector and regulatory T-cell. Crohn's disease is a mainly a Th1 and Th17 mediated process, while ulcerative colitis appears to be predominately mediated through Th2 and NK T-cells. Two papers review the effects of these components in the immunopathogenesis of IBD[5,6].

Once the inflammation has occurred and is perpetuated by the dysfunctional immune system, the clinician is faced with distinct clinical phenotypes. Fortunately, the integrity of the gastrointestinal surface epithelium is rapidly reestablished even after extensive destruction. Rapid resealing of the epithelial barrier following injury is accomplished by a process termed epithelial restitution, followed by more delayed mechanisms of epithelial wound healing including increased epithelial cell proliferation and epithelial cell differentiation. Restitution of the intestinal surface epithelium is modulated by a range of highly divergent factors among them a broad spectrum of structurally distinct regulatory peptides, variously described as growth factors or cytokines[7].

Recent advances in our understanding of the pathophysiology of inflammation and in bioengineering have led to new therapeutic concepts targeting almost every aspect of the inflammatory process and help with the restitution of mucosal integrity. This provides clinicians with the opportunity of selecting from and combining conventional compounds and concepts as well as modern biologics and novel approaches to regimens tailored to the individual patient's needs[8].

Special issues in pediatric inflammatory bowel discussed are discussed in a separate paper[9].

Surgery has become an integral part of the management of inflammatory bowel disease and should not be considered a failure of medical management. Modern surgical techniques including minimally invasive procedures and current issues of surgical management are reviewed[10].

Inflammatory bowel disease is a systemic illness, not limited to the gastrointestinal tract. A substantial fraction of patients develops extra-intestinal manifestations, which itself can cause additional morbidity and complications. Hepatic manifestations and especially primary sclerosing cholangitis are among the most common, sometimes overlap and cause diagnostic and therapeutic challenges[11].

Finally, patients with chronic inflammatory conditions, including inflammatory bowel disease are prone to develop malignant complications. The final paper reviews current knowledge about the incidence and prevention of cancer[12].

Abstract

Primary sclerosing cholangitis (PSC) is a chronic progressive disorder of unknown aetiology characterised by chronic inflammation and stricture formation of the biliary tree. Symptoms include itch and lethargy and in advanced cases cholangitis and end-stage liver disease, however increasing numbers of asymptomatic individuals are being identified. The disease is rare in the general population but is strongly associated with inflammatory bowel disease (IBD) affecting up to 5% of patients with Ulcerative Colitis, with a slightly lower prevalence (up to 3.6%) in Crohn's disease. The strength of this association means that the vast majority (> 90%) of patients with PSC also have IBD, although many may have only mild gastro-intestinal symptoms. Usually IBD presents before PSC, although vice-versa can occur and the onset of both conditions can be separated in some cases by many years. Mean age of diagnosis of PSC is in the fifth decade of life with a strong male predominance. Risk is increased in those with a family history of PSC, suggesting a genetic predisposition and the disease is almost exclusive to non-smokers. The ulcerative colitis associated with PSC is characteristically mild, runs a quiescent course, is associated with rectal sparing, more severe right sided disease, backwash ileitis and has a high risk of pouchitis post-colectomy. Most worrisome is the high risk of colorectal malignancy which necessitates routine colonoscopic surveillance. Cholangiocarcinoma is also a frequent complication of PSC with a 10%-15% lifetime risk of developing this condition. Treatment with high dose ursodeoxycholic acid offers some chemoprotective effects against colorectal malignancy and may decrease symptoms, biochemical and histological progression of liver disease. Small duct PSC patients characteristically have normal cholangiography, and liver biopsy is required for diagnosis, it appears to have a more favourable prognosis. Autoimmune Hepatitis (AIH) is also more prevalent in patients with IBD, with up to 16% of patients with AIH also having ulcerative colitis. A small subgroup of patients have a AIH-PSC overlap syndrome and the management of these patients depends on liver histology, serum IgM levels, autoantibodies, degree of biochemical cholestasis and cholangiography as some of these patients may respond to immunosupression.

Saich R, Chapman R. Primary sclerosing cholangitis, autoimmune hepatitis and overlap syndromes in inflammatory bowel disease. *World J Gastroenterol* 2008; 14(3): 331-337 Available from: URL: http://www.wjgnet.com/1007-9327/14/331.asp DOI: http://dx.doi.org/10.3748/wjg.14.331

INTRODUCTION

The first association between colonic ulceration and liver disease was made in 1874 by Thomas CH, who described a young man who died of a 'much enlarged, fatty liver in the presence of ulceration of the colon'[1]. The association was confirmed by James Lister in 1899, who reported a patient with ulcerative colitis and secondary diffuse hepatitis[2]. Over the next 100 years it has become well established that there is a close relationship between inflammatory bowel disease and various hepatobiliary disorders. These disorders are listed in Table 1.

PRIMARY SCLEROSING CHOLANGITIS

First described by Smith and Loe in 1965[3] Primary sclerosing cholangitis (PSC) is a chronic progressive disorder of unknown aetiology characterised by inflammation, fibrosis and stricture formation in medium and large sized ducts in the biliary tree[4,5]. Common symptoms include itch and lethargy although many patients (up to 45%) are asymptomatic, even with advanced disease[5]. The disease is strongly associated with Inflammatory Bowel Disease and may be detected as an incidental finding of a raised serum alkaline phosphatase. Magnetic resonance

Table 1 Hepatobiliary disorders associated with inflammatory bowel disease

Hepatobiliary disorders	Associated with	
	Ulcerative colitis	Crohn's disease
Primary sclerosing cholangitis (PSC)		
Large duct PSC	+	+
Small duct PSC ('pericholangitis')	+	+
Cirrhosis	+	+
Hepatoma	+	+
Cholangiocarcinoma	+	+
Miscellaneous disorders		
Fatty liver	+	+
Granulomas		+
Amyloidosis		+
Hepatic abscess		+
Gallstones		+
Autoimmune hepatitis	+	
Primary biliary cirrhosis	(+)	
Budd-Chiari syndrome	(+)	(+)

+: Definite association; (+): Possible association.

Table 2 Prevalence of primary sclerosing cholangitis in patients with ulcerative colitis

Country of origin	Number of patients with ulcerative colitis	Percentage with primary sclerosing cholangitis
Oxford, UK[9]	681	2.9
Oslo, Norway[12]	336	4
Stockholm, Sweden[11]	1500	3.7 (5.5 in total colitis)

cholangography (MRCP) and endoscopic cholangiography (ERCP) are diagnostic, demonstrating the diffuse multifocal strictures and dilatation giving rise to a characteristic 'beaded' appearance (Figure 1).

Prevalence

PSC is rare in the general population. Data from Olmsted County (USA) in the year 2000 identified 20.9 cases of PSC per 100 000 of the population in men and 6.3 per 100 000 in women[6], which is similar to that seen in the UK[7]. There has been a suggestion that the incidence may be rising. In Spain the prevalence in 1988 was 2.24 per million having been 0.78 cases per million in 1984[8]. It is however unclear if this represents a true increase in the disease or improved case recognition due to improved diagnostics particularly in asymptomatic individuals.

PSC in IBD

Because of its strong association with inflammatory bowel disease (IBD) PSC is far more common in patients with ulcerative colitis (UC). The prevalence quoted in different case series varies widely, largely due to differences in the number of patients included with severe, active, or extensive inflammatory bowel disease studied and also in the method used to investigate liver dysfunction. Studies on unselected patients provide the most accurate data but are ethically difficult as both liver biopsy and ERCP are associated with significant morbidity. In an early study of unselected adult patients from Oxford, 5%-6% of the 300

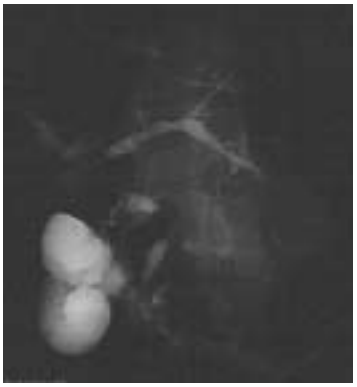

Figure 1 Endoscopic Retrograde Cholangiogram showing the classic 'beaded' appearance of bile ducts in Primary Sclerosing Cholangitis.

patients with ulcerative colitis had significant histological abnormalities on hepatic histology compared with 10% of 100 unselected patients with Crohn's disease; none of these patients underwent cholangiography[9,10]. Studies (Table 2) using selected patients include a large Swedish study of 1500 patients with UC where it was found that 5% of patients had increased serum Alkaline Phosphatase and, of those who underwent ERCP, 85% had evidence of PSC, being more common in men and those with pancolitis[11]. Other reports have found similar results. In a study from Oslo, 14% of patients had evidence of hepatobiliary pathology with 4% of patients with UC having PSC[12]. Thus it is generally accepted that approximately 5% of patients with UC will have associated PSC.

