Abstract

Crohn's disease (CD) and ulcerative colitis (UC) are chronic inflammatory diseases of the gastrointestinal tract. While a cure remains elusive, both can be treated with medications that induce and maintain remission. With the recent advent of therapies that inhibit tumor necrosis factor (TNF) alpha the overlap in medical therapies for UC and CD has become greater. Although 5-ASA agents have been a mainstay in the treatment of both CD and UC, the data for their efficacy in patients with CD, particularly as maintenance therapy, are equivocal. Antibiotics may have a limited role in the treatment of colonic CD. Steroids continue to be the first choice to treat active disease not responsive to other more conservative therapy; non-systemic steroids such as oral and rectal budesonide for ileal and right-sided CD and distal UC respectively are also effective in mild-moderate disease. 6-mercaptopurine (6-MP) and its prodrug azathioprine are steroid-sparing immunomodulators effective in the maintenance of remission of both CD and UC, while methotrexate may be used in both induction and maintenance of CD. Infliximab and adalimumab are anti-TNF agents approved in the US and Europe for the treatment of Crohn's disease, and infliximab is also approved for the treatment of UC.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are the principle syndromes encompassed by the classification of inflammatory bowel disease (IBD). While CD can affect any part of the gastrointestinal tract, it most commonly occurs in the distal ileum and colon, whereas UC by definition affects only the colon. The etiology appears multifactorial: an underlying immune dysregulation coupled with an intolerance to gut flora seems fundamental to the pathogenesis that, in some cases, are associated with genetic mutations or are initiated by environmental factors. Apart from a total proctocolectomy for UC, there is no cure for IBD. Medications, however, aid in the induction and maintenance of remission, and target various points along the disordered immune pathway implicated in IBD.

CROHN'S DISEASE

Aminosalicylates

While there is solid data supporting 5-aminosalicylic acid (5-ASA, mesalazine or mesalamine) in the induction and maintenance of remission for UC, their efficacy in the treatment of CD is not as clear. Interpretation of the data is often confounded by the use of different formulations, doses, and varied applications to different disease scenarios (disease location, concomitant medications, and prior therapies). 5-ASA agents are likely to have multiple anti-inflammatory effects, including inhibition of cyclooxygenase, lipoxygenase, B-cells, and several key inflammatory cytokines. Most recently, 5-ASA has been shown to activate selective peroxisome proliferators-activated receptor ligand-γ (PPAR-γ), a nuclear receptor that controls cell proliferation and apoptosis[1]. Originally designed as treatment for rheumatoid arthritis (RA), sulfasalazine was discovered to also benefit patients with IBD[2]. An azo-bond links sulfapyridine to 5-ASA and is cleaved by bacterial azo-reductase in the colon, thus allowing delivery of the active 5-ASA moiety to

the large intestine. Limitations of sulfasalazine include allergic reactions and side effects, largely attributed to the sulfapyridine moiety, as well as its lack of efficacy in isolated small bowel disease that is proximal to the colonic release of 5-ASA. Two newer non-sulfa-containing 5-ASA agents, balsalazide and olsalazine were developed to treat colonic inflammation; further, mesalamine formulated to release in a pH (Asacol®, Claversal®, Mesasal®, and Salofalk®) or time-dependent manner (Pentasa®) can treat either small or large bowel CD[2].

Active disease

The National Cooperative Crohn's Disease Study (NCCDS) and European Cooperative Crohn's Disease Study (ECCDS) were large multicenter randomized controlled trials published in 1979 and 1984 that evaluated the comparative efficacy of sulfasalazine, prednisone and azathioprine in the treatment of both active and quiescent CD. While the NCCDS found sulfasalazine 6 g/d superior to placebo overall in treating active disease, when stratified by disease location only those with colonic and ileocolonic (but not isolated small bowel) disease obtained benefit[3]. In contrast, the ECCDS did not demonstrate efficacy for sulfasalazine 3 g/d alone, but only in combination with 6-methylprednisolone[4].

Subsequently, newer mesalamine agents have been evaluated in clinical trials for CD. In the largest of these studies (n = 310), patients with active ileal or ileocolonic CD were randomized to receive Pentasa®, 1, 2 or 4 g/d or placebo. The 4 g/d group experienced a greater decrease in CDAI than the placebo group (72 *vs* 21 points, $P < 0.01$), an effect more pronounced in isolated ileal disease, and remission was achieved in 43% *vs* 18% respectively[5]. Subsequently, two similarly designed trials described in a meta-analysis failed to replicate these findings although there was an overall statistical benefit for the 4 g dose of mesalamine that was of questionable clinical significance[6,7]. Several other trials also have demonstrated benefit for mesalamine in CD, but the quality of the trials was less robust[8,9]. When compared to other agents in controlled trials approximately 40%-55% of patients treated with mesalamine 4 g/d achieve remissions but the efficacy was less than budesonide (9 mg/d) for the induction of remission at both 8 wk (45% *vs* 65%, $P = 0.001$) and 16 wk (36% *vs* 62%, $P < 0.001$)[10] and comparable to ciprofloxacin 1 g/d[11].

Maintenance after medical remission

Sulfasalazine at reduced doses compared to the induction phase provided no benefit compared to placebo in the maintenance phase of the NCCDS and ECCDS, nor in a smaller study[3,4,12]. Gisbert *et al* have reviewed nine randomized placebo-controlled studies of mesalamine as a maintenance agent, four of which showed a significantly decreased risk of relapse compared to placebo, although there was great heterogeneity in formulation, dosage, duration of treatment, and disease location[13]. Further, a Cochrane review of seven randomized placebo-controlled trials concluded that treatment with 5-ASA agents for at least six months did not confer an advantage over placebo in patients with medically-induced remission[14]. When initiated within three months of a medically-induced remission, mesalamine (2 g bid), in contrast to placebo, prevented more relapses over a two year period[15]. In the context of a steroid-induced remission, short-term weaning from steroids may be slightly facilitated with mesalamine 4 g/d, but there was no benefit at one year in relapse rate between patients maintained on mesalamine compared with placebo[16].

Post-operative maintenance

The natural history of CD after ileocolonic resection is variable, and may be influenced by such factors as pattern, extent, and duration of disease pre-operatively as well as smoking history. Endoscopic recurrence rates range from 28%-93% at one year[17], while clinical relapse rates have been reported at 20% and 34% at one and three years respectively[18]. Approximately 30% of patients require re-operation within 10 years[17], highlighting the relevance of identifying an effective post-operative maintenance strategy. Except for one study that showed a benefit at one (but not three) years, sulfasalazine has not been statistically superior to placebo in preventing post-operative relapse[17]. Data for mesalamine has been equivocal in the setting of post-operative maintenance trials. While a meta-analyses of 15 randomized controlled studies (n = 2097) of mesalamine as a maintenance medication in CD found a 13% pooled risk reduction for those patients with surgically-induced remissions[19], the largest (n = 318) and most rigorously conducted trial to date in which patients began mesalamine therapy (4 g/d) within ten days of surgery did not show benefit over placebo. While a post-hoc analysis did suggest efficacy for patients with isolated small bowel disease (21% *vs* 39% relapse rate, $P < 0.02$)[20], if this trial had been included in the meta-analysis, the overall findings of benefit compared to placebo would no longer have been significant[21]. Most recently, mesalamine at 3 g/d was inferior to mercaptopurine at 50 mg/d at preventing post-operative recurrence[22].

In summary, for the treatment of mild to moderate active CD, 5-ASA agents, while less efficacious than budesonide for ileal and or right colonic disease, may be a reasonable choice as first-line therapy: sulfasalazine should be reserved for patients with predominantly colonic disease, while time or pH-dependent release mesalamine are appropriate for patients with small bowel disease. The role of 5-ASA as a maintenance medication is equivocal at best, but is clearly of no benefit in patients with a steroid-induced remission and in the setting of post-operative maintenance, at least 3 g/d would need to be initiated immediately after surgery to provide any benefit for patients with small bowel disease.

ANTIBIOTICS

Active disease

Metronidazole, ciprofloxacin, combination anti-mycobacterials, and most recently ornidazole and rifaximin have been evaluated in the treatment of active CD. The few randomized controlled trials to study the efficacy of metronidazole and/or ciprofloxacin have been mostly small and provided negative results[7] despite subgroup

analyses suggesting a trend towards significant benefit in patients with colonic disease[23-25]. One small study (n = 47) showed ciprofloxacin 1 g/d for six months decreased CDAI scores significantly more than placebo ($P < 0.001$)[26] and while an eight month cross-over study between sulfasalazine 3 g/d and metronidazole 800 mg/d showed no treatment differences in the initial four months, 15 patients who switched from sulfasalazine to metronidazole had significant decreases in the CDAI compared to none of the group who crossed-over from metronidazole to sulfasalazine[27]. As previously described, 16-wk remission rates were similar for ciprofloxacin and mesalamine in a small, randomized trial[11] while another trial reported no differences in remission rates between the combination of ciprofloxacin and metronidazole *versus* methylprednisolone, despite a trend favoring steroids[28]. In contrast, a combination of ciprofloxacin and metronidazole provided no additional benefit over budesonide, alone, aside from a post-hoc analysis for patients with colonic disease[25]. A recent study that compared rifaximin 800 mg bid, 800 mg/placebo and placebo bid failed to show a significant difference between the three groups in clinical response or remission, despite a trend toward benefit with the higher dose[29].

Perianal disease and post-operative maintenance

Although antibiotic therapy is frequently used in the treatment of perianal fistulae, there are no randomized controlled trials to support this practice. Data from several small open-label trials conducted in the early 1980s reported the efficacy of metronidazole in healing perianal fistulae[30-32]. In the post-operative setting a three month course of metronidazole (20 mg/kg per day) decreased the severity of endoscopic lesions at one year (but not at two years) and delayed onset of clinical recurrence[33]. Most recently, ornidazole (1 g/d), started within 10 d of resection and continued for one year, showed significant benefit over placebo in both clinical and endoscopic recurrence rates[34]. The main limitation of long-term metronidazole and ornidazole is peripheral neuropathy.

In summary, while antibiotics are used frequently to treat perianal disease, their role in the treatment of active luminal disease and a safe and effective dose schedule in the post-operative setting, remain to be established.

SYSTEMIC STEROIDS

Mechanism of action

By binding to intracytoplasmic glucocorticoid receptors found in most cell types, glucocorticosteroids activate glucocorticoid-responsive elements (GREs), resulting in a broad spectrum of effects on the immune system including inhibition of the recruitment and proliferation of lymphocytes, monocytes and macrophages, migration of neutrophils to sites of inflammation, and decreased production of soluble inflammatory mediators including cytokines, leukotrienes, and prostaglandins[35].

Natural history

The natural history of 171 CD patients diagnosed between 1970 and 1993 has been studied in the Olmsted County, Minnesota population[36]. Of this cohort, only 43% ever required steroids before 1997 and of these, 58% were in complete remission after one month while 26% were in partial remission and 16% had no response. Of those who responded, the one-year outcomes were concerning as only 32% of patients had a prolonged response to corticosteroids, 28% became steroid-dependent and 38% had undergone surgery. These are data that are similar to the reported Danish, Copenhagen County experience[37]. Both exemplify the likelihood of developing steroid refractory or dependent disease with an accelerated course toward surgery. Hence, the requisite for steroids may be considered the "tipping point"[38] of CD that heralds a more complex subsequent course[39], including the need for surgery or the addition of an immunomodulatory agent.

Efficacy

Glucocorticosteroids are effective inductive agents for CD. The first definitive data came from the NCCDS, in which 60% of patients treated with prednisone (0.25-0.75 mg/kg per day) were in remission at 17 wk compared to 30% of placebo-treated patients[3]. Even more impressive were the results from the ECCDS in which 80% of patients treated with methylprednisolone (48 mg) achieved remission at 18 wk compared to less than 40% of placebo patients[4]. More recent randomized controlled studies have compared prednisolone (40 mg) or 6-methylprednisolone (48 mg) to budesonide (9 mg) in the treatment of active CD ileocolitis, with similar rates found for the induction of remission at 66% and 73% for the two systemic steroids[40,41].

Although in one retrospective review, 60% patients treated with alternate-day prednisone treatment (mean dose of 25 mg q.o.d.) maintained "favorable responses" for an average of 6.6 years[42], the overwhelming evidence does not support the use of corticosteroids for maintenance of remission. Neither the NCCDS nor ECCDS studies showed benefit of corticosteroids over placebo in maintaining remissions[3,4]. Conventional corticosteroids are not effective at preventing post-operative relapse[43] and a recent Cochrane review of three randomized double-blind placebo controlled studies showed no benefit of corticosteroid therapy in preventing relapses in patients with quiescent CD over 24 mo[44].

NON-SYSTEMIC STEROIDS

Budesonide, in delayed or controlled-release formulations that deliver the potent glucocorticoid to the ileum and/or right colon, has low systemic side effects owing to a high (80%-90%) first-pass metabolism[45]. Two randomized controlled studies demonstrated superiority of budesonide in the induction of remission in patients with ileal or ileo-right colonic disease[46]. In the first trial, 258 patients received 15, 9, or 3 mg of budesonide, daily, or placebo, with 43%, 51%, 33% and 20% of patients respectively achieving clinical remission in 8 wk ($P < 0.001$, $P = 0.009$ for the higher doses compared to placebo respectively)[47]. In the second study (n = 200), 9 mg/d, 4.5 mg BID twice daily budesonide or placebo yielded remission rates of 48%, 53%, and 33% respectively after 8 wk of treatment.

Although differences between the groups were not significant, when data from the two treatment groups were pooled, the budesonide group had a significantly greater decrease in CDAI than the placebo group ($P < 0.05$)[48]. One study comparing daily 18 mg, 9 mg, and 6 mg of budesonide found a dose-dependent effect, with 66%, 55% and 36% achieving remission. While for most patients, 9 mg/d is a sufficient dose, high disease activity (CDAI $\geqslant$ 300) or disease distal to the transverse colon responded better to the highest budesonide dose[49] and as discussed above, budesonide 9 mg/d has also been shown to be a more effective treatment than mesalamine for the induction of remission in mild-moderate active ileal and right-sided colonic CD[10]. When compared to prednisone, budesonide 9 mg/d there were no significant differences found in clinical remission rates[40,41,50,51] although a meta-analysis revealed the pooled rate difference of response of budesonide *vs* conventional corticosteroids to be - 8.5%, $P = 0.02$[52]. Budesonide was associated with fewer steroid side effects overall in three studies[40,41,50] and reduced incidence of moon facies and adrenal impairment in the other[51].

While extended treatment with budesonide has been shown to prolong the time to relapse compared to placebo, the difference was not sustained at one year with 3 mg[53] or 6 mg[54-56]. Similarly, another study found no difference in relapse rate at any time point over a one year period between patients treated with either 3 mg or 6 mg budesonide and placebo[57]. Neither budesonide 3 nor 6 mg/d was shown to be more effective than placebo in preventing post-operative clinical[58] or endoscopic recurrence[58,59]. Both a Cochrane review and meta-analysis confirmed that budesonide is ineffective at maintaining CD remissions[52,60]. However, in a trial that allowed flexible dosing of budesonide or prednisone over two years to maintain clinical quiescence and examined bone mineral density (BMD) in relation to efficacy and side effects in CD patients, only 37% of budesonide-treated patients withdrew from the study because of failure to improve or worsening disease. However, the average dose of budesonide required to maintain remissions was higher than (6.8 mg/d) doses used in the placebo-controlled trials. Nevertheless, among patients who were steroid-naïve prior to entering the study, smaller reductions in BMD were seen in the budesonide group compared to the prednisolone group (mean, -1.04% *vs* -3.84%; $P = 0.0084$)[61].

Budesonide at doses below 6 mg/d has been demonstrated to be safe for long-term (one year) use. Results from a pooled analysis of five one-year controlled trials using budesonide 6 mg/d showed that while the overall number of adverse events were not different between the budesonide and placebo groups, patients treated with budesonide had more endocrine and "resistance mechanism" disorders (infection) ($P = 0.0042$ and $P = 0.042$, respectively). The higher incidence of endocrine problems was primarily driven by acne and moon facies, while viral infections accounted for the difference in infection rate. Serious adverse events were reported as rare[62].

In summary, while budesonide is an effective and safe medication for the induction of remission in patients with mild-moderate ileal and proximal colonic disease, optimal dosing schedules to maintain remissions have yet to be established. While budesonide > 6 mg/d or an adjustable dose may maintain remission, a randomized controlled trial is needed to confirm the results of the open-label studies.

IMMUNOMODULATORS

Azathioprine (AZA)/6-Mercaptopurine (6-MP)

6-MP and its prodrug AZA are purine analogs that are converted into 6-thioguanine nucleotides (6-TG); the therapeutically active metabolites interfere with nucleic acid synthesis, exhibit anti-proliferative effects on activated lymphocytes and, most recently, have been shown to induce apoptosis[63,64]. These agents have been studied for the treatment of CD since the late 1960s, with multiple uncontrolled trials showing favorable results. A meta-analysis of AZA and 6-MP for the induction of remission included eight randomized placebo controlled trials ($n = 425$) while another for maintenance of remission included five trials ($n = 319$); three trials with induction and maintenance arms were included in both analyses[65,66]. For active disease, the overall response rate was 54% for patients receiving treatment compared to 33% for those on placebo, yielding a pooled odds ratio (OR) of 2.36 and the number needed to treat (NNT) for one patient to respond was 5; for quiescent disease, overall remission was seen in 67% of patients on treatment compared to 52% of those on placebo, for an OR of 2.16 and NNT of 7. In active disease, those receiving AZA or 6-MP for $\geqslant$ 17 wk resulted in an increased pooled OR of 2.51 and decreased NNT to 4. No dose effect was seen for active disease, but in the maintenance analysis, the OR increased from 1.2 for those taking 1 mg/kg per day to 4.13 at 2.5 mg/kg per day. Fistula healing in the induction studies (defined as complete closure or decreased drainage) was not reported consistently and numbers were small, but a response rate of 55% for treatment compared to 29% for placebo was seen, with an OR of 4.58. One study that was not included because number of fistulae rather than number of patients with fistulae were reported also showed favorable results: 9/29 fistulae (31%) in patients treated with 6-MP compared to 1/17 (6%) in patients taking placebo closed completely[67]. Steroid sparing effects were seen in both the induction and maintenance meta-analyses, with an OR of 3.86 and 5.22 respectively. Patients under treatment for both active and quiescent disease were also more likely to suffer an adverse event leading to withdrawal from studies, with an OR of 3.01 and 4.36 respectively; these events were typically nausea, allergic reactions including fever and rash, pancreatitis and leukopenia. From these studies, it can be concluded that AZA and 6-MP are effective in both the induction and maintenance of remission for CD, although given that maximal clinical benefit may not be evident for three to four months, use of this medication in active disease is best initially coupled with another induction regimen such as steroids, and further, dosing should be optimized for long-term care.

Candy & Wright conducted what is probably the most cited study included in these meta-analyses and elucidates both of these points. Sixty three patients with

active CD were administered a three month taper of prednisolone while randomized to receive either AZA (2.5 mg/kg) or placebo. Although there was no difference in the number of patients achieving remission at wk 12, 42% of the AZA group compared to 7% of the placebo group were in remission at 15 mo ($P = 0.001$)[68]. Further, several studies have evaluated the maintenance benefits of AZA in "withdrawal" trials. In a 12 mo open trial in which 29 patients in remission on AZA for more than two years (median 37 mo) were randomized to continued AZA or withdrawal of AZA, 11/13 (85%) of patients who continued treatment remained in clinical remission compared to 7/15 (47%) of patients who had not continued AZA ($P = 0.043$). This difference was amplified when a subgroup analysis of patients treated with AZA > 1.6 mg/kg per day was performed: 89% of those continued on AZA remained in remission compared to 33% of those withdrawn from AZA ($P = 0.017$)[69]. A larger, longer randomized, controlled trial enrolled patients who had been maintained in remission on AZA for ⩾ 42 mo. Forty patients were randomized to continue the same dose of AZA and 43 to receive placebo for 18 mo. At the end of the study, three patients in the AZA group compared to nine in the placebo group had relapsed: the hypothesis that placebo was inferior to AZA was not rejected ($P = 0.195$). The authors concluded that for patients maintained in remission on AZA, medication should be continued beyond 3.5 years[70].

There is also expanding evidence that AZA is effective as a post-operative maintenance therapy. In an open-label study, 142 patients who had undergone limited bowel resection and/or stricturoplasty were randomized to receive either mesalamine 3 g/d or AZA 2 mg/kg per day within 2 wk of surgery for 24 mo. While risk of clinical (28% *vs* 17% respectively, $P = 0.2$) or surgical (10% *vs* 6% respectively, $P = 0.5$) relapse was equivalent between the two groups, AZA was more effective in preventing clinical relapse among those patients who had undergone more than one surgery for CD (36% *vs* 13%, $P = 0.03$). In this study, adverse events occurred more frequently in AZA-treated patients and caused more frequent study withdrawal (22% *vs* 8%, $P = 0.04$)[71]. In a double-blind, double-dummy multi-center trial, 131 patients who had undergone ileocolonic resection were randomized to daily 6-MP 50 mg, mesalamine 3 g or placebo and were assessed clinically, endoscopically and radiologically at regular intervals over 24 mo. 6-MP was superior at preventing clinical relapse (77%) *vs* mesalamine (58%) or placebo (50%) ($P = 0.045$ for 6-MP *vs* placebo) and endoscopic recurrence (63%, 63%, 43% respectively, $P = 0.03$ 6-MP *vs* placebo) over two years[22].

Thus, treatment with AZA or 6-MP is usually of an "indefinite" duration for patients who have responded. A recent, large European retrospective review of patients treated long-term with AZA demonstrated that in patients with CD, risk of relapse was not greater in patients who discontinued therapy after three to four years, although treatment beyond this time frame improved clinical activity and decreased steroid requirements. The authors conclude that for asymptomatic, steroid-free patients, it may be reasonable to consider discontinuing medication after three to four years of treatment[72].

While thus far treatment with 6-MP or AZA has often been reserved for patients who have required steroids on more than one occasion, there may be benefit to starting these medications earlier in the disease course. A pediatric study randomized children with CD diagnosed within the previous 8 wk to receive 6-MP or placebo for 18 mo, each given with concomitant prednisone. Similar to the Candy study the short-term remission rates were not different between the groups, although patients in the placebo group relapsed significantly more than the 6-MP group (47% *vs* 9%, $P = 0.007$) and required more steroids and for a longer duration[73].

Increased risk of lymphoma with 6-MP and AZA has been debated, with discrepant findings among large series. A recent meta-analysis of six studies ($n = 3891$) showed a four-fold increased risk of lymphoma in IBD patients treated with 6-MP or AZA as compared to the general population: this translated to needing to treat over 4300 patients aged 20-29 and 355 patients aged 70-79 to cause one additional case of lymphoma per year. It is unknown whether this risk relates directly to the medication or to the severity of the disease[74]. Increased risk of hematologic malignancies has also been associated with prolonged leucopenia in IBD patients on 6-MP[75], and EBV-positive lymphomas have also been found more frequently in patients exposed to 6-MP or AZA[76]. The risk of infection with these medication ranges between 0.3%-7.4%[77] and include herpes viruses, human papilloma virus and upper respiratory infections. Physicians prescribing 6-MP and AZA should understand how thiopurine methyltransferase (TPMT) activity affects metabolism of these drugs and should monitor for potential leukopenia and/or hepatotoxicity on a quarterly basis. Measurement of the active metabolite 6-TG may be useful in guiding dosage of these medications.

Methotrexate (MTX)

Methotrexate is a folate analog and reversible competitive inhibitor of dihydrofolate reductase (DHFR). Methotrexate interferes with DNA synthesis and also has multiple anti-inflammatory effects including decreased pro-inflammatory cytokine production and lymphocyte apoptosis[78]. Two exploratory, open-label trials in medically-refractory CD patients with oral[79] or intramuscular (IM)[80] MTX led to the large, multicenter study by Feagan *et al*, in which 141 steroid-refractory patients with active CD were randomized to MTX 25 mg or placebo, intramuscularly over 16 wk. Prednisone was stabilized at 20 mg/d and subsequently tapered over 10 wk. After four months, 39.4% in the MTX group compared to 19.1% in the placebo group had achieved remission (CDAI ⩽ 150 and discontinuation of steroids)[81]. Patients taking MTX suffered significantly more adverse events than the placebo group (16/94) leading to study withdrawal in 17% compared to 2%, although the majority of these side effects were either nausea or asymptomatic liver test abnormalities[81]. Two smaller randomized controlled trials in patients with chronic active disease that compared oral

MTX (12.5 and 15-22.5 mg/wk) did not demonstrate differences in remission rates[82] or flares[83]. More than likely, these unfavorable results are attributable to low, oral dosing with smaller sample sizes as compared to the larger trial. Indeed the bioavailability of oral MTX has been shown to have great variability, averaging 73% that of subcutaneously administered medication[84]. Retrospective data have also reported comparable remission rates to those of Feagan[85-87]. When compared to AZA (2 mg/kg per day) or 6-MP (1.5 mg/kg per day), MTX (25 mg IM changed to po after 3 mo or 15 po/wk) yielded equal rates of remission[88,89], and oral MTX (15 mg/wk) resulted in higher remission rates than 5-ASA 3 g/d (80% *vs* 14%, $P < 0.01$)[89].

MTX also maintains remission in CD. Seventy-six patients who achieved remission with MTX 25 mg IM were randomized to MTX 15 mg IM/wk or placebo. At wk 40, 65% of the MTX group were still in remission as compared to 39% of those in the placebo group and fewer patients required prednisone (28% *vs* 58%, $P = 0.01$). There were no serious adverse events and only one withdrawal from the study secondary to nausea[90]. Several retrospective studies have shown comparable rates patients maintained in remission with MTX[85-87,91].

Mycophenolate mofetil

Mycophenolate mofetil is an ester prodrug of mycophenolic acid which not only inhibits synthesis of guanosine nucleotides and thereby indirectly interferes with T- and B-cell activity, but also inhibits growth of intestinal smooth muscle and synthesis of fibronectin and thus, theoretically could decrease stricture formation. A randomized controlled trial comparing mycophenolate mofetil to AZA in 70 steroid-dependent CD patients with moderately active disease showed equivalent response rates but those with highly active disease seemed to benefit more from mycophenolate mofetil than AZA[92]. Smaller non-randomized studies or series have yielded a combined response rate of 52% overall and 69% in patients with perianal disease[93].

Tacrolimus

Tacrolimus is a macrolide antibiotic used primarily to prevent allograft rejection in the transplant setting. Similar to cyclosporine, it binds to calcineurin and suppresses transcription of activated T-cells leading to decreased pro-inflammatory cytokines such as IL-2, TNFα and INFγ as well as inducing T-cell apoptosis, modifying expression of IL-10 and TGFβ, and may have local effects on the intestine. In a recent review that pooled data from 22 studies with a combined total of 286 patients who had been treated with tacrolimus, promising results in fistulizing disease, unresponsive CD and UC as well as extra-intestinal manifestations were reported[94].

BIOLOGIC AGENTS

Infliximab

Infliximab (Remicade® Centocor, Malvern PA) is a chimeric (75% mouse/25% human) anti-TNFα monoclonal antibody; TNFα mediates multiple pro-inflammatory processes central to the pathogenesis of IBD. The first study that defined efficacy of infliximab in the treatment of active CD randomized patients with moderate-severe, medically-refractory, disease to receive a single infusion of placebo or 5, 10 or 20 mg/kg of infliximab. Seventeen percent, 81%, 50% and 64% of patients respectively had a response (CDAI decrease ⩾ 70 points) at wk 4 ($P < 0.001$ for all infliximab patients *vs* placebo). Overall, 33% of all infliximab patients compared to 4% of placebo achieved remission at wk 4 ($P = 0.005$). While significantly more infliximab patients maintained a response at 12 wk, 37% had relapsed, suggesting that a single dose was insufficient[95]. Those patients who had an initial response to the single infusion were subsequently randomized to receive continued dosing with 10 mg/kg every 8 wk or placebo. After 44 wk, 53% of the infliximab group were in remission compared to 20% of the placebo group ($P = 0.013$)[96].

The ACCENT I study expanded on the potential maintenance benefits of infliximab after an initial response. In the trial, 573 patients received a 5 mg/kg intravenous (Ⅳ) infusion of infliximab at wk 0, after which they were assessed for clinical response by CDAI (decrease in score ⩾ 70 and a 25% reduction in total score). Three hundred and thirty five patients (58%) met this criterion and were randomized to one of three treatment groups: placebo at wk 2 and 6 and then every 8 wk (group Ⅰ), infliximab 5 mg/kg on the same schedule (group Ⅱ) or 5 mg/kg at wk 2 and 6 followed by 10 mg/kg every 8 wk (group Ⅲ). Treatment was continued for 46 wk. At wk 14 or later, patients in all groups who initially had response and then worsened were allowed to cross over to active episodic retreatment (infliximab 5, 10 or 15 mg respectively for groups Ⅰ, Ⅱ, and Ⅲ given on an "as needed" basis). At wk 30, 21% of patients in group Ⅰ, 39% in group Ⅱ ($P = 0.003$) and 45% in group Ⅲ ($P = 0.0002$) respectively were in remission, while median time to loss of response was reported as 19, 38 ($P = 0.002$) and more than 54 wk ($P = 0.0002$) respectively. Significantly more patients in groups Ⅱ and Ⅲ combined (29%) compared with group Ⅰ (9%) had discontinued steroids at wk 54, and fewer hospitalizations and surgeries related to CD occurred in the maintenance therapy groups. There were no differences in serious adverse events between the three groups[97]. A recently published endoscopic sub-analysis of the ACCENT Ⅰ trial showed that scheduled maintenance therapy compared to episodic treatment resulted in greater improvement in mucosal ulceration and higher rates of mucosal healing although the correlation between clinical and endoscopic responses was weak[98].

Infliximab is also effective in the treatment of fistulizing CD. In an initial induction trial, 94 patients with actively draining perianal or abdominal fistulas were randomized to receive three infusions at 0, 2, and 6 wk of placebo, 5 or 10 mg/kg infliximab. Twenty six percent, 68% and 56% of patients respectively achieved reduction in drainage from greater than 50% of fistulas ($P = 0.002$ and $P = 0.02$). Only 13% on placebo compared to 55% and 38% of patients on infliximab had closure of all fistulas ($P = 0.001$ and $P = 0.04$)[99]. In the ACCENT Ⅱ study, 306 patients with one or more draining abdominal or perianal fistulas (⩾ three months duration) received an induction regimen of three infliximab infusions (5 mg/kg).

One hundred ninety-five patients with a response at wk 10 and 14 as well as 87 with no response were randomized to placebo or infliximab (5 mg/kg) every 8 wk to wk 54. Time to loss of response was significantly longer for patients in the infliximab group than placebo (> 40 *vs* 14 wk, $P < 0.001$). Furthermore, at wk 54, 36% in the infliximab group compared to 19% in the placebo group had no draining fistulas ($P = 0.009$)[100]. Relapse of perianal disease after cessation of infliximab may occur earlier than in patients with luminal disease[101].

Antibodies to infliximab are known as both ATIs or HACAs (human anti-chimeric antibodies), and have been associated with lower serum drug concentration levels[97,102] and in turn, with decreased efficacy with episodic treatment[102,103]. In the ACCENT I population, however, equal numbers of antibody-positive and negative patients maintained clinical responses[97]. Additionally, although ATIs are also associated with an increased risk of transfusion reactions[102,103], most ATI positive patients will not have a reaction after re-treatment with infliximab and therefore ATI should not be routinely tested in the absence of loss of response or an infusion reaction[104]. Risk of antibody formation may be decreased by the three-dose induction followed by maintenance therapy[97,103], concomitant use of steroids and/or immunomodulators[97,99,102,103], and pretreatment with hydrocortisone[103]. Sex, location of disease, and smoking status does not appear to correlate with development of ATI[102].

Approximately 30% of patients have no response to infliximab and not all responders have a complete response. As reviewed by Rutgeerts and colleagues, positive predictors of response include elevated CRP, non-stricturing and pure colonic disease subtypes, and concomitant use of immunomodulators[105]. AZA or 6-MP are the immunomodulators most commonly paired with infliximab for CD and it is not clear if the higher response rates seen in combination therapy compared to infliximab alone represents an effect of decreased antibody formation alone or combined efficacy *via* other mechanisms. In contrast to IBD, infliximab has been used concomitantly with MTX in rheumatoid arthritis and a small pilot CD study showed that MTX dosed concomitantly with infliximab may increase remission rates, speed time to remission and decrease steroid use as compared to infliximab monotherapy[106]. Smoking has been found to be a negative predictor of response in two studies[107,108], but surprisingly not in one of the larger studies to examine factors influencing response to infliximab[109].

There has been considerable debate as to whether duration of infliximab treatment must necessarily be life-long or "indefinite," or whether episodic treatment may be a viable alternative. While the clinical and endoscopic benefits of maintenance therapy are demonstrated by ACCENT I and Ⅱ, it has been proposed that the traditional three-dose infliximab induction regimen 0, 2, and 6 wk could serve as a bridge to AZA, but this strategy appeared effective for only six to twelve months[110]. Thus, currently infliximab continues to be recommended for an indefinite period. Another emerging debate is how to position infliximab in the Crohn's treatment algorithm since current regulatory approvals have reserved indications for infliximab for patients who are steroid-refractory or dependent despite immunomodulator therapy. Some argue that this pyramid should be turned upside-down to position infliximab closer to the top, as it has been demonstrated that in steroid-free patients, initial treatment with infliximab and AZA compared with steroids and later addition of AZA leads to significantly more patients in remission and off steroids at 26 wk (60% *vs* 41%, $P = 0.03$) and mucosal healing[111]. If treating early in the disease course with infliximab proved to be disease-modulating, then the "top-down" approach could prove to be the better option to treat those patients on the brink of needing steroids. Arguments against this strategy include the economic costs and the possible safety risks[112].

The safety of infliximab also remains a significant concern with potential serious adverse events including infusion reactions, opportunistic infections including tuberculosis, non-Hodgkin's lymphoma (NHL) and other malignancies, as well as death. A true risk has been difficult to calculate, since most clinical trials did not have continuous placebo arms but instead, were cross-over designs or employed episodic treatment regimens such that most patients were exposed to infliximab at some point[113]. Serious infections were reported in 4% of patients overall in ACCENT I [97] and infliximab-related infections were seen in 8% of a large Mayo ($n = 500$) cohort study of infliximab-treated patients, half of which were serious[114]. As of February 2005, 709 cases of reactivated TB had been reported with infliximab, including 62 deaths[105]. The risk of lymphoma and other malignancies has been difficult to elucidate. The ACCENT I and the Mayo cohort study reported extra-colonic malignancy rates of 1% and 1.5% respectively, but a causal link to infliximab is unclear. CD patients overall likely have a slightly higher risk of NHL[115,116] and squamous cell cancer[116,117].

The TREAT registry has enrolled over 6000 patients from community and academic practices who have been classified in two groups: those who had received infliximab and those who had been treated only with other therapies. The infliximab and non-infliximab patients had similar risks of death, lymphoma and other malignancies; risk of serious infection was slightly higher in the infliximab-treated patients but Cox proportional hazard analysis later found that this risk was independently associated with steroid and narcotic use[118]. In contrast, a recently published decision analytic model projected a slightly increased rate of lymphoma and death in those treated with infliximab compared to those treated with standard therapy, although more quality-adjusted life years were demonstrated in the infliximab group[119]. Twelve cases of hepatosplenic T-cell lymphoma, a rare and incurable type of lymphoma, have been reported in a largely pediatric population (ages 12-31) on combination infliximab and 6-MP or AZA therapy; this association has led to a heightened concern for using these medications concomitantly especially in children, and studies are ongoing to better understand efficacy and safety issues with regard to combination *vs* single agent therapy.

Adalimumab

Adalimumab (D2E7, Humira®; Abbott Laboratories,

Chicago, IL) is a subcutaneously administered recombinant human IgG_1 monoclonal antibody that binds with high specificity and affinity to human TNFα and consists of human-derived heavy and light chain variable regions and human IgG_1 constant region. Adalimumab is now approved in the US and Europe for the treatment of CD. Two open-label trials treated patients with adalimumab who had previous exposure to infliximab. In the first, 24 patients who had lost responsiveness or developed intolerance to infliximab were treated with an initial dose of adalimumab 80 mg and then 40 mg every other week for 12 wk. Although 79% required dose escalation to 40 mg weekly, clinical remission and response at wk 12 was seen in 29% and 59% respectively[120]. In the second trial, 15 patients with attenuated response to infliximab were treated for six months with the same schedule of adalimumab as in the first study. Of the 13 patients who completed the trial, 54% had a complete response, 31% had a partial response, and 73% were able to discontinue steroids[121]. Most recently, the CLASSIC- I trial randomized 299 moderate to severe CD patients naïve to anti-TNF therapy to one of three dose combinations administered at wk 0 and 2 (160/80 mg, 80/40 mg, or 40/20 mg) or placebo. At wk 4, 36% (P = 0.001), 24% (P = 0.06), and 18% (P = 0.36) in the adalimumab groups, respectively, were in clinical remission compared to 12% in the placebo group[122]. Fifty-five patients who were in remission at wk 4 of CLASSIC I were randomized to receive continued adalimumab 40 mg every other week, weekly or placebo for up to one year as part of the CLASSIC Ⅱ trial in which 74%, 83% and 44% of patients, respectively, maintained remission at wk 56[123]. Similar to the ACCENT I study with infliximab, immunomodulator therapy again did not alter these results[124]. Finally, the CHARM trial (n = 854) examined adalimumab induction and maintenance efficacy in patients with moderately to severely active CD. An 80 mg dose at week zero and 40 mg dose at wk 2 were administered to all patients, with 499 (58%) achieving clinical response and then randomized to placebo, adalimumab 40 mg every other week, or 40 mg weekly through wk 56. Significantly higher rates of remission were seen in the adalimumab groups compared to placebo at both wk 26 (40% and 47% *vs* 17%, $P < 0.001$) and wk 56 (36% and 41% *vs* 12%, $P < 0.001$). The adalimumab groups also had significantly more steroid discontinuation and complete fistula closure. Safety data was comparable to other TNF therapy[125].

Certolizumab

Certolizumab pegol or CDP870 (UCB; Smyrna, GA) is a monoclonal humanized anti-TNFα antibody Fab' fragment linked chemically to polyethylene glycol (PEG). In contrast to infliximab and adalimumab the antibody fragment does not induce apoptosis[126]. Certolizumab has been evaluated in both induction and maintenance trials for CD[126,127]. In 92 patients with moderate to severe CD randomized to a single intravenous dose of 1.25, 5, 10 or 20 mg/kg of CDP870 or placebo, the primary endpoints of clinical response or remission after four weeks were not different between treatment groups and placebo, but the remission rate at wk 2 was 47% in the 10 mg/kg group compared to 16% in the placebo group (P = 0.041)[127]. The PRECISE 1 study compared subcutaneous certolizumab (100, 200 or 400 mg) to placebo administered at wk 0, 4, and 8 in 292 patients with moderate-severe CD. While all doses of certolizumab produced significant clinical benefit over placebo at wk 2, 400 mg had the strongest effect at all time points, most markedly at wk 10 (52.8% *vs* 30.1%, P = 0.006); however, no statistical significance in clinical response was seen at wk 12, the primary endpoint. When re-analyzed according to stratification by C-reactive protein level (> 10 mg/L), the 400 mg group had a significantly better response at wk 12 (53.1% *vs* 17.9%, P = 0.005) that was attributed to a lower placebo response rate than those patients with a CRP < 10[126]. In the PRECISE 2 trial, patients who responded to a 400 mg induction dose at wk 0 and 2 (428/668, 64%) were randomized to receive 400 mg certolizumab or placebo every 4 wk for 26 wk. Significantly more patients in the certolizumab arm achieved clinical response (62.8% *vs* 36.2%, $P < 0.001$) and remission (47.9% *vs* 28.6%, $P < 0.001$) at wk 26[128]. Safety and tolerability were similar to other anti-TNF agents, although patients treated with certolizumab had lower rates of autoantibody formation.

Fontalizumab

Interferon γ is cytokine with wide-ranging proinflammatory activity implicated in both animal models of colitis and found to have mucosal elevations in CD. Fontalizumab (Protein Design Labs Inc, Fremont, CA, USA) is a humanized form of mouse antihuman interferon γ antibody recently studied in CD. A controlled trial randomized 133 patients with moderate-severe CD to receive one or two doses of fontalizumab 4 mg/kg, 10 mg/kg, or placebo (28 d apart). Although no differences in response were demonstrated with single dose therapy, in those receiving two doses, response rate at d 56 was found to be 69% and 67% for the fontalizumab groups compared to 32% in the placebo groups (P = 0.02 and 0.03 respectively). This difference was more robust in patients with elevated CRP. Adverse rates were similar across treatment and placebo groups, and all serious adverse events except one were related to CD exacerbations[129].

SELECTIVE ADHESION MOLECULE INHIBITORS

Leukocyte emigration from the vascular space to inflamed tissue is a complicated process involving multiple leukocyte-endothelial interactions including tethering, rolling, firm adhesion, spreading, and migration. Leukocyte adhesion to activated endothelium is mediated primarily by the α_4 and β_2 integrins. The α_4 integrin is expressed on all types of white blood cells and can pair with either the β_1 or β_7 subunit. Endothelial ligands recognized by α_4 integrin include vascular cell adhesion molecule-1 (VCAM-1) and mucosal addressin cell adhesion molecule-1 (MadCAM-1); the former is induced at sites of inflammation, whereas the latter is expressed constitutively on the endothelium within Peyer's patches and other gut-associated lymphoid tissues[130].

Natalizumab

Natalizumab is a recombinant humanized antibody derived from a murine monoclonal antibody (AN100226m) (95% human and 5% mouse-derived) and targets human α_4 integrin. Antibodies to α_4 integrin have shown efficacy in animal models of multiple sclerosis and colitis[131,132]. The preliminary data supporting the use of natalizumab as an induction agent was equivocal as two trials of natalizumab in CD showed a trend toward clinical benefit with either one or two doses of 3 or 6 mg/kg compared to placebo, but primary endpoints did not reach significance[133,134]. Similarly, ENACT-1 did not demonstrate significant differences in clinical response or remission at 10 wk between CD patients (n = 905) treated with an intravenous infusion (300 mg) of natalizumab and placebo at wk 0, 4, and 8[135]. In contrast, the ENCORE study enrolled only patients with an elevated CRP (n = 509) and showed significantly higher rates of clinical response and remission at all time points in those treated with three doses of 300 mg natalizumab (0, 4 and 8 wk) compared to placebo[136].

More consistent outcomes have been shown in maintenance trials for natalizumab. In ENACT-2, initial responders to natalizumab (n = 339) received natalizumab (300 mg) or placebo every 4 wk through wk 56. Significantly more patients in the treatment group compared to placebo had a sustained response (61% *vs* 28%, $P < 0.001$) and remission (44% *vs* 26%, $P = 0.003$) through wk 36[135] and concomitant use of immunomodulators did not affect efficacy[137]. An open-label extension study of ENCORE showed that 84% of patients who were in remission after one year remained in remission for two years after continued monthly treatment with natalizumab[138].

In early 2005, three cases of progressive multifocal leukoencephalopathy (PML) were reported in patients treated with natalizumab, two of them fatal. Two patients had multiple sclerosis and one had CD. Natalizumab trials were subsequently suspended by the U.S. Food and Drug Administration (FDA) and the drug was removed from the market. A safety trial that included 90% of all CD, multiple sclerosis and rheumatoid arthritis participants from all previous natalizumab clinical trials failed to find any additional cases of PML, and the overall risk of PML was estimated at 0.1%[139]. In June 2006, the FDA approved resumption of natalizumab marketing targeting a restricted distribution program for selected MS patients.

MLN02

MLN02 is a humanized monoclonal antibody which specifically recognizes the α_4B_7 heterodimer but does not cross-react with the individual component monomers[140]. The major ligand for α_4B_7 is MadCAM1, and therefore this antibody should be gut-specific in theory. Although clinical and endoscopic efficacy has been demonstrated in patients with UC, patients with mild to moderate CD (n = 185) who received two doses of either 0.5 or 2.0 mg/kg at 0 and 29 d did not achieve the primary endpoint of clinical response at two months. On the other hand, clinical remission was seen in 36.9% of the 2.0 mg/kg group compared with 20.7% of the placebo group ($P < 0.05$)[141].

OTHER BIOLOGIC AGENTS

Visilizumab

Visilizumab (Nuvion™, Protein Design Labs) is a humanized IgG_2 monoclonal antibody (HuM291) to the CD3ε chain of the T-cell receptor expressed on activated T-cells. Designed to capitalize on the potent immunosuppressive effect of OKT3 (a mouse monoclonal antibody used primarily in the transplant setting), it minimizes the anti-mouse antibody response and also the adverse effects of the cytokine release syndrome. While trials in UC have demonstrated safety and efficacy, only one small open-label trial in medically-refractory (including infliximab) CD patients (n = 14) given two doses of visilizumab10 μg/kg on d 0 and 1, 58% and 33% experienced clinical response and remission respectively on d 89, with the mean prednisone dose dropping from 19 mg/d at baseline to 4 mg/d[142].

Anti IL-6 receptor antibody

IL-6 is another cytokine that plays a central role in the inflammatory process of CD. A monoclonal antibody to IL-6 receptor (IL-6R) has been shown to decrease expression of adhesion molecules and multiple pro-inflammatory cytokines in animal models of colitis. A randomized pilot study of humanized anti IL-6R (MRA) in 36 patients with active CD found that those given a biweekly infusion of MRA had an 80% clinical response rate compared to 31% of placebo patients ($P = 0.019$), although endoscopic and histologic examination showed no differences[143].

Anti IL-12 antibody

Interleukin-12 is an important cytokine in the Th1-mediated inflammatory response. A monoclonal antibody targeting IL-12 has been evaluated in a randomized trial in which uninterrupted weekly dosing at 3 mg/kg for seven weeks yielded higher response rates than placebo (75% *vs* 25%, $P = 0.03$), but a statistically significant difference was lost at 18 wk (69% *vs* 25%, $P = 0.08$). The more robust clinical response in the anti-IL-12 group was paralleled by decreases in colonic mononuclear cell secretion of IL-12, INF-γ, and TNFα[144].

Thalidomide

Because of its anti-TNFα and anti-IL-12 properties, thalidomide has been studied in two small open-label trials in mixed IBD populations, with the majority of patients in each achieving either clinical response or remission[145,146]; use of this medication is severely restricted because of its well-known teratogenicity and it is further limited by side effects of sedation and mood disturbances.

IMMUNE STIMULATION

Although immune dysregulation is believed to be a part of the pathogenesis of IBD, an alternative hypothesis proposes that an altered innate immune response is inherent to the etiology of CD. Based upon positive results in other disorders of neutrophil function, granulocyte-

macrophage colony-stimulating factor (GM-CSF), a myeloid growth factor that stimulates the growth and function of phagocytic cells, has been studied in CD. One hundred and twenty-four patients were randomized to receive sargramostim (GM-CSF) 6 mcg/kg per day subcutaneously or placebo for 8 wk: while the primary endpoint of a clinical response (defined by a decrease in CDAI of $\geqslant$ 70 points) was not met, significantly more patients in the sargramostim group reached the secondary endpoints of a decrease in CDAI of $\geqslant$ 100 points (48% *vs* 26%, $P = 0.01$) and remission at d 57 (40% *vs* 19%, $P = 0.01$). The sargramostim group suffered from significantly more injection site reactions and experienced more bone pain[147].

PROBIOTICS AND HELMINTHS

The theory of dysbiosis maintains that a decrease in protective or "good" bacteria and a concomitant increase in harmful or "bad" bacteria contribute to the pathogenesis of IBD. As a result, probiotics have been studied as both induction and maintenance treatment in CD. Open label and small randomized controlled trials using various preparations of probiotics have shown inconsistent results as summarized by Rioux and Fedorak[148]. Large randomized placebo controlled trials are needed in order to determine true efficacy. Similarly, observations that IBD is uncommon in developing countries where helminthic colonization is prevalent and that helminths downregulate Th1 immune responsiveness have led to trials utilizing non-pathogenic helminthes in an attempt to treat UC and CD. An open-label trial of *Trichuris suis* (porcine whipworm) has been studied as a therapy for CD in which 29 patients with active CD ingested 2500 live *Trichuris suis* ova every 3 wk for 24 wk: as defined by CDAI scores, 79% responded and 72% remitted[149]. While results from this study are intriguing, a controlled trial again is essential before deeming worm therapy beneficial.

ULCERATIVE COLITIS

Aminosalicylates

Aminosalicylates (5-ASA) remain the first-line therapy for both induction and maintenance of mild-moderate UC. The efficacy of sulfasalazine specifically has been well-established, but dose-dependent intolerance to the sulfa moiety limits its use in up to one-third of patients[150]. Therefore, non-sulfa-containing 5-ASA agents have been studied as well. Recent Cochrane reviews analyzed the effectiveness of these newer 5-ASA medications both in comparison to placebo and sulfasalazine for the induction and maintenance of remission in UC. Twenty one randomized controlled trials ($n = 2124$) of 5-ASA were included in the induction meta-analysis, nine comparing 5-ASA to placebo and 12 to sulfasalazine[151]; results were reported in terms of failure rates. 5-ASA provided benefit over placebo in the induction of remission, with a pooled OR of 0.53 overall and 0.36 when only the Asacol trials were included. While 5-ASA was better than placebo across all dosage ranges, there was a trend toward a dose-effect. 5-ASA was also more likely to elicit a global or clinical response than placebo, with a pooled OR of 0.40 and higher doses yielding better results, $P = 0.002$. 5-ASA was also superior to placebo at inducing endoscopic remission, but only at doses $\geqslant$ 3 g/d. No significant differences were found between 5-ASA and sulfasalazine in induction of remission or response, although a trend towards 5-ASA superiority was observed. Significantly more patients taking sulfasalazine withdrew from studies secondary to adverse events, with an OR of 0.34; it should be noted that tolerance to sulfasalazine was an inclusion criteria for most of the studies, which may have made this effect less robust.

Sixteen trials ($n = 2479$) were included in the 5-ASA maintenance of remission meta-analysis, five comparing 5-ASA to placebo and 11 to sulfasalazine[152]. 5-ASA was more effective than placebo in maintaining endoscopic or clinical remission, with an OR of 0.47; a dose effect was not observed. Sulfasalazine was superior to 5-ASA in the maintenance of remission in trials of six month duration, with an OR of 1.29, but the statistical significance was lost when only studies with endpoints at 12 mo were included. In subgroup analyses by specific 5-ASA preparation, only olsalazine was found inferior to sulfasalazine, likely secondary to the greater number of adverse events (the most common being diarrhea) and subsequent withdrawals in patients receiving this medication. The authors stated that conclusions could not be reached with regard to other 5-ASA preparations. Save for olsalazine, there were no differences in adverse events between 5-ASA when compared to placebo or sulfasalazine. If sulfasalazine truly has superiority over 5-ASA in maintenance of remission (beyond olsalazine), the authors conjecture that unknown pharmacologic effects of the sulfapyridine moiety previously thought to function only as a carrier of 5-ASA to the colon, could contribute to this finding.

5-ASA formulations

There is no definitive data to suggest that one 5-ASA preparation is superior to another. In one study, balsalazide 6.75 g/d (Colazal®, Salix Pharmaceuticals, Morrisville, NC, USA) was found to induce remission in a greater number of patients with active moderate-severe UC than equivalent doses of Asacol 2.4 g/d (62% *vs* 37% at 12 wk, $P = 0.02$). Further, the median time to complete symptom relief was significantly shorter in the balsalazide than mesalamine group (10 *vs* 25 d, $P = 0.004$)[153]. Two subsequent studies comparing these same medications at the same doses did not demonstrate differences in primary endpoints of rectal bleeding and at least one other sign or symptom at wk 8[154] or symptomatic remission at wk 8[155]. Secondary endpoints showing balsalazide to have a faster time to onset[154,155] or better effect in new onset left-sided disease[155] cannot be considered more than preliminary given that primary endpoints were not met[156]. Further, no differences between balsalazide and sulfasalazine or Salofalk® (a delayed-release pH dependent mesalamine formulation) have been found[156]. Additionally, as will become evident below, a suboptimal dose of Asacol® was used in these studies[157]. As well, non-traditional clinical assessments were employed[158], and the Asacol® was not equivalent to that used in the US and in pivotal trials, as demonstrated by *in vitro* dissolution experiments[159].

Pharmacokinetic data in healthy patients demonstrates no differences in systemic absorption of 5-ASA between Asacol and balsalazide at equimolar doses[160]. Therefore, choice of 5-ASA agent should be based upon tolerability, ability to titrate dose to effect and cost.

Dose-effect

The recent ASCEND trial showed a dose-effect based on severity of disease. An overall response rate of 72% at wk 6 was found in patients with moderate activity (n = 268) treated with mesalamine 4.8 g/d (investigational 800 mg tablet, Procter and Gamble Pharmaceuticals, Mason, OH) compared to 59% in those receiving Asacol® 2.4 g/d (P = 0.036). No difference in response rate in patients with mild disease was demonstrated with the two different doses[161]. Patient compliance in taking 5-ASA may be enhanced by a higher dose tablet, SPD476 (1.2 g/tablet) which uses both a gastro-resistant polymer film to delay release of active drug until it reaches the terminal ileum and Multi Matrix System (MMX) which helps deliver 5-ASA evenly throughout the colon. MMX 2.4 g/d and 4.8 g/d are superior to placebo in the induction of remission in mild-moderate UC[162].

Topical mesalamine

Rectal mesalamine induces remission more effectively than placebo or topical steroids in distal UC[163,164], although both medications taken concomitantly are superior to mesalamine alone[164]. Topical mesalamine is superior to placebo and at least as effective as oral mesalamine in the maintenance of remission for distal UC[163,164].

STEROIDS

For patients without sufficient response to 5-ASA agents or those with moderate-severe disease, glucocorticosteroids have remained the foundation for inducing remission in UC since the early 1950s when Truelove and Witts reported significant benefit for cortisone over placebo[165]. For mild to moderate UC, a dose effect for prednisone 20-60 mg/d has been reported, but doses greater than 60 mg/d confer no additional benefit[166]; further, there does not appear to be a difference between once daily and divided dosing[167]. For those with severe colitis or not responding to oral regimens, parenteral steroids are administered. While mineralocorticoid and anti-inflammatory potencies vary, no data suggests one preparation is superior to another; methylprednisolone 40-60 mg/d or an equivalent dose of hydrocortisone is the most commonly used. Adrenocorticotropic hormone (ACTH) promotes endogenous corticosteroid production and may have benefit in steroid-naïve patients, but is no longer commonly utilized due to the potential for adrenal hemorrhage[35]. Pulse-dose steroids in the form of dexamethasone 100 mg/d have shown efficacy in a small open-label trial[168], but a controlled trial has not yet been conducted and a recent systematic review suggests the absence of a dose-response above the equivalent of 40 mg of prednisone[169]. Dividing intravenous bolus dosing is equally effective to a continuous infusion[170].

Predictors of decreased response rate to steroids and increased risk for colectomy include greater severity and extent of colitis[171,172], and most recently persistence of stool frequency > 8/d or CRP > 45 mg/L beyond three days of treatment[173]. Higher levels of glucocorticoid receptor beta (GRβ) have also been associated with glucocorticoid resistance in several studies[174-176]. Of those patients who will respond to IV steroids, the majority do so within five days[177], but most practitioners will continue treatment for 7-10 d[35].

NON-SYSTEMIC STEROIDS

With the multitude of adverse effects of systemic steroids, non-systemic steroids have generated great interest in UC given their high-first pass metabolism and minimal toxicity. Because most of budesonide is released in the distal ileum and proximal colon, making it an effective medication for the treatment of CD in this location, its role in UC is likely very limited, although one study showed equal efficacy to prednisolone in those with left-sided or extensive colitis[178]. An oral formulation of beclomethasone dipropionate (BDP) coated with Eudragit L preventing gastric dissolution and releasing at pH 6.0 for delivery in the terminal ileum and throughout the colon was evaluated in a single-blind randomized trial enrolling 177 patients with mild-moderate UC[179]. Patients who received BDP 5 mg/d for 4 wk had equivalent reductions in mean disease activity index or DAI (assessment of clinical and endoscopic response) and clinical remission rates as those receiving 5-ASA 2.4 g/d, although a significantly greater improvement in DAI was seen in those with extensive disease in the BDP group. BDP was also found to have an additive effect when given in conjunction with 5-ASA[180].

Non-systemic steroid enemas are beneficial in the treatment of active distal UC. Budesonide enemas have significantly higher remission rates than placebo, between 19%-51% with daily 2 mg/100 cc dosing[181,182]; higher doses do not appear to be of greater benefit but may result in more adrenal impairment[182]. While 2 mg twice weekly was not any more effective than placebo in the maintenance of remission[182], it is possible that the optimal dosage for preventing relapses has not been defined. When compared to topical mesalazine (1 g/100 mL per day), budesonide enemas were equally effective in improving histologic and endoscopic scores but clinical remission rates were higher in the mesalazine group[183]. Budesonide enemas are equally or more beneficial than traditional steroid enemas in clinical, endoscopic and histologic measures and induce less adrenal suppression[184-186]. Budesonide foam and enemas resulted in similar clinical remission rates in a large double-blind, double-dummy trial[187]. Similarly, BDP enemas have shown equal efficacy to 5-ASA[188] and prednisolone enemas[189], but are not associated with adrenal axis suppression[189]. The combination of 5-ASA and BDP was superior to either alone[188].

IMMUNOMODULATORS

AZA and 6-MP

The first reported use of AZA in the treatment of UC was in the 1960s, but results from initial controlled trials

in the mid-1970s did not show clinical or endoscopic benefits over placebo[190,191]. However, it became apparent that treatment with AZA consistently permitted significant steroid reduction compared to placebo[191,192]. Patients with UC in remission on AZA ⩾ six months relapsed at a higher rate over one year when withdrawn to placebo (59%) as compared to those who continued AZA (36%), $P = 0.039$; this effect was more pronounced with longer pre-trial remission rates[193]. Later retrospective studies also reported the steroid-sparing effect of AZA and 6-MP[194-197], higher relapse rates with cessation of 6-MP[194,195], and fewer colectomies in those patients maintained on AZA[196,197]. Length of treatment appears to correlate with efficacy: a large retrospective review of both CD ($n = 272$) and UC ($n = 346$) patients treated with AZA found a remission rate of 87% in those patients treated more than six months, compared to 59% overall. Other factors predictive of remission were the diagnosis of UC (*vs* CD), lower white blood cell (WBC) or neutrophil count, a higher mean corpuscular volume and older age. On continued AZA, 95%, 69%, 55% of patients at 1, 3 and 5 years respectively were maintained in remission compared to 63%, 44%, and 35% after discontinuation of AZA; risk of relapse was lower in those with WBC ⩽ 5.0×10^5 ($P = 0.03$)[198].

Compared to mesalazine at a dose of 3.2 g/d, significantly more steroid-dependent patients treated with AZA, 2 mg/kg, achieved both clinical and endoscopic remission as well as steroid discontinuation (53 *vs* 21%, $P = 0.006$)[199]. The addition of 5-ASA to AZA does not confer greater benefit than AZA alone in the maintenance of remission[200,201] or steroid-withdrawal[200].

METHOTREXATE (MTX)

While an initial small open-label study of MTX in IBD held promise for both CD and UC[80], randomized controlled trials have shown benefit in CD only[81,90]. Although several additional open-label or retrospective studies of MTX in UC showed favorable effect[91,202,203], two randomized controlled trials showed no differences in the induction or maintenance[89,204] of remission between patients given oral MTX 12.5[204] or 15 mg[89] per week compared to placebo. It should be noted, however, that in the definitive study that established the efficacy of MTX in the induction of remission in CD, patients were given 25 mg IM; ideally, a second randomized controlled trial in UC utilizing a higher dose of MTX would be conducted.

CYCLOSPORINE

Cyclosporine (CSA) is a lipophilic peptide with multiple anti-inflammatory effects including downregulation of IL-2, thus inhibiting proliferation and activation of T-helper cells[205]. After the first promising open-label trial in 1990 in which 73% of 15 severe, steroid-refractory UC patients treated with Ⅳ CSA (4 mg/kg) improved over an average of 5.8 d and avoided colectomy[206], a double-blind controlled trial that randomized 20 patients with severe steroid-refractory UC to Ⅳ CSA (4 mg/kg) or placebo showed an 82% response rate in the CSA group at a mean of seven days compared to zero in the placebo group ($P < 0.001$). All five placebo group patients given CSA during the open-label phase responded to treatment and over two-thirds of all responders avoided colectomy at six months[207]. In non-randomized controlled trials, long-term remission rates have been less impressive ranging between 14%-40%[208-212]; "bridging" to AZA after induction with Ⅳ CSA and a short course of oral CSA improves maintenance rates, with 40%-90% of patients avoiding colectomy after 16-78 mo[213-215]. Similarly, in a retrospective review at the University of Chicago, 62% of all UC patients ($n = 42$) treated with CSA avoided colectomy over a mean follow-up of 23 mo. This rate improved to 72% among initial CSA responders and to 80% in initial responders who were later transitioned to 6-MP or AZA[216]. Skipping oral CSA and transitioning directly to (6-MP or AZA) after Ⅳ therapy does not seem to alter long-term outcome[217].

CSA is associated with significant morbidity, including opportunistic infections, neurologic and renal toxicity, hypertension, and rarely, death[218]. Several variations in therapy may decrease the risk of these adverse events without compromising efficacy: the use of low-dose CSA (2 mg/kg)[218-220], oral microemulsion CSA (Neoral®) with 60% bioavailability[221-223], and Ⅳ CSA without concomitant steroids[224]. Higher percentages of band forms on differential WBC count[225], tachycardia > 90 bpm, fever > 37.5℃, elevated CRP > 45 mg/L, and greater than one severe endoscopic lesion are negative predictors of response[226]. Ideally, administration of CSA should be limited to physicians trained or experienced in the use of potent immunosuppressants or transplantaion[227].

TACROLIMUS

UC patients with active refractory moderate-severe disease ($n = 63$) were randomized to tacrolimus dosed to maintain either a high (10-15 ng/mL) or low (5-10 ng/mL) trough or placebo for two weeks with an open-label extension segment. Sixty-eight percent of patients in the high-trough group achieved partial response as measured by the UCDAI (number of bowel movements, bleeding and physician's global assessment) compared to 10% in the placebo group ($P < 0.001$). While 38% in the low-trough group achieved a partial response, this did not meet statistical significance; however, significant differences were found on multiple components of the UCDAI between the low-trough group and placebo. When placebo patients crossed-over to the open-label extension, 58% achieved response ($P = 0.012$). While no differences in overall adverse events were found, patients in the high-trough group experienced more medication-related adverse events than the placebo group[228]. A recent review of tacrolimus in IBD patients also found overall favorable results in the treatment of refractory UC[94].

MYCOPHENOLATE MOFETIL

Few trials have examined the efficacy of mycophenolate mofetil (MMF) in UC. In a six month open-label uncontrolled study, 24 steroid-dependent chronic active IBD patients received MMF 2 g/d and were tapered to

5 mg of prednisone per day by the second three months. Among the 13 UC patients, six achieved remission by three months, but all relapsed during the second part of the study[229]. The results were equally disappointing in the CD population, with only one patient maintaining remission by the end of the study. A retrospective study of 39 largely steroid-dependent and AZA-refractory or intolerant IBD patients given a median dose of MMF 1.5 g/d reported more favorable results, with 40% of patients in remission off steroids after a mean duration of 19 mo of treatment[230]. An open-label study randomized 24 patients with active UC to receive either MMF (20 mg/kg) or AZA (2 mg/kg), each given with a tapering dose of prednisolone over one year. While the AZA group experienced significantly greater decreases in the clinical colitis activity index (CAI) than the MMF group at three and six months, these differences were no longer significant at nine and twelve months. Further, although at almost all time points, more AZA-treated patients were in remission and using fewer steroids than the MMF group, none of these differences were statistically significant[231].

BIOLOGIC AGENTS

Infliximab

While several small studies of infliximab collectively showed equivocal efficacy in UC, the ACT (Active Ulcerative Colitis Trials) 1 and 2 provided definitive evidence supporting its efficacy in this population[232]. ACT 1 patients were refractory or intolerant to steroids and/or AZA/6-MP, while ACT 2 also included those refractory or intolerant to 5-ASA agents as well. In each trial, 364 patients received either placebo or infliximab 5 or 10 mg/kg at wk 0, 2, and 6 and then every 8 wk through wk 46 and 22 with follow-up data collected to wk 54 and 30 respectively. In ACT 1 and 2, infliximab at either dose was significantly more beneficial than placebo at all time points in achieving clinical response and remission, mucosal healing, and discontinued use of steroids. Overall, approximately two-thirds in the infliximab group achieved clinical response and one-third achieved long-term remission, while 22% discontinued steroids. Rates of adverse events were similar between groups, although one case each of tuberculosis and histoplasmosis (the latter resulting in death) as well as three neurologic complications occurred in the infliximab group. ATIs were found in 6% and conferred a mildly higher risk of infusion reaction. Concomitant immunomodulator therapy was associated with a lower rate of antibody formation, but no conclusions can be reached given the small numbers with ATI overall. Five mg/kg is the recommended starting dose given that there were no significant differences found between the two doses.

While the ACT studies have established infliximab as effective treatment for UC in the outpatient setting, the role of infliximab in the treatment of hospitalized patients is uncertain. Forty-five moderate-severe or fulminant UC patients refractory to Ⅳ steroids at 5 and 3 d respectively were treated with a single dose of infliximab 5 mg/kg or placebo. Overall, infliximab patients avoided colectomy within the first three months more often than placebo patients (67% *vs* 29%, $P = 0.017$); however, in a subgroup analysis of those with fulminant colitis compared to placebo, this difference was no longer significant (69% *vs* 47%, $P = 0.276$)[233]. In an open-label trial of infliximab in 12 hospitalized steroid-refractory UC patients, nine underwent colectomy within three months[234]. Two recent studies showed favorable response profiles to infliximab in patients with acute severe UC[235,236], and it has been hypothesized that this subset of patients may be different than those with established disease.

SELECTIVE ADHESION MOLECULE INHIBITORS

Natalizumab (Tysabri®, Elan and Biogen Inc, USA)

Only one open-label trial of natalizumab has been conducted in UC, in which 10 patients with active disease were given a single dose of 3 mg/kg: while significant clinical and quality of life improvement were seen at one month, only two patients entered remission and by 8 wk, 80% of patients required rescue medication[237]. Given the association of PML with this medication in CD and MS patients, the status of future trials is unknown.

MLN02

Compared to those who received placebo, mild-moderate UC patients ($n = 181$) who received two doses of MLN02 0.5 or 2.0 mg/kg over one month experienced higher rates of clinical remission (33% and 32% *vs* 14%, $P = 0.03$), clinical response (66% and 53% *vs* 33%, $P = 0.002$), endoscopic remission (28% and 12% *vs* 8%, $P = 0.007$) and endoscopic improvement (48% and 35% *vs*16%, $P = 0.001$)[140]. Antibodies to MLN02 were found in 44% of patients; of those with titers ⩾ 1:125, 24% had loss of saturation to $\alpha_4\beta_7$ binding sites with the clinical remission rate in this group close to that of placebo. There were no differences in adverse events. MLN02 appears promising, but more research will need to assess long-term response and optimal dosing.

Alicaforsen

Alicaforsen (ISIS 2302, Isis Pharmaceuticals, Inc. Carlsbad, CA) is a 20-base phosphorothioate oligodeoxynucleotide antisense molecule that down-regulates messenger RNA for intracellular adhesion molecule I (ICAM-1), a transmembrane glycoprotein that is up-regulated by pro-inflammatory mediators. ICAM-1 is involved in leukocyte activation and migration and elevated levels in serum and mucosa have been found in animal models and patients with IBD[238]. Parenteral alicaforsen was not effective in CD[239], but enema formulations appear beneficial in UC and pouchitis in small studies. In one trial ($n = 40$), mild-moderate active distal UC patients who received daily alicaforsen enemas at 0.1, 0.5, 2, or 4 mg/mL for one month experienced an overall dose-dependent improvement in disease activity index (DAI) ($P = 0.003$). At three months, DAI in the 4 mg/mL group dropped by 72% compared with 11.5% in the placebo group ($P = 0.016$), and no one in the alicaforsen group needed additional therapy at six months compared to 50% of placebo patients[240]. No serious adverse events were reported.

ANTI-INTERLEUKIN-2 (IL-2)

IL-2 is a cytokine produced by activated T-cells that binds to the high affinity receptor IL-2R in the presence of the α-chain CD25 and thereby perpetuates T-cell proliferation and activation[241]. Further, high levels of IL-2 have been associated with steroid-resistance[242]. Two anti-IL2 antibodies have been evaluated in UC.

Daclizumab (Zenapax, Roche, Basel, Switzerland), is a recombinant humanized monoclonal antibody (IgG_1) to IL-2R. Although a small, open-label pilot study initially held promise for this antibody[243], a recently published randomized controlled trial (n = 159) found no difference in response or remission rates between two doses of daclizumab and placebo given every other week for 8 wk[244]. Basiliximab, a chimeric monoclonal antibody to the IL-2R (CD25) α-chain, induced remission in the majority of 10 steroid-resistant UC patients given a single dose in an open-label trial[241]. Additionally, *in vitro* testing performed in healthy volunteers and quiescent UC patients as part of this study showed that basiliximab reverses steroid-resistance, and thus anti-IL-2 treatment might have particular potential in steroid-resistant patients.

VISILIZUMAB (NUVION)

Visilizumab, an anti-CD3 monoclonal antibody is undergoing evaluation in severe UC. In an open-label phase I trial, 79% and 54% of steroid-refractory UC patients treated with 10 mcg/kg per day (n = 24) for two consecutive days experienced response and remission respectively at d 30, and 100% of those treated with 15 mcg/kg per day (n = 8) achieved both response and remission[245]. Sixty-three percent of patients receiving the higher dose remained in remission at one year. Almost two-thirds of patients experienced symptoms of cytokine release syndrome 1-3 h post-infusion, including nausea, chills, fever, headache and arthralgias. Decreased T-cell levels persisted for a mean of three weeks post-infusion. Because elevations in EBV titers were reported in patients with graft versus host disease who received visilizumab[246], this UC study excluded EBV+ patients, but a large open-label trial including EBV+ patients is ongoing.

INTERFERONS

Interferon-alpha (IFNα)

IFNα has a range of anti-viral, anti-tumor and anti-inflammatory activity, including induction of IL-1 receptor antagonist and soluble TNF receptor p55, and downregulation of Th-2 cytokines[247]. With the recognition that IFNα does not induce colitis flares in those being treated for chronic hepatitis who have co-morbid UC[248,249] IFNs have been studied as treatment for UC.

In a small (n = 28) open-label trial of IFNα2a given subcutaneously for 6-12 mo in UC patients, 93% achieved and maintained clinical and endoscopic remission for two years[250], while another small study showed only short-lived benefit of IFNα2a over prednisolone enemas in treating distal UC[251]. In the only randomized placebo controlled trial, UC patients refractory to 5-ASA agents, steroids or AZA (n = 60) received either weekly pegylated INFα2b 0.5 or 1 mg/kg or placebo: no difference in clinical or endoscopic response was demonstrated, and a high attrition rate was seen in all groups, mostly secondary to lack of efficacy[247]. Thus, while INFα does not appear to exacerbate UC when treating chronic hepatitis, it is not effective as a primary treatment for UC.

Interferon B

Interferon β (INF-β) also has anti-inflammatory properties including the upregulation of IL-10 and IL-1 receptor antagonist and downregulation of TNF and IL-2. INF-β has had varied results in the treatment of UC. In an open-label pilot study, 88% of 25 steroid-refractory UC patients treated with either Ⅳ human natural IFN-β or subcutaneous recombinant IFN-β for a mean of 52 wk achieved remission lasting over a year[252]. While one small randomized trial showed endoscopic benefit in patients treated with IFNβ1 compared to placebo[253], a larger controlled trial failed to show any advantage recombinant IFNβ1a over placebo in clinical response or remission, endoscopic index, or steroid reduction[254].

GROWTH FACTORS

Growth factors may restore the protective and reparative foundation of the colon, and therefore represent a possible therapeutic option for UC. Growth factors that have been identified as potentially beneficial in treating UC include transforming growth factor β (TGF-β), epidermal growth factor (EGF), keratinocyte growth factor-1 and 2 (KGF-1 or 2, also known as fibroblast growth factor 7 or 10). Repifermin is a truncated, purified KGF-2 expressed in *Escheria coli*, and induces the proliferation of intestinal and colonic mucosa and reduces intestinal ulcers and inflammation in animal models[255]. Intravenously administered repifermin (1-50 μg/kg) for five consecutive days did not yield different rates of clinical response or remission at wk 4 compared to placebo in patients with active UC[255]. Among other reasons, the authors suggested that under-dosing and/or under-powering could have accounted for the negative findings. EGF is a mitogenic peptide produced by salivary and duodenal Brunner's glands: topical application is beneficial in wound healing and systemic EGF is useful in treating neonatal necrotizing enterocolitis[256]. An 83% remission rate was demonstrated in patients with mild to moderate left-sided UC (n = 24) randomized to daily EGF enemas for 2 wk compared to 8% in the placebo group ($P < 0.001$); disease activity, endoscopic and histologic scores remained significantly better in the EGF group through 12 wk[256]. Rebamipide is an amino acid analog of 2-(1H)-quinolinone used to treat gastric ulcers in Japan. It aids mucosal healing by stimulating local prostaglandin synthesis and epithelial cell regeneration *via* upregulation of EGF and its receptor, neutrophil suppression, and decreased production of inflammatory cytokines stimulated by NSAIDs and/or *H pylori*[257]. A small open-label trial in which twice daily Rebamipide enemas were given to patients with UC proctitis for one month demonstrated significant clinical, endoscopic and histopathologic improvement[258]. Larger

controlled trials are needed to evaluate this class of therapy in UC.

CURCUMIN

Derived from tumeric, curcumin appears to inhibit NFκB and possesses anti-inflammatory, anti-microbial and tumor-suppressing characteristics; it has been shown to prevent and treat colitis in animal models. Fewer patients with quiescent UC (n = 82) randomized to 5-ASA plus curcumin compared to 5-ASA plus placebo relapsed over six months (2 *vs* 8, $P = 0.04$)[259].

NICOTINE

While CD is exacerbated and more difficult to treat in active smokers, UC by contrast is a disease of non-smokers. Older patients diagnosed with UC are commonly ex-smokers[260]. One study showed that while the risk of developing UC was not statistically different between those who never smoked and active smokers, ex-smokers were at greater risk to develop UC, suggesting that cessation of smoking increases risk[261]. It is speculated that nicotine alters systemic and/or gut immune function in a protective way; the exact mechanism remains unknown[262]. A Cochrane review found that transdermal nicotine (15-25 mg/d for 4-6 wk) induces remission more readily than placebo although benefit was not greater than mesalamine or corticosteroids. More patients experienced side effects (nausea and light-headedness) with nicotine compared to the other medications[263]. In contrast, transdermal nicotine is no more effective than placebo in the maintenance of remission[264], and nicotine enemas are no more effective than placebo in achieving remission in patients with distal UC[265].

APHERESIS

Selective apheresis of leukocytes, including the targeted removal of monocytes, granulocytes, and lymphocytes is a growing area of research in the treatment of UC. Review of leukocyte apheresis studies shows efficacy in inducing remission across various UC populations in small, open trials[266], but the inherent process of apheresis makes controlled studies difficult to conduct. Two larger trials have demonstrated that leukocyte apheresis (n = 76) and granulocyte/monocyte apheresis (Adacolumn®) (n = 69) are equally or more effective than steroids in the induction of remission[267,268], with fewer adverse events[267] and greater steroid-sparing effects[268]. In the only sham-controlled trial to date, 19 patients with moderate to severe UC treated with five weekly sessions of either leukocyte apheresis (followed by every other week for 4 wk) or sham apheresis demonstrated that the leukocyte apheresis group had significantly greater clinical improvement (80%) than the sham group (33%)[269]. Maintenance of remission after apheresis has been equivocal: in one study of 71 patients with active UC treated with leukocyte apheresis, only 27% of those with an initial response (n = 53) maintained remission for more than six months; rapid response to treatment was the only factor correlated with long-term response in multivariate analysis[270]. In another study, however, 26 of 33 patients maintained remission at one year after 11 weekly sessions of granulocyte/monocyte apheresis[271]. Apheresis may be effective in other settings as well, including a small group of patients with toxic megacolon[272], acute pouchitis[273] and a patient with pyoderma gangrenosum[274].

PROBIOTICS

While there is suggestion that probiotics may benefit patients with active UC, data are limited. Open-label studies with VSL #3[275] and *Saccharomyces boulardii*[276] have shown promise, while a small randomized controlled trial of bifidobacterium fermented milk (100 cc/d for 12 wk) in 20 patients demonstrated significant clinical, endoscopic and histologic improvement over placebo[277]. *Bifidobacterium longum* combined with Synergy, a prebiotic (inulin oligofructose growth substrate) showed a trend toward endoscopic improvement over placebo and significantly decreased inflammatory cytokines such as TNFα and IL-1 in the treated group[278]. No difference in relapse rates were seen among 327 patients with quiescent UC given *Escherichia coli* Nissl 1917 compared to mesalamine over 12 mo[279]. Among 187 patients with inactive UC given either *Lactobacillus* GG, mesalamine or a combination of the two treatments, no differences in relapse rates at six or twelve months were seen across the three groups, although treatment with lactobacillus GG alone or together with mesalamine prolonged relapse-free time[280]. A review by Rioux and Fedorak, showed that VSL #3 has also been beneficial in the maintenance of remission for pouchitis[148].

TRICHURIS SUIS

Although the mechanism is unclear, helminthic colonization has been theorized to be protective against the development of IBD based both on epidemiologic and animal model data. In a randomized controlled trial of 54 patients with active UC, those who received *Trichuris suis* ova every 2 wk for 12 wk had a greater response rate (43%) compared to those who received placebo (16.7%), $P = 0.04$[281]. While intriguing, this study has been questioned regarding whether the statistically significant decrease in activity index of the treated group represents a clinically significant difference[282].

CONCLUSION

The treatment of IBD is a burgeoning field: in particular, the introduction of infliximab, an anti-TNFα medication, almost a decade ago, has been the most significant addition to the spectrum of therapeutic options in IBD, which for many years was primarily limited to 5-ASAs, antibiotics, steroids and immunomodulators. Medications may be used either to induce or maintain remission. Choice of therapy depends largely on the severity of disease, and may also be influenced by such factors as disease location, side effects and adverse events, as well as cost. While there is much debate presently regarding "top-down" compared to the traditional "step-up" treatment a reversal of the

"therapeutic pyramid" awaits more data regarding short- and long-term efficacy, safety, and pharmacoeconomic data. Aminosalicylates remain the standard induction and maintenance therapies for UC but have a more equivocal role in CD. Despite a paucity of evidence, antibiotics are also commonly used in CD, especially with colonic and perianal disease. Budesonide is effective as a first-line agent for ileal and/or right colonic CD although maintenance benefits remain to be proven. Conventional steroids induce remission for both CD and UC but are reserved for patients with moderate-severe disease or for those who have failed more first-line therapy. Immunomodulators such as 6-MP and azathioprine, as well as methotrexate, are effective steroid-sparing and maintenance therapies. Cyclosporine or tacrolimus can be effective for severe or refractory UC. Anti-TNF agents have been effective for patients with moderate-severe UC and CD, independent of concomitant medications. Potential side effects, costs and immunogenicity remain issues relating to current and future biologic agents. Novel therapies continue to be explored as the immunopathophysiologic underpinnings of IBD continue to be elucidated and an ultimate etiopathogenesis remains undetermined.

Abstract

Patients with long-standing inflammatory bowel disease (IBD) have an increased risk of developing colorectal cancer (CRC). Many of the molecular alterations responsible for sporadic colorectal cancer, namely chromosomal instability, microsatellite instability, and hypermethylation, also play a role in colitis-associated colon carcinogenesis. Colon cancer risk in inflammatory bowel disease increases with longer duration of colitis, greater anatomic extent of colitis, the presence of primary sclerosing cholangitis, family history of CRC and degree of inflammation of the bowel. Chemoprevention includes aminosalicylates, ursodeoxycholic acid, and possibly folic acid and statins. To reduce CRC mortality in IBD, colonoscopic surveillance with random biopsies remains the major way to detect early mucosal dysplasia. When dysplasia is confirmed, proctocolectomy is considered for these patients. Patients with small intestinal Crohn's disease are at increased risk of small bowel adenocarcinoma. Ulcerative colitis patients with total proctocolectomy and ileal pouch anal-anastomosis have a rather low risk of dysplasia in the ileal pouch, but the anal transition zone should be monitored periodically. Other extra intestinal cancers, such as hepatobiliary and hematopoietic cancer, have shown variable incidence rates. New endoscopic and molecular screening approaches may further refine our current surveillance guidelines and our understanding of the natural history of dysplasia.

INTRODUCTION

The two forms of inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC), are characterized by chronic, relapsing inflammation of the intestines. First described in a report by Crohn and Rosenberg in 1925[1], colorectal cancer (CRC) in patients with IBD has long been recognized. Even years after their disease is controlled with medications, IBD patients still live with the fear of developing cancer. CRC is the most common site of cancer in IBD, although cancer in other organs can occur. Together with the hereditary syndromes of familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer, IBD is among the top three high-risk conditions for CRC. To date, our understanding of CRC pathobiology has come from studies of patients with UC more so than Crohn's colitis. This review will focus mainly on the problem of CRC, and then address other cancers such as small intestinal adenocarcinoma, cholangiocarcinoma, and hematologic malignancies.

COLORECTAL CANCER IN PATIENTS WITH IBD

Prevalence and Incidence of CRC

The exact magnitude of the risk of cancer has been difficult to quantify due to various biases and methodological errors in published studies. Early estimates of CRC complicating UC were based on crude percentages and all were from major medical institutions, predominantly tertiary referral centers. Studies from these centers often included a greater proportion of patients who had more severe disease and cancer had already complicated their colitis. These center-based studies often overestimate the risk. Later population-based studies tended to include more patients with limited disease or those who have undergone colectomy and may thereby underestimate the true risk. Based on a 2001 meta-analysis by Eaden *et al*, including 116 studies from around the world, the prevalence of CRC in patients with UC is approximately 3.7% overall and 5.4% for those with pancolitis[2]. In comparison, CRC in Crohn's disease has been less well studied. Early studies showed no statistically significant increase in cancer risk among the Crohn's disease patients. However, the lack of the risk of cancer in these studies was often due to inclusion of all patients with Crohn's disease and failed to correct for the small subsets of those with extensive, longstanding and unresected colonic disease. Hence, when patients with longstanding,

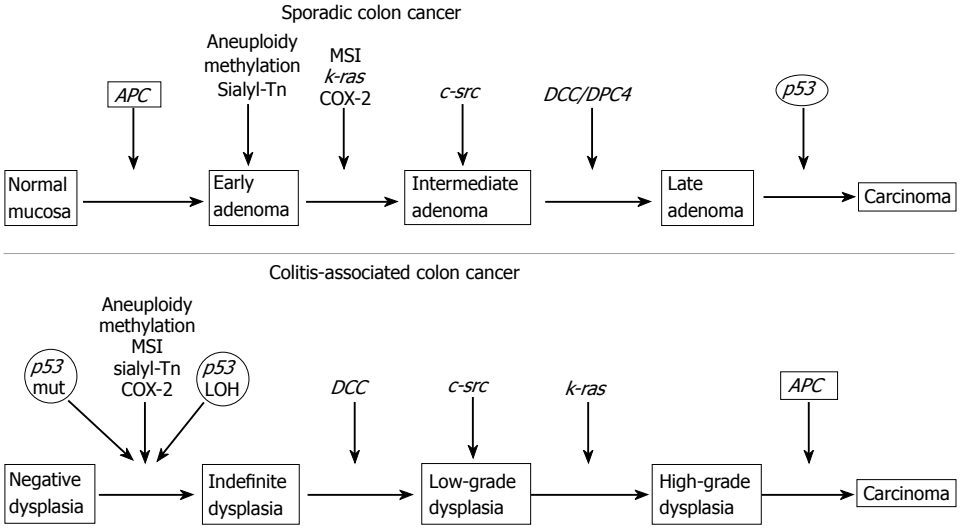

Figure 1 Comparison of molecular alterations in sporadic colon cancer and colitis-associated colon cancer. Mut, mutation. Modified from Ref 71. With permission.

anatomically substantial Crohn's colitis are considered, the risk of CRC is similar between Crohn's colitis and UC[3]. Indeed, a population-based study from Manitoba, Canada found that the risk for colon cancer among patients with both UC and Crohn's colitis is approximately 2-3 fold greater than the general population and that the risk of rectal cancer is increased 2-fold in UC but not Crohn's colitis[4].

Clinical features of colitis-associated CRC

Compared with sporadic colorectal carcinoma (SCC), CRC arising in patients with IBD has several distinguishing clinical features. Colitis-associated colorectal cancer (CAC) affects individuals at a younger age than the general population. CAC progresses to invasive adenocarcinoma from flat and nonpolypoid dysplasia more frequently than SCC. CACs more often have a higher proportion of mucinous and signet ring cell histology. There is background of chronic inflammation in colitis and a higher rate of two or more synchronous primary CRCs. The multifocality of CAC relates to the broader field effect of mucosal inflammation that gives rise to the neoplasia. In some studies, patients were found to have cancer more proximal in the colon. Finally, the sequence of molecular events leading from dysplasia to invasive adenocarcinoma is different from that of SCC (discussed below).

Molecular features of sporadic colon cancer

To place the molecular pathogenesis of colitis-associated neoplasia in proper perspective, it is important to appreciate the molecular events involved in the development of SCC. SCC arises as a result of genomic instability. The two main types of genomic instability that contribute to colon carcinogenesis are chromosomal instability (CIN) and microsatellite instability (MSI), accounting for 85% and 15% of SCC, respectively. Chromosomal instability results in abnormal segregation of chromosomes and abnormal DNA content (aneuploidy). As a result, loss of chromosomal material (loss of heterozygosity) often occurs, such as *APC* and *p53*. These genes can also be rendered nonfunctional by mutation.

Loss of *APC* function is typically an early event in SCC pathogenesis. The *APC* gene thus has been considered the "gatekeeper" of the colon (Figure 1). Some 85% of all sporadic and inherited colorectal tumors show loss of *APC* function, usually through protein truncation or allelic loss[5]. The *APC* gene is located on chromosome 5q21-q22. The key tumor suppressor function of the *APC* protein lies in its ability to destabilize free β-catenin[6]. Among the 15% of colon carcinomas that retain wild-type *APC*, point mutations have been found in β-catenin that change one of the four serine/threonine residues in the N-terminus, the putative targets of glycogen synthase kinase-3β (GSK-3β)[7]. These mutations thus render β-catenin refractory to phosphorylation by GSK-3β, increasing free β-catenin levels. Accumulation of stabilized free β-catenin is an early event and perhaps the initiating event in intestinal tumorigenesis. Inactivation of both *APC* alleles is found in a majority of small colorectal adenomas in humans and in the smallest detectable tumors in mice heterozygous for an inactivating mutation in *APC*[8]. Furthermore, intestine-specific expression of a dominant-negative form of β-catenin, which lacks the putative GSK-3β targets sites, leads to the development of adenomas[9]. How the loss of *APC* or stabilization of β-catenin leads to development of cancer is not yet fully understood. Once a sporadic adenoma forms, other changes in genetic regulation occur, such as induction of *k-ras* oncogene and loss of function of tumor suppressor genes on chromosome 18q in the region of the deletion in colon cancer (*DCC*) and in pancreatic cancer (*DPC*4) genes. Loss of *p53* gene function occurs late and is believed to be the defining event that drives the adenoma to carcinoma.

Tumors that arise *via* the CIN/tumor suppressor gene pathway are typically microsatellite stable (MSS). The remaining 15% of sporadic CRCs arise through the MSI pathway. The MSI pathway involves the primary loss of function of genes that usually repair DNA base-pair mismatches that occur during the normal process of DNA replication in dividing cells. In humans, at least six different proteins (*hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, *hMSH6*, and *hMLH3*) comprise the mismatch repair system[10]. These proteins form specific heterodimers to coordinate DNA repair and the recruitment of other proteins, such

as polymerases and helicases, necessary for mismatch repair. Germline mutations of DNA mismatch repair genes, predominantly *hMLH1* (33%) and *hMSH2* (31%), are responsible for the familial syndrome of heriditary nonpolyposis colon cancer[11]. In addition, approximately 15% of sporadic tumors from the colon, rectum, and other organs demonstrate MSI[12]. Interestingly, the most common mechanism causing MSI in sporadic colon cancers is not genetic mutation, but rather transcriptional silencing of *hMLH1* as a consequence of methylation of the *hMLH1* promoter[13].

Epigenetic alterations can also contribute to altered gene expression in colon carcinogenesis. The CpG island methylator phenotype occurs when cytosines in the promoter region of genes become extensively methylated. A number of human cancer genes that contain hypermethylation of promoter CpG islands have been identified[14]. These include *hMLH*, $p16^{INK4a}$, and *E-cadherin*. The process of methylation is an area of intense investigation, and it is anticipated that this line of research should help to define further the molecular pathways involved in CRC in a variety of clinical settings.

Molecular features of CRC in IBD

The neoplastic transformation in IBD is thought to be similar to the adenoma-carcinoma sequence in sporadic CRC (Figure 1). However, unlike SCC, where dysplastic lesions arise in one or two focal areas of the colon, in colitic mucosa, it is not unusual for dysplasia or cancer to be multifocal, reflecting a broader "field effect". Many of the molecular alterations responsible for sporadic CRC development also play a role in colitis-associated colon carcinogenesis. The emerging evidence suggests that the two major pathways of CIN and MSI also apply to CACs and with roughly the same frequency (85% CIN, 15% MSI). Distinguishing features of CAC, however, are differences in the timing and frequency of these alterations (Figure 1). For example, *APC* loss of function, considered to be a very common early event in SCC, is much less frequent and usually occurs late in the colitis-associated dysplasia-carcinoma sequence. Conversely, *p53* mutations in sporadic neoplasia usually occur late in the adenoma-carcinoma sequence, whereas in patients with colitis, *p53* mutations occur early and are often detected in mucosa that is non-dysplastic or indefinite for dysplasia.

Methylation is assuming increasing importance as a mechanism contributing to the genetic alterations in CAC (Figure 1). Methylation of CpG islands in several genes seems to precede dysplasia and is more widespread throughout the mucosa of UC patients[15].

CRC risk factors

Several factors have been identified which either increase or decrease CRC risk in the setting of IBD (Table 1). With respect to increasing CRC risk, the most important factor, reproducibly found across many studies, is the duration of colitis. CRC is rarely encountered before 7 years of colitis. The pooled estimate of cumulative CRC incidence in UC in Eaden's meta-analysis was 2% at 10 years, 8% at 20 years, and 18% after 30 years of disease[2]. This may overestimate the risk since many studies in the meta-analysis were from the pre-surveillance era. Thus, a recent study by Rutter *et al* showed lower cumulative incidence of CRC in patients with UC even at the referral-based St. Mark's Hospital in London: 2.5% after 20 years of disease, 7.6% after 30 years, and 10.8% after 40 years of follow-up[16].

Table 1 Factors associated with CRC risk

Factors that increase CRC risk
Longer duration of colitis
Greater extent of colonic involvement
Family history of colorectal cancer
Primary sclerosing cholangitis
Young age of IBD onset (some studies)
Backwash ileitis (possibly)
Severity of histologic inflammation
History of dysplasia
Factors that decrease CRC risk
Prophylactic total proctocolectomy
Regular doctor visits
Surveillance colonoscopy
Chemoprevention

Extent of colitis is an independent risk factor for the development of CRC. The more colonic surface that is involved with colitis, the greater the CRC risk. However, different criteria exist regarding classification of the extent of colitis. Most early reports of surveillance programs used barium enema results at diagnosis as the standard for defining disease extent. A population-based study of over 3000 UC patients in Sweden examined by barium enema demonstrated that patients with proctitis had a standardized incidence ratio (SIR) of 1.7 [95% confidence interval (CI) 0.8-3.2] compared with age-matched population controls without UC, whereas those with left-sided colitis had a SIR 2.8 (95% CI 1.6-4.4), and those with pancolitis had SIR 14.8 (95% CI 11.4 to 18.9)[17]. Endoscopic and histologic evidence of inflammation are valid alternative criteria particularly in high risk patients. Very few studies have correlated CRC risk with histologic extent of disease, even though microscopic evidence of colitis is arguably a better indicator of disease extent than either endoscopic or radiographic changes. Mathy *et al*[18] reviewed 30 colectomy specimens and showed that dysplasia and CRC can arise in areas of microscopic colitis that are proximal to areas of gross colitis, suggesting that indeed histologic changes, even without colonoscopic alterations, might better define disease extent for the purposes of cancer risk. Backwash ileitis, defined as pancolitis with superficial involvement of the terminal ileum, has been suggested as an additional increased risk of CRC[19], but this requires additional confirmation.

IBD patients with a family history of CRC have at least a two-fold higher risk of CRC[20-22]. Both UC and Crohn's disease patients with primary sclerosing cholangitis (PSC) are at particularly high risk for developing colorectal neoplasia[23]. In a population-based Swedish study, the cumulative incidence of CRC in UC patients with PSC was 33% at 20 years[24]. By comparing patients with UC with and without PSC, Shetty *et al*[25] reported an adjusted relative risk (RR) for dysplasia or cancer of 3.15 (95% CI, 1.37 to 7.27) in patients with PSC. Current practice

guidelines recommend all patients with PSC not previously known to have IBD should undergo a colonoscopy to determine their status. For those patients with IBD, screening and subsequent surveillance should begin at the diagnosis of PSC, and if the patient progresses to the point at which liver transplantation is necessary, prophylactic colectomy should be considered. Young age at onset of colitis has been reported to be an independent risk factor for CRC in some[2,17,26], but not all studies[27,28]. There is insufficient evidence to support starting screening and surveillance before 8 years of disease in these patients. The severity of colitis has not been considered an independent risk factor for CRC when activity of disease is defined according to the frequency of clinical exacerbations[22]. However, a case-control study by Rutter *et al* showed that increased severity of inflammation, both endoscopically and histologically, correlates with increased frequency of dysplasia[29]. It is important to realize that the patient with quiescent IBD is also at increased CRC risk.

With regard to reducing CRC risk, there are two main choices: removing the colon versus conducting a lifelong program of surveillance (Table 1). Although prophylactic total proctocolectomy after 7-10 years of colitis would prevent most cancers, it would result in many colectomies that were not necessary and a substantially altered quality of life for patients. Thus cancer prevention in this patient population has focused on periodic surveillance colonoscopies. Surveillance should be viewed as a program that includes regular visits to the doctor, the use of medications to control inflammation (some of which may have chemopreventive effects, see below), and regular colonoscopies. The goal of surveillance colonoscopy is to detect neoplastic lesions before they become biologically dangerous. Thus, the detection and interpretation of dysplasia is crucial to successful surveillance.

DIAGNOSING DYSPLASIA

Macroscopic classification of dysplasia

By definition, dysplasia is unequivocal neoplasia. Despite considerable heterogeneity in appearance[30], dysplasia in IBD is often classified macroscopically as raised or flat, depending on whether it corresponds to an endoscopically visible lesion. Raised lesions, conventionally referred to by the term DALM (dysplasia associated lesion or mass)[13], can appear as polyps, bumps, plaques and velvety patches[31,32]. Such lesions can blend easily with the gross inflammatory abnormalities commonly encountered in colons with IBD, making their endoscopic detection difficult even for experienced practitioners.

Unlike sporadic cancers arising from polypoid lesions, IBD-associated cancers can arise from flat dysplastic lesions. Flat dysplasia is detected microscopically in random biopsies from unremarkable mucosa. Its detection therefore depends on adequate sampling of the mucosa by the endoscopist, or more recently, by chromoendoscopy methods which highlight suspicious lesions and permit targeted biopsies (see below). If random biopsies are performed without dye spray enhancement, it has been estimated that to exclude dysplasia with a 90% certainty, 33 biopsy specimens are required, and to increase the accuracy to 95%, nearly twice the number of biopsy specimens are required[33]. Current surveillance strategies recommend annual colonoscopy with multiple biopsy specimens (4 circumferential) taken from every 10 cm of diseased colon, with additional biopsy specimens at sites of strictures or raised lesions[34]. However, questionnaire surveys have suggested that the number of biopsies taken by endoscopists in routine practice often falls short of recommended guidelines[35,36].

The significance of dysplasia in endoscopically visible lesions came from studies that reported high rates of cancer when patients with such lesions underwent colectomy[31,32]. Blackstone *et al* reported cancers in 7 of 12 DALM-bearing colons, including 5 with only mild or moderate dysplasia in the preoperative biopsies[31]. A subsequent compilation of published results from ten surveillance programs reported cancers in 17 of 40 (43%) colectomies performed because of a DALM[37]. It was concluded that DALM is an indication for colectomy irrespective of the grade of dysplasia in preoperative biopsies. While not fully appreciated at the time, the original studies of DALMs dealt exclusively with lesions that could not be removed endoscopically for microscopic examination. Thus, the significance of such lesions as an indication for surgery is similar to that of endoscopically non-resectable sporadic adenomatous polyps, which frequently harbor invasive cancer at the polyp base despite the presence of low-grade dysplasia in their more biopsy-accessible upper portions.

More recently, we have come to realize that not all types of polypoid dysplasia in patients with IBD carry the same significance. Some polyps may be adenomatous polyps unrelated to colitis and can be managed by endoscopic polypectomy like polyps in the general population[38-40]. One example is the dysplastic polyp encountered in a bowel segment that is entirely free of disease (e.g., in the proximal colon of a patient with left-sided ulcerative colitis). In such cases, one would take the precaution to biopsy the mucosa surrounding the polyp to assure the absence of microscopic disease. Similarly, a dysplastic polyp with a well-defined stalk can be regarded as a sporadic adenoma, even when encountered in a colitic region, if the mucosa lining its stalk is non-dysplastic.

Conservative management is also reasonable for dysplastic polyps that are "adenoma-like"[41,42]. These polyps are endoscopically indistinguishable from sporadic sessile adenomatous polyps, i.e., discrete and ovoid or round, are completely resectable by the endoscope, and are not surrounded by flat dysplasia. Such lesions have long posed a dilemma for endoscopists who were familiar with the DALM concept but reluctant to advocate colectomy for what appeared to be innocuous lesions and possibly nothing more than fortuitous adenomas. Histology has not provided a reliable means of making this distinction in individual cases[43], since the histological features of dysplasia in the setting of IBD and in true adenomas can be virtually identical. A 1999 study from The Mount Sinai Hospital in New York reported that conservative management of a cohort of 48 UC patients with a total of 70 such polyps, including 3 with high-grade dysplasia, resulted in no adverse outcomes during a mean follow-up

period of 4.1 years[41]. Similar conclusions were reached in a concurrent study from Brigham and Women's Hospital[42] that was confirmed upon longer follow-up[44]. As a result, the burden of deciding whether a polyp qualifies as adenoma-like rests with the endoscopist. Molecular markers may ultimately afford a more objective means of making these distinctions[45,46], but to date, these analyses are not applicable to routine clinical practice.

Microscopic classification of dysplasia

Gastrointestinal dysplasia is defined microscopically as replacement of the native intestinal epithelium by an unequivocally neoplastic, but noninvasive, epithelium[47]. It is synonymous with the term "intraepithelial neoplasia" used in other organ systems. A standardized classification system of dysplasia in IBD was established and divided dysplasia into five categories: negative for dysplasia, indefinite for dysplasia, low-grade dysplasia (LGD), high-grade dysplasia (HGD) or invasive cancer[47]. A further subdivision of the indefinite category includes probably negative, probably positive, unknown, however many pathologists regard this as optional.

The cellular abnormalities that define dysplasia in IBD are analogous to those characterizing neoplastic tissue in general, namely nuclear abnormalities reflecting inappropriate cellular proliferation and cytoplasmic abnormalities reflecting clonality and aberrant differentiation. The distinction between low- and high-grade dysplasia depends upon the distribution of nuclei within the cells, low-grade dysplasia being characterized by nuclei that remain confined to the basal half of the cells and high-grade by nuclei that are stratified haphazardly between the basal and apical halves[47]. Not surprisingly, pathologists are frequently confronted with biopsies that lie in a gray zone between the two categories, and some degree of subjectivity is therefore unavoidable. The diagnostic category "indefinite for dysplasia" is an acknowledgement of the difficulty pathologists face in discriminating between dysplasia and reactive epithelial changes, although experienced pathologists are usually able to discriminate between the two.

There is inconsistency among pathologists in the diagnosis of dysplasia on biopsy. In one study[48], there was only 60% agreement for a diagnosis of LGD. Similarly Lim *et al*[49] found that the kappa coefficient for interobserver agreement between ten pairings of five specialist gastrointestinal (GI) pathologists ranged from 0.06 to 0.39. Other studies comparing diagnoses of dysplasia among different pathologists, both prospectively and retrospectively, have concluded that levels of interobserver agreement are fair at best even among specialists in gastrointestinal pathology[50-54]. The best agreement levels tend to occur at the two extremes of negative and high-grade dysplasia and the poorest levels in the two gray zones between low-grade and high-grade dysplasia and on either side of indefinite for dysplasia. From a practical standpoint, it has been recommended that diagnoses carrying serious management implications be reviewed by at least one additional pathologist with expertise in this area[55].

BIOLOGY OF DYSPLASIA

Natural history of dysplasia

The natural history of dysplasia is a key factor contributing to the outcome and success of surveillance. The model shown in Figure 1 suggests that colitic mucosa progresses in a systematic fashion: no dysplasia, indefinite dysplasia, LGD, HGD, and finally invasive cancer. Although this is a useful paradigm that facilitates the study of cancer risk markers in IBD, it remains unclear whether dysplasia of one grade may "progress" (or "regress") to another grade. For example, patients undergoing regular colonoscopic surveillance have developed CRC without any prior dysplasia, and it is not necessary for LGD to progress to HGD before cancer arises in the colon[30,56]. This highlights the need to develop markers that are complementary to dysplasia for predicting CRC risk in IBD patients-a subject of ongoing investigation.

In the meantime, we currently rely upon the histological identification of dysplasia to make management decisions. Refinements in interpreting dysplasia based on the 1983 standardized histological criteria[47] have enabled a more accurate prediction of which patients are more likely to progress to advanced neoplasia by excluding those whose biopsies only show reactive changes secondary to inflammation. This was amply illustrated by the St. Marks group who found that the 5-year cumulative rate of progression from LGD to HGD or cancer rose from 16% to 54% once biopsies were more precisely reclassified[53,57].

Dysplasia (of any grade) is associated with a risk of concurrent CRC in IBD. An early study reported 12 cases, described as unresectable single polypoid masses, collections of polyps, or plaque-like lesions, 7 were found to have adenocarcinoma upon colectomies despite multiple biopsies that had not detected it[31]. In a review of ten prospective surveillance trials, 43% of patients who underwent colectomy because of DALM had coexistent CRC, 42% (10 of 24) patients with HGD, and 16% (3 of 19) patients with LGD who underwent immediate colectomy had synchronous CRC[37]. Ullman and colleagues at The New York Mount Sinai Hospital performed a retrospective cohort analysis of 46 patients with UC who had flat LGD but did not undergo immediate colectomy. They found that 27% (3 of 11) patients who underwent colectomy within 6 months of the initial detection of flat LGD had a surprise finding of cancer or HGD[56]. More recently, Rutter *et al* from the St. Mark's Hospital reported 20% of patients with LGD who proceeded to colectomy had concurrent adenocarcinoma and 39.1% who had follow-up of the LGD progressed to subsequent HGD or CRC[16].

Assuming that early colectomy is not performed, what is the subsequent rate of progression? In the case of patients with HGD, 32% were found to have CRC after some follow-up period[37]. For those with LGD, the probability of eventually progressing to HGD or CRC was 16%-29%[37]. Data from St. Mark's Hospital indicate that the 5-year cumulative probability of progressing from LGD to HGD or cancer is 54%[53]. Strikingly similar results were obtained from The Mount Sinai Hospital, with a 5-year progression rate of 53% among 46 patients

with initial flat LGD[56]. A recent follow-up analysis from the St. Marks' group indicates slightly lower, but still substantial rates of progression[16]. Likewise, a series of 18 patients with LGD followed at the Mayo Clinic demonstrated a 33% 5-year progression rate[58]. Despite these rather similar results from three different patient populations, some authors have reported a substantially lower rate of progression. Befrits *et al* followed 60 patients with flat LGD from the Karolinska Institute in Sweden and found that none developed cancer and only 2 cases of progression to HGD in DALMs over a mean follow-up period of 10 years[59]. In the series by Lim *et al* from Leeds in the U.K., they reported that only 3/29 (10%) patients with LGD progressed to HGD or cancer after 10 years[49]. It is worth noting that in the latter two studies, the designation of LGD included specimens that were interpreted prior to the 1983 consensus guidelines, so they might have included cases with indefinite dysplasia.

Because of uncertainty of flat LGD[56,60], these studies have failed to achieve consensus on proper management of flat LGD. Hence, competing options should be discussed with each patient. A patient confirmed to have multifocal flat LGD (2 or more biopsies with LGD from a single screening or surveillance examination) or repetitive flat LGD (2 or more examinations with at least a single focus of LGD), should be strongly encouraged to undergo prophylactic total proctocolectomy. Furthermore, even for patients with confirmed unifocal LGD (only 1 biopsy positive for LGD in a screening or surveillance examination) should also be offered the option of undergoing prophylactic proctocolectomy, since evidence indicates that a 5-year rate of progression to HGD or CRC in this patient group seems to be similar to that of multifocal LGD[56].

THE MANAGEMENT OF DYSPLASIA

Once a decision is made to place a patient under surveillance, it is recommended that the patient formally agree to enter such a program and is willing to comply. Patients must be made to understand the limitations of surveillance and accept the concept that despite their own cooperation, dysplasia and cancer can still arise even in the hands of skilled endoscopists and pathologists[53].

The best proof that surveillance colonoscopy effectively reduces CRC mortality would be a prospective, randomized, controlled trial in which patients with longstanding IBD would undergo colonoscopic surveillance whereas controls matched for a similar risk profile would not. However, due to ethical, financial and practical limitations, this type of study will likely never come to pass. We must therefore rely on retrospective studies for insights as to the efficacy of surveillance colonoscopy. In a retrospective study by Choi *et al*, patients with chronic UC who developed cancer were divided into those who had surveillance colonoscopy and those who did not. Patients undergoing surveillance colonoscopy were found to have less advanced Dukes' stage CRC than those who did not and correspondingly had an improved 5-year survival rate (77.2% *vs* 36.3%, $P = 0.026$)[61]. However, the best evidence that colonoscopy reduces mortality from CRC in UC comes from case-control studies. In one such study, Karlen and colleagues identified 2 of 40 patients with UC and 18 of 102 controls who had undergone at least one surveillance colonoscopy who died as a result of CRC (RR = 0.29), CRC mortality was reduced by as much as 78%, although this did not reach statistical significance[62]. Another study found a similar degree of protection[22]. In these studies, a protective effect was found for individuals who had even one or two surveillance exams. There is also good evidence from prospective, albeit uncontrolled, studies of surveillance colonoscopy that in general, patients who comply with surveillance have cancers detected at earlier stages compared to those who do not comply[53,63]. Of course, cancers will still arise even within a surveillance program, but in balance, the practice of surveillance is beneficial[64].

Although the gastroenterology community has put its faith in surveillance colonoscopy to prevent CRC in IBD patients, surveillance has its limitations. Previous studies have shown low rates of observer agreement for the histopathologic interpretation of biopsy specimens between general pathologists and GI pathologists, or even among expert GI pathologists[47,48]. Endoscopists fail to take a sufficient number of biopsies to exclude the presence of dysplasia or cancer[33]. Unlike the dysplastic sporadic adenoma which typically assumes a discrete, polypoid shape surrounded by normal mucosa, dysplasia in the colitic colon can be flat or polypoid and is often difficult to discern. This may be particularly troublesome in a colon that is replete with inflammatory pseudopolyps. Furthermore, there is poor understanding of dysplasia amongst trained gastroenterologists. A survey of practicing gastroenterologists and senior GI fellows in the U.S. found that only 19% of respondents correctly identified dysplasia as neoplastic change[35]. Patient drop-out or non-compliance with surveillance contributes importantly to CRC mortality in IBD[49,53] and this must be considered when embarking upon, or continuing, a course of surveillance in individual patients.

RECOMMENDED SURVEILLANCE STRATEGY

Despite the limitations of surveillance colonoscopy, dysplasia remains the best marker for managing cancer risk in IBD. After approximately 7-8 years of colitis, patients should undergo an "initial" surveillance colonoscopy to determine the extent of colitis and check for neoplasia[55]. The entire colon should be examined, with approximately 4 biopsies taken every 10 cm. Some experts suggest taking more biopsies in the distal rectosigmoid (e.g., approximately every 5 cm) since the distribution of neoplasia in UC still shows a distal predominance. Biopsies should be taken from flat mucosa, but if any raised or suspicious lesions are encountered, these should be removed if possible and processed in separate specimen containers (with additional biopsies taken near the base of the polyp). If a patient is experiencing moderate-severe colitis symptoms, one option is to control the inflammation medically prior to performing the examination in order to minimize difficulties with the histological interpretation of

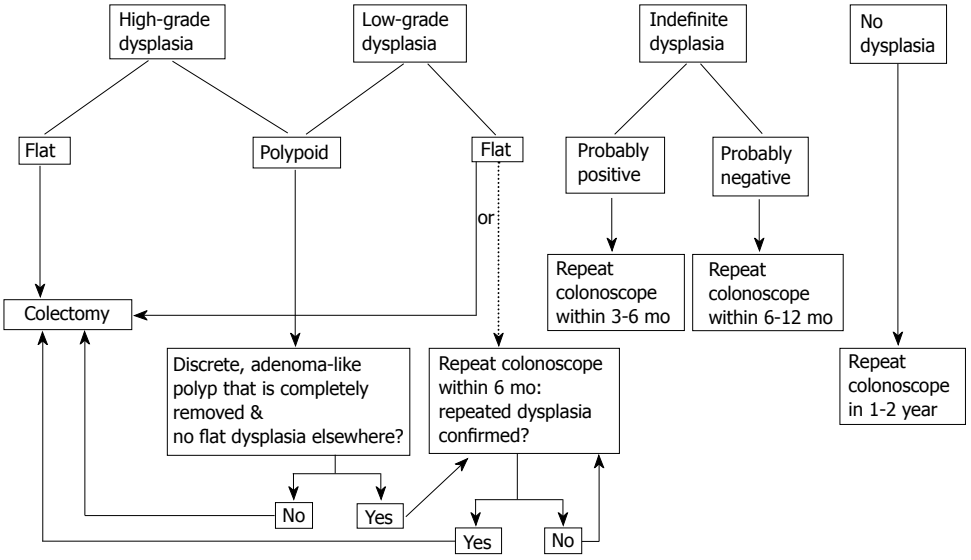

Figure 2 Suggested management scheme for dysplasia. Modified from Ref 71. With permission.

dysplasia. However, one should not defer the colonoscopy too long, since many expert pathologists now feel that they can readily interpret dysplasia even in the presence of active inflammation.

Figure 2 depicts a recommended surveillance strategy. If no dysplasia is detected, the examination should be repeated in 1-2 years. This interval derives in part from studies reporting that interval cancers can develop within 2 years after a surveillance examination[53]. If indefinite dysplasia is reported, the nature of the uncertainty should be discussed with the pathologist. If the suspicion of dysplasia is high (i.e., probably positive), repeat biopsy within 3-6 mo or less may be indicated; if low, the interval can be lengthened to every 6-12 mo. If LGD is detected in a discrete polyp that can be readily resected endoscopically and there is no flat dysplasia immediately adjacent to the polyp or elsewhere in the colon, surveillance can be continued, although the frequency of examinations can be temporarily reduced to every 3-6 mo, particularly to re-evaluate the area of polypectomy. Tattoo of the polypectomy site is advised to permit relocalization of the area on subsequent exams. If LGD is detected in flat mucosa (whether unifocal or multifocal), and is confirmed by a second expert GI pathologist, colectomy should be strongly considered. If the patient refuses, repeat surveillance exams should be undertaken within 3-6 mo or less. However, the patient should be advised that a negative subsequent examination is no assurance of safety, and that temporizing until there is histological progression to HGD or cancer as the indication for colectomy is risky. A patient in whom flat HGD or adenocarcinoma is found and confirmed by two expert pathologists should undergo colectomy unless serious co-morbidities dictate otherwise. If HGD is diagnosed in an adenoma-like polyp but it is completely removed without evidence of flat dysplasia in the adjacent mucosa or elsewhere in the colon, continued surveillance can be entertained. As with any set of recommendations, decisions should be individualized according to the situation of the patient. Hopefully, strategies for surveillance will become more refined as more knowledge of the natural history of dysplasia is obtained.

Patients who have only had small intestinal Crohn's disease without colonic involvement are not considered to be at high risk for CRC. For patients with Crohn's colitis, much less is known. To date, only one practice-based retrospective surveillance study has been reported in patients with Crohn's colitis[65]. Of 259 patients with Crohn's colitis affecting at least one-third of the colon for at least 8 years, 16% were found to have dysplasia or cancer over a 16 year period in which 663 examinations were performed, and there were no cancer deaths. While we await additional data on the subject, it seems wise to follow a UC-based surveillance strategy for patients with at least 8 years of substantial Crohn's colitis. An important question that remains to be clarified is whether patients with dysplasia or cancer in the setting of segmental Crohn's colitis can undergo segmental resection of the involved area or should proceed to a more extensive UC-like surgical approach. Another dilemma that is encountered with Crohn's colitis is the management of strictures. This occurs more so than with UC. Finding a stricture in a colon of a patient with UC usually means an underlying malignancy, especially if the stricture is causing symptoms, and is located in the proximal colon[66]. However, since most strictures in Crohn's colitis are benign, the patient can often be managed conservatively. Surveillance of such patients often requires using a narrower colonoscope or sometimes dilating a stricture to visualize the proximal mucosa[65]. Consideration should be given to adding brush cytology of strictures to regular forceps biopsies, and performing a barium enema to evaluate for colonic wall irregularity.

New endoscopic techniques and molecular screening approaches

Recent publications on chromoendoscopy have demonstrated a greater yield for dye-spray targeted biopsies compared with numerous non-targeted biopsies and thus enhance the endoscopic detection of dysplastic lesions in colitic colons. In a randomized trial by Kiesslich *et al*[67], intraepithelial neoplasia was more than three times as likely to be detected using chromoendoscopy compared with surveillance using nontargeted biopsies (32/84 compared

with 10/81; $P = 0.003$). Rutter *et al* detected no dysplasia in 2904 non-targeted biopsies in 100 patients, but in targeted biopsies, nine dysplastic lesions were detected, seven of which were visible only with dye spraying by using indigo carmine instead of methylene blue[68]. A recent report by Ochsenkuhn *et al* from Munich, Germany showed a low frequency of colorectal dysplasia in patients with long-standing IBD by fluorescence colonoscopy with 5-aminolevulinic acid[69].

Other approaches worth mentioning are to examine the biopsy tissue of patients with IBD for molecular alterations. The best tested of these are aneuploidy, mutations in p53 and ras, and glycosylation abnormalities, particularly increased expression of sialyl Tn antigen (sialyl 2,6 N-acetylgalactosamine)[70]. Because the DNA shed into stool should theoretically provide a more comprehensive sampling of abnormal cells than random pinch biopsies, stool DNA testing could potentially contribute to the management of patients with long-standing IBD who are at risk for developing CRC.

Chemoprevention

Despite the relative protection afforded by surveillance colonoscopies in IBD, there are still patients who develop CRC despite seemingly optimal surveillance. This raises the issue of whether chemoprevention in the form of either medications or dietary supplements might help reduce the risk of CRC in IBD[71].

Aspirin and other NSAIDs markedly reduce the incidence of, and mortality from, sporadic CRC. Since many patients with IBD take NSAIDs in the form of 5-aminosalicylates (5-ASA), investigators have asked whether 5-ASA compounds might also be protective. Although no study to date has been performed in a prospective manner specifically to address this question, the available data suggest that this may be so[72]. If 5-ASA compounds prevent colonic neoplasia by suppressing inflammation, it follows that other anti-inflammatory medications used in IBD patients should also be protective against CRC. Although one study reported that the use of systemic steroids, and even topical steroids resulted in a significant CRC risk reduction[22], and others confirm this observation[73], steroids cannot be used long-term for chemoprevention. There appears to be no chemopreventive activity of 6-mercaptopurine or azathioprine[74].

In the setting of sporadic CRC, low folate intake has been associated with an increased risk for developing colorectal adenomas and carcinomas[75,76]. Patients with chronic IBD are predisposed towards folate deficiency because of inadequate nutritional intake, excessive intestinal losses with active disease, and reduced intestinal absorption from competitive inhibition from sulfasalazine use. Results of two studies suggest a trend towards protection against CRC in folate users, although neither study demonstrated statistical significance[77,78]. Nonetheless, since it is rather safe and inexpensive, folate supplementation should be considered for CRC risk reduction in patients with longstanding IBD.

In animal models of colon carcinogenesis, ursodiol inhibits carcinogenesis-an effect that may be due to the ursodiol reducing the colonic concentration of the secondary bile acid deoxycholic acid. Ursodiol also has anti-oxidant activity. A study of UC patients with PSC demonstrated that ursodiol use was strongly associated with decreased prevalence of colonic dysplasia[79]. This protective effect remained after adjusting for duration of colitis, age at onset of colitis, and sulfasalazine use. In a follow-up to the randomized, placebo-controlled trial by Pardi *et al* at the Mayo Clinic, 52 patients with chronic PSC and chronic UC (mean 13 years) were followed for a total of 335 person-years. Ursodiol use was associated with a significant protection against the development of dysplasia and cancer (RR = 0.26, $P = 0.034$)[80]. At the present time, however, we do not know whether ursodiol can prevent neoplastic progression in UC patients without PSC.

Recently, there has been interest in the role statins may play as chemopreventive agents in a variety of cancers. In a population-based case-control study of patients who had diagnosis of CRC in northern Israel between 1998-2004, statin therapy was associated with a modest reduction in CRC in the non-IBD population, but a substantial 94% risk reduction in patients with IBD was observed in a subset analysis of a small number of patients[81]. Further studies will need to verify this benefit.

Although a single retrospective cohort study suggests that therapy with 6-mercaptopurine is not chemopreventive (or carcinogenic), there remain insufficient data regarding the chemopreventive role of immunomodulators in order to make recommendations and likewise, whether patients who require immunomodulator therapy should continue their 5-ASA therapies[74].

Small bowel cancer in IBD

Most cancers of the small bowel in Crohn's disease are adenocarcinoma, usually in the terminal ileum or jejunum. The most common clinical presentation of small bowel cancer is intestinal obstruction[82]. Other important symptoms include diarrhea, weight loss, and abdominal fistulae. These symptoms are also found in Crohn's disease. Risk factors for developing carcinoma in small bowel segments of involved mucosa in patients with Crohn's disease are poorly defined, although case reports document them in strictured mucosa and fistulae[83-85]. Surgery should be considered if the fistulae or stricture cannot be adequately examined, or symptoms substantially worsen. There is some suggestion that 5-ASA compounds might lower the risk of small intestinal adenocarcinoma[86].

A number of studies have demonstrated an increased risk of developing adenocarcinoma of the small intestine with small intestinal Crohn's disease. Although the absolute number of cases of small bowel adenocarcinoma is low, because of the rarity of this cancer in the general population, the risk is approximately 10-12-fold greater than the general population[4,86]. In the Uppsala study[87], the investigators reported only one observed case compared with 0.3 expected cases, but the confidence interval was wide. In the Copenhagen study[88], two cases were observed *vs* 0.04 expected cases, a 50-fold increased occurrence. In the Tel Aviv study[89], none of the patients developed small cancer. The material was probably far too small to expect any small bowel cancer cases. In Oxford, a 10-fold increased relative risk was observed for cancer of the small

intestine[90]. A population-based Swedish study revealed a significantly increased number of cancer of the small intestine (standardized morbidity ratio, 15.64; 95% CI, 4.26-40.06), however, the occurrence of colorectal cancer was not increased[91]. Another population-based Canadian study encompassing the years 1984-1997 demonstrated an increased incidence rate ratio of carcinoma of the small intestine (17.4; 95% CI, 4.16-72.9)[4].

Patients with UC who have undergone total proctocolectomy with ileal pouch anal-anastomosis (IPAA) have a very small risk of dysplasia arising within the ileal mucosa of the pouch itself. The risk is thought to be higher in patients with chronic pouchitis and associated severe villous atrophy[92], but this has not been shown in all series[93]. Indeed, a study of 160 patients who underwent biopsy a total of 222 times with an average surveillance time of 8.4 years after surgery showed that in 1800 pouch-years of surveillance, only one patient had focal LGD of the pouch[94]. The risk of neoplasia is greater in the anal transitional mucosa between the pouch and the anal canal, particularly if a cuff of rectal mucosa has been left, and if the indication for the IPAA was rectal dysplasia or cancer[95]. While there are currently no guidelines for endoscopic surveillance after an IPAA procedure, in those patients who have chronic pouchitis and severe villous atrophy or whose original indication for IPAA was dysplasia or cancer, a program of periodic endoscopy with biopsies, paying particular attention to any anal transition zone, is reasonable.

Other cancers in patients with IBD

Squamous cell carcinoma of the anus has been reported in patients with longstanding, complicated perianal Crohn's disease[85]. Worsening perianal symptoms in such patients should warrant heightened vigilance for this tumor which often requires examination under anesthesia for adequate tissue diagnosis.

An increased risk for hepatobiliary cancers in patients with UC has been found in several[4,96-98] but not all[87] studies. For many of these patients, primary sclerosing cholangitis was the predisposing factor.

The risk of hematopoietic cancer in patients with IBD has been a growing concern. Early case series from The Cleveland Clinic[96] and The Mount Sinai Hospital[99], as well as other centers[100] reported an increase in leukemia in patients with UC. A recent large cohort study from Sweden[101], which included nearly 50 000 IBD patients concluded this population has a marginally increased risk of hematopoietic cancer, and in UC, lymphoma occurred as expected (SIR 1.0) but myeloid leukemia occurred significantly more often than expected (SIR 1.8). In Crohn's disease, there was a borderline significant increased lymphoma risk (SIR 1.3), essentially confined to the first years of follow up. However, population-based studies from Denmark[97], Sweden[87] and Canada[4] have failed to substantiate any increased risk of leukemia. Likewise, although an increased number of lymphomas have been reported in some case series[99,102], other series[96] and several population-based studies[87,91,97,98] do not support the notion that patients with UC or Crohn's disease are at increased risk of lymphoma. However, a population-based study from Canada reported an increased rate of lymphoma among male patients with Crohn's disease[4].

The risk of lymphoma or leukemia in IBD has raised concerns regarding the lymphogenic potential of immunomodulatory therapy. Following the introduction of tumor necrosis factor inhibitors in the treatment of Crohn's disease, subsequent reports indicated an excess of malignant lymphoma among treated patients[103,104] and raised fears of an iatrogenic lymphoma risk. However, these reports have also highlighted the lack of robust data on the expected occurrence of malignant lymphomas in TNF naïve (but otherwise treated) patients with IBD[105-107]. Studies examining the risk of lymphoma associated with azathioprine (AZA) and 6-mercaptopurine (6-MP) have yielded variable results. Heterogeneity in the type, dose, and duration of immunomodulatory therapy may be responsible for this discrepancy. A few studies with suboptimal dosing failed to demonstrate an increased risk of lymphoma[4,108-112]. In contrast to these reports, other studies have demonstrated an increased risk of lymphoma after purine analog therapy[113-115]. In one such study, Kandiel *et al* reported a 4-fold-higher risk of lymphoma inpatients treated with AZA or 6-MP compared with the general population[114]. Another recent study showed a statistically significant increase in the development of malignancies among IBD patients treated with 6-MP who developed sustained leucopenia[115].

FUTURE DIRECTIONS

The future looks promising with respect to new developments in the management of cancer risk in IBD. Chromoendoscopy is likely to be used more for management, but whether the predictable increase in the yield of dysplasia will alter the overall natural history remains to be studied. In the modern era of molecular diagnostics, tissue and even stool samples of patients with IBD can be investigated for molecular alterations. For example, University of Washington investigators have demonstrated that because there is often widespread genomic instability throughout the colon of IBD patients, it may be possible to analyze rectal biopsies by DNA fingerprinting or fluorescence *in situ* hybridization methods[116] to identify patients at particularly high risk. The advent of technology to extract human DNA from stool and look for specific DNA mutations associated with sporadic colon carcinogenesis[117,118] implies that a similar approach may also be worthwhile in IBD patients. It is anticipated that refinements in our knowledge of cancer biology, clinical practice, and molecular discovery will bring a new level of sophistication to the management of patients with longstanding IBD and lower the incidence of CRC in this high-risk population.

Abstract

Crohn's disease and ulcerative colitis are chronic relapsing immune mediated disorders that results from an aberrant response to gut luminal antigen in genetically susceptible host. The adaptive immune response that is then triggered was widely considered to be a T-helper-1 mediated condition in Crohn's disease and T-helper-2 mediated condition in ulcerative colitis. Recent studies in animal models, genome wide association, and basic science has provided important insights in in the immunopathogenesis of inflammatory bowel disease, one of which was the characterization of the interleukin-23/Th-17 axis.

INTRODUCTION

Inflammatory bowel disease (IBD) results from a complex series of interactions between susceptibility genes, the environment, and the immune system. The clinical features of the disease, histopathological findings, and the therapeutic efficacy of immunosuppressive drugs indicate an involvement of the immune system in the pathogenesis of the disease. Various components of the mucosal immune system are implicated in the pathogenesis of IBD. These components include luminal antigens, intestinal epithelial cells (IECs), cells of the innate and adaptive immune system, and their secreted mediators. An overview of the working hypothesis of IBD is depicted in Figure 1. Either a mucosal susceptibility or defect in sampling of gut luminal antigen leads to activation of innate immune response, possibly mediated by enhanced Toll-like receptor (TLR) activity. The stimulated dendritic cells (DC) then mediate the differentiation of naïve T-cells into effector T-cells. Crohn's disease (CD) is a predominately Th1 and Th17 mediated process, while ulcerative colitis (UC) appears to be predominately mediated through Th2 and NK T-cells. In this review, the effects of these components in the immunopathogenesis of IBD will be discussed.

BACTERIA AND THEIR ASSOCIATED MOLECULES IN THE INTESTINE

The distal ileum and colon contain high concentrations of bacteria (> 10^{12} organisms/g). These may include pathogens that could be directly responsible for initiating and promoting IBD in the context of an underlying genetic mucosal or immune defect. Studies have shown that there are differences in the microbiota between healthy and IBD subjects (Table 1). One of the differences is that there is a decrease biodiversity in IBD compared to healthy subjects by 30%-50%[1]. The reduction in diversity in inflammatory bowel disease was due to loss of normal anaerobic bacteria such as *Bacteroides*, *Eubacterium*, and *Lactobacillus* species[1]. Diversity is generally thought to be desirable by conferring resiliency to an ecosystem[2]. For example diversity would provide functional redundancy in the microbial community to ensure that key processes such as breaking down nutrients and preventing random chaotic fluctuation of bacterial subpopulations. Restriction of biodiversity in the human gut may lead to dysbiosis and result in mucosal insult. A second difference is that there are fewer *Firmicutes* in IBD compared to healthy subjects; 13 distinct *Firmicutes* ribotypes were identified in CD microbiota compared to 43 in healthy microbiota ($P < 0.025$)[3]. *Firmicutes* are Gram-positive class of bacteria that include the genus *Clostridium* and *Bacillus*. Third, there are pathogens that are found in increasing frequency in IBD and have been implicated to associate with its development. These pathogens include *Pectinatus*, *Sutterella*, *Fusobacterium*, *Verrucomicrobium*, various *Clostrodia*, *Mycobacterium paratuberculosis*, *M. paramyxovirus*, Listeria monocytogenes, and Helicobacter hapaticus[4,5]. Despite the differences in the microbiota, one must keep in mind that the dysbiosis seen in IBD patients may not be causal, but simply reflect the different ecological conditions of the inflamed gut such as changes in pH,

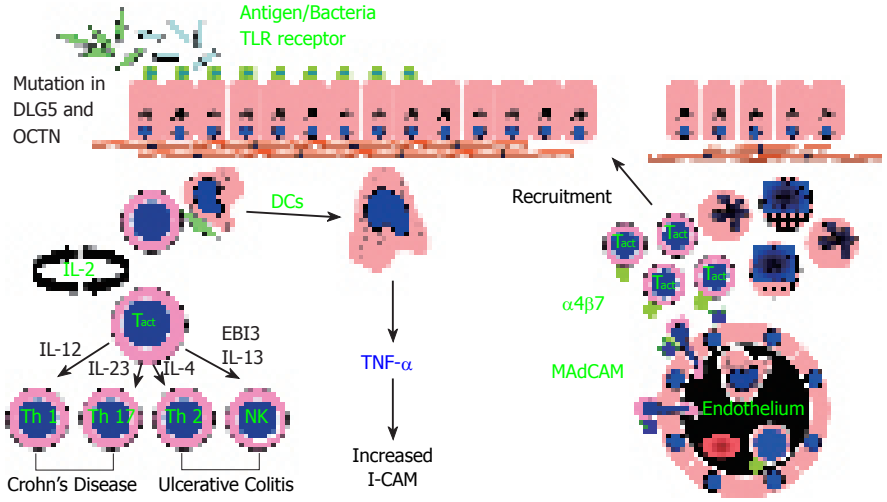

Figure 1 Working hypothesis of inflammatory bowel disease. A defect occurs in sampling of gut luminal antigen, possibly mediated by enhanced Toll-like receptor activity and controlled by other genetic factors (mutations in DLG5 and OCTN). Over-response to antigens results in stimulated dendritic cells (DC) that recruits and generates various T-cell subtypes, which then initiate a cascade of immunologic events leading to mucosal inflammation. Adhesion molecules such as intercellular cell adhesion molecule 1 (ICAM1) are important for circulating mononuclear and polymorphonuclear cells to adhere and migrate to the inflamed gut mucosa. Crohn's disease (CD) is a predominately Th1 and Th17 mediated process, while ulcerative colitis (UC) appears to be predominately mediated through Th2 and NK T-cells.

Table 1 Comparison of microbiota between healthy and IBD subjects

Healthy subjects	IBD subjects
High biodiversity	Low biodiversity
Stable microbiota	Dysbiosis
Increased gut commensals	Increased gut pathogens
Higher firmicutes	Lower firmicutes

redox potential, substrate availability, *etc.*

The importance of the microflora in the induction of and maintenance of disease has been demonstrated in murine model of colitis. For example, mice that are deficient in the cytokines IL-2 or IL-10 or rats containing the *HLA-B27* transgene develop IBD in the presence of a normal microflora but not in a sterile germ-free environment[6-8]. Moreover, experimental colitis is attenuated when animals are treated with broad spectrum antibiotics[9]. Different bacteria may lead to different types of colitis in the same genetic host. In *IL-10*$^{-/-}$ mice, *E. coli* induced proximal colitis whereas *Enterococcus faecalis* lead to distal colitis[10]. Indirect evidence suggesting a role of the intestinal microbiota in IBD came from a double blinded, randomized controlled trials that showed imidazole antibiotics decrease the risk of post-operative recurrence of CD[11].

The surfaces of microorganisms typically bear repeating pattern of molecular structures as do their nucleotides. These motifs are designated as Pathogen Associated Molecular Patterns (PAMP). Some of the PAMPs include complex macromolecules such as lipopolysaccharide (LPS), peptidoglycan (PGN), polypeptides (flagellin), and nucleic acid (CpG rich DNA). Receptors of the PAMPs are called pattern recognition receptors (PRR). Toll like receptors (TLR) are examples of PRR. TLR recognition usually triggers the innate immune system, leading to an inflammatory response. Interaction between PAMPs and PRR are illustrated by the CpG dinucleotides activation of innate immunity *via* TLR9 (Figure 2). Oligonucleotides containing CpG motifs (CpG-ODN) prevented lesions and reduced the release of inflammatory cytokines when given before the DSS-induced colitis[12-14]. However, if CpG-ODN is given after DSS-colitis induction, the colitis is worsened[13-15]. In TLR9-deficient mice, the onset of DSS-induced colitis was not prevented, but chronic inflammation was reduced[12,15]. This is due to the dual anti-inflammatory effect of TLR9 signaling that is mediated through type I interferon (IFN)[16].

The study of autoantibody has provided evidence that immunologic responses to bacterial products is involved in the induction of inflammatory bowel disease. Reactivity to bacterial antigens was initially shown by findings of modest increase in serum antibodies to 7 bacterial pathogens in a group of CD patients[17]. Subsequently, several studies showed serum responses to various bacterial antigens and loss of tolerance to pathogenic as well as commensal bacteria in clones derived from peripheral and lamina propria T-cells from CD subjects[18-22]. This indicates that disordered features of T-cell microbial recognition and effector function are likely to be important to IBD disease biology.

Antibodies to specific bacterial antigens are clustered into 4 major groups in IBD patients: (1) antibody responses against oligomannan [anti-Saccharomyces cerevisiae (ASCA)][23]; (2) antibody responses to both *Escherichia coli* outer membrane protein C (anti-OmpC) and a CD-related protein from *Pseudomonas fluorescens* (anti-CD-related bacterial sequence)[24,25]; (3) antibody response to nuclear antigens [perinuclear antinutrophil cytoplasmic antibody (pANCA)][26]; or (4) antibody response to the flagellin, CBir1[27]. These antibodies provides immunophenotypic associations to distinguish between UC and CD. CD patients with high levels of IgG and IgA ASCA and the absence of pANCA have more aggressive, small bowel fistulizing and fibrosing disease, and patients with high-level pANCA, in the absence of ASCA, have an ulcerative colitis-like colonic disease[28-30]. In a prospective study, pANCA expression is associated with development of pouchitis after ileal pouch-anal anastomosis (IPAA)[30]. The site of pANCA production has been localized to the gastrointestinal mucosa and was not found in detectable amounts in the periphery, suggesting the importance of mucosal immune response to luminal antigen[31]. In fact, absorption of either human or mouse pANCA-positive sera with enteric bacterial antigens greatly reduced or abolished the specific perinuclear staining of pANCA,

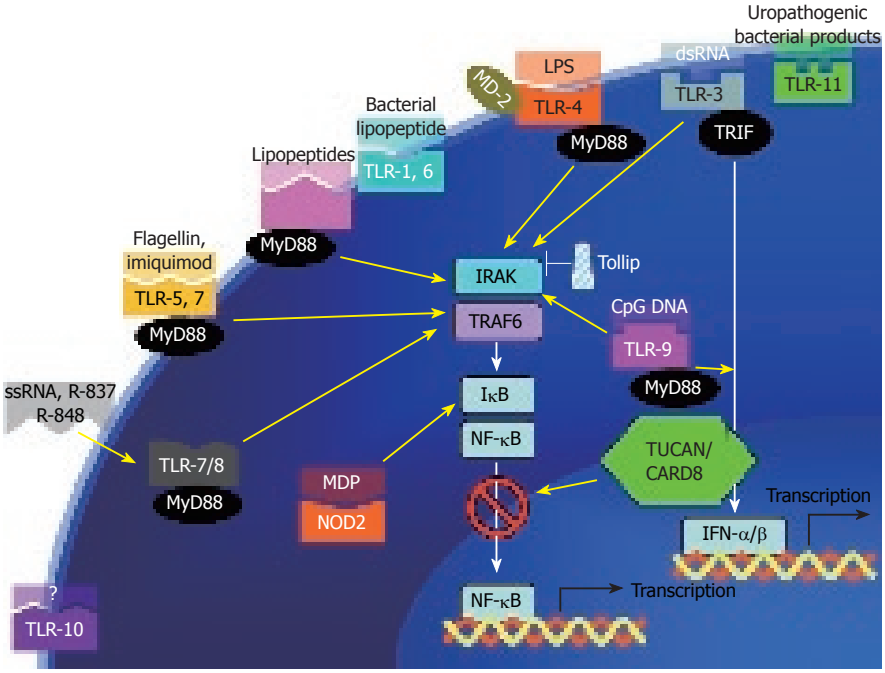

Figure 2 PRRs and their corresponding ligands. Toll-like receptors on the cell membrane (TLR-1, -6, -10, and -11) and intracellular (TLR-7, -8, and -9) selectively bind to various bacterial, viral, or fungal components. A major convergent pathway is through myeloid differentiation primary response protein MyD88, which activates NF-κB. The death domain of MyD88 then recruits downstream IL-1 receptor-associated kinase (IRAK) to the receptor complex. IRAK is then autophosphorylated and in turn recruits TNF receptor-associated factor 6 (TRAF6). TRAF6 then activates kinases including NF-κB-inducing kinase (NIK) and mitogen-activated protein kinase/ERK kinase kinase 1 (MEKK1). Inhibitor of NF-κB degradation (IκB) is subsequently phosphorylated and degraded, resulting in NF-κB nuclear translocation. NF-κB then activate genes involved in inflammatory response including IL-1b, TNF, IL-6, IL-8, and ICAM1. Toll-inhibitory protein (Tollip) is one of the negative regulators of the innate immunity. Activation of type I IFN (IFN-α/β) also has anti-inflammatory function in colitis.

indicating that pANCA seroreactivity reflects a cross-reactivity to enteric bacterial antigens[32].

The flagellin, CBir1, has been identified as an immunodominant antigen that is capable of inducing severe colitis in mice and eliciting antibody responses in approximately 50% of CD patients[33]. In contrast, patients with UC or other inflammatory gastrointestinal diseases and control subjects have little or no reactivity to CBir1[33]. Serum responses to CBir1 independently identify a subset of patients with small-bowel, internal-penetrating, and fibrostenosing CD that have no correlation to levels of ASCA, OmpC, and pANCA[23]. Molecular studies in CBir have also shed light on the underlying immunopathophysiologic mechanisms related to this antigenic response. CBir involves both the innate and the adaptive immune system. CBir flagellin is found to be the ligand for TLR5 (Figure 2)[34]. Bacterial flagellin is a structural protein that makes up flagella, which functions in bacterial chemotaxis and adhesion of host tissues. TLR5 is expressed on the basolateral surface of intestinal epithelial cells and hypothesized to be important in the recognition of invasive flagellated bacteria at the mucosal surface. TLR5-flagellin interaction leads to the activation of the transcription factor NF-κB, resulting in the transcriptional induction of proinflammatory cytokines and maturation of human dendritic cells (Figure 1)[35,36]. The expression of antibodies to CBir1 and transferring of a CBir1-specific CD4 + Th1 cells to induce colitis in mice is indicative of an adaptive immune response to this antigen[27].

These results show that some endogenous micro-organisms provide antigenic stimulation through PAMP activation of PRR to maintain intestinal homeostasis: either inflammation through the release of inflammatory cytokines or mucosal protection through type I IFN. In addition, serum reactivity to bacteria and their associated molecules may indicate a predisposition to certain mucosal antigen that could reflect the clinical manifestation and type of IBD. These distinct antibody response patterns to either UC or CD indicate unique pathophysiologic mechanisms to IBD.

INTESTINAL EPITHELIAL CELLS

The 400-mm^2 single layer of gut epithelial cells is the primary cellular barrier to prevent antigens from encountering the immune system. The gut maintains an extensive and active gut-associated lymphoid tissue (GALT). Peyer's patches (PP) are aggregates of lymphoid tissue that are interspersed at intervals just beneath the gut epithelium. They are comprised of B-cell follicles located under specialized areas, or 'domes,' of epithelium known as follicular-associated epithelium (FAE), with T-cell zones occupy the areas between follicles[37]. FAE contains cells called multi-fenestrated or M cells whose function is to transport luminal antigen into the dome area of the follicle[37]. Dendritic cells (DCs) are antigen presenting cells that act as sentinels, sending processes between gut epithelial cells and sample commensal and pathogenic bacteria[38]. Defects in the epithelial barrier may allow GALT to be exposed to excess or harmful luminal antigens, resulting in the production of pro-inflammatory cytokines such as TNF-α and mucosal inflammation.

Tight junction between epithelial cells allows for the selective entry of fluids, nutrients, and micro-organisms. Normal gut permeability is dependent on an intact epithelium, surface mucus, peristalsis, and the secretion of host protective factors. Alterations in gut permeability factors have been reported. Two genes that are associated with Crohn's disease which affect mucosal permeability are the IBD 5 gene organic cation transporter (*OCTN*) and guanylate kinase *DLG5* (Figure 1). Missense mutations in the *OCTN* gene form a haplotype that is associated with susceptibility to Crohn's disease and the mutant protein has impaired ability to pump xenobotics and amino acids across cell membrane[39]. The other protein, *DLG5*, is a scaffold protein involved in the maintenance of

epithelial integrity. Two distinct haplotypes in the *DLG5* gene represented by nonsynonymous single-nucleotide polymorphism in the gene are associated with IBD[40]. It is proposed that the mutation probably impedes scaffolding of *DLG5* and thus, affect epithelial polarity[40]. Altered mucus production has also been found in IBD patients with thinner than normal colonic mucus layer in UC and a thicker than normal layer in CD[41]. Several studies have shown that the there is an increased number of adherent bacteria in IBD patients[42-44]. This relationship holds true in both the mucus layer and at the epithelial surface where bacteria are less abundant. It is possible that the disruption of the function of *OCTN* and *DLG5* and abnormal mucus composition alters the gut permeability. Altered gut permeability may lead to increased bacteria adherence and inappropriate exposure of the mucosal immune system to bacterial products causing inflammation.

INNATE IMMUNITY

Studies described above indicate that microbial structures can cause gut mucosal inflammation by involving the innate immune system. Adhesion molecules such as intercellular cell adhesion molecule 1 (ICAM1) are important for circulating mononuclear and polymorphonuclear cells to adhere and migrate to the inflamed gut mucosa (Figure 1)[45]. Proinflammatory molecules are preferentially produced by innate immune cells that have migrated to the inflammatory mucosa owing to increased expression of PRR such as TLR[46]. Antigen-presenting cells such as dendritic cells (DCs) and macrophages possess TLRs with different specificities for microbial products and induce innate immune response. Immunopathogenic role of TLR signaling in IBD is in the process of being elucidated.

NUCLEOTIDE-BINDING OLIGOMERIZATION DOMAIN (NOD) PROTEINS

NOD proteins are a distinct subset of PRRs that have important roles in innate immunity as cytoplasmic sensors of microbial components, allowing for regulation of inflammatory processes and apoptosis[47]. The importance of these PRRs is highlighted by the fact that mutations in the gene that encodes NOD2 occur in a subset of patients with CD and polymorphisms in the gene that encodes NOD1 are associated with IBD[48-50]. The NOD1 protein (encoded by caspase-recruitment domain 4 gene, *CARD4*) and NOD2 protein (encoded by CARD15) are expressed by antigen-presenting cells (APCs) and epithelial cells[47]. NOD2 is a general sensor of most bacteria because it recognizes muramyl dipeptide (MDP), which is a component of both Gram-positive and Gram-negative bacteria[51]. In contrast, NOD1 senses mostly Gram-negative bacteria because the ligand for NOD1, peptidoglycan (PGN) derived peptide γ-D-glutamyl-mesodiamino-pimelic acid (iE-DAP), is not present in Gram-positive bacteria except for *Listeria* and *Bacillus spp*[52]. The main outcomes of NOD1 and NOD2 activation is the activation of NF-κB and mitogen-activated protein kinase (MAPK) pathway (Figure 2)[51,53-55]. In addition, activation of NOD1 by its ligands leads to the activation of JUN N-terminal kinase (JNK)[47]. Activations of NF-κB, MAPK, and JNK pathways lead to the production of pro-inflammatory mediators[47].

There are 3 models of how *CARD15* mutations are associated with CD, however, studies have shown inconsistencies in these models. The first view is based on the study that showed NOD2 is a negative regulator of IL-12 mediated by PGN[53]. Loss-of-function mutation in CARD15 results in an excessive NF-κB dependent IL-12 response by splenic macrophages to create a milieu that supports Th1 cell mediated colitis. This is supported by findings that production of IL-12p70 by peripheral blood monocytes derived dendritic cells in response to PGN is higher in patients with CARD15 mutation than in normal subjects[56]. In contrast to the study by Watanabe *et al*, another study that used bone-marrow derived macrophages did not result in enhanced proinflammatory cytokine production[55]. Other studies show that CARD15 mutation results in reduced anti-inflammatory cytokine responses (IL-10 and TGF-β) to several TLR ligands[57,58]. These indicate that NOD2 signaling should augment an anti-inflammatory response and not inhibition of TLR responses in normal individuals. However, defective anti-inflammatory response secondary to CARD15 mutation does not sufficient explain increased cytokine production that is characteristic of CD.

The second model suggested that a loss-of-function NOD2 lead to susceptibility to CD as a consequence of impaired host defense. This may be due to impaired NOD2-dependent α-defensin production by Paneth cells, and thus, lead to impaired control of pathogenic bacteria and inflammatory condition[59]. This is also supported by the finding that CD patients with CARD15 mutation have a more pronounced defective production of a-defensin-5 and -6[60]. Consistent with the impaired mucosal host defense, NOD2 deficient mice developed worse liver infection to *L. monocytogenes* when the pathogen was given orally compared with systemic administration[55]. However, there are several studies that did not support the idea that CD is due to impaired host defense as a consequence of NOD2 mutation. One of the strongest argument is the data that mice in with ablation Paneth-cell population or mice that lacks α-defensins develop evidence of acute or chronic inflammation[61,62]. In addition, NOD2-deficient mice that were administered *L. monocytogenes* did not cause mucosal infection[55].