The percentage of Crohn's disease patients affected by PSC is much smaller[13]. In one study of 262 patients, 38 (15%) had abnormal liver function tests and underwent ERCP and liver biopsy, 9 of these (3.4% of the total) had PSC[14]. Crohn's disease associated with PSC is generally seen in patients who have extensive colonic or ileocolonic disease, or in paediatric populations.

IBD in PSC

Vice versa the great majority of patients with PSC have underlying IBD. The frequency with which it is recognised again varies widely depending on the intensity with which it is sought, varying from a minimum 25% of all PSC patients having IBD if identified by clinical history alone to 90% of patients if biopsies of rectum and sigmoid are taken at the time of flexible Sigmoidoscopy[15]. There are also large geographical variations in the prevalence of IBD in PSC (Table 3). Since the recognition of inflammatory bowel disease has important implications in terms of risk of colorectal cancer (PSC patients without IBD are not at increased risk of colorectal cancer and do not require colonoscopic surveillance[16]) it is the authors practice to perform colonoscopy and serial biopsies in all patients with newly diagnosed PSC.

Aetiology

The aetiology of PSC itself is unknown. The 2:1 male to female gender ratio of patients and the relatively poor response of the disease to immunosuppression suggest that PSC is not a classic autoimmune disease. However the association of PSC with IBD, autoimmune diseases, and a host of other humoral and cellular immune abnormalities

Table 3 Prevalence of inflammatory bowel disease in patients with primary sclerosing cholangitis (PSC)

Institution (country of origin)	Number of patients with PSC	Percentage with IBD
Royal Free Hospital (UK)[17]	29	72
Mayo Clinic (USA)[18]	50	70
Huddinge (Sweden)	305	72
King's College London (UK-children)	13	77
Okolicsanyi (Italy)[19]	82	54
Escorsell (Spain)	43	47
Okada (Japan)[20]	155	23

(Table 4) make an immunopathogenic mechanism likely. Particularly common serological abnormalities are raised IgM levels in up to 50% and positive anti-smooth muscle antibodies and antinuclear antibodies in up to 75%[21]. Anti Neutrophil Cytoplasmic Antibodies with a pericellular pattern (pANCA) are also a common finding, being present in 80% of patients being and unrelated to the presence or absence of UC. Cellular immunity anomalies include portal tract infiltration of functional T cells, restricted T cell receptor repertoire, and aberrant expression of HLA and costimulatory molecules on biliary epithelial cells.

Immunogenetic studies have identified a number of key HLA haplotypes (Table 5) associated with PSC, HLA-B8/DR3 haplotype being particularly common in patients with PSC and UC and infrequent in patients with PSC alone[22]. This haplotype is also associated with other organ-specific autoimmune disease including coeliac disease, thyrotoxicosis, lupoid autoimmune hepatitis, myasthenia gravis, and type 1 diabetes mellitus. However PSC, independent of HLA type, is also associated with a range of autoimmune diseases, diabetes mellitus and Graves disease being the most common. Saarinen *et al* found that 25% of patients with PSC had one or more autoimmune disease, compared to 9% of patients with inflammatory bowel disease alone[23].

Possible explanations for the PSC association with IBD include the development of autoantibodies to an unknown antigen in an immunogenetically susceptible host which cross reacts with biliary and colonic epithelium and is capable of inducing complement activation[24]. Alternatively, the initiation of the immune response may be the ingress of bacteria or other toxic metabolites through the diseased bowel wall.

CLINICAL COURSE

Onset

PSC is a disease of middle age with a mean age of diagnosis is 40 years in men and 45 years in women. Bowel symptoms have usually developed before those of PSC and UC is therefore usually diagnosed several years before PSC. However occassionally symptoms of PSC may precede IBD by up to 4 years[25]. The age of onset of the symptoms also has important implications as there is evidence to suggest patients with Colitis in childhood have a high prevalence

Table 4 Evidence for the influence of immune mechanisms on the aetiology of PSC

Humoral immunity	Increased circulating immune complexes
	Elevated immunoglobulin levels (IgG and IgM)
	Low titres of non-organ specific autoantibodies (ANA and SMA)
	High titres of antineutrophil antibodies
	Autoantibodies to BEC surface antigens
Cell mediated immunity	Decreased levels of circulating peripheral CD8+ve Tcells
	Portal T cell and NK cell infiltrate
	Increased activated and memory T cells
	Restricted T cell receptor repertoire (Vβ3)
	Aberrant expression of HLA-DR on BEC
	Coexpression of costimulatory molecules and HLA-DR on BECs
	Increased circulating and tissue bound adhesion molecules
Immune effector mechanisms	Enhanced cytokine expression in the liver
Immunogenetic mechanisms	HLA associations

Table 5 Key HLA haplotypes associated with primary sclerosing cholangitis

Haplotype	Significance in PSC
B8-TNF*2-DRB3*0101-DRB1*0301-DQA1*0501-DQB1*0201	Strong association with disease susceptibility
DRB3*0101-DRB1*1301-DQA1*0103-DQB1*0603	Strong association with disease susceptibility
DRB5*0101-DRB1*1501-DQA1*0102-DQB1*0602	Weak association with disease susceptibility
DRB4*0103-DRB1*0401-DQA1*03-DQB1*0302	Strong association with protection against disease
MICA*008	Strong association with disease susceptibility

of liver abnormalities than adults, with up to 60% children having abnormal liver function tests[26].

Risk factors

Unlike other immune mediated diseases PSC is far more common in men with 70% of all PSC patients being male. This male preponderance is absent in PSC patients without associated IBD, being equally common in both males and females[27]. In addition to IBD and male sex, another recognised risk factor is a family history of the disease, There is a 0.7% risk in first degree relatives of patients with PSC rising to 1.5% in siblings of affected individuals[28].

Smoking is a well recognized protective factor against the development of ulcerative colitis, and three studies have suggested that cigarette smoking may also additionally protect against the development of PSC. Moreover, this protective effect was more marked in patients with primary sclerosing cholangitis than ulcerative colitis and was seen in patients with and without inflammatory bowel disease[29-31]. The mechanism of protection in both disorders remains unknown.

Clinical characteristics of IBD associated with PSC

There are a number of unique features of Ulcerative

Colitis associated with PSC (Table 6). The colitis is often mild, asymptomatic and runs a quiescent course[32]. It is associated with rectal sparing[33]; and therefore not seen on rigid sigmoidoscopy; is often more severe proximally and associated with backwash ileitis. It may be visible microscopically with a relatively normal macroscopic appearance and pouchitis is far more common after colectomy and ileo-anal pouch formation, occurring in up to 60% of PSC patients compared to 15% in patients with UC alone[34].

Most importantly PSC is a significant risk factor for the development of carcinoma of the colon in patients with inflammatory bowel disease[35-37]. A meta-analysis demonstrated a four fold increase in colon cancer in UC patients with PSC when compared to UC alone (RR 4.26 95% CI 2.8-6.48)[38]. The risk of proximal cancer is particularly increased[37,39]. Additional risk factors are duration and extent of disease and a family history of colorectal cancer[40]. Current U.K. guidelines therefore recommend annual screening colonoscopy in IBD patients with PSC[41].

Treatment of PSC with ursodeoxycholic acid appears to have a chemopreventative effect decreasing the incidence of carcinoma of the colon and is therefore recommended[42]. Treatment with 5-aminosalicylic acid (5-ASA) compounds have also been shown to reduce the risk of colorectal cancer in general patients with UC[43]. There are no studies specific for PSC/IBD patients in this context but it is reasonable to infer that it will be protective and is also therefore recommended.

Prognosis

Despite treatment however PSC is generally progressive and prognosis poor. Median survival without liver transplantation after diagnosis is approximately 12 years[44] with survival worse for those who are symptomatic at presentation[45].

The major cause of mortality is the occurrence of cholangiocarcinoma, which is significantly increased in patients with PSC who display a 10%-15% lifetime risk of developing the disease. This risk is higher in patients with associated inflammatory bowel disease than those with PSC alone, with an estimated annual incidence of 0.5%-1%[46-48]. Unfortunately there remains no validated screening tool for cholangiocarcinoma and therefore tumours often present at an advanced stage and have a poor prognosis. Other complications of PSC include osteoporosis, this is a frequent finding the mechanism of which remains unclear[49]. Bone density measurement should therefore be considered in these patients.