The third model proposes gain-of-function mutations in the *CARD15* gene that are associated with CD. This possibility is supported by studies in mice carrying a mutation that is analogous to the most common CD susceptibility allele, 3020insC[63]. The mutant mice show increased NF-κB activation and enhanced production of IL-1β upon MDP stimulation of bone marrow-derived macrophages[63]. Inconsistent with the above study, peripheral-blood mononuclear cells isolated from CD patients that carrie the 3020insC allele show a defect in IL-1β secretion[64]. Additionally, epithelial cells transfected with 3020insC CARD15 mutation have defective NF-κB activation upon MDP stimulation[51,65].

There are several views and contradictory findings on the role of NOD protein in the pathogenesis of IBD.

Among the unanswered questions are whether CARD15 mutations confer a gain- or loss-of protein function. Perhaps the mutations have different effects in different context, i.e. in the APC *versus* epithelial cells or in the mucosa *versus* the periphery. More studies are needed to elucidate the immunopathogenesis of CARD15 mutations in IBD.

TOLL LIKE RECEPTOR AND ACTIVATION OF INNATE IMMUNE RESPONSE

Eleven TLRs have been identified which are characterized by three common structural features: (1) divergent ligand binding extracellular domain with leucine rich repeats; (2) short transmembrane region; (3) a highly homologous cytoplasmic Toll/interleukin 1 receptor (TIR) domain. Even though each type of TLR engages a different PAMPs, a major convergent pathway is through myeloid differentiation primary response protein MyD88, which activates NF-κB. Upon activation, TLRs form homodimers leading to a conformation change in the cytoplasmic TIR domain and recruitment of MyD88[66]. The death domain of MyD88 then recruits downstream IL-1 receptor-associated kinase (IRAK) to the receptor complex[66]. IRAK is then autophosphorylated and in turn recruits TNF receptor-associated factor 6 (TRAF6). TRAF6 then activates kinases including NF-κB-inducing kinase (NIK) and mitogen-activated protein kinase/ERK kinase kinase 1 (MEKK1)[67]. Inhibitor of NF-κB degradation (IκB) is subsequently phosphorylated and degraded, resulting in nuclear translocation of NF-κB[66]. NF-κB belongs to Rel family of DNA binding transcription factor that bind characteristic sequence motifs and activate genes involved in immune and inflammatory response[66]. This is illustrated in Figure 2.

Activation of NFκB stimulates expression of numerous molecules relevant to the pathogenesis of IBD including factors involved in the inflammatory response (IL-1b, TNF, IL-6, IL-8, ICAM1, and other chemokines and adhesion molecules), co-stimulatory molecules (CD40, CD80, CD86, and the inducible T–cell co-stimulator ICOS)[68]. In addition, inhibition of NF-κB can attenuate experimental colitis, illustrating its proinflammatory effect[69]. Other studies have shown that NFκB maintains gut epithelial homeostasis by exerting mucosa protective effects. For example, failure to activate epithelial cell NF-κB *in vivo* results in a significant increase in radiation-induced epithelial cell apoptosis[70]. Indirectly blocking NFκB activation *via* targeted deletion in *MyD88* gene worsens DSS induced colitis in mice in gut epithelial cells, this will be discussed in further detail below[71].

NEGATIVE REGULATORS OF INNATE IMMUNE RESPONSE

TLR signaling in the gut is kept under control by inhibitors of TLR signaling. One such negative modulator is Toll-inhibitory protein (Tollip). Prolonged exposure to LPS (most commensal organisms contain LPS in their cell wall) leads to elevated Tollip expression which makes intestinal epithelial cells poorly responsive to TLR-dependent response to commensal microflora[72]. Other negative regulators of TLR signaling include SIGIRR (single immunoglobulin-IR-related molecule or Tir8) and peroxisome proliferator-activated receptor-γ (PPAR-γ)[73,74]. Consistent with the biological plausibility that reduced expression of these inhibitors lead to IBD, intestinal inflammation is enhanced in SIGIRR-deficient mice[73]. In addition, expression of PPAR-γ is decreased in patients with active UC (but not CD) and up-regulated by 5-aminosalicylic acid[75,76].

Negative regulation of the host innate immune responses to the indigenous microflora maintains gut homeostasis. Key players in the negative mucosal regulation include interleukin-10 (IL-10) and IL-2, as evidenced by mice with deficiencies in these factors develop spontaneous intestinal inflammation, but are protected from intestinal disease when raised in germ-free environments[77-79]. This indicates that at steady state, pathologic consequences of immune activation by commensal microflora are constitutively inhibited by IL-10 and -2 dependent mechanisms. Colitis can be prevented when *IL-10*$^{-/-}$ mice are crossed to MyoD88 deficient mice, demonstrating that IL-10 maintains intestinal immune homeostasis by negatively regulating MyD88-dependent, commensal-induced inflammation[71]. In contrast, colitis in IL-2 deficient mice is independent of MyD88 and TRIF pathway. This indicates that the commensal dependent colitis in IL-2 deficient mice is driven by either nonclassical TLR-dependent signaling (independent of MyD88 and TRIF) or through a non-TLR innate pathway.

The development of colitis in IL-10 and IL-2 deficient mice is mediated by a pathologic T-helper type 1 (Th1) immune response through instructive signals induced upon innate recognition of microbes[79,80]. The Th1 response in IL-10 deficient mice is dependent on MyD88-dependent IL-12 or -23 p40 signaling[71,81]. In contrast, the aberrant Th1 response in the absence of IL-2 does not go through a classical microbial induction of MYD88/TRIF pathway and is also independent of IL-12 or -23 p40 signaling[71]. IL-27, a new bioactive member of the IL-12 cytokine family composed of an IL-12 p40 related polypeptide (EBI3) and a unique p28 subunit, may be the candidate instructive cytokine to drive a MyD88 independent Th1 response[71,82]. Its expression is associated with commensal-dependent, Th1 polarized colitis in IL-2 deficient mice[71]. Interestingly, IL-27 expression also is correlated with *IL-10*$^{-/-}$ Th1 polarized colitis, suggesting that IL-27 is regulated by both the TLR/MyD88 dependent and independent pathway[71].

The differential expression of TLRs may also in part explain how host intestinal mucosa discriminates between commensal (most of which are gram-negative bacteria that contain LPS in their cell wall) and pathogenic bacteria. Oral tolerance is believed to be controlled by antigen-presenting cells in the Peyer's patches by stimulating the activity of regulatory T-cells which suppresses adaptive immune response[83]. These Peyer's patch DCs produce IL-10 in response to inflammatory stimulation such as LPS, which is a ligand for TLR4. Unlike other TLRs, TLR5 is expressed mainly on CD11C+LPMC and not on conventional DCs or macrophages[84]. Interestingly, TLR4

expression is low in CD11C+LPMC[84]. Low expression of TLR4 in CD11C+LPMCs may prevent inappropriate immune response to commensal bacteria whereas TLR4 expression in Peyer's patch DCs leads to IL10 production and immune tolerance to commensal bacteria. In contrast, expression of TLR5 on CD11C+LPMC may allow mucosal inflammation following exposure to pathogenic flagellated bacteria.

ADAPTIVE IMMUNITY

It is established that the recognition of commensal-derived antigens by the adaptive immune system or its stimulation by the innate immune system play a key role in the pathogenesis of IBD. In particular, studies in genetically engineered systems and in inducible and adoptive transfer models of chronic intestinal inflammation have shown a key role of effector T lymphocytes for the inflammatory process in the gut. Importantly, both T helper 1 (Th1) and Th2 T cells have been shown to cause chronic gut inflammation, with CD having a predominately Th1 cytokine profile and UC having a Th2 cytokine profile (Table 2).

Differentiation of naïve T-cells into various T-cell subsets is summarized in Figure 3. IL-12, composed of P40 and p35 subunits, induces the formation of IFN-γ producing Th1 cells. In contrast, IL-4 induces STAT6 activation, promoting the expression of GATA-3, which feed forward to induce IL-4 expression and Th2 cell differentiation. IL-23 (composed of p19 and p40) promotes the development of an IL-17 producing CD4+ helper T cell subset through mechanisms that are distinct from the Th1 (STAT1, STAT4, and T-bet) and Th2 (STAT6) pathways[85,86]. Tregs, an immune-modulating subset of CD4+ T-cells, can suppress the differentiation and function of Th1 and Th2 cells. Interestingly, in the presence of IL-6, Treg-derived TGF-b can induce the differentiation of Th17 cells[87]. These T-cell subsets and their effect in IBD are discussed below.

T-CELL RESPONSES IN CROHN'S DISEASE

Immunologically it is proposed that inflammation in CD is the product of an exaggerated Th1 response mounted by genetically susceptible host in reaction to components of commensal bacteria[88]. The Th1 cytokine profile, including IFN-α, IL-12 (composed of p35 and p40), and TNF-α, is elevated in patients with CD[89-91]. Polarization of naïve T-cells towards Th1 type differentiation occurs through the activation of signal transducer and activator of transcription-1 (STAT1) and its stimulation of transcription factor T-bet, a Th1 "master switch" that upregulates and stabilizes the expression of IL-12[92-94]. IL-12 can amplify Th1 response by upregulating IL-18 on T-cells. IL-18 then stimulates NF-κB and AP1, and in synergy with STAT4 (activated by IL-12), transactivates IFN-α expression. The proposed pathway of TH1 polarization is summarized in Figure 3.

TNF-α and its family member are important in the pathogenesis of CD. Increased expression of TNF-α is seen in the intestinal mucosa of patients with Crohn's disease and Antibodies to TNF-α such as Infliximab decrease Th1 response in parallel with clinical and endoscopic healing[90]. The expression of LIGHT, another member of the TNF family, is also up-regulated in intestinal biopsies from CD patients and stimulation of the LIGHT receptor (herpesvirus entry mediator) induced IFN-γ production in lamina propria T cells, while blocking LIGHT inhibited CD2-dependent induction of IFN-γ synthesis, indicating a role for LIGHT in the regulation of IFN-γ and may be a way in which T-T cell interactions propagate intestinal inflammation[95,96].

TL1A is a recently identified member of the TNF superfamily that interacts with the death domain-containing receptor DR3 and found to be a strong co-stimulator of T-cells. Activation of T-cells by IL-12/IL-18 induces expression of DR3[97]. In T-cells, ligation of DR3 by TL1A activates NF-κB and leads to powerful co-stimulation of IFN-γ[98]. Co-activation is most evident for CD4+/CCR9+ T-cells which are enriched in the lamina propria and intraepithelial lymphoid compartment of the small intestine[99,100]. These T-cells are also enriched in the peripheral circulation of patients with CD and Celiac disease. IL-12 and IL-18 can also augment IFN-γ production in CD4+/CCR9+ T-cells[101]. In addition, peripheral CD4+/CCR9+ T-cells have been shown to express surface membrane (sm) TL1A, which appears to co-stimulate IFN-γ production independent of, but in synergy with IL12 and IL 18 (Figure 3)[102]. A recent study has provided a genetic perspective on the role of TL1A in

Table 2 Cytokine profile in IBD

Innate Immune Response			Adaptive Immune Response		
Cytokine	Crohn's disease	Ulcerative colitis	Cytokine	Crohn's disease	Ulcerative colitis
IL-1β	I	I	IL-5	N	I
IL-6	I	I	IL-13	N	I
IL-8	I	I	IL-17	I	N
IL-12	I	N	IL-21	I	N
IL-18	I	I	IFN-γ	I	N
IL-23	I	N	TL1α	I	?
IL-27	I	N			
TNF-α	I	I			
Light	I	I			
TL1α	I	?			

IL: Interleukin; TNF: Tumor necrosis factor; IFN: Interferon; I: Increase; N: Normal.

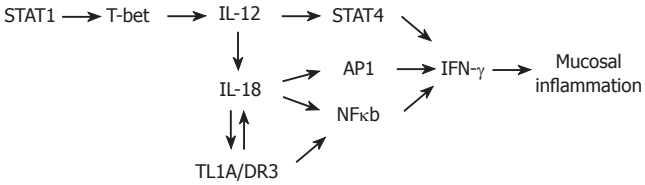

Figure 3 Th1 Polarization Pathway. Polarization of naïve T-cells towards Th1 cell subtype is initially induced by IL-12, a heterodimer of the p40 and p35 subunits. Activation of signal transducer and activator of transcription-1 (STAT1) and its stimulation of transcription factor T-bet, a TH1 "master switch" that upregulates and stabilizes the expression of IL-12. IL-12 can then amplify TH1 response by upregulating IL-18 on T-cells. IL-18 then stimulates NF-κB and AP1, and in synergy with STAT4 (activated by IL-12), transactivates IFN-γ expression.

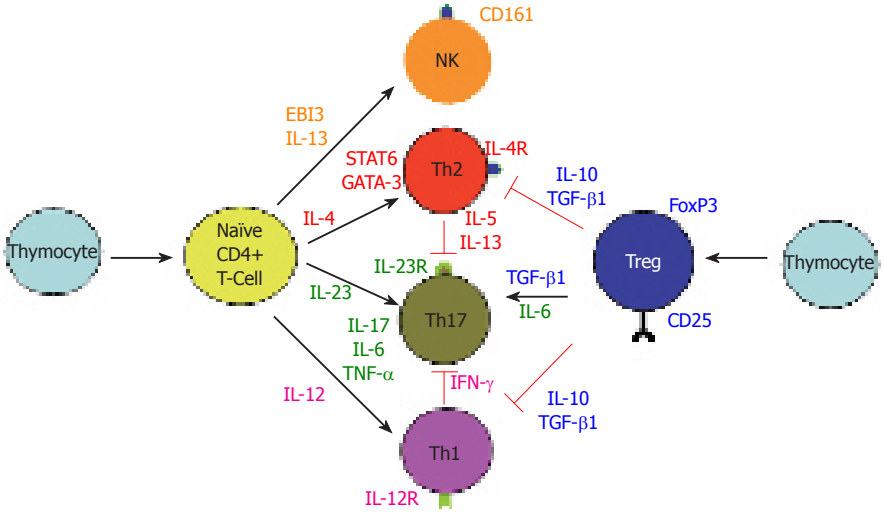

Figure 4 Differentiation of T-cell Subsets. Upon stimulation, naïve CD4+ T-cells differentiate into 3 main subsets, Th1, Th2, and Th17 cell. IL-12 induces the formation of IFN-γ producing Th1 cells. IL-23 promotes the development of an IL-17 producing CD4+ helper T cells. IL-4 induces STAT6 activation, promoting the expression of GATA-3, which feed forward to induce IL-4 expression and Th2 cell differentiation. An EBI3-associated cytokine was hypothesized to be necessary for activation of IL-13 producing NK T-cells. Tregs, an immune-modulating subset of CD4+ T-cells, can suppress the differentiation and function of Th1 and Th2 cells. Interestingly, in the presence of IL-6, Treg-derived TGF-β can induce the differentiation of Th17 cells.

the human TH1 mucosal response in CD. This genome-wide association revealed a highly significant association of SNP haplotypes of the TL1A gene with CD in a large cohort of Japanese patients as well as in two separate, smaller European cohorts[103]. These findings suggest that TNF mediated signaling is an important immune regulatory mechanism in mucosal inflammatory responses.

The IL-23/IL-17 immune axis

A subset of T cells producing IL-6 and IL-17, now known as Th17 cells, has emerged as an important mediator of the T-cell response in gut inflammation (Figure 4). IL-17 is a proinflammatory cytokine that enhances T-cell priming and stimulates fibroblasts, endothelial cells, macrophages, and epithelial cells to produce multiple pro-inflammatory mediators such as IL-1, IL-6, TNF, NOS2, metalloproteases, and chemokines[104]. IL-23 (composed of p19 and p40) promotes the development of an IL-17 producing CD4+ helper T cell subset through mechanisms that are distinct from the Th1 (STAT1, STAT4, and T-bet) and Th2 (STAT6) pathways[85,86,105]. Through this pathway, IL-23 regulates inflammatory processes in several mouse disease models[106-108]. In addition, bacterial colonization stimulates IL-23 expression by ileal dendritic cells[109] and the levels of both IL-23 and IL-17 are increased in Crohn's disease tissue[110,111].

CD is thought to be mediated by Th1 cells because of high levels of IL-12 and IFN-γ are detected and treatment with anti-IFN-γ mAb or anti-IL12 (p40) mAB suppresses disease development[112,113]. However, as IL-23 shares the p40 subunit with IL-12, the improved clinical disease may also be an effect of IL-23 inhibition. To determine the contribution of IL-23 in intestinal inflammation, mice with deficiency of IL-23 ($p19^{-/-}$) or IL-12 ($p35^{-/-}$) were used. A recent study showed that the development of colitis was suppressed by IL-23p19 deficiency but not IL-12p35 deficiency in $IL\text{-}10^{-/-}$ mice (model of T-cell mediated gut inflammation)[114]. Administration of IL-23 accelerated the onset of colitis in $Rag^{-/-}$ mice reconstituted with $IL\text{-}10^{-/-}$ CD4+ T-cells[114]. The suppression of inflammation in IL-23p19 deficient mice is not due to impaired Th1 (preserved IFN-γ expression) or Th2 (preserved IL-4 expression) but likely due to IL-17 pathway[114]. Notably, IL-23 (but not IL-12) augments IL-17 and -6 expressions by anti-CD3 mAB-stimulated memory CD4+ T-cells, distinguishing the ability of IL-12 to stimulate naïve CD4+ T-cells[114]. Antibodies that neutralize IL-6 and IL-17 ameliorated the severity of intestinal inflammation in $Rag^{-/-}$ mice reconstituted with $IL\text{-}10^{-/-}$ CD4+ T-cells[114]. These observations indicate that IL-23 promotes development and expansion of a pathogenic IL-6/IL-17 producing memory-activated T-cell population that can trigger the inflammatory cascade leading to intestinal inflammation.

The above findings do not exclude the role of exaggerated Th1 response in CD since IL-12/IFN-γ and IL-23/IL-17 may be parallel pathways involved in inflammatory response. Interestingly, IL-12/IFN-γ and IL-23/IL17 pathways are mutually exclusive, since IFN-γ suppress IL-17 and vice versa (Figure 4)[104]. It is of pathogenic importance to consider all of the major immune pathways that are responsible for the development of CD. For example, therapeutic targeting of only the newly discovered IL-23/IL-17 immune axis may actually exacerbate CD by accelerating the IL-2/IFN-γ Th1 pathway.

T-CELL RESPONSES IN ULCERATIVE COLITIS

In ulcerative colitis, it appears that the T-cell response is Th2 dominant (IL-4, IL-13) and mediated by specialized cells such as NK T-cells. By determining the cytokine profile of lamina propria mononuclear cells (LPMC) isolated from tissue recovered from colonic resection from UC and CD patients, it is found that LPMC from UC patients secreted high amounts of Th2 cytokines IL-13 and IL-5[115]. The IL-13 and -5 LPMC cells bear NK specific markers CD161 and recognizes CD1d, indicating that they are NK T-cells[115]. These NK T-cells are "nonclassical" because they do not express invariant NK T-cell receptors characteristic of most "classical" NK T-cells. They express noninvariant (diverse) TCRs that recognize antigens in association with CD1d, a MHC class I-like molecule present on the surface of dendritic cells

and on non-professional antigen presenting cells (APC) such as intestinal epithelial cells[116]. The "nonclassical" NK T-cells isolated from UC patients exhibited cytotoxicity towards an epithelial cell line (HT-29)[115]. This cell population possibly could be the cells causing epithelial cell cytotoxicity in UC described in 1960-1980s[117]. Together, these data show that ulcerative colitis is associated with an atypical Th-2 response mediated by a distinct subset of NK T-cells that produce IL-13 and are cytotoxic for epithelial cells. However, the extent to which this leads to the ultimate cascade of inflammation in ulcerative colitis remains to be determined.

Colonic epithelial cells express both CD1d and the Epstein-Barr virus-induced gene (EBI3), a protein related to IL-12p40. An EBI3-associated cytokine was hypothesized to be necessary for activation of IL-13 producing NK T-cells[118]. This is consistent with the fact that EBI3 is increased in mucosa from patients with UC as compared with CD or control tissues[119]. In addition, EBI3-deficient mice manifest poor Th2 responses and are resistant to the development of oxazolone colitis, a Th2 colitic murine model[120]. The EBI3-deficient mice have markedly reduced numbers of NK T-cells while the number of both naïve and mature CD4+ and CD8+ cells represerved[120]. These collective data indicate EBI3-associated cytokine (e.g. IL-27) may be necessary for the development of the Th2-cytokine-producing NK T-cells in both UC and oxazolone colitis.

CONCLUSION

Available evidence indicates that IBD is the result of dysregulated immunogenetic parameters that depends on impaired coordination between luminal microorganisms, gut epithelium, and the host immune system in genetically susceptible individual (Figure 1). These immunogenic parameters are complex and biologically divergent, which explains the heterogeneous clinical manifestations and lack of a universal therapeutic response to any single agent. The challenge for the future is to better understand the precise molecular mechanisms of disease immunopathogenesis. This can be achieved by identification of novel immunogenetic parameters, characterization of the heterogeneous parameters, and integrated multiparameter assessment of distinct aspects of the disease biology that are already known. These multi-disciplinary approaches are likely to stratify this complex disease into distinct subgroups that are more biologically homogenous with more defined pathogenic parameters and guidance for a more predictable response for individualized IBD therapy.

Abstract

A critical function of the intestinal mucosa is to form a barrier that separates luminal contents from the interstitium. The single layer of intestinal epithelial cells (IECs) serves as a dynamic interface between the host and its environment. Cell polarity and structural properties of the epithelium is complex and is important in the development of epithelial barrier function. Epithelial cells associate with each other *via* a series of intercellular junctions. The apical most intercellular junctional complex referred to as the Apical Junction Complex (AJC) is important in not only cell-cell recognition, but also in the regulation of paracellular movement of fluid and solutes. Defects in the intestinal epithelial barrier function have been observed in a number of intestinal disorders such as inflammatory bowel disease (IBD). It is now becoming evident that an aberrant epithelial barrier function plays a central role in the pathophysiology of IBD. Thus, a better understanding of the intestinal epithelial barrier structure and function in healthy and disease states such as IBD will foster new ideas for the development of therapies for such chronic disorders.

INTRODUCTION

The functioning of the gastrointestinal tract with its balanced microflora depends on the establishment and preservation of distinct compartments which are lined by a sheet of epithelial cells. The gastrointestinal epithelial lining consists of a monolayer of columnar cells that are held together by circumferential intercellular junctions to form a selectively permeable barrier to the luminal contents. Thus, the epithelium prevents unwanted solutes, microorganisms, and luminal antigens from entering the body[1,2]. Components of the intestinal mucosal barrier include luminal secretions such as mucus which is secreted on the apical surfaces of epithelial cells, followed by IECs with lipid plasma membranes, specific membrane transport systems responsible for transepithelial passage of different molecules, and the stromal compartment below the epithelial layer. The intestinal barrier has to be permeable for nutrients and macromolecules which are important for growth and development. At the same time, it has to provide an effective barrier to harmful macromolecules and microorganisms. The mechanisms that have evolved to deal with these physiological events are extremely complex. On the one hand, the structural and functional properties of the epithelium limit the amount of antigens reaching the surface of the epithelium. On the other hand, both specialized cells of the follicle-associated epithelium (M-cells) and dendritic cells sample luminal antigens that are then delivered to the cells of the mucosal immune system thereby guaranteeing permanent immunosurveillance. An intercellular junction referred to as the tight junction (TJ) is located at the apical end of the lateral intercellular space and is considered a key player that regulates paracellular movement of fluid and solutes[3]. Altered TJ structure and epithelial permeability has been observed in IBD[2]. Additionally, pathogens and bacterial toxins influence epithelial permeability by modulating TJ proteins[4-6]. Although the permeability defects could conceivably be due to the marked apoptosis that occurs during the inflammation processes, numerous studies have clearly shown that epithelial cell apoptosis alone does not account for the entire permeability deficits[7-10]. In addition, the importance of the intestinal microflora and more specifically its composition in physiological and pathophysiological processes in the human GI tract is becoming more evident. New discoveries relate to the beneficial effects of normal microflora and probiotics in preventing gastrointestinal infections[11-13]. Probiotics released by bacteria may functionally modulate the intestinal epithelial barrier of the host by different mechanisms, including the competition of whole organisms for contact

with the epithelial surface as well as stabilization of the cytoskeleton and barrier function and the induction of mucin expression.

Some of the most recently available data are discussed in this review. This field is changing rapidly and it is increasingly becoming accepted that immunogenetics play an important role in the predisposition, modulation and perpetuation of IBD. The role of the intestinal environment and the enteric flora in particular appears to be of greater significance than previously thought. This complex interaction of genetic, microbial and environmental factors culminates in a sustained activation of the mucosal immune system. This is facilitated by defects in the intestinal epithelial barrier and its mucosal immune system and results in active inflammation and tissue damage. We will concentrate on the role of the intestinal barrier, its regulation and modulation in IBD.

THE INTESTINAL BARRIER

Mucosal integrity and repair

The small and large intestine have potent mucosal defense and repair mechanisms. These mechanisms include a fast rate of cell renewal, a capable mucosal blood flow, a continuous adherent mucus layer and the presence of regulatory peptides that can stimulate repair mechanisms. The epithelial monolayer which lines the intestinal tract originates from multipotent stem cells present in the crypts[14]. Four major IECs are generated by these multipotent cells: (1) the absorptive enterocytes (reviewed in[15]), (2) the goblet cells responsible for the assembly of mucins[16] and trefoil peptides needed for epithelial growth and repair, (3) the enteroendocrine cells which export peptide hormones (reviewed in[17]) and (4) the paneth cells which secrete antimicrobial cryptidins or defensins, digestive enzymes and growth factors[18]. Injury to the epithelial lining resulting in mucosal erosion/ulceration can occur following exposure to pathogens and chemical therapeutic agents, decreased mucosal defense such as an abnormal mucus layer or reduced production of growth regulatory peptides. The GI tract epithelium has a remarkable capacity to rapidly reseal superficial erosions by migration of epithelial cells, a process referred to as restitution. Epithelial cell proliferation contributes to resealing of larger ulcers. Wound closure is influenced by a diverse array of peptides and growth factors released into the milieu of the regenerating epithelium. For example, the mucosal integrity peptide, TGFα (transforming growth factor α) directly acts on the enterocytes to stimulate proliferation and migration. TGFβ, and the pancreatic secretory trypsin inhibitor (PSTI) protect the overlying mucus layer from excessive digestion by luminal proteases and are involved in maintaining normal mucosal integrity[19]. Epidermal growth factor has been proposed as mucosal protector, playing an important role in luminal surveillance and rapid response to injury[20,21]. Mucosal epithelial cells and paneth cells produce a variety of antimicrobial peptides (defensins, cathelicidins, cryptidin related sequence peptides, chemokine CCL20) and bacteriolytic enzymes (lysozyme, group Ⅱ A phospholipase A2) that protect mucosal surfaces and crypts containing intestinal stem cells against invading microorganisms[21-23]. Trefoil peptides found in the goblet cells of the intestine are a family of three small proteins (TFF1, 2 and 3) which bind to the membrane-anchored glycoproteins of the filamentous brush border glycocalyx of the IECs. These peptides promote cell migration and interact with mucins such as MUC2, suggesting cooperation between the two in epithelial cell protection[24] and preservation of mucosal integrity[25]. Such peptides are rapidly up-regulated at sites of injury and inflammation. Recent experimental data has shown that the physiological role of TFF2, a member of the gastrointestinal trefoil factor family is associated with modulation of the immune system[25] and that the TFF2 rhythm is impaired in cohorts of individuals known to suffer from gastric symptoms, like *H pylori* infection and sleep deprivation[26].

KEY PLAYERS OF THE INTESTINAL BARRIER

Components

Intercellular junctions in epithelial cells play a vital role in regulating mucosal barrier properties. Specifically, the epithelial AJC consisting of the TJ and adherens junction (AJ) (Figure 1) is important in regulating cell-cell adhesion and paracellular movement of fluids and solutes. TJs are continuous, circumferential belt-like structures that form a permeability barrier at the apical end of the intercellular space. TJs regulate vectorial transport of water and electrolytes across the intestinal epithelium and prevent leakage of macromolecules from the gut lumen[27,28]. Additionally, TJs restrict the diffusion of lipids and proteins between the apical and basolateral plasma membranes (fence function) thereby preserving cellular polarity and, in combination with transcellular vectorial transport processes, generate distinct environments in the opposing compartments across the epithelium. Lastly, TJ proteins play an important role in the overall epithelial differentiation of cells, and their deregulation has been observed in epithelial cancers[29-31]. By freeze-fracture electron microscopy, TJs are viewed as a series of anastomosing intramembranous strands, the complexity of which correlates with barrier properties of the epithelium[32,33]. The TJ is a highly dynamic structure that regulates physiologic processes such as glucose absorption[3] and undergoes rapid regulatory changes in response to inflammation[34]. The AJs reside immediately subadjacent to TJs and play an important role in cell recognition and in mediating intercellular associations[35,36]. Both the TJ and AJ are intimately linked in their regulation and function and have therefore been collectively referred to as the AJC. Lastly, subadjacent to the AJC are spot-like intercellular junctions referred to as desmosomes (DMs). Although DMs create strong intercellular associations important in the integrity of stratified epithelia such as the epidermis, the function of DMs in the intestinal epithelium is poorly understood.

At a structural level, all the above intercellular junctions consist of transmembrane proteins that affiliate with the cytoskeleton *via* cytoplasmic plaque proteins. The association of AJC proteins with an underlying perijunctional filamentous actin (F-actin) ring plays an

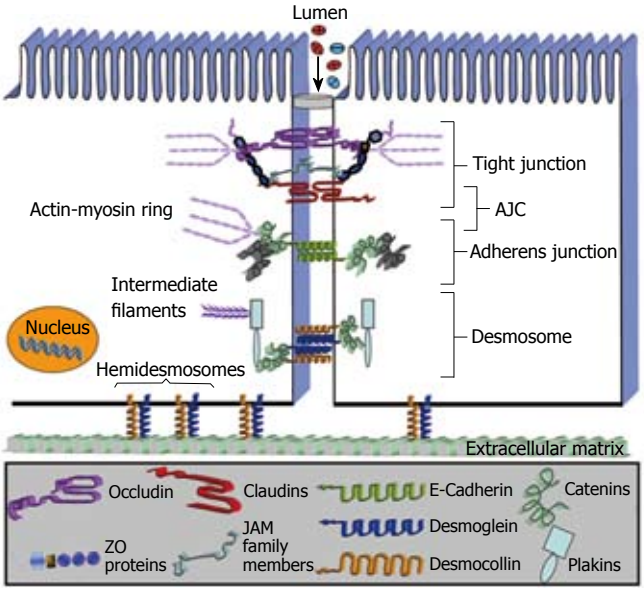

Figure 1 Intestinal epithelial intercellular junctions.

important structural and regulatory role in the AJC[37]. Key integral membrane proteins of the TJ include occludin, claudin family members, junction adhesion molecule-A (JAM-A) and the coxsackie adenovirus receptor (CAR). These proteins are believed to interact in a heterotypic or homotypic fashion in the extracellular space to create the selectively permeable epithelial barrier[37-39]. The intracytoplasmic domains of these TJ proteins interact with scaffolding proteins like the zonula occludens proteins (ZO), which contain several protein-protein interaction domains such as the PDZ domains (PSD 95, Discs large, ZO-1) important in mediating interactions of AJC-associated proteins. E-cadherin is a major transmembrane protein in AJs that associates with the apical perijunctional F-actin ring *via* cytoplasmic proteins in the catenin family[28,36,40]. The intestinal epithelial intercellular junctions are not static extracellular domains. Their adaptive mechanisms can undergo rapid regulatory changes in response to inflammation processes affiliated with IBD. Moreover the appropriate function of the AJC is coordinated by a complex array of signaling proteins which include the Rho and Rap family of GTPases, kinases and phosphatases[9,10,28].

INTESTINAL BARRIER AND REGULATION OF PERMEABILITY IN IBD

Most current treatments for IBD are aimed at reducing disease severity and at prolonging periods of disease-free remission by pharmaceutical suppression of inflammation. It appears that the pathophysiology of IBD is multifactorial. The enormous complexity of IBD pathophysiology therefore requires a systematic approach to identify the molecular events that cause and sustain the chronic, recurring inflammation. It has been suggested that the continuous stimulation of the mucosal immune system due to an increased permeability of the IECs may be the primary defect in patients suffering from IBD, whereas a healthy epithelium provides an effective barrier against luminal antigens. Increased paracellular permeability has been documented in the epithelial lining from both the acutely inflamed and chronically damaged areas of the intestine[41,42]. Animal studies support the tendency for development of inflammation in areas of the intestine lying beneath the permeability defect[43] or even for an increased permeability prior to the onset of a spontaneous intestinal inflammation[44]. It is well known that intestinal permeability is regulated directly through alteration of TJ proteins, or indirectly through effects on the cytoskeleton. A broad array of inflammatory cytokines have been reported to regulate TJs and barrier function by recruiting additional inflammatory cells into the intestinal wall and by re-distribution of TJ proteins in IECs and endothelial cells[45].

CROHN'S DISEASE

Besides genetic linkage like CARD15/NOD2 mutations on chromosome 16[46,47], OCTN1 and 2 mutations on chromosome 5 and DLG5 mutations on chromosome 10[48], abundant evidence indicates that increased intestinal permeability is implicated in the pathogenesis of CD[49]. The integrity of the intestinal barrier in patients with Crohn's disease is known to be compromised. Moreover, first degree relatives of patients with CD have been documented to have increased enteric permeability[50-52]. Interestingly, spouses of patients with CD suffered from increased intestinal permeability[53], which suggests that environmental factors may play a role. It has not been investigated whether these individuals develop CD or other gastrointestinal disorders. However, the debate continues if the increased enteric permeability is to blame for the development of CD or if the barrier defect is a consequence of an existing immune or inflammatory response. Animal models mimicking CD such as the SAMP1/Yit model, showed increased paracellular permeability across intestinal epithelial cells at an early stage of disease (three week old mice), prior to the onset of inflammation[54]. Transgenic animal models revealed the importance of E-cadherin in maintaining the epithelial barrier by demonstrating that dysfunction of AJ proteins contributed to an IBD-like process[55]. In addition, a number of studies have shown a potential role for inflammatory cytokines like TNF-κ and IFN-γ in directly increasing intestinal epithelial permeability. *In vitro* model systems have demonstrated that such pro-inflammatory cytokines influence barrier function by inducing disassembly of TJs in epithelial cells[7,9,10,56]. Furthermore, a role for TNF-κ in both apoptosis independent disruption of epithelial barrier function *via* alteration of TJs and upregulation of epithelial apoptosis (reversible by anti-TNF-κ antibody treatment) in the absence of changes in the expression of TJ proteins was reported, suggesting that TNF-κ may be one of the major links between the leaky bowel and Crohn's disease[57,58]. Soderholm *et al*[59] reported that non-inflamed ileac mucosa from patients with CD showed increased epithelial permeability and that increased endosomal uptake of antigens in ileac CD may be mediated by TNF-κ[60]. A recently published study

pertaining to the expression of TJ proteins (occludin and zonula occludens), alpha2-smooth muscle actin, TGF-κ with a cytoskeletal protein (F-actin) in the intestinal epithelium of patients with inflammatory bowel disease showed that latent dislocation of TJ proteins, without disturbance of the cytoskeleton in the inactive mucosa of patients with CD, may permit the invasion of gut antigens secondary to the functional disruption of TJs, that in turn could initiate an altered immune response[61]. Some reports have demonstrated that IFN-γ increases permeability across model intestinal epithelial cell lines[7,56]. Recently published data suggest that normally poorly invasive enteric bacteria may, in situations of inflammatory stress, exploit lipid raft-mediated transcytotic pathways to cross the intestinal epithelium because of INF-γ-induced disruption of TJs[62]. Although the mechanisms by which IFN-γ induces permeability changes across the epithelium are still incompletely understood, our data demonstrated that the permeability changes occur secondary to endocytosis of TJ transmembrane proteins occludin, JAM-A and claudin-1[9]. Furthermore, we believe that such endocytosis of TJ proteins is initiated by activation of the Rho GTPases and subsequent downstream activation of Rho kinase and actin-myosin II contraction[10].

ULCERATIVE COLITIS

UC is characterized by diffuse mucosal chronic inflammatory disease in the colon. Analogous chronic mucosal inflammation has been observed in animal models such as the mdr1a-/- mice. In this mdr1a-/- animal model a link between epithelial barrier dysfunction and development of colitis has been proposed[63]. Moreover, UC is associated with a mutation of the Toll-like receptor (TLR)-4 gene in humans, resulting in impaired lipopolysaccharide (LPS) signaling[64]. LPS comprises the major cell wall component of gram-negative bacteria and is mainly recognized *via* TLR-4. Stimulation of TLR-4 with bacterial LPS or other ligands[65] leads to activation of the NF-κB signaling system and subsequent induction of inflammatory responses[66]. Kiechl *et al*[67] showed that carriers of these mutations displayed an increased risk of gram-negative infections stressing that the predisposition of UC is associated with a genetic background. Besides these genetic factors, it has been demonstrated that an activated mucosal immune system leads to impaired epithelial barrier function and tissue destruction in patients suffering from UC[6,68]. In contrast to patients with CD, where the cytokines IFN-γ and TNF-κ play a central role in altering the epithelial barrier function, it still remains unclear which panel of cytokines regulates inflammation and induces epithelial barrier dysfunction in UC. Recently published data has shown that IL-13 produced by CD1-reactive natural killer T cells (NKT) played a central role in a murine model of colitis[69]. The IL-13 producing cells were also found in patients suffering from UC which suggests that this cytokine is one of the key mediators in the intestinal pathology of UC. Interestingly Heller *et al* showed that IL-13 mediates a drop of transepithelial resistance without any induction of necrosis in model IECs by increasing the paracellular permeability stressing the profound effect of IL-13 on epithelial barrier function[34]. Furthermore, it has been shown that IL-13 is produced in large amounts in the lamina propria of patients with UC. This is accompanied by increased expression of the pore-forming tight junction molecule claudin 2, which leads to the development of impaired barrier function for small cations and is thought to be responsible for the diarrhea in UC[70].

PROBIOTICS AND BARRIER FUNCTION IN UC AND ANIMAL MODELS OF COLITIS

Data from different *in vitro* and *in vivo* models support the involvement of luminal bacteria in mucosal inflammation and alteration of the intestinal barrier function especially in UC. In contrast to CD, ulcerative colitis is a disease involving mucosa only. Intestinal inflammation is accompanied by direct adherence of bacteria to this mucosal surface while the protective function of the mucus layer seems to be disrupted[71]. Studies have shown that bacteria like *E. coli*, *lactobacilli*, *bifidobacteria* and *streptococci* are able to interact with immunocompetent cells, using the mucosal interface and locally modulate the production of proinflammatory cytokines[72]. They may also directly change the structure of the intestinal epithelial barrier. Although the treatment of CD with probiotics has not demonstrated any sufficient results yet[73-75], the treatment of UC has shown encouraging data[76-81]. Generally the mechanisms by which probiotic microbial agents contribute to the protection of the inflamed intestinal epithelium involve two main categories: (1) competition for binding sites and inhibition of pathogen growth as well as epithelial attachment or invasion[82,83] and (2) stimulation of the mucosal immune system including the stimulation of anti-inflammatory cytokine levels and enhancement of the barrier function. Recent work provided evidence that protective effects of probiotic microorganisms in a DSS model of experimental colitis are mediated by DNA, which was recognized by the mucosal TLR9 receptor and this interaction consequently lead to an increased production of β-defensins. Defensins are known to be responsible for the destabilization and disruption of microorganism cell membranes, leading to an increase in permeability and leakage of small molecules[84,85]. To combat invading pathogens, phagocytes need to be recruited to sites of bacterial entry. Leukocyte recruitment occurs along gradients of chemotactic factors, including chemokines and defensin chemoattractants at nanomolar concentrations[86,87]. In addition, it has been shown that the probiotic compound VSL #3 was effective as primary therapy in a colitis model of IL-10 gene-deficient mice. A direct effect on epithelial barrier function was described. The treatment resulted in a normalization of colonic physiologic function and barrier integrity along with a reduction in mucosal levels of proinflammatory cytokines and a significant improvement in histological disease by secretion of soluble factors enhancing the barrier integrity[88]. This stabilization of the intestinal barrier function is an important target in the treatment of intestinal inflammatory disorders. Otte *et al*[89]

reported that the treatment of cultured IECs with VSL #3 lead to an increase of the transepithelial electrical resistance (TEER). In addition, this probiotic mixture was found to diminish Salmonella-induced alterations in the cellular cytoskeleton[90,91], including the distribution of the tight junction protein ZO-1. The stabilization of the cytoskeleton by regulation of tight junctions is important in the preservation of the epithelial architecture and, thereby, in the maintenance of the intestinal barrier, which might be affected by the MAPK pathway as postulated by the authors[89]. Interestingly, the incubation of IECs with these probiotics also induced the expression of several mucins, leading to less adhesion of microorganisms and its compounds like LPS to the epithelial surface. Together these housekeeping mechanisms might be responsible for the homeostasis of the intestinal barrier function during inflammatory disorders like UC.

CONCLUSION AND PERSPECTIVES

The pathophysiology of intestinal inflammation is multifactorial. Whatever the trigger, increased epithelial permeability plays a central role in the inflammatory process. The permeability changes and inflammation are intimately linked and play a central role in perpetuating the chronic mucosal damage observed in IBD. TJs do not merely represent static junctions between epithelial cells but are multifunctional protein complexes involved in numerous vital and diverse functions of epithelial cells. It is becoming evident that the TJs are extremely dynamic structures involved in developmental, physiological, and pathological conditions like CD and UC, where defects in mucosal integrity and repair remain key elements in initiation and perpetuation of the disease. Future studies will be focused on the mechanisms by which the epithelial barrier can be made "less leaky". The mucosal immune system is the central effector of intestinal inflammation and injury, with cytokines playing a central role in modulating inflammation and epithelial barrier function. Cytokines are, therefore, logical targets for IBD therapy. Finally, preliminary clinical trials of probiotic therapies in IBD may offer a valuable tool for prevention and control of IBD. Understanding the function and action of these probiotics will lead to the selection of useful probiotic strains for clinical application. As more work is directed at the function and modulation of the intestinal barrier, further potential therapeutic targets will provide more options to combat CD and UC.

Abstract

Surgery is required in the vast majority of patients with Crohn's disease (CD) and in approximately one-third of patients with ulcerative colitis (UC). Similar to medical treatments for IBD, significant advances have occurred in surgery. Advances in CD include an emphasis upon conservatism as exemplified by more limited resections, strictureplasties, and laparoscopic resections. The use of probiotics in selected patients has improved the outcome in patients with pouchitis following restorative proctocolectomy for UC. It is anticipated that ongoing discoveries in the molecular basis of IBD will in turn identify those patients who will best respond to surgery.

INTRODUCTION

Significant strides have been made toward more effective medical management of inflammatory bowel disease (IBD) over the past several decades. Surgery, however, is still an essential component of the current multi-modality approach to both Crohn's disease (CD) and ulcerative colitis (UC). The current surgical approach to CD, with its emphasis on bowel conservation, was born out of decades of surgical experience. Early published series on the surgical management of ileal CD supported ileocolostomy with exclusion, the so-called "Berg" or "Mount Sinai" operation, as a safe and often therapeutic surgical approach. Concern that the remaining bypassed segment of diseased intestine placed the patient at risk for recurrent symptomatic CD and adenocarcinoma as well as an incidence of stump blow-out influenced a shift towards resectional techniques. Efforts to resect disease with margins free of microscopic disease gave way to a more conservative approach with the realization that radical resection did not result in lower rates of disease recurrence[1].The addition of strictureplasty techniques to the surgical armamentarium has furthered this trend towards surgical conservatism.

In contrast, the history of the surgical management of UC is marked by a shift from non-resectional strategies to the current emphasis on near-total resection of the colon and rectum. Early approaches to the surgical management of UC involved the construction of appendectomies to facilitate colonic irrigation or diverting ileostomies. The application of proctocolectomy with permanent ileostomy in UC addressed the morbidity associated with not resecting the diseased colon and became standard-of-care for most of the 20th century. The refinement of techniques for constructing a neo-rectum using the ileum in the 1980's led to the wide acceptance of total proctocolectomy with ileal pouch-anal anastomosis (IPAA) as a viable and often preferable surgical option.

Today, 70%-80% of patients with CD and 30%-40% of patients with UC ultimately require surgery. The current indications for surgery in both CD and UC are well described and will be reviewed in this article. In addition, we will focus on more recent developments in the surgical and peri-operative management of IBD including the increasingly broad application of laparoscopic techniques, multimodality therapy for anorectal CD, and the use of post-operative probiotics therapy after IPAA.

CROHN'S DISEASE

The surgical approach to CD is dictated, in large part, by the anatomic distribution of the disease. CD of the distal ileum with a varying degree of colonic involvement is present in 40% of patients. Isolated small bowel disease, isolated colonic, and isolated perineal and anorectal disease are present in 30%, 20%-25%, and 5%-10% of patients respectively. Gastroduodenal disease is not uncommon and has been endoscopically documented in 20% of

CD patients, usually with concomitant ileal disease. Symptoms related to gastroduodenal disease, however, are uncommon, and gastroduodenal disease necessitating operative intervention is rarer still[2].

Irrespective of its anatomic distribution, CD can be classified on the basis of histopathologic and pathophysiologic criteria. The three major subtypes of CD are fibrostenotic disease, which presents with varying degrees of intestinal obstruction, fistulizing disease, and aggressive inflammatory disease. The former two often require operative intervention, while the latter is primarily managed medically.

Operative intervention for CD is indicated when medical therapies fail to adequately alleviate symptoms, or when patients develop one of several complications of the disease; specifically, these include fistula, abscess, obstruction, and malnutrition. Persistent symptoms which compromise quality of life despite several months of aggressive medical management, or recurrent symptoms following repeated attempts to taper aggressive therapies are well described indications for surgery. Adverse reactions to medical therapies, most often steroids, sometimes prompt a more aggressive surgical approach to the control of CD symptoms as well.

Fistula formation is a common component of CD but is infrequently an isolated indication for surgery. Fistulas may be accompanied by abscesses, inflammatory masses, obstructive symptoms, and in rare cases peritonitis, all of which may prompt surgical intervention. Enterocutaneous fistulas and peri-anal or perineal fistulas may significantly compromise quality of life. Operative intervention to alleviate symptoms is often warranted even if these fistulas do not constitute a significant threat to a patient's physical well being. Enteroenteric fistulas are frequently discovered during surgical exploration for other indications. The presence of these fistulas does not mandate surgical repair unless they result in significant sequelae of malabsorption; namely malnutrition, dehydration or extremely frequent bowel movements. Enterovaginal and enterovesical fistulas may necessitate surgery if they are associated with significant symptomatology, vaginosis or urinary tract infections.

Obstruction is a relatively common indication for surgery. The specific character of obstructive symptoms is largely dependent upon the site of obstruction. Most commonly, terminal ileal narrowing causes chronic crampy abdominal pain associated with oral intake, often resulting in malnutrition. Additional less common indications for surgery in CD include acute hemorrhage, malignancy, and fulminant colitis[3].

SMALL BOWEL DISEASE

As stated previously, indications for operative intervention for CD of the small bowel include obstruction and fistula, particularly when accompanied by abscess or an inflammatory mass. When small bowel resections are undertaken, anastomoses should be constructed between segments of bowel grossly free of active disease. In the setting of multiple strictures, strictureplasty may allow for conservation of bowel length. Conventional strictureplasty involves the longitudinal incision of a stenotic segment of bowel with subsequent transverse closure of the enterotomy to increase lumen diameter. Resection and strictureplasty are often used in conjunction with the former technique applied to longer stenotic segments and the latter technique applied to shorter stenotic segments. Strictureplasty techniques aimed at addressing longer stenotic segments have been described in the recent surgical literature and are being applied with increasing frequency[4].

The operative management of small bowel fistulas is a complex subject; the surgical approach is dictated by the structures involved. Generally, fistulous tracts are transected, diseased intestine is resected, the contents of the tracts are evacuated, and necrotic tissue is debrided. In the setting of enterocutaneous fistulas, the opening at the skin is typically excised and allowed to close secondarily. When fistulas involve intra-abdominal organs free of Crohn's disease, the opening in the non-diseased organ is debrided and closed primarily[5].

COLONIC DISEASE

Complications of segmental CD of the colon may be addressed with segmental resection. Diffuse disease may require proctocolectomy with ileostomy, or total abdominal colectomy with ileorectostomy if the distal rectum is free of disease. In the setting of toxic colitis, total abdominal colectomy with construction of an ileostomy and Hartmann pouch is the preferred approach. In principle, the management of fistulous disease of the colon is similar to that described for fistulous disease of the small bowel. Colon with gross disease should be resected. Fistulous tracts to the colon from a diseased small bowel are typically managed with small bowel resection, excision and primary closure of the colonic opening.

ANORECTAL DISEASE

Typical manifestations of anorectal CD include fissures, fistulas, abscesses, and anal canal stenosis. Perianal disease resulting in fistulas and abscesses is frequently treated in stages. Perianal sepsis from abscess formation is addressed with incision and drainage. Subsequent abscess formation may be prevented by placement of seton drains. Fistulotomy and rectal advancement flaps are additional options in the management of chronic fistulas. Fistulotomy is specifically applicable to low fistulas. Rectal advancement flaps are less frequently successful in the CD population and candidates for these approaches must be carefully selected. The absence of significant rectal mucosal disease is a prerequisite for successful advancement flap coverage. The construction of a diverting ostomy may render active disease quiescent and is a useful option in selected patients with debilitating perianal or perineal disease who are poor candidates for a larger operation. Finally, proctectomy and proctocolectomy are appropriate options for patients with persistent, severe disease[6].

ULCERATIVE COLITIS

In contrast to CD, UC may be cured with surgery. The

specific indications for surgical intervention fall into two broad categories: emergent and elective. Emergent indications include massive hemorrhage, toxic colitis, toxic megacolon, and intestinal perforation. Elective indications include the inability of medical therapy to alleviate symptoms, severe malnutrition, the presence of dysplasia, and cancer.

EMERGENCY INDICATIONS

Toxic colitis, characterized by diffuse abdominal tenderness, tachycardia, fever, and leukocytosis is initially treated with fluid resuscitation, intravenous steroids and antibiotics. Surgery is indicated if clinical parameters do not improve with medical therapy in 48 to 72 h. The operation of choice in this setting is a subtotal colectomy and ileostomy with Hartmann pouch or rectal mucous fistula. Pelvic dissection is avoided to allow for a subsequent safe conversion to a proctocolectomy. Toxic megacolon is a variant of toxic colitis characterized by severe dilation of the colon. Toxic megacolon may be acutely managed with a subtotal colectomy and ileostomy. Construction of a skin-level transverse colostomy for decompression and a loop ileostomy for diversion has been described as an alternative approach in this setting. Colonic perforation is typically managed with a subtotal colectomy and ileostomy. Massive hemorrhage is similarly treated with a subtotal colectomy and ileostomy following proctoscopic confirmation that the majority of the bleeding is proximal to the rectum.

ELECTIVE INDICATIONS

Severe persistent symptoms that compromise quality of life are an indication for surgical resection as are complications of long term steroid dependence. Malnutrition and growth retardation are common indications for resection in the pediatric population. Finally, dysplasia or colorectal cancer detected by colonoscopy mandate surgical resection.

Surgical options for chronic ulcerative colitis include proctocolectomy with ileostomy, proctocolectomy with continent ileostomy, and proctocolectomy with IPAA. Proctocolectomy with ileostomy remains an important surgical option with curative potential in UC and relatively low morbidity when compared to proctocolectomy with IPAA. In healthy individuals who are motivated to maintain fecal continence and are willing to accept the potential associated morbidity, restorative proctocolectomy with IPAA is the procedure of choice. Though the necessity of a temporary diverting ileostomy has been called into question by some investigators, the majority of experienced surgeons routinely divert patients undergoing IPAA for a period of two to three months. The construction of continent ileostomies was more popular prior to the refinement of IPAA techniques. Continent ileostomies are prone to failure from valve slippage and this approach is only applicable in highly selected patients. Conversion to a continent ileostomy may be appropriate in patients with an IPAA who develop septic complications but are uncomfortable with the realities of a conventional ileostomy[7].

ADVANCES IN THE SURGICAL MANAGEMENT OF IBD

Crohn's disease

The role of laparoscopy in the surgical management of CD has been the focus of considerable investigation over the past decade. Several non-randomized trials suggested equivalent morbidity and mortality following laparoscopic or open ileocecal resection. Benefits of the laparoscopic approach, such as shorter length of hospital stay and lower rates of post-operative bowel obstruction, were suggested in some series. More definitive data in the form of two published prospective randomized trials have shed further light on these topics. In the study published by Milsom *et al*[8], 60 male patients were randomized to either laparoscopic or conventional ileocolic resection. Serial pulmonary function tests (PFT's) were measured post-operatively and were used as an objective surrogate for recovery. While the laparoscopic group's PFT's normalized more rapidly than did those of the conventional surgery group, the return of GI function and length of hospital stay was not significantly different between the two groups[8]. In the study reported by Maartense *et al*[9], sixty patients were randomized to either laparoscopic-assisted or open surgery. Importantly, post-operative care of the enrolled patients, regardless of which operation they received, was standardized. The primary outcome parameter was post-operative quality of life as measured by responses to two standardized questionnaires during a three month follow-up period. Secondary outcomes included operating time, morbidity, hospital stay, post-operative morphine requirement, and costs. Median operating time was longer (115 min *vs* 90 min, $P < 0.003$), median hospital stay was shorter (5 d *vs* 7 d, $P = 0.008$), and costs were lower in the laparoscopic group when compared to the open surgery group. Quality of life did not differ between the two groups[9]. In summary, there is no demonstrable difference in outcomes after open and laparoscopic ileocecal resection. Evidence is somewhat contradictory with regards to recovery time, but there is some evidence suggesting a more rapid recovery following laparoscopic ileocecal resection (Table 1).

As stated previously, 70%-80% of patients with CD eventually require surgery. Unfortunately, rates of disease recurrence remain high with a median time of ten years between a first and second bowel resection. A number of studies have proposed lower rates of disease recurrence after bowel resection when side-to-side stapled anastomoses are performed as opposed to hand-sewn end-to-end anastomoses. The widespread observation that disease recurrence invariably affects

bowel proximal to the prior anastomosis has led some surgeons to hypothesize that some element of relative obstruction at the anastomosis contributes to the pathogenesis of proximal disease. If this is the case, it follows that techniques allowing for a larger, more widely patent, anastomosis might lower recurrence rates. A number of retrospective, and non-randomized prospective studies suggest longer intervals of time prior to second resections when the stapled technique is employed[10]. A multicenter randomized trial is ongoing to investigate these observations.

Several interesting observations and advances have been reported regarding the operative treatment of anorectal CD. As mentioned previously, the placement of a draining seton is of considerable utility in the management of perianal fistulas. Perianal fistula recurrence following the removal of draining setons, however, is common. A combined medical and surgical approach to anorectal disease has been widely advocated. Specifically, the use of infliximab therapy in combination with examination under anesthesia and seton placement is supported by retrospective data published by Regueiro and Mardini[11], and by Topstad *et al*[12]. Irrespective of pharmacologic and surgical intervention, anorectal fistulizing disease remains a difficult problem as evidenced by the 44% rate of fistula recurrence after combined seton placement and infliximab therapy cited in Regueiro and Mardini's study. Surgical diversion is an often effective, if relatively radical, strategy for severe, medically refractory anorectal disease. Galandiuk *et al* reviewed their extensive experience in treating patients with anorectal CD. They identified the presence of anal canal stenosis and concomitant colonic CD as predictors of the need for permanent fecal diversion[13].

Ulcerative colitis

Laparoscopic surgery for UC has attracted considerable interest in recent years. Several case series and case-control studies established the feasibility of laparoscopic restorative proctocolectomy with ileal pouch anal anastomosis[14]. One randomized study comparing hand-assisted laparoscopic and open surgery for both UC and familial adenomatous polyposis has been published[15]. Maartense *et al* randomized sixty patients and documented their post-operative recovery at three months after surgery as measured by two standardized quality of life questionnaires. Secondary parameters included post-operative morphine requirement, operating time, morbidity, hospital stay and costs. Recovery in the two groups was equivalent. The laparoscopic operation took longer and was more costly[15]. At the current time, there is little evidence to suggest a benefit to laparoscopic restorative proctocolectomy as compared to the open operation with the exception of cosmesis. Interest in this approach, however, both in the medical and patient communities, remains great. With increased experience the role for this operation will, presumably, become more clearly defined.

Morbidity associated with restorative proctolcolectomy with IPAA remains significant. Pouchitis is the most common long-term complication following IPAA. This syndrome, most often characterized by increased stool frequency, urgency, and abdominal discomfort, remains poorly understood. The efficacy of antibiotic therapy in the majority of patients suggests an infectious etiology. Promising data supporting probiotic maintenance therapy for relapsing pouchitis after initial treatment with antibiotics was published by Gionchetti *et al*[16]. Forty patients were randomized to receive a probiotic called VSL#3 containing viable lyophilized bacteria including four strains of Lactobacillus, three species of Bifidobacterium and Thermophilus, or placebo. Over a nine month follow-up period, 15% of patients treated with VSL#3 compared to 100% of patients treated with placebo relapsed[16]. Similarly impressive results for VSL#3 were published by Mimura *et al*[17] VSL#3 has also been studied as prophylaxis against pouchitis during the first year following IPAA in a randomized prospective study. Of 20 patients randomized to VSL#3, 2 (10%) developed pouchitis within 12 months. Comparatively, 8 of 20 patients randomized to placebo (40%) developed pouchitis[18]. These results warrant further study of probiotics in the prevention of, and as maintenance therapy following initial therapy for, pouchitis.

CONCLUSION

Surgery remains an important component of the multi-modality treatment of IBD, required in 70%-80% of patients with CD and 30%-40% of patients with UC. Operative intervention for CD is indicated when symptoms are refractory to medical therapies, or when patients develop complications of the disease. Emergent indications for surgical intervention in UC include massive hemorrhage, toxic colitis, toxic megacolon, and intestinal perforation. Elective indications include refractoriness to medical therapy, severe malnutrition, the presence of dysplasia, and cancer. During the last decade significant efforts have been made to apply laparoscopic techniques to the surgical management of IBD. Additionally, significant advances in medical therapy have been made which promise to impact positively on outcomes following surgical interventions. The role of laparoscopy in the surgical management of CD has been the focus of considerable investigation. No significant difference in outcomes after open and laparoscopic ileocecal resection has been demonstrated but shortened recovery time following laparoscopic resection has been suggested in some studies. Except for improved cosmesis, there is little evidence to suggest a benefit to laparoscopic restorative proctocolectomy as compared to the open operation. Morbidity associated with restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) remains significant. Pouchitis is the most common long-term complication following IPAA. Probiotic maintenance therapy for relapsing pouchitis after initial treatment with antibiotics and as prophylaxis against pouchitis during the first year following IPAA is promising and further investigations are warranted.

Abstract

The incidence of pediatric inflammatory bowel disease (IBD) is rising and recent advances in diagnostics and therapeutics have improved the care provided to these children. There are distinguishing features worth noting between early onset and adult onset IBD. Physical and psychosocial development remains a critical target for the comprehensive management of pediatric IBD. Children are not just little adults and consideration must be given to the stages of development and how these stages impact disease presentation and management. The final stage will be the transition from pediatric care to that of adult oriented care and special consideration must be given to make this a successful process. This review highlights special considerations in the management of the child with IBD.

INTRODUCTION

Inflammatory bowel disease (IBD) first presents in childhood and adolescence in approximately 20% of all cases. A European study reported that in the entire IBD population (children and adults) the incidence of Crohn's disease (CD) increased significantly (+23%), while the incidence of ulcerative colitis (UC) decreased (-17%)[1]. One of the best North American studies reported the incidence of IBD in Wisconsin children to be 7.05 per 100 000, with the incidence for Crohn's disease being 4.56, more than twice the rate of ulcerative colitis (2.14). An equal IBD incidence occurred among all ethnic groups, and children from sparsely and densely populated counties were equally affected and the majority (89%) of new IBD diagnoses were non-familial[2]. The median age of onset is 12 years and there appears to be a slight male predominance in the younger age group. Given the rise in incidence and the onset of disease coinciding with growth and development it is very important to highlight the considerations that should be taken into account when managing childhood onset IBD. This review with underscore the many unique facets involved in the presentation, diagnosis, treatment and psychosocial well being of the child with IBD.

ETIOPATHOGENESIS

The underlying pathogenesis of IBD in children appears to be similar to that in adult onset such that IBD results from a complex interaction of environmental, genetic, and immune factors. Genetics, however, may play an even greater role in disease onset and susceptibility in patients who present earlier in life. Despite research efforts, a gene specific to pediatric onset disease has not been identified. It does appear however that the NOD2 gene is similarly present in both 30%-35% of adult and pediatric CD patients. NOD2 was first identified in 2001. Although the true pathogenic role of NOD2 in CD remains unknown, it is an important gene involved in innate immunity which lends support to the notion that genetically determined defects in innate, and likely adaptive immunity alter the way our mucosal immune system interacts with our resident bacterial flora[3]. This dysregulated interaction leads to the adaptive immune response that is, in large part, responsible for the chronic inflammatory lesions, characteristic of patients with IBD. NOD2 has been well studied in the Caucasian population, however, the frequency of this gene among patients with CD of other racial/ethnic groups in the United States is not well known. Despite similar clinical characteristics significantly lower frequencies of read NOD2 mutations have been seen in African American and Hispanic children with CD compared with Caucasian children with CD[4]. There has been some evidence to suggest that the ethnic background of a child with CD may be associated with different genetic variants. A study from Israel suggested that G908R (SPN 12) allele-variant of the NOD2/CARD15 gene is closely related to the appearance of CD at a young age in Jewish Ashkenazi patients[5]. Research is ongoing to further examine the influence of

ethnicity on disease susceptibility and disease modification. Initial genotype-phenotype correlation studies in children demonstrated that NOD2 is associated with fibrostenosing CD and more rapid progression to surgery[6]. It appears that genetics is only part of the story when it comes to understanding the influences or risk factors at predicting the natural history of disease in pediatric patients. Initial work suggested that there are specific immune markers present in the serum of children with IBD[7]. These markers were initially used to help differentiate CD from UC and to aid in the distinction between functional GI symptoms and those due to underlying IBD, CD in particular. The concept that sero-reactivity to specific microbial antigens seen in a subgroup of patients with IBD likely represents a surrogate measure of an individual's adaptive immune response has resulted in this being an important area of investigation. Since reactivity to yeast oligomannan (anti-*Saccharomyces cerevisiae* antibody; ASCA) was first described in Crohn's disease (CD), the number of CD-specific antigens for which reactivity can be measured has expanded to include the *Pseudomonas fluorescens* related protein (I2), *Escherichia coli* outer membrane-porin (OmpC), and CBir1 flagellin (CBir1)[8-10].

The evolution of serum immune response from diagnostic markers to markers of disease behavior and perhaps prognostic information has resulted in studies that have shown that the presence and magnitude of immune responses in a given child is associated with more aggressive disease phenotypes and more rapid disease progression to complication and surgery. Larger scale studies are underway to confirm these preliminary findings and to further develop a risk assessment tool to identify children at risk of more aggressive disease and subsequent introduction of early intervention[11,12].

DIAGNOSIS

The diagnostic approach to IBD in children is a two-tiered approach. The first diagnostic question is whether the presenting symptoms are compatible with a diagnosis of IBD. In the face of classic, alarm, symptoms the differentiation between IBD and diseases that mimic the symptoms of IBD can be relatively simple. Diarrhea and abdominal pain are the most common symptoms in both CD and UC with rectal bleeding more commonly seen in UC and weight loss and anorexia more characteristic of CD. Perianal disease, like in adults, remains characteristic of CD. However unlike adults, growth failure is an important presenting sign in pediatric onset IBD, most commonly in CD patients. The standard diagnostic approach is employed including routine labs looking for signs of inflammation (ESR, CRP, platelet count) complete blood count with a focus on the hemoglobin for anemia and other labs such as iron panel and albumin to look at nutritional/absorptive state. Stools studies should be done to rule out infection especially in the presence of a travel history. Endoscopic evaluation and tissue diagnosis remains the gold standard[13]. It is recommended that all children undergo both an upper endoscopy and colonoscopy at the time of initial investigation. The findings on upper endoscopy, although often non-specific, may provide additional information in a patient with indeterminate disease of the colon especially if granulomas are found. A recent study found upper gastrointestinal inflammation in 29 of 54 children (22 CD; 7 UC)[14]. Epigastric and abdominal pain, nausea and vomiting, weight loss and pan-ileocolitis were predictive of upper gastrointestinal involvement. However, 9 children with upper gastrointestinal involvement were asymptomatic at presentation (31%). Overall upper gastrointestinal tract inflammation was most common in the stomach (67%), followed by the esophagus (54%) and duodenum (22%). Thus, absence of specific upper gastrointestinal symptoms do not preclude presence of upper gastrointestinal inflammation. It is important to biopsy macroscopically involved and non-involved tissue so to maximize the yield on the initial invasive evaluation. Small bowel radiography is also part of the initial diagnostic evaluation of pediatric IBD patients especially in CD patients. This is especially so for patients in whom ileal intubation was not successful at the time of the colonoscopy or diagnosis is indeterminate. It has been suggested that a normal small bowel radiography alone should not be used to rule out pediatric inflammatory bowel disease when the symptoms suggest it. Colonoscopy with terminal ileal intubation is feasible and safe; it should be attempted in all children with symptoms consistent with inflammatory bowel disease[15]. Radiographic evaluation of the small bowel has evolved to include MRI enterography and CT enterography. Recent advances in gadolinium-enhanced magnetic resonance imaging (G-MRI) have been developed to enhance the resolution of the intestinal mucosa and facilitate the differentiation of UC from CD[16]. Until the MRI scanners are faster and the radiologists are more comfortable interpreting the scans, MRI remains experimental and should be limited to use in centers that have a radiologists who are trained in this technology. CT enterography on the other hand is evolving into the best method of assessing the small bowel and large bowel. The use of Volumen for oral contrast allows for accurate visualization and distension of the mucosa. The radiation is somewhat greater than a standard CT scan however is less than a small bowel follow through with prolonged fluoroscopy[17]. Experience is growing among pediatric gastroenterologists in this area. Positron emission tomography (PET) using fluorine-18-fluoro-deoxyglucose to identify metabolically active tissues was evaluated as a simple noninvasive alternative to conventional studies in identification and localization of active intestinal inflammation in children with IBD[18]. The authors concluded that PET may not be able to replace conventional studies; however, it may be useful when conventional studies cannot be performed or fail to be completed. The cost associated with this test is an important limiting factor. White cell scans have also been proposed as a noninvasive way of evaluating active inflammation, however there can be many false negatives and advances in technology such as the video capsule endoscopy (VCE) provides a unique way of evaluating the small bowel mucosa with increased sensitivity and specificity[19]. VCE may be helpful in patients with persistent small bowel symptoms despite what has been reported as a normal small bowel x-ray particularly those

children with persistent growth failure. Moreover in cases of indeterminate colitis, children may benefit from more detailed small bowel visualization[20].

In the face of diagnostic uncertainty, such as in children presenting with symptoms compatible but not diagnostic of IBD, the pediatric approach tends to be less invasive then the approach to an adult patient presenting with similar symptoms. In this setting pediatricians tend to use non-invasive testing first to gather information that may increase the probability of disease and hence lead to more evidence to support invasive diagnostic testing. Other than routine laboratory tests as noted above, there are fecal markers, such as calprotectin and lactoferrin, and serological markers, such as ASCA and pANCA, that may aid in the differential diagnosis. Earlier reports demonstrated that fecal calprotectin correlated closely with the best invasive measures of colonic and small bowel inflammation in childhood inflammatory bowel disease and lends itself particularly to the monitoring and assessment of therapeutic interventions in children with inflammatory bowel disease[21]. Subsequent experience with calprotectin has yielded similar findings and in some practices is used frequently to differentiate functional from inflammatory GI disorders. Novel technologies have led to the development of a diagnostic algorithm to evaluate the sensitivity and specificity of serological immune markers as predictors of IBD *vs* non IBD. Historically these tests were accurate in differentiating IBD from non-IBD in 2/3 of cases[22]. The addition of novel immune responses and a change in technology may improve the diagnostic accuracy of non-invasive testing to close to 90%. Further validation studies in pediatric patients are needed to determine if indeed these tests will help pediatric gastroenterologist increase the likelihood of diagnosing IBD in the face of positive markers. In the adult cohort that these tests were validated in, it appears that disease was ruled out with approximately 90% certainty. This would be an important advance in pediatrics where invasive testing is avoided if possible.

The next tier in the diagnostic process of IBD is the differentiation between CD and UC. In the face of a classic CD presentation which includes small bowel localization, presence of granulomas, typical endoscopic and histological findings, the differentiation is simple. However there are some features of pediatric onset IBD that may pose more of a diagnostic dilemma when disease is confined to the colon. Despite the classic teachings of UC always involving the rectum, there are reports of rectal sparing in pediatric patients carrying a diagnosis of UC. The group from Boston reported that a significant proportion of children with new-onset UC had patchiness of microscopic features of chronicity (21% of patients), relative (23%), or absolute (3%), rectal sparing, and had little or no crypt architectural distortion in their rectal biopsies (8%). Of interest, these features were not observed in adult patients with UC. In addition, a higher proportion of children with UC initially presented with subtotal or with pancolitis compared with the adults[23]. Another study demonstrated that children < 10 years of age had significantly less crypt branching, plasma cells in the lamina propria, cryptitis, crypt abscesses, and epithelial injury than adults. Endoscopic rectal sparing was also seen in another study in 23% of children with newly diagnosed, untreated UC, and this feature did not correlate with presenting symptoms. However, the presence of rectal sparing may indicate more aggressive disease that is less responsive to medical treatment[24]. These studies must be interpreted with caution as these patients likely have what has become known as UC-like CD and although clinically present with UC symptoms, there are endoscopic and histological features more characteristic of CD. In these cases a more accurate evaluation of the small bowel with video capsule endoscopy may be warranted and perhaps serological immune responses will be helpful in differentiating between CD and UC. Studies have shown that pANCA is more commonly seen in patients with ulcerative colitis and ASCA and OmpC are prevalent in CD patients. It was then found that pANCA may be present in 25% of all CD patients, predominantly in patients with disease confined to the colon. A novel CD marker, anti-CBir1, has been shown to be present in approximately 50% of pANCA positive CD patients but rare (< 5%) of pANCA positive UC patients[25]. This marker may help differentiate CD from UC in indeterminate cases. This may be important as the efficacy of therapies may differ between the 2 pANCA subgroups. Further research is underway to delineate further the role of these markers in predicting response to therapy and post surgical prognosis[26].

TREATMENT

Modern approaches to IBD therapy calls upon the need for disease modifying targets with the goal of mucosal healing . It is hypothesized that mucosal healing should reduce disease related complications and in turn maximize the quality of life of IBD patients. This may be even more of an important issue when treating children with IBD given the long term consequences of early onset aggressive disease presentations. Currently there are few therapies approved for children with IBD, however, the concepts of targeting the full spectrum of the inflammatory cascade and the notion of mucosal healing can be applied. The main goals of targeting therapy in pediatric IBD are to: (1) Maximizing efficacy; (2) Maximize adherence; (3) Minimize toxicity; (4) Maximize quality of life; (5) Maintain physical and psychosocial growth; (6) Prevention of disease complications.

Like their adult counterparts, the current approach to the treatment of children with IBD is based on disease severity. In other words the traditional "step up" approach is applied in most cases. This approach also takes into account medication safety as the more milder/less toxic medications are often employed first letting patients declare themselves failures necessitating navigating up the pyramid to more aggressive anti-inflammatory agents. Pediatric gastroenterologists are limited in their ability to interpret whether this is the correct strategy given few studies have been done in children to support use of these medications especially the Mesalamine based therapies. Often we are forced to extrapolate information from adult study populations which may not be applicable to a child.

Given the potential growth and development implications of persistent inflammation and corticosteroid dependency, efforts are made to maximize both anti-inflammatory and steroid sparing strategies. Aside from the potential growth effects, the esthetic changes associated with corticosteroid use can be devastating to a child. Nutritional therapy is typically unique to pediatric patients however compliance can be an obstacle to administration. A recent prospective, 10-week open-label trial in children with active naive CD randomized children to orally polymeric formula alone or oral corticosteroids. In this small study, children with active and recently diagnosed CD, a short course of polymeric diet was more effective than corticosteroids in inducing healing of gut inflammatory lesions[27]. Further large scaled studies are needed to further evaluate the short and long term benefits of this treatment strategy. In the USA, enteral nutrition is used more so as supplemental nutrition in the face of malnutrition and growth failure.