PSC treatment

Treatments which have been tried in an attempt to prevent progression of the liver disease to cirrhosis and to decrease the risk of complications especially malignancy include tacrolimus[50], methotrexate[51], corticoteroids[52], D-penillamine[53], etanercept[54], cyclosporin[55], azathioprine, 6-mercaptopurine[56] and pentoxifylline[57]. None of these agents have demonstrated any consistent benefit.

Ursodeoxycholic acid (UDCA) is the only drug which has been demonstrated to have a positive effect. It is also the most extensively studied[58] with some, but not all, studies showing improvements in biochemistry, symptoms and histology[59-64]. The most promising data is for long term UDCA used at high dose, 20-30 mg/kg per day (in divided doses), as this may increase clinical benefit and decrease histological progression of disease[65,66]. In view of its chemopreventative effect against colon cancer and its low incidence of side effects, high-dose UDCA is currently the best available treatment for PSC.

Table 6 Clinical, Endoscopic, and Histological findings that characterize IBD-PSC

Male predominance
Quiescent colitis
Pancolitis
Rectal sparing
Backwash ileitis
Pouchitis
Colorectal dysplasia/carcinoma
Different extracolonic manifestations

The concurrence of both conditions also requires that the impact of treatment of either disease on the other must be considered. Proctocolectomy appears to have no effect on liver biochemistry, histology or survival of patients with PSC and chronic UC[67]. However the natural history of UC following liver transplantation is variable[68-72]. One study showed approximately a third had improvement in colitis, a third remained unchanged and a third suffered increased activity of colonic disease[73]. Several series report increased rates of colon cancer and colectomy after liver transplantation[74-76]. It remains unclear if this is due to longstanding immunosuppressant use or confounding variables such as long duration of disease.

SMALL DUCT PSC

A variant of the disease called 'small duct PSC' is applied to the small percentage of patients with characteristic clinical findings but who have a normal cholangiogram. The absence of macroscopic abnormalities necessitates liver biopsy for the diagnosis of small-duct PSC. Characteristic features of PSC on liver biopsy are concentric rings of connective tissue around bile ducts, the so-called 'onion ring' appearance[77]. Other features which are less specific include enlargement of the portal triads, periportal inflammation with mononuclear and polymorphonuclear cells, oedema and bile duct proliferation. Extension into the hepatic parenchyma with bridging fibrosis and ultimately cirrhosis represents advanced disease.

Small duct PSC appears to have a more favourable prognosis with a median survival 29.5 years compared to 17 years for classical PSC[78-81], although occasionally patients with small duct PSC progress to large duct disease.

AUTOIMMUNE HEPATITIS AND OVERLAP SYNDROMES IN IBD

Patients with IBD are also at increased risk of other of

immune mediated liver disease including autoimmune hepatitis (AIH). In one study, UC was present in 16% of patients with AIH[82]. AIH and PSC may also occur within the same individual and it remains unclear if this represents the independent occurrence of both diseases, either sequentially or concurrently, the presence of a distinct overlap syndrome or different stages in the evolution of a single disease entity.

Difficulties with definitions and thus classification of these patients has led to widely varying estimates as to the frequency of the coexistence of the two conditions with studies ranging from 7.6% to 53.8%. of patients with PSC have features of AIH[83-89]. and conversely an abnormal cholangiogram being present in 42% of patients with AIH and UC. The association between AIH and PSC appears more common in the paediatric population.

Patients with PSC should be suspected of having associated AIH or AIH-PSC overlap if they have interface hepatitis on biopsy, high serum IgG levels, lower ALP and the presence of autoantibodies (ANA or SMA titre > 1:40). It is important to identify these patients as they maybe responsive to treatment with steroids[85].

Patients with AIH should be suspected of having associated PSC or AIH-PSC overlap[90] if they have pruritis, UC, bile duct abnormalities on histology, cholestatic liver biochemistry (ALP × 2 ULN) and abnormal cholangiography. These patients tend to be unresponsive to steroids[87,91-93].

CONCLUSION

From the original descriptions of liver disease associated with disease of the bowel over a century ago much progress has been made. The association of inflammatory bowel disease with PSC, AIH and overlap syndromes is now well established and much is known on the epidemiology and course of the conditions. Although there remain many more questions than answers, an increasingly developed concept of hepatobiliary disorder in inflammatory bowel disease has emerged. It is suggested that the major hepatobiliary diseases seen in association with both UC and Crohn's disease, namely PSC, cirrhosis, cholangiocarcinoma, and most cases of autoimmune hepatitis, represent different aspects of the same spectrum of hepatobiliary disease. However what is cause, what is consequence and what is coincidence remains to be seen.

Abstract

Genome-wide association studies have firmly established that many genomic loci contribute to inflammatory bowel disease, especially in Crohn's disease. These studies have newly-established the importance of the interleukin 23 and autophagy pathways in disease pathogenesis. Future challenges include: (1) the establishment of precisely causal alleles, (2) definition of altered functional outcomes of associated and causal alleles and (3) integration of genetic findings with environmental factors.

INTRODUCTION

The fields of genetics and epidemiology share a common goal of identifying specific factors, present in some individuals, and absent in others, that contribute to disease causation. As with many diseases, in inflammatory bowel disease (IBD), carefully performed epidemiologic studies provide an ongoing basis for the rationale and design of genetic studies. Observations on the nature and magnitude of familial clustering of IBD cases provided the framework for the present genetic observations that Crohn's disease (CD) and ulcerative colitis (UC) share some susceptibility alleles (e.g. *IL23R*) whereas others are unique to one disease subtype or the other. This review summarizes present understanding of the genetics and epidemiology of IBD, and describes the encouraging early results from genome-wide association studies which demonstrate significant consistency between studies.

EPIDEMIOLOGIC OBSERVATIONS FORM THE BASIS FOR GENETIC STUDIES IN IBD

Familial risk in IBD

The observation that cases of IBD cluster within families suggested that both shared genetic and environmental factors could contribute to disease pathophysiology. That monozygotic (MZ) twin concordance is significantly higher than dizygotic (DZ) twin concordance for both CD (20%-50% *vs* 0%-7%, respectively) and UC (14%-19% *vs* 0%-5%, respectively) indicates that genetic factors definitively contribute to both disorders[1-4]. The observation that, even among MZ twins, disease concordance is significantly less than 100% demonstrates the significant role that environmental and developmental factors play in disease pathogenesis. Like most genetic disorders, inheritance in IBD does not follow a simple Mendelian pattern. This would indicate that no single gene mutation is sufficient and/or necessary to contribute to disease, indicating that IBD represents complex, multigenic genetic disorders. In complex genetic disorders, any single gene mutation/polymorphism will not confer a simple determinative effect of disease development (as is the case for Mendelian, single-gene disorders), but rather merely confers a statistically increased, but non-determinative susceptibility to developing disease. Approximately 5% to 20% of patients with IBD have a family history of IBD[5,6]. A family history of IBD is generally more prevalent among CD than UC patients[6]. The relative risk to siblings, λs, (sibling risk compared to general population risk) ranges from 30-40 for CD and 10-20 for UC[7,8]. Furthermore, the relative risk for UC to siblings of a CD proband was observed to be 3.9 and the cross-disease relative risk to siblings of a UC proband was observed to be 1.8, suggesting that CD and UC are genetically related[9].

Comparative prevalence of IBD

The prevalence of CD and UC is highest in North America, northern Europe, and the United Kingdom, with averages ranging from 100 to 200 cases per 100 000[10-13]. IBD is more common in European Americans compared with African Americans, and the lowest rates of IBD have been reported in Hispanics and Asians[7,14-17]. The

prevalence of CD based on inpatient and outpatient visits in a Southern California Kaiser HMO study was 43.6 per 100 000 for European Americans, 29.8 per 100 000 for African-Americans, 5.6 per 100 000 for Asians and 4.1 per 100 000 for Hispanics[18]. However, two different Kaiser HMO studies found similar rates of hospitalizations among African-American and European ancestry individuals[18,19]. In addition, a more recent study demonstrated a similar incidence of IBD in African-Americans and European Americans[20]. Within European ancestry populations, the rates of IBD are higher in persons of Jewish ancestry than other ethnic groups[14,21], and higher in Ashkenazi (Central and Eastern European) Jews than in Sephardic (Middle Eastern and Spanish ancestry) Jews[14,21].

The hygiene hypothesis

Generally, IBD incidence is lower in developing countries and higher in industrialized countries, such as in North America and Europe; as a country undergoes the transition to industrialization, the prevalence of UC rises first, followed by a rise in the prevalence of CD[10]. The hygiene hypothesis proposes that lack of exposure to select microbial agents in childhood causes IBD[22]. In support of this, in Manitoba, patients with CD are less likely to have lived on a farm and less likely to have drunk unpasteurized milk. Furthermore, CD patients were more likely to have used tap water rather than well water, and more likely to have had a pet[23]. Against this hypothesis, a separate study of pediatric IBD observed that owning a pet, day-care attendance, and "physician diagnosed infection" between 5 and 10 years of age was associated with increased CD risk, and regular use of a personal towel and lesser crowding in the home with decreased risk[24].

The measurable changes in disease incidence in various geographic regions highlights the contributory role of environmental factors in IBD pathogenesis. A leading culprit for such environmental contributions is a changing intestinal intraluminal microbial milieu. At birth, the intestinal lumen is largely sterile[25], with rapid bacterial colonization ensuing in the neonatal period. There is some evidence to suggest that fecal colonization patterns may reflect environmental cues in the perinatal period and thus may be manipulable[26,27] as a potential means of preventing disease in high risk individuals.

Tobacco and IBD

Within Western countries, smoking is the most well established environmental risk factor, increasing risk for CD by approximately two-fold[28] and non-smoking decreasing risk for UC two- to five-fold[14]. Being an ex-smoker increases the risk of developing UC two-fold[29]. Ex-smokers make up an increasing percentage of older patients diagnosed with UC, accounting for more than 35% of the attributable risk of late onset (> 45 years) UC and a large component of the second peak in diagnosis[30]. Interestingly, Bridger *et al* observed that in IBD pedigrees with UC/CD sibling pairs, smokers tend to develop CD and non-smokers UC (O.R. 10.5)[31]. A significant increase in smoking in younger patients with familial CD has been reported[30]. Smoking is also associated with early recurrence of CD following surgery[32]. Future genetic studies in IBD will explore whether specific genetic associations will be stratifiable based on tobacco status at the time of diagnosis. However, tobacco may exert many of its phenotypic effects through epigenetic (reversible, changes in gene regulation that occur without a change in DNA sequence or genotype) mechanisms, such as DNA methylation effects on transcriptional activation[33].

HUMAN GENETIC VARIATION AND THE HAPMAP PROJECT

The most abundant of the human genetic variants are single nucleotide polymorphisms (SNPs). A SNP is a DNA sequence variation occurring when a single nucleotide, A, T, C, or G, in the genome differs between individuals, or between homologous chromosomes within an individual. Three salient features of SNPs include, (1) their allele frequencies within a population of interest, (2) their correlation, or linkage disequilibrium, with SNPs in the immediate genomic vicinity, and (3) whether or not the SNP of interest results in a measurable phenotypic change in protein function and/or expression, that is, represents a functional polymorphism.

As a very general rule, SNPs with a minor allele frequency approaching 50%, are genetically more ancient, having had a longer time to increase in frequency, and are more likely to be observed in all racial groups. In contrast, uncommon SNPs having a minor allele frequency of less than 5% (that is 5 of 100 chromosomes tested from 50 individuals carry the minor allele) are more likely to be evolutionarily more recent, and are often observed uniquely in one racial group or another. A number of factors besides the evolutionary age of a SNP can affect its frequency within a population, notably whether or not the SNP confers a selective advantage or disadvantage with respect to reproductive fitness within a population. It may be speculated that functional SNPs that contribute to the development of chronic inflammatory disorders such as IBD may confer a selective advantage with respect to combating historically significant infectious pathogens.

It is estimated that there are 5 million SNPs common SNPs having a minor allele frequency greater than 10%[34]. In order to comprehensively sample all common variation throughout the genome, however, it is not required that millions of SNPs be directly tested, due to the high degree of correlation, or linkage disequilibrium that exists between SNPs throughout the human genome. The Human HapMap Project empirically defined the linkage disequilibrium patterns in European, African and Asian cohorts and provided the basis for the genome-wide association studies that increasingly being reported for various complex genetic disorders[35]. It is estimated that genotyping several hundred thousand SNPs in European ancestry cohorts will sample nearly 80% of the common human variation with an r^2 (measure of linkage disequilibrium) of greater than 0.8[36].

The costs of genotyping several hundred thousand SNPs continue to decrease, and therefore genotyping sufficiently large cohorts to identify IBD genes through genome-wide association studies is now feasible. Once

associations with SNPs are identified, the challenge remains to identify the functional polymorphisms that account for the statistical association. The precedent from Mendelian disorders would suggest that those amino acid variants which directly affect protein structure are likely to disproportionately contribute to disease susceptibility. Within amino acid polymorphisms, those variants in highly conserved (between species) regions or contained within key functional domains are more likely to have significant functional effects. Ultimately, however, proof of disease contribution requires demonstration of altered functional effects associated with the mutation of interest.

IBD GENETIC ASSOCIATIONS PRIOR TO THE ADVENT OF GENOME-WIDE ASSOCIATION STUDIES

Because the statistical effects observed in multigenic disorders are relatively modest, the hallmark for accepting genetic associations is replication in independent cohorts. However, interpretation of disease association studies has been complicated by the reporting of often conflicting studies. In such instances, meta-analyses of all reported studies can provide some insight, with the caveat that publication bias (e.g. negative studies may be more difficult to publish than positive ones) may occur.

Nod2 (CARD15) associations to ileal CD

The most well-replicated IBD genetic associations is the Nod2 gene association with ileal CD[37,38]. Nod2 was the first definitive risk factor for CD and one of the first genes identified for a common complex genetic disorder. It functions as an intracellular sensor for bacterial peptidoglycan[39], and can be activated by a minimal bioactive component, muramyl dipeptide (MDP)[40,41]. MDP is present in both gram positive and negative bacteria and activates NF-κB and MAP kinase pathways[42]. Three uncommon (minor allele frequency less than 5% in healthy controls) polymorphisms, Arg702Trp, Gly908Arg, and Leu1007fsinsC are each highly associated with CD. These findings have been extensively replicated by a number of subsequent studies. A meta-analysis of 39 studies showed an odds ratio for simple heterozygotes of 2.4 (confidence interval, C.I. 2.0-2.9), and for homozygous/compound heterozygous carriers of 17.1 (C.I. 10.7-27.2)[43]. Nod2 carriage has been specifically associated with ileal involvement, stricturing complications and a modestly earlier age of onset.

Each of the three CD polymorphisms are located within or near the leucine rich repeat, sensing domain of Nod2, and each results in a decreased capacity to activate NF-κB in response peptidoglycan or MDP stimulation[39,44-48]. The frameshift mutation, Leu1007fsinsC demonstrates a largely complete deficiency in the capacity to signal in response to MDP stimulation[45]. Therefore, these functional polymorphisms represent direct risk alleles for CD. Importantly, the Nod2 discovery provides specific support for the long-held hypothesis that CD results from a genetically dysregulated host immune response to luminal bacteria. These Nod2 mutations have not been observed in Japanese, Chinese and Koreans with IBD[49-51], and they are rare in African-American IBD[52].

Despite the high odds ratios associated with the Nod2 mutations, it is estimated that the disease penetrance, even for homozygous or compound heterozygous carriers is limited, suggesting that these Nod2 variants alone are insufficient to produce disease. As each of the three major mutations demonstrates decreased function in primary human cells[39,44-48], Nod2-deficient murine models provide an important model for human disease. The absence of intestinal inflammation in Nod2-deficient mice further highlights the insufficiency of this pathway alone to induce CD[42,53]. Since the discovery of the CD-association with Nod2, a number of studies have added to understanding of the Nod2 functional pathway.

Given the dysregulation in intestinal immune homeostasis characteristic of CD, it is logical to hypothesize that Nod2 is important for either impaired tolerance mechanisms critical in limiting excessive activation of the intestinal immune system and/or altered initial defenses against intestinal bacteria. There are a broad range of tolerance mechanisms operating in the intestine to regulate excessive immune responses in the context of its unique exposure to a continuous bacterial load. Regarding initial defenses, a defect in bacterial recognition and responses at the intestinal epithelial surface might result in alterations in the population of commensal organisms, and/or increased invasion, which in turn, could contribute to an increased propensity toward intestinal inflammation. Nod2 is highly expressed in Paneth cells of the small intestine[54,55] and Nod2 mutations are associated with ileal location of disease[56]. Studies in humans and mice have shown that normal Nod2 function is required for optimal defensin expression and therefore, impaired defensin expression and regulation may contribute to the increased CD susceptibility observed in Nod2 risk allele carriers[57-59].