Recently, there has been a lot of discussion surrounding the notion of turning the therapeutic pyramid upside down, aka "top-down" therapy. In other words in patients who are candidates for corticosteroids, more potent biological therapies, such anti-Tumor Necrosis Factorα (anti-TNFα) therapies, may be considered as alternatives[28]. However the strategy of short term corticosteroids with 6-MP as bridge therapy may be a safer and equally effective strategy in this patient population. Markowitz *et al* demonstrated that a significant proportion of children were off steroids and in remission 600 days after the combination therapy was initiated[29]. If however the desired outcome of a steroid free remission is not achieved in the expected time frame (4-6 months) of this combination then at that time the introduction of a biological therapy should be considered. The hesitation to go directly to a biologic stems from the fact that the thiopurines work well in children and the serious safety concerns. There are definitely safety concerns associated with thiopurines as well, however, TPMT screening and metabolite monitoring enable clinicians to identify at risk patients and dose adjust so to minimize toxicity and dose escalate safely in patients with sub-therapeutic levels and not responding to their current dose[30]. The REACH trial was the first of its kind in pediatrics to evaluate in a multi-center fashion the efficacy and safety of infliximab in 113 patients[31]. The study was not powered for efficacy but the results do support its use in children with the response rate at 10 wk was close to 90% and a remission rate at 54 wk of approximately 50% which includes children off of corticosteroids when receiving drug every 8 wk as opposed to every 12 wk. The safety may have been more favorable among patients receiving the every 12 wk infusions, however the efficacy benefit of every 8 wk may outweigh its safety risks. The data lead to the approval of infliximab for children with luminal Crohn's disease. Clinical trials are underway to evaluate the efficacy and safety of infliximab in children with ulcerative colitis as well as adalimumab for pediatric CD. Weighing the risks and benefits of each therapy must be considered and should be communicated with the child and the family. New safety information has emerged which has already started to alter the approach to patients receiving infliximab. There have been 18 confirmed cases of hepato-splenic T cell lymphoma (HSTCL) reported in patients receiving combination thiopurines and anti-TNFα therapy. Although rare, the majority of cases are fatal which has forced pediatricians to rethink their approach to this patient population. This calls into question of concomitant immunomodulation for the purpose of immunogenicity and perhaps improvement in response rates and how it relates to safety. In REACH all children had to be on concomitant therapy to be eligible so it is not known whether monotherapy would have been as effective. In the adult ACCENT1 trial only one-third of patients were on concomitant thiopurine or methotrexate and at the end of one year the remission rate off corticosteroids was only 24%[32]. Although the median duration of disease at the time of a patient's first infliximab exposure was much lower in REACH as compared to ACCENT 1 and the patient populations are different, one must question as to whether there is an efficacy advantage of the combination as opposed to monotherapy. A significant proportion of children are being removed from thiopurines and continuing the infliximab and some clinicians are extrapolating data from the rheumatoid arthritis literature that suggests that low dose methotrexate (7.5 mg po weekly) is associated with increased through infliximab levels and decreased levels of antibodies to infliximab[33]. There is no data among pediatric patients and further research is needed to validate this strategy. Methotrexate in any form of administration has not been common place in pediatrics. There was always the notion that injections are traumatizing to children and that the oral form may be associated with treatment limiting nausea and the bioavailability was inferior to that when given subcutaneously or intramuscularly. A more recent report however showed that the bioavailability of methotrexate in patients with inflammatory bowel disease is no different from that observed in other disease states[34]. Perhaps the key to deciding the best strategy for an individual patient will be in identifying the at risk patient up front whose risk of untreated progressive disease outweighs the risk of the medications. A recent study reported that imunomodulators are used in approximately 60% of children with CD within 1 year of diagnosis and suggested that lower serum albumin levels and hematocrit, and elevated erythrocyte sedimentation rate at diagnosis may predict the need for immunomodulators earlier in the disease course[34].

Future research will evaluate the role genetics and immune responses as immunological risk factors for aggressive disease. In other words, stratify patients into high risk and low risk which will in turn modify treatment approaches.

SPECIAL CONSIDERATIONS

Bones and growth

Consideration must be given to those issues which are unique to children. Most adult and pediatric gastroenterologists would agree that the presence of growth and pubertal delay is a key factor in the management of pediatric IBD. Puberty is the most dynamic phase of growth in childhood.

Maintaining adequate nutrition, minimizing inflammation and maximizing treatment off of corticosteroids remains an integral part of managing the potential growth stunting effects of active IBD, most specifically small bowel CD. Growth failure has been reported in up to 40% of children with CD and < 10% of UC. On occasion growth and pubertal delay is the only presenting sign of IBD and can precede any GI symptoms[36]. Growth failure is secondary to malnutrition with decreased intake contributing significantly to the malnutrition. Other factors such as increased GI losses, malabsorption, psychosocial factors and medication effects can certainly impact an individual's nutritional state. Ongoing inflammation with release of specific cytokines that suppress growth factors has been shown to be a very important determinate of growth failure. Evidence suggests that IL-6 mediates growth failure in children with Crohn's disease[37]. Nutritional supplementation and need for "catch-up" growth should be an important part of the evaluation of a pediatric IBD patient. A child's self esteem can be significantly impacted by growth failure and every effort should be made to make this a priority in the management plan. Administration of growth hormone was examined in a pilot study (7 patients) and did not demonstrate any effect on growth[38]. However the combination of growth hormone with nutritional supplementation in an IBD patients would likely yield positive results given the important of adequate caloric intake in patients with ongoing inflammation.

Defective bone mass accrual is another complication of chronic inflammatory disease and the major causative factor is growth failure. There are, however, other variables, such as physical activity, altered body composition, and disordered calcium and vitamin D metabolism which certainly play a role in bone mass. Persistent inflammation in the face of IBD can also impact the maintenance of bone mass. The method for assessment of bone mass in children is very important and what is currently used in adults does not apply to the pediatric age group. Bone mineral density (BMD) T-scores are appropriate for individuals that have reached skeletal maturity, but they should not be used in pediatric DEXA reports[39]. Instead, a Z-score should be calculated by subtracting the measured BMD from the expected BMD for individuals of the same age and sex, and dividing the result by the standard deviation. Additional adjustments may be needed in small or physically immature children (e.g., using height age or bone age instead of chronological age for Z-score calculation). It is important to note that a diagnosis of osteoporosis should not be made in children based on DEXA results alone. Experts in the field suggest that a Z-score of < -2.0 in children should be reported descriptively as "reduced bone mineral mass for age"[40]. Because of these limitations, total body bone mineral content may be clinically more useful than BMD in children, especially when studying patients over a longitudinal time frame. Quantitative computed tomography (QCT) is an alternative to measure BMD in both adults and children[41]. QCT offers the advantage of providing a true volumetric BMD, and it can distinguish the individual contributions of cortical and trabecular bone. QCT can be performed in conventional CT scanners, usually in the lumbar vertebrae. It involves a higher radiation dose than

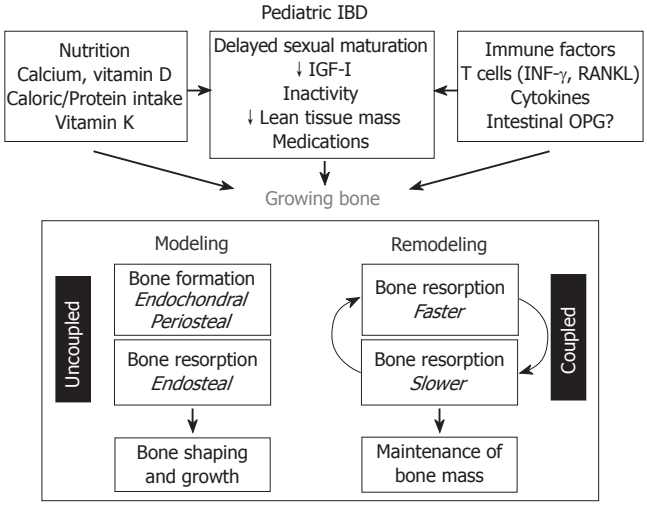

Figure 1 The effect of IBD on skeletal development.

DEXA. CT devices are available that measure BMD in the peripheral skeleton, with minimal radiation exposure, but the clinical significance of these measurements in children and adults with IBD is not known. Other experts in the field have shown that the apparent prevalence of osteopenia in children with IBD differs according to the method of data analysis used. Failure to account for bone age led to a label of moderate or severe osteopenia in 65% of cases. After adjustment for bone age, the proportion of children with osteopenia fell to 22%. Data suggests that children with IBD often have small bones for age because they have growth retardation. When DEXA data are interpreted with adjustment for bone size, most children were found to have adequate bone mass. Correct interpretation of DEXA is important for identifying children who may be at a real risk of osteoporosis[42] (Figure 1).

Quality of life and psychosocial issues

The burden of disease, both physical and psychosocial, imposed on children by Crohn's disease (CD) and ulcerative colitis (UC) can be considerable. In order to asses this burden the IMPACT questionnaire, a disease-specific measure of health related quality of life (HRQOL), was developed and validated for use in children and youth with IBD ages 10 to 18 years inclusive[43,44]. One study reported that the majority of patients perceived an improvement in HRQOL within 1 year of diagnosis and this improvement was in keeping with the overall improvement in disease severity[45]. Hester *et al* asked whether it may prove helpful to ask significant others or caregivers besides the patients themselves when evaluating health and the perception of health of patients[46]. This study reported that parents and children with IBD show high agreement when reporting observable aspects of the child's HRQOL. On the other hand, agreement was lower when it concerns more subjective aspects of HRQOL, such as social functioning and emotions. It is worth noting that children reported fewer problems than their parents. Through the CCFA, summer

camp programs are available for children with CD and UC. The goal of such camp programs is to allow children to participate in normal camp activities surrounded by their peers dealing with similar childhood issues. It has been suggested that camp may provide additional psychosocial benefits such as increased self esteem, altered perceptions and attitudes towards illness[47]. A prospective analysis of quality of life was completed at an overnight camp using the IMPACT Ⅱ questionnaire (Canada and United States) and the State-Trait Anxiety Inventory for Children. These questionnaires were administered to the campers at the beginning and at the end of a 1-wk camp to assess HRQOL and anxiety. No difference was found between anxiety scores before and after camp on either the state or trait anxiety inventories. HRQOL, however, improved after the week of summer camp suggesting that camp may normalize the chronic illness experience[48] (Figure 2).

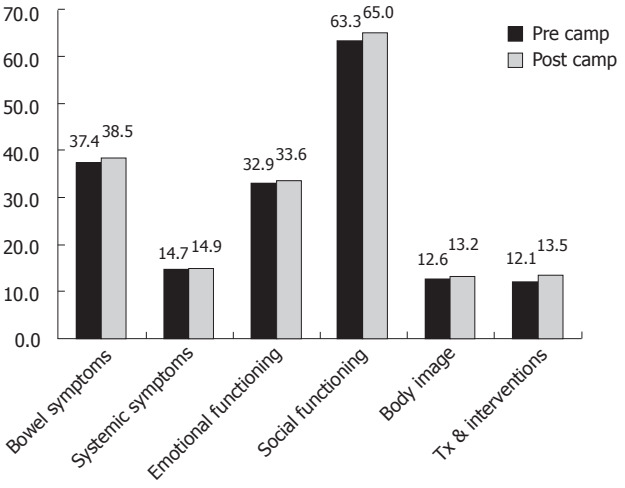

Figure 2 The impact of summer camp on HRQOL in children with IBD.

Psychosocial functioning and medication adherence

When comparing self-reported psychosocial functioning (behavioral/emotional functioning, social competence, self-esteem, stress coping strategies, and social support) of children with IBD to that of healthy children, it appears that most children with mild IBD report normal psychosocial functioning that is similar to that of healthy children[49]. Although rates range, adherence rates among chronic disease in children are typically reported to be approximately 50% with adherence being the lowest in adolescence and when maintenance medications are used even when the disease is in remission[50]. There are multiple factors that impact adherence in pediatric chronic illness which makes it potentially a more complex issue than in the adult population. Parents are often responsible for ensuring their children take their medication, so when evaluating adherence, both the patient and parent must be considered. One study examined the reports of adherence to oral medications, parent-child concordance in reports of adherence, and factors associated with poor adherence in adolescents with IBD. Mean parent- and child-reported adherence scores fell between the "most of the time" and "always" categories, although perfect adherence was low. Among IBD-specific medications < 50% of children and < 40% of parents reported being always adherent to all medications and parent-child concordance was high. Family dysfunction and poor child coping strategies were associated with worse adherence and there appeared to be a trend between more behavioral/emotional problems and lower adherence. Based on these results the authors concluded that adherence should be monitored in families that lack appropriate child discipline and in children who cope by simply wishing stressors would go away[51].

Transition of care

The transition from pediatric to adult medical care of patients with IBD can be difficult for the child and care givers. Clinicians must be sensitive to this transition and the barriers it may present. It has been recommended that the child be approached from the commonly accepted developmental stages, roughly defined chronology by ages 11-13, 14-16, 17-19, and 20-23[52]. These are certain traits needed to make a successful transition of care and allow for the ability to navigate through the adult healthcare milieu. Communication is critical in order for the child and caregiver to anticipate the new roles each member will play in this transition. The process of transition should be a gradual and if the process is delayed the transition may be less successful as the time to prepare and anticipate change has been limited. It is not unusual for the process to be more difficult on the family/primary caregivers than the child themselves. Family members need to relinquish responsibility and the weaning process should begin fairly early in adolescence so that when the time comes to meet with an adult gastroenterologist the patient and caregiver are prepared. In preparation patients may want to put a portfolio together whereby key documents can be brought to their visit to minimize duplication of history taking and perhaps procedures and tests. Examples would include, medical summaries, procedure reports, surgical reports, medication history, recent laboratory results and health insurance information.

Immunization status

Immunosuppressants/immunomodulators have become an integral part of the medical management of IBD both in adults and children. Guidelines have been proposed that take into account the interplay of host susceptibility to infection and the safety and efficacy of immunization for vaccine-preventable diseases. The guidelines suggest that with the exception of live agent vaccines [MMR (measles, mumps, rubella) and Varicella (chicken pox)], most immunizations (killed/attenuated) can be safely administered to patients with IBD even when immune compromised. Moreover, protection against vaccine-preventable illness may be of even greater benefit to those at risk for morbid or lethal complications of infections because of an immune compromised state. It was concluded that for most patients with IBD, recommendations for immunization do not deviate from recommended schedules for the general population[53]. Highlights of the recommendations from this report are the following: (1) Standard recommended immunization schedules for

children and adults should be generally adhered to. (2) At diagnosis, children and adults should have complete review of immunization history for completeness. All patients with incomplete series should commence catch-up vaccination. (3) Children who are not immune by vaccination or acquired immunity through infection should receive varicella vaccine. (4) Live bacterial or viral vaccines should be avoided in immune compromised children with IBD: (a) Treatment with glucocorticoids (prednisone 20 mg/d equivalent, or 2 mg/kg per day if less than 10 kg, for 2 wk or more, and within 3 mo of stopping); (b) Treatment with effective doses of 6-mercaptopurine/azathioprine (effect on safety not established) and within 3 months of stopping; (c) Treatment with methotrexate (effect on safety not established) and within 3 months of stopping; (d) Treatment with infliximab (effect on safety not established) and within 3 months of stopping; (e) Significant protein-calorie malnutrition. (5) Whenever possible, adequate immune response (ie. Tetanus toxoid antibody, H influenza B antibody) should be ascertained for individuals who have required immunization while immune-suppressed. Repeat dosing may be considered when immune response to immunization is insufficient.

CONCLUSION

Approximately one-quarter of IBD presents in childhood, most commonly among the adolescent age group which corresponds to the most dynamic phase of growth. The disease can impact both physical and psychosocial development. Growth failure and bone health are important consideration in the pediatric age group. The diagnosis and treatment requires a comprehensive approach to improve the health related quality of life of children with IBD. Treatments are improving but individualized therapeutic strategies will be a critical part in the management of pediatric IBD so to maximize the therapeutic efficacy and minimize toxicity. Parents and patients must be prepared for the transition from pediatric to adult care and tools are available to improve the success of this process.

Abstract

AIM: To investigate integrin β3 mRNA and vascular endothelial growth factor (VEGF) protein expression in gastric carcinoma, and its correlation with microvascular density, growth-pattern, invasion, metastasis and prognosis.

METHODS: *In situ* hybridization (ISH) of integrin β3 mRNA and immunohistochemistry of VEGF and CD34 protein were performed on samples from 118 patients with gastric cancer.

RESULTS: The positive rate of integrin β3 mRNA in non-tumor gastric mucosa (20%) was significantly lower than that of the gastric cancer tissue (52.5%, χ^2 = 10.20, P < 0.01). In patients of infiltrating type, stage T_3-T_4, vessel invasion, lymphatic metastasis, hepatic or peritoneal metastasis, the positive expression rates of integrin β3 mRNA were significantly higher than those in patients of expanding type (P < 0.01), stage T_1-T_2 (P < 0.01), non-vessel invasion (P < 0.01), without lymphatic metastasis (P < 0.01), without hepatic and peritoneal metastasis (P < 0.01), respectively. In patients of infiltrating type, stage T_3-T_4, vessel invasion, lymphatic metastasis, hepatic or peritoneal metastasis, the positive expression rates of VEGF protein were significantly higher than those in patients of expanding type (P < 0.01), stage T_1-T_2 (P < 0.01), non-vessel invasion (P < 0.01), without lymphatic metastasis (P < 0.01), without hepatic and peritoneal metastasis (P < 0.01), respectively. It was found that the positive expression rate of integrin β3 mRNA was positively related to that of VEGF protein (P < 0.01) and MVD (P < 0.05), meanwhile the positive expression rate of VEGF protein was positively related to MVD (P < 0.05). The mean survival period in patients with positive expression of integrin β3 mRNA and VEGF, and MVD ⩾ 54.9/mm^2 was significantly shorter than that in patients with negative expression of integrin β3 mRNA (P < 0.05) and VEGF (P < 0.01), and MVD < 54.9/mm^2 (P < 0.01). Five-year survival rate in patients with positive expression of integrin β3 mRNA and VEGF, and MVD ⩾ 54.9/mm^2 was significantly lower than those with negative expression of integrin β3 mRNA (P < 0.05), VEGF (P < 0.05), and MVD < 54.9/mm^2 (P < 0.01).

CONCLUSION: Integrin β3 and VEGF expression can synergistically enhance tumor angiogenesis, and may play a crucial role in invasion and metastasis of gastric carcinoma. Therefore, they may be prognostic biomarkers and novel molecular therapeutic targets.

INTRODUCTION

Gastric cancer is the leading cause of death in China.

For patients with gastric cancer, metastasis is the most common cause of death and is a major obstacle to successful treatment[1]. The spread of tumor cells from a primary to metastatic site is a complicated and multistage process, which may include cell proliferation and migration, degradation of basement membrane, invasion, and adhesion[2]. Current clinical methods cannot accurately predict which patients will develop metastasis. To develop effective new strategies for the prediction, diagnosis and treatment of metastasis of gastric cancer, molecular mechanisms controlling metastasis must be identified.

Angiogenesis, the process leading to the formation of new blood vessels, plays a central role in cancer cell survival, local tumor growth, and development of distant metastasis. The degree of intratumoral microvascular density (MVD) is thought to influence tumor metastasis and consequently prognosis in various human cancers, including gastric cancer[3-6].

Recent investigations have shown that high expression of integrin β3 is positively correlated with invasion and metastasis of cancer cells and tumor angiogenesis[7,8], but only a few studies have investigated the relationship between integrin β3 and prognosis of gastric cancer. In our study, we evaluated integrin β3 mRNA and vascular endothelial growth factor (VEGF) expression in gastric carcinoma and its relationship to pathological markers such as MVD, infiltration, metastasis and prognosis of gastric cancer.

MATERIALS AND METHODS

Patients and specimens

A total of 118 patients (79 male, 39 female; aged 38-80 years, median age 57.8 years) who underwent gastrectomy for gastric carcinoma at Zhejiang Provincial People's Hospital from October 1990 to November 1998 were included in this study. Five-year follow-up data were obtained, and the follow-up ended in November 2003. According to the WHO standard classification (2002), there were 39 tubular adenocarcinomas, 19 papillary adenocarcinomas, 37 poorly differentiated adenocarcinomas 12 mucinous adenocarcinomas, and 11 signet ring cell carcinomas. These patients were also classified into well- and moderately-differentiated (G1 + G2, 70 patients), and poorly-differentiated (G3 + G4, 48 patients) types, based on the predominant differentiation mode, and classified into the expanding (51 patients) and infiltrating (67 patients) type. According to the AJCC TNM staging system (6th ed, 2002), there were 21 stage T_1, 26 stage T_2, 45 stage T_3, and 26 stage T_4; 89 patients with and 29 without vessel invasion; 84 patients with lymphatic metastasis and 34 without; 55 patients with distant metastasis (35 with peritoneal dissemination, 20 with hepatic metastasis) and 63 without. A control study was carried out in 20 samples obtained from non-tumor gastric mucosa 5 cm away from the primary tumor without hyperplasia or atypical hyperplasia.

Reagents

Integrin β3 probe: oligonucleotide probe labeled with digoxigenin was obtained from Chinese Wuhan Boster Biotechnology (MK1602). The target gene mRNA sequence of human integrin β3 is: (1) 5'-GACACCTGTG AGAAGTGCCCCACCTGCCA-3'; (2) 5'-GGATG ACTGTGTCGTCAGATTCCAGTACTA-3'; and (3) 5'-GCTAAATTTGAGGAAAGGCGCGCCAGAGC-3'. Immunohistochemical reagents: first antibody and EnVision kit (DAKO Denmark), mouse monoclonal antibody to VEGF (1:100) and CD34 (1:120); VEGF clone: JH121; CD34 clone: QBEnd 10.

In situ hybridization

The samples in our study were from histological sections from paraffin blocks. *In situ* hybridization was performed according to the manufacturer's instructions. This experiment used RNase-free conditions and APES-treated slides, which were baked at 60℃ for 2-4 h before use. The samples were cut at 4-μm intervals, dewaxed with xylene, hydrated by a series of ethanol solutions (100%, 95%, 80% and 70%); inactivated with endogenous peroxidase using 3% hydrogen peroxide for 10 min at room temperature; washed three times with distilled water, each for 5 min; digested with Pepsin Reagent for 30 min at 37℃; rinsed three times in PBS for 5 min each, rinsed once in distilled water; fixed for 10 min at room temperature using 1% paraformaldehyde plus 1/1000 DEPC, washed three times with distilled water; then incubated in 50 μL pre-hybridization solution for 4 h at 40℃; and then superfluous liquid was absorbed. Each slide was incubated with 20 μL hybridization solution (concentration of the hybridization probe was 2 ng/μL) overnight at 40℃; then washed twice with 2 × SSC at 37℃ for 5 min each, once with 0.5 × SSC at 37℃ for 15 min, once with 0.2 × SSC at 37℃ for 15 min, and once with 0.2 × SSC at room temperature for 15 min. These sections were incubated in blocking solution for 30 min at 37℃ and superfluous liquid was absorbed. Following that, the sections were incubated in mouse biotinylated anti-digoxigenin for 60 min at 37℃, washed three times with PBS for 5 min each; incubated in SABC for 30 min at 37℃; washed three times with PBS for 5 min each; incubated in biotin/peroxidase for 30 min at 37℃; washed three times with PBS for 5 min each; stained with DAB for 3 min at room temperature, and washed thoroughly. The slides were counterstained with Harris hematoxylin, washed, dehydrated in ethanol, cleared in xylene, and enveloped with neutral gum. Negative controls included: (1) hybridization solution without probe; and (2) specimens pre-treated with RNase.

Immunohistochemistry

The EnVision two-step method was done according to the manufacturer's instructions. Tissue sections were cut at 4-μm intervals, dewaxed with xylene, hydrated by a series of ethanol solutions (100, 95, 80 and 70%). Method of high temperature and high pressure (CD34: 0.01 mol/L Sodium Citrate buffering Solution, pH 6.0; VEGF: 0.01 mol/L EDTA buffering solution, pH 9.0) were taken to repair the needed antigen. The sections were washed with distilled water, washed three times with PBS for 5 min each, inactivated endogenous peroxidase using 3% hydrogen peroxide for 10 min at room temperature; washed three times with PBS for 5 min each; incubated overnight with dilute first antibody at 4℃, and rinsed three times with

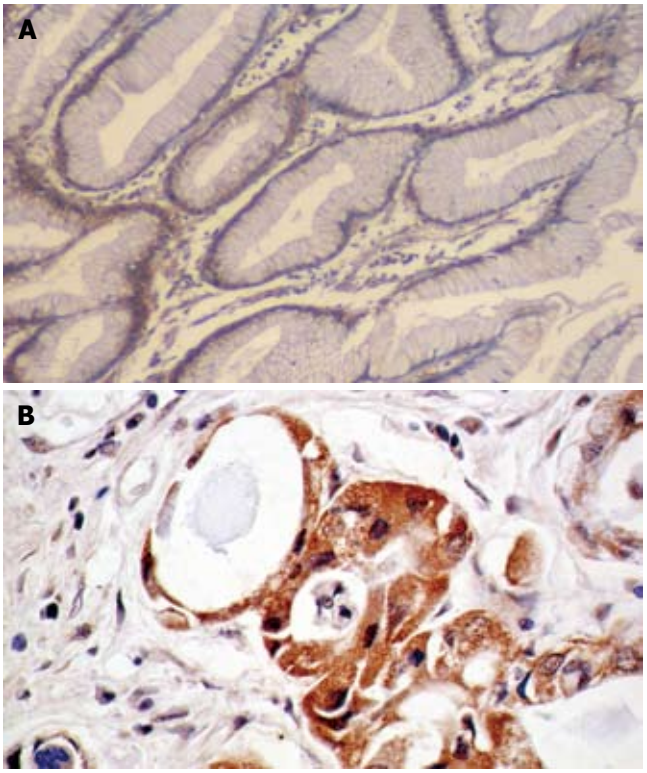

Figure 1 *In situ* hybridization of integrin β3 mRNA. **A**: Negative expression in the plasma of non-tumor gastric mucosa (ISH, × 100); **B**: Positive expression in the plasma of gastric adenocarcinoma (ISH, × 200).

PBS for 5 min each; incubated overnight with goat anti-mouse IgG antibody/HRP polymer for 40 min at 37℃, and washed three times with PBS for 5 min each. Visualization was achieved with DAB for 3 min. After counterstaining with Harris hematoxylin, the slides were dehydrated in 95% and 100% ethanol, cleared in xylene, and enveloped with neutral gum. The negative control included replacement of the first antibody with PBS, and the positive slides provided by the reagent kit were used as the positive control.

Results evaluation

Brown cytoplasm was indicative of positive expression of integrin β3 mRNA. The clearly-stained areas were chosen at high power (× 400), and > 200 cells were quantified in every visual field. According to the percentage of positive tumor cells, all these cells were scored as negative (-) (< 10% or no staining); weak positive (+) (11%-50%); positive (++) (51%-75%); or strongly positive (+++) (> 75%). Positive staining for VEGF was brown in the cytoplasm and/or cell membrane. These cells were scored as negative (-) (no staining); weak positive (+) (< 25%); positive (++) (26%-50%); strongly positive (+++) (> 50%), based on the percentage of positive VEGF cells. Assessment of MVD was performed as follows. Each slide was first evaluated at low power to capture the areas with the highest vascularization. Vessels with a clearly defined lumen or well-defined linear vessel shape, but not single endothelial cells were considered for microvascular assessment. We quantified positive vessels in five chosen fields (× 200) with the highest vascularization[3]. MVD was statistically recorded as the mean ± SD. The patients were divided into a high MVD ($\geqslant$ 54.9/mm^2) and low MVD (< 54.9/mm^2) group based on the mean MVD value (54.9/mm^2) of 118 gastric cancer patients.

Statistical analysis

Statistical analyses were performed using SPSS 10.0 software. Significant differences were compared with Student's *t* test. The χ^2 test was performed on the numerative data. Survival analysis was carried out using the Kaplan-Meier product-limit method, and survival curves were plotted. The differences were evaluated by the log rank test. $P < 0.05$ was considered statistically significant.

RESULTS

Correlation between integrin β3 mRNA expression and clinicopathological features

The positive expression rate of integrin β3 mRNA in non-tumor mucosa was 20% (6/30). Positive signals were distributed in the cytoplasm of non-tumor glandular cell in gastric pit epithelium and the lamina propria, and the majority appeared weakly positive or positive. However, the positive expression rate of integrin β3 mRNA in gastric cancer was 52.5% (62/118). There were significant differences between the two groups ($\chi^2 = 10.20$, $P < 0.01$). Positive cancer cells were stained in the cytoplasm, and most tumor cells infiltrating the muscularis mucosa, serosal layers, extra-serosal layers, and greater omentum positively expressed integrin β3 (Figure 1). In patients of infiltrating type, poorly-differentiated cases, stage T_3-T_4, vessel invasion, lymphatic metastasis, hepatic and peritoneal metastasis, the positive expression rates of integrin β3 mRNA was significantly higher than those of the expanding type ($\chi^2 = 8.42$, $P < 0.01$), well-, moderately-differentiated case ($\chi^2 = 6.47$, $P < 0.01$), stage T_1-T_2 ($\chi^2 = 26.60$, $P < 0.01$), non-vessel invasion ($\chi^2 = 32.13$, $P < 0.01$), without lymphatic metastasis ($\chi^2 = 31.85$, $P < 0.01$), without hepatic and peritoneal metastasis ($\chi^2 = 20.48$, $P < 0.01$; $\chi^2 = 34.72$, $P < 0.01$) (Table 1).

Correlation between VEGF expression and clinicopathological features

VEGF was rarely expressed in normal gastric mucosa (Figure 2A). Of 118 gastric carcinoma patients, 64 positively expressed VEGF (54.2%), and VEGF staining was mainly located in the cytoplasm of tumor cells and usually observed at the tumor margins (Figure 2B). In patients of infiltrating type, stage T_3-T_4, vessel invasion, lymphatic metastasis, hepatic and peritoneal metastasis, the positive expression rates of VEGF protein were significantly higher than those of the expanding type ($\chi^2 = 10.44$, $P < 0.01$), stage T_1-T_2 ($\chi^2 = 34.19$, $P < 0.01$), non-vessel invasion ($\chi^2 = 39.96$, $P < 0.001$), without lymphatic metastasis ($\chi^2 = 34.71$, $P < 0.01$), without hepatic and peritoneal metastasis ($\chi^2 = 27.25$, $P < 0.01$; $\chi^2 = 52.77$, $P < 0.01$). However, no correlation was found between the different histological types (Table 1).

Correlation between MVD and clinicopathological features

CD34 staining was positive in vascular endothelial cells.

Table 1 Correlation of integrin β3 mRNA, VEGF protein and MDV with clinicopathological features

Clinicopathological parameters	*n*	Integrin β3 mRNA			VEGF				MVD

Peritoneal dissemination	35	4	31	34.72[b]	< 0.01[b]	1	34	52.77[b]	< 0.01[b]	75.79 ± 9.48	10.46[b]	< 0.01[b]

[a]Compared between patients with liver metastasis and those without distant metastasis. [b]Compared between patients with peritoneal dissemination and those without distant metastasis.

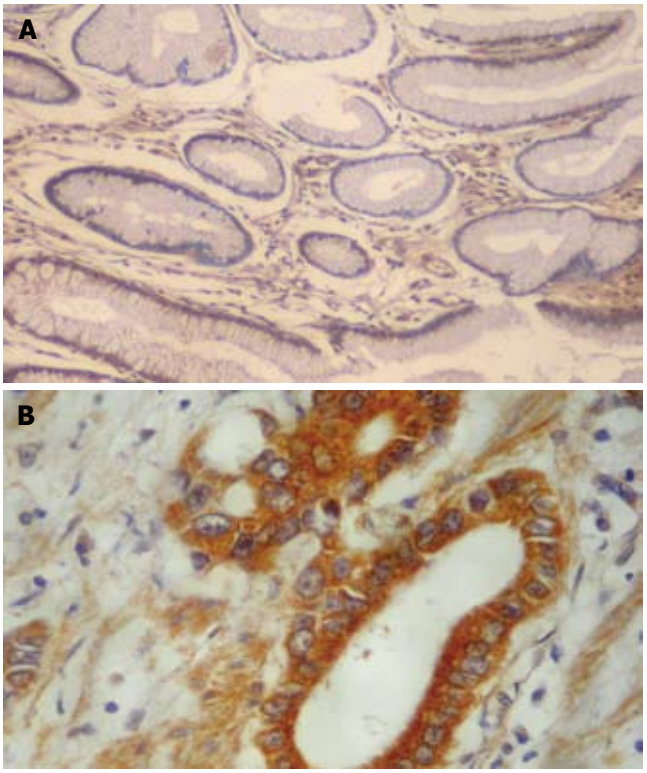

Figure 2 Immunohistochemical staining of VEGF. **A**: Negative staining in the cytoplasm of non-tumor gastric mucosa (EnVision, × 100); **B**: Positive staining in the cytoplasm of gastric adenocarcinoma with greater omentum infiltration (EnVision, × 200).

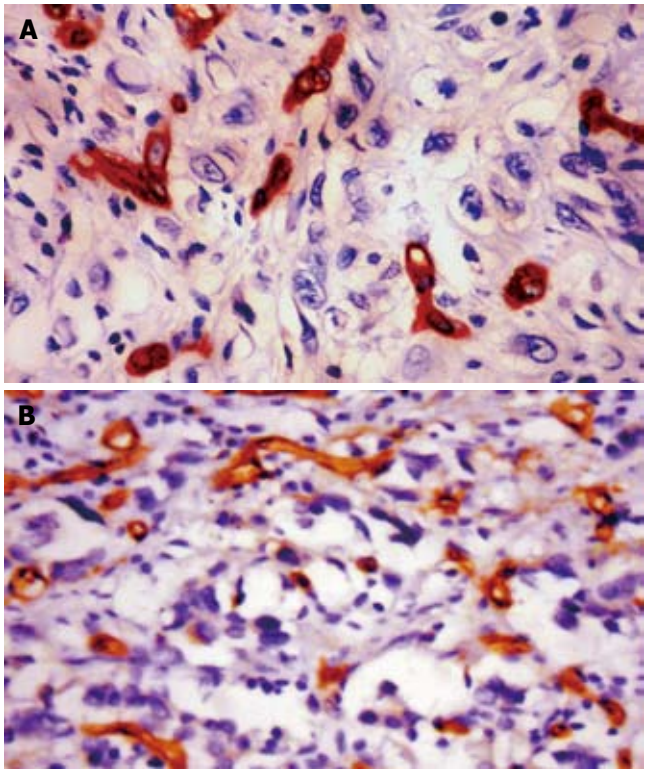

Figure 3 Microvessels in gastric cancer. **A**: Positive staining for CD34 in the vascular endothelial cells of gastric adenocarcinoma with MVD < 54.9/mm^2 (EnVision, × 400); **B**: Positive staining for CD34 in the vascular endothelial cells of gastric adenocarcinoma with MVD ≥ 54.9/mm^2 (EnVision, × 400).

Most microvessels in cancer tissue and surrounding carcinoma were brown or dark brown, strongly stained (Figure 3). In patients of infiltrating type, stage T_3-T_4, vessel invasion, lymphatic metastasis, hepatic and peritoneal metastasis, the mean MVD were significantly higher than those of the expanding type (t = 3.92, P < 0.001), stage T_1-T_2 (t = 6.41, P < 0.01), non-vessel invasion (t = 7.96, P < 0.01), without lymphatic metastasis (t = 8.45, P < 0.001), without hepatic and peritoneal metastasis (t = 7.65, P < 0.01; t = 10.46, P < 0.01), respectively. But no correlation was found within the different histological types (P > 0.05) (Table 1).

Table 2 Correlation of integrin β3 mRNA, VEGF protein and MVD with survival period

Groups		*n*	Mean survival period (mo)	*t*	*P*	5-yr survival rate (%)	χ^2	*P*
Integrin β3 mRNA	-	56	38.46 ± 29.20	2.27	< 0.05	71.4 (40/56)	5.60	< 0.05
	+ - +++	62	27.18 ± 24.73			11.3 (7/62)		
VEGF	-	54	41.70 ± 30.62	3.40	< 0.01	70.4 (16/54)	6.52	< 0.05
	+ - +++	64	24.80 ± 21.78			10.9 (7/64)		
MVD (n/mm^2)	< 54.90	47	44.70 ± 32.05	3.84	< 0.01	63.8 (17/47)	13.85	< 0.01
	⩾ 54.90	71	24.48 ± 20.40			8.5 (6/71)		

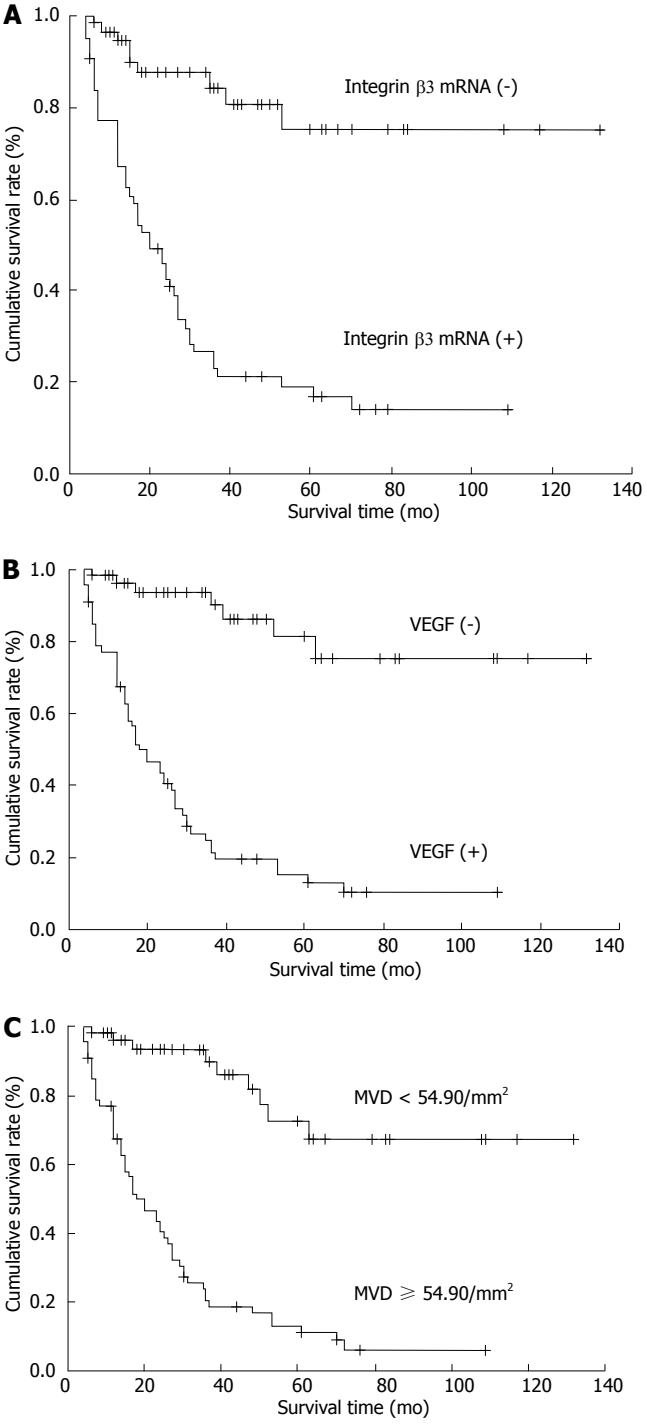

Figure 4 Kaplan-Meier survival curves. **A:** Survival curves with positive and negative integrin β3 mRNA expression in gastric adenocarcinoma ($P < 0.05$); **B**: Survival curves with positive and negative VEGF expression in gastric adenocarcinoma ($P < 0.05$); **C**: Survival curves with MVD ⩾ 54.90/mm^2 and < 54.90/mm^2 in gastric adenocarcinoma ($P < 0.01$).

Correlation between integrin β3 mRNA, VEGF protein expression and MVD

The mean MVD (70.45 ± 14.33/mm^2) in gastric carcinoma specimens with positive expression of integrin β3 mRNA was higher than that of the negative expression group (43.68 ± 18.77/mm^2; $t = 8.78$; $P < 0.01$). Similarly, the mean MVD in gastric carcinoma specimens with positive expression of VEGF (72.96 ± 1.38/mm^2) was higher than that of the negative expression group (37.76 ± 1.84/mm^2; $t = 8.78$; $P < 0.01$). In addition, the rate of VEGF in carcinoma tissues with positive expression of integrin β3 mRNA was 87.1% (54/62), which was significantly higher than that in the integrin β3 mRNA negative expression group (21.4%, 12/56; $\chi^2 = 51.48$; $P < 0.01$). Therefore, there was a positive expression relationship between integrin β3 mRNA, VEGF protein and MVD.

Correlation between integrin β3 mRNA, VEGF, MVD and prognosis

The survival time in patients with positive expression of integrin β3 mRNA, VEGF protein and MVD ⩾ 54.9/mm^2 was significantly shorter than that in patients negative for expression of integrin β3 mRNA ($P < 0.05$), VEGF protein ($P < 0.01$) and MVD < 54.9/mm^2 ($P < 0.01$). The five-year survival rate in patients with positive expression of integrin β3 mRNA, VEGF and MVD ⩾ 54.9/mm^2 was significantly lower than that of patients negative for expression of integrin β3 mRNA ($P < 0.05$), VEGF protein ($P < 0.05$) and MVD < 54.9/mm^2 ($P < 0.01$) (Figure 4A-C; Table 2).

DISCUSSION

Integrins are a major family of cell adhesion molecules, which mediate cell-cell adhesion or cell-extracellular matrix (ECM) adhesion, and affect signal transduction, cell proliferation, differentiation, survival and apoptosis[9]. Integrins are essential for invasion and metastasis of carcinoma cells. Integrins are transmembrane α β heterodimers that require divalent cations for their non-covalent association. To date, 19α and 8β subunits have been identified, and these can combine to form at least 25 different integrins. The ligands of integrins are type I and type Ⅳ collagen, laminin, fibronectin, vitronectin and fibrinogen. Integrins can bind to the ligands in ECM through the specific amino acid sequence in the ligands, which is a tripeptide that features in the integrin-interaction site of many ECM proteins, known as arginine-glycine-aspartic acid (RGD)[10,11]. Different adhesion

receptors play separate roles in intercellular homotypic or heterotypic adhesion, and the connection between cancer cells and ECM[12]. The connection between integrin αvβ3 and fibronectin enables membrane type-matrix metalloproteinase (MT-MMP) to be activated in human endothelial cells, and can also enforce cell invasion[13]. Ria *et al*[14] have found that integrin β3 interacts with fibronectin and vitronectin, which play a role in enhancing proliferation and migration of tumor cells.

Hosotani *et al*[15] have indicated integrin αvβ3 expression is elevated in pancreatic cancer, and expression in patients with lymphatic metastasis is significantly higher than that in patients without lymphatic metastasis. Furthermore, some studies have shown that, in malignant melanoma, ovarian, breast and prostate cancer, the invasive ability of tumor cells with positive integrin β3 expression is powerful, which suggests that integrin β3 is closely related to cancer invasion and metastasis[16-18].

Our study showed that integrin β3 mRNA expression in gastric carcinoma samples was stronger than that in non-tumor gastric mucosa, and the positive expression rate were significantly higher in the infiltrating type group, poor differentiation, perforating serosa layer, lymphoid node invasion, hepatic metastasis and peritoneal dissemination. This result was consistent with previous studies, and showed that increased expression of integrin β3 in gastric cancer influenced the adhesion between tumor cells and ECM. Moreover, it may influence signal transduction, thereby changing the biological behavior of tumor cells, and enhancing the potency of infiltration and migration[19].

Angiogenesis not only accelerates tumor growth, but also increases the opportunity of tumor cells for invading the vasculature, hence it promotes tumor metastasis. As the bridge between vascular endothelial cells and ECM, integrins play an important role in angiogenesis[8,20]. Previous studies have shown that integrin αvβ3 is minimally expressed on resting or normal blood vessels, but is significantly up-regulated in vascular cells within human tumors, and integrin αvβ3 has been implicated in tumor-induced angiogenesis[21,22].

CD34 protein, an endothelial-specific marker, was immunohistochemically stained, and MVD was determined in our study. Statistical analysis showed that β3 integrin mRNA expression ratio was positively correlated with MVD and VEGF. β3 integrin mRNA, VEGF and MVD were all associated with tumor clinicopathological features such as growth pattern, depth of invasion, vessel invasion, and lymph node and distant metastasis, which indicates that VEGF and β3 integrins contribute greatly to the progress of gastric cancer, by modulating angiogenesis. VEGF, the most specific and most potent regulator of angiogenesis, can stimulate the activation of endothelial cells, degradation of the matrix membrane, and migration and proliferation of cells to form new blood vessels[23]. Meanwhile, integrins and ECM are necessarily involved in proliferation and migration of endothelial and vascular smooth muscle cells[24-26]. Integrin β3 may enable VEGF to stimulate endothelial cell proliferation and capillary angiogenesis through activating VEGF receptor-2 (Flk-1) and VEGF receptor-3 (Flt-4)[27,28]. Therefore, integrin β3 and VEGF can enhance synergistically tumor angiogenesis, and lead to proliferation, infiltration and migration of tumor cells.

This study also demonstrated the relationship between integrin β3 mRNA, VEGF protein expression, MVD, survival period, and 5-year survival rate of gastric carcinoma patients. The results suggest positive integrin mRNA and VEGF protein expression, and MVD $\geqslant$ 54.9, are indicative of poor prognosis.

In summary, integrin β3 and VEGF synergistically enhance tumor angiogenesis, and may play crucial roles in invasion and metastasis of gastric carcinoma. Therefore, they can be used as biomarkers for diagnosis and prognosis, and as novel molecular therapeutic targets[29,30].

COMMENTS

Background

Metastasis is the most common cause of death and is a major obstacle to the successful treatment of gastric cancer. It is necessary to develop effective new strategies for the prediction, diagnosis and treatment of gastric cancer metastasis. Angiogenesis plays a central role in tumor growth and development.

Research frontiers

Recent investigations have shown that integrin β3 expression is elevated in pancreatic and breast cancer. High expression of integrin β3 is positively related to cancer cell invasion and metastasis and tumor angiogenesis, but few studies have investigated integrin β3 expression in gastric cancer, and the impact of integrin β3 and VEGF on prognosis.

Innovations and breakthroughs

Integrin β3 and VEGF expression can synergistically enhance tumor angiogenesis, and may play a crucial role in invasion and metastasis of gastric carcinoma.

Applications

This study cannot only define further the mechanism of metastasis of gastric cancer, but can also aid the development of tumor angiogenesis inhibitor. Integrin β3 and VEGF can be used as prognostic biomarkers and as novel molecular therapeutic targets.

Terminology

Angiogenesis is the process that leads to the formation of new blood vessels, and it plays a central role in cancer cell survival, local tumor growth, and development of distant metastasis.

Peer review

The authors studied integrin β3 mRNA and VEGF protein expression in gastric carcinoma by *in situ* hybridization and immunohistochemistry. They concluded that high expression of integrin β3 mRNA and VEGF protein were related to invasion and metastasis, and poor prognosis of gastric cancer.

Abstract

AIM: To investigate the roles and mechanism of signal transducer and activator of transcription 3 (STAT3) in invasion of human colon cancer cells by RNA interference.

METHODS: Small interfering RNA (siRNA) targeting Signal transducer and activator of transcription 3 (STAT3) was transfected into HT29 colon cancer cells. STAT3 protein level and DNA-binding activity of STAT3 was evaluated by western blotting and electrophoretic mobility shift assay (EMSA), respectively. We studied the anchorage-independent growth using colony formation in soft agar, and invasion using the boyden chamber model, anoikis using DNA fragmentation assay and terminal deoxynucleotidyltransferase-mediated dUTP nick-end labeling (TUNEL), respectively. Western blot assay was used to observe the protein expression of Bcl-xL and survivin in colon cancer HT29 cells.

RESULTS: RNA interference (RNAi) mediated by siRNA leads to suppression of STAT3 expression in colon cancer cell lines. Suppression of STAT3 expression by siRNA could inhibit anchorage-independent growth, and invasion ability, and induces anoikis in the colon cancer cell line HT29. It has been shown that knockdown of STAT3 expression by siRNA results in a reduction in expression of Bcl-xL and survivin in HT29 cells.

CONCLUSION: These results suggest that STAT3 siRNA can inhibit the invasion ability of colon cancer cells through inducing anoikis, which antiapoptotic genes survivin and Bcl-xL contribute to regulation of anoikis. These studies indicate STAT3 siRNA could be a useful therapeutic tool for the treatment of colon cancer.

Inhibition of signal transducer and activator of transcription 3 expression by RNA interference suppresses invasion through inducing anoikis in human colon cancer cells. *World J Gastroenterol* 2008; 14(3): 428-434 Available from: URL: http://www.wjgnet.com/1007-9327/14/428.asp DOI: http://dx.doi.org/10.3748/wjg.14.428

INTRODUCTION

Signal transducers and activator of transcription, STATs, are a family of transcription factors that transmit signals from cell surface receptors directly to the nucleus[1]. Activation of all the STAT proteins is caused by phosphorylation of a single tyrosine residue that leads to dimerization *via* an intermolecular SH2 phosphotyrosine interaction[2-5]. The dimerized STATs then translocate to the nucleus where they regulate gene expression by binding directly to high affinity DNA binding sites or by associating with other transcription factors[6-11]. They play a critical role in mediating cytokine and growth factor signaling involved in cell growth, differentiation and survival[12-14]. Among the seven members of the mammalian STAT family, STAT3 has been the most strongly implicated in oncogenesis[15].

Some studies showed that constitutively activated STAT3 is found in a wide variety of human tumors including multiple myelomas, breast, ovarian, prostate, and head and neck tumors[16-18]. Inhibition of STAT3 signaling with either dominant negative or antisense oligonucleotides against STAT3 suppresses the transformation process in some tumors[19]. Recent studies have shown that treatment of tumor cells with inhibitors of STAT signaling results in decreased cell viability and induction of apoptosis[20]. Together these findings demonstrate that STAT3 signaling

plays a critical role in both the transformation process and tumor progression in some types of cancer.

Recent reports showed that STAT3 has a significant association with tumor invasion and metastasis of a few cancers[21-25]. In renal cell carcinoma, the positive rate of the expression of p-STAT3 correlated well with the depth of tumor invasion and with metastasis[21]. In colorectal adenocarcinoma, p-STAT3 protein was significantly correlated with the depth of tumour invasion, venous invasion, lymph node metastasis, and increasing stages of the Dukes' classification[25]. In addition, blockade of activated STAT3 *via* ectopic expression of dominant-negative STAT3 significantly could suppress angiogenesis, tumor growth, and metastasis in pancreatic cancer[26]. Together these findings demonstrate that STAT3 activation might be a new potential target for therapy of human cancer metastasis. Recently it has been shown that STAT3 is constitutively activated in colon cancer[25], however, the role and mechanism of STAT3 signaling in metastasis of colon cancer remains elusive.

Colorectal cancer is the third most common malignant neoplasm worldwide[27] and the second leading cause of death due to cancer[28]. Despite recent advances in diagnostic and therapeutic measures, the prognosis of colorectal cancer patients with distant metastasis still remains poor. Liver metastasis is a major cause of morbidity and mortality in patients with colon cancer. Colorectal liver metastasis is associated with a very poor prognosis; most patients die within 2 years of diagnosis despite the availability of numerous therapies. To improve the choice of therapeutic strategy, it is critical that the mechanism of invasion and metastasis of colon cancer be clarified. Here we will show that knockdown of STAT3 expression by siRNA inhibit invasion ability and reduces anoikis resistance in colon cancer cells.

MATERIALS AND METHODS

Human colon cancer cell lines

The human colon cancer cell lines HT29, SW620 and SW480 were obtained from the Institute of Cell Biology, Shanghai, China. All cancer cells were cultured in RPMI 1640 supplemented with 10% fetal calf serum (FCS). These studies were carried out with Medical Ethical Committee approval of Jiangsu University.

STAT3 siRNA and siRNA transfections

A double stranded siRNA oligonucleotide against STAT3 (5'-AACAUCUGCCUAGAUCGGCUAdTdT-3'; 3'-dTd TGUAGACGGAUCUAGCCGAU-5') was designed and synthesized by Dharmacon Research, Inc. Oligofectamine (Invitrogen, Inc.). In brief, 1 d prior to transfection, cancer cells were seeded, without antibiotics, into a 24 well plate, 1×10^5 cells/well, corresponding to a density of 60%-70% at the time of transfection. There were the following groups: siRNA groups: cells transfected with siRNA at different doses; control groups: cells treated with oligofectamine alone without siRNA. All transfections were performed in triplicate for each time point. At different times after the beginning of the transfection period, all cells were harvested and the following assays were performed.

Western blot analyses

HT29 cells were harvested and lysed in a buffer containing 10 mmol/L Tris-HCl (pH 8.0), 150 mmol/L NaCl, 1% NP40, 0.5% sodium deoxycholate, 0.1% SDS, 1 mmol/L EDTA (pH 8.0), 2 mmol/L phenylmethylsulfonyl fluoride, 2 μg/mL aprotinin, 2 μg/mL leupeptin, and 1 mmol/L Na_3VO_4. For western blot analyses, 30 μg of total extracted proteins were applied per lane before SDS-PAGE. Following transfer to nitrocellulose membranes, protein expression levels were detected using polyclonal anti-STAT3 (Santa Cruz, CA), anti- phospho-STAT3, anti-Bcl-xL and anti-survivin (Alpha Diagnostics International, TX). The expression of β-actin (Sigma-Aldrich, MO) was used as a normalization control for protein loading.

Electrophoretic mobility shift assay (EMSA) for STAT3-DNA binding activity

The STAT3-DNA binding activity was assessed by EMSA using the nuclear extract from the three cell lines. The sense strand that binds activated STAT3 protein was 5'-TCGACATTTCCCGTAAATC-3'. Double-stranded oligonucleotide was end-labeled with [γ-^{32P}] ATP using a T4 polynucleotide kinase according to the manufacturer's instruction. The final concentration of probe was 1.75 pmol/L. The labeled probes were then purified by G-25 spin columns. One microliter of ^{32}P-labeled STAT3 oligonucleotide was added to each reaction. For STAT3 specific tests, a 150-fold unlabeled STAT3 probe was applied as a competitor. The final volume of reaction was 20 μL, including 10 μg of nuclear extract and 5 × binding buffer. The reactions were placed on ice for 30 min. The 45 g/L nondenaturing acrylamide gel was pre-run in 1 × TBE buffer at 25 mA for 60 min. After loading of the samples, the gel was run at room temperature in 1 × TBE buffer at 25 mA for 90 min. The gel was dried on a gel dryer, then exposed to X-ray film overnight at -80℃ with intensifying screen. The protein-DNA complex was detected by autoradiography. The Quantity one software was used to analyze the scanned EMSA gel bands.

Anchorage-independent growth assay

For the anchorage-independent growth experiments, HT29 cells (8×10^3 cells/well) were seeded in 0.3% Difco Bactoagar (Difco, MI) supplemented with complete culture medium. This suspension was layered over 0.5 mL of 0.8% agar-medium base layer in 24 multiwell cluster dishes (Becton Dickinson, Italy). After 15 d, the colonies were stained with nitroblue tetrazolium, and colonies larger than 50 μm were acquired with a micro-Scopeman camera system (Moritex Europe Ltd, Italy) and analyzed with an Image-Pro Plus (Media Cybernetics, MD) computer program.

Cell invasion assay

Cell invasion assay was performed using Boyden chambers and 8 μm pore size polyvinylpyrrolidone-free polycarbonate filters coated with 25 μg/filter Matrigel (Beckton Dickinson). After transfection for 48 h, Sub-confluent HT29 control or HT29 STAT3 cell lines were harvested by a mild trypsinization, washed twice with Cellect medium and counted. Cells (2×10^5 viable cells/sample) were

allowed to invade Matrigel toward 10% FBS/Cellect at 37℃, 5% CO_2 for 3 h. At the end of the assay, cells on the lower surface of the filter were fixed in ethanol, stained with hematoxylin, and 10 random fields/filter were counted at 200 × magnification. Data represent the average of three experiments, all performed in triplicate.

Induction of anoikis

To prevent cell adhesion, 6-well plates were coated with a solution of polyhydroxyethylmethacrylate (poly-HEMA,Sigma-Aldrich), dissolved at 10 mg/mL in ethanol[29,30]. To coat 6-well plates, 3 mL of poly-HEMA solution was added to each well. Plates were kept at 37℃ for at least 3 d until the solvent had completely evaporated. To induce anoikis, 48 h after transfection, cells were harvested and moved to plates coated with poly-HEMA. 1×10^6 resuspended cells were cultured in DMEM medium containing 15% FCS for 12 h on poly-HEMA-coated dishes at 37℃ and 5% CO_2. Subsequently, cells were gently recovered and submitted to apoptosis detection assays.

Terminal deoxynucleotidyltransferase-mediated dUTP nick-end labeling (TUNEL) assay

The TUNEL assay was performed according to a previous report[31]. Apoptosis index (AI) determination: apoptosis cells/total cell × 100%.

DNA fragmentation assay

For demonstration of internucleosomal DNA fragmentation, after cells were plated in 6-well plates coated with poly-HEMA for different times, the cells were harvested, washed with PBS solution at 4℃, and suspended in lysis buffer (10 mmol/L Tris-HCl pH 7.5, 10 mmol/L EDTA, and 0.2% Triton × 100). After incubation for 15 min at 4℃, samples were centrifuged at 13000 × *g* for 10 min at 4℃. The supernatant containing the fragmented DNA was precipitated with NaCl 0.5 mol/L and 1 volume of isopropanol for at least 1 h at -70℃. Samples were centrifuged at 13000 × *g* for 10 min at 4℃, and the pellet was washed once with 70% ethanol, and air-dried. The precipitates were dissolved in 10 μL TE-RNase (0.1 mg/mL) and incubated at 37℃ for 30 min. Finally, the samples were electrophoresed through a 1% agarose gel.

Statistical analysis

Statistical significance of results was evaluated by SSPS10.0 software. All results with P values $\leqslant 0.05$ were considered significant.

RESULTS

Effects of siRNA on the expression and DNA binding activity of STAT3 in the colon cancer cell line HT29

To inhibit STAT3 expression in colon cancer cells, we used the RNAi method adapted for mammalian cell culture by Elbashir *et al*[32]. A number of 21 bp double stranded RNAs to human STAT3 were synthesized and tested for their ability to knockdown STAT3 expression in colon cancer HT29 cells. The human colon cancer cell line HT29, harboring activated STAT3, was transfected with STAT3 siRNA using oligofectamine. Twenty-four and 72 h after transfection, the protein levels and DNA-binding activities of STAT3 were measured by western blot and EMSA, respectively. Transfection of cells with STAT3 siRNA (Figure 1A) resulted in a highly significant and reproducible decrease in STAT3 expression levels as judged by western blotting (Figure 1B). Figure 1A shows that STAT3 siRNA diminished STAT3 protein compared with control groups, accompanied by a significant decrease in STAT3 DNA-binding activity (Figure 1B). STAT3 knockdown by siRNA was found to be time dependent with the maximum effect achieved at 48-72 h of siRNA treatment (Data not shown).

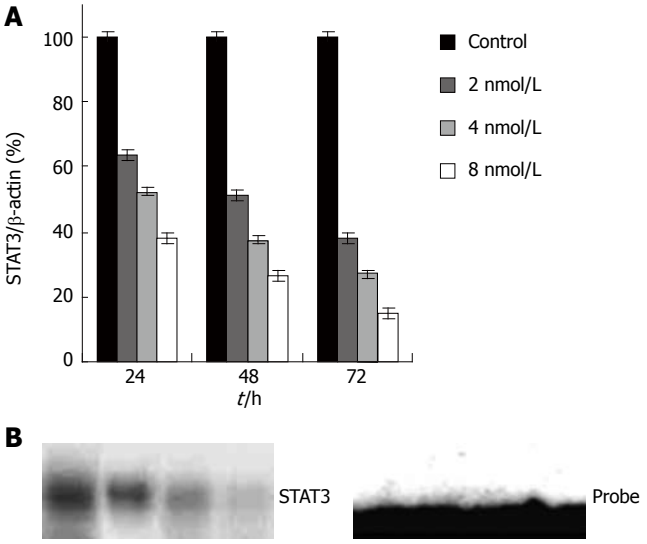

Figure 1 **A**: Expression of STAT3 protein in HT29 cells; **B**: STAT3 DNA-binding activity by EMSA in HT29 cells. 1: Control; 2, 3, 4: siRNA 2, 4, 8 nmol/L.

STAT3 RNAi inhibits anchorage-independent growth in colon cancer cells

Next we evaluated the biological effects of STAT3 suppression in colon cancer HT29 cells by using several different types of assays. Colony formation in soft agar is a property closely associated with malignancy[33]. Figure 2 shows that treatment with STAT3 siRNA induced significant anchorage-independent growth inhibition in a dose-dependent manner.

STAT3 RNAi suppresses invasion in colon cancer cells

Next, we assessed whether STAT3 suppression might decrease the ability of cancer cells to invade the extracellular matrix. HT29 cancer cells were subjected to cell invasion assays, by using Boyden chambers and 8 μm pore size filters coated with Matrigel. Compared with the control group, HT29 cells transfected with siRNA exhibited a scarce ability to cross Matrigel (Figure 3). This difference was statistically significant as compared with control groups ($P < 0.01$).

Effects of STAT3 suppression on anoikis

To explore the molecular mechanisms of invasion of colon cancer, anoikis was studied. To investigate the effect of STAT3 siRNA on anoikis, HT29 cells were subjected to plates seeded in poly-HEMA. After transfection for 48 h,

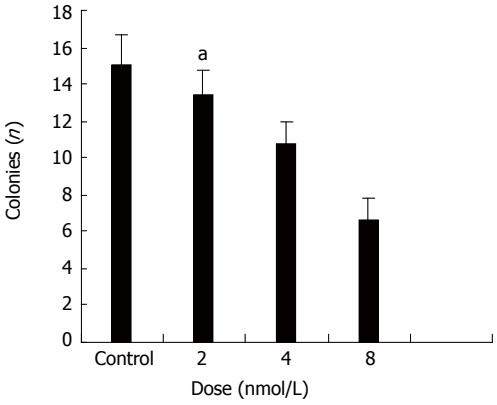

Figure 2 Effects of STAT3 siRNA on anchorage-independent growth of HT29 cells. It shows that treatment with STAT3 siRNA inhibit anchorage-independent growth in a dose-dependent manner. $^{a}P < 0.05$ between siRNA 8 nmol/L and control groups.

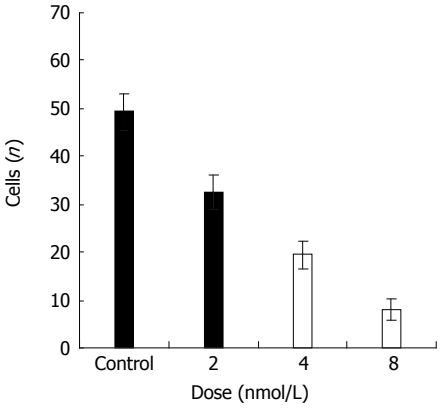

Figure 3 Effects of STAT3 suppression on the invasion ability of HT29 cells.

all cells were removed to plates seeded in poly-HEMA for 12 h. TUNEL and DNA ladder were performed to evaluate the anoikis of HT29 cells. There was little apoptosis in all cancer cells in attached culture. When in a suspended culture, there was significant apoptosis in cancer cells treated with STAT3 siRNA. A significantly higher percentage of apoptotic index was observed in STAT3 siRNA treated cells than in only oligofectamine treated cells (Figure 4A). Consistent with this observation, agarose electrophoresis analysis of HT29 cancer cell extracts showed that there was DNA ladder in cells treated with STAT3 siRNA (Figure 4B). Together these data indicate that siRNA-mediated suppression of the STAT3 gene reduces resistance to anoikis of HT29 cells.

Knockdown of STAT3 expression down regulates survival genes

Recent data indicate that some genes, especially anti-apoptotic genes, contribute to regulation of anoikis[34]. Constitutive activation of STAT3 induces the expression of a number of anti-apoptotic genes including Bcl-xL, a member of the Bcl-2-family of anti-apoptotic genes[20,35], and survivin, a member of the IAP, inhibitors of apoptotic proteins family[36]. Moreover, both of these genes are expressed in colon cancer[37,38]. In order to determine

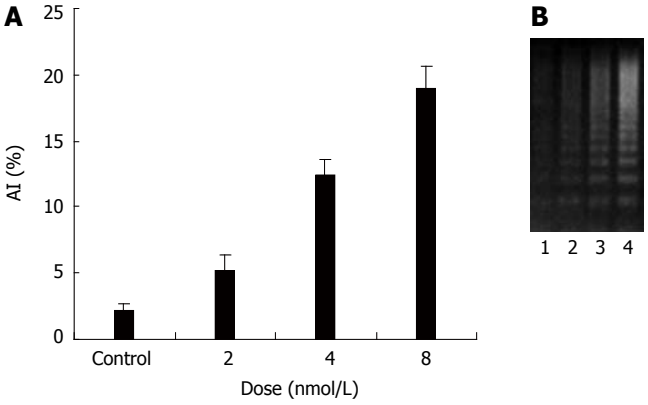

Figure 4 Effects of STAT3 siRNA on anoikis of human colon cancer cell line HT29. **A**: AI (Apoptosis index) induced with STAT3 siRNA in HT29 cells; **B**: DNA ladder by STAT3 siRNA in HT29 cells. 1: Control; 2, 3, 4: siRNA, 2, 4, 8 nmol/L.

whether these two genes might be involved in the STAT3 mediated anoikis resistance in colon cancer, western blot analyses were performed to examine the expression levels of the two genes. Western blot analysis showed that Bcl-xL and survivin protein levels were drastically reduced upon treatment with STAT3 siRNA. Thus, these data show that STAT3 regulates anoikis of at least two distinct antiapoptotic genes in colon cancer HT29 cell (Figure 5).

DISCUSSION

STAT3 is activated by a number of cytokines and growth factors and has diverse functions during embryogenesis and early development[12-14]. Some studies showed that there is persistent activation of STAT3 in a number of human solid tumors including colon cancer[16-18]. Elevated STAT3 activity has been shown to render cells resistant to apoptosis, and inhibition of STAT3 signaling in a number of tumor cell lines with some ways causing a decrease in cell viability and subsequent apoptosis[16,17]. Lots of studies have demonstrated that the transformation process induced by diverse oncogenic protein tyrosine kinases is dependent on STAT3 activation[18,39,40]. Recently it has been shown that STAT3 is constitutively activated in colon cancer. However, the relationships of STAT3 with invasion and metastasis in colon cancer cells remain unclear.

In order to determine the role of STAT3 in colon cancer directly, we have used RNAi to specifically knock down the expression of STAT3, studied the effects of anchorage-independent growth and invasion in the colon cancer cell line HT29. SiRNAs are short oligonucleotides of 21-23 nucleotides in length that can be used *in vitro* to produce sequence specific gene silencing of mammalian cells[32]. It has been shown that siRNAs can be used effectively *in vivo* to suppress gene expression in adult mice[41,42]. SiRNAs can be directly introduced into the CNS to reduce endogenous gene expression[43]. Transfection of colon cancer HT29 cells with STAT3 siRNA resulted in colonies forming membranes with reduced biochemical changes indicative of invasion. In addition, consistent with the results from HT29 cancer cell, SW480 and SW620 cancer cells transfectd with the STAT3 siRNA led to a decrease of both invasion and anchorage-independent

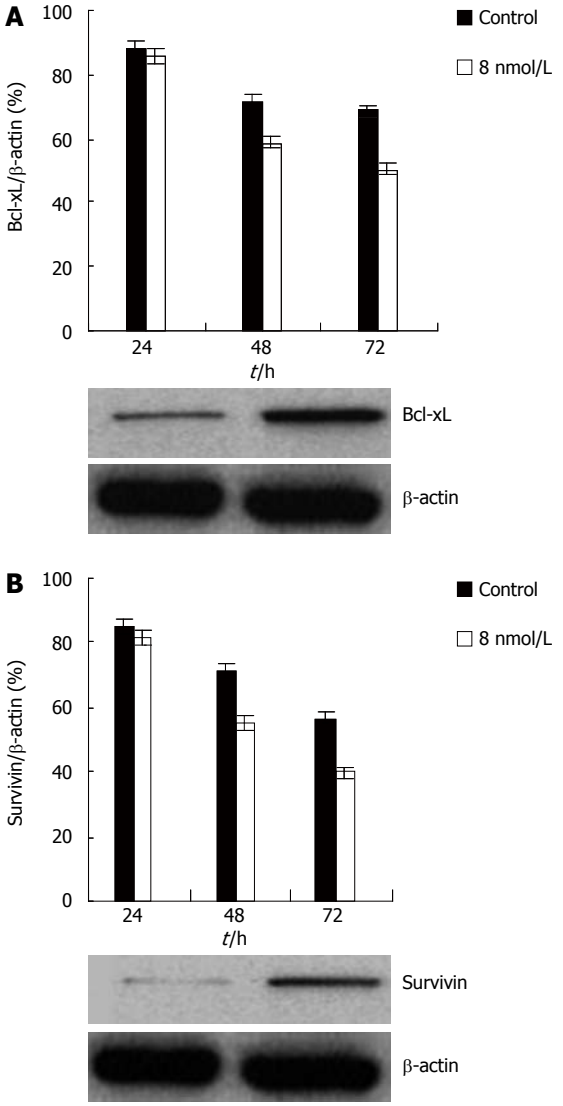

Figure 5 Knockdown of STAT3 expression downregulates Bcl-xL and survivin protein level in the HT29 human colon cancer cell line. **A**: Inhibition of transfection with STAT3 siRNA on Bcl-xL expression of colon cancer HT29 cell; **B**: Suppression of transfection with STAT3 siRNA on survivin expression of colon cancer HT29 cell.

growth. These results are similar to reports previously observed with AG490 inhibiting STAT3 in pancreatic cancer cells[34]. All data suggest that STAT3 down-regulation by RNAi inhibit metastasis of human cancer cell *in vitro*.

The metastasis and invasion of cancer cells were involved in a lot of mechanisms. Anoikis resistance was thought to be high. Anoikis is a peculiar form of apoptosis that is induced by disruption of the interactions between epithelial cells and extracellular matrix[29]. Induction of apoptosis upon loss of anchorage has been termed anoikis (Greek for homelessness)[30]. Anoikis can be considered as a safety program for maintaining normal cell and tissue homeostasis, which prevents survival and reattachment of detached cells to new matrices at inadequate locations. Anoikis has been suggested to act as a physiological barrier to metastasis; resistance to anoikis may allow survival of cancer cells during systemic circulation, thereby facilitating secondary tumour formation in distant organs. Gaining anoikis resistance or anchorage-independent survival is a hallmark of oncogenic transformation. For these experiments, cells are usually seeded in tissue culture dishes that are coated with poly-HEMA, which does not allow cells to attach by preventing matrix deposition. Tumor cells are usually resistant to anoikis[30]. Our results here showed that, in attached culture, neither control cells nor transfected cells exhibited significant apoptosis, suggesting HT29 cells are resistant to anoikis. When seeded in poly-HEMA plates, compared to the control group, there were significant signs of apoptosis in cancer cells treated with STAT3 siRNA. It was shown that clear DNA ladder, the augmented the apoptosis index. These results suggest that STAT3 siRNA induces anoikis of HT29 colon cancer cells.

One mechanism by which STAT3 participates in tumorigenesis is by inhibiting apoptosis through the induction of anti-apoptotic genes such as Bcl-2, Bcl-xL, and Mcl-1[18]. STAT3 responsive elements are found in the promoter region of these genes, suggesting that they are directly regulated by STAT3[16,36]. Interestingly, some reports showed that some anti-apoptotic genes regulate anoikis. Biochemical studies have shown that Bcl-xL, a member of the Bcl-2 family of proteins, induce anoikis of some cancer cells[34,45], and we have found survivin gene is overexpressed in gastric cancer and survivin siRNA reduced the resistance of anoikis of gastric cancer cells (data not shown). In the present study, we have found that both Bcl-xL and survivin are expressed in HT29 cells. Treating HT29 cells with STAT3 siRNA significantly reduces expression levels of both of these genes. These findings suggest that induction of Bcl-xL and/or survivin gene by constitutively activated STAT3 contributes to regulating anoikis of colon cancer cells.

Data presented in this paper are consistent with the growing body of evidence suggesting STAT3 may be an ideal therapeutic target in tumors including colon cancer. We are the first to report that STAT3 siRNA can suppress invasion of colon cancer through inducing anoikis. These results suggest that siRNA may become a useful clinical tool in the future. Since STAT3 signaling is important for the survival of a number of human tumors, STAT3 siRNA could become an effective therapeutic agent for STAT3 dependent tumors.

COMMENTS

Background

Some reports showed that STAT3 has a significant association with tumor invasion and metastasis of a few of cancers, however, the role and mechanism of STAT3 signaling in metastasis of colon cancer remain elusive.

Research frontiers

Induction of apoptosis upon loss of anchorage has been termed anoikis, and anoikis has been suggested to act as a physiological barrier to metastasis. Here we will show that knockdown of STAT3 expression by siRNA inhibit invasion ability by reducing the resistance anoikis in colon cancer cells. In addition, down-regulation of Bcl-xL and/or survivin by STAT3 siRNA might play an important role in inducing anoikis in human colon cancer cell.

Innovations and breakthroughs

The paperwork showed that that STAT3 siRNA can inhibit invasion ability of colon cancer cells through inducing anoikis, and suppression of Bcl-xL and/or survivin by STAT3 siRNA might contribute to regulation of anoikis of human colon cancer cell.

Applications

Here we will show that knockdown of STAT3 expression by siRNA inhibits invasion ability and reduces the resistance anoikis in colon cancer cells. The paper would help to clarify the mechanism of invasion and metastasis of colon cancer and improve the choice of therapeutic strategy.

Terminology

Anoikis (Greek for homelessness) is a peculiar form of apoptosis that is induced by disruption of the interactions between epithelial cells and extracellular matrix.

Peer review

This is an interesting paper investigating the *in vitro* effect and mechanisms of STAT3 siRNAs in a colorectal cancer (CRC) cell line. The main finding of the study was that STAT3 siRNA can inhibit the invasion ability of colon cancer cells through inducing anoikis, in addition antiapoptotic genes survivin and Bcl-xL may contribute to regulation of anoikis.

Abstract

AIM: To study the effect of Daxx on cholesterol accumulation in hepatic cells.

METHODS: Sprague Dawley (SD) rats were fed a normal or high fat diet for 6 wk, and serum lipids and Daxx expression of hepatic tissues were measured by immunoblot assays. $HepG_2$ cells were transfected with the pEGFP-C1/Daxx or pEGFP-C1 plasmid. Cells stably transfected with Daxx were identified by RT-PCR analysis. Total cholesterol levels were determined by high performance liquid chromatography. Activated-SREBP and caveolin-1 were assayed by western blotting.

RESULTS: Hepatic Daxx protein was higher in normal rats than in high fat diet-fed rats. Noticeable negative correlations were seen between Daxx and LDL-C (γ = -7.56, P = 0.018), and between Daxx and TC (γ = -9.07, P = 0.01), respectively. The total cholesterol of $HepG_2$/GFP-Daxx cells was lower than that of control cells or $HepG_2$/GFP cells (9.28 ± 0.19 *vs* 14.36 ± 4.45 or 13.94 ± 2.62, both $P < 0.05$). Furthermore, in $HepG_2$/GFP cells, the expression of activated SREBP was lower than that of control cells, whereas caveolin-1 expression was higher.

CONCLUSION: Overexpression of Daxx in $HepG_2$ cells decreased intracellular cholesterol accumulation, which might be associated with inhibition of SREBP activity and an increase in caveolin-1 expression.

INTRODUCTION

Daxx was first identified as a death-associated protein capable of binding the cytosolic domain of fas, an apoptosis-inducing member of the tumor necrosis factor (TNF) receptor family[1]. Daxx co-localizes with Promyelocytic Leukemia Protein (PML) within nuclear promyelocytic oncogenic domains (PODs)[2,3]. PML and/or POD-associated proteins may function as an important cofactor in governing nuclear hormone receptor transcriptional activity and function[4,5]. Recent studies[6,7] implied Daxx could negatively modulate androgen receptor (AR) transcriptional activity. Androgens affect lipogenic gene expression not only in tumor cells, but also in normal androgen target tissues *in vivo*[8]. AR can directly upregulate sterol regulatory element-binding protein (SREBP) cleavage-activating protein (SCAP) by binding an androgen response element in intron 8 of the SCAP gene[9]. Activated SREBP can increase the mRNA and protein levels of genes involved in fatty acid (fatty acid synthase and acetyl-CoA-carboxylase), and cholesterol synthesis (HMG-CoA-reductase and farnesyl diphosphate synthase)[10]. These results indicate that Daxx could possibly regulate cellular cholesterol metabolism by the SREBP pathway.

In the present study, we investigated the correlations between Daxx expression and cholesterol accumulation in liver cells. The findings herein show that overexpression of Daxx in $HepG_2$ cells may decrease intracellular cholesterol, which may be associated with inhibition of SREBP activity related to cholesterol synthesis and an increase in caveolin-1 expression related to excretion.

MATERIALS AND METHODS

Materials

Modified Eagle medium (MEM) and fetal bovine serum

were purchased from Gibco BRL. An antibody (Santa Cruz) directed against active SREBP was used to detect the activation of SREBP, and polyclonal anti-Daxx antibody or anti-caveolin-1 antibody (Santa Cruz) was used to assay the respective protein expression. The plasmids of pEGFP-C1/Daxx and pEGFP-C1 were gifts from Dr. Yanping[11]. The pEGFP-C1/Daxx contains a full-length cDNA of hDaxx in pEGFP-C1 vector. All reagents were of analysis grade.

Animal and diets

Male Sprague Dawley (SD) rats (210 g ± 10 g) were obtained from the animal laboratory of Nanhua University. The animals were individually housed in plastic cages in a temperature (23℃ ± 2℃) and light (alternating 12 h periods of light and dark) controlled room. The rats were randomly divided into two groups. The control group was fed a normal diet, and another group was fed a high-fat diet (15%, lard, wt/wt, HFD) for 6 wk. Rats were allowed free access to food and deionized water throughout the test period. At the end of the experiment, the rats were anesthetized with ketamine and injected with 150 IU of heparin per kilogram of body weight. Fifteen minutes later, the rats were sacrificed by disarticulation. Blood samples were taken from the neck into glass tubes, and serum was obtained by centrifugation (2000 × *g* for 10 min at 4℃). The livers were removed and rinsed with physiological saline. All samples were stored at -70℃ until use.

Estimation of serum lipids

For determination of serum total cholesterol (TC), low density lipoprotein-cholesterol (LDL-C), triacylglycerol (TG) concentration, and high density lipoprotein-cholesterol (HDL-C), the corresponding diagnostic kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, China) were used according to the manufacturer's instructions.

Cell culture and transfections

$HepG_2$ cells, a human hepatocyte cell line, were obtained from Zhong Shan University (Guangzhou, China). The cells were maintained in RPMI 1640 medium (Gibco BRL, Grand Island, NY) supplemented with 10% heat-inactivated fetal bovine serum (FBS) and penicillin/streptomycin, at 37℃ in a humidified incubator containing 5% CO_2. Cells were seeded at a density of 1×10^5 cells/well in a 24-well plate and cultured for 24 h to 60%-80% confluency. To obtain stable transfectants, $HepG_2$ cells were transfected with the pEGFP-C1/Daxx or pEGFP-C1 plasmid using Lipofect 2000 Plus reagent (Invitrogen) in serum-free medium for 4 h at 37℃, according to the manufacturer's recommendations. The transfection medium was removed, and fresh complete growth medium was added. After 24 h post-transfection, the cells in two wells were split into 10-cm dishes in a medium containing 500 μg/mL geneticin (G418; Amresco, Solon, USA), and the medium was changed every 3 d until G418-resistant colonies were clearly evident. Individual colonies were transferred into 6-well plates to continue incubation with G418 selection medium. Individual colonies were evaluated for Daxx expression by Immunofluorescent Microscopy, and a monoclonal cell line was used for all experiments successively.

Reverse transcription-PCR

Total RNA was extracted from the cells using Trizol reagent (Gibco BRL) according to the manufacturer's protocol. Three micrograms of total RNA were used for reverse transcription in a total volume of 20 μL with the SuperScript preamplification system (Promega, Madison, MI). Aliquots of 2 μL cDNA were subsequently amplified in a total volume of 25 μL using the GeneAmp PCR kit (Promega) following conditions recommended by the manufacturer. The sense and antisense primers for Daxx were 5'-TGGCGCTCTATGTGGCAGAGATC-3' and 5'-CTGCATCTGTTCCAGATCCTCCT-3' (829 bp); the sense and antisense primers for actin that were used as an internal control were 5'-GGTGGCACCTGTGGTCCACC T-3' and 5'-CTTCACTTGTGGCCCAGATAG-3' (420 bp), respectively. The cycling conditions were as follows: 94℃ for 5 min, followed by 28 cycles of 94℃ for 30 s, 58℃ for 30 s, and 72℃ for 1 min, and a final extension of 72℃ for 10 min. PCR products were separated on the 1.5% agarose gel viewed by ethidium bromide staining. These data were acquired with Alpha Imager 2200 software.

Lipid analysis by high performance liquid chromatography (HPLC)

Cells were scraped from culture flasks into 0.9% NaCl (1 mL per 50 cm^2 flask) and homogenized by sonication for 10 s on ice. The protein concentration of cell lysate was determined by a bicinchoninic acid (BCA) kit. An equal volume of freshly prepared cold (-20℃) KOH in ethanol (150 g/L) was added. The cell lysate was repeatedly vortexed until clear. An equal volume of hexane-isopropanol 3:2 (v/v) was then added. The mixture was vortexed for 5 min, followed by centrifugation at 800 × *g* (15℃ for 5 min). The extraction procedure was repeated twice. The combined organic phase was transferred to clean tapered glass tubes and thoroughly dried under nitrogen at 40℃. The tubes were allowed to cool to room temperature. One hundred μL of isopropanol-acetonitrile 20:80 (v/v) was added. The sample was solubilized in an ultrasound water bath at room temperature for 5 min. After centrifugation at 800 × *g* for 5 min, the samples were introduced into the HPLC device using an Agilent 1100 series. Cholesterol was eluted at a flow rate of 1 mL/min, temperature of 40℃ using an eluent consisting of isopropanol-acetonitrile 20:80 (v:v), and detected by UV-absorption at 206 nm[12].

Western blot analysis

Liver tissues excised from rats were analyzed by western blot with an antibody directed against Daxx. $HepG_2$ cells were washed with PBS, and then 0.5 mL of TME lysis buffer (10 mmol/L Tris, pH 7.5, 5 mmol/L $MgCl_2$, 1 mmol/L EDTA, and 25 mmol/L NaF) containing fresh 100 μmol/L Na_3VO_4, 20 μg/mL leupeptin, 1 μg/mL pepstatin A, 4 μg/mL aprotinin, and 1 mmol/L DTT were added. Cell lysates were prepared by freezing and thawing of the cells on ice, and subsequent scraping and sonicating for 30 s. The cell lysates were centrifuged for 30 min at 15 000 × *g*. Protein concentrations in the supernatants were determined by a BCA protein assay kit, and the samples were stored at -80℃. For western blot analysis, 20 μg of protein was

Data are the mean ± SE of three independent experiments. Control: normal food. HF: Added high fat to normal food. TC: Total cholesterol; TG: Triglyceride; LDL-C: Low-density lipoprotein cholesterol; HDL-C: High-density lipoprotein cholesterol. $^{a}P < 0.05$ *vs* control.

subjected to SDS-PAGE under reducing conditions, and proteins were then transferred to polyvinylidene difluoride membrane as described previously[13]. The membrane was blocked for 2 h at room temperature with a commercial blocking buffer from Life Technologies, Inc. The blots were incubated for 1 h at room temperature with the respective primary antibody (1:2000 dilution), which was followed by 1 h incubation with a secondary antibody (horseradish peroxidase-conjugated, 1:4000 dilution). Target proteins were visualized by a chemiluminescent assay (Amersham-Pharmacia Biotech).

Statistical analysis

The values are expressed as the mean ± SE. The correlation between cholesterol of serum and Daxx was analyzed by SPSS. Statistical analysis of the data was performed using student's *t* test or ANOVA. Values with $P < 0.05$ were considered statistically significant.

Images show the location and expression of Daxx in HepG2 cells, which were taken at 400 × magnitude. (**D**) RT-PCR of Daxx mRNA expression.

RESULTS

Correlation of Daxx and cholesterol

HFD feeding for 6 wk resulted in the development of hyperlipidemia in experimental rats, as shown in Figure 1A. Significant increases in TC (211%), TG (231%), HDL-C (197%), and LDL-C (246%) contents were observed in HFD-fed rats compared with those in control rats. At the same time, hepatic Daxx expression in the HFD-fed rats was decreased to one third of the control (Figure 1B and C). These data suggested that Daxx might have possible association with the change of blood lipid content as determined by correlation analysis. Further analysis revealed that there were negative correlations between Daxx and LDL-C (γ = -7.56, P = 0.018) and between Daxx and TC (γ = -9.07, P = 0.01), respectively.

Location and expression of Daxx in HepG2 hepatocytes

HepG2 cells were transfected with pEGFP-C1-Daxx or pEGFP-C1 plasmid. Daxx was mostly located in the nucleus of HepG2 cells (Figure 2A). Because the efficiency of transient-transfection was low, we screened out G418-resistant colonies. The majority of the colonies had fluorescence. PT-PCR analysis indicated that Daxx mRNA expression was significantly increased in HepG2/GFP-Daxx cells when compared with control or HepG2/GFP cells (Figure 2B).

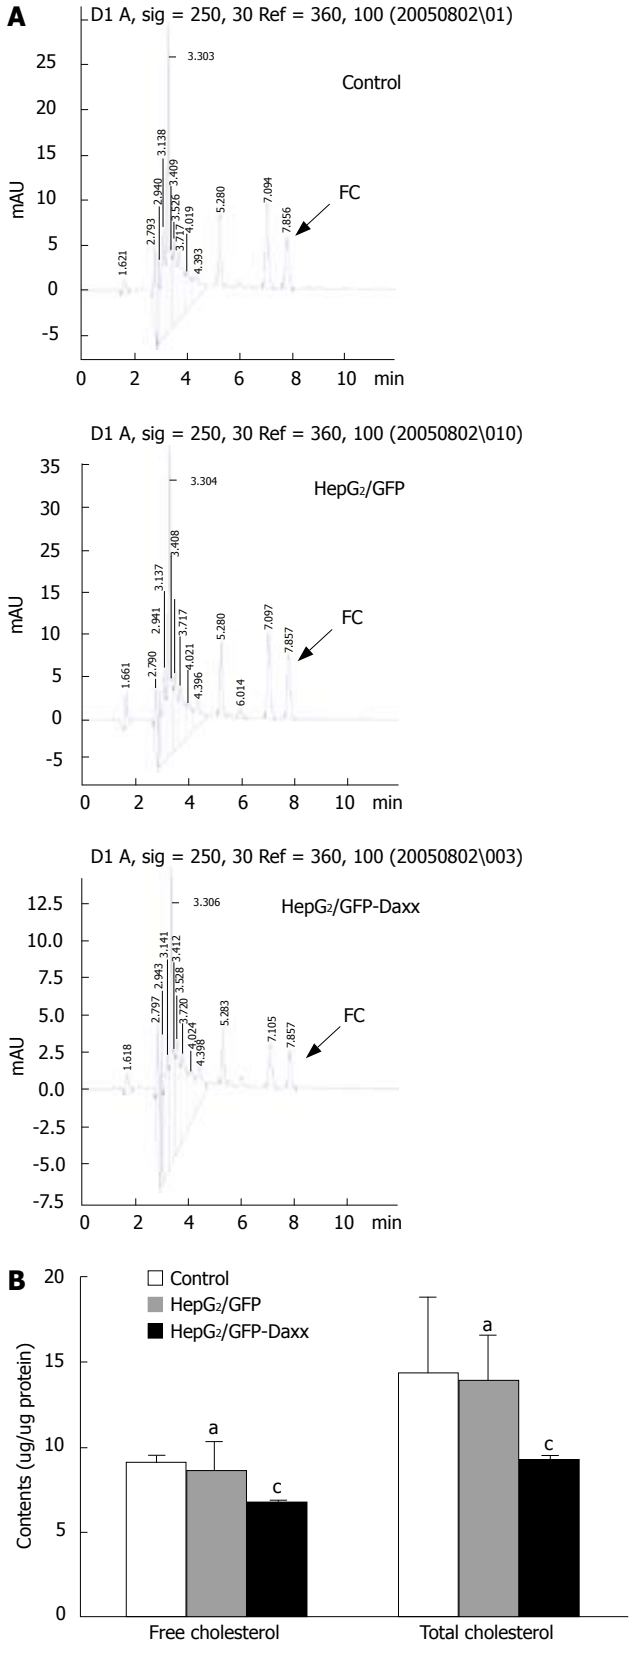

Figure 3 Effect of Daxx overexpression on cholesterol accumulation in HepG2 hepatocytes. **A**: Representative change of intracellular cholesterol levels in HepG2 cells, as determined by HPLC; **B**: The contents of free and total cholesterol in HepG2 cells. FC: Free cholesterol. [a]*P* > 0.05 *vs* control; [c]*P* < 0.05 *vs* control or HepG2/GFP cells.

Effect of Daxx on cholesterol content in HepG2 hepatocytes

Figure 3 shows the effect of Daxx on cholesterol concentration in HepG2 cells as analyzed by HPLC. The arrows show the area of apices which represent the contents of free cholesterol. The area of apices before the arrow represents the total cholesterol (Figure 3A). There was a significant decrease ($P < 0.05$) of the cholesterol concentration in HepG2/GFP-Daxx cells compared with other samples. The free cholesterol in HepG2/GFP-Daxx cells was 6.74 ± 0.13 (μg/μg protein), whereas those of control and HepG2/GFP cells were 9.21 ± 0.37 and 8.66 ± 1.72, respectively. The total cholesterol in HepG2/GFP-Daxx cells was lower than that of control or HepG2/GFP cells (9.28 ± 0.19 *vs* 14.36 ± 4.45 or 13.94 ± 2.62, both $P < 0.05$). The empty vectors did not show obvious effects on cholesterol concentrations in HepG2 cells (Figure 3B).

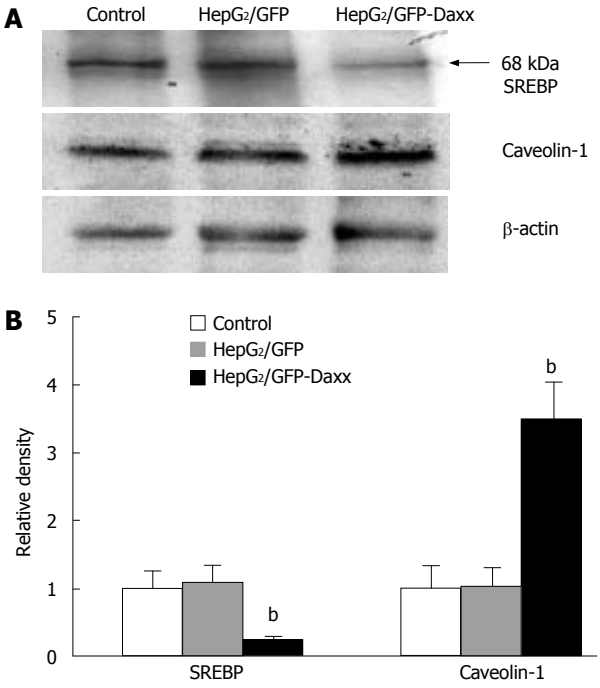

Figure 4 Effect of Daxx on the expression of SREBP and caveolin-1 proteins in HepG2 hepatocytes. **A**: Representative western blot data showing the effects of Daxx on SREBP and caveolin-1 proteins in HepG2 cells; **B**: Quantitative data of the Daxx effect on SREBP and caveolin-1 expression. Data are the mean ± SE of three independent experiments. [b]*P* < 0.01 *vs* control or HepG2/GFP cells.

Effect of Daxx on SREBP and caveolin-1 protein expression in HepG2 hepatocytes

Overexpression of Daxx in HepG2 cells significantly decreased the expression of activated-SREBP from 1 ± 0.23 to 0.21 ± 0.05. Likewise, caveolin-1 expression increased nearly 3.5 times compared to the control (1 ± 0.31 to 3.48 ± 0.56). The empty vectors did not show any effect on the proteins of HepG2 cells (Figure 4A and B).

DISCUSSION

In the animal experiment, we observed that expression of Daxx in hepatic tissues was negatively correlated with hyperlipidemia. The liver is a very important organ for maintaining the physical balance of lipids, and has many proteins (such as SREBP and caveolin) responsible for mediating cholesterol synthesis and excretion[14-16].

It has been reported that hepatic cells predominantly express Daxx[17], but the direct relation between Daxx and cholesterol still remains unclear. Recently, Daxx has been shown primarily to function as a transcriptional regulator[18-20]. These results indicate that Daxx could possibly affect cholesterol accumulation in hepatic cells.

In cultured $HepG_2$ cells, Daxx overexpression decreased the levels of FC and TC compared to those untransfected or transfected with GFP, which indicated that Daxx could affect cholesterol homeostasis of hepatic cells. HMG-CoA-reductase is a key enzyme of cholesterol synthesis and is regulated by sterol regulatory element binding proteins (SREBPs)[21,22]. SREBP-1 represents an important protein of the transcription regulator family (SREBP-1a, -1c, and -2) controlling lipid homeostasis in cells[23,24]. SREBP-1 are synthesized as 125-kDa inactive precursor proteins, and inserted into the membranes of the endoplasmic reticulum where they form tight complexes with SCAP. SREBP is proteolytically cleaved and activated by SCAP when the complex translocates to the Golgi apparatus[25]. The active 68-kDa SREBP fragment migrates to the nucleus and increases the transcription of sterol-responsive element (SRE) that contains many genes encoding lipogenic enzymes belonging to the pathways of cholesterol synthesis[26]. Daxx can inhibit AR transcriptional activity[6,7], which can down-regulates the activity of SCAP[9]. Thus, we checked the activity of SREBP-1 and detected that Daxx has the potential to decrease the expression of active SREBP-1. This also revealed that Daxx might mediate intracellular cholesterol accumulation by inhibiting cholesterol synthesis.

SREBP-1 represses caveolin expression by the SRE/SREBP pathway. In this case, SREBP inhibits *caveolin* gene transcription in contrast to its stimulating effect on other gene promoters[27,28]. Caveolin-1, a type of free cholesterol-binding protein, is another significant protein involved in cholesterol homeostasis[29]. Transfection of cells with full-length caveolin-1 cDNA resulted in the expression of morphologically authentic caveolae structure and FC efflux[30]. The expression of caveolin may represent a mechanism, by which FC excretion became facile[31]. The results of experiments showed that Daxx promoted the expression of caveolin-1. These findings show the possibility of Daxx mediating intracellular cholesterol accumulation presumably by increasing cholesterol excretion.

In conclusion, our results confirm that Daxx is likely to decrease the intracellular cholesterol accumulation by regulating cholesterol synthesis and excretion. One of the main future challenges will be the generation of suitable animal models to be used to dissect Daxx function in cholesterol homeostasis.

COMMENTS

Background

Death-associated protein (Daxx) could negatively modulate androgen receptor (AR) transcriptional activity. Androgens affect lipogenic gene expression not only in tumor cells but also in normal androgen target tissues *in vivo*. AR can directly upregulate sterol regulatory element-binding protein (SREBP) cleavage-activating protein (SCAP) by binding an androgen response element in intron 8 of SCAP gene. Activated SREBP can increase the mRNA and protein levels of genes involved in fatty acid, and cholesterol synthesis. These results indicate that Daxx could possibly regulate cellular cholesterol metabolism by the SREBP pathway.

Research frontiers

Hypercholesrerolemia is mainly a pathologic feature of cardiovascular diseases. The liver is a very important organ for maintaining the physical balance of cholesterol. In liver SREBPs are very important proteins which have been responsible for mediating cholesterol metabolism. Some studies have shown Daxx can regulate SREBP indirectly, but no evidences have suggested Daxx can affect cholesterol balance.

Innovations and breakthroughs

In the present study, we investigated the correlations between Daxx expression and cholesterol accumulation in liver cells. The findings herein show that overexpression of Daxx in $HepG_2$ cells may decrease intracellular cholesterol, which may be associated with inhibition of SREBP activity related to cholesterol synthesis and increase in caveolin-1 expression related to excretion.

Applications

Our study will provide academic value in finding a new function of Daxx, and experimental reference for clinical treatment of hypercholesterolemia.

Peer review

The authors demonstrated the inverse relationship between Daxx expression and cholesterol accumulation in hepatocytes. It appears that the effect of Daxx on cholesterol level in liver cells may be associated with inhibition of SREBP activity and an increase in caveolin-1 expression. The study was well performed and the data are clearly presented.

Abstract

AIM: To assess the patency of pancreaticoenterostomy and pancreatic exocrine function after three surgical methods.

METHODS: A pig model of pancreatic ductal dilation was made by ligating the main pancreatic duct. After 4 wk ligation, a total of 36 piglets were divided randomly into four groups. The piglets in the control group underwent laparotomy only; the others were treated by three anastomoses: (1) end-to-end pancreaticojejunostomy invagination (EEPJ); (2) end-to-side duct-to-mucosa sutured anastomosis (ESPJ); or (3) binding pancreaticojejunostomy (BPJ). Anastomotic patency was assessed after 8 wk by body weight gain, intrapancreatic ductal pressure, pancreatic exocrine function secretin test, pancreatography, and macroscopic and histologic features of the anastomotic site.

RESULTS: The EEPJ group had significantly slower weight gain than the ESPJ and BPJ groups on postoperative weeks 6 and 8 ($P < 0.05$). The animals in both the ESPJ and BPJ groups had a similar body weight gain. Intrapancreatic ductal pressure was similar in ESPJ and BPJ. However, pressure in EEPJ was significantly higher than that in ESPJ and BPJ ($P < 0.05$). All three functional parameters, the secretory volume, the flow rate of pancreatic juice, and bicarbonate concentration, were significantly higher in ESPJ and BPJ as compared to EEPJ ($P < 0.05$). However, the three parameters were similar in ESPJ and BPJ. Pancreatography performed after EEPJ revealed dilation and meandering of the main pancreatic duct, and the anastomotic site exhibited a variable degree of occlusion, and even blockage. Pancreatography of ESPJ and BPJ, however, showed normal ductal patency. Histopathology showed that the intestinal mucosa had fused with that of the pancreatic duct, with a gradual and continuous change from one to the other. For EEPJ, the portion of the pancreatic stump protruding into the jejunal lumen was largely replaced by cicatricial fibrous tissue.

CONCLUSION: A mucosa-to-mucosa pancreaticojejunostomy is the best choice for anastomotic patency when compared with EEPJ. BPJ can effectively maintain anastomotic patency and preserve pancreatic exocrine function as well as ESPJ.

INTRODUCTION

Pancreaticoduodenectomy is a well-established operation for resectable periampullary carcinoma. The anastomosis

between the remaining distal pancreas and the gastrointestinal tract after pancreaticoduodenectomy has, however, been the site of complications responsible for considerable morbidity and mortality. Pancreatic leakage is the most common and severe postoperative complication[1-5]. At present, most techniques have been directed toward the prevention of fistulas[3,6-11]. However, long-term anastomotic patency has not been of great importance in the past because of early cancer recurrence and death. Now that the results are improving in both cancer therapy and pancreatic transplantation, the issue of long-term anastomotic patency will grow in importance. Pancreaticoduodenectomy is an unusual gastrointestinal anastomosis in that a hollow muscular organ is being sewn to the side of a solid organ, with a small accentrically placed duct. Therefore, the anastomosis is prone to stenosis and obstruction because of the narrow lumen of the duct and fibrosis of the proximal pancreas after operation. At present, clinical and experimental studies have indicated a better patency rate for duct-to-mucosa anastomosis[12-20]. In theory, the optimum technique is to secure a leakproof anastomosis that will not subsequently produce stenosis and exocrine deficiency. The most important factor affecting the function of the remnant pancreas is the patency of the pancreaticojejunostomy and pancreaticogastrostomy. Data suggest that such stenosis and obstruction often results in eventual exocrine and endocrine dysfunction in animal models and patients[12-20].

Recently, Pen Shuyou *et al* have advocated the use of binding pancreaticojejunostomy (BPJ) after Whipple's resection to minimize pancreatic leakage. Clinical studies have revealed that the present technique is safe, simple and effective in fulfilling current demands on resectional pancreatic surgery[21-23]. So far, few studies appear to have investigated pathophysiological changes induced by BPJ following pancreaticoduodenectomy, particularly in relation to the anastomotic patency and function of the remnant pancreas. In the present study, we attempted to examine anastomotic patency and postoperative pancreatic exocrine function in piglets after three different methods of joining the body and tail of the pancreas to the gastrointestinal tract.

MATERIALS AND METHODS

Materials and animal model for pancreatic duct dilatation (first operation)

Thirty-six domestic piglets of both sexes, weighing 19-21 kg, were obtained from the Animal Center of Zhejiang University. All animals were treated humanely according to the national guidelines for the care of animals. The experiment was approved by the Animal Experiment Committee of the University of Zhejiang. The animals were fasted for 24 h before the experiment and allowed food and water *ad libitum* after the operation. The piglets underwent a preliminary sterile laparotomy under general anesthesia with 25 mg/kg sodium pentobarbital. The main pancreatic duct draining the body and tail was carefully separated and ligated with 1/0 silk thread, which produced total obstruction, and left the duodenal vascular arcade intact, as described by Pitkaranta *et al*[24]. This was then relieved by one of three methods at a second operation. For both operations, the animals were fasted the night before surgery. Intravenous cannulation and endotracheal intubation were performed after anesthetic induction. Animals received 1 L of normal saline during each procedure. Penicillin G benzathine in aqueous suspension (4 MU) was administered intramuscularly before the operation and continued the following day. The operation was performed under strict aseptic conditions. The controls underwent laparotomy only.

Pancreatic anastomosis (second operation)

Four weeks after ligation of the main duct, laparotomy was performed again. After resection of the pancreatic head (5 cm), the diameter of the duct at the cut surface was measured, and the pigs underwent sequentially one of three types of pancreatico-intestinal anastomosis, or were kept as controls. The management of the pancreatic stump was: (1) end-to-end pancreaticojejunostomy invagination (EEPJ) to a Roux-Y loop in nine piglets, using two layers (1/0 silk interrupted inner and outer layer); (2) end-to-side duct-to-mucosa sutured anastomosis to a Roux-Y loop (ESPJ) in nine piglets, using two layers (1/0 silk interrupted inner and outer layer), completed by a second layer between the pancreatic capsula and jejunal seromuscular wall; or (3) binding pancreaticojejunostomy (BPJ) in nine piglets. The surgical techniques have been described previously[21-23]. The main procedure was as follows. End-to-end duct-to-mucosa sutured (1/0 silk interrupted) anastomosis to a Roux-Y loop was performed, the pancreatic duct and jejunal mucosa were sutured, and the stitch was only inserted to the submucosal layer of the jejunal wall (Figure 1A). This procedure was slightly modified from those previously described. Finally, a piece of unabsorbable thread (7/0 silk) was used to bind circumferentially together the jejunal seromuscular sheath and pancreatic remnant (Figure 1B). The thread tie is just tight enough to allow the tip of a medium-sized hemostatic forceps to be passed underneath the ligature. No stent was used in any of the anastomoses. Roux-Y limbs of 45 cm were created using a standard side-to-side technique. After 2 d of water, the animals had free access to standard lab chow. Animals were kept in individual living quarters. Body weight was determined with a cage scale preoperatively and repeated at 2, 4, 6 and 8 wk during follow-up, until the third operation.

Measurement of intrapancreatic ductal pressure

Eight weeks after the second operation, laparotomy was again performed. Intrapancreatic ductal pressure was measured in all animals. As described by Bradley[25], a No 21 scalp vein needle (attached to a short length of connecting tube, a three-way stopcock, a manometer, and a 2-mL syringe, all filled with saline solution) was introduced into the duct of Wirsung directly through the surface of the pancreas. Fluid aspirated from the pancreatic duct into the syringe to confirm the position of the needle was meticulously replaced from the syringe before pressure measurement. The saline manometer was arbitrarily zeroed at the level of the anastomotic site. Fluctuation in pressure was noted with respiration in most animals. All pressures were recorded in the duct of Wirsung before operative pancreatography and surgical manipulation.

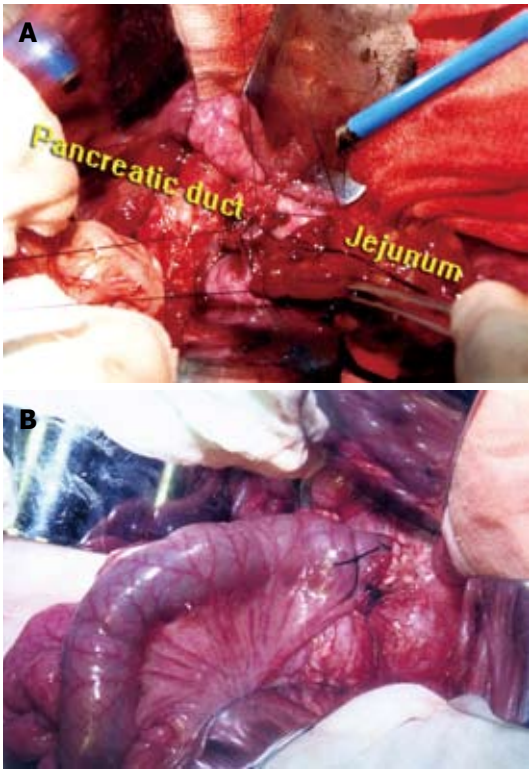

Figure 1 **A**: Pancreatic duct and jejunal mucosa are sutured, and stitch is only inserted to the submucosal layer of the jejunal wall; **B**: A piece of unabsorbable thread (7/0 silk) is used to bind together circumferentially the jejunal seromuscular sheath and pancreatic remnant.

Secretin test and minimal pressure required to obtain flow through the anastomosis

The jejunal wall was incised. The anastomotic site was grossly examined, and the status of the pancreatic drainage flow at the anastomosis was inspected by direct visual observation. Pancreatic exocrine function was evaluated by the secretin test. After 30 min basal secretion collection, secretin was administered (2 U/kg iv bolus; Sigma, St. Louis, MO, USA), and pancreatic juice at the anastomotic site was collected at intervals of 10 min for 60 min. Secretory volume, flow rate of pancreatic juice, and bicarbonate concentration were determined using standard laboratory techniques.

Pancreatographic investigation

After resection of the remnant pancreas and jejunum *en masse*, pancreatography was performed immediately by inserting a catheter into the main duct at the tail of the pancreas. The contrast medium (meglumine diatrizoate) was instilled from a height of 10 cm to equalize the pressure as uniformly as possible. The extracted pancreas was placed on an X-Omat TL film (Eastman Kodak, Rochester, NY, USA) for roentgenography at 300 mA, 26 kVp, 1.0 s and a film-focus distance of 88 cm. The maximum diameter of the main pancreatic duct was measured.

Macroscopic and histologic assessment

The pancreatic duct was examined for patency by cannulating the anastomosis distally, and testing to see if a catheter could be passed freely into the duct. Then, the anastomotic site and the long axis of the pancreatic duct of the body and tail were incised and examined macroscopically, and the specimens were fixed in 10% neutral formalin for 3 d. Sections containing the anastomotic site were prepared, embedded in paraffin, and stained with hematoxylin and eosin for histologic evaluation.

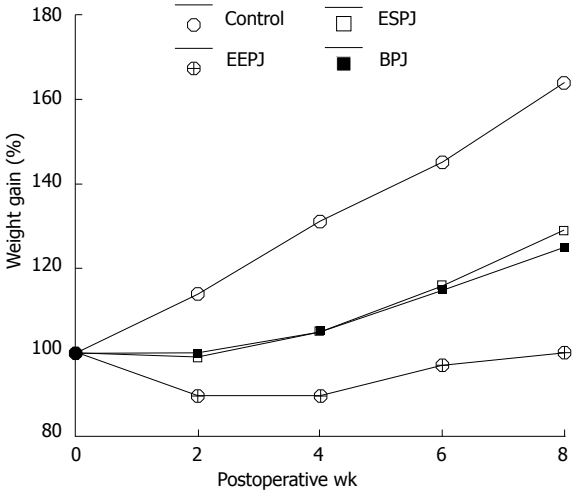

Figure 2 Percentage weight gain in pigs undergoing three types of pancreatoenteric anastomosis and in control pigs.

Statistical analysis

Data are presented as mean ± SD unless otherwise indicated. Statistical significance was assessed by analysis of variance or Student's *t* test where appropriate. Results were considered significant at $P < 0.05$.

RESULTS

Mean body weight changes

A percentage body weight change in relation to the preoperative value was determined for each animal. The postoperative weight gain for each group is shown in Figure 2. Duct-to-mucosa sutured anastomoses (ESPJ and BPJ) differed significantly from controls and EEPJ on postoperative week (POW) 2, 4, 6 and 8 ($P < 0.05$). The animals in the ESPJ and BPJ groups had a similar body weight gain, and these two types of anastomoses did not differ significantly from each other on POW 2, 4, 6 and 8 ($P > 0.05$). These mean body trends, however, suggested that the status of the anastomosis had some physiologic effect.

Intraperitoneal findings

All piglets recovered from the operation, and no fatality was encountered. Atrophy of the pancreatic parenchyma was shown in all animals in the three groups, and the main pancreatic duct at the cut surface of the pancreatic stump was markedly dilated at the end of POW 4 after the first operation (Figure 3, range 3.1-3.5 mm). At the end of POW 8 after the second operation, adhesion of the anastomotic portion to adjacent tissue was detected in all animals, the anastomotic site was healed completely, and no suture failure and intraperitoneal abscess formation

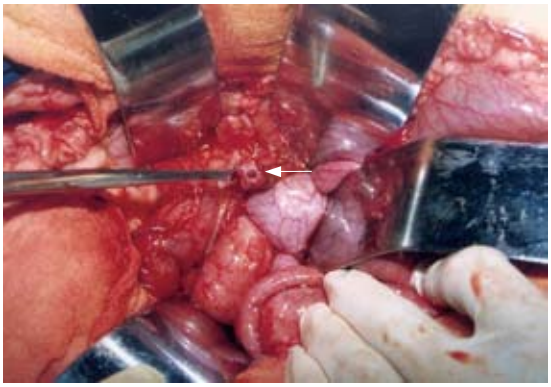

Figure 3 Duct at the cut surface of pancreatic stump was markedly dilated at the end of POW 4 after ligation of the main pancreatic duct.

Table 1 Average intraductal pressure in three types of pancreatic anastomosis and in controls

Group	*n*	Intraductal pressure (cm H_2O)
Control (normal)	9	13.24 ± 1.31
EEPJ	9	32.51 ± 2.19[a]
ESPJ	9	18.41 ± 1.42[a,c]
BPJ	9	19.13 ± 1.72[a,c]

[a]$P < 0.05$ *vs* control; [c]$P < 0.05$ *vs* EEPJ.

Table 2 Pancreatic secretion in three types of pancreatic anastomosis and in controls

Group	*n*	Secretory volume (mL/h)	Flow rate (mL/kg/30 min)	Bicarbonate concentration (mEq/L)
Control (normal)	9	137.56 ± 12.18	1.38 ± 0.13	133.56 ± 13.95
EEPJ	9	34.78 ± 4.82[a]	0.35 ± 0.10[a]	72.78 ± 10.58[a]
ESPJ	9	108.33 ± 10.65[a,c]	1.11 ± 0.15[a,c]	110.44 ± 12.52[a,c]
BPJ	9	101.23 ± 12.87[a,c]	1.05 ± 0.19[a,c]	112.67 ± 17.68[a,c]

[a]$P < 0.05$ *vs* control; [c]$P < 0.05$ *vs* EEPJ.

around the anastomotic site were observed in any animal. None of the piglets showed anastomotic complications.

Intrapancreatic duct pressure

Intrapancreatic duct pressure on POW 8 is shown in Table 1. The levels were similar in ESPJ and BPJ, and no significance was found between the two procedures ($P > 0.05$). However, pressure in EEPJ was significantly higher than that in ESPJ and BPJ ($P < 0.05$).

Pancreatic exocrine function assessed by the secretin test

The results of the secretin test for each group are summarized in Table 2. All three parameters, secretory volume, flow rate of pancreatic juice, and bicarbonate concentration, were significantly higher in ESPJ and BPJ compared to EEPJ ($P < 0.05$). However, the levels of the three parameters were similar in ESPJ and BPJ, with no significant difference between these two techniques ($P > 0.05$). These parameters suggested that the status of the anastomosis had some mechanical effect on pancreatic exocrine function.

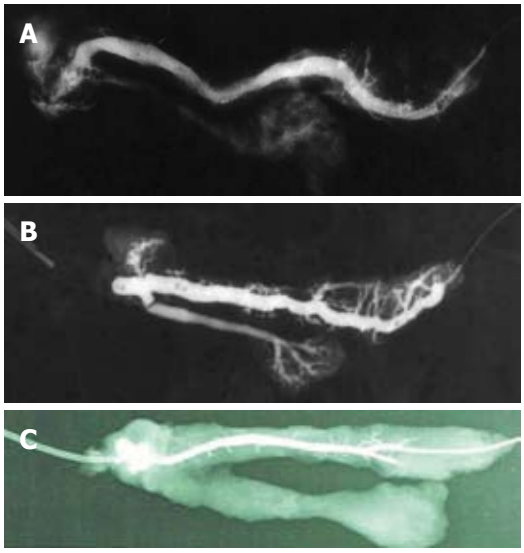

Figure 4 **A**: Anastomotic site was incompletely obstructed; **B**: Duct was blocked in the anastomotic region; **C**: Normal ductal patency without stenosis at the anastomotic site and without ductal dilatation proximal to it.

Pancreatography and maximum diameter of the main pancreatic duct

Pancreatography performed after EEPJ revealed dilation and meandering of the main pancreatic duct, together with indistinct depiction of the secondary and tertiary bifurcation of the duct, and the anastomotic site exhibited a variable degree of occlusion (Figure 4A). The duct was partially blocked in one animal and completely blocked in another in the anastomotic region (Figure 4B). Pancreatography of both ESPJ and BPJ, however, showed normal ductal patency without stenosis at the anastomotic site and without ductal dilatation and meandering of the main pancreatic duct, but distinct secondary and tertiary bifurcations of the ducts (Figure 4C). In one animal only, a slight dilatation of the anastomosed duct was detected in BPJ. Macroscopically, cicatricial narrowing of the main pancreatic duct was not observed, which suggested effective pancreatic juice drainage. The maximum diameter of the main pancreatic duct is shown in Table 3. Significant differences were found in both the ESPJ and BPJ groups in comparison with the EEPJ group ($P < 0.05$). Main pancreatic duct diameters showed no significant differences between ESPJ and BPJ ($P > 0.05$).

Macroscopic and histologic features of the anastomotic site

Macroscopically, in all specimens, there was firm union at the site of anastomosis, and the pancreas had an atrophic appearance. The specimens removed 8 wk after ESPJ and BPJ clearly showed complete mucosal continuity and good connective tissue union between the pancreatic duct and the jejunal lumen (Figure 5). The results were verified histologically, and microscopy showed that the intestinal mucosa had fused with that of the pancreatic duct, with gradual and continuous changes from one to the other (Figure 6). In contrast, in biopsies obtained in EEPJ, the portion of the pancreatic stump protruding into the jejunal lumen was largely replaced by cicatricial fibrous tissue in

Table 3 Maximum diameter of the main pancreatic duct

Group	*n*	Maximum diameter (mm)
Control	9	2.08 ± 0.33

BPJ	9	3.02 ± 0.45[a,c]

[a]$P < 0.05$ *vs* control; [c]$P < 0.05$ *vs* EEPJ.

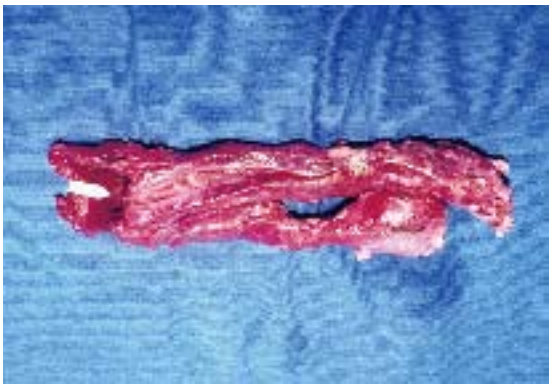

Figure 5 Longitudinal specimen reveals good connective tissue union between the pancreatic duct and the jejunal lumen.

which concentric fibrous bands with scattered mononuclear inflammatory cells were seen, and no intestinal mucosa was observed to cover the remnant cut surface.

DISCUSSION

Since Whipple's introduction of pancreaticoduodenectomy in 1935 for the treatment of cancer of the ampulla of Vater and the pancreatic head, it has become the treatment of choice in the management of periampullary cancer. However, the procedure incurs much criticism because of its high morbidity and mortality. Operative mortality has decreased dramatically over the past decades, due in part to improvement in operative technique and perioperative care[4,5,26]. Additionally, long-term survival has significantly improved and this has engendered a need to consider the importance of postoperative quality of life after resectional pancreatic surgery. The approaches involve the preservation of the exocrine and endocrine function by different techniques of anastomosis between the pancreatic stump and the digestive tract. Most of the proposed techniques are aimed at preventing leakage. Common procedures include EEPJ, ESPJ, and pancreatogastrostomy (which seems to be the least-performed procedure).

It is generally accepted that pancreatic consistency during Whipple resection is generally classified into one of two groups: normal, soft, and friable with non-dilated ducts, or firm and fibrotic with dilated ducts, with the former group having a high susceptibility to anastomotic leakage. The soft nature of the pancreatic remnant, combined with a relatively high pancreatic juice secretion rate through a non-dilated pancreatic duct, is thought to contribute to anastomotic leakage[27]. In many

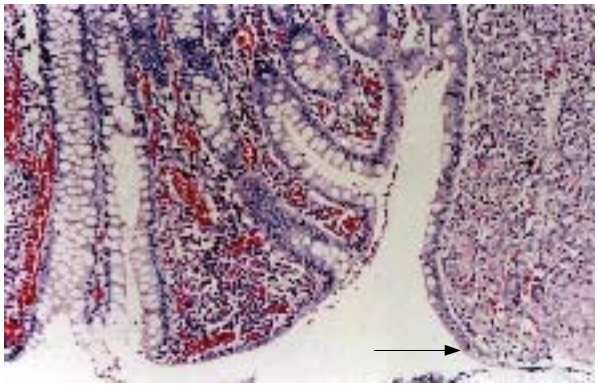

Figure 6 Section showing that the intestinal mucosa had fused with that of the pancreatic duct, with gradual and continuous changes from one to the other. Original magnification × 100.

patients with cancer and pancreatitis, the duct is dilated from obstruction, and the obstructed gland is fibrotic and easier to sew than when normal. Theoretically, the perfect approach is based on a simple general surgical principle: the absence of immediate leakage and the long-term patency of any intestinal pancreatic anastomosis. Previous studies have indicated the most important factor that influences the function of the remaining pancreas after pancreatoduodenectomy is the patency of pancreaticoenterostomy. There is a definite relationship between the degree of duct obstruction and the severity of the exocrine changes[12-20]. Therefore, preserving anastomotic patency may be essential for good remnant pancreatic function.

Tiscornia and Dreiling[28] ligated the main pancreatic duct and studied pancreatic secretion in 12 dogs with Thomas cannulas. After 7-46 d, the ligated segment of the main pancreatic duct was resected, and a primary duct-to-duct anastomosis was created to reestablish flow. Secretion was studied for up to 7 mo, and they found progressive improvement in bicarbonate and enzyme secretion, with eventual return to normal. Through clinical and experimental study, Tanaka and his colleagues[13] have revealed that the exocrine pancreas before pancreaticoduodenectomy was impaired due to obstructive pancreatitis, and that postoperative pancreatic function was well preserved at a level close to that in the control group, even after 50% resection of the pancreas, if pancreatic duct drainage was effectively performed. Several authors[12-20] have pointed out occlusion of the pancreatic duct after pancreaticoduodenectomy, which leads to an insufficiency in pancreatic exocrine and possibly endocrine function in later years. If this happens, the advantages of lower mortality and morbidity immediately after pancreaticoduodenectomy could be offset. It is conceivable that after the Whipple operation with extirpation of the sphincter of Oddi, the only outflow resistance encountered would be that due to stenosis at the site of pancreaticoenterostomy. At present, data obtained from both clinical and experimental studies have indicated that mucosa-to-mucosa pancreaticojejunostomy or pancreaticogastrostomy is the best choice for anastomotic patency[12-20].

Recently, the new method of BPJ has increasingly

been performed, especially in China, although other pancreaticojejunostomy techniques are also common. The clinical and experimental data have demonstrated that it is a safe, simple and efficient technique that avoids the primary complication of anastomatic leakage, whether the pancreatic remnant is soft or hard[21-23]. On the basis of these data, we have modified that approach slightly to test whether the patency of anastomosis and the function of the remnant pancreas of modified BPJ (mBPJ) is likely to be as good as, or better than that of the mucosa-mucosa anastomosis, for which the pancreatic remnant is hard and the pancreatic duct is dilated. To the best of our knowledge, no adequate studies appear to have been carried out.

The study of the patency of pancreaticoenterostomy and function of the remaining pancreas requires a suitable pancreatic duct dilatation model that results in an easier and more reliable experiment, although careful and meticulous anastomosis can be performed with microsurgical techniques. The digestive system of the pig closely resembles that of humans[24], therefore, we chose a duct-ligated model in piglets. This piglet model is reproducible and easy to perform, it produces changes in the pancreas analogous to those usually found in patients undergoing pancreatoduodenectomy, and the conclusion of the study is more convincing. Total obstruction of the main pancreatic duct in the experimental animals resulted in distention of pancreatic ducts and ductules.

In our previous study, we have demonstrated that there is a stronger anastomosis (bursting pressure and breaking strength) in BPJ than in EEPJ, and the anastomotic healing is better and more rapid, thus we conclude that BPJ is a safer and more reliable method than EEPJ, although no comparison has been made between BPJ and ESPJ[29]. However, the principle objectives of this study were to assess the patency of anastomosis, the exocrine function of the remnant pancreas, and the feasibility of mBPJ. The patency of anastomosis of mBPJ was the endpoint of the study.

In our present study, pancreatic duct patency without stenosis at the anastomotic site was confirmed directly by ductography and gross examination in all animals studied by ESPJ and BPJ. Similar patency was found in both ESPJ and BPJ. However, EEPJ revealed dilation and meandering of the main pancreatic duct, which seemed to be caused by pancreatic juice retention, due to poor drainage of pancreatic juice in the anastomosed pancreas. The degree of dilatation of the main pancreatic duct seems to correspond to the likelihood of anastomotic stenosis of pancreaticoenterostomy. The body weight gain (which is positively related to the pancreatic exocrine secretion[30]), secretin test, and intrapancreatic ductal pressure are in agreement with the functional status of the pancreatic duct and anastomotic site. Jejunal mucosa is in continuity with the pancreatic duct at the anastomotic site in ESPJ and BPJ. Consequently, we were able to obtain a very secure patent anastomosis in the piglet model. Our data were in accordance with those of previous studies that reported better patency with mucosa-mucosa anastomosis compared with EEPJ. According to the results of our study, and taking into consideration the advantage of preventing anastomotic breakdown or pancreatic leakage and maintaining patency of the pancreatic duct by BPJ, we believe that the procedure will result in a more anatomically secure anastomosis than that with the standard method, and should decrease the morbidity and mortality of the operation, thus increasing its acceptability as the operation of choice for Whipple resection.

COMMENTS

Background

Resectional pancreatic surgery is carried out with increasing frequency for both malignant and benign diseases. However, no adequate studies appear to have been made of the pathophysiological changes following pancreaticoduodenectomy, particularly of anastomotic patency and function of the remnant pancreas. The most important factor affecting the function of the remnant pancreas is the patency of the pancreaticoenterotomy. In the present study, we attempted to examine anastomotic patency and postoperative pancreatic exocrine function in piglets after three different anastomotic methods using end-to-end pancreaticojejunostomy invagination (EEPJ), end-to-side duct-to-mucosa sutured anastomosis (ESPJ) and binding pancreaticojejunostomy (BPJ) (a new method).

Research frontiers

There is little agreement about the best technique for pancreatic anastomosis of the gastrointestinal tract. The optimum technique is to secure a leakproof anastomosis that will not subsequently produce stenosis and exocrine deficiency. However, few clinical and experimental studies have focused on the postoperative pancreatic exocrine function. The main findings of this study were that the animals undergoing ESPJ and BPJ were much better than those undergoing EEJP, using several parameters of measurement, weight gain, intraductal pressure, secretory volume and flow of pancreatic juice, ductal patency and absence of duct dilatation.

Innovations and breakthroughs

As a new method of anastomosis, BPJ has been proven to be a safe, simple and efficient technique that avoids the primary complication of anastomatic leakage clinically and experimentally. The authors also confirmed that BPJ may effectively maintain anastomotic patency and preserve pancreatic exocrine function as well as ESPJ, and a mucosa-to-mucosa pancreaticojejunostomy is the best choice for anastomotic patency, when compared with EEPJ.

Applications

Our data were in accordance with those of previous studies that have reported better patency with mucosa-mucosa anastomosis when compared with EEPJ. According to our results, and taking into consideration the advantage of preventing anastomotic breakdown or pancreatic leakage and maintaining patency of the pancreatic duct by BPJ, we believe that this procedure will result in a more anatomically secure anastomosis than that with the standard method, and should decrease the morbidity and mortality of the operation, thus increasing its acceptability as the operation of choice for Whipple resection.

Terminology

BPJ, a new method introduced to pancreatic surgery by Pen Shuyou *et al*, has increasingly been performed, especially in China, although other pancreaticojejunostomy techniques are also common. Clinical studies have revealed that the present technique is safe, simple and effective in fulfilling current demands on resectional pancreatic surgery. However, the anastomotic patency and residual exocrine pancreatic function after BPJ continues to require adequate evaluation.

Peer review

The authors are to be commended on their excellent piece of research. There have been few clinical and experimental studies with a focus on the pathophysiological changes of pancreaticoenterotomy, particularly of anastomotic patency and function of the remnant pancreas. This is an interesting study, well designed and well performed. The discussions are to the point and not overstated. The authors' findings certainly merit attention.

Abstract

AIM: To examine the portal hemodynamics of gastric fundal varices (GV) without gastro-renal shunt (GRS), and to retrospectively investigate the effects of various kinds of treatment on eradication.

METHODS: Ninety-four liver cirrhosis patients at high-risk of GV were treated in our hospital and enrolled in this study. We retrospectively examined their characteristics, liver function, and portal hemodynamics of GV. We performed balloon-occluded retrograde transvenous obliteration (BRTO) at first. If it was not technically possible to perform BRTO, endoscopic injection sclerotherapy using α-cyanoacrylate glue (CA) or percutaneous transhepatic obliteration (PTO) was performed.

RESULTS: Among the 94 patients, a GRS was present in 79 (84.0%), and absent in the remaining 15 (16.0%). The subphrenic vein was connected to the inferior vena cava as the drainage vein in 13 (86.7%) out of the 15 cases without GRS. We performed BRTO in 6 patients, CA in 4 patients and PTO in 5 patients. The eradication rate was 100% for each procedure, but the rate of early recurrence within 6 mo was 16.7% for BRTO, 50.0% for CA and 40.0% for PTO, respectively.

CONCLUSION: We should examine the hemodynamics before treatment of GV irrespective of the existence of GRS. If this hemodynamic examination reveals that the drainage vein connects directly to the inferior vena cava in GV without GRS, BRTO may be an effective treatment for GV with GRS.

INTRODUCTION

Rupture of esophagogastric varices is one of the most severe complications of portal hypertension in patients with liver cirrhosis. Gastric varices bleed less frequently than esophageal varices, but bleeding from gastric fundal varices (GV) tends to be more severe and is associated with a high mortality rate[1,2]. Effective management of such bleeding is essential. Endoscopic injection sclerotherapy and endoscopic variceal ligation are currently the mainstay of treatment for esophageal varices. Most cases of GV cannot be treated effectively with endoscopic injection sclerotherapy alone[3-5] because of the rapid blood flow within their vessels with a large diameter. Endoscopic injection of n-butyl-2-cyanoacrylate or isobutyl-2-cyanoacrylate is used as the standard first-line treatment for bleeding GV[6] in the Western countries. However, the reported severe complications related to embolization of other organs have raised concerns for the safety of injection of tissue adhesive agents[7-11]. Transjugular intrahepatic portosystemic shunt (TIPS) placement, one of the interventional radiological techniques, is currently the second-line treatment for bleeding esophagogastric varices[6,12] and can effectively control GV bleeding[13-15]. However, it was reported that this treatment is associated with a lower success rate for GV than for esophageal varices[16-18].

Recently, some newer interventional radiological techniques have been used to treat GV with good results. Balloon-occluded retrograde transvenous obliteration (BRTO) is a very useful treatment for GV in terms of efficacy, safety, and degree of invasiveness[19-29], and the recurrence rate of GV has been also reported to be 0%-10%[23-29] after BRTO, which shows excellent long-term results. Prophylactic treatment with BRTO can effectively prevent GV rupture, and improve patient survival[28]. Ninoi *et al*[29] showed that GV bleeding is better controlled with BRTO than with TIPS. Therefore, not only radiologists but also hepatologists and gastroenterologists in Japan have considered BRTO the standard first-line treatment for GV in place of endoscopic variceal obturation therapy or TIPS. However, it is generally considered that BRTO cannot be used in the treatment of GV without GRS because BRTO is performed through GRS, which exists in almost 85% of GV[7]. It is very crucial to investigate whether BRTO can be feasible for GV without GRS and the effects of BRTO compared with other methods.

The portal hemodynamics of GV without GRS is not well known, and there is no well-established treatment for the eradication of these GV. This study was to examine the portal hemodynamics of GV without GRS compared with those with GRS, and to retrospectively investigate the effects of BRTO compared with some kinds of treatment on the eradication of these varices.

MATERIALS AND METHODS

Ninety-four liver cirrhosis patients at high-risk of GV were treated in our hospital between February 1996 and June 2002 and enrolled in this study. All patients had GV with acute bleeding or were at high-risk of GV. GV were evaluated based on esophagogastroduodenoscopy (EGD) criteria according to the system adopted in Japan[30,31]. In brief, the location of gastric varices (Lg) was classified as being adjacent to the cardiac ring (Lg-c), separated from the cardiac ring (Lg-f), or continuing from the Lg-f to the gastric fundus (Lg-cf). Varices were further classified as straight and small caliber varices (F1), beaded varices (F2), or tumor-shaped varices (F3). We categorized GV as a high risk according to the criteria reported by Kim *et al*[32], who found that a diameter of at least 5 mm and the presence of red spots are independent factors that predict a high-risk of variceal bleeding. All patients were evaluated for variceal hemodynamics with color Doppler endoscopic ultrasonography (CD-EUS) and multidimensional computed tomography (MDCT) or CD-EUS and magnetic resonance angiography (MRA). Of the 94 patients, 23 were urgent or elective cases with episodes of variceal bleeding, and 71 were prophylactic cases. We retrospectively examined their characteristics, liver function, and portal hemodynamics of GV. CD-EUS (FG-32UA, Pentax Co., Ltd., EUB-555 US scanner, Hitachi Co., Ltd., Tokyo, Japan) was performed in all patients to measure the diameters of variceal vessels as well as blood flow velocity before treatment. Blood flow was calculated from blood vessel diameter and blood flow velocity. All patients underwent MDCT or MRA to detect the supply and drainage vein and to determine whether they had a gastro-renal shunt. The patients underwent repeated CD-EUS within 1 wk after treatment to assess the sclerosing effect. The efficiency of each treatment was confirmed by the rate of disappearance of varices. EGD was done every 3-6 mo after treatment to evaluate the status of GV. The recurrence of GV was defined as detection of appearance of high-risk signs (as described above) or variceal bleeding. The follow-up period for recurrence was calculated as days from the date of treatment until the first date when EGD revealed recurrence.

Regarding the selection of the method for treatment, BRTO is the first-line treatment for GV with GRS in our hospital because it is generally considered the first-line treatment in Japan[19-29]. Therefore, in cases where it was possible, we performed BRTO even for varices without GRS. If it was not technically possible to perform BRTO, endoscopic injection sclerotherapy using α-cyanoacrylate glue (CA) or percutaneous transhepatic obliteration (PTO) was used.

BRTO procedure

BRTO is a method for treating GV by injection of a sclerosant after the main drainage vein of GV is blocked angiographically to stagnate blood flow. In general, a balloon catheter is inserted *via* the right femoral vein and wedged into the left adrenal vein. After the balloon is inflated, the gastro-renal shunt is visualized with the contrast agent iopamidol to judge whether shunt occlusion has been achieved. In case of GV without GRS, if the drainage vein is connected directly to the inferior vena cava, BRTO could be performed after an occlusive balloon catheter is placed in the drainage vein through the right femoral vein (Figure 1A and B). If retention of contrast agent is insufficient in GV because of other collateral veins, metallic coils are placed in the collateral veins to reduce the blood flow. In our study, after venography showed sufficient retention of contrast agent in GV, 5% solution of ethanolamine oleate with iopamidol (EOI) was continuously injected through the catheter in the drainage vein until the varices were sufficiently filled with the sclerosant. Thereafter, the catheter was left in place for 24 h to allow sclerosis to occur within the gastric fundal varices.

Modified PTO procedure with injection of sclerosant

The modified PTO using sclerosant and metallic coils[29,33] can embolize GV more selectively than original PTO[34]. In our study, percutaneous transhepatic portography was performed, and the supply and drainage veins of the GV were identified on portography. After metallic coils were placed in the supply vein to reduce blood flow in the GV, EOI was injected through the catheter until the gastric fundal varices were sufficiently filled with the sclerosant.

CA procedure

CA is a method for treating GV by injection of a sclerosant endoscopically. In our study, a sclerotherapy injector, with a 20 gauge needle, was used for variceal injection. The GV were endoscopically punctured and

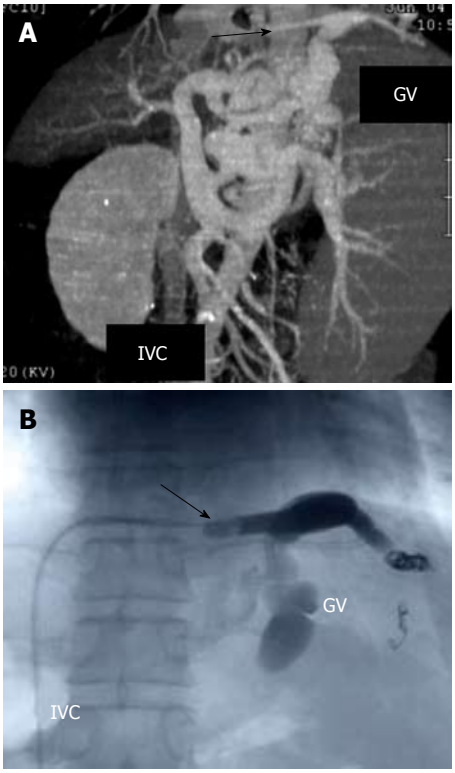

Figure 1 Multidimensional computed tomography (MDCT) revealing the varices supplied by the left gastric vein and drained into the subphrenic vein (arrow) which is connected to the inferior vena cava (IVC) (**A**), and fluoroscopic image of BRTO showing placement of the occlusive balloon catheter in the subphrenic vein (arrow) (**B**). After the blood vessels from the GV except for the main drainage vein were blocked with coils, 5% solution of ethanolamine oleate with iopamidol (EOI) was injected into the varices.

injected with 2.5 mL of a lipiodol-α-cyanoacrylate mixture (64% α-cyanoacrylate) in one shot, and injection was stopped when the varices were filled sufficiently after several injections.

Statistical analysis

Values are presented as mean ± SD, or as percentages. The Mann-Whitney *U* test was used to assess differences in age, sex, form, location, diameter of variceal vessels, blood flow velocity, blood flow volume, and liver function tests. Categorical variables were analyzed by the chi square test, with Yates' correction for continuity where appropriate, or by the Fisher's exact test. The Kaplan-Meier method was used to calculate the recurrence rate for GV. Differences between the groups were compared by means of the log-rank test. Statistical software (SPSS 10.0J, SPSS Japan Inc., Tokyo, Japan) was used in statistical analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Ninety-four patients (60 men, 34 women; mean age 62.3 ± 9.7 years, range 33-80 years) underwent hemodynamic evaluation of GV with CD-EUS and MDCT or CD-EUS and MRA. Among the 94 patients, hepatic function was classified as class A in 53, class B in 36 and class C in 5 by the Child-Pugh classification. The location of GV was at Lg-f in 16 patients and at Lg-cf in 78 patients. The form of gastric varices was F2 in 32 patients and F3 in 62 patients. There were 14 patients who had red color spots on the GV. Among the 94 patients, a GRS was present in 79 (84.0%), and absent in the remaining 15 (16.0%) (Table 1).

Table 1 Clinical characteristics of patients and profile of varices in GRS (+) and GRS (-) groups *n* (%)

NS: Not significant. GV: Gastric fundal varices; GRS: Gastro-renal shunt; CD-EUS: Color doppler endoscopic ultrasonography. Values for age and findings of CD- EUS are the median. [a]$P < 0.05$ *vs* GRS (+) group.

Regarding the hemodynamics of GV without GRS, there were a number of different supply veins, including the left gastric vein (21.7%), the short gastric vein (18.8%), and the retrogastric vein (59.4%). However, among the 15 cases without GRS, the subphrenic vein was connected to the inferior vena cava as the drainage vein in 13 cases (86.7%) out of the 15 cases without GRS (Table 2). Between the GRS (+) and GRS (-) groups, there were no significant differences in age, sex, form and location of the varices, presence of red-colored spots, velocity of blood flow in the GV, or in Child-Pugh classification. The diameter of varices and blood flow volume were higher in the GRS (+) group than in the GRS (-) group ($P = 0.009$, $P = 0.043$) (Table 1). Regarding the treatment of GV without GRS, we performed BRTO in 6 patients, CA in 4 patients and PTO in 5 patients, without severe complications (Table 2). The GV eradication rate in the GRS (-) group for each procedure was 100%.

The rate of early recurrence, within 6 mo, was 16.7% for BRTO, 50.0% for CA and 40.0% for PTO, respectively, in the GRS (-) group (Table 3). When the main drainage vein was found to be connected to the inferior vena cava, BRTO was the most effective treatment even for GV without GRS. No severe complication occurred in each method except for slight abdominal discomfort or hematuria. Most of the patients treated with BRTO or PTO revealed hematuria caused by sclerosant, but it was recovered when haptoglobin was used without renal damage (haptoglobin was used prophylactically in all cases treated with BRTO or PTO).

DISCUSSION

The present study is the first clinical study examining the portal hemodynamics of GV without GRS compared with those with GRS and the effects of some kinds of treatment for high-risk GV without GRS. The hemodynamic patterns in patients with GV are distinctly different from those in patients with esophageal varices[6,35]. Solitary GV are more frequently supplied by the short and posterior gastric veins, and drain to the inferior vena cava through GRS. However, this shunt is absent in around 15% of patients with GV[25]. The present study revealed that in 13 (87%) of 15 cases without GRS, the subphrenic vein was connected to the inferior vena cava as a drainage vein. Although the varices in the GRS (-) group had thinner veins and a lower blood-flow volume than those in the GRS (+) group, the hemodynamics in the GRS (-) group was more complicated than that in the GRS (+) group, suggesting that it is necessary to examine hemodynamics before treatment, so that the most suitable treatment can be selected.

There is no established treatment for the eradication of GV in these patients without GRS. Our results show that the effect of BRTO on GV without GRS was excellent. The eradication rate of GV without GRS for each procedure (BRTO, PTO, and CA) was high, but BRTO was superior to CA and PTO in early recurrence rate within 6 mo (16.7% for BRTO, 50.0% for CA and 40.0% for PTO). In this respect, no randomized controlled trials comparing BRTO with CA or PTO are available. Regarding the long-term efficacy of CA, GV rebleeding occurs in 23%-50% of patients with most of them occurring in the first year[6]. In our hospital, the recurrence rates at 1, 3, and 5 years of GV with GRS are 2.7%, 2.7%, and 2.7%, respectively, for BRTO in 78 patients[27], 4%, 41.5%, and 53.2%, respectively, for CA in 38 patients, and 28.6%, 42.9%, and 61.9%, respectively, for PTO in 13 patients (data not shown). These results suggest that recurrence rates of GV after BRTO are lower than those of GV after other procedures, showing the excellent long-term effect of BRTO. We speculate that the reason why CA and PTO are associated with a higher recurrence rate than BRTO may be due to insufficient injection of the occlusive substances into the gastric varices and the drainage vein with the PTO and CA procedures, leading to recanalization of the GV. The results of this study suggest that BRTO is an effective treatment for GV without GRS as well as for GV with GRS.

When examination of the hemodynamics reveals that the main drainage vein is connected directly to the inferior vena cava, BRTO is indicated for GV not only with GRS but also without GRS if a catheter can be inserted into the main drainage vein. The purpose of this method is to inject the sclerosant from the drainage vein, so the efficacy of treatment may depend on the sufficient retention of the sclerosant rather than on the approach route. Therefore there is no difference in efficacy depending on the presence or absence of GRS. The most important factor for performing BRTO is the presence of the major shunt directly connected to the inferior vena cava. If the drainage vein is too thin to insert the catheter or not connected to the inferior vena cava, it is impossible to perform BRTO.

Various techniques are now available for the treatment of GV (Figure 2). PTO is used for the treatment of ruptured varices, but the use of this method has decreased following the development of endoscopic treatment. The modified PTO using sclerosant and metallic coils[29,33] can embolize GV more selectively than the original PTO[34]. When the drainage vein is not connected to the inferior vena cava, the modified PTO might be a good option for the treatment of GV without GRS, and some good results have been reported[29,33]. However, this method is not used outside Japan as BRTO. TIPS placement is currently the second-line treatment for bleeding esophagogastric varices[6,12] and can effectively control GV bleeding[13-15]. However, it was reported that its rate (25%-63%) is lower for GV than for esophageal varices[14-16]. Because patients with GV are reported to have a lower portocaval pressure gradient[35], they have extensive spontaneous portosystemic shunts and respond poorly to TIPS. Ninoi *et al*[29] reported that transcatheter sclerotherapy using BRTO

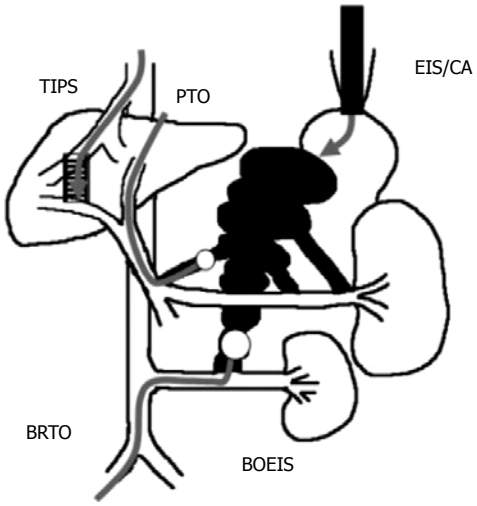

Figure 2 Treatment of gastric fundal varices with balloon-occluded retrograde transvenous obliteration (BRTO), percutaneous transhepatic obliteration (PTO), balloon-occluded endoscopic injection sclerotherapy (BO-EIS), endoscopic injection sclerotherapy using α-cyanoacryrate glue (CA), transjugular intrahepatic portosystemic shunt (TIPS).

and modified PTO can control GV bleeding better than TIPS[29]. However, larger prospective studies need to be performed. We reported that balloon-occluded endoscopic injection sclerotherapy (BOEIS) has an advantage in that it appears to be applicable to patients with GV without GRS[36]. However, BOEIS needs both interventional and endoscopic methods, and is more invasive than other methods. BOEIS is limited only to cases for which other methods are not suitable.

In conclusion, we should examine the hemodynamics before treatment of GV irrespective of the existence of GRS. If this hemodynamic examination reveals that the drainage vein is connected directly to the inferior vena cava in GV without GRS, BRTO might be an effective treatment for GV with GRS as well.

COMMENTS

Background

Recently, a newer interventional radiological technique has been used to treat gastric fundal varices (GV) with good results. Balloon-occluded retrograde transvenous obliteration (BRTO) is a very useful treatment for GV in terms of efficacy, safety, and degree of invasiveness.

Research frontiers

The present study is the first clinical study examining the portal hemodynamics of GV without gastro-renal shunt (GRS) compared to those with GRS and the effects of some kinds of treatment for high-risk GV without GRS.