IBD5 association on chromosome 5q31

Within the IBD5 linkage region, association of CD with a 250 kb region on chromosome 5q31 was reported[60]. This association has been subsequently replicated in a number of studies[61-64], for both CD and UC[62,65]. Candidate polymorphisms found on this haplotype within the organic cation transporter OCTN1 (*SLC22A4*) and OCTN2 (*SLC22A5*) genes have been reported[66,67]. However, statistically equivalent evidence for association has been observed throughout the risk haplotype[68] encompassing several genes, highlighting the need for additional genetic and functional investigation in this region. Phenotypic correlates have been reported for perianal disease[61,69], colonic location[70], disease complications and progression[68,71], extensive disease in UC[72], as well as for decreased height and weight at diagnosis in pediatric cohorts[73]. In contrast, some studies have not observed clear genotype-phenotype correlations[74,75].

HLA associations

Replicated HLA class Ⅱ associations in IBD include HLA-DRB1*1502 (serological marker HLA-DR2)[76] association with UC, and HLA-DRB1*0103 association with UC and colonic CD[77,78]. HLA-DRB1*0103 is noteworthy in that

it is a risk factor for both UC and colonic CD, suggesting it may play a role in chronic inflammation of the colon independent of major IBD phenotype (i.e., CD or UC)[78]. As with IBD5, the DRB1*0103 and DRB1*1502 class Ⅱ variants are in strong linkage disequilibrium with SNPs on multiple immunologically active candidate genes. Present approaches have not been able to discern whether these other genes or the class Ⅱ genes are the true risk genes in the HLA locus.

Reported, but unconfirmed IBD associations

Associations which have been reported within linkage regions to IBD but have not been consistently replicated include an indel polymorphism in the promoter region of the *NF-κB1* gene on chromosome 4q[79-82], multiple polymorphisms in the *MDR1/ABCB1* gene on chromosome 7q[83-92], and polymorphisms in the *DLG5* gene on chromosome 10q[70,93-102]. (See section C.4.1.) Haplotypes in the terminal exons of the chromosome 7p Nod1 (*CARD4*) gene and a Nod1 (*CARD4*) indel polymorphism were associated in two different study populations[47], although other studies have not replicated evidence for association[103-105]. Finally, studies of candidate genes that are not located within IBD linkage regions have revealed weak associations between UC and a variable number of tandem repeats polymorphism in the *IL1RN* gene[106] and between IBD and the TLR4 gene[107-113]. In a large case-control study, association was observed in UC and CD for Ala1011Ser within the Myo IXb (*MYO9B*) gene[114] that had been previously been implicated in celiac disease[115]. If replicated, this would indicate shared susceptibility pathways between multiple types of intestinal inflammation.

GENOME-WIDE ASSOCIATION STUDIES IN IBD

Emerging technologies now provide for the direct testing of a large number of SNPs throughout the genome in genome-wide association studies. The multiple genome-wide association studies reported below vary with respect to the genotyping platform utilized and the population cohort tested. Despite these differences, however, the first glimpses of comparative results between the genome-wide association studies are demonstrating encouraging consistency of findings between studies. Taken together, the early results from these studies would suggest that significant advances in defining well-replicated gene associations in IBD, especially in European ancestry cohorts, will shortly ensue.

TNFSF15 association to CD

The first genome-wide association study in IBD involved testing nearly 80 000 SNPs in a Japanese CD cohort[116]. The most significant findings implicated SNPs and haplotypes within the TNFSF15 (TNF superfamily) gene. These results were subsequently confirmed in European IBD cohorts[117]. TNFSF15 is a Th-1 polarizing cytokine which has been reported to be increased in IBD mucosa[118]. In a separate Belgian CD cohort, however, no significant evidence for association was observed[119]. These differences could reflect differences in markers genotyped and/or different contributions of susceptibility genes between Asian and European IBD cohorts. Future studies in a variety of population cohorts will provide important comparative insight.

IL23R is associated with CD and UC

A genome-wide association study testing over 300 000 autosomal SNPs was recently reported[120]. Three SNPs had nearly two orders of magnitude greater significance compared to the next most significant markers. Two of the three markers, were in the known CD susceptibility gene, Nod2. The third marker, rs11209026 ($P = 5.05 \times 10^{-9}$, corrected $P = 1.56 \times 10^{-3}$), was a non-synonymous SNP (Arg381Gln) in the *IL23R* gene on chromosome 1p31. Replication of these findings was observed in an independent cohort of 883 nuclear families and observed significant association in CD and non-Jewish UC. Therefore, *IL23R* represents both a CD and a UC susceptibility gene. The less common glutamine allele of Arg381Gln has an allele frequency of 1.9% in non-Jewish CD and 7.0% in non-Jewish controls and therefore protects against IBD[120]. Other variants within *IL23R* are also associated with IBD, independent of the Arg381Gln association. Since the initial report, these findings have subsequently been replicated in Scottish pediatric IBD[121] and Belgian CD[119] cohorts, indicating a clear role for *IL23R* in IBD susceptibility.

Given the IL-23 pathway's role in activation and perpetuation of organ-specific inflammatory responses, the genetic findings suggest that targeting the IL-23 pathway may be a rational therapeutic approach. In this regard, anti-p40 administration, which blocks both IL-23 and IL-12 activities, has proved promising[122]. The contribution of the *IL23R* pathway to IBD will likely involve more than simple gain or loss of function *IL23R* variants and ongoing studies of this pathway may reveal new therapeutic options. Future studies should examine mechanisms of the strong protective effect of the Arg381Gln allele could potentially be exploited to define clinical outcomes. The genetic association and the pro-inflammatory role of IL-23 strongly prioritize this pathway as a therapeutic target in IBD.

The *IL23R* genetic association to IBD correlates precisely with recent immunologic advances in understanding of the IL-23 pathway. A number of murine models of colitis, including IL-10 deficiency, T cell mediated (CD45Rbhigh reconstituted in RAG deficiency) and non-T cell mediated (agonistic anti-CD40 RAG deficiency, H. hepaticus-induced) colitis demonstrated significant amelioration when crossed with p40 and p19-deficient mice. This demonstrates the requirement for an intact IL-23 pathway for a variety of intestinal inflammation pathways[123-126].

A complete understanding of the strongly protective effect of *IL23R* polymorphisms in IBD should not be solely restricted to pharmacologic approaches to mimic the Arg381Gln polymorphism. While it is logical to test anti-p19 antibodies in IBD[127], the underlying paradigm is one of an ongoing requirement for continued immune

suppression. However, it is unlikely that the approximately 14% of European ancestry individuals heterozygous for the glutamine allele harbor significant immunodeficiencies, and therefore these individuals provide a unique opportunity to better understand the lifelong, dynamic host-intestinal microbial interactions that are the key to IBD. We are born with a sterile intestine[25] and an immature immune system[128], with the rapid acquisition of intestinal flora evolving dynamically with early instruction signals to the host immune response. The significant susceptibility of neonates to infection may correlate with their incapacity to induce IL-12p35 with lipopolysaccharide stimulation[129], with IL-23p19 induction being largely intact[130]. This would suggest that functional IL-23 pathway polymorphisms may be particularly important in modulating neonatal development of intestinal tolerance and bacterial colonization.

ATG16L association to CD

In a genome-wide survey of nearly 20 000 nonsynonymous SNPs, an amino acid polymorphisms, Thr300Ala within the *ATG16L1* gene was found to be highly associated with CD. The *ATG16L1* protein is comprised of N-terminal APG16 domain consisting of coiled coils and eight C-terminal WD repeats. The Thr300Ala variant is located at the N-terminus of the WD-repeat domain in *ATG16L1*. The *ATG16L1* gene is part of the autophagosome pathway and has been implicated in the processing of intracellular bacteria. Of interest, no association was observed in UC and a statistical interaction was reported with the Nod2 (*CARD15*) CD associations. Since the initial report, this association has been confirmed in a separate, Belgian CD cohort[119]. In addition, in this cohort, no association was observed in UC. Taken together, the *ATG16L1* association represents a well-replicated CD-specific association.