Innovations and breakthroughs

BRTO is a very useful treatment for GV. However, it is generally considered that BRTO cannot be used in the treatment of GV without GRS. The results of this study suggest that BRTO may be an effective treatment for GV without GRS as well as for GV with GRS.

Applications

When hemodynamic examination reveals that the drainage vein is connected directly to the inferior vena cava in GV without GRS, BRTO might be an effective treatment for GV with GRS as well.

Terminology

BRTO: A method for treating GV by injecting a sclerosant after the main draining vein of GV is blocked angiographically to stagnate for blood flow.

Peer review

In this study, the authors described the hemodynamics and response to different treatments modalities for gastric varices without GRS. The authors support the use of BTRO as the first line treatment for patients in which the drainage vein is connected directly to the inferior vena cava.

Abstract

AIM: To explore the efficacy and safety of herbal medicines (HM) in the treatment of irritable bowel syndrome (IBS).

METHODS: A computer-based as well as manual literature search was performed. We reviewed randomized controlled trials on the treatment of IBS with and without HM.

RESULTS: A total of 22 studies with 25 HMs met the inclusion criteria. Four of these studies were of good quality, while the remaining 18 studies involving 17 Chinese herbal medicine (CHM) formulas were of poor quality. Eight of these reports using 9 HMs showed global improvement of IBS symptoms, 4 studies with 3 HMs were efficacious in diarrhea-predominant IBS, and 2 studies with 2 HMs showed improvement in constipation-predominant IBS. Out of a total of 1279 patients, 15 adverse events in 47 subjects were reported with HM. No serious adverse events or abnormal laboratory tests were observed. The incidence of the adverse events was low (2.97%; 95% CI: 2.04%-3.90%).

CONCLUSION: Herbal medicines have therapeutic benefit in IBS, and adverse events are seldom reported in literature. Nevertheless, herbal medicines should be used with caution. It is necessary to conduct rigorous, well-designed clinical trials to evaluate their effectiveness and safety in the treatment of IBS.

INTRODUCTION

Irritable bowel syndrome (IBS) is associated with a variable combination of chronic or recurrent symptoms such as abdominal pain, bloating, constipation and diarrhea. There is generally no structural or biochemical abnormality detected by conventional laboratory tests. IBS is one of the most common functional gastrointestinal disorders accounting for 3% of all primary consultations[1]. In western countries, the prevalence of IBS is around 10%, depending upon the definition used[2]. Moreover, there is increasing prevalence of IBS in the newly developed Asian countries[3]. The potential etiological factors include stress, anxiety, visceral hypersensitivity, altered bowel motility, neurotransmitter imbalances, and inflammation.

Herbal medicines have been used in Asia for a long time. An increasing number of IBS patients are beginning to receive complementary and alternative medicines in the West, most frequently herbal remedies (43%)[4]. Patients may seek HM for symptomatic relief when conventional medicines (CM) are unsuccessful. In such situations, an important question is whether herbal medicines are effective and safe for IBS patients. In the present study, we systematically reviewed the literature and evaluated the effects of HM as well as their potential adverse events in patients with irritable bowel syndrome.

MATERIALS AND METHODS

Search strategy

We carried out a literature search using MEDLINE (1966-2005), EMBASE (1980-2005), Cochrane Database (1992-2005), TCMLARS Database (1984-2005), CJA Full-Text Database (1994-2005), and Chongqing VIP Database (1989-2005) for relevant randomized controlled clinical trials, meta-analysis and systematic reviews published in all languages until October 2005. We used MeSH terms including 'irritable bowel syndrome, functional colonic

disease, drugs, Chinese medicines, traditional medicines, herbal medicines, alternative medicines, complement medicines, plant, oriental traditional medicine' for the database search.

In addition, a hand search of reference lists, review articles, editorials and abstracts from major meetings was also conducted to supplement the electronic search. We included articles published in all languages. Titles and abstracts of all potentially relevant studies were screened before retrieval of the full articles. However, if the title and the abstract were ambiguous, the full articles were scrutinized. Two independent reviewers (J.S and H-X. L) participated in the literature search. Any disagreements were resolved by discussions in order to reach a consensus.

Inclusion and exclusion criteria

The following inclusion criteria were used: (1) Diagnostic criteria used for IBS were ROME I [5] or ROME Ⅱ [6] criteria or the 1986 National symposium on chronic diarrhea (Chengdu China) criteria[7]; (2) Study design with randomized controlled clinical trials, irrespective of blinding; (3) Studies using HM alone for treating IBS in the treatment groups; (4) Identification and description of adverse events; (5) The treatment group received orally administered HM; (5) The control groups received placebo, CM or no treatment.

We excluded studies in which HM was used in combination with CMs, in children and in control groups. Administration of HM by other routes such as injections were also excluded.

Information on HM products derived from a single herb, Chinese proprietary medicines, complex extracts of different herb preparations such as decoction, tablet, capsule, pill, powder and plaster were collected. Standardized extracts of whole plants were included, but isolated 'active' phytochemical ingredients were excluded as these are generally considered as plant chemical products.

Data extraction

Data was collected independently by the reviewers. Any disagreement between the reviewers was resolved by discussion in order to achieve consensus.

Assessment of study quality

The reviewers also assessed independently the quality of each study by Jadad scale[8] and Cochrane Handbook[9].

Statistical analysis

The relative risk (RR) and 95% confidence interval (95% CI) were calculated using raw data derived from each study. Intention-to-treat analysis was performed if possible. Meta-analyses was performed with either fixed effects model or random effects model according to the presence or absence of heterogeneity when HM was compared with control. Statistical analysis was performed with RevMan 4.2 to detect any bias in studies using the funnel plot.

RESULTS

Our initial search generated 572 citations. After analyzing the titles and abstracts, and reading the full text articles, only 22 studies[10-31] with 25 arms involving 1279 patients and 763 controls met the predefined inclusion criteria. Eighteen of the studies were conducted in China and published in Chinese, four were published in English, one each from Australia[11] and Israel[20], and two from Germany[29,31] (Table 1).

Three studies[11,20,29] used computer software and two[21,25] used random number tables to generate the allocation sequence. Four studies[11,20,29,31] used an adequate concealed allocation method of randomization. Six studies[11-12,20,27,29,31] used placebo as control, four of these studies[11,20,29,31] were considered to be adequate, while two[12,27] demonstrated an inadequate comparison between placebo and CTM decoction; Four studies[11,20,29,31] provided statistical data with intention-to-treat protocol.

Using the Jadad Score and Cochrane handbook, four studies[11,20,29,31] were judged to be of high quality, whereas the remaining reports were of poor quality.

Efficacy of herbal medicines

Global symptoms of IBS: Two studies[11,29] with 3 HMs showed significant benefit compared to placebo with respect to the global improvement of IBS symptoms: standard CHM formula[11] (RR 2.15; 95% CI: 1.26-3.65 rated by patient and RR 2.62; 95% CI: 1.44-4.78 assessed by gastroenterologist), STW5[29] (RR 1.68; 95% CI: 1.13-2.51), STW5-Ⅱ[29] (RR 1.90; 95% CI: 1.30-2.78) (Figure 1). The following seven CHMs using complex herbal formulas appeared to be effective in improving global IBS symptoms compared to CM: Lizhong huoxie decoction[10] (RR 1.40; 95% CI: 1.11-1.76), Huatan Liqi Tiaofu decoction[13] (RR 1.24; 95% CI: 1.05-1.47), Geqin Shujiang Saocao decoction[14] (RR 1.24; 95% CI: 1.05-1.47), Huanchang decoction[16] (RR 1.41; 95% CI: 1.08-1.84), Congpi Lunzhi Formula[17], (RR 1.74; 95% CI: 1.35-2.24), Xiangsha Liujunzi decoction[18] (RR 1.28; 95% CI: 1.00-1.63, $P = 0.015$), and Shunji mixture[19] (RR 1.23; 95% CI: 1.01-1.49).

By contrast, the following compounds were not effective in the treatment of global IBS symptoms compared to placebo or CM: Individualized CHM[11] (RR 1.51; 95% CI: 0.83-2.73 assessed by patients and RR 1.54; 95% CI: 0.77-3.05 assessed by gastroenterologist), Bitter candytuft[29] (RR 1.23; 95% CI: 0.78-1.92), Curcuma [31] (RR 0.97; 95% CI: 0.60-1.55), Fumitory[31] (RR 1.13; 95% CI: 0.74-1.72) (Figure 1), Changkang Capsule[21] (RR 1.03; 95% CI: 0.92-1.14), and Jiejing Yiji decoction[30] (RR 1.09; 95% CI: 0.96-1.23) (Figure 2).

Diarrhea: As shown in Figure 3, a meta-analysis of Tongxie Yaofang modified decoction[12] and Tongxie Yaofang plus Sini San decoction[27] (RR 1.14; 95% CI: 1.04-1.24) showed that compared to CM these products had antidiarrheal effects in patients with diarrhea-predominant IBS patients. We combined the data from these two studies[12,27] since their herbal ingredients and dosages were very similar. Their effects were similar to Liyiting decoction[26] (RR 1.28; 95% CI: 1.02-1.62), and Tongxie yihao capsule[28] (RR 1.22; 95% CI: 1.01-1.46).

Three studies demonstrated an insignificant improvement in diarrhea: Xianshi Capsule[15] (RR 1.20; 95% CI: 0.98-1.48), Changning Yin decoction[24] (RR 1.19; 95%

CI: 0.99-1.42), Changjitai decoction[25] (RR 1.14; 95% CI: 0.81-1.60) (Figure 3).

Constipation: One study[20] showed that compared to placebo Padma Lax was more effective in relieving symptoms in patients with constipation-predominant IBS (RR 7.24; 95% CI: 2.37-22.12) (Figure 4). Similarly, another study[23] demonstrated that Gegan Qinlian pellet was therapeutically effective (RR 1.28; 95% CI: 1.03-1.60). By contrast, Wuma Simo decoction[22] had no advantages over CMs in the patients with constipation-predominant IBS (RR 1.07; 95% CI: 0.91-1.25) (Figure 5).

Therapeutic period and follow-up

The duration of treatment was 8 weeks or more in five studies[11,15,20,25,31], and 5 or 6 wk in three studies[17,24,26]. In one study[16] the treatment duration was 3-6 wk, whereas the other studies[10,12-14,19,21,23,28,29] lasted 3 or 4 wk, while the shortest[18,22,27,30] period of the treatment was only 2 wk. Five studies[10-11,16,28,30] reported follow-up assessment after herbal medicine treatment. Two[10,28] reported that the symptom recurrence rates were lower in the treatment group compared to the conventional treatment group (25.5% *vs* 60%; 23.1% *vs* 50%, $P < 0.01$), after one-year and one-half-year respectively, following completion of the treatment. Another study[11] presented the result as bowel symptom scale. There was significant improvement in the individualized group (75%), and standard group (63%) compared with placebo group (32%) after 14 wk of follow-up. One study[16] reported the number of subjects that were lost to follow-up, but the reasons were not provided. Another study[30] reported symptom recurrence in 3 of 48 patients in the treatment group after 2 wk without treatment.

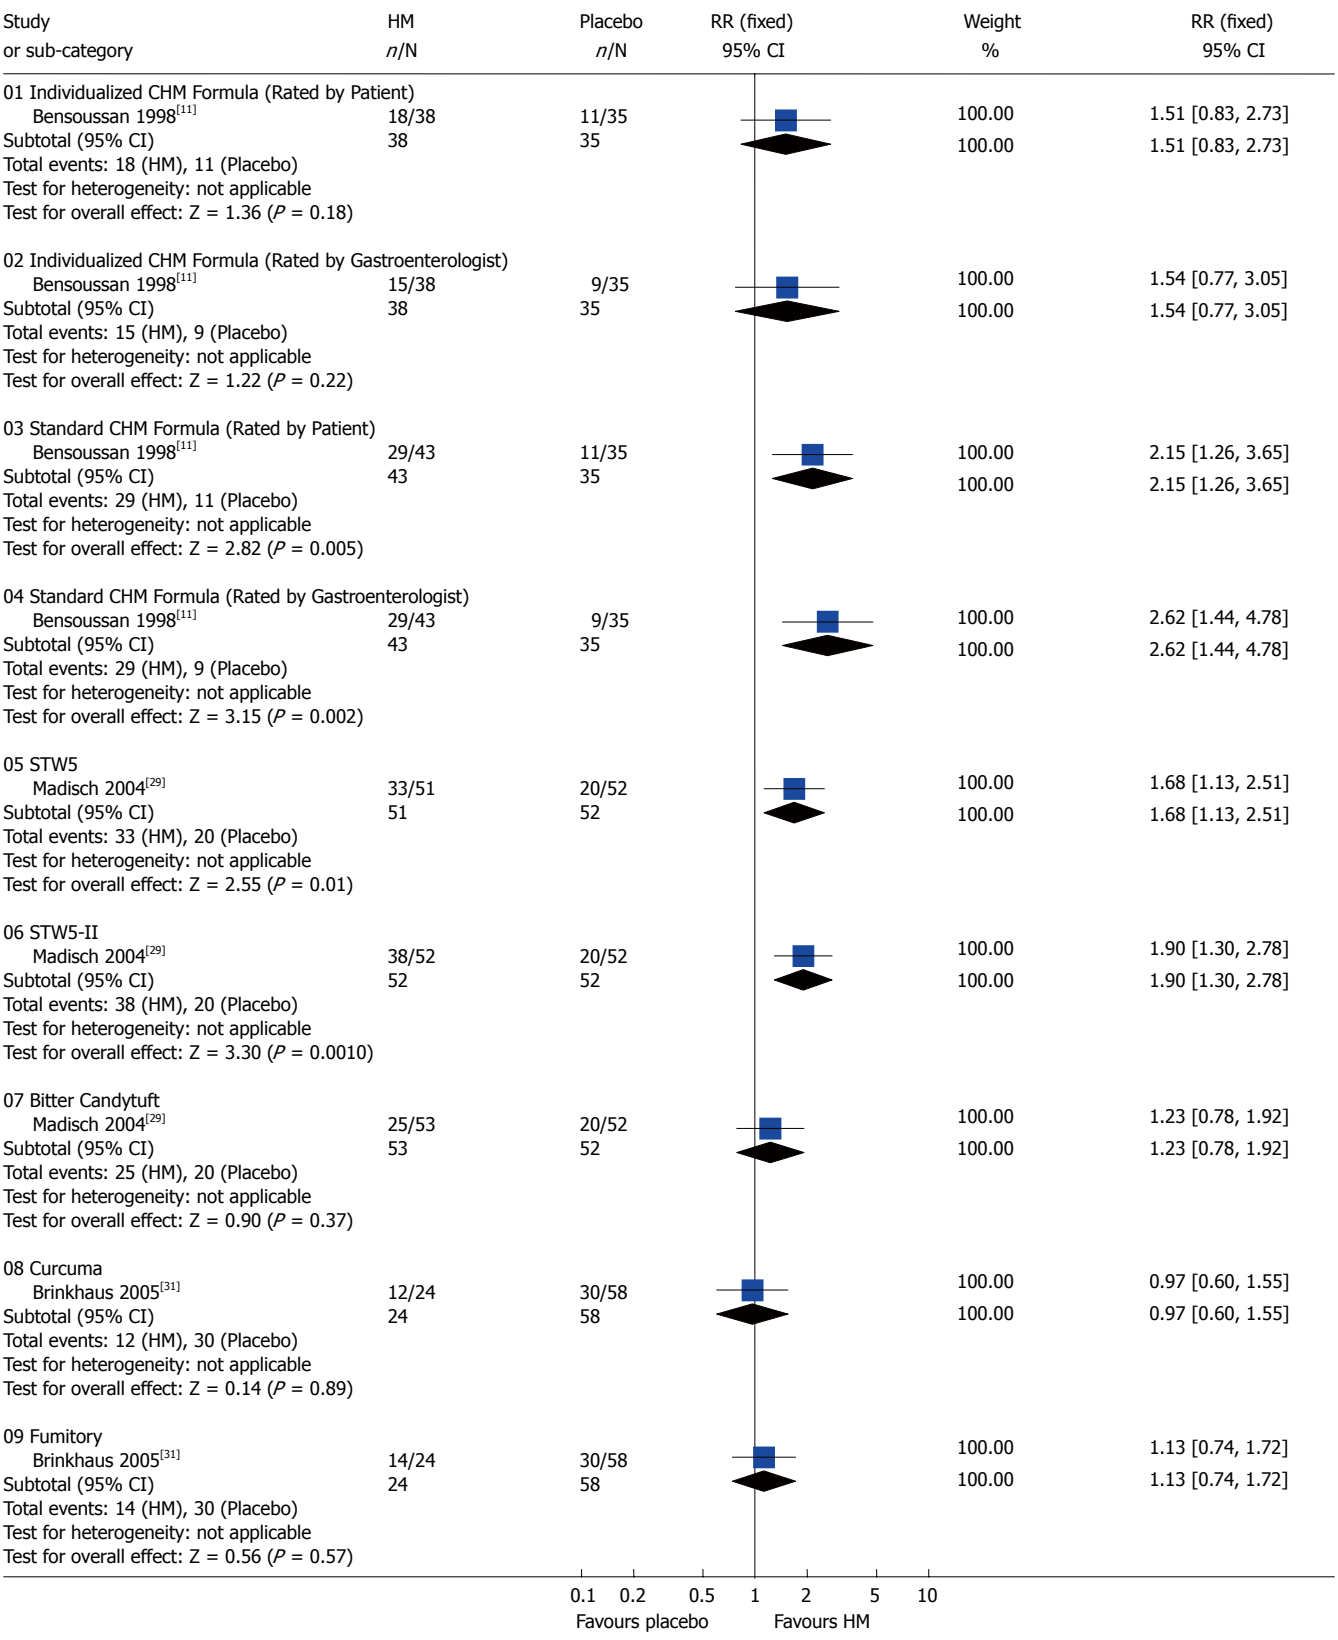

Figure 1 Comparison of herbal medicine and placebo (Outcome: global improvement of symptoms). HM: Herbal medicine; RR: Relative risk; CI: Confidence interval; Fixed: Fixed effects model.

Adverse effects of herbal medicine

In the total study group of 1279 patients, only 15 adverse events in 47 subjects were observed (Table 2). The most common symptoms were abdominal distention, constipation and abdominal pain. None of the subjects developed any serious adverse events or abnormal laboratory tests. The percentage of adverse events associated with HM was 3.67% (95% CI: 2.64-4.71%) in the 1279 patients in the different treatment groups.

Bias analysis

Funnel plots indicated an asymmetry (Figure 6).

DISCUSSION

In the present review, 3 out of the 4 good quality studies[11,20,31] demonstrated 4 different herbal interventions: one Chinese herbal medicine (standard formula), one Tibetan herbal formula (Padma Lax) and two complex extracts of herbs: STW5 and STW5-Ⅱ which could potentially relieve abdominal pain, constipation, diarrhea and alternating constipation and diarrhea. Moreover, three[11,29,31] out of these four studies showed that four

interventions including one individualized formula and three mono-extracts of single herb (Bitter Candytuft, Curcama and Fumitory) were not effective in IBS. We recognized that some complex herbal formulas may improve IBS symptoms, whereas three mono-extracts of single herbs had no beneficial effect. A possible explanation for these findings is that the therapeutic effect may be enhanced by the synergic actions of compounds in a mixture of different herbs.

Twelve[10,12-14,16-19,23,26-28] out of the 18 poor quality studies showed that some Chinese herbs formulas, such as, Huatan Liqi Tiaofu decoction, Tongxie Yaofang modified and Tongxie Yaofang plus Sini San decoction, Geqin Shujiang Saocao decoction, Huanchang decoction, Congpi Lunzhi Formula, Xiangsha Liujunzi decoction, Shunji mixture, Gegan Qinlian Pellet, and Liyiting decoction were more beneficial than CMs in the treatment of IBS.

However, these studies revealed several methodological flaws. We found that the longest duration of treatment was 18 wk, while the shortest was just 2 wk, and only 5 studies lasted more than 8 wk. The most frequent treatment duration was 3-4 wk. With such a short period of treatment, it is hard to reach the therapeutic goal in IBS. Some studies reported the long-term effects of herbs and the rate of symptom recurrence. Thus, it is necessary to have a relatively long treatment duration with herbal medicines as well as the duration of the follow-up period; Funnel plot of inclusion trials indicated asymmetry, the major interpretation is the presence of publication bias and variable methodological quality. In the studies that we reviewed, 18 out of 22 were conducted in China and published in Chinese. Chinese studies more frequently showed favorable therapeutic results compared to articles in English, particularly those with a high rate of positive outcome (99%)[32]. The large number of poor quality studies is another source of bias. Furthermore, the small size of studies and the variability of the control treatment may cause asymmetry of the funnel plot. We noticed that most of the studies with Chinese herbs were of poor methodological quality and would not provide strong evidence to confirm the efficacy of CHM. However, the lack of good evidence supporting the effectiveness of CHM does not mean that these preparations are not effective in the treatment of IBS, instead we need to improve the methodological quality of trials in order to verify the efficacy of CHM as a therapeutic approach. We agree with the opinion of Liu[33] that the potential beneficial effects of CHM need to be confirmed in rigorous trials with well-designed, randomized, double blinded, placebo controlled studies. A good example is the study performed by Bensoussan and colleague[11].

There is growing interest in placebo response in patients with IBS. A systematic review of RCTs showed that global improvement in IBS symptoms with placebo was 40.2% (range 16%-71.4%)[34].Other investigators have reported placebo response rate of 57% in IBS[35]. Placebo response rate correlated with factors such as frequency of intervention, methodological quality of study, duration of the study, the patient-practitioner interaction and the diagnosis treated[34,36-38]. Since the number of studies using placebo were small, we did not explore the response effect of placebo in the present study.

In the 22 trials that we reviewed, there were only 15 adverse events associated with HM. These were abdominal distention, constipation, abdominal pain, diarrhea, dizziness and hypersomnia, headache and nausea. However, no serious side effects or abnormalities of laboratory parameters such as liver function, renal function or haematological tests were reported with the treatment. Studies conducted in the West reported more adverse events than those from China. It is possible that because of the lack of rigorous monitoring, several adverse effects including serious events may not have been reported. Similarly, because of publication bias, adverse events related to herbal medicine may not be reported properly.

In summary, the use of HM for treating IBS is increasing worldwide. Most of the studies included in our review showed a beneficial effect on IBS symptoms. However, the methodological quality of the studies was variable, with 82% being of poor quality which may have overestimated the effectiveness of treatment. Although adverse events arising from the use of herbs were mild and infrequent, HM should be used with caution because of the reasons discussed above. It is therefore necessary to conduct Level I studies in order to provide evidence for Grade A recommendations[39] and clarify whether Chinese herbal medicines are reliable and safe therapy in IBS.

COMMENTS

Background

Irritable bowel syndrome (IBS) is a common functional bowel disorder that affects the patient's quality of life. No single treatment is reliably effective, and an increasing number of patients worldwide are seeking herbal medicines to cure their illness.

Research frontiers

We assessed the efficacy and adverse events of herbal medicines in IBS.

Innovations and breakthroughs

We made a comprehensive search of studies using herbal medicines for the treatment of IBS. The studies were analyzed to determine if herbal medicines are appropriate for IBS patients.

Applications

Based on this evaluation, we concluded that herbal medicines could not be reliably recommended because of methodological flaws in the studies. Further studies of better methodological quality should be carried out to determine the efficacy of herbal medicines in IBS.

Peer review

The authors explored the efficacy and safety of herbal medicines (HM) in the treatment of IBS. It was concluded that herbal medicines have therapeutic benefit in IBS.

Abstract

AIM: To investigate whether oral glutamine pretreatment prevents impairment of intestinal mucosal integrity during ischemia-reperfusion (I/R) in rats.

METHODS: The study was performed as two series with 40 rats in each. Each series of animals was divided into four groups. The first group was used as a control. Animals in the second group were only pretreated with oral glutamine, 1 g/kg for 4 d. The third group received a normal diet, and underwent intestinal I/R, while the fourth group was pretreated with oral glutamine in the same way, and underwent intestinal I/R. Intestinal mucosal permeability to ^{51}Cr-labeled EDTA was measured in urine in the first series of animals. In the second series, histopathological changes in intestinal tissue and plasma endotoxin levels were evaluated.

RESULTS: Intestinal I/R produced a significant increase in intestinal permeability, plasma endotoxin level and worsened histopathological alterations. After intestinal I/R, permeability was significantly lower in glutamine-treated rats compared to those which received a normal diet. However, no significant change was observed in plasma endotoxin levels or histopathological findings.

CONCLUSION: Although glutamine pretreatment seems to be protective of intestinal integrity, upon I/R injury, such an effect was not observable in the histopathological changes or plasma endotoxin level.

INTRODUCTION

Intestinal injury as a result of ischemia and subsequent reperfusion plays an important role in a variety of clinical conditions such as shock, and in those undergoing cardiovascular surgery[1]. In these situations, the small intestine may suffer ischemia of varying duration. Intestinal ischemia-reperfusion (I/R) disrupts intestinal mucosal integrity[2,3], and causes an increase in intestinal permeability[4,5] and bacterial translocation[6]. Plasma endotoxin level also increases after I/R[6]. All these have been increasingly recognized as potential causes of multi-system organ failure in critically ill patients[7-9].

Intestinal permeability is assessed non-invasively *in vivo* by measuring urinary excretion of orally administered test substances. Lactulose, various polymers of polyethylene glycol, ^{51}Cr-labeled EDTA and ^{99m}Tc diethylenetriaminepentaacetate are the most commonly used test substances. Test results may be influenced by a change in any of the pre- or post-mucosal factors, apart from intestinal permeability itself[10]. Measurement of intestinal permeability by some test substances may give an idea about some harmful factors such as microorganisms passing through the mucosal barrier, from the intestinal lumen to the systemic circulation. It is thought an increase in plasma endotoxin level is one of the responsible factors which may contribute to the clinical results of intestinal I/R injury[11]. Measurement of plasma endotoxin levels seems to be important in assessing the systemic effect of intestinal I/R.

Glutamine (Gln) is a non-essential amino acid, and the most abundant free amino acid in whole blood and the

intracellular amino acid pool[12]. It is an important respiratory fuel, and nucleotide precursor for the gastrointestinal tract[13]. Gln-supplemented parenteral nutrition protects rats against morphological and functional mucosal injury[14], and improves survival in animals after intestinal I/R[15]. Some other experimental studies have also shown that intraluminal injection of Gln protects the mucosa, and diminishes the accumulation of neutrophils in the lamina propria of the small bowel during I/R[16]. Generation of reactive oxygen intermediates (ROI) during reperfusion is thought to be one of the major causes of intestinal mucosal injury[17,18]. Gln is also essential for the synthesis of the intrinsic ROI scavenger glutathione. Therefore, this protective action may be due to augmentation of ROI scavenging in intestinal mucosa[19].

In this study, we aimed to investigate the effects of orogastric Gln pretreatment on intestinal mucosal permeability, plasma endotoxin level and intestinal histopathology during intestinal I/R injury in rats.

MATERIALS AND METHODS

Experimental design

The experiment was performed in female Wistar albino rats weighing 200-230 g. It was approved by the Ankara University Ethical Committee, and was conducted according to the European Community guidelines for the use of experimental animals. Animals were fed with their ordinary diet and allowed to drink water *ad libitum*. Owing to the time difference between urine collection and blood sampling, the study had to be completed in two series of experiments (Table 1).

Table 1 Characteristics of study groups

Groups	Measurement of intestinal permeability by ^{51}Cr-EDTA		Measurement of plasma endotoxin levels and histopathological changes	
	Gln	I/R	Gln	I/R
Ⅰ (Control)	–	–	–	–
Ⅱ (Gln)	+	–	+	–
Ⅲ (I/R)	–	+	–	+
Ⅳ (I/R and Gln)	+	+	+	+

Time-matched, sham-operated animals undergoing laparotomy and dissection of the SMA without occlusion served as controls (group Ⅰ). The Gln group (group Ⅱ) was pretreated with Gln (1 g/kg per day) by the orogastric route for 4 d[20,21]. Gln was prepared in 0.9% NaCl for daily use. Intestinal I/R group (group Ⅲ) underwent 1 h intestinal ischemia, and 1 h reperfusion. In the I/R and Gln group (group Ⅳ), I/R periods and Gln administration were the same as in Gln (Ⅱ) and I/R (Ⅲ) groups.

Induction of intestinal I/R

A rat model of transient mesenteric occlusion was used to obtain intestinal I/R. Rats were anesthetized with ketamine (80 mg/kg, im) and xylazine (10 mg/kg, im). Intestinal I/R was induced by 60 min occlusion, followed by 60 min reperfusion[22]. During the 2 h of the surgical procedure, animals were kept at room temperature, and given intraperitoneal fluid as 0.9% NaCl (10 mL/kg). The superior mesenteric artery (SMA) was exposed through a midline abdominal incision, and both this artery and the collateral branches coming from the celiac axis, and the inferior mesenteric artery were occluded with atraumatic vascular clamps (Vascu-Statt Ⅱ original No. 1001-532-3; Scanlan International, St Paul, MN, USA) for 1 h, followed by 1 h reperfusion. Existence of pallor and absence of pulsation ensured mesenteric occlusion during the ischemic period. Recovery of pulsation and pink color were controlled in each animal when the clamps were removed. The existence of intestinal I/R in this model was also confirmed in our laboratory by the appearance of pulses at the marginal arteries (direct vision of mesenteric circulation by microscopy), as well as by fluorescein angiography in preliminary experiments[23].

Measurement of intestinal mucosal permeability

Intestinal mucosal permeability was measured on the basis of urinary radioactivity levels following oral administration of ^{51}Cr-EDTA. ^{51}Cr-EDTA was employed as a well accepted marker of mucosal integrity[24,25]. After 60 min reperfusion, rats were given 5 μCi ^{51}Cr EDTA in 0.5 mL saline solution by the orogastric route. Urine samples were collected in metabolic cages for 6 h following the reperfusion period. During urine collection, animals did not receive any food; however, they were allowed to access tap water. The level of radioactivity in the urine samples of 500 μL was then determined by counting on a gamma counter (DPC Gambyt CR, Los Angeles. USA). The amount of ^{51}Cr-EDTA excreted in urine during 6 h was calculated as a percentage of the ingested dose.

Measurement of plasma endotoxin level

Plasma endotoxin level was measured by the colorimetric Limulus amebocyte lysate (LAL) test. The test was performed by using the Pyrochrome test kit (Pyroquant Diagnostik, Mörfelden, Germany). All glassware, solutions and surgical instruments used in the experiment were autoclaved at 121℃ for 15 min. The non-pyrogenicity of solutions was tested using the LAL test (Charles River Endosafe, Charleston, SC, USA).

Venous blood samples (3-4 mL) were collected using heparin-coated pyrogen-free disposable syringes. Platelet-rich plasma (PRP) was prepared from the blood by centrifugation at 150 g for 10 min. Fifty microliters of PRP was transferred into a polystyrene plastic tube and kept frozen at -80℃ until the assay. Frozen PRP samples were kept at room temperature for about 30 min before the assay. Fifty microliters of 0.18 mol/L NaOH was added to 50 μL PRP, and incubated at 37℃ for 5 min. Next, 50 μL 0.32 mol/L perchloric acid was added, and incubated at 37℃ for a further 10 min. To dissolve the formed precipitate, 100 μL 0.18 mol/L NaOH was added, and vortexed. Twenty-five microliters of the solution was transferred into sterile non-pyrogenic microplates (Pyroquant Diagnostik), and 25 μL 0.2 mol/L Tris/HCl buffer (pH 8.0) was added to the wells[26]. Finally, 50 μL pyrochrome test solution was added to all wells, and mixed for 30 s. Plates were incubated at 37℃. Optical density was read at 405 nm. Standard curves from 0.04 to 1.28 EU/mL were used to evaluate the concentration of endotoxin.

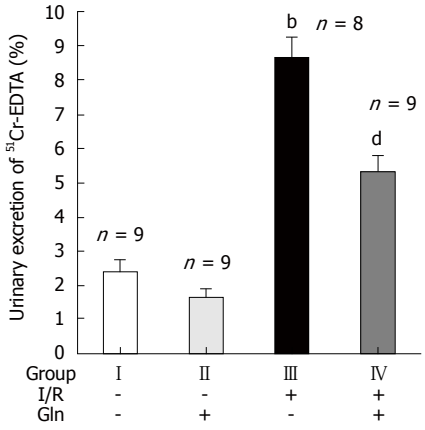

Figure 1 The effect of enteral Gln pretreatment (1 g/kg per day for four days) on intestinal permeability during I/R injury in rats. Intestinal I/R was induced by 60 min of occlusion, followed by 60 min of reperfusion. Changes in intestinal permeability were measured by urinary excretion of ^{51}Cr-EDTA after its oral administration in rats. Data are expressed as means ± SEM. $^{b}P < 0.001$ *vs* group Ⅰ, Ⅱ and Ⅳ; $^{d}P < 0.001$, *vs* groups Ⅰ, Ⅱ and Ⅲ.

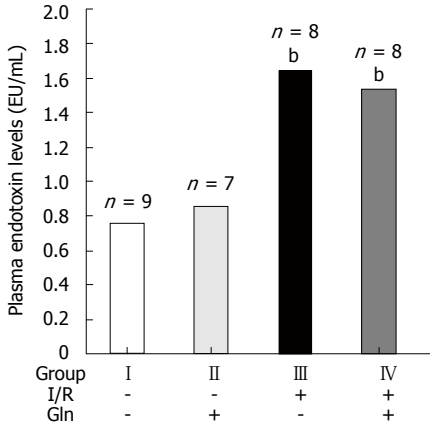

Figure 2 The effect of enteral Gln pretreatment (1 g/kg per day for four days) on plasma endotoxin levels during I/R injury in rats. Intestinal I/R was induced by 60 min of occlusion, followed by 60 min of reperfusion. Changes in plasma endotoxin levels were measured by LAL test. Data are expressed as medians. $^{b}P < 0.001$ *vs* groups Ⅰ and Ⅱ.

Results were calculated by using non-linear regression of a four-parameter logistic model.

Histopathological assessment of ileal tissues

After the collection of blood samples, ileal tissue samples, 10 cm proximal to the cecum, were harvested and evaluated for histopathological changes. Sections were stained with hematoxylin and eosin, and were examined by light microscopy by two pathologists in a blinded manner. Mucosal injury was scored on a scale from 0 to 5, as described by Chiu *et al*[2].

Statistical analysis

The SPSS program was used for statistical analysis. Comparison of the various protocols on the changes in intestinal permeability was made by one-way analysis of variance (ANOVA) following a Bonferroni post-hoc test. Changes in plasma endotoxin levels, and intestinal histopathology were determined using a Kruskal-Wallis test following a multiple comparison post-hoc test[27]. Data on changes in intestinal permeability were presented as means ± SEM. Data of plasma endotoxin levels, and intestinal histopathology were presented as medians. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of Gln pretreatment on intestinal permeability during I/R injury

To investigate the effect of intestinal I/R and Gln pretreatment on intestinal permeability, renal clearance of ^{51}Cr-EDTA was assessed. Statistically significant differences were detected in intestinal permeability in the I/R group when compared to the control group (8.6% ± 1.7% *vs* 2.4% ± 1.1%, $P < 0.001$). Gln pretreatment significantly lowered the increased intestinal permeability due to intestinal I/R (8.6% ± 1.7% *vs* 5.3% ± 1.3%, $P < 0.001$). There was no statistically significant difference in intestinal permeability between the control and Gln groups (Figure 1).

Effect of Gln pretreatment on plasma endotoxin level during I/R injury

In the second series of experiments, plasma endotoxin level was evaluated after intestinal I/R injury. There was a statistically significant difference in plasma endotoxin level between the control (group Ⅰ), and intestinal I/R injury (group Ⅲ) groups (0.76 EU/mL *vs* 1.64 EU/mL, $P < 0.001$). Enteral Gln pretreatment lowered the plasma endotoxin level (group Ⅳ), which was increased due to intestinal I/R injury (group Ⅲ) (1.54 EU/mL *vs* 1.64 EU/mL, $P = 0.48$). However, this decrease failed to reach statistical significance. There was no significant difference in plasma endotoxin levels between the control (group Ⅰ), and Gln (group Ⅱ) groups (0.76 EU/mL *vs* 0.86 EU/mL, $P = 0.59$) (Figure 2).

Effect of Gln pretreatment on intestinal histopathological changes during I/R injury

Intestinal histopathological changes were also evaluated in the second series of experiments. There was significant intestinal injury due to intestinal I/R when the control group was compared to the I/R group (0 *vs* 3, $P < 0.001$). Gln pretreatment did not significantly decrease intestinal injury compared to the I/R group (3 *vs* 2, $P = 0.389$). There was no significant difference in histopathological changes between the control and Gln groups (Figure 3).

DISCUSSION

Ischemia and subsequent reperfusion is one of the major causes of cell injury. The mechanisms of I/R injury are complex, and are likely to differ with respect to the duration of ischemia, the specific tissue involved, and the species studied[3,28]. The small intestine may experience ischemia and reperfusion during septic shock[29], hemorrhagic shock[30] or cardio-vascular surgery[31,32]. These clinical situations can result in some serious postoperative complications such as delay in anastomotic healing[33]. Intestinal mucosa is known to be sensitive to I/R injury. Its basal high rate of oxygen use renders the intestine relatively incapable of increasing oxygen transport in cases of hypoxic stress, and thus is

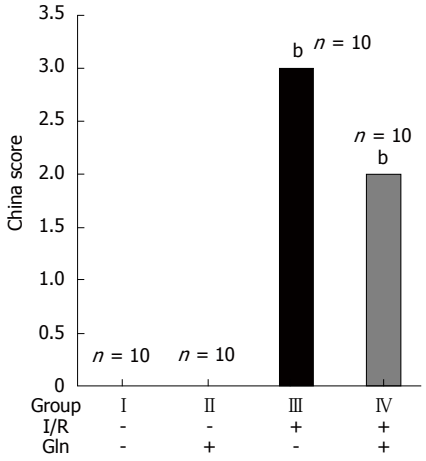

Figure 3 The effect of enteral Gln pretreatment (1 g/kg per day for four days) on histopathological changes during I/R injury in rats. Intestinal I/R was induced by 60 min of occlusion, followed by 60 min of reperfusion. Histopathological changes were scored by the "Chiu" intestinal ischemia scoring system. Data are expressed as medians. $^{b}P < 0.001$ *vs* groups Ⅰ and Ⅱ.

more susceptible to ischemic injury. Intestinal ischemia predisposes the gut to subsequent necrosis. Restoration of blood flow and reintroduction of oxygen after deprivation accelerates tissue injury[34]. Reperfusion of ischemic intestine may lead to more severe functional and morphological changes than the injury produced by ischemia itself[3]. Oxygen free radicals are thought to be generated during the reperfusion phase, with the addition of oxygen to previously ischemic tissues causing the formation of reactive oxygen species[35].

Intestinal I/R disrupts the functional intestinal mucosal barrier, which results in an increase in mucosal permeability to ^{51}Cr-EDTA[5]. The results of the present study also demonstrated a significant increase in intestinal permeability to ^{51}Cr-EDTA, due to intestinal I/R injury (Figure 1). An increase in mucosal permeability also promotes bacterial translocation[36]. Bacteria colonizing the gastrointestinal tract can translocate from the intestinal lumen to the bloodstream, and this may cause both systemic infection and/or infections in distant organs, such as mesenteric lymph nodes, spleen and liver[9]. Intestinal I/R injury does not only result in bacterial translocation, but also promotes an increase in plasma endotoxin level[6,37]. Our study also demonstrated a significant increase in plasma endotoxin level parallel to disruption of intestinal tissue in the intestinal I/R group when compared to the control group. Bacterial translocation and increased levels of endotoxin in the circulation may initiate a systemic inflammatory response, and the secretion and activation of inflammatory mediators, including cytokines[38] and metabolites of arachidonic acid[39]. An increase in intestinal permeability, and the deleterious effect of endotoxin in non-steroidal anti-inflammatory drug (NSAID)-induced ulcers has also been observed in experimental NSAID-induced enteropathy[40]. Gut decontamination decreases plasma endotoxin levels, and attenuates the systemic injury in intestinal I/R in rats[11]. A beneficial effect of antibiotics was also observed in NSAID-induced enteropathy[41,42].

The results of our study demonstrated that glutamine pretreatment prevented the increase in intestinal permeability during intestinal I/R, which has been reported previously[6,43]. However, glutamine pretreatment itself did not change the intestinal permeability significantly when compared to that in the control group. It has previously been shown that administration of glutamine-enriched nutritional support protects the bowel from injury due to abdominal irradiation[44], chemotherapy[45] and sepsis[46].

Glutamine pretreatment also caused a decrease in plasma endotoxin level, which did not reach statistical significance in our study. Contrary to our result, Wu *et al* have reported that an increase in plasma endotoxin level due to intestinal I/R can be reduced by Gln-supplemented total parenteral nutrition[6]. However, our study differed from that of Wu *et al* regarding the dose, route and timing of Gln administration. Furthermore, Gln was delivered in a total parenteral nutrition solution containing various amino acids and lipids in the study of Wu *et al*. Entrance of ^{51}Cr-EDTA and endotoxin to the systemic circulation from the intestinal lumen may be driven by different mechanisms, which may also explain differential effects of Gln on the above-mentioned parameters. The possibility that colonic epithelial cells contain specific transport systems for endotoxin has been reported[47]. Intestinal I/R disrupted intestinal tissue significantly. Gln pretreatment did not prevent histopathological disruption. It has also been observed that there is no correlation between histopathological alterations and intestinal permeability during recovery after hemorrhagic shock which is accepted as a model of intestinal I/R[30].

In conclusion, although Gln pretreatment reversed increased intestinal permeability, it did not prevent an increase in plasma endotoxin levels or histopathological alterations in intestinal I/R. Further studies are necessary to clarify the effects of different doses and administration periods of Gln on plasma endotoxin levels and histopathological changes in intestinal I/R.

COMMENTS

Background

Impairment of microcirculation during I/R in the gastrointestinal tract may diminish intestinal mucosal integrity and cause an increase in intestinal permeability. Increased plasma endotoxin levels after I/R are a major threat to many surgical patients. Different Gln treatments are known to have protective effects on mucosal integrity in intestinal I/R.

Research frontiers

Injury to the intestinal barrier results in an increase in permeability to intraluminal substances. Correlation between morphological alterations and the degree of increased intestinal permeability is uncertain. Recent studies have demonstrated that morphological alterations after intestinal mucosal injury cannot reflect the function of the intestinal barrier.

Innovations and breakthroughs

Recent studies suggest that gastrointestinal epithelial cells contain specific transport systems for lipopolysaccharides.

Applications

Intestinal permeability can be measured by many different *in vitro* and *in vivo* methods. Endotoxin passing through the intestinal mucosa into the circulation indicates loss of the intestinal barrier function. Measurement of plasma endotoxin level ensures the assessment of real pathogenic factors that arise in the systemic circulation as a result of intestinal mucosal injury.

Terminology

Bacterial translocation: indigenous bacteria that colonize the gastrointestinal tract can cross the epithelial mucosa to infect distant organs. Under normal conditions, the epithelial lining prevents the escape of these bacteria from the gut lumen. Intestinal permeability: relates to the properties and function of the epithelial barrier that enables unmediated passage of substances through the intestinal mucosa. The use of intestinal permeability tests for screening of intestinal disease and assessment of treatment efficacy, to understand the normal intestinal physiology and pathogenesis of disease, is described and reviewed. There is now a need for research into the basic mechanisms of regulatory control of the intestinal barrier function.

Peer review

Peer reviewers considered this to be a very interesting paper with a great deal of potential clinical benefit. These basic results may be of value in clinical applications in organ or cellular transplantion.

Abstract

AIM: To compare the results from computed tomography (CT) colonography with conventional colonoscopy in symptomatic patients referred for colonoscopy.

METHODS: The study included 227 adult outpatients, mean age 60 years, with appropriate indications for colonoscopy. CT colonography and colonoscopy were performed on the same day in a metropolitan teaching hospital. Colonoscopists were initially blinded to the results of CT colonography but there was segmental unblinding during the procedure. The primary outcome measures were the sensitivity and specificity of CT colonography for the identification of polyps seen at colonoscopy (i.e. analysis by polyp). Secondary outcome measures included an analysis by patient, extracolonic findings at CT colonography, adverse events with both procedures and patient acceptance and preference.

RESULTS: Twenty-five patients (11%) were excluded from the analysis because of incomplete colonoscopy or poor bowel preparation that affected either CT colonography, colonoscopy or both procedures. Polyps and masses (usually cancers) were detected at colonoscopy and CT colonography in 35% and 42% of patients, respectively. Of nine patients with a final diagnosis of cancer, eight (89%) were identified by CT colonography as masses (5) or polyps (3). For polyps analyzed according to polyp, the overall sensitivity of CT colonography was 50% (95% CI, 39%-61%) but this increased to 71% (95% CI, 52%-85%) for polyps $\geqslant$ 6 mm in size. Similarly, specificity for all polyps was 48% (95% CI, 39%-58%) increasing to 67% (95% CI, 56%-76%) for polyps $\geqslant$ 6 mm. Adverse events were uncommon but included one colonic perforation at colonoscopy. Patient acceptance was high for both procedures but preference favoured CT colonography.

CONCLUSION: Although CT colonography was more sensitive in this study than in some previous studies, the procedure is not yet sensitive enough for widespread application in symptomatic patients.

INTRODUCTION

CT colonography is a newer radiological procedure that might be suitable for screening for colorectal lesions in symptomatic and asymptomatic individuals[1-6]. An obvious consideration is the sensitivity, specificity and accuracy of the investigation in different patient populations. A second consideration is the frequency of colorectal abnormalities on CT colonography that will require subsequent colonoscopy. Ideally, this percentage should be relatively low. Yet a third consideration is the cost of the procedure in money and time and the frequency of minor and more serious complications.

In previous studies that have compared CT colonography

with colonoscopy, the sensitivity, specificity and accuracy of CT colonography has shown substantial variation. In one large screening study in asymptomatic adults, CT colonography had a similar sensitivity to colonoscopy for the detection of polyps greater than 6 mm in diameter[7]. In contrast, studies in symptomatic patients have shown a sensitivity for the detection of cancers of approximately 75% and lower sensitivities for the detection of polyps[8,9]. This variation may reflect differences in bowel preparation, colonic distension, CT scanners, collimation, software, scan evaluation and use of fecal tagging[10-13]. In this study, the comparison of CT colonography with colonoscopy included the routine use of hyoscine butylbromide (Buscopan) during CT colonography, unblinding of the results of CT colonography during colonoscopy and repeat colonoscopy for discrepant findings.

MATERIALS AND METHODS

The study included 227 patients with appropriate indications for colonoscopy. Symptoms included rectal bleeding in 77 patients, abdominal pain in 56 and a change in bowel habit in 41. In addition, some patients had a family history of colorectal cancer (51), previous colonic polyps (43) and a recent positive fecal occult blood test (30). Exclusion criteria included inflammatory bowel disease and major coexisting medical disorders. Patients had a mean age of 60 years with an age range of 25 to 85 years. There were similar numbers of men (51%) and women (49%). All patients gave informed written consent and the study was approved by the local institutional Ethics Committee in 2003.

CT colonography and colonoscopy were performed on the same day. The type of bowel preparation was determined by the colonoscopist but most patients had Picolax, Colonlytely or both preparations. CT colonography was performed with a Toshiba multislice helical CT scanner with 2 mm collimation that was reconstructed into intervals of 1.0-1.5 mm. Colonic distension was achieved by insufflation of carbon dioxide and the use of intravenous Buscopan (20 mg). Patients were scanned in both supine and prone positions during a single breath hold (average scanning time, 25 s). With this technique, the radiation dose is lower than that of a barium enema X-ray. Images obtained with a Compaq® PC using ColonScreen (Voxcar Ltd., Edinburgh) were read in 2-dimensional format with use of a targeted 3-dimensional format when necessary. The CT images were reported by one of three radiologists within 60 min of completion of the scan. All had received previous training in CT colonography and had been reporting CT colonography on a routine basis prior to the study. The adequacy of the bowel preparation was recorded and the presence and size of polyps and masses were reported for eight segments (caecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid colon and rectum).

Colonoscopy was performed by a consultant gastroenterologist or colorectal surgeon. Patients were sedated with intravenous fentanyl and midazolam, sometimes supplemented with propofol. The colonoscope was passed to the caecum and then slowly withdrawn to the splenic flexure. At that point, CT colonography findings in the right colon were made available to the colonoscopist and colonoscopy was repeated if there were discrepant results. This also applied for CT colonography findings in the left colon after withdrawal of the colonoscope to the rectum. Masses and polyps detected at colonoscopy were reported in eight segments as above.

The quality of the bowel preparation was recorded on a scale of 1-5 using the system of Yee *et al*[14]. Patient discomfort with both CT colonography and colonoscopy were assessed by a questionnaire soon after CT colonography and during recovery after colonoscopy. Patients also completed a similar questionnaire 1 wk after the procedures that included a question on preference for CT colonography or colonoscopy. All adverse events were recorded.

Statistical analysis

Comparisons of CT colonography with colonoscopy were analyzed according to polyp and according to patient using Stata Version 9. In the more important analysis according to polyp, confidence intervals were produced using logistic regression and reflect an allowance for clustering of polyps within patients. Polyps were judged to be identical if they were located in the same or adjacent segments and if they were of similar size (± 50%). In the analysis according to patient, exact confidence intervals were calculated by the Stata contributed program "diagt". Patients with at least one polyp identified by colonoscopy were a true positive if they had at least one polyp at CT colonography. It was not necessary for the lesions to be assessed as identical.

RESULTS

CT colonography was compared with colonoscopy in 202 of 227 patients. Twenty-five patients (11%) were excluded from the analysis because of incomplete colonoscopy or poor bowel preparation that largely affected CT colonography. Polyps and masses were detected at CT colonography and colonoscopy in 42% and 35% of patients, respectively.

Detection of cancer

Of the 9 patients with a final diagnosis of cancer, 8 were diagnosed at colonoscopy and confirmed by biopsy while 1 patient had cancer within a polyp that was diagnosed histologically. Cancers were located in the sigmoid colon (3), rectum (3), ascending colon (2) and splenic flexure (1). All of these lesions were seen at CT colonography but only 5 were considered as probable cancers. The remaining lesions were interpreted as polyps (3) and fecal material (1). Three additional patients were diagnosed with probable cancer at CT colonography but only 1 had a corresponding polyp at colonoscopy. Polyps and cancers detected at both CT colonography and colonoscopy are shown in Figure 1.

Detection of polyps

At colonoscopy, 163 polyps were detected in 69 patients. The most common sites were the sigmoid colon (30%), rectum (27%), transverse colon (22%) and ascending colon (12%). Histologically, the majority of polyps were

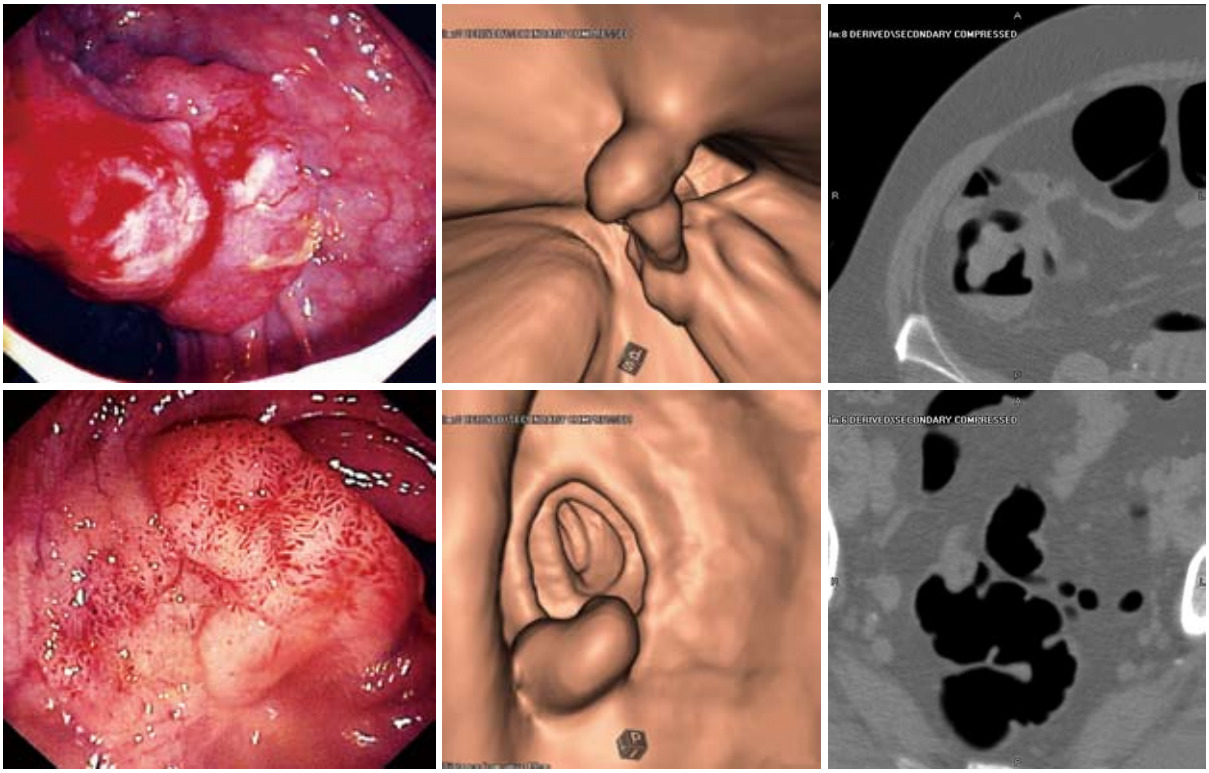

Figure 1 The figure shows the endoscopic appearance and images at CT colonography (3-D and 2-D) for 2 colonic lesions. The upper panel shows a cancer in the ascending colon while the lower panel shows a large tubulovillous adenoma at the rectosigmoid junction.

adenomatous (67%) while the remainder were hyperplastic, serrated or unspecified. In the analysis according to polyp, the sensitivity, specificity and accuracy of CT colonography for the detection of polyps of various sizes is shown in Table 1. The sensitivity for all polyps was 50% but this increased to 71% for polyps $\geqslant$ 6 mm in size. In the analysis according to patient, CT colonography had an overall sensitivity, specificity and accuracy of 62% (95% CI, 50%-74%), 76% (95% CI, 67%-83%), and 71% (95% CI, 64%-77%), respectively. For polyps $\geqslant$ 6 mm analyzed by patient, sensitivity, specificity and accuracy were 78% (95% CI, 58%-91%), 82% (95% CI, 76%-88%) and 82% (95% CI, 76%-87%). In relation to the sensitivity of colonoscopy, one polyp was detected by CT colonography that was missed at the initial colonoscopy but detected by repeat colonoscopy.

Extracolonic findings

Data on extracolonic findings were available in 225 of 227 patients (99%). One patient had a renal mass and was subsequently diagnosed with renal cell cancer. Other findings of potential clinical significance included renal stones (7%), gallbladder stones (6%), adrenal masses (4%), ovarian cysts (3%), non-cystic liver lesions (2%), small aortic aneurysms (2%), lung nodules (1%) and calcific chronic pancreatitis (1%).

Bowel preparation at CT colonography

Only 33% of patients had a clean bowel (grade 1) while 62% had "pools of liquid" (grade 2) and 5% had "solid and liquid" or "collections of solid feces" (grades 3 and 4). Patients categorized as "impossible" (grade 5) were excluded from the study.

Adverse events

These were reported by 4 patients after CT colonography and included nausea (2), dizziness (1) and significant abdominal pain (1). Adverse events after colonoscopy included rectal bleeding (1) and moderate or severe abdominal pain (2). One of these patients was subsequently diagnosed with colonic perforation and treated by resection of the sigmoid colon. There were no postoperative complications. Other recorded complications during colonoscopy included hypoxia (1), hypertension (1) and bradycardia (1).

Patient acceptance and preference

Selected results from a questionnaire administered 1 wk after the procedures are included in this report. The questionnaire was completed by 195 of 202 patients (96%). The experience of CT colonography and colonoscopy was "better than expected" or "as expected" in 84% and 94% of patients, respectively. Overall, 87% of patients were "very satisfied" or "satisfied" with CT colonography while 90% were "very satisfied" or "satisfied" with colonoscopy. Furthermore, 89% of patients indicated that they "definitely would" or were "most likely" to have repeat CT colonography compared to 96% for colonoscopy. These differences were not statistically significant. However, when asked to choose between CT colonography and colonoscopy for a repeat procedure, 61% chose CT colonography and 39% chose colonoscopy ($P = 0.005$, Chi-square test).

DISCUSSION

CT colonography, also called virtual colonoscopy, is an

Table 1 Sensitivity, specificity and accuracy of CT colonography when analyzed by polyp (%)

Polyp size	*n*	Sensitivity	Specificity	Accuracy
< 6 mm	125	42 (30-55)	63 (52-73)	54 (46-62)
6-10 mm	27	78 (52-92)	75 (65-83)	75 (66-83)
> 10 mm	11	62 (39-81)	86 (77-92)	82 (73-89)
All polyps	163	50 (39-61)	48 (39-58)	49 (42-56)
⩾ 6 mm	38	71 (52-85)	67 (56-76)	68 (59-76)

Values in brackets are 95% confidence intervals that reflect an allowance for clustering of polyps within patients.

evolving technology that may have a role in screening for colorectal polyps and cancer. However, using colonoscopy as the gold standard, concordance between the two investigations has varied widely in different studies. In relation to the patient population, better results have been achieved in screening studies in asymptomatic individuals than in patients with symptoms. This may reflect the younger age and better health of asymptomatic individuals who are more able or more motivated to comply with bowel preparation procedures. In any event, the quality of the bowel preparation is more important for CT colonography than for colonoscopy. In the present study, the adequacy of the bowel preparation was recorded by the reporting radiologist. Only 33% of patients had a "clean bowel" while the remainder had either "pools of liquid" (62%) or "solid and liquid" (5%). Whether bowel images can be improved by modified preparation protocols[15] or by "electronic cleansing"[16] remains unclear. Intravenous Buscopan is not routinely used during CT colonography but does enhance colonic distension[17].

Other factors that may contribute to variable results from CT colonography include the type and settings of CT scanners, the use of fecal tagging, the mode of imaging and the experience of the reporting radiologist. In one meta-analysis[10], better results were achieved with scanners with multiple detectors, thinner collimation and the standard use of three-dimensional ("fly-through") technology. Fecal tagging using oral contrast did not appear to be a relevant factor and has the potential to impair the quality of colonoscopy. When images are reported by different radiologists, variation has ranged from "minimal"[7] to "substantial"[18], apparently independent of previous experience with the technique. There are also potential biases in comparative studies of this type with over-reporting in the investigation under study, specifically CT colonography.

The experience of both CT colonography and colonoscopy was widely accepted by patients. Although responses to specific questions about each technique showed a trend in favour of colonoscopy, more patients chose CT colonography when given a choice between the two procedures. These responses can be influenced by the structure of the questions but might also reflect real concerns about sedation, potential complications and the degree of "invasiveness". In this study, complications were uncommon but one patient had a colonic perforation that required surgery. This complication has an overall frequency of approximately 1 in 1000 colonoscopies[19,20] but can also occur after CT colonography, perhaps with a frequency of 1 in 1700 procedures[21].

In this study, CT colonography was more sensitive than in previous studies in symptomatic patients[8,9]. For example, CT colonography identified cancers as either masses or polyps in 8 of 9 patients (89%) in this study and in 6 of 8 (75%)[8] and 7 of 9 (78%)[9] in previous studies. For polyps analyzed by polyp, the overall sensitivity for detection of polyps was 50% in this study increasing to 71% for polyps 6 mm in size or greater. In previous studies, sensitivities for polyp detection (⩾ 6 mm) were reported as 32%[8] and 47%[9]. The possibility that inaccurate localisation of polyps at colonoscopy contributed to low sensitivity rates seemed unlikely as sensitivities for polyps ⩾ 6 mm analyzed by patient were only marginally higher (78%) than those analyzed by polyp (71%).

Criteria for the introduction of new technologies into clinical practice are difficult to establish. For example, issues such as sensitivity and specificity need to be considered in relation to direct and indirect costs, complications and the proportion of patients who will be referred for further investigation. In the present study, CT colonography identified polyps or masses in 42% of patients. This is not a cost-effective option if all patients with abnormalities are referred for colonoscopy[22]. However, CT colonography becomes increasingly cost-effective if colonoscopy is restricted to lesions that are ⩾ 6 mm or ⩾ 10 mm in size. Such recommendations, if introduced, would invite a new series of questions related to the frequency of repeat scans and the mutagenic effects of accumulating doses of radiation[23-25]. Although small polyps have a low frequency of features of advanced neoplasia, there is only limited data on the natural history of small polyps and the identification of those polyps that will eventually evolve into cancer[7,26].

Although CT colonography is not yet ready for widespread clinical application, it is likely that results will improve with better bowel preparation, technical developments and increasing familiarity with the technique. Results from this study highlight the importance of bowel preparation although, in the future, it may be possible to reliably differentiate fecal material from polyps using fecal tagging[10], "electronic cleansing" of colonic fluid[16] or contrast-enhanced studies[27]. Other helpful developments may also include new fecal subtraction algorithms[28], workstation modifications to facilitate polyp detection[29], improved software and new training programs for radiologists[30].

ACKNOWLEDGMENTS

We are grateful for support from Professor B Kearney. This study was funded by the South Australian Department of Health. A preliminary protocol was developed by Dr. R Davies and Dr. F Cheok in 2003.

COMMENTS

Background

It is not yet clear whether computed tomography (CT) colonography will be widely adopted for the detection of colonic polyps and cancer. Current issues include

the sensitivity and specificity of the investigation, direct and indirect costs and the longer-term effects of radiation.

Research frontiers

This study indicates that residual liquid and solid material after bowel preparation limits the accuracy of the procedure. Whether this can be overcome by modified laxative preparations, fecal tagging or "electronic" bowel cleansing remains unclear.

Innovations and breakthroughs

In this study in symptomatic patients, CT colonography was more sensitive for the detection of polyps than in some previous studies. This study included the routine use of intravenous Buscopan but the study was not designed to determine whether this modification improved either sensitivity or specificity.

Applications

There is widespread interest in screening for colon cancer in symptomatic and asymptomatic individuals. Colonography, either using CT or magnetic resonance imaging, may play a central role if there are further improvements in sensitivity and specificity.

Peer review

The paper by Roberts-Thomson IC *et al* is interesting. The selection of patients, sample size and the overall design of the study are fair, the results adequate to provide clinical evidence and to support valid conclusions.

Abstract

AIM: To evaluate the therapeutic effect of alanyl-glutamine dipeptide (AGD) in the treatment of severe acute pancreatitis (SAP) in early and advanced stage.

METHODS: Eighty patients with SAP were randomized and received 100 mL/d of 20% AGD intravenously for 10 d starting either on the day of (early treatment group) or 5 d after (late treatment group) admission. Groups had similar demographics, underlying diseases, Ranson score, Acute Physiology and Chronic Health Evaluation Ⅱ (APACHE Ⅱ) score, and Balthazar's computed tomography (CT) score at the beginning of the study and underwent similar other medical and nutritional management.

RESULTS: The duration of acute respiratory distress syndrome (2.7 ± 3.3 d *vs* 12.7 ± 21.0 d, $P < 0.01$), renal failure (1.3 ± 0.5 d *vs* 5.3 ± 7.3 d, $P < 0.01$), acute hepatitis (3.2 ± 2.3 d *vs* 7.0 ± 7.1 d, $P < 0.01$), shock (1.7 ± 0.4 d *vs* 4.8 ± 3.1 d, $P < 0.05$), encephalopathy (2.3 ± 1.9 d *vs* 9.5 ± 11.0 d, $P < 0.01$) and enteroparalysis (2.2 ± 1.4 d *vs* 3.5 ± 2.2 d, $P < 0.01$) and hospital stay (28.8 ± 9.4 d *vs* 45.2 ± 27.1 d, $P < 0.01$) were shorter in the early treatment group than in the late treatment group. The 15-d APACHE Ⅱ score was lower in the early treatment group than in the late treatment group (5.0 ± 2.4 *vs* 8.6 ± 3.6, $P < 0.01$). The infection rate (7.9% *vs* 26.3%, $P < 0.05$), operation rate (13.2% *vs* 34.2%, $P < 0.05$) and mortality (5.3% *vs* 21.1%, $P < 0.05$) in the early treatment group were lower than in the late treatment group.

CONCLUSION: Early treatment with AGD achieved a better clinical outcome in SAP patients.

INTRODUCTION

Acute pancreatitis (AP) contributes to thousands of annual hospital admissions, of which severe acute pancreatitis (SAP) accounts for 10%-20%[1-3]. Despite considerable improvement in the treatment, the mortality of SAP still ranges between 10%-15%[2-5].

The course of SAP tends to be prolonged and the patients usually are hypermetabolic and high protein catabolic due to systemic inflammatory response syndrome (SIRS) induced by acute local inflammatory process and subsequent vital-organ dysfunction[6]. Thus, if nutritive support is not appropriately administrated to match rapidly increased demand in the treatment of SAP, the patients consequently come down with metabolic disorder and nutrition deficiency, which is considered to increase mortality due to impaired immune function, increased risk of infections and intractable vital-organ failure.

In recent years, research showed a conditional deficiency of glutamine would be an independent predictive factor for a poor outcome and its correction improved survival by restoring cellular protective mechanisms, improving immune function and resistance of the gut barrier to hypoperfusion, metabolic stress and subsequent bacterial translocation, and decreasing the risk of infection in critical illness[7-10]. Since free glutamine is instable in solution, intravenous administration is limited[7]. Alanyl-glutamine

dipeptide (AGD), however, can be taken *via* vein and hydrolyzed into alanine and glutamine in circulation as a substitute[7]. Presently AGD supplement in parenteral nutrition is a worth-trying approach and an evidence-based recommendation in the management of SAP[11], but there has been no study describing an optimal protocol of AGD administration. Our study aims to evaluate the favorable effects of early supplement with AGD in the treatment of SAP.

MATERIALS AND METHODS

Patient selection

In this study, the diagnostic criteria[12] formulated for SAP at the Bangkok World Congress of Gastroenterology 2002 in Thailand was employed. All of the patients, who had been diagnosed with SAP and admitted to our hospital within 72 h after onset of symptoms, were included. The patients who had histories of trauma, operation or prior treatment with AGD were excluded, and the patients who died within 5 d after admission were also rejected.

Methods

In this study, 80 identified SAP patients who were admitted to West China Hospital of Sichuan University from May 2004 to March 2005 were randomized and treated with 100 mL/d of 20% AGD intravenous infusion for 10 d (SSPC No. SF1505) starting either on the day of (early treatment group) or 5 d after (late treatment group) admission.

Upon admission, all of the patients were treated with intensive care, oxygen inhalation, intermittent gastrointestinal decompression, and fluid infusion. Prophylactic antibiotics were used for 7-14 d. H2 receptor antagonist or proton pump inhibitor agent was given for 7 d; the acid-base balance and the electrolyte balance were maintained. When patients developed respiratory failure, the respirator was employed to assist respiration. When hypoalbuminaemia occurred, 20% human serum albumin 50 mL was used daily until the serum albumin was recovered to normal, and fat emulsion was also given for 14 d.

The following parameters were measured: 24-h APACHE Ⅱ score and initial Balthazar's CT score, 15-d APACHE Ⅱ score, incidence and duration of complications including acute respiratory distress syndrome (ARDS), renal failure, acute hepatitis, encephalopathy and enteroparalysis, infection rate, hospital stay, operation rate and mortality.

Hospital stay: Hospital stay was defined as the duration from hospital admission to discharge. The duration of hospital rehabilitation due to cholecystectomy was not taken into account in this study, although cholecystectomy was regarded as a promising treatment to prevent recurrent pancreatitis.

Operation rate: Surgical intervention was performed if infected pancreatic necrosis, or pancreatic abscess, or (per)pancreatic hemorrhage or (per)pancreatic pseudocyst was identified or if the patient did not respond to intensive care treatment.

Table 1 Baseline in the two groups

Baseline	Late treatment group (n = 38)	Early treatment group (n = 38)
Sex (Male/Female)	21/17	22/16
Age (mean ± SD, yr)	47.5 ± 12.6 (22-76)	46.9 ± 12.8 (27-74)
Etiology, n (%)		
Gallstones	20 (52.6)	16 (42.1)
Alcohol abuse	2 (5.3)	7 (18.7)
Hyperlipidemia	7 (18.4)	9 (23.7)
Idiopathic	9 (23.7)	6 (15.8)
48-h Ranson score (mean ± SD)	4.5 ± 1.7	4.8 ± 1.6
24-h APACHE Ⅱ score (mean ± SD)	10.8 ± 3.5	10.2 ± 3.1
CT score (mean ± SD)	5.8 ± 2.3	5.9 ± 2.4

APACHE Ⅱ: Acute Physiology and Chronic Heath Evaluation Ⅱ; CT: Computed Tomography.

Statistical analysis

Data were expressed as mean ± SD or percentage. Data in normal distribution was analyzed using t test; data in non-normal distribution was analyzed using Wilcoxon rank sum test. Categorical data was analyzed using Chi-square test. $P < 0.05$ was considered statistically significant.

The medical ethics committee of West China Hospital at Sichuan University approved this study. All patients gave their informed consent, and the study was conducted according to the recent principles of the Declaration of Helsinki (World Medical Association, 2000).

RESULTS

Four patients including 1 death within 24 h after admission and 1 death on the 5th day after admission in the early treatment group and 2 deaths within 24 h in the late treatment group withdrew from the study, which were not included in any of the analyses. Therefore, there were 38 patients in the early treatment group and 38 in the late treatment group.

Baseline

There were no statistical differences between the two groups in sex, age and etiology ($P > 0.05$, Table 1), and in the 48-h Ranson score, 24-h APACHE Ⅱ score and CT score in the initial stage of hospitalization ($P > 0.05$, Table 1).

Complications

There were no statistical differences between the two groups in the incidences of ARDS, renal failure, shock, acute hepatitis, encephalopathy and enteroparalysis ($P > 0.05$), but the duration of ARDS, renal failure, acute hepatitis, encephalopathy and enteroparalysis was shorter in the early treatment group than in the late treatment group ($P < 0.01$), and the duration of shock was also shorter in the early treatment group ($P < 0.05$) (Table 2).

Prognosis

The 15-d APACHE Ⅱ score was lower in the early treatment group than in the late treatment group ($P < 0.01$).

Table 2 Incidence and duration of complications in the two groups (*n*, %) (mean ± SD)

Complications	Late treatment group (*n* = 38)		Early treatment group (*n* = 38)	
	Cases (%)	Duration (d)	Cases (%)	Duration (d)
ARDS	18 (47.4)	12.7 ± 21.0	21 (55.3)	2.7 ± 3.3[b]
Renal failure	9 (23.7)	5.3 ± 7.3	7 (18.4)	1.3 ± 0.5[b]
Acute hepatitis	19 (50.0)	7.0 ± 7.1	17 (44.7)	3.2 ± 2.3[b]
Shock	6 (15.8)	4.8 ± 3.1	9 (23.7)	1.7 ± 0.4[a]
Encephalopathy	4 (10.5)	9.5 ± 11.0	4 (10.5)	2.3 ± 1.9[b]
Enteroparalysis	27 (71.1)	3.5 ± 2.2	29 (76.3)	2.2 ± 1.4[b]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* late treatment group; ARDS: acute respiratory distress syndrome.

Table 3 Fifteen-day APACHE Ⅱ score, hospital stay (d), infection, operation and mortality in the two groups

Prognosis	Late treatment group (*n* = 38)	Early treatment group (*n* = 38)
15-d APACHE Ⅱ score (mean ± SD)	8.6 ± 3.6	5.0 ± 2.4[b]
Hospital stay (d, mean ± SD)	45.2 ± 27.1	28.8 ± 9.4[b]
Infection, *n* (%)	10 (26.3)	3 (7.9)[a]
Operation, *n* (%)	13 (34.2)	5 (13.2)[a]
Deaths, *n* (%)	8 (21.1)	2 (5.3)[a]

[a]$P < 0.05$, [b]$P < 0.01$.

The infection rate, operation rate and mortality were also lower in the early treatment group ($P < 0.05$). The hospital stay was shorter in the former group than in the latter group ($P < 0.01$) (Table 3).

DISCUSSION

In the early stage of SAP, the patients tend to be hypermetabolic due to occurrence of SIRS and subsequent multiple organ dysfunction syndromes (MODS), resulting in the greatly increased demand for nutrition[13-15]. In the late stage, the demand for nutrition increases continuously due to infection, resulting from intestinal bacterial translocation and immunosuppression. Thus, insufficient nutritive support inevitably leads to nutrition deficiency in SAP patients[16].

When a nutritional deficiency arises in critical illness including SAP, glutamine, which is very abundant and readily synthesized under most situations, tends to be a conditional depletion[17]. The low concentration of plasma glutamine was found to be an independent predictive factor for a poor outcome in critical illness[18].