Association of a gene desert on chromosome 5p13.1 which modulates the expression of the prostaglandin receptor EP4 (*PTGER4*)

In a genome-wide association study in a Belgian CD cohort, in addition to the *CARD15*, *IL23R* and *ATG16L1* associations, association was observed in a region on chromosome 5p13.1. The most significant association was observed in a gene desert region flanked by a number of potential candidate genes, including *CARD6*, complement factors C6, C7 and C9 and the prostaglandin receptor, EP4 (*PTGER4*). No association was observed in UC for markers in this region. *PTGER4* is a compelling candidate, in part because *PTGER4* deficient mice develop a more severe colitis with dextran sodium sulfate treatment[131]. In elegant analyses, the investigators compared SNP data in this genomic region with mRNA expression levels of flanking genes from the corresponding, individual lymphoblastoid cell lines. Throughout the region of association, a number of SNPs were significantly associated with mRNA expression levels of *PTGER4*, including at least one SNP demonstrating both CD association as well as correlation with *PTGER4* expression. However, the susceptibility allele at this marker corresponds with increased *PTGER4* expression, which is not consistent with the increased colitic susceptibility observed in *PTGER4*-deficient mice[131]. However, taken together, these findings strongly suggest that genetic variation in this region is associated with IBD and significantly regulates *PTGER4* expression.

Assessment of genome-wide association studies in IBD

It is anticipated that the most significant associations observed in various genome-wide association studies will be largely replicable between studies in comparable population cohorts. Genome-wide association studies provide a comprehensive, unbiased landscape of common variation contributing to disease. Three relative limitations to these studies should be noted, however. Apart from the highly significant, outlying associations such as those observed for the Nod2 and *IL23R* gene associations, many of the most biologically significant disease associations may confer less significant statistical associations, and be obscured by surrounding "noise" conferred by false positive associations. Study design approaches to dissect true disease associations from surrounding noise remains a major methodological challenge moving forward. A second limitation is that the genotyping platforms typically utilized for these studies are limited to testing common genetic variation, with minor allele frequencies of greater than 5%. In the presence of significant allelic heterogeneity for uncommon variants within a disease gene, genome-wide association approaches will be relatively insensitive. The Nod2 associations are observed in genome-wide surveys so clearly because all three of the uncommon CD variants by chance share a common haplotype background. Therefore, the identification and characterization of uncommon variants may largely be missed by a complete reliance of genome-wide association approaches. Finally, many of the early genome-wide genotyping platforms were specifically developed to efficiently test European ancestry cohorts, and may not as efficiently assay Asian or African populations. Particularly for African populations which have shorter regions of linkage disequilibrium, testing of larger numbers of genetic markers will be required.

From genetics to genetic epidemiology: defining risks in patient subsets to assist clinical practice

A more complete pathophysiologic genetic definition of IBD will require integration of clinical observations, genetic data, statistical analyses, and delineation of underlying biologic processes. Interrogating GWA data for gene-gene interactions analyses has been proposed as being more powerful than traditional, single locus analyses under a range of interactive models. However such analyses may be more powerful if prior biologic knowledge on signaling pathways, *in vivo* models of inflammation and integration of genetic insight is applied. The growing catalogue of functional polymorphisms contributing to distinct chronic inflammatory disorders, while not necessarily demonstrating disease association, may contribute to IBD pathophysiology as disease modifiers. Stratification of genetic associations by phenotype variation and/or use of covariates may benefit genetic understanding of IBD by reducing heterogeneity that can obscure association evidence. Because of the strength of the Nod2 association

in CD, and because ileal CD represents a large fraction of overall cases of CD, the Nod2 associations were easily observed in the "all CD" analyses, and even the "all IBD" analyses. However, as the Nod2 genotype risk represents one of the largest among complex disorders, it would be anticipated that many IBD association signals may require correct subsetting, of which disease location is most well-established. Integration of clinical and genotype data may provide the capacity to predict complications and disease course in a clinically useful way. While the integration of definitive IBD risk alleles would be the most straightforward factors to include in such predictive models, it is possible that many key genetic factors (particularly well-established functional polymorphisms from related disorders) may, by themselves, not be associated with the major phenotypes, but rather function solely as disease modifiers. For example, it is possible that certain key genetic factors (particularly well-established functional polymorphisms from related disorders) may, by themselves, not be associated with the major phenotypes but rather serve to modify disease expression. Detecting such relationships requires a conditional analysis restricted to those with IBD in which certain phenotypic characteristics are modeled as a function of the presence of one or more genetic variants. Such models will also provide a framework for generating predictions about clinical course among newly diagnosed cases-providing clinicians important information for use in treatment planning.

The identification of major single gene associations such as *IL23R* and Nod2 provides a framework around which risk models for multigenic disorders can be developed. A major research interest moving forward will be identifying gene-gene interactions that contribute to increased disease risk or define pathophysiological subsets within the disease. This will be explored through: (1) a broad-based, systematic search of genomic regions demonstrating the most significant evidence for association, (2) pathway analyses integrating specific knowledge regarding functional human polymorphisms relevant to the *IL23R* and Nod2 pathways, and (3) studying key mechanistic intermediates known to be particularly relevant to disease pathogenesis.

As functional genetic variants that predispose to IBD are identified, their effect on modifying disease phenotype and/or disease course will need to be examined. For example, the CARD15 mutations increase susceptibility to CD generally, affect disease location (increase susceptibility to ileal location), and modify disease behavior. Because of the challenges of longitudinal follow-up, prospective evaluation of IBD-associated mutations represents a major challenge. The efficient abstraction of critical research datapoints from active clinical practices in an accurate and reproducible manner will be required. Interpretation of disease course from multi-center studies given differences in practice patterns represents an additional interpretative challenge. However, such studies will provide the basis for improved translation of genetic discovery in IBD and will need to be designed *via* active communication and collaboration throughout the IBD research community.

Abstract

Inflammatory bowel disease is characterized by a chronic inflammation of the intestinal mucosa. The mucosal epithelium of the alimentary tract constitutes a key element of the mucosal barrier to a broad spectrum of deleterious substances present within the intestinal lumen including bacterial microorganisms, various dietary factors, gastrointestinal secretory products and drugs. In addition, this mucosal barrier can be disturbed in the course of various intestinal disorders including inflammatory bowel diseases. Fortunately, the integrity of the gastrointestinal surface epithelium is rapidly reestablished even after extensive destruction. Rapid resealing of the epithelial barrier following injuries is accomplished by a process termed epithelial restitution, followed by more delayed mechanisms of epithelial wound healing including increased epithelial cell proliferation and epithelial cell differentiation. Restitution of the intestinal surface epithelium is modulated by a range of highly divergent factors among them a broad spectrum of structurally distinct regulatory peptides, variously described as growth factors or cytokines. Several regulatory peptide factors act from the basolateral site of the epithelial surface and enhance epithelial cell restitution through TGF-β-dependent pathways. In contrast, members of the trefoil factor family (TFF peptides) appear to stimulate epithelial restitution in conjunction with mucin glycoproteins through a TGF-β-independent mechanism from the apical site of the intestinal epithelium. In addition, a number of other peptide molecules like extracellular matrix factors and blood clotting factors and also non-peptide molecules including phospholipids, short-chain fatty acids (SCFA), adenine nucleotides, trace elements and pharmacological agents modulate intestinal epithelial repair mechanisms. Repeated damage and injury of the intestinal surface are key features of various intestinal disorders including inflammatory bowel diseases and require constant repair of the epithelium. Enhancement of intestinal repair mechanisms by regulatory peptides or other modulatory factors may provide future approaches for the treatment of diseases that are characterized by injuries of the epithelial surface.

THE MUCOSAL DEFENSE SYSTEM

The surface of the digestive tract is covered by epithelial cells that constitute an efficient physical barrier between the dietary and enteric flora pathogens found in the intestinal lumen and the individuum, but also allows an exchange between nutrients and the systemic circulation[1]. The epithelial defense mechanism can be categorized into three key components: pre-epithelial, epithelial and post-epithelial, the latter is represented by the lamina propria[2]. The pre-epithelial mucus barrier is composed of mucin associated with other proteins and lipids and forms a continuous gel into which a bicarbonate-rich fluid is secreted, maintaining a neutralizing pH at the epithelial surface. Phosphatidylcholine is the predominant surface bioactive phospholipid found within the gastrointestinal tract[3]. Intestinal epithelial cells secrete mucins and glycocalyx, which contain membrane-anchored negatively charged mucin-like glycoproteins and hydrophobic phospholipids[4]. The tight adherence of mucin to the apical surfaces of epithelia is owed to the existence of the specific complex between mucin oligosaccharides and the mucin binding protein of the apical mucosal membrane[5]. The hydrophobic lining of the luminal surface has an important functional role. It prevents microorganisms

Table 1 Important modulators of intestinal epithelial cell function

Localization	Modulator
Gastrointestinal lumen	Dietary compounds
	Alimentary secretions from salivary glands, stomach, pancreas or intestinal glandular cells
	Secreted regulatory peptides
	Physiological and pathogenic intestinal microflora
	Non-peptides factors (e.g. phospholipids, polyamines, short chain fatty acids and other)
	Drugs
	Other
Epithelium	Regulatory peptides
	IEL
	Local cell-cell interactions
	Non-peptide factors (e.g. phospholipids, adenine nucleotides, polyamines and others)
	Other
Lamina propria and basal lamina	Regulatory peptides expressed by various constituents of the lamina propria
	Extracellular matrix factors

	Nerval interactions
	Various mediators that are transported *via* the blood stream
	Non-peptide factors (e.g. phospholipids, adenine nucleotides, polyamines and others)
	Other

from getting into contact with and to adhering to the plasma membrane. It furthermore protects the mucosal epithelium against chemical and mechanical injuries[6]. Epithelial cells provide the second line of the mucosal defense system. Whereas in the upper digestive tract this layer consists of a stratified epithelium, the stomach, small, and large bowel are surfaced with a simple epithelial layer sealed by tight junctions[7]. When intact, the uptake of antigens, macro- and microorganism through this layer is restricted by luminal cell-surface structures. The mucosal surface epithelial cells are rapidly proliferating with a complete turnover every 24 to 96 h[8]. The proliferative compartment of epithelial cells is localized in the crypt region and is segregated from a gradient of increasingly differentiated epithelial cells present along the vertical axis of the functional villus compartment[9,10].

INTESTINAL WOUND HEALING

Damage and impairment of the intestinal surface barrier are observed in the course of various diseases and may result in an increased penetration and absorption of toxic and immunogenic factors into the body leading to inflammation, uncontrolled immune response, and disequilibrium of the homeostasis of the host. Thus, rapid resealing of the epithelial surface barrier following injuries or physiological damage is essential to preserve the normal homeostasis. Observations over the past several years have demonstrated the ability of the intestinal tract to rapidly reestablish the continuity of the surface epithelium after extensive destruction[11-14]. The continuity of the epithelial surface is reestablished by at least three distinct mechanisms. First, epithelial cells adjacent to the injured surface migrate into the wound to cover the denuded area. Those epithelial cells that migrate into the wound defect dedifferentiate, form pseudopodia-like structures, reorganize their cytoskeleton, and redifferentiate after closure of the wound defect. This process has been termed epithelial restitution and does not require cell proliferation[15]. Intestinal epithelial restitution occurs within minutes to hours both *in vivo* and *in vitro*. Secondly, epithelial cell proliferation is necessary to replenish the decreased cell pool. Third, maturation and differentiation of undifferentiated epithelial cells is needed to maintain the numerous functional activities of the mucosal epithelium. The separation of intestinal epithelial wound healing in three distinct processes is rather artificial and simplified. These three wound-healing processes overlap and distinct processes may not be observed *in vivo* where these processes overlap. The preservation of this barrier following injuries is regulated by a broad spectrum of structurally distinct regulatory factors, including cytokines, growth factors, adhesion molecules, neuropeptides and phospholipids[16-19]. However, this artificial and simplified model provides a tool to better understand the physiology and pathophysiology of intestinal epithelial wound healing. Moreover, deeper lesions or penetrating injuries will require additional repair mechanisms that involve inflammatory processes and non-epithelial cell populations. Inflammatory processes especially may interfere with epithelial cell migration and proliferation and thus modulate intestinal epithelial healing.

IMPORTANT MODULATORS OF THE INTESTINAL EPITHELIAL CELL FUNCTION

The epithelial cell populations of the intestinal mucosa are modulated by a number of factors that are present within the lumen, the epithelium itself or the underlying lamina propria (Table 1). Although the full variety of regulatory factors that play a role in the control of intestinal epithelial and non-epithelial cell populations has not been fully defined yet, there is increasing appreciation of the diversity of these factors in general and the importance of several specific peptide and non-peptide factors produced or released within the intestine. The identification and characterization of numerous regulatory peptide and non-peptide factors has led to the recognition of a network of interrelated factors within the intestine (Figure 1). The constituents of this network generally possess multiple functional properties and exhibit pleiotropism in their cellular sources and targets. As a result, this network is highly redundant in several dimensions[20]. Regulatory peptides especially seem to play a key role in intestinal epithelial wound repair, as they are abundantly detectable in the intestinal lumen, intestinal epithelium and the underlying lamina propria. Various members of several distinct regulatory peptide families have been recognized to modulate a broad spectrum of intestinal epithelial cell functions including cell migration, proliferation and/or differentiation (Figure 2). As outlined above the latter epithelial cell functions are highly relevant for the modulation of intestinal epithelial wound repair.

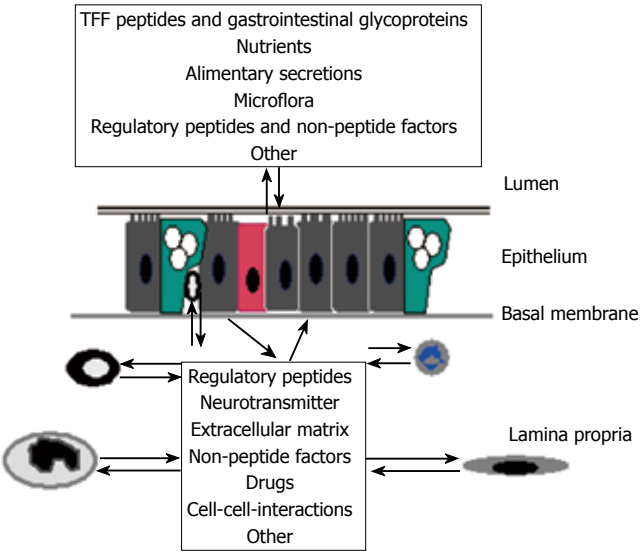

Figure 1 Regulatory network within the intestinal mucosa (adopted and modified from Reference 32).

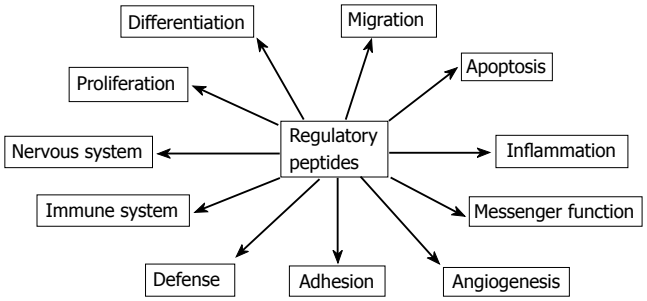

Figure 2 Functional activities of peptide growth factors within the intestinal mucosa (adopted and modified from Reference 32).

THE ROLE OF REGULATORY PEPTIDES FOR INTESTINAL EPITHELIAL WOUND HEALING

A broad spectrum of structurally distinct regulatory peptides is expressed from various cell populations within the mucosa of the intestinal tract. These regulatory peptides, conventionally designated as growth factors and cytokines play an essential role in regulating differential epithelial cell functions in order to preserve normal homeostasis and integrity of the intestinal mucosa[20-25]. The terminology of regulatory peptides is often confusing and arbitrary. The term cytokines is now increasingly used to describe a bunch of regulatory peptides that can be variously identified as regulatory peptides, peptide growth factors, interleukins, interferons and colony stimulating or hematopoetic stem cell factors. For the purpose of simplification, the term regulatory peptide or cytokine will be used in this paper to address all the different classes of regulatory peptide factors. Regulatory peptides can be reasonably classified on the basis of structural homologies and disparities into several discrete families. Peptide growth factor families and selected members with functional activities in the modulation of intestinal wound healing. In addition to growth factor families, a number of regulatory peptide factors, seemingly without structural similarities to other regulatory peptide family members like vascular endothelial cell growth factor (VEGF) and platelet-derived growth factor (PDGF) have been identified to be expressed within the intestinal tract and to modulate wound healing properties within the intestinal mucosa[25]. Furthermore, a countless number of classical cytokines like IL-1, IL-2, IL-15, IL-22 and IFN-γ are expressed within the intestine and modulate numerous intestinal epithelial cell functions[26-30].