AGD was shown to improve clinical outcome of SAP[11,16]. In this study, we treated SAP patients with 100 mL/d of 20% AGD infusions intravenously for 10 d to compare the effects of AGD between the two groups and study its optimal protocol. The baseline data showed no significant difference between the two groups ($P > 0.05$). APACHE Ⅱ score, the parameter for predicting and monitoring the development of local and systemic complications of SAP, was evaluated on the 15th day after admission, which was lower in the early treatment group than in the late treatment group ($P < 0.01$). The duration of ARDS, renal failure, acute hepatitis, shock, encephalopathy and enteroparalysis were also shorter in the early treatment group than in the late treatment group, as was lower mortality ($P < 0.05$). These might result from a possible consequence of early suppression of inflammatory response and restoring cellular protective mechanisms by early AGD supplementation, which is associated with mediating anti-inflammatory/immunologic factors[19] and antioxidant/inducible nitric oxide synthase (iNOS)[20], decreasing the level of TNF-alpha and interleukin-8 in mononuclear cell[21,22] and C-reactive protein in serum[23]. In this study, the hospital stay was also shorter in the early treatment group ($P < 0.05$), which might be correlated to the shorter duration of complications.

Intestinal tract, the greatest "storeroom" of microorganisms, also is one of the most possible injury organs besides pancreas itself[24]. Intestinal bacterial translocation resulting from the impaired mucosal barrier, microorganism barrier, chemical barrier and immune barrier is an early event[25] and the main cause of infection in SAP[26]. The infection rate of SAP was 30%-50%[27-30], leading to a mortality of 40%-80%[31,32]. Glutamine is used as a major fuel and nucleotide substrate for rapidly dividing cells such as intestinal mucosal cells and the gut-associated immunocytes[33-37]. Glutamine can prevent atrophy of the intestinal epithelial cells through HSP 70 generation[38] and improve the intestinal immune barrier[39-41]. A meta-analysis by Novak F *et al*[42] revealed that glutamine could reduce the infectious morbidity (RR 0.84, 95% CI: 0.68-1.03) and mortality (RR 0.76, 95% CI: 0.56-0.98) in critical illness. Our study showed that early treatment with AGD in SAP patients could shorten the duration of enteroparalysis ($P < 0.01$) and reduce the infection rate ($P < 0.05$). This result may indicate that early nutrition with AGD in SAP patients could timely protect and restore the function of intestinal tract, shorten the duration of enteroparalysis, lower the risk of bacterial translocation, thus reducing the infection rate.

In conclusion, early treatment with AGD yields a better clinical outcome in SAP patients by reducing the duration of vital-organ dysfunction, decreasing the risk of infection and operation, and lowering the mortality.

COMMENTS

Background

Severe acute pancreatitis (SAP) is a hypermetabolic disease. Appropriate nutrition support is essential to the management of SAP. In recent years, the supplement of glutamate, the most abundant free amino acid playing vital roles in the body, has been shown to improve survival rate. Presently, the supplement of alanyl-glutamine dipeptide, as a substitute of glutamate which is stable in circulation, is a promising and worth-trying approach.

Research frontiers

Besides nutritional management of SAP, restoring an optimized immune system plays a role in improving survival rate. Previous pilot studies of alanyl-glutamine dipeptide (AGD) supplementation in nutritive support have revealed good outcome by restoring cellular protective mechanisms, improving the immune function and lowering the infection rate. Although this treatment was recommended by evidence-based studies, this treatment principle has not yet been systematically applied and further study is still needed in this field.

Innovations and breakthroughs

The optimal protocol for the AGD treatment is not yet available in published

studies. Early AGD treatment in SAP is a breakthrough in this study, which reveals for the first time that early AGD treatment achieved a better clinical outcome in SAP patients.

Applications

As free glutamine is instable in solution, intravenous administration is limited. AGD, however, can be given *via* vein and hydrolyzed into alanine and glutamine in circulation as a substitute. This study showed that early treatment with AGD achieved a better clinical outcome in SAP patients. This treatment can be applied in the management of SAP patients.

Terminology

Severe acute pancreatitis is a common acute abdominal disorder, characterized by various degrees of necrosis of pancreatic parenchyma together with local and systemic complications, such as SIRS and multiple organ dysfunction syndromes. Alanyl-glutamine dipeptide is an important component of parenteral nutrition ingredients with its molecular formula ingredient as N (2)-L-alanyl-L-glutamine. SIRS is a clinical response to one of the nonspecific insults caused by ischemia, inflammation, trauma, infection, or a combination of several insults, which was defined by a journal in 1992 and described as occurrence of two or more clinical symptoms of fever or hypothermia, tachypnea, tachycardia, and leukocytosis.

Peer review

AGD supplementation has been shown to be effective by previous studies. In this pilot study, the authors focused on the clinical effects of early treatment with AGD comparing with late treatment, which shows early AGD treatment indicates a better clinical outcome. Further researches are needed to explore its mechanism.

Abstract

AIM: To compare the clinical performance of a real-time PCR assay with the COBAS Amplicor Hepatitis B Virus (HBV) Monitor test for quantitation of HBV DNA in serum samples.

METHODS: The reference sera of the Chinese National Institute for the Control of Pharmaceutical and Biological Products and the National Center for Clinical Laboratories of China, and 158 clinical serum samples were used in this study. The linearity, accuracy, reproducibility, assay time, and costs of the real-time PCR were evaluated and compared with those of the Cobas Amplicor test.

RESULTS: The intra-assay and inter-assay variations of the real-time PCR ranged from 0.3% to 3.8% and 1.4% to 8.1%, respectively. The HBV DNA levels measured by the real-time PCR correlated very well with those obtained with the COBAS Amplicor test (r = 0.948). The real-time PCR HBV DNA kit was much cheaper and had a wider dynamic range.

CONCLUSION: The real-time PCR assay is an excellent tool for monitoring of HBV DNA levels in patients with chronic hepatitis B.

INTRODUCTION

It is estimated that 350 million individuals are chronically infected with hepatitis B virus (HBV) worldwide, and about one-third of these live in China[1]. HBV infection can cause chronic hepatitis, cirrhosis and hepatocellular carcinoma[2]. Among patients with active viral replication, cirrhosis will develop in 15%-20% within 5 year[3], and 70-90 percent of cases of hepatocellular carcinoma occur against a background of cirrhosis[4]. Quantitation of HBV DNA in serum or plasma has been an important tool in identifying individuals with active hepatitis B, to monitor the efficiency of antiviral treatment, and to predict whether the treatment will be successful[5-9].

Several commercial molecular assays have been developed for quantitation of HBV DNA in serum or plasma samples. One of these assays is the COBAS Amplicor HBV Monitor, which is based on the amplification of DNA targets by the use of HBV-specific primers. Other methods, such as the VERSANT HBV DNA 3.0 assay, which is based on branched-DNA signal amplification, and Hybrid Capture Ⅱ, which is based on hybridization of a chemiluminescent probe, are also routinely used in diagnostic laboratories[10,11]. However, the costs of these assays are too high to be used in developing countries such as China, and in these countries the HBV burden is much heavier than in developed countries.

Recently, quantitative real-time PCR has been used to detect and quantify HBV levels in serum or plasma samples. This assay is based on the relationship between the initial DNA target levels and the threshold cycle (Ct) of the amplification products. The Ct value is smaller when the initial DNA target level is higher. Several evaluation studies have shown that real-time PCR has a higher sensitivity, a broader dynamic range, and an accurate quantitation of HBV DNA compared to those of the existing commercial methods[12-15].

The Fosun real-time PCR HBV kit is a commercial

assay for quantitation of serum HBV DNA levels based on TaqMan PCR technology. It has been approved by the State Food and Drug Administration (SFDA) of China for *in vitro* diagnostic use. This assay is widely used in Chinese laboratories for quantitative detection of serum HBV levels in patients with HBV infection. However, the clinical performance of this real-time PCR assay has not been compared with that of commercial assays routinely used in the United States and Europe. The aim of this study was to evaluate the clinical performance of the Fosun real-time PCR HBV assay on the ABI 7500 sequence detector for the quantitative detection of HBV DNA in serum samples. The results were compared to those obtained with the same samples using the COBAS Amplicor HBV Monitor system.

MATERIALS AND METHODS

Patients and samples

Serum samples from 158 individuals, including 118 patients with chronic hepatitis B (46 genotype B, 65 genotype C, and 7 mixed genotype B and C), and 40 blood donors, were analyzed in parallel by the Fosun real-time PCR HBV kit (Fosun Diagnostics, Shanghai, China) and COBAS Amplicor HBV Monitor (Roche Diagnostics). All the patients were positive for hepatitis B surface antigen (HBsAg) for at least 6 mo, and were negative for antibodies to hepatitis A, C, D and E viruses. None of these patients had received any antiviral treatment at the time of serum collection.

An HBV reference serum from the National Center for Clinical Laboratories of China with a DNA level of 7.5×10^8 copies/mL was used to determine the linearity and detection limit of the real-time PCR. This reference serum was 10-fold serially diluted into a spectrum of reference samples with HBV DNA levels ranging from 7.5×10^1 to 7.5×10^8 copies/mL.

A set of HBV reference sera established by the Chinese National Institute for the Control of Pharmaceutical and Biological Products (NICPBP), with HBV DNA concentrations ranging from < 1000 to 6.17×10^8 copies/mL of genotype C were used for standardization.

Real-time PCR assay

For Fosun real-time PCR, HBV DNA was extracted from 100 μL serum by using the extraction reagents included in the kit, in accordance with the manufacturer's instructions. The amplification was performed on an ABI 7500 sequence detector (Applied Biosystems, Foster City, CA, USA) by incubating the reaction mixture (50 μL) at 50℃ for 2 min, 94℃ for 5 min, followed by 40 cycles of PCR amplification at 93℃ for 30 s and 60℃ for 90 s. The Ct value was defined as the number of fractional cycles in which the fluorescence emitted by the reaction mixture exceeded a preset threshold, and marked the beginning of an exponential growth of the fluorescence signal. The results were analyzed with ABI Prism software (Applied Biosystems). A four-point external standard set was used to calculate the initial copy number of the samples. The dynamic range of Fosun real-time PCR HBV DNA kits, as stated by the manufacturer, is 4.2×10^2-7.5×10^8 copies/mL.

COBAS Amplicor assay

Amplicor tests were performed by using the COBAS Amplicor system and the AMPLICOR HBV Monitor assay according to manufacturer's instructions. The highly conserved HBV precore/core region and the internal standard DNA were amplified in the same well, but hybridized in separate wells. The amount of HBV DNA was calculated from the ratio of the HBV well to the internal standard well, and the copy number per milliliter was calculated from a standard curve. The dynamic range of the Amplicor test was 3×10^2-2×10^5 copies/mL.

Statistical analysis

Statistical analyses were performed using the Statistical Program for Social Sciences (SPSS 13.0 for Windows; SPSS, Chicago, IL, USA). Correlation between the quantitative results from the two assays was determined with scatter plots and Spearman's coefficient analysis, after logarithmic transformation of data with skewed distribution. The Bland-Altman method was used to assess the agreement between the values obtained with the two assays[16].

RESULTS

Linearity and detection limit

The real-time PCR was able to detect seven (87.5%) of the eight dilutions of the reference serum. The tested values and the normal values of the dilutions were well matched ($r = 0.999$, $P < 0.001$). The converting formula was:

Log (HBV DNA level by real-time PCR) = 1.098 [Log (Reference HBV DNA level)] - 0.735

The real-time PCR was able to detect HBV DNA levels as low as 750 copies/mL, which is similar to the detection limit claimed by the manufacturer.

Inter-assay variation and accuracy of real-time PCR

To determine the dynamics and accuracy of the Fosun real-time PCR kit, the reference serum of the Chinese NICPBP was tested three times with kits with different lot numbers. Fosun real-time PCR kits detected all seven dilutions of the reference serum, and all the quantitative results were within the reference ranges (Table 1). The inter-assay variation ranged from 0.3% to 3.8%. The detection limit of the real-time PCR was 442 copies/mL.

Intra-assay variation and reproducibility of real-time PCR

For evaluation of the intra-assay variation of the Fosun real-time PCR kits, three samples with high, medium and low HBV titers were tested. Each sample was tested in 12 replicates. Table 2 shows the mean $\log_{10}$ (copies/mL) viral loads, SD and coefficient of variation (CV) of the samples. The viral load values from the Fosun real-time PCR assay were highly reproducible over the various HBV titers (CV, 1.4%-8.1%), especially for the samples with high and medium HBV titers, and the intra-assay CV was 1.4% and 2%, respectively.

Comparison of real-time PCR with COBAS Amplicor HBV Monitor

A total of 158 clinical serum samples were tested in

3768	12	3.97	0.32	8.1
3785	12	6.00	0.12	2.0
3770	12	7.84	0.11	1.4

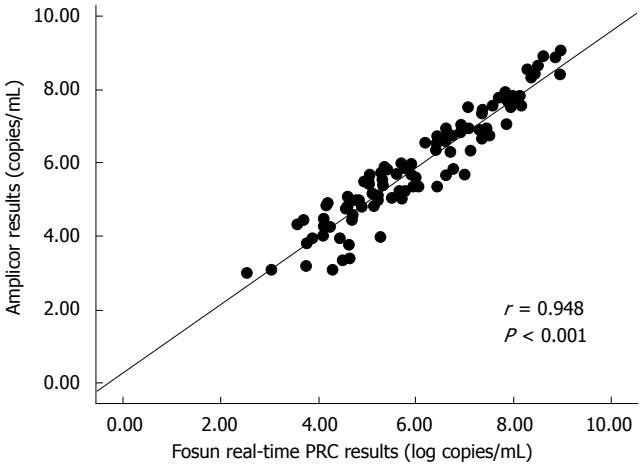

Figure 1 Correlation of HBV DNA levels measured by the Fosun real-time PCR and Amplicor tests.

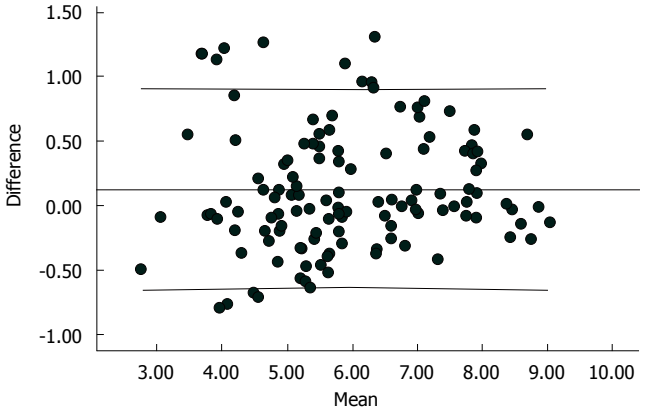

Figure 2 Differences between viral loads obtained by the two assays versus the average for each specimen.

parallel with the Fosun real-time PCR kits and the COBAS Amplicor HBV Monitor system. Samples were divided into three groups: group A, samples from healthy blood donors (n = 40); group B, samples from HBV infected patients with viral loads within the range of both tests (n = 43); group C, samples from HBV infected patients with viral loads above the upper limit of the Amplicor test (n = 75). These samples were diluted and re-tested with the Amplicor test. Viral loads were converted into logarithms. In group A, all the samples were negative for HBV with both assays. A comparison between the two assays was performed from samples in group B and C. Spearman's coefficient showed a significant correlation between the two assays (r = 0.948, P < 0.0001, Figure 1). The differences between viral loads obtained with the two assays versus the average for each specimen was analyzed with the Bland-Altman method[8] (Figure 2). Of the 158 samples, two (1.3%) samples had viral loads slightly above the upper limit and one (0.6%) sample was below the lower limit of the Fosun real-time PCR. However, viral loads of 75 (47.5%) samples were above the upper limit of the Amplicor test. In addition, HBV genotypes did not influence the quantitative results obtained with both assays.

Assay time and costs

The assay times and costs of both tests were compared. For a 24-sample work unit (controls were handled in the same way as clinical samples), Fosun real-time PCR required 3 h and the Amplicor test required 7 h. The cost of the Fosun real-time PCR per test, including consumables and DNA extraction reagents, was 5 US dollars. The cost of the Amplicor test was approximately 100 US dollars per test. If the samples were diluted and retested, the cost would be much higher.

DISCUSSION

China has the greatest burden of HBV infection in the world. Many commercially available HBV DNA assays in the United States and Europe are unaffordable for Chinese patients. Reliable but inexpensive HBV DNA assays are very important for control and treatment of HBV infection in low-income countries such as China. Fosun real-time PCR HBV DNA kits are produced by a Chinese company and approved by the Chinese SFDA for *in vitro* diagnostic use. Compared to the COBAS Amplicor test, this assay has equivalent reliability at a reduced cost.

Many studies have shown that real-time PCR is accurate, reproducible, sensitive, and rapid for quantitative detection of HBV levels in clinical samples[13,14,17-21]. Real-time PCR also has the widest dynamic range among all

the assays available commercially[14]. In this study, Fosun real-time PCR was able to quantitatively detect HBV in all seven reference sera from NICPBP, which showed a dynamic range of 8 logs. The majority (97.5%) of the HBV-positive samples used in this study were quantified within the manufacturer's recommended dynamic range for the Fosun real-time PCR, which indicates that this assay is superior to the Amplicor test for detection of HBV DNA in patients with high viral loads.

The results for the 158 clinical samples obtained with the Fosun real-time PCR and Amplicor tests were concordant very well. Comparison of the two assays for quantitative detection of HBV DNA levels in the 118 serum samples showed that the two sets of results were highly correlated ($r = 0.948$, $P < 0.001$). This was in accordance with the results of previous studies that have evaluated other real-time PCR assays for quantitation of HBV DNA[13,14,22-26].

One of the advantages of the Fosun real-time PCR kits is its low cost compared to that of the Amplicor test (5 *versus* 100 US dollars per test) and other commercially available tests[14]. With its low cost, it can be used to monitor antiviral therapy in economically disadvantaged patients with chronic HBV infection. As recommended by the American Association for Study of Liver Diseases and the Asian-Pacific Consensus Update Working Party on Chronic Hepatitis B, HBV DNA should be monitored at least every 3 mo during therapy. After the end of therapy, HBV DNA should be monitored monthly for the first 3 mo and then every 3-6 mo[27,28]. This will be a great economic burden for chronic hepatitis B patients in countries such as China, where most people have no medical insurance. Reliable and inexpensive assays for quantitation of HBV DNA are helpful for controlling HBV infection in such countries.

As with many other real-time PCR tests, the Fosun real-time PCR has no internal control included in the test. Internal controls can compensate for the differences in DNA extraction efficiency between specimens, and possible PCR inhibition in the reaction mixture[14,29-31]. In addition, standardization with international reference standards is also needed for wide acceptance of this assay. Further comparison with other commercially available assays such as the COBAS TaqMan 48 real-time PCR system will be helpful for evaluating the clinical performance of the Fosun real-time PCR assay.

In conclusion, the Fosun real-time PCR HBV DNA kit, with its much lower costs, is capable of providing reliable and rapid HBV DNA quantitation, which is useful for monitoring HBV DNA levels in patients with chronic hepatitis B.

COMMENTS

Background

Commercial real-time PCR assays are widely used for quantitation of hepatitis B virus (HBV) DNA in China. However, these assays have not been fully evaluated for their clinical performance.

Research frontier

Several methods are routinely used for quantitation of HBV DNA in serum or plasma samples. However, differences do exist among these methods. Comparison and evaluation of these methods are the focus of research efforts.

Related publications

Lindh *et al* and Gordillo *et al* have evaluated the clinical performance of commercial real-time PCR assays. However, they have not compared the cost and time between the real-time PCR and reference methods.

Innovations and breakthroughs

This study compared a real-time PCR assay widely used in China with the COBAS Amplicor test, which is widely used in the United States and Europe, for detection of HBV DNA in serum samples. Clinical performance, time required, and cost of the assays were analyzed.

Applications

This commercial PCR assay is suitable for quantitation of HBV DNA in serum samples.

Terminology

TaqMan PCR is one of the real-time PCR methods for the determination of copy number of PCR templates. It requires a pair of PCR primers and a fluorogenic probe, which is an oligonucleotide with both a reporter fluorescent dye and a quencher dye attached. The fluorescence can be monitored at frequent intervals during the PCR reaction with a real-time PCR machine.

Peer review

This is a well designed and prepared study with important conclusions. The most important point is that the real-time PCR is significantly cheaper than other commercial tests.

Abstract

Aorto-duodenal fistulae (ADF) are the most frequent aorto-enteric fistulae (80%), presenting with upper gastrointestinal bleeding. We report the first case of a man with a secondary aorto-duodenal fistula presenting with a history of persistent occlusive syndrome. A 59-year old man who underwent an aortic-bi-femoral bypass 5 years ago, presented with dyspepsia and biliary vomiting. Computed tomography scan showed in the third duodenal segment the presence of inflammatory tissue with air bubbles between the duodenum and prosthesis, adherent to the duodenum. The patient was submitted to surgery, during which the prosthesis was detached from the duodenum, the intestine failed to close and a gastro-jejunal anastomosis was performed. The post-operative course was simple, secondary ADF was a complication (0.3%-2%) of aortic surgery. Mechanical erosion of the prosthetic material into the bowel was due to the lack of interposed retroperitoneal tissue or the excessive pulsation of redundantly placed grafts or septic procedures. The third or fourth duodenal segment was most frequently involved. Diagnosis of ADF was difficult. Surgical treatment is always recommended by explorative laparotomy. ADF must be suspected whenever a patient with aortic prosthesis has digestive bleeding or unexplained obstructive syndrome. Rarely the clinical picture of ADF is subtle presenting as an obstructive syndrome and in these cases the principal goal is to effectively relieve the mechanical bowel obstruction.

INTRODUCTION

Aorto-duodenal fistulae (ADF) are the most frequent aorto-enteric fistulae (80%). The most frequent presenting sign of ADF is upper gastrointestinal bleeding (UGI). We report the first case of a man with a secondary aortoduodenal fistula presenting with a history of persistent occlusive syndrome, which was treated with surgical exploration.

CASE REPORT

A 59-year old male patient who underwent an aortic-bi-femoral bypass 5 years ago, was admitted to the Emergency Room for a 5-day history of persistent occlusive syndrome with dyspepsia and biliary vomiting. Physical examination revealed a distended abdominal pain. Full blood examination was unremarkable.

Computed tomography (CT) scan showed in the third duodenal segment the presence of an area with the characteristics of inflammatory tissue including air bubbles between the duodenum and aortic-bi-femoral prosthesis adherent to the third duodenal portion ("comma sign") (Figure 1). Microbiological cultures and scintigraphy were unremarkable. Esophago-gastro-duodenoscopy showed the aortic prosthesis crossing the third segment of the duodenal wall occluding the intestinal lumen (Figure 2). At laparotomy, after viscerolisis, the prosthesis was detached from the duodenal wall and the intestine failed to close transversely (Figure 3). To protect the intestinal wall, a pedunculated fragment of the greater omentum was placed between the duodenum and aortic bypass. Furthermore, a gastrojejunal Roux anastomosis was employed. The prosthesis was not changed because there were no local or systemic signs of infection. The post-operative course was uneventful. The patient was discharged 10 days after operation and received a regular follow-up for 6 mo.

DISCUSSION

ADF are the most frequent aorto-enteric fistulae (80%)[1]. They may be primary due to a spontaneous communication between the lumen of aortic aneurysm

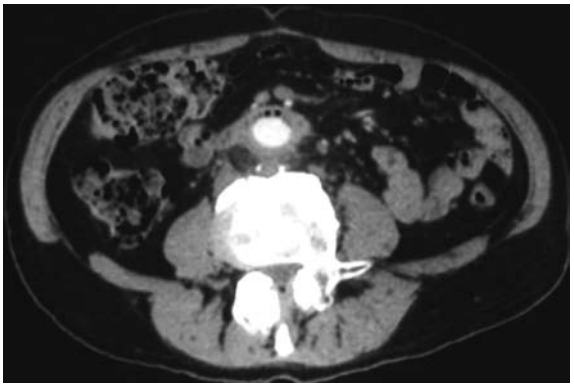

Figure 1 CT scan showing an area with the characteristics of inflammatory tissue including air bubbles between the duodenum and aortic-bi-femoral prosthesis adherent to the third duodenal portion.

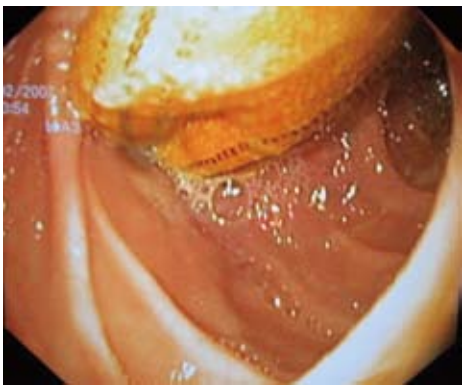

Figure 2 Esophago-gastro-duodenoscopy showing the aortic prosthesis crossing the third segment of the duodenal wall occluding the intestinal lumen.

and intestinal loop, or secondary due to surgical repair of aneurysms with prosthetic implants. The most frequent presenting sign of ADF is UGI bleeding. Clinical suspicion is essential in the diagnosis of ADF and the most commonly used techniques for its diagnosis are esophago-gastro-duodenoscopy (EGDS) and CT.

Secondary ADF is an uncommon (0.3%-2%) and life-threatening long-term complication of aortic reconstructive surgery[2]. Although the exact pathogenesis remains speculative, mechanical erosion of the prosthetic material into the adjacent bowel may be due to the lack of interposed retroperitoneal tissue or the excessive pulsation of redundantly placed grafts or septic procedures (low-grade, Staphylococcus epidermidis "biofilm" infection). Finally, some authors have described cases of inadequate prosthetic materials[2,3]. In our case, ADF formation was related to graft pulsation on the duodenal wall (in this patient, the blood pressure was stably high and not controlled by drugs).

The time between the first intervention and development of fistula can vary from months to years[3,4]. The presentation is often subtle with herald bleeding followed by a period of grace, or catastrophic bleeding, or rarely an episode of intestinal obstruction. The third or fourth duodenal segment is the most frequently involved site. In Dacron prosthesis patients, fistula develops in the

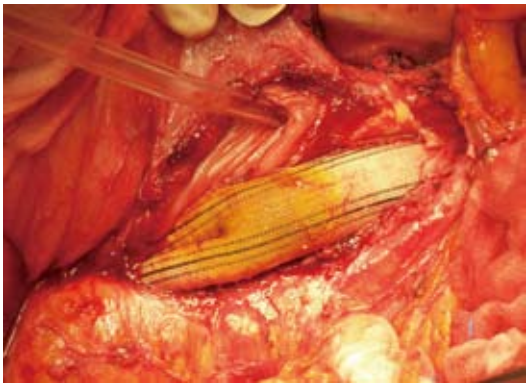

Figure 3 Isolated prosthesis in the context of eroded duodenal wall during laparotomy (the tube indicates the proximal duodenal lumen).

proximal graft tract opening in the third segment of the duodenum[1]. The right diagnosis of ADF can be difficult. It needs an early and correct suspicion index to establish the diagnosis of ADF in all patients who have undergone aortic graft surgery and present with gastrointestinal haemorrhage, sometimes fever, abdominal pain or mass or obstructive syndrome[5,6].

Though difficult, diagnosis can be achieved through EGDS or CT scan. Additional diagnostic procedures are often not useful. EGDS, the main diagnostic procedure, is able to demonstrate the fistula and rule out other possible causes of obstruction, but the most important tool to achieve diagnosis is clinical suspicion[3,6]. Because of the high mortality and morbidity, associated with secondary aorto-enteric fistula, surgical treatment is always recommended. Explorative laparotomy is the treatment of choice. Surgical procedures help guide the diagnosis and constitute the main part of treatment with suture of the duodenum and evaluation of vascular prosthesis.

In the case of non-treated aortic-enteric fistula presenting with massive UGI-bleeding, the mortality rate is near to 100%. While the morbidity (limb loss in 10%-40%) and mortality related to treated ADF are also high (75%) and require preventive measures, including more particularly delicate surgery and antibiotic therapy in case of any episode of infection. Several surgical procedures are possible[4,7].

ADF must be suspected whenever a patient with aortic prosthesis has digestive bleeding or unexplained obstructive syndrome[8]. More rarely, the clinical picture of ADF is subtle presenting as an obstructive syndrome and in these cases the principal goal is to effectively relieve the mechanical bowel obstruction. Further study is necessary to establish the more effective diagnostic mode.

Abstract

Natural killer T cells (NKT) are an important subset of T lymphocytes. They are unique in their ability to produce both T helper 1 and T helper 2 associated cytokines, thus being capable of steering the immune system into either inflammation or tolerance. Disruption of NKT cell numbers or function results in severe deficits in immune surveillance against pathogens and tumor cells. Growing experimental evidence suggests that hepatosteatosis may reduce resident hepatic as well as peripheral NKT cells. Those models of hepatosteatosis and the change in NKT cell numbers are associated with a disruption of cytokine homeostasis, resulting in a more pronounced release of proinflammatory cytokines which renders the steatotic liver highly susceptible to secondary insults. In this letter to the editor, we focus on recently published data in the *World Journal of Gastroenterology* by Xu and colleagues demonstrating reduced peripheral NKT cells in patients with non-alcoholic fatty liver disease, compare those findings with ours and others in different animal models of hepatosteatosis, and hypothesize about the potential underlying mechanism.

TO THE EDITOR

We are excited to read a recent report in the *World Journal of Gastroenterology* by Xu and colleagues demonstrating a reduction in the numbers of peripheral natural killer T cell (NKT) cells in patients with non-alcoholic fatty liver disease[1]. A growing body of experimental data demonstrates a link between hepatosteatosis and defects in NKT numbers and/or function. Over the past years, reductions in NKT cell numbers was reported in the fatty liver by a number of groups including ours[2-4]. Observations by our group show an inverse correlation between hepatic NKT cell numbers with the accumulation of hepatic lipid using the choline-deficient diet model of hepatosteatosis[4]. Although different animal models of diet-induced hepatic steatosis using high fat, high sucrose and choline-deficient diet or leptin deficient *ob/ob* mice showed depletion or decrease in hepatic NKT cell numbers[2-4], it has remained unclear if those findings were relevant to human fatty liver disease.

NKT cells play a critical role both in the liver and peripherally in the regulation of the innate and adaptive immune response. Decreased hepatic NKT cell numbers correlate with increased local production of pro-inflammatory T helper 1-associated cytokines[4,5]. We and others have shown that T helper 1-associated cytokines, such as tumor necrosis factor alpha, interleukin 12 and interferon gamma, are significantly elevated in steatotic livers in mouse models of obesity[3-5]. Similar findings have been reported in obese individuals with low levels of adiponectin and increased levels of circulating tumor necrosis factor alpha[6,7], although those studies did not examine hepatic or peripheral NKT cell numbers. NKT cells are unique in their ability to produce both T helper 1- and T helper 2-associated cytokines. The loss of NKT cells likely contributes to disrupted cytokine balance within the liver[5,8,9]. Consistent with their function as a regulator of the immune response, loss of NKT cell-associated interleukin 4 production promotes beta cell destruction in the *db/db* mouse model of type I diabetes[10]. Finally, NKT cells also function to clear tumor cells within the liver, as NKT cell activation promotes tumor cell clearance in several mouse models of hepatic metastasis[11]. Therefore, it is apparent that NKT cells play an important immunological and potentially regulatory role in both the liver and peripheral organs. The ability of hepatic lipid accumulation to alter this multifunctional cell population may have important and widespread pathophysiological consequences.

It remains unclear how hepatosteatosis reduces hepatic

and peripheral NKT cells. Previous studies implicated that interleukin 12 is a key activator of NKT cells, a process which is linked to activation-induced cell death of this cell population[12]. Therefore, it is likely that increased levels of interleukin 12 in fatty livers directly reduce the viability of NKT cells. We hypothesize that increased interleukin 12 expression in combination with hepatic lipid accumulation might be directly responsible for the reduced NKT cell population in non-alcoholic fatty liver disease (NAFLD).

The current study by Xu and colleagues is the first of its kind to establish this inverse relationship between NKT cell numbers and hepatosteatosis in humans and provides strong support to animal models of steatotic liver disease and immune cell dysfunction. Future research should focus on hepatic resident NKT cell numbers in humans suffering from NAFLD, and the relationship between hepatic and systemic cytokine levels of those patients should be monitored.

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008
Istanbul

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327/ CN 14-1219/R) is a weekly journal of with a circulation of more than 15707, published on the 7th, 14th, 21st and 28th of every month. *WJG* is a peer-reviewed journal. The number of overseas users with an independent IP address was 15600, representing 123 countries worldwide. Original research, reviews, comments, and case reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted elsewhere simultaneously.

Publication model

WJG is a journal with a so-called public beneficial publication model, which consists of an Open Access and the commercialized publication model (i.e. payment by the third party). This publication model has been proven very effective and produced fruitful outcome. By 21st December 2007, the number of visit hits to the *WJG* website has reached 21350084. *WJG* advocates the tenet that the research funding granted to scientists be used to serve scientists, by which high quality scientific articles can be published.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from the organization in which the author(s) works should be provided with the contributed article to warrant not give away any secret and if the contributed article is completed in cooperation by authors from different organizations, a letter of recommendation from each of the organizations should be provided to ensure not given away any secret.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained in the mailing process.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381901-600. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. font with ample margins. The preferred font is Book Antiqua. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, author contributions; disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analysed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend. Otherwise, article is rejected. Reviewers are acknowledged in the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou Univerisity, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, that reflect the content of the study.

Text
For articles of these sections, original articles, rapid communicatin and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. As require, figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. The examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is nessesary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to make out the high resolution-figures of E-version or the printed one.

Tables
Three-line tables should be numbered 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate that already contained in the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "Fom references [19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement
PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement
A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464.

The accuracy of the information of the journal citations is very important. We will interlink all references with DOI in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter and responses, to reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a CAF from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After the manuscript goes online, links to PDF edition of submitted manuscript, peer-reviewers' report and revised manuscript will be created. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors could benefit from the feedbacks and revise the manuscript according to the comments in real time.

Science news releases

Authors of accepted manuscripts are suggested to write science news to their articles as both following guidelines and samples, and the news will be released soon at EurekAlert/AAAS --http://www.eurekalert.org. The title for news is less than 90 characters. The summary for news is less than 75 words, and main body less than 500 words. The science news should be lawful, ethical, and tightly based on your original contents with attractive title and amusing pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Biliary complications are significant causes of morbidity and mortality after orthotopic liver transplantation (OLT). The estimated incidence of biliary complications after OLT ranges between 10%-25%, however, these numbers continue to decline due to improvement in surgical techniques. The most common biliary complications are strictures (both anastomotic and non-anastomotic) and bile leaks. Most of these problems can be appropriately managed with endoscopic retrograde cholangiography (ERC). Other complications such as bile duct stones, bile casts, sphincter of Oddi dysfunction, and hemobilia, are less frequent and also can be managed with ERC. This article will review the risk factors, diagnosis, and endoscopic management of the most common biliary complications after OLT.

INTRODUCTION

Complications of the biliary tract after orthotopic liver transplantation (OLT) are an important cause of morbidity and mortality in liver transplant recipients. The most frequent biliary complications following LT are biliary tract strictures, bile leaks, and bile duct stones. Biliary complications arising after a liver transplantation occur in 10% to 25% of cases, with biliary strictures, bile leaks, and bile duct stones accounting for the majority of the complications[1-6].

These complications can be successfully managed with endoscopic retrograde cholangiography (ERC) in most cases. This article will review the different types of biliary complications after OLT and their endoscopic management.

RISK FACTORS

Risk factors for the development of biliary complications after OLT are shown in Table 1. A major risk factor is the type of biliary reconstruction (duct-to-duct choledocho-choledochostomy *vs* Roux-en-Y choledochojejunostomy). The risk of biliary complications with the Roux en Y reconstruction is similar or only slightly higher compared with the duct-to-duct anastomosis[2,7-10]. Duct-to-duct anastomosis of the common bile duct has the advantage of including easy access to the biliary system after OLT and preservation of the sphincter of Oddi[11]. The use of T-tubes has also been implicated as a risk factor after OLT, although this issue is controversial. Some centers prefer the routine use of T-tubes for bridging of the biliary anastomosis as it allows the assessment of the quality and quantity of bile, biliary tract anatomy, and reduces the incidence of strictures. Despite these benefits, comparative studies indicate that routine T-tube placement is associated with higher incidence of bile leaks and cholangitis[12-15].

Acute hepatic artery thrombosis, which may lead to ischemic strictures unless vascular flow is immediately reconstituted, is one of the major risk factors for the development of complications after OLT[12]. Other risk factors for the development of biliary complications include technical factors during surgery (excess dissection of periductal tissue during procurement and tension of the duct anastomosis), ischemia/reperfusion injury, cytomegalovirus infection, non-heart beating donors, ABO incompatibility and primary sclerosing cholangitis[12,16-22].

DIAGNOSIS

Patients may present with asymptomatic elevations of serum transaminases, serum bilirubin, alkaline phosphatase and/or γ-glutamyl transferase levels. In some cases patients may have non-specific symptoms, such as fever and anorexia[10,11,16]. In the initial evaluation of these

Table 1 Risk factors for the development of biliary complications after OLT

1	T-tube
2	Roux-en-Y anastomosis
3	Ischemia/Reperfusion injury
4	Acute hepatic artery thrombosis
5	Infections
6	ABO mismatch
7	Non-heart beating donors
8	Primary sclerosis cholangitis

patients, an abdominal/liver ultrasound (US) should be performed to evaluate the biliary tree and the hepatic vessels. If hepatic artery stenosis is suspected, a hepatic angiography is usually indicated. Liver biopsy is useful in order to exclude rejection, but histological features of biliary obstruction can sometimes be misleading and confused with rejection or hepatitis C recurrence[23]. In cases where there is biliary dilation on the abdominal US, liver biopsy is not initially performed due to the risk of causing a bile leak. The yield of abdominal US in detecting biliary complications is sometimes limited by a lack of good sensitivity and accuracy to detect common bile duct obstruction or stones. Hence, the absence of bile duct dilation on US should not preclude further evaluation with other sensitive techniques (see below) in patients in whom there is suspicion of biliary tract complications.

If there is a strong clinical suspicion of bile duct obstruction or bile leak, a cholangiogram, by means of endoscopy or radiology, should always be performed. In recent years, the role of magnetic resonance cholangiopancreatography (MRCP) as a tool to evaluate the biliary tract of post-OLT patients has significantly improved. Recent studies demonstrate that MRCP has high sensitivity and specificity in detecting biliary complications after OLT (93%-100% and 92%-98%, respectively). MRCP is particularly useful in patients with a low suspicion of biliary complications or when there is a low probability of ERC or percutaneous transhepatic cholangiography (PTC)[24,25] (Figure 1). In patients with an indwelling T-tube, a T-tube cholangiography is the method of choice to evaluate the biliary tract. The best diagnostic approach (ERC *vs* PTC) depends on the type of biliary reconstruction, the likelihood of therapeutic intervention, and the center's expertise. ERC is probably the best diagnostic intervention in patients with duct-to-duct anastomosis, while PTC should be performed in cases of failed ERC or in patients with a Roux-en-Y anastomosis. In high volume centers with experienced endoscopists, ERC can be successfully performed with a variable stiffness pediatric colonoscope. In one report from the Mayo Clinic, 22 out of 31 patients post-OLT with Roux-en-Y anastomosis referred for ERC were successfully treated with endoscopy[26].

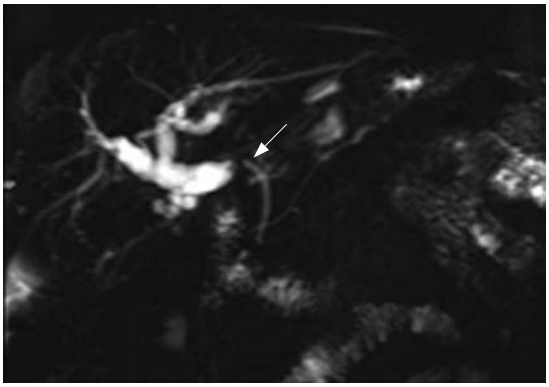

Figure 1 Magnetic resonance cholagiopancreatography (MRCP) image of the biliary tract of a patient that developed abnormal liver enzymes 8 mo after liver transplantation. The MRCP showed a severe biliary stricture at the anastomotic site (arrow).

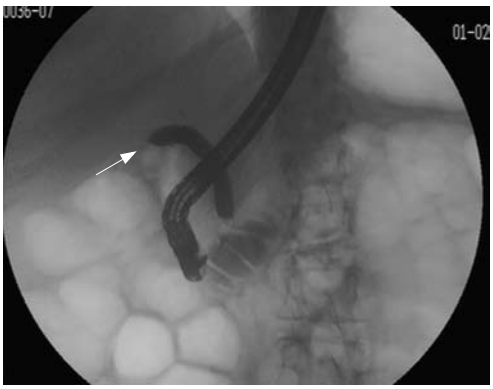

Figure 2 Endoscopic retrograde cholangiography (ERC) in a patient that developed pruritus and cholestasis 6 mo after liver transplantation. The ERC showed a severe anastomosis stricture (arrow). This stricture was successfully managed with biliary balloon dilation and stent placement.

MANAGEMENT

Strictures

Bile duct strictures are the most common biliary complication after OLT with an incidence ranging between 4% and 16%[1-6,10,11,16,27-30]. Strictures are divided into early (within 1 mo of OLT, usually related to technical problems) and late strictures (after 1 mo of OLT, mainly secondary to vascular insufficiency). In addition, bile duct strictures are classified as anastomotic (AS) or non-anastomotic (NAS) depending on the stricture site[16].

In some patients, within the first two months after surgery, a narrowing of the anastomosis (mainly due to postoperative edema and inflammation) may occur and in general responds to one session of endoscopic biliary balloon dilation (6-8 mm) and plastic stent placement (7 French) with removal 6-8 wk later[10]. The majority of true AS occur between the first 3 and 12 mo after OLT (Figure 2). The preferred endoscopic treatment for AS is the repeated combination of biliary balloon dilation (6-10 mm) plus the use of plastic stents ranging from 7-11.5 F with increasing diameter and number, if possible[30-33]. These strictures often recur (recurrence rate of 30%-40%) and in many cases require long-term stenting (up to 24 mo)[31]. The efficacy of this combined approach has been confirmed in at least two studies. In one study of 24 patients, combination treatment of biliary balloon dilatation and stent placement was more effective than balloon dilation alone (success rate of 88% *vs* 37.5%, respectively)[32]. In another study, 22 patients with AS

Table 2 Key points in the management of bile duct strictures

- Bile duct strictures can be classified as anastomotic or non-anastomotic
- Early anastomotic strictures usually respond to endoscopic dilation and short-term stenting
- Late anastomotic strictures have a high rate of recurrence (30%-40%) requiring long-term stenting (up to 24 mo).
- If endoscopic or percutaneous treatment fails, surgical repair or conversion to Roux-en-Y choledochojejunostomy may be necessary
- Non-anastomotic strictures require long-term stenting
- Some patients do not respond and finally undergo re-transplantation or die because of this complication

underwent endoscopic dilation plus maximal stenting [up to 4 stents (range 7-11.5 French)] and in 81% cases complete resolution of the stenosis was achieved in a mean period of 4.6 mo[33]. It is recommended that plastic stents be exchanged every 3-mo to avoid stent occlusion. With this approach 67%-91% of patients respond to endoscopic treatment alone[3,29,30,32,33]. In patients with Roux-en-Y anastomosis, PTC and dilation followed by placement of a percutaneous transhepatic catheter are recommended. If endoscopic or percutaneous therapy fails, surgical repair or conversion to a Roux-en-Y anastomosis may be necessary for successful long-term outcome.

NAS are mainly due to vascular problems and ischemia. Recurrence of primary sclerosing cholangitis is also a cause of NAS. The incidence of NAS ranges between 0.5% and 9.6%[2,6,8,28,29,34,35]. These strictures tend to occur earlier than AS (3-6 mo after OLT)[29,34]. Endoscopic treatment of NAS is similar to that for AS, and typically consists of 4-6 mm biliary balloon dilation (compared to 6-10 mm for AS) and placement of plastic stents[29]. The time to response is longer in NAS compared to AS. In one study, the median time to response was 185 d for NAS compared to 67 d for AS[35]. Despite endoscopic treatment with biliary balloon dilation and stenting, nearly 30%-50% of patients undergo re-transplantation or have a fatal outcome as a consequence of NAS[11,16,29,34,36]. The key features in the management of bile duct strictures post-OLT are described in Table 2.

Bile leaks

Bile leaks are a common complication after OLT with an incidence ranging between 2%-25%[1-6,16,27,37]. Leakage may arise from the anastomosis, the cystic duct, or T-tube (Figure 3). Bile leaks can also be divided into early (within 4 wk after transplantation) and late[16]. Early bile leaks usually arise from the anastomosis and are related to technical problems, such as insufficient blood flow from the hepatic artery to the anastomosis and other factors described in Table 1. Patients with bile leaks may be asymptomatic (bile leak detected by the presence of fluid collection on abdominal ultrasound or CT scan) or present with a clinical picture of peritonitis. In patients with a T-tube in place, bile leaks may be detected with a T-tube cholangiogram and managed by leaving the tube open without further intervention[16]. In patients without a T-tube, ERC is the preferred diagnostic test. In addition, ERC with biliary sphincterotomy and stent placement is the method of choice to treat bile leaks (success rate of 95%)[4,5,38,39]. In these patients, the stent is left in place for 2-3 mo[16]. Small leaks can be managed with biliary sphincterotomy alone[40]. In patients with Roux-en-Y anastomosis, bile leaks can be managed with percutaneous internal-external drainage, however, they often require surgical management. Late bile leaks are commonly related to the removal of the T-tube because the tract is often not mature due to immunosuppressive therapy. Patients that complain of abdominal pain after T-tube removal should raise the concern for a bile leak. In these cases, symptoms resolve with analgesia without further intervention[1-6,16,37,41].

Figure 3 Endoscopic retrograde cholangiography (ERC) image of a biliary leak in a patient after a liver transplantation. The arrow is pointing to the area of extravasation of contrast from the biliary tree.

OTHER COMPLICATIONS

Biloma

Bilomas occur due to bile rupture and extravasation of bile within the liver or the abdominal cavity. If the biloma communicates with the biliary tree, it may resolve spontaneously or occasionally with the placement of a plastic stent in the extrahepatic bile duct. Large bilomas not communicating with the bile ducts should be treated with percutaneous drainage along with antibiotics. If bile leaks cannot be effectively controlled with the abovementioned treatments, surgery is indicated.

Common bile duct filling defects

Most filling defects are caused by gallstones[5]. Other causes include sludge, blood clots, casts and migrated stents. Biliary stones and sludge are relatively common after OLT, with an incidence between 3% and 12%[3-5,8,42]. Factors related to the formation of stones and sludge are the presence of strictures, bacterial infection and obstruction[10,16,27]. In many cases (66%), one session of ERC with sphincterotomy stone extraction is adequate to clear the duct[3]. Bile casts are seen in the setting of ischemia. Clearance of casts may be difficult to achieve with endoscopic methods. Various combinations of sphincterotomy, balloon and basket extraction, stent placement and lithotripsy are often necessary and many of these patients require management with PTC[43].

Sphincter of Oddi dysfunction

It has been postulated that denervation of the common bile duct in the ampullary region secondary to surgical

intervention may lead to the development of a hypertonic sphincter causing sphincter of Oddi dysfunction[11,27]. Endoscopy therapy with biliary sphincterotomy is the treatment of choice in cases of a uniformly dilated common bile duct with cholestasis without any other obvious cause for abnormal liver chemistries.

Mucocele

A mucocele is a rare complication after OLT caused by a collection of mucus from the cells lining the cystic duct remnant. The diagnosis can be confirmed with MRCP. Patients usually require surgical or radiological drainage[16,44].

CONCLUSION

Biliary complications arising after OLT occur in approximately 10%-25% of cases. Biliary strictures, bile leaks and bile duct stones account for the majority of these complications. The diagnostic approach of biliary complications after OLT should begin with a liver US and Doppler examination of the hepatic artery. In cases with a strong clinical and radiological suspicion of biliary pathology, the patient should proceed directly to ERC. MRCP is an excellent diagnostic tool for the evaluation of the biliary tree after OLT and should be performed in cases where there is a lower suspicion for biliary pathology. Patients with AS and NAS should undergo repeated ERC sessions with biliary balloon dilatation and placement of plastic stents to achieve maximal diameter with routine stent changes every 3 mo. In most cases, patients require between 3 and 5 sessions. In patients with bile leaks, ERC with or without sphincterotomy with placement of a plastic stent, which should be left in place for 2-3 mo, is recommended. Other complications such as common bile duct stones, casts, mucocele or sphincter of Oddi dysfunction can be managed successfully with ERC and standard techniques for removal of stones and sphincterotomy.

Abstract

As the increase in lifespan brings to light diseases that were previously not clinically detectable, osteoporosis has become an issue of worldwide significance. The disease is marked by a loss of bone mass; the bones become less dense, fragile and more prone to fracturing. Because it is regulated by endocrine and environmental factors, osteoporosis presents a multifactorial etiopathogenesis, with the genetic component accounting for 70% of an individual variation in bone mass density (BMD), the principal determinant, with age, of fracture risk. Pathological conditions such as celiac disease (CD) exacerbate the process of bone loss, so that the occurrence of osteoporosis in celiac subjects is of particular note: indeed, the screening of osteoporosis patients for this disease is advisable, since it may be the only sign of undiagnosed CD. An increase in interleukin IL-1β, of the IL-1 system, in the relatives of celiac patients confirms the genetic predisposition to osteoporosis and its presence is evidence of an association between the two conditions. The direct effect on the bones of CD is secondary to poor absorption of calcium and vitamin D. In women osteoporosis is indirectly associated with early menopause and amenorrhea, and it may follow prolonged breast-feeding and frequent pregnancies, while in men it is associated with hypogonadism and GH deficit. These endocrine and non-endocrine factors exert their effects on bones by modulating the RANK/RANK-L/OPG system. An appropriate lifestyle from adolescence onwards, together with early diagnosis of and treatment for CD and primary and secondary endocrine pathologies are important for the prevention of damage to the bones.

INTRODUCTION

Osteoporosis has only recently been accorded the clinical importance that its evolution and potential health impact deserve. Thanks to considerable increases in life expectancy this pathology is becoming more visible, and is now treated as a serious public health issue, as well as one of social and economic importance.

Osteoporosis generally manifests in late middle age, but its causes are rooted in the years of development[1]: a lower peak of bone mass in the first 20 years of life can influence the evolution of this disease in later years. The impoverishment of bone mass may become irreversible and lead to serious disability necessitating long-term assistance and treatment, with increasing social and economic costs: for these reasons prevention is of fundamental importance. Prevention should be initiated early on, particularly during adolescence, when calcium ingested with food is absorbed by the organism and contributes effectively to consolidating bone density; it is also important that children and young people engage in regular physical activities from the earliest schooldays through to the completion of secondary schooling. In diseases such as osteoporosis an individual's gender, race and constitution, as well as variations in complex endocrine systems associated with factors such as the menopause, aging and the presence of other pathologies,

can all interact with the lifestyle to determine its onset[2].

In order better to understand the changes in endocrine-environmental factors that can cause damage to bone tissue, the following brief description of its physiology and pathology may be helpful.

THE PHYSIOPATHOLOGY OF OSTEOPOROSIS

Bone is a mineralized tissue consisting of an organic matrix of collagenous fibers (proteins) dispersed throughout an inorganic mass of minerals (calcium hydroxyapatite). Osteoporosis is a quantitative and qualitative alteration in the components of this tissue, in which the process of demineralization becomes intense and prolonged and minerals are used up more quickly than they can be replaced, to the point where bones become fragile and break easily. In this it differs from osteomalacia, which is marked by qualitative alterations due to mineralization defects of the proteinic matrix.

The organic and inorganic matrix, together with the cells (osteoblasts, osteoclasts, osteocytes, lining cells) make the biodynamic units of the process of remodelling and resorption, the basic multicellular units (BMU).

The particular characteristic of bone tissue is that during an individual's lifetime it is subject to processes of transformation that can be summarized in the following stages:

- -the stage of bone mass increase that parallels growth in stature;
- -the stage of consolidation marked by a slow but steady increase in bone mass, which lasts until 20-25 years of age;
- -the stage at which each individual's peak bone mass is reached and in which the difference between men and women is evident;
- -the stage of decline in which bone mass is reduced and which lasts for the rest of an individual's life.

Thus, notwithstanding their apparent solidity, bones are the dynamic and continually evolving sites of two constant and inter-related processes (bone turnover): a slower process of accumulation and a more rapid one of resorption. Then there are the various functions in which calcium is involved: its endocrine function, nerve conduction, muscle contraction, cell metabolism and blood coagulation. Calcium is carried by the blood to and from all bodily tissues, where a dynamic equilibrium is reached between the body's use of calcium and the need to sustain the calcium load. This equilibrium is finely regulated by various endocrine, environmental and genetic factors, responsible for the multifactorial origin of osteoporosis, in which the genetic component plays an important part[3]. Numerous studies performed in recent years to identify the genes and allelic variants involved in osteoporosis have shown its polygenic determinants, but the identity of genes involved has not yet been disclosed. It is estimated that genetic factors account for 70% of individual variations in bone mass density (BMD), the principal determinant, with age, of fracture risk, and that BMD accounts for 70% of bone solidity.

The elucidation of the role of the (IL)-1 interleukin system, localized on chromosome 2q14-21 and comprising IL-α, IL-1β and the IL-1 receptor antagonist (IL-1ra), has shown that IL-α and IL-1β are potent stimulators of bone resorption by inducing the proliferation and differentiation of both osteoclast precursors and mature active osteoclasts[4].

Studies on the allelic variants of the IL-1 system in postmenopausal women of different ethnic origins have revealed the existence of associations between BMD and the system's different genetic polymorphisms. Investigations on the relations between polymorphisms of the IL-1 system and BMD in 220 postmenopausal Korean women aged between 48 and 70 years showed that BMD in those carrying the A2 allele of the IL-1ra gene was significantly lower than that of those who did not carry the allele. Moreover, the A2 allele was more frequent in women with osteoporosis than in those who did not suffer from the disease. There is thus a relation between this allele and BMD; it presumes that polymorphism of the IL-1ra gene is an important genetic factor that affects the BMD of Korean women[4].

Other studies have identified regulators of bone remodelling, such as the Ciz gene (Castor-interacting zinc finger protein), which could also possible be used as therapeutic targets[5] particularly for the treatment of individuals also affected by CD. The existence of an association between the two pathologies was demonstrated by a study performed by Taranta *et al*[6], in which the authors showed the presence of a cytokine imbalance affecting bone metabolism in the sera of celiac patients and the direct effect of these sera on bone cell activity *in vitro*. They found an increase in IL-1β and in tumor necrosis factor alpha (TNF-α) in all patients, while patients who did not follow a gluten-free diet (GFD: only sure treatment for CD) also had increased IL-6 and IL-18 and an additional increase in TNF-α. These findings suggest that the loss of BMD could be caused partly by this imbalance, which directly affects osteoclastogenesis and osteoblast activity.

Besides cytokines, parathyroid hormone (PTH), estrogens, androgens, corticosteroids and vitamin D all affect bones by modulating the receptor activator of nuclear factor B/receptor activator of nuclear factor B-ligand/osteoprotegerin (RANK/RANK-L/OPG) system[7].

The RANK-L is the final mediator of the cytokine (IL-1, TNF, IL-6) and hormone (PTH) network. This soluble polypeptide is produced by osteoblasts and expressed on their cell membrane and binds with high affinity to its specific RANK receptor, present in hemopoietic osteoclast precursors of bone marrow and on the membrane of osteoclasts. OPG is a polypeptide of 380 amino acids that is produced in several cell types, including those of the immune system and osteoblastic stromal cells, and has been identified as the soluble biological RANK-L inhibitor able to contrast its osteoclastogenetic, pro-resorption and anti-apoptotic effects on mature osteoclasts[8]. OPG is thought to act as a 'decoy' receptor, competing with the specific RANK receptor to inhibit RANK-L/RANK binding[7].

The importance of the increase in IL-1β is supported by its presence in relatives of celiac patients, confirming

the genetic susceptibility for bone loss pathogenesis[9]. Other studies of families and twins have produced further evidence that genetic factors play a significant role in osteoporosis and that they affect not only BMD but also skeletal geometry and bone turnover, with an increased fracture risk[3].

In addition to pathologies such as, for example, Cushing's disease and prolactinomas, other factors can indirectly affect bone homeostasis. One of these is stress due to physical strain, which produces a cytokine and hormonal imbalance. Strenuous physical exercise leads to an imbalance in which the central nervous system and the hypothalamus-pituitary-suprarenal axis react by increasing catecholamines, cortisol and the activation of corticotropin-releasing hormone (CRH) neurons, with consequences for gonad function. IL-6, growth hormone (GH) and prolactine (PRL) are also activated. It is worth emphasizing that physical exercise in men not only increases muscle mass but also has an indirect effect on bone structure. In female athletes the so-called 'exercise-related reproductive dysfunction' may be present, the consequences of which may include not only osteoporosis but also amenorrhea, infertility, food-related disorders, coronary disease and "euthyroid sick" syndrome[10].

As we have already seen, the phase of decreasing body mass, which continues throughout the lifespan, is a physiological fact: there nonetheless exist risk situations which, by interacting with the balance of hormonal (e.g. estrogen deficiency), nutritional (e.g. calcium deficiency) and environmental (e.g. lifestyle) factors, accelerate bone loss and can harm the organism[11]. Because bones are highly susceptible to interference, it is very important to maintain this balance which, together with genetic equilibrium, helps to preserve bone health. Pathologies such as celiac disease (CD), which manifests when genetic and environmental factors interact, can affect this equilibrium and increase the risk that an individual will develop bone diseases such as osteoporosis and osteomalacia[12].

On account of both its frequency (one in four women and one in eight men over 50) and related complications, osteoporosis represents a serious health emergency of considerable economic importance; when it is associated with CD it may cause additional damage to bone health; indeed, screening for CD is recommended for patients with idiopathic osteoporosis[13,14]. If these patients also suffer from endocrine-reproductive disorders, such screening becomes even more advisable, since these disturbances are a significant risk factor for osteoporosis[2].

SOME ASPECTS OF THE ETIOPATHOGENESIS OF CELIAC DISEASE

While discussing the association between CD and osteoporosis in persons also affected by reproductive problems, it is worth emphasizing certain aspects of the etiology and pathogenesis of celiac disease.

For genetically predisposed individuals, CD is a permanent gluten intolerance, for which the only treatment currently available is lifelong adherence to GFD. The disease is a chronic enteropathy featuring with villous atrophy, crypt hyperplasia and lymphocytosis in which fundamental in inflammatory processes occurs in the proximal part of small intestine mucosa. The adaptive immune pathway is thought to provide the major immune response, but recent evidence has also indicated the involvement of the innate immune system[15]. Besides increased T lymphocytes, other cell types are also increased, including B lymphocytes, NK cells, neutrophils, eosinophils, macrophages and mastocytes. In particular, a chronic recruitment of activated neutrophils is present even in completely normalized remission of CD[16].

In the pathogenesis of CD exposure of the mucosa of the small intestine to gluten leads to hyperproduction of cytokines by T cells, triggering an inflammatory process that includes the release of IL-2, IL-6, IFN-γ and TNF-α and activation of B lymphocytes with production of specific antibodies and the activation of autoimmune mechanisms. IL-15, a mediator of the innate immune system, is thought to be of particular importance in damage to the mucosa and in the persistence of inflammatory processes[17].

CD used to be considered a rare disease typical of infancy, with generalized symptoms of poor absorption combined with chronic diarrhea and slow growth. It is now recognized that along with this classic form of the disease there are other clinical and subclinical forms that may manifest later and in which there may be no intestinal symptoms; these forms can be associated with symptoms affecting the liver, thyroid, skin, reproductive system and bones[18]. The effects of CD on these systems are mediated not only by gluten but also by the combination of other genetic and environmental factors, indicating that CD, like osteoporosis, has a multifactorial pathogenesis[19]. The poor absorption induced by CD leads to deficiencies of nutrients such as iron, folic acid and vitamin K that are essential for organogenesis, of fat-soluble vitamins important for spermatogenesis, and of vitamin D and calcium, essential for the maintenance of bone structure[18]. Osteoporosis deserves particular consideration as a non-intestinal sign of CD; indeed, bone metabolism disorders and a decrease in BMD may be the only signs of otherwise 'silent' CD[20]. In particular, studies have shown that osteoporosis is more serious in individuals also affected by CD[18] and is an important example of a non-intestinal sign of the disease, a factor that acquires additional importance if we consider that 1% of the total population suffers from CD[21]. Osteoporosis is more prevalent in celiac (3.4%) than in non-celiac (0.2%) subjects. In addition, severe cases of CD are accompanied by more severe osteoporosis[13], and celiac individuals who also suffer from reproductive disorders are affected even more severely[2].

In light of the available evidence, it is useful to see how endocrine and reproductive factors interfere in osteoporosis, with special focus on problems associated with CD.

OSTEOPOROSIS IN WOMEN

For women the risk of osteoporosis is linked primarily to a fall in the production of estrogens, the female

steroid hormones *par excellence*. In order to understand the importance of these hormones, it is useful to emphasize that, as well as influencing reproduction and bone integrity, they are major actors in numerous physiological processes: it is thus no surprise to find that they are implicated in the development and progression of several diseases ranging from various types of tumor (e.g. breast, ovaries, colon-rectum, prostate, endometrium) to neurovegetative and cardiovascular disorders, insulin resistance, lupus erythematosus, endometriosis and obesity. In several of these diseases estrogens act through estrogen receptors (ER), and our understanding of this mechanism forms the basis of a number of treatments[22].

After the menopause the decrease in estrogen is evident in the absence of regular modulation of cellular activity in tissue[2]. The biological effects, mediated through the interaction between estrogen and ERα and ERβ, are expressed as a form of protective action in which bone turnover is inhibited, with a consequent reduction in both resorption and the formation of new bone[23].

Estrogen deficiency promotes calcitonin-induced hypocalcemia and a secondary increase in PTH consistent with the effects of calcitonin in increased bone turnover. By promoting the interaction of calcitonin and PTH, estrogens thus regulate calcium homeostasis and bone turnover[24]. In addition, patients with resection of the small intestine also show low levels of 25-hydroxyvitamin D [25(OH)D] associated with increased PTH and decreased BMD values[25]. This is of particular interest when we consider that this part of the intestine is the target of CD, a factor that makes a common pathogenetic mechanism for the two diseases all the more plausible.

The RANK/RANK-L/OPG cytokine system is essential to bone turnover biology; metabolic bone diseases are related to alterations in this system[26]. Functional links between bone remodelling and the immune system in inflammatory processes are also mediated, in part, by the RANK/RANK-L/OPG cytokine system. In these processes, neutrophils play a crucial role; RANK-L is expressed by inflammatory and normal neutrophils, unlike OPG and RANK, which are expressed only by neutrophils exposed to an inflammatory environment. This suggests that neutrophils may contribute to bone remodelling at inflammatory sites where they are present in significantly large numbers[27]. Interestingly in both active and remission CD enhanced neutrophiles infiltration is observed[16]. The risk of osteoporosis is higher in women suffering from CD, which can act both indirectly and directly. The indirect effects of CD include early menopause[28] and amenorrhea[29], two pathologies that are themselves an osteoporosis risk[18]. An early menopause in female patients increases the risk of early development of osteoporosis. Amenorrhea is a major clinical consequence of increased levels of PRLs, which in turn promote disruptions in BMD[30]. In some women other factors such as long periods of breast-feeding and frequent pregnancies may represent a risk of early osteoporosis[31].

In these conditions, latent CD may become manifest or be reactivated in women who have followed GFD for some time, suggesting the existence of immune or hormonal changes peculiar to pregnancy and puerperium[32], such as increased PRL which, as already emphasized, bring changes in BMD[30].

Early menopause should be treated by the immediate adoption of measures to prevent and treat osteoporosis, such as dietary supplements of calcium and vitamin D, physical exercise, not smoking, moderating alcohol consumption and, where necessary, the administration of drugs and/or hormone replacement therapy (HRT). These strategies are necessary to prevent increased fracture risk, largely because most patients are not aware that they have osteoporosis until a fracture occurs[33]. It is also advisable, during critical periods such as pregnancy and breast-feeding, to take calcium and vitamin D supplements[34].

To complete the effects of hormones on bone balance it should be remembered that hyperthyroidism, evident in low serum levels of TSH, is accompanied by a decrease in bone mass[35]. Over treatment for postmenopausal hypothyroidism can lead to a reduction in normal TSH values (0.5-4.0 mU/L), which, by causing subclinical hyperthyroidism, can lead to osteoporosis. It is useful here to remember that thyroiditis may first appear as periods of metabolic hyperfunction leading to hyperthyroidism.

In adults osteoporosis associated with hyperthyroidism is traditionally viewed as a secondary consequence of altered thyroid function[36]. Some studies have provided evidence for a direct effect of TSH on skeletal remodeling mediated *via* the TSH receptor (TSH-R) found on osteoblast and osteoclast precursors. Even a 50% reduction in TSH-R expression produces serious osteoporosis together with focal osteosclerosis (localized bone formation). These studies define a role for TSH as a single molecular switch in the independent control of both bone formation and resorption. In particular, TSH inhibits osteoclast formation and survival by interacting with the RANK-L/RANK system and TNF-α[37].

Because of their endocrine-environmental implications, forms of thyroiditis often occur in combination with CD[38] and are among the pathologies most frequently associated with it. Bearing in mind that forms of thyroiditis can lead to spontaneous abortion, neonatal mortality, retarded fetal growth and congenital malformations[39] and that CD has an important impact on the reproductive system[18], it can be appreciated that the genetic and environmental factors associated with these diseases are correlated. A direct effect of CD is that the process of bone remodeling is increased in these patients in relation to calcium malabsorption, secondary hyperparathyroidism and vitamin D deficiency, with marked bone loss[40].

A further consideration in support of a direct effect of CD in the development of osteoporosis is that patients with this disorder suffer not only from generalized poor absorption but also from a deficiency of specific micronutrients fundamental both to normal male and female reproductive development[18] and to the regular growth and maintenance of bone tissue[12]. The presence of osteoporosis in CD patients, particularly in subclinical cases, thus underscores the significance of a shortage of specific nutritional elements. This is further emphasised by the malabsorption of calcium and vitamin D that affects women with CD. Eastell[41] highlights this fact given that women are affected not only by a lack of estrogens but also by a deficiency of these important

micronutrients in the pathogenesis of osteoporosis. Regarding the loss of calcium it is useful to emphasize that this occurs both as a direct consequence of damage to the mucosa[42] and with secondary steatorrhea, one of the major effects of CD, through a chelating mechanism involving the intraluminal fats[43,44]. All the above considerations assume even greater significance if we remember that, in general, the poor absorption of calcium by postmenopausal women and estrogen-related calcium deficiency unquestionably represent a major risk factor for postmenopausal osteoporosis, as evidenced by improved calcium levels following hormone replacement therapy (HRT). Approximately 20 million women worldwide use HRT, and while its beneficial effects for osteoporosis and menopausal symptoms are known, the well-documented higher risk of breast tumors in these subjects cannot justify its long-term use. Besides, several recent trials have indicated that HRT carries a higher risk of cardiac and cerebral events, contradicting its protective effects on the cardio-and cerebrovascular systems[45].

With regard to preventing or slowing the progression of chronic diseases such as osteoporosis and combating the increased risk of breast cancer, the consumption of soy isoflavones is gaining ground, particularly in the US. These natural substances are similar to estrogen in their action; their beneficial effects on bones may be specific to each phase of an individual's life, as well as depend on the number of estrogen receptors and on the endogenous hormonal environment. Menopausal or premenopausal women, who have greater numbers of these receptors, may be more receptive to the therapeutic effects of isoflavones on bone loss than postmenopausal women, in whom estrogen receptors decrease. Studies on pubertal laboratory animals exposed to high levels of soy isoflavones showed negative effects. This is important if we remember that no clinical studies on adolescents are available to confirm or challenge research carried out on animals. Studies should, in any case, be performed on individuals at all stages of the lifespan to identify possible long-term effects of these substances: indeed, this aspect should be the basis of research aimed at assessing the risk-benefit ratio[46]. Bearing in mind that osteoporosis is associated with genetic-environmental pathologies such as CD, the use of soy isoflavones, which albeit gluten-free nonetheless contain estrogen-like substances, should be carefully evaluated.

Alongside calcium and vitamin D, the prevention of osteoporosis through the development and maintenance of bone mass also calls for other vitamins (A, C, E, K) and minerals (phosphorus, fluoride, iron, zinc, copper, boron) that, by improving BMD, are necessary for a normal metabolism[47] and for bone turnover[48]. The administration of these nutrients from adolescence, particularly in individuals with CD, could help to prevent the onset of osteoporosis. Among them, vitamin K merits special attention, given that its deficit in pregnant women can harm the fetus, leading to chondrodysplasia punctata with nasal hypoplasia and spinal cord abnormalities[49]. In menopausal women vitamin K deficiency disrupts bone calcification on account of reduced osteocalcin (GLA) carboxylation[50]. A deficiency of zinc is also particularly important, as this mineral affects BMD through its effect on the ovaries and consequent changes in estrogen levels; moreover, low maternal serum zinc levels are associated with fetal malformations such as neural tube deficit[51]. This suggests that a shortage of these micronutrients may also have a harmful effect on fetal bone metabolism. Because of the direct involvement of CD in the availability of micronutrients, the above factors may be more significant in celiac women who do not follow the GFD correctly or who are unaware they have the disease.

OSTEOPOROSIS IN MEN

The longer lifespan of humans brings an increased risk of osteoporosis in men and in women, but while in women it is undoubtedly associated with the menopause, in men it is often linked to the effect of GH and hypogonadism[52]. During infancy and adolescence GH stimulates growth and sexual development as well as increasing muscle mass and the formation of bone tissue, while in adults it is important for metabolism in various tissues. The association between CD and GH deficiency is evident in the low stature of celiac children, although after a year on GFD these children will resume normal growth, particularly if the diet is combined with hormone therapy[53,54].

With regard to hypogonadism, osteoporosis is strongly influenced by the homeostasis of steroid hormones[55], changes in which are indicated as one of the commonest causes of this type of pathology[56], while the presence of CD may represent an additional risk factor for osteoporosis[57]. Celiac males are at greater risk of infertility and hypogonadism: indeed, the GFD can improve both sperm count and sperm motility[58]. Gonad dysfunction is caused by a reduction in the conversion of testosterone (T) to 5-alpha-dihydrotestosterone (DHT) resulting from the low levels of 5-alpha-reductase in CD subjects, which disrupts the hypothalamus-pituitary-gonad axis[59]. Hypogonadic males who also have CD are thus more likely to develop osteoporosis, an important consideration if we bear in mind that the malabsorption associated with CD makes this disease *per se* a risk factor for osteoporosis[57]. This further highlights the significance of nutritional deficiencies in these dysfunctions and the sensitivity of the endocrine system to changes in food habits. Another aspect of hypogonadism is its association with increased levels of PRL, which in males lead not only to fertility problems, erectile dysfunction and loss of libido but also, as in females, to altered BMD[30].

Individuals with active CD have increased serum PRL levels, which correlate with the degree of atrophy of the intestinal mucosa and with the serum concentration of anti-endomysial antibodies. The presence of PRL could become a marker for the active disease if it is indeed found to have a role in modulating intestinal damage[60]. High serum levels of PRL are present not only in adults with CD but also in celiac children who do not follow the GFD[61].The above considerations suggest that in these patients the increases in PRL could also affect normal skeletal development, since in men changes in pituitary function from other causes such as, for example, tumors (prolactinoma) and drugs (antipsychotics) lead to osteopenia and osteoporosis. Bone loss in men associated

with hyperprolactinemia and hypogonadism is in fact an indirect effect of increased estrogen levels[62]. It should also be borne in mind that increased levels of PRL not associated with infertility may be indicators of a more general hypothalamus-pituitary imbalance, which may imply an increased risk of osteoporosis in men with CD[18]. The changes in PRL levels are nevertheless reversible if GFD is followed[63]. Other hormones such as GH[64], PTH[65] and Ghrelin also respond in the same way to GFD[66]. These data emphasize the importance of early diagnosis whenever there is a clinical reason to suspect the presence of CD, as for example in otherwise unexplained male osteoporosis or hypogonadism.

Celiac disease leads to a deficiency of specific micronutrients such as vitamin A, which is fundamental for the maintenance of spermatogenesis[67] and T secretion[68]. Retinols appear to act on three main types of testicular cells (Sertoli cells, germ cells and Leydig cells) of both adult and fetus[68]. A decrease in T production leads to atrophy of the accessory sex organs and, because T secretion also induces anabolic effects on these tissues[69], has negative effects on muscle and bone tissue. In addition, low circulating levels of GH lead to an altered body composition, with increased fat and reduced lean body and skeletal muscle mass[70].