The various effects of a number of regulatory peptides on cell adhesion, migration, proliferation, differentiation, intestinal epithelial barrier function and angiogenesis suggest that these peptides are likely relevant factors for intestinal repair mechanisms. Both *in-vitro* and *in-vivo* studies have demonstrated that several growth factors and cytokines can enhance epithelial cell restitution[31,32]. A spectrum of growth factors and cytokines including EGF, VEGF, HGF, GLP-2, various FGF peptides, IL-1, IL-2 and IFN-γ have been demonstrated to enhance epithelial cell restitution through a TGF-β-dependent pathway[33-36]. Interestingly, it appears that restitution-enhancing cytokines use different mechanisms to modulate TGF-β-peptide levels. While TGF-β, EGF, IL-1, IFN-γ and HGF only increased the concentration of bioactive TGF-β, acidic and basic FGF and also IL-2 enhanced both the bioactivation of TGF-β and the expression of TGF-β mRNA and production of latent TGF-β peptide. This might reflect a different mechanism, by which acidic and basic FGF and also IL-2 modulate the synthesis and bioactivation of TGF-β. In contrast to the above mentioned growth factors and cytokines that are assumed to act from the basolateral site of the epithelial surface and that seem to stimulate intestinal epithelial restitution through a common TGF-β-dependent pathway, various members of the trefoil factor family (TFF Peptide family) appear to stimulate epithelial restitution in conjunction with mucin glycoproteins through a TGF-β-independent mechanism from the apical pole of the epithelium[35,37,38]. In this regard, our group recently also demonstrated that mesalamine promotes intestinal wound healing *in vitro* through a TGF-β-independent mechanism[39]. Recent studies suggest that modulation of repair mechanisms by trefoil peptides may be mediated by modulation of the E-cadherin/catenin complex[40,41]. However, a double-blind, randomized, placebo-controlled study treating 16 patients with mild-to-moderate left sided ulcerative colitis with enemas containing human recombinant trefoil factor family-3 did not reveal any additional benefit above that of adding 5-aminosalicylic acid alone[42].

It has been demonstrated, that keratinocyte growth factor (KGF) has an important function in wound re-epithelialization[43] and KGF expression is strikingly increased in surgical specimens from patients suffering from Crohn's disease and ulcerative colitis[44]. Furthermore, in an experimental model of colitis, administration of KGF after but not before induction of colitis significantly ameliorated tissue damage demonstrating that exogenous KGF might promote IBD[45]. However, clinical studies

Table 2 Selected non-peptide factors with relevance for intestinal epithelial wound healing

Factor	Mechanism of action	References
Lysophosphatidic acid	Stimulates intestinal epithelial restitution and inhibits intestinal epithelial proliferation	[61,67]
Polyamines	Stimulate intestinal epithelial restitution and proliferation	[11,66,75]
Adenine nucleotides	Stimulate intestinal epithelial restitution and inhibit intestinal epithelial proliferation	[59]
Short chain fatty acids	Stimulate intestinal epithelial migration	[63,76]
Glutamine	Stimulates intestinal epithelial proliferation and migration	[76,77]

treating patients with CD or UC with exogenous KGF have not been performed yet. In addition to their potent effects on epithelial restitution, a number of regulatory peptide factors act also as potent modulators of epithelial cell proliferation[17,18,32,46-49]. The most important modulators of intestinal epithelial cell proliferation include EGF and TGF-β which both act as potent stimulators of intestinal epithelial proliferation and TGF-β which inhibits intestinal epithelial cell proliferation and plays an important counterbalancing role in the regulation of intestinal epithelial cell proliferation. TGF-β is the most potent inhibitor of intestinal epithelial cell proliferation overriding the stimulatory effects of other stimulatory factors. The growth stimulating effect of IL-2, FGF peptides, IGF and HGF is rather moderate compared to the effects of EGF and TGF-β that stimulate epithelial cell proliferation five- to ten-fold in several intestinal epithelial cell lines *in vitro*[33,34,48,50]. Thus, it is not astonishing that in a randomized, double-blind clinical trial, after a 2-wk treatment period, patients receiving EGF enemas had a significant lower disease activity score than the control patients[51]. Concerning basic FGF, in a mouse DSS-model of experimental colitis, rectal administration of human recombinant basic FGF ameliorated the inflammation score and suppressed TNF-α gene expression in the colonic tissue[52,53]. Recently, the important role of Glucagon-like-peptide-2 (GLP-2), which is secreted from local neuroendocrine epithelial cells and promotes epithelial cell proliferation *via* stimulation of enteric neurons[54], has received more attention. GLP-2 demonstrating ability to ameliorate murine short bowel syndrome and experimental colitis[55,56] has consequently lead to clinical studies, evaluating the effect of GLP-2 in patients with short bowel syndrome.

However, it has also to be considered that cytokines have pleiotropic activities. For example, FGF also induces stricture formation in Crohn's disease[57] and GLP-2 might have undesired effects in tumorogenesis[58], which might limit their therapeutic use. In addition, it has to be considered that these factors and also various non-peptide factors may act in an additive or even synergistic fashion which may potentiate their single effects. Notably, in addition to TGF-β the TGF-β family member Activin A has been identified to also inhibit epithelial cell proliferation, thus providing an additional mechanism to counterbalance the effects of proliferative factors present within the intestinal mucosa and to inhibit unrestrained cell growth[59,60].

MODULATION OF INTESTINAL EPITHELIAL WOUND HEALING BY NON-PEPTIDE FACTORS

In addition to the potent modulation of intestinal epithelial wound healing by regulatory peptides, it is increasingly appreciated that a broad spectrum of non-peptide factors exerts potent effects on intestinal epithelial cell populations and modulates those epithelial cell functions that are involved in the healing of intestinal injury (Table 2). These non-peptide factors encompass a broad spectrum of unrelated factors like phospholipids, nutrients (adenine) nucleotides, polyamines, short chain fatty acids (SCFA), products of the intestinal microflora, trace elements, pharmacological agents and other factors. Some of these factors are released by injured or dying mucosal cell populations (e.g. adenine nucleotides, phospholipids), other reach the intestinal mucosa *via* the intestinal lumen or the blood stream. These non peptide factors may exert growth factor like activities and exert potent effects on cell growth and differentiation in different cell populations including fibroblasts, vascular smooth muscle cells, endothelial cells and keratinocytes[20,35,61-63]. As some of these non-peptide factors are stable within the gastrointestinal tract despite high concentrations of acid, bile salts, proteases and microorganisms and as they exhibit only limited toxicity *in vivo*, they may serve as potential future targets to improve the armamentarium for the healing of mucosal epithelial injury.

Especially phospholipids and polyamines seem to be of special interest, as these non-peptide factors can be easily added to the regular diet and their overall content and biological activity can be modulated by various pharmacological agents[62,64-66]. Lysophosphatidic acid (LPA) is a key intermediate in the early steps of phospholipid biosynthesis and is rapidly produced and released from thrombin-activated platelets and growth factor stimulated fibroblasts to influence target cells by activating a specific 38-40 kDa G-protein coupled receptor that is expressed in many cells[67]. As a product of the blood-clotting process, LPA is a normal constituent of serum, where it is present in an albumin-bound form in physiologically relevant concentrations[64]. Major sources of LPA in the vicinity of injured epithelial cells are activated platelets, stimulated fibroblasts and presumably injured cells that release LPA due to non-specific phospholipase activation[67]. LPA promotes platelet aggregation and induces cellular tension and cell surface fibronectin assembly[68], which are also important events in wound repair suggesting an important role of LPA in inflammatory disorders. This was confirmed by our group when we demonstrated, that LPA not only promotes epithelial wound healing *in vitro* by a TGF-β-independent pathway, but also ameliorates experimental colitis in an experimental model of colitis in rats[61]. Interestingly, also lysophosphatidylethanolamine and lisofylline, which decreases lipid peroxidation, significantly

reduced the degree of inflammation and necrosis in an experimental colitis model[69], demonstrating that the administration of anti-inflammatory lysophospholipids and suppression of pro-inflammatory lipid metabolites by lisofylline may provide new approaches to ameliorate intestinal inflammation. This beneficial effect could also be demonstrated in other diseases since lisofylline and its analogs reversed autoimmune diabetes in a non-obese diabetic (NOD) mouse model and thus might act as a potential treatment for Type 1 diabetes[70,71].

Many studies have reported that bone marrow cells may have the potential to contribute to the repair of many non-hematopoetic tissues, including the intestinal epithelial cells. Bone-marrow derived cells are capable of promoting regeneration of damaged intestinal epithelial cells[72]. However, the underlying effects are not fully understood[18]. Nevertheless, bone-marrow transplantation combined with immune-suppressive therapy improves epithelial wound healing[73] and recombinant granulocyte-macrophage colony-stimulating factor have a therapeutic effect in patients with active Crohn's disease[74].