Testosterone therapy for the prevention and treatment of osteoporosis in men is still a matter of controversy, but it is probable that osteoporotic men with evident hypogonadism[56], as well as those with CD with which it is often associated, can benefit from this treatment.

Strict adherence to GFD is thus necessary to avoid damage to both the reproductive system and bones. The negative effects on bones are more evident in older men with late-onset CD, for whom the risk of osteoporosis with its attendant fracture risk is greater, particularly in subjects who do not exercise regularly[71] and for whom vitamin D and calcium supplements should be recommended.

The use of pharmacological therapy (for exemple bisphosphonates) for the prevention and treatment of osteoporosis in postmenopausal women has long been recognized. The use of these agents has been traditionally based on date obtained predominantly from postmenopausal women and cases glucocorticoid-induced osteoporosis, but data are becoming increasingly available to justify their use in osteoporotic men[72]. Moreover, there is evidence that treatment with risedronate increases BMD and reduces hip fractures in elderly men[73].

CONCLUSION

Variations in the alimentary and endocrine systems in both women and men have a fundamental role in the development of osteoporosis: if these variations are combined with an inappropriate lifestyle (e.g. inadequate physical exercise, alcohol abuse or smoking), pathologies such as hyperparathyroidism, thyrotoxicosis and/or the use of drugs such as antipsychotics or corticosteroids[41], the risk of osteoporosis is increased[66]. All of these factors are able to interact with the systemic signs of CD[41]. Osteoporosis and CD are often found together and are both modulated by genetic and environmental factors, confirming their multifactorial etiopathogenesis[18,19]. The incidence of osteoporosis is higher in celiac subjects (3.4%) than in the population as a whole (0.2%) and this disease is an important extra-intestinal sign of CD. Bearing in mind that approximately 1% of the total population has CD[21], the screening of patients with idiopathic osteoporosis for CD is advisable[14]. In subjects who are also affected by endocrine-reproductive disorders, themselves a major risk factor for osteoporosis[2], this screening acquires even more importance.

Increased risk of osteoporosis should not be considered as an isolated factor, but as part of a more generalised endocrine-environmental imbalance with possible serious effects on health on account of its influence on a fairly broad range of tissues and functions and of which metabolism and bone structure are a major target. This risk of osteoporosis is further increased if the imbalance is accompanied by CD, which also causes problems for both male and female reproductive systems on account of deficiencies of important micronutrients.

One important strategy to conserve bone integrity could be the adoption of a suitable lifestyle from adolescence. Early diagnosis of CD is also indispensable so that measures to prevent and treat it, such as GFD, can be initiated in early, thereby averting an increased risk of pathologies such as osteoporosis.

Abstract

Intestinal capillariasis caused by *Capillaria philippinensis* appeared first in the Philippines and subsequently in Thailand, Japan, Iran, Egypt and Taiwan; major outbreaks have occurred in the Philippines and Thailand. This article reviews the epidemiology, history and sources of *C. philippinensis* infection in Thailand. The annual epidemiological surveillance reports indicated that 82 accumulated cases of intestinal capillariasis were found in Thailand from 1994-2006. That made Thailand a Capillaria-prevalent area. Sisaket, in northeast Thailand, was the first province which has reported intestinal capillariasis. Moreover, Buri Ram presented a high prevalence of intestinal capillariasis, totaling 24 cases from 1994-2006. About half of all cases have consumed raw or undercooked fish. However, even if the numbers of the intestinal capillariasis cases in Thailand is reduced, *C. philippinensis* infection cases are still reported. The improvement of personal hygiene, specifically avoiding consumption of undercooked fish and promoting a health education campaign are required. These strategies may minimize or eliminate *C. philippinensis* infection in Thailand.

INTRODUCTION

Capillaria species, being round worm, are members of the superfamily Trichinelloidae. Only three major genera of this group cause human diseases: *Trichuris*, *Trichinella* and *Capillaria*. These worms have an esophagus which is surrounded by glandular cells or stichocytes. This esophageal pattern is called stichosomal esophagus. *Capillaria* species are parasites in many vertebrate animals but only three species infect humans; *Capillaria hepatica*, *C. aerophila* and *C. philippinensis*[1]. *C. philippinensis* which causes intestinal capillariasis is the most important and found to infect the human more than other species.

In 1964, the first case of *C. philippinensis* infection was found in the autopsy of a 29-year-old man from Ilocos Norte province, Northern Luzon, the Philippines, who died from intractable diarrhea[2]. After that, between 1965 and 1967, this disease spread to Pudoc West village, which is approximately 150 kilometers south of the first case. More than 1000 capillariasis cases were found and 77 died of this disease. Lately, Cross reported of the total number of intestinal capillariasis cases in Northern Luzon from 1967 to 1990 to be 1884 cases and 110 deaths[3]. In addition, sporadic cases had been reported from Japan[4], Korea[5], Taiwan, China[6-8], Indonesia[9], Iran[10] and Egypt[11-14]. *C. philippinensis* causes intermittent or continuous diarrhea leading to weight loss, abdominal pain, borborygmi, muscle wasting, weakness and edema. If the intestinal capillariasis patients are not treated, they will have severe muscle wasting, cachexia, edema and death. Most patients died from electrolyte loss resulting in heart failure and/or septicemia[3].

The earliest case of *C. philippinensis* in Thailand was reported in 1973 from an 18-mo old Thai girl[15]. Since then sporadic cases had been recorded in other parts of Thailand. In 1981, the first epidemic of intestinal capillariasis was found in Srisaket province in Northeastern part of Thailand, there had been 20 cases and 9 deaths from the disease[16]. However, even when the numbers of the intestinal capillariasis cases in Thailand are reduced, the *C. philippinensis* infection cases are still reported. Moreover, it probably contributes significantly to morbidity in humans. Therefore, the epidemiology, history and sources of *C. philippinensis* infection in Thailand, have been reviewed in this paper.

HISTORICAL REVIEW OF INTESTINAL CAPILLARIASIS IN THAILAND

The first record of intestinal capillariasis in Thailand

was in 1973. The patient was an 18-mo old Thai girl from Bangpree District of Samut Prakan province. She had diarrhea 2 or 3 times per day, for at least 6 months and edema was found for 3 d. Laboratory examination showed low albumin and potassium in blood. The feces examination revealed eggs, larvae and adults of *C. philippinensis* in her stool[15]. In 1974, Saraburi Provincial hospital reported the second case of *C. philippinensis* infection. The 46-year old man who had watery diarrhea 4-5 times a day was admitted to hospital. The result of his blood chemistry and stool examination were similar to the first case. His feces showed a large number of eggs and adults of *C. philippinensis*[17]. After the two first cases, intestinal capillariasis cases were found in other provinces in Thailand; Nakorn Panom, Surin[18], Phetchabun[19] and Maha Sarakham[20]. All patients presented edema, weight loss and had a history of watery diarrhea 3 to 6 times a day. The low level of albumin and potassium in blood were found and their feces had all stages of *Capillaria* worm. Most of them lived in raw fish eating regions and some of the cases consumed raw fresh water fish such as Koi Pla, chopped raw fish mixed with lemon juice, finely cut red onion and chili.

The first outbreak of intestinal capillariasis in Thailand was in 1981 from a small village, Phrai Bueng district, Sisaket province. This outbreak had 20 patients and 9 deaths. Most of the cases were adults who were over 20 years of age and 80% of them habited in the same household. The authors believed that man to man transmission may be a possibility because each of the cases was sequent diarrhea[16]. In 1983, Kunaratanapruk *et al* reported that 100 cases of *C. philippinensis* infection in hospital had occurred from 1979 to 1981. There were 15 cases that died from intestinal capillariasis. Seventy three percents of the patients were aged in a range between 20 and 49 years and males were more commonly infected than females, about 2.3 times[21].

After the first epidemic in 1981, a number of cases in other parts of Thailand were reported. For example, three intestinal capillariasis patients who lived in the Northeastern part of Thailand were diagnosed by Bamrasnaradura hospital[22]. Seventeen chronic diarrhea patients with *C. philippinensis* were diagnosed at Srinagarind hospital, Khon Kaen University, from 1983 to 1991. Hypoalbuminemia and ova of *C. philippinensis* in feces were found in all those cases[23]. Two intestinal capillariasis patients from the North; Phayao and Chaing Mai who had chronic watery diarrhea were admitted to the Maharaj Nakorn Chaing Mai hospital. Both patients showed eggs of *C. philippinensis* in feces and they were very fond of raw fish food[24]. The latest report, a 27-year-old man who had a history of chronic watery diarrhea for two years was found to contain *C. philippinensis* ova and worms in his jejunum[25].

LIFE CYCLE

The life cycle of *C. philippinensis* was proposed by Cross in 1992[3]. From his experimental study, larvae of *C. philippinensis* from the digestive tract of a freshwater fish (*Hypselotris bipartita*) in the endemic area were given by stomach tube to Mongolian gerbils (*Meriones unguiculatus*). Ten to eleven days post infection; larvae developed to adult stage and female worms generated larvae in 13 to 14 d. After that, these capillaries larvae developed to adults which could release unembryonated eggs within 22-24 d. Moreover, this experiment proposed that autoinfection was found in gerbils. Because they fed only two larvae from fish to gerbils but 852 to 5353 worms were recovered[26].

The biological aspect of fish as the intermediate host of *C. philippinensis* was reported by several studies. In a study in Thailand, *Cyprinus carpio* (Pla Nai), *Puntius gonionotus* (Pla Tapien Khao) and *Rasbora boraperensis* (Pla Sew), which always are prepared to Koi Pla, were fed *C. philippinensis* eggs by self feeding or forced feeding. After 10-30 d the results showed the larvae of *C. philippinensis* were recovered from fish intestines and could develop to egg producing adult in gerbils after feeding them by those larvae[27]. Likewise, Cross *et al* reported *Elotris melanosoma* (birut), *Ambassis commersoni* (bagsang) and *Apagon* sp. (bagsit), which are fresh water fish in the Philippines, were found to be intermediate hosts in experimental infection. *C. philippinensis* larvae were recovered from the digestive tract of those fresh water fish and led to intestinal capillariasis after being fed to monkeys[28]. Moreover, two specimens of *Apagon* sp. were found naturally infected with *C. philippinensis* larvae but how *C. philippinensis* can naturally infect fish is not known. The authors suggest that defecation from humans to a water resource in the endemic area is an excellent opportunity for *C. philippinensis* eggs to contact and be ingested by naturally susceptible fish[28].

Bhaibulaya *et al* reported fish-eating birds (*Amaurornis phoenicurus* and *Ardeola bacchus*) were susceptible to *C. philippinensis* infection; adults and larvae were recovered from birds' intestinal content[29]. Similarly, Cross and Basaca-Sevilla revealed *C. philippinensis* larvae from fish and experimentally infected gerbils could develop to adult males, oviparous and larviparous females in several species of fish-eating birds from Taiwan (*Nycticorax nycticorax*, *Bubulcus ibis*, *Ixobrychus sinensis*, *Gallinula chloropus*, *A. phoenicurus* and *Rostratula benghalensis*) and eggs from those birds hatched and developed to larvae and adults in fish intestines[30]. Therefore, fish-eating birds may be a natural reservoir host that upon defecation, *C. philippinensis* eggs are released to a water resource in the endemic area or eat *C. philippinensis* infected fish. These mechanisms can maintain a parasite life cycle in nature.

SYMPTOMS AND PATHOLOGY

The intestinal capillariasis patients usually present watery diarrhea weight loss, abdominal pain, borborygmi, muscle wasting, weakness, edema and laboratory examination showed low levels of potassium and albumin in blood[15,18,31] and malabsorption of fats and sugar[3,23]. Those patterns may result from *C. philippinensis* secretion of a proteolytic substance or direct penetration of the intestinal wall that causes cellular injury and dysfunction[23]. Several studies showed intestinal pathological findings in *C. philippinensis* infection which showed atrophied crypts, flattened villi, and leukocyte cell infiltration that were signs of intestinal cell injury[25,31,32]. Therefore, the destruction

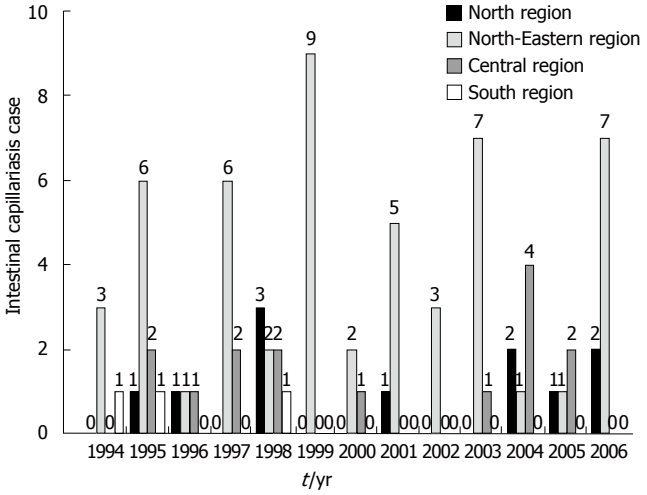

Figure 1 Intestinal capillariasis cases in Thailand from 1994 to 2006.

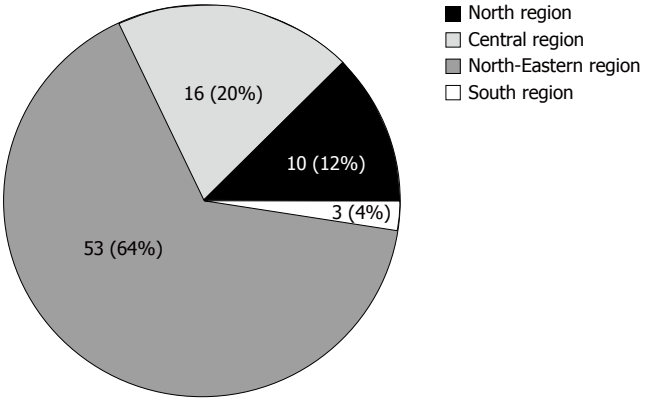

Figure 2 Intestinal capillariasis cases (82) reported in Thailand by region from 1994 to 2006.

of the intestinal cell membrane may interrupt nutrient absorption that causes weight loss in intestinal capillariasis patients. Moreover, the intestinal cells' destruction may lead to fluids, proteins and electrolytes loss because those intestinal cells are dysfunctional and cannot control fluids and electrolytes balance in the body[33] that results in a low level of potassium and albumin in the blood of *C. philippinensis* infection patients. The edema in patient, due to hypoalbuminemia[31] according to albumin levels, is plasma protein which controls the fluid in blood vessels by maintaining the osmotic pressure. If the osmotic pressure decreases, the plasma fluid in vessels leaks out of the capillaries into the interstitium and leads to edema in intestinal capillariasis patients[34].

DISTRIBUTION AND PREVALENCE OF INTESTINAL CAPILLARIASIS IN THAILAND

The epidemic of *C. philippinensis* infection was first recognized from Ah Huad village in a province with an incidence of 20 patients and 9 dead cases[16]. Thereafter, Kunaratanapruk *et al* recorded intestinal capillariasis cases at hospital. The reports showed 72 cases and 12 died

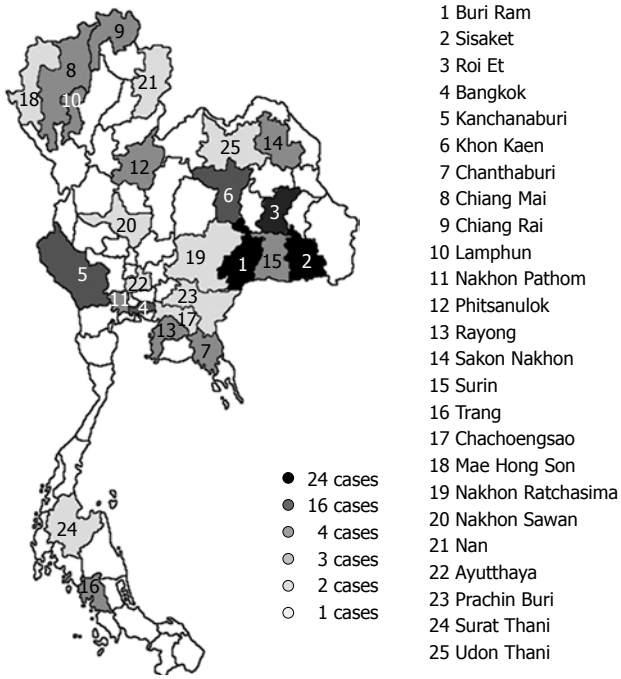

Figure 3 Twenty-five provinces in Thailand with intestinal capillariasis cases reported from 1994-2006. Each number in the map represents each province.

in 1981 and 24 cases and 2 died in 1982[21]. The annual epidemiological surveillance reports indicated that 82 accumulated cases of intestinal capillariasis were found in Thailand from 1994-2006 (Figure 1). Most of the cases occurred in 1995 and only 1 case died from intestinal capillariasis in 1996 (data not show).

Human intestinal capillariasis has occurred in many parts of Thailand, but is more common in the northeastern area. Owing to the life style, most people in this area like to eat raw fish which is believed to be the source of *C. philippinensis* infection in the area. Interestingly, no intestinal capillariasis cases were reported from the southern region during 1999 to 2006 (Figure 1). From 1994 to 2006, most of the intestinal capillariasis accumulated cases were found in the northeastern region (53 cases) and the second highest was the central region (16 cases) (Figure 2). This report was similar to previous studies which found most of the intestinal capillariasis cases in the northeastern region[16,21,23]. The provinces in the northeastern region which were found with *C. philippinensis* infection in 1994 to 2006 were Buri Ram, Khon Kaen, Nakhon Ratchasima, Roi Et, Sakon Nakhon, Surin and Udon Thani (Figure 3). Buri Ram was had the highest reported intestinal capillariasis cases which had 24 cases from 1994-2006. From 1995 through 2006, children ages less than 1 year to 9 years had been mostly infected by *C. philippinensis* (Figure 4). Contrarily, in the Philippines[3] and Egypt[35] most intestinal capillariasis cases were found in middle-aged or the active age group. This result might be caused by the child playing in the cooking area while their parent prepared food and the child eating small pieces of raw fish similarly reported by El-Dib and Doss[35]. However, working age groups (25-54 years) were still infected by *C. philippinensis* and had 38 reported cases from 1995-2006 (Figure 4).

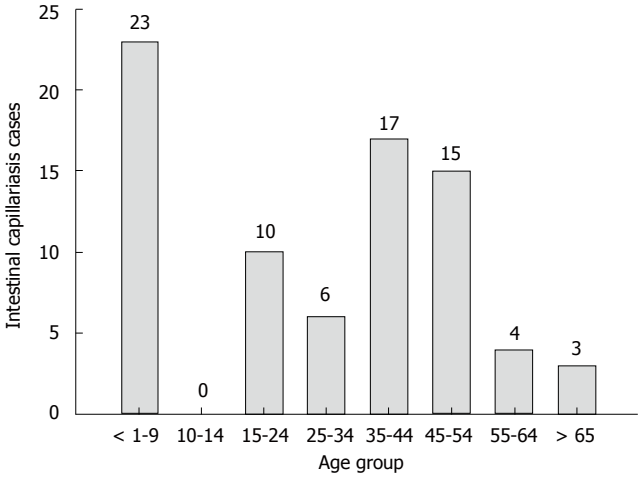

Figure 4 Intestinal capillariasis cases in Thailand by age from 1995 to 2006.

DIAGNOSIS OF INTESTINAL CAPILLARIASIS IN THAILAND

The detection of *C. philippinensis* is based on the recovery of eggs, larvae and/or adult worms in the stool of the patients. Unembryonated *C. philippinensis* eggs are peanut-shaped with flattened bipolar plugs and a striated shell. Larvae are found in the feces but difficultly identified as *C. philippinensis*[3]. An inexperienced laboratory worker may confuse with *Trichuris trichiura* eggs which are prominent mucoid bipolar plugs. The eggs of *C. philippinensis* are excreted sporadically in feces that lead to delayed diagnoses as intestinal capillariasis. Therefore, multiple stool samples may be important to early diagnosis in some cases[3]. In most of the intestinal capillariasis cases reported in Thailand eggs, larvae or adult worms in feces were found[15,16,18-20,22], but there were some patients that died from *C. philippinensis* infection in whom *Capillaria* eggs or larvae were not found in the feces[31]. However, small intestinal aspiration or biopsy may be necessary to confirm *Capillaria* infection[3]. For example, gastroduodenoscopy in a 13-year-old boy from central Thailand showed *C. philippinensis* eggs in a jejunal biopsy[32]. Moreover, jejunal mucosal biopsy and microscopic jejunal content examinations were successfully used to identify intestinal capillariasis in a 27-year-old Thai man who had negative repeated stool tests[25]. Immunodiagnosis may be a supplementary diagnostic tool which helps to detect *C. philippinensis* infection. Recently, Intapan *et al* investigated the intestinal capillaries using *Trichinella spiralis* antigen[36]. The study revealed sera from intestinal capillariasis patients were positive with *T. spiralis* antigen. This may be useful for screening of persons who have intestinal capillariasis-like symptoms before discovering *Capillaria* eggs or larvae in their stool[36].

SOURCE OF INTESTINAL CAPILLARIASIS IN THAILAND

C. philippinensis infection is mostly found in raw fish eating areas. For example, the people in Ilocos Norte province, in the Philippines, like to eat raw bagsit (*Hypseleotris bipartita*), *Capillaria* larvae containing fish, in a single bite leads to infection by *C. philippinensis*[3]. Similarly in Thailand, Koi pla and Taab Kaab are common foods that cause infection with intestinal capillariasis. Koi pla is made from chopped raw fish mixed with lemon juice, finely cut red onion and chili. Taab Kaab is made from pounded raw whole fish mixed with lemon juice, finely cut red onion and chili. These foods are favorite dishes in agricultural areas because they are easy to prepare and fresh water fish are found plentiful chiefly in these regions. In experimental study, fresh water fish in Thailand such as *C. carpio* (Pla Nai), *P. gonionotus* (Pla Tapien Khao) and *R. boraperensis* (Pla Sew), which are used to prepare Koi pla and Taab Kaab, could serve as experimental intermediate hosts for *C. philippinensis*[27]. Moreover, some people usually chew the fish freshly caught because those fish are too small to eviscerate. So the raw fresh water fish eating behavior is a major factor associated with intestinal capillariasis in Thailand.

STRATEGY FOR INTESTINAL CAPILLARIASIS CONTROL

Intestinal capillariasis is a severe disease that may lead to death unless patients are treated. The symptoms of *C. philippinensis* infection are continuous or intermittent watery diarrhea associated with severe weight loss, severe protein-loss and severe electrolyte depletion. These lead patients to die from intestinal capillariasis, so the strategy to fight the disease consists of not eating raw fish, promoting a health education program and early diagnosis are necessary to minimize or eradicate *C. philippinensis* infection in Thailand.

The health education campaign aims to promote the consumption of cooked fish and to avoid defecation into a water resource in order to eliminate *C. philippinensis* infection. The early diagnosis is necessary for treating intestinal capillariasis patients, especially improving the experience of laboratory workers and multiple stool examination must be required.

ACKNOWLEDGMENTS

The authors would like to extend our most heartfelt thanks to Dr. Suwit Piankijagum from Faculty of Science and Technology, Huachiew Chalermprakiet University for his morale encouragement and the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health for supporting data of capillariasis cases in Thailand.

Abstract

AIM: To investigate the anti-proliferative and apoptotic effects of Chaga mushroom (*Inonotus obliquus*) water extract on human hepatoma cell lines, HepG2 and Hep3B cells.

METHODS: The cytotoxicity of Chaga extract was screened by 3-[4,5-dimethylthiazol-2-yl]-2, 5-diphenyltetrazolium bromide (MTT) assay. Morphological observation, flow cytometry analysis, Western blot were employed to elucidate the cytotoxic mechanism of Chaga extract.

RESULTS: HepG2 cells were more sensitive to Chaga extract than Hep3B cells, as demonstrated by markedly reduced cell viability. Chaga extract inhibited the cell growth in a dose-dependent manner, which was accompanied with G_0/G_1-phase arrest and apoptotic cell death. In addition, G_0/G_1 arrest in the cell cycle was closely associated with down-regulation of p53, pRb, p27, cyclins D1, D2, E, cyclin-dependent kinase (Cdk) 2, Cdk4, and Cdk6 expression.

CONCLUSION: Chaga mushroom may provide a new therapeutic option, as a potential anticancer agent, in the treatment of hepatoma.

INTRODUCTION

Chaga mushroom (*Inonotus obliquus*), a white rot fungus, belongs to the hymenochaetaceae family of Basidomycetes. Chaga mushroom grows on birch trees in colder northern climates[1]. Since the sixteenth century, Chaga has been used as a folk medicine in Russia and western Siberia[2]. Recently, many polyphenolic compounds including triterpenoids, steroids, and ergosterol peroxides from *Inonotus sclerotia* have shown various biological activities, including anti-bacterial[3], hepato-protective[4], and anti-tumor[5-7] effects. However, its molecular mechanisms to the anti-tumor effects have not been well documented, in spite of its increasing usage.

Natural products including thousands of compounds that exist in fruits, vegetables, mushrooms and medical plants have been used as a source of therapeutic agents for several types of cancer or health food supplements in humans[8,9]. Especially, medicinal mushrooms, including genera *Auricularia, Flammulina, Pleurotus,* and *Trametes*, have been proven to express promising anti-tumor, immune modulating, antiviral, and antiparasitic effects[4]. It has been reported that medicinal mushrooms showed the cytotoxic effects in cancer cells by induction of apoptosis accompanying modulated cell cycle progression[10].

Cell proliferation and death are involved in the maintenance of homeostasis in normal cells; however, homeostasis is often disrupted in tumor cells with uncontrolled proliferation. Anti-tumor effects could be attributed to altered biochemical mechanisms, including inhibitions of proliferation, induction of cell cycle arrest at various cell cycle checkpoints, enhanced apoptosis, and regulation of signal transduction pathways, which are

related to altered expressions of key enzymes[11]. Cyclin-dependent kinases (Cdks), CDK inhibitors (CDKIs), and cyclins are important regulators of cell cycle progression. Also, each phase of the cell cycle is governed by different Cdks associated with their individual regulatory subunits, cyclins. The G_0/G_1 phases of the cell cycle were controlled by Cdk4/Cdk6 associated with cyclin D, late G_1 into early S phase by Cdk2 with cyclin E, S phase by Cdk2 with cyclin A, and G_2/M phase by Cdc2 kinase (CDK1) with cyclin A/cyclin B[12]. An increased expression of Cdks and cyclins accompanied by an enhanced CDK activity have been observed in most cancer cells, which could be involved in uncontrolled and unchecked cell proliferation[13]. Recently, many studies have shown that the inhibition of CDK activity, which led to cell cycle arrest, has turned out to be the most promising strategy for the discovery and design of novel anticancer agents. Therefore, cell cycle arrest and the induction of apoptosis in cancer cells become the major indicators of anti-cancer effects[14].

In this study, we investigated the anti-tumor effects of Chaga extract and the molecular mechanisms by which Chaga extract exerts inhibitive effects on liver cancer cells, HepG2 cells.

MATERIALS AND METHODS

Preparation of Chaga Mushroom Water extract

The water extract of Chaga mushroom was prepared as follows. The Chaga mushroom, *Inonotus obliquus*, collected in Russia was used in this study. Chaga mushroom was extracted under optimal water extraction condition. The crushed dry mushroom (1.00 kg) was boiled for 4 h at 100℃, cooled to room temperature, and then filtered. The extract was evaporated to dryness with a rotary vacuum evaporator and freeze-dried to give a powder (250 g). The stock solution of Chaga extract was prepared by dissolving Chaga powder in distilled water (50 mg/mL) and the experimental concentrations were diluted in the basal medium.

Cell culture and reagents

Human hepatoma cell lines, HepG2 and Hep3B, and the Chang normal liver cell line were obtained from American Type Culture Collection (Rockville, MD) and maintained in MEM (Gibco, Grand Island, NY) supplemented with heat-inactivated fetal bovine serum (FBS, Gibco), penicillin (100 U/mL) and streptomycin (100 μg/mL) under 5% CO_2 in a humidified incubator at 37℃. Propidium iodide (PI), Triton X-100, and ribonuclease-A were purchased from Sigma (St. Louis, MO, USA). Antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA).

Cell viability analysis

Cell viability was quantified using 3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT). Briefly, the cells were plated in 48-well culture plates at a density of 5×10^4 cells/well and allowed to adhere at 37℃ for 12 h. The following day, various doses of Chaga extract were added to the cells and further incubated for 48 h. Then, MTT (0.5 mg) was added to 1 mL of cell suspension for 4 h. The ability of cells to form formazan crystals by active mitochondrial respiration was determined by using a Microplate reader (Titertek Multiskan, Flow Laboratories, North Ryde, Austria) after dissolving the crystals in DMSO. An empty well was used as a blank. Cytotoxicity was expressed as a relative percentage of the absorbencies measured in the control and Chaga-treated cells. Morphological changes after exposure to Chaga extract were observed by a phase-contrast inverse microscope (Olympus, Japan).

DNA cell cycle analysis

For the measurement of cellular DNA content, flow cytometric analysis was used. Briefly, 5×10^5 cells were seeded in six-well plates, and allowed to attach overnight. Cells were treated with different concentrations of Chaga extract (250, 500, 750, 1000 μg/mL) for 48 h. The cells were then harvested by trypsin treatment, washed with cold PBS, and then stained with propidium iodide (PI) solution (50 μg/mL of PI, 100 μg/mL RNase, and 0.1% Triton X-100 in PBS). The stained cells were analyzed for DNA histograms and cell cycle phase distribution by flow cytometry (FACSCalibur, BD Bioscience). Data from 10 000 cells per sample were collected and analyzed with CellQuest™ software (Becton Dickinson). To determine G_1, S, and G_2/M-phase cell populations, the settings for 2 mol/L and 4 mol/L DNA content peaks were obtained within each experiment using the G_0/G_1 arrested cell (2 mol/L) in control as the reference and applied to all samples within a given experiment.

Western blotting

Cytosolic protein extracts were prepared as in previously described methods[15]. Briefly, cells were collected by centrifugation at 300 × *g* for 5 min at 4℃ and washed with cold PBS. The cell pellet was then resuspended in 500 μL of lysis buffer (20 mmol/L HEPES- KOH, pH 7.5, 250 mmol/L sucrose, 70 mmol/L mannitol, 1.5 mmol/L $MgCl_2$, 10 mmol/L KCl, 10 μg/mL leupeptin, and 10 μmol/L digitonin). After 10 min incubation at 25℃, the sample was spun at 14 000 × *g* for 15 min, and the supernatant containing cytosolic proteins was stored at -70℃ until analyzed by polyacrylamide gel electrophoresis (SDS-PAGE). The protein extract was subjected to standard SDS-PAGE, transferred onto polyvinylidene difluoride membranes (Millipore), and probed with appropriate antibodies as described individually in the figure legends. The bound primary antibody was detected by using appropriate horseradish peroxidase-conjugated secondary antibody, and the reaction band was visualized using an enhanced chemiluminescence detection kit. Western blot analysis was done using primary antibodies against pRb, p53, p27, Cyclin E, D2, D1, Cdk2, 4, 6, pro-caspase 3, and β-actin (Santa Cruz Biotechnology) at optimal dilution. β-actin was used as an internal control to confirm that the amounts of protein load were equal.

Statistical analysis

The data shown are a summary of the results from at least three experiments and are presented as the mean ± SD. Statistical evaluation of the results was performed by one-

way ANOVA. The results were considered significant at a value of $P < 0.05$, $P < 0.01$.

RESULTS

Cytotoxicity of Chaga extract on HepG2 cells

To evaluate the effects of Chaga extract on cell proliferation and morphology of hepatoma cells, we first determined the antiproliferative effects of Chaga extract on human hepatoma cells, HepG2 and Hep3B, as well as immortalized normal liver cells, Chang. The cells were exposed to various doses of Chaga extract for 48 h and cell viability was determined by MTT assay. As shown in Figure 1A, the survival curve showed that Chaga extract had dose-dependent cytotoxic effects on HepG2 and Hep3B cells; however HepG2 cells were more sensitive to Chaga extract than Hep3B cells (Figure 1A). Within 48 h after exposure to 750 μg/mL of Chaga extract to HepG2, cell viability was reduced by 60% of control ($P < 0.01$). After treatment with 1000 μg/mL of Chaga extract for 48 h, cell viabilities of HepG2 and Hep3B were 36% and 67%, respectively. In contrast, Chang normal liver cells were not markedly affected by the treatment with Chaga extract (1000 μg/mL) for 48 h (Figure 1A). Taken together, these data indicated that Chaga extract significantly exerted apoptotic death in hepatoma cells, such as HepG2 and Hep3B cells. We next examined whether the cytotoxicity of Chaga extract is related to the induction of apoptosis. HepG2 cells were treated with 750 μg/mL of Chaga extract for 48 h, and morphological change of the cells was assessed using light microscopy. Chaga extract-treated cells (Figure 1B) showed a distinct decreased cell population compared with control cells.

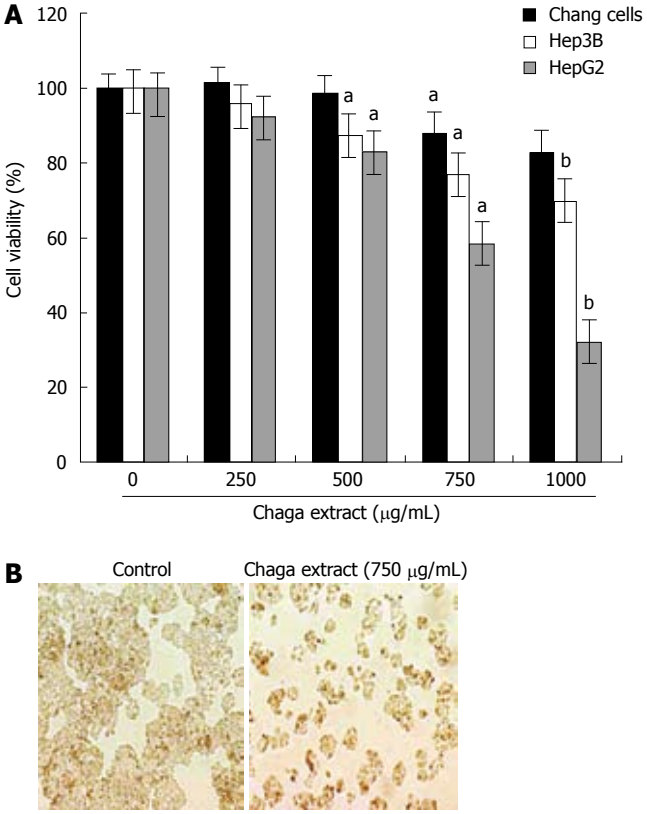

Figure 1 Cytotoxic effect of Chaga extract on human hepatoma cells. **A**: The various cells, HepG2, Hep3B, and Chang normal liver cells, were treated with various doses of Chaga extract for 48 h. Cell viability was measured by MTT assay. Data represented as means ± SD of three independent experiments. $^{a}P < 0.05$, $^{b}P < 0.01$, *vs* control cells; **B**: The morphological changes of HepG2 cells after exposure to Chaga extract (750 μg/mL) for 48 h. The photomicrography was taken under a phase contrast microscope (× 200).

Apoptotic cell death of HepG2 by Chaga extract

Since the cell growth and inhibition are both tightly regulated by cell cycle control[16], next, we investigated the possible inhibitory effect of Chaga extract on cell cycle distribution by flow cytometry analysis. Representative histograms for cell cycle distribution in HepG2 cells following exposure to various concentrations of Chaga extract are shown in Figure 2A. The effects of Chaga extract on HepG2 cell cycle distribution are summarized in Figure 2B. As shown in Figure 2B, treatment of HepG2 cells with 750 μg/mL of Chaga extract for 48 h resulted in a higher number of cells in the G_0/G_1 phase (75.3%) compared to media control (62.1%). This increase was coupled with the decreased percentage of cells in S phase. After a 48 h treatment, the percentage of S phase in Chaga extract-treated cells was 2.78%, whereas 9.25% in control cells. In addition, flow cytometry analysis also revealed the effect of Chaga extract on the induction of apoptosis: increase of cell percentage in the sub-G_0/G_1 phase. As shown in Figure 2C, the percentage of the sub-G_0/G_1 fraction in Chaga extract-treated cells was increased in a dose-dependent manner, indicative of apoptotic cell death. In a while, caspases are activated during apoptosis by proteolytic processing at specific aspartate cleavage sites[17]. Therefore, we determined whether the induction of apoptosis by Chaga extract resulted in an activation of caspase-3, which is a key caspase activated in apoptotic cell death (Figure 2D). As shown in Figure 3D pro- caspase-3 was markedly decreased in Chaga extract-treated HepG2 cells. These data suggest that inhibition of cell proliferation or induction of cell death in HepG2 cells by Chaga extract may be exerted by the induction of G_0/G_1 phase arrest and subsequent apoptotic process accompanying caspase-3 activation.

Effect of Chaga extract on the modulators of cell cycle

Tumor suppressor gene p53 has been shown to play an important role in the induction of cell cycle arrest and apoptosis[18]. Also, pRB has been known to play a critical role in the G_1 to S phase cell cycle transition[19]. Since the inhibitory mechanism of Chaga extract on cell proliferation might be caused by the expression of negative regulators of the cell cycle, we evaluated the protein expression of p53, pRb, and p27. As shown in Figure 4, we found that p53 and pRb protein was obviously decreased by Chaga extract in a dose-dependent manner in HepG2 cells (Figure 3). The p27, a specific inhibitor of CDKs, is mainly involved in G_1/S transition of the cell cycle. The p27 was also markedly down-regulated by treatment with Chaga extract in a dose dependent manner (Figure 3).

Down-regulation of G_0/G_1 regulatory proteins

To analyze the underlying biochemical mechanisms

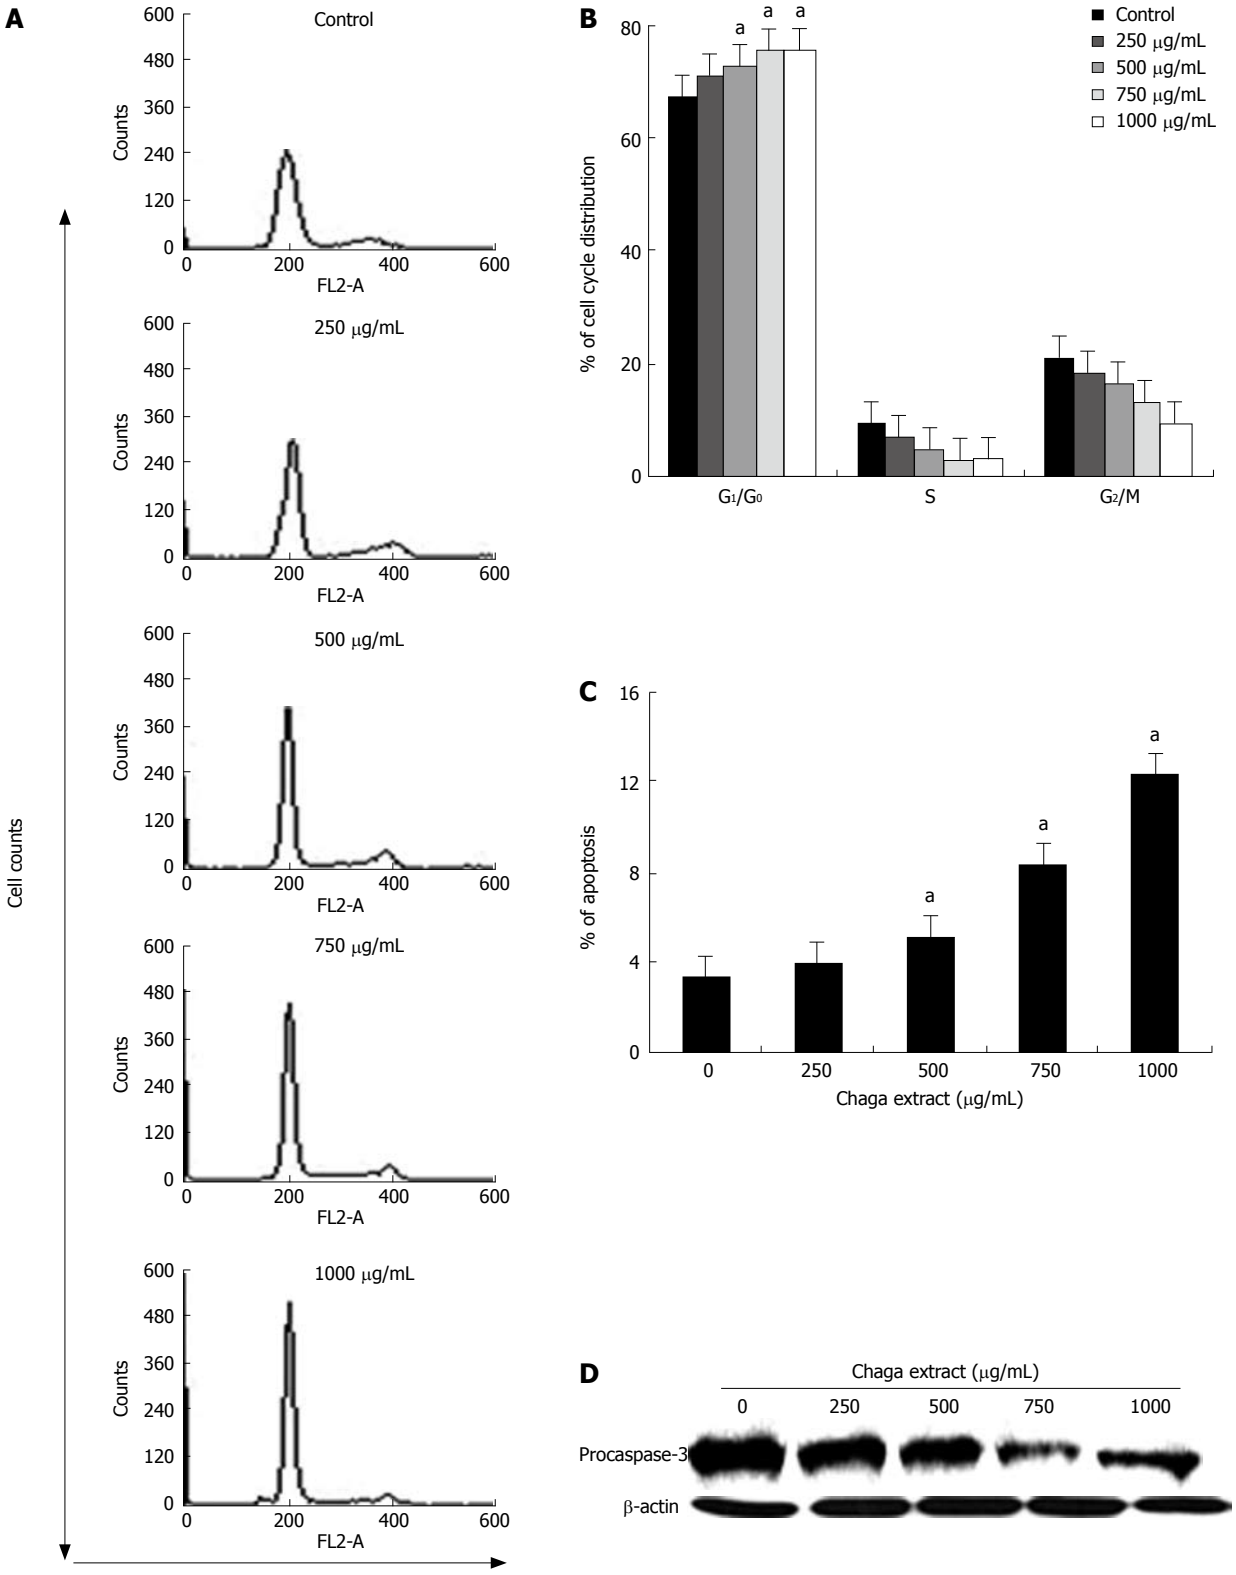

Figure 2 Apoptotic cell death of HepG2 by Chaga extract. The effect of Chaga extract on cell cycle progression of HepG2 cells was determined. HepG2 cells were treated with various doses of Chaga extract for 48 h. Then, cells were harvested and washed with cold PBS. **A**: Cellular DNA content was stained with PI solution and flow cytometric analysis was performed to analyze the cell cycle distribution. Cell cycle histogram was shown; **B**: A summary of cell cycle distribution data in histograms. Data represented as means ± SD of three independent experiments. $^{a}P < 0.05$, *vs* control cells; **C**: The percentage of subG$_0$/G$_1$ phase was represented as % of apoptosis. Data represented as means ± SD of three independent experiments. $^{a}P < 0.05$ *vs* control cells; **D**: Caspase-3 activation, which was measured by cleavage of procaspase-3, in Chaga extract-treated HepG2 cells was determined by western blot analysis.

involved in the regulation of the G$_0$/G$_1$ cell cycle arrest, we investigated the effect of Chaga extract on the protein levels of the Cdks and cyclins during G$_0$/G$_1$ cell cycle arrest progression. As shown in Figure 4A, treatment of HepG2 cells for 48 h with Chaga extract resulted in a prominent decrease in the expressions of Cdk2, Cdk4, and Cdk6 in a dose-dependent manner. Of note, a marked reduction in Cdk2 and Cdk6 was observed even at a dose

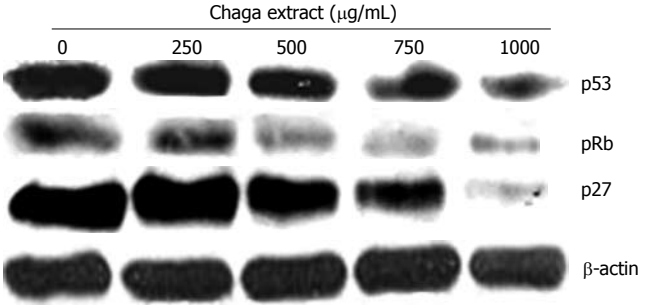

Figure 3 Effect of Chaga extract on the modulators of cell cycle such as p53, pRb, and p27. Western blot analysis for p53, pRb and p27 was performed using specific antibodies with β-actin as a loading control.

of 250 μg/mL of Chaga extract. In addition, Chaga extract markedly decreased the expression of Cyclin D1, D2, and E (Figure 4B). These observations suggest that the down-regulation of the levels of cyclin/Cdk proteins in Chaga extract-treated HepG2 cells is closely related to the induction of G_0/G_1 arrest of cell cycle progression.

DISCUSSION

Several anti-cancer drugs or compounds for cancer treatment have been found in natural products. In this study, we found that aqueous extracts of Chaga mushroom (*Inonotus obliquus*) caused a growth inhibition of human hepatoma HepG2 cells, and this was closely associated with the arrest of the cell cycle in G_0/G_1 phase and induction of apoptosis.

The eukaryotic cell cycle is regulated by signal transduction pathways mediated by a series of cell-cycle regulators. Cyclins are positive regulators of cell cycle progression and function by forming a complex with CDKs. CDK inhibitors are negative regulators of the cell cycle and bind to cyclin-CDK complexes and inhibit the activity of those complexes[20]. Therefore, induction of cell cycle arrest and apoptosis by chemopreventive drugs could be an effective approach to treat uncontrolled cell proliferation and survival in tumor cells.

In recent years, mushroom extracts have been found to have anti-inflammatory, anti-tumor properties[21]. Although it has been reported that the Chaga mushroom and other mushrooms have therapeutic effects such as anti-tumor, anti-inflammatory and hepatoprotective effects[4], the mechanisms of anti-inflammatory and anti-tumor effects of the Chaga mushroom have not been clearly elucidated[22]. In the present investigation, we showed that the water extract of the Chaga mushroom, which has been used in the treatment of cancers and digestive system diseases[2], significantly inhibited the viability and proliferation, and induced apoptotic cell death in human hepatoma HepG2 cells (Figure 1A), but this effect was not found in Chang cells, the human immortalized non-tumor cell line (Figure 1C). These data indicate that Chaga extract has selective cytotoxic effects on human hepatoma cells. This selectivity may be the great advantage of the Chaga extract for therapeutic or preventative use in cancer treatment. Though there were several reports that many natural products induce cell cycle arrest in various cell

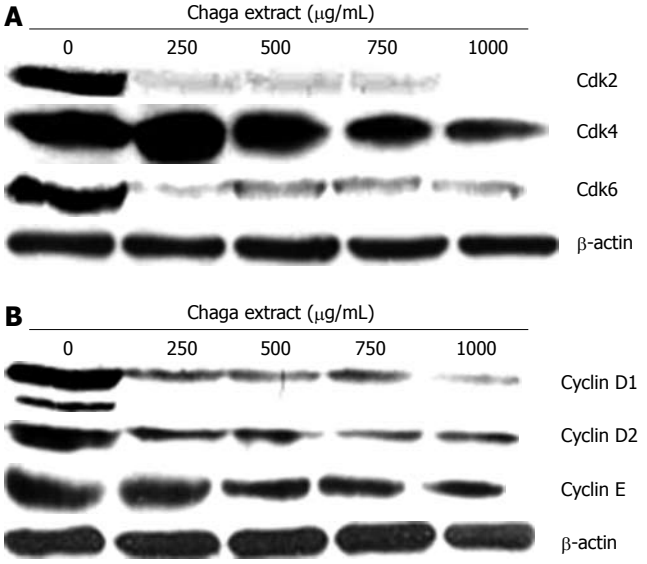

Figure 4 Effect of Chaga extract on the protein levels of G_0/G_1 regulatory Cdks and cyclin in HepG2 cells. The effect of Chaga extract on the protein levels of G_0/G_1 regulatory Cdks and cyclin in HepG2 cells was determined by western blot. Western blot analysis for Cdks (**A**: Cdk2, Cdk4, and Cdk6) and Cyclins (**B**: Cyclin D1, Cyclin D2, and Cyclin E) was performed using specific antibodies with β-actin as a loading control.

cycle phases, this study is the first report that reveals the inhibitory effect of Chaga extract on the cell cycle in cancer cell lines. In this study, flow cytometric analysis clearly revealed that HepG2 cells were dose-dependently arrested by Chaga extract at the G_0/G_1 phase of the cell cycle (Figure 2A).

The blockade of survival pathways or the induction of apoptosis pathways by anti-cancer agents prevents the proliferation of cancer cells, which may be exploited for cancer therapy[23]. p53 is a tumor suppressor gene encoding a transcription factor. Its tumor-suppressive activity involves inhibition of cell proliferation through cell cycle arrest and/or apoptosis. Mutation in p53 occurs in more than half of human cancers[24-26]. Therefore, the activation of p53 by anticancer agents may induce the cell cycle arrest and apoptosis in cancer cells leading to the inhibition of tumor progression. HepG2 has a functional p53 (wt p53), however Hep3B does not have a functional p53 (delete p53)[27]. In our study, HepG2 cells were more sensitively damaged by Chaga extract than Hep3B cells (Figure 1). Therefore, we speculated that wt p53 plays an important role on the apoptosis-inducing effect of Chaga extract in HelpG2 cells. However, our data did not show whether the activation of p53 may mediate the cytotoxicity and cell cycle arrest in Chaga extract-treated HepG2 cells, because wt p53 was down-regulated by Chaga extract (Figure 4). Interestingly, Park *et al* (2006)[28] showed that 6-gingerol, a major phenolic component in ginger, induced G_0/G_1 arrest with up-regulation of $p21^{WAF1}$ expression and down-regulation of p53/pRb expression in pancreatic cancer cells. In the present study, the down-regulation of pRb and p27 protein expression as well as p53 was detected in the Chaga extract-treated HepG2 cells. Our major question remaining to be addressed is that the down-regulation of p53, pRB, and p27 protein, are closely associated with the

terminal differentiation or the other signaling pathways levels. However, unfortunately, this question cannot be addressed at the present time.

Eukaryotic cell cycle progression involves sequential activation of Cdks, whose activation is dependent upon their association with cyclins. G_1-phase arrest of cell cycle progression provides an opportunity for cells to either undergo repair mechanisms or proceed by the apoptotic pathway[29]. It has been suggested that Cdk activities control G_1/S transition in mammalian cells[30]. Both D- and E-type cyclins are known to be important regulators in G_1/S control, even though some reports raised the possibility that they have other distinct roles[31]. In our results, we found that treatment with Chaga extract causes a significant decrease in the expression of cyclin D1, D2 and E and Cdk 2, Cdk4, Cdk6 in HepG2 cells. Thus, we speculated that the reduction of cyclin or Cdk expression resulted in the blocking of cyclin/Cdk complex formation and that lowered the levels of pRb (Figure 3). When Rb proteins remain in an unphosphorylated form, E2F cannot be activated and the cells fail to enter the S phase[28]. Based on the data (Figure 4), it seems that cyclin D1 and Cdk2, and Cdk6 are responsible for most of the cell cycle arrest observed in response to Chaga extract because these regulators are effectively deceased at the lowest dose of Chaga extract (250 μg/mL).

Taken together, we concluded that Chaga extract induced the growth inhibition, G_0/G_1-phase arrest, and apoptosis in human hepatoma HepG2 cells, but not in normal Chang liver cells. The present results can provide new hope for chemotherapy of hepatoma cancer. Furthermore, an improved understanding of the interactions between phytochemicals with the genes that are critical to the regulation of cancer cell growths will provide strong armaments to cancer therapy.

COMMENTS

Background

Chaga mushroom (*Inonotus obliquus*), a white rot fungus, belongs to the hymenochaetaceae family of Basidomycetes. Since the sixteenth century, Chaga has been used as a folk medicine in Russia and western Siberia. Chaga mushroom have shown various biological activities, including anti-bacterial, hepato-protective, and anti-tumor effects. However, its molecular mechanisms to the anti-tumor effects have not been well documented, in spite of its increasing usage. Therefore, we investigated the anti-tumor effects of Chaga extract and the molecular mechanisms by which Chaga extract exert inhibitive effects on liver cancer cells, HepG2 cells.

Research frontiers

Eukaryotic cell cycle is regulated by signal transduction pathways mediated by a series of cell-cycle regulators. Therefore, induction of cell cycle arrest and apoptosis by chemopreventive drugs could be an effective approach to treat uncontrolled cell proliferation and survival in tumor cells. Though there were several reports that many natural products induce cell cycle arrest in various cell cycle phases, this study is the first report that reveals the inhibitory effect of Chaga extract on cell cycle in cancer cell lines.

Innovations and breakthroughs

Chaga extract has selective cytotoxic effects on human hepatoma cells. Many reports indicated that cell cycle regulatory proteins such as p53 and p27, are up-regulated in G_0/G_1 cell cycle arrest. Nevertheless, we observed that Chaga extract induced the down-regulation of p53, pRb, and p27 expression in G_0/G_1 arrest. However, the precise molecular mechanisms involved in the decrease of the cell cycle regulator proteins, p53, pRb, and p27, are still unclear.

Applications

Chaga mushroom may provide a new therapeutic option, as a potential anticancer agent, in the treatment of hepatoma.

Peer review

The authors investigated the anti-proliferative and apoptotic effects of Chaga mushroom (*Inonotus obliquus*) water extract on human hepatoma cell lines, HepG2 and Hep3B cells. Chaga mushroom may provide a new therapeutic option, as a potential anticancer agent, in the treatment of hepatoma.

Abstract

AIM: To evaluate the preventive effects of phosphorus-32 glass microspheres (P^{32}-GMS) in the recurrence of massive hepatocellular carcinomas (HCCs) after tumor resection.

METHODS: Twenty-nine patients with massive HCCs received local P^{32}-GMS implantation after liver tumors were removed, while the other 38 patients with massive HCCs were not treated with P^{32}-GMS after hepatectomies. The radioactivity of the blood, urine and liver were examined. The complications, HCC recurrence and overall survival rates in the patients were analyzed.

RESULTS: P^{32}-GMS implanted in the liver did not cause systemic absorption of P^{32}. There were no significant differences of postoperative complications between the patients with and without P^{32}-GMS treatment. The short-term (six months and 1 year) and long-term (2, 3 and over 3 years) recurrence rates in patients who received P^{32}-GMS radiotherapy were significantly decreased, and the overall survival rates in this group were significantly improved.

CONCLUSION: P^{32}-GMS implantation in the liver can significantly decrease the postoperative recurrence and improve the overall survival in HCCs patients after hepatectomy. This therapy may provide an innovative method in prevention of HCC recurrence after operation.

Key words: Hepatocellular carcinoma; Recurrence; Phosphorus-32 glass microspheres; Hepatectomy

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors in southeastern China. The mortality of this disease has ranked as the second highest in cancer nationwide and responsible for an estimated one million deaths annually since the 1990s, and its morbidity is increasing among males[1,2]. Currently, the prognosis of HCC mainly depends on the results of surgical treatment of the tumors. The surgical treatments include the tumor resection and liver transplantation, which offer the only chance for radical treatment of HCC patients[3].

Clinically, with the characteristics of rapid infiltrating growth, early local and/or distant metastasis and high postoperative recurrence, the massive HCCs are usually diagnosed when they are at advanced stages with poor prognosis. The recurrence rate of intrahepatic carcinomas varies from 36.8% to 82%, which caused death in about 50% of the patients[4-7]. Prevention of cancer recurrence and metastasis after curative surgical resection has become a key issue for improvement of the surgical outcome and long-term survival of the patients.

In the past decades, many adjuvant interventional therapies have been continuously extended as a result of the technical development of locoregional approaches for HCCs. The combined multimodal therapies have played important roles in preventing postoperative recurrence of HCCs. Recently, nuclide labeled with undegradable micro-carriers has become a new radioactive therapy for malignant liver cancers.

Phosphorus-32 (P^{32}) is a radioisotope which emits

relatively high energy beta particles as it decays. Recent experimental studies and clinical trials showed that intrahepatic arterial application of P^{32} labeled with undegradable glass microsphere could cause death of tumor cells in the animal model and reduce the size of the tumor[8-10]. However, this therapy was only reported for unresectable liver cancers. Since the postoperative recurrence of HCC is closely related with the peritumor micrometastasis and portal vein tumor invasion[11,12], development of the local radiotherapy may provide a method to prevent the recurrence of HCCs after radical hepatectomy. In this study, the outcome and complications of implantation of phosphorus-32 glass microspheres (P^{32}-GMS) in a series of patients with massive HCCs were analyzed after hepatectomy. We present for the first time the preventive effect of the local radiation therapy with P^{32}-GMS in HCC recurrence after radical hepatectomy.

MATERIALS AND METHODS

P^{32}-GMS preparation

P^{32}-GMS was generated by activation of standardized glass microspheres through a nuclear-chemical reaction, in which the nonradioactive P^{31} (P^{31}-GMS, cold sphere) was transformed into the radioactive P^{32} glass microsphere (provided by Nuclear Power Research Institute of China). The diameter of glass sphere is between 46 μm and 76 μm, with radioactivity of 550-3700 MBq/g per unit and P^{32} elution rate of less than 0.1% within 30 d. The radioactive nuclide purity was more than 99% with the physical half-life 14.28 d, and the average β ray energy was 0.695 MeV (maximum energy 1.711 MeV) per disintegration, and soft tissue penetration distance was 3.2 mm in average (maximum 8.0 mm). The P^{32}-GMS suspension was prepared by mixing P^{32}-GMS with 1 mL super-liquid iodized oil or 50% glucose solution to a concentration of 100 g/L on oscillator.

Implantation of P^{32}-GMS

The P^{32}-GMS suspension was soaked into a piece of the absorbable gelatin sponge. After hepatectomy, the gelatin sponge was buried within the liver resection surface during closure. The dose of P^{32}-GMS implantation depends on the size of the tumor and calculated by the formula: $Dt = 34.6 \times T \times C \times \sum\Delta i\ (1\text{-}E^{-0.693t/T})$. The mean dose of radiation for the patients was 5.27 ± 0.27 Gy. The total tissue absorbed dose after radioactive P^{32} disgregation was 135.18 Gy in average.

Patients

From June 1999 to September 2003, 67 patients were diagnosed as having HCCs and underwent hepatectomy. Among them, 29 patients received P^{32}-GMS radiotherapy after hepatectomy (group A), and the other 38 patients without radiotherapy after operation served as controls (group B). The patients' age, sex, preoperative intervals, tumor size, hepatitis B virus (HbsAg) infection rate, positive alpha-fetoprotein (α-FP), microvenous tumor invasion in both groups were evaluated.

After surgery, the liver radioactivity distributions were measured by a photo-emission computed tomography (ECT) on postoperative d 1, 7 and 14. The radioactivity of blood and urine were also measured daily with γ-ray counter in the first postoperative week and on postoperative d 14. The postoperative complications including death, subdiaphragm infection, bile leakage, leucopenia, jaundice, and pleura effusion and/or ascites were analyzed in each group. The survival of the patients (six months, 1 year, 2 years, 3 years and over 3 years) and cancer recurrence rates were compared between the two groups.

Table 1 General information of patients in groups A and B

	Group A (n = 29)	Group B (n = 38)	P value
Age (yr)	53.83 ± 2.20	55.26 ± 6.67	$P > 0.05$
Sex (male/female)	24/5	32/6	$P > 0.05$
Tumor size (cm)	7.58 ± 2.50	7.76 ± 3.13	$P > 0.05$
Preoperative interval (d)	23.34 ± 2.45	21.79 ± 4.19	$P > 0.05$
HbsAg positive rate (%)	75.9	81.58	$P > 0.05$
α-FP positive rate (%)	65.5	72.97	$P > 0.05$

Statistical analyses

The data were expressed as the mean ± SEM and mean ± SD. Differences between groups were compared using Kaplan-Meier method, un-paired Student's t test, and Chi-square. A P value less than 0.05 was defined as significant. All data were analyzed using SPSS11.5 statistics software (SPSS Inc., Chicago, IL).

RESULTS

Patients

The general information of the HCC patients is shown in Table 1. The average tumor size was 7.58 ± 2.50 cm in group A and 7.76 ± 3.13 cm in group B. There was no significant difference between the two groups. The positive rates of alpha-fetoprotein (α-FP) were 65.5% and 72.97% in groups A and B, respectively ($P > 0.05$). The postoperative pathologic examination revealed that the microvenous tumor invasion rate was 10.3% in group A and 13.16% in group B, respectively ($P > 0.05$). The comparisons of other parameters also showed no significant differences between the two groups.

Radioactivity

In patients of group A, the β rays of P^{32} in liver was detected by ECT (Figure 1), and the postoperative disgregation of radioactivity is shown in Figure 2. The radioactivity of P^{32} decreased on postoperative d 7 and d 14 when compared with postoperative d 1. The half life of P^{32} was about 14 d. The disgregation of the P^{32} radioactivity in liver matched the dynamic eradication of the radioisotope P^{32}.

The radioactivity in blood and urine was also measured in group A. The results showed that there was no significant radioactivity enhancement in blood and urine after P^{32}-GMS was implanted (Figure 3), which indicated that P^{32} was not systemically absorbed in the patients.

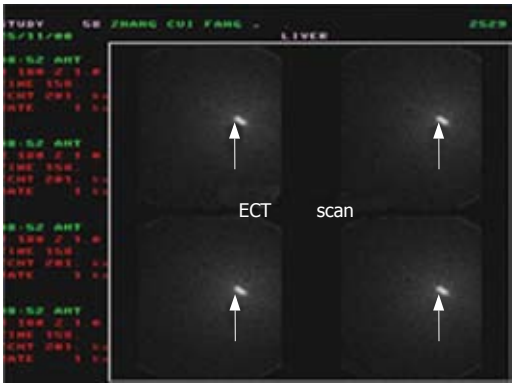

Figure 1 Liver ECT scan. Arrow: The site where P^{32}-GMS was implanted.

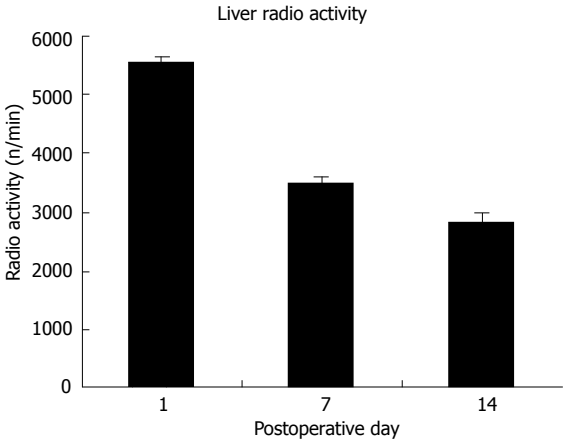

Figure 2 P^{32} Radioactivity in liver of the patients with P^{32}-GMS (n/min). The radio activity of P^{32}-GMS decreased on POD 7 and POD 14 as compared with POD 1. (POD = postoperative day).

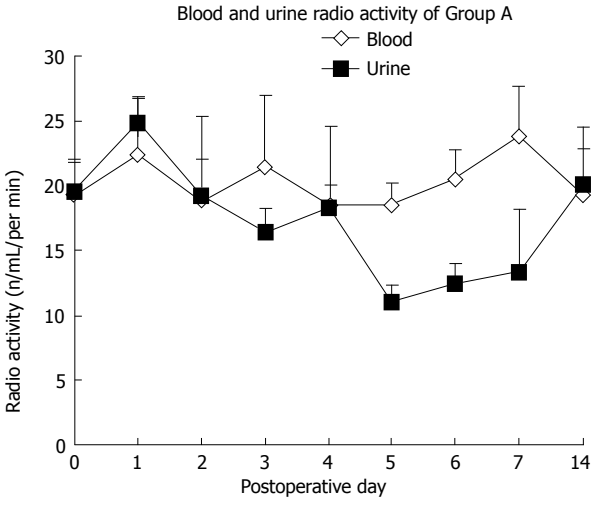

Figure 3 Radioactivity in blood and urine of the patients with P^{32}-GMS (n/mL/min). The radio activity in blood and urine were low. It was familiar with the sample without P^{32}-GMS implanted (d 0).

Complications

There was no perioperative patient death within 30 d after surgery in both groups. After hepatectomy, liver failure occurred in 3 patients (10.3%) of group A and 3 patients (7.89%) of group, respectively. The morbidity of other postoperative complications was also compared between the two groups (Table 2). There were no significant differences between the two groups.

Table 2 Postoperative complications in patients with and without P^{32}-GMS radiotherapy, *n* (%)

Complications	Group A (*n* = 29)	Group B (*n* = 38)	*P* value
Liver failure	3 (10.3)	3 (7.89)	$P > 0.05$
Perioperative death	0	0	$P > 0.05$
Subdiaphragm infection	1 (3.45)	2 (5.26)	$P > 0.05$
Bile leakage	0	0	$P > 0.05$
Leukopenia	0	0	$P > 0.05$
Jaundice	1 (3.45)	2 (5.26)	$P > 0.05$
Liver wound rupture	0	0	$P > 0.05$
Pleural effusion and/or ascites	5 (17.24)	5 (13.15)	$P > 0.05$

Table 3 HCC recurrence rates in patients with and without P^{32}-GMS, *n* (%)

Postoperative intervals	Group A (*n* = 29)	Group B (*n* = 38)	*P* value
6 mo	4 (13.8)	15 (39.5)	$P = 0.021^a$
1 yr	7 (24.1)	20 (52.6)	$P = 0.018^a$
2 yr	13 (44.8)	29 (76.3)	$P = 0.008^b$
3 yr	18 (62.1)	33 (86.8)	$P = 0.018^a$
Over 3 yr	18 (62.1)	33 (86.8)	$P = 0.018^a$

$^aP < 0.05$; $^bP < 0.01$.

Table 4 Survival rates in patients with and without P^{32}-GMS, *n* (%)

Postoperative intervals	Group A (*n* = 29)	Group B (*n* = 38)	*P* value
6 mo	28 (96.6)	35 (92.1)	$P = 0.454$
1 yr	27 (79.3)	27 (71.1)	$P = 0.024^a$
2 yr	22 (75.9)	17 (44.7)	$P = 0.010^b$
3 yr	19 (65.5)	8 (21.1)	$P = 0.000^b$
Over 3 yr	14 (48.3)	8 (21.1)	$P = 0.018^a$

$^aP < 0.05$; $^bP < 0.01$.

Recurrence rate and survival rate

The recurrent risk was estimated in both groups. The follow-up investigations showed that the short-term (6 mo and 1 year) and long-term recurrence rates at 2, 3 and over 3 years in group A were significantly reduced when compared with those who did not receive preventative radiotherapy (Table 3).

Although there was no significant difference in the six-month survival rates between two groups, the overall survival rates at 1 year, 2 years, 3 years and over 3 years in group A were significantly higher than those patients without radiotherapy (Table 4). Figure 4 shows a case of a 56-year-old woman who was diagnosed having progressive liver cancer. The patient received preventive P^{32}-GMS implantation at a dose of 6.83 Gy radioactivity after hepatectomy. There were no signs of liver radiation damage and cancer recurrence in the CT scans during the 4-year follow-up.

Arrows: implanted P^{32}-GMS.

DISCUSSION

The radical hepatectomy is now considered a major choice for the patients with resectable HCC. Recent development of surgical techniques and perioperative management have remarkably reduced the death that is caused by surgery[13,14]. In the past two decades, the advanced techniques of the curative tumor resection has also significantly improved the long-term survival of the patients. A recent report has shown that about a 50% survival rate has been achieved for the patients treated with surgery in a five-year follow-up[15]. However, the high postoperative recurrence rate is still a major problem for the long-term survival of the patients with HCCs after hepatectomy.

It has been reported that the 5-year recurrence rate of HCCs after curative resection ranges from 38% to 61.5%[16,17]. The recurrent peak is found at six months or 1 year after operation and most of the early postoperative recurrence is intrahepatic metastasis[18], which is attributed to the characteristics of vascular invasion propensity of HCCs. The appearance of tiny tumors through venous invasion in the liver is the main sign for potential HCC recurrence after surgery[19-29]. The intrahepatic metastasis of the tumor cells through the portal venous system is believed to be an important mechanism for HCC recurrence[24,30,31].

Since the tumors usually are located close to the major vessels or the severe liver cirrhosis coexists, extensive excision of liver frequently results in hepatic failure. The microvenous tumor embolus or existence of the residual tumor in the margin of remnant liver due to inadequate resection may cause the early postoperative recurrence of HCCs. Therefore, combination of adjuvant interventional therapies may play an important role in preventing postoperative recurrence of HCCs.

Several adjuvant interventional therapies for preventing postoperative recurrence of HCCs were investigated around the world. Some adjuvant approaches were effective in reducing the postoperative recurrence of HCC and improving survival of the patients. The postoperative transcatheter arterial chemoembolization (TACE) was shown to postpone the peak of recurrence rate in patients from 6 to 12 mo. However, the recurrence rate in the group with TACE treatment was even higher than that of the control group without TACE at a 18-mo follow-up[32]. One study showed that postoperative application of interferon alpha might postpone the recurrence of the HBV-related HCC after curative resection and improve the overall survival of patients[33]. In another study, postoperative intra-arterial injection of iodine131 labeled lipiodol (131I-Lip) was found to decrease the HCC recurrence rate in patients after hepatectomy, improving the 1-, 2-, and 3-year survival rates when compared with the survival rates in the control group receiving no 131I-Lip treatment[34]. The adjuvant chemotherapy was not effective in preventing the postoperative recurrence[35].

The mechanisms of the anticancer effect of P^{32}-GMS have been discussed. The experimental studies showed that the β-ray energy could directly destroy or injure the DNA of tumor cells while inducing death of the cells. Simultaneously, the β-ray irradiation could induce generation of several types of free radicals and superoxides, which could damage the tumor cells[36]. The β-ray was also found to induce the apoptosis of tumor cells[37,38]. In an experimental study in the nude mice model, intra-mass injection of P^{32}-GMS into the implanted human liver cancer was found to cause the death of many

tumor cells[9]. In some studies, intra-tumor injection of P^{32} chromic phosphate resulted in remarkable regression of the tumors[39,40]. The current study was to examine if local implantation of P^{32}-GMS in the liver after hepatectomy could decrease the risk of postoperative tumor recurrence.

In our study, the short-term (six months and 1 year) and the long-term (2, 3 and over 3 years) recurrence rates were significantly decreased in patients who received P^{32}-GMS radiotherapy. Decrease of tumor recurrence results in significant increase of survival of the patients. These findings demonstrated that the implantation of P^{32}-GMS in the liver after hepatectomy can provide a preventive effect in postoperative recurrence of HCC and improve the overall survival of the patients. This preventive effect of P^{32}-GMS is probably through damaging the tumor cells from the microvenous tumor embolus in the margin of remnant liver. However, the implantation of P^{32}-GMS under liver incision edge may not prevent the tumor recurrence from the distant intrahepatic metastasis prior to hepatectomy or the multi-centric HCCs.

Our study has also shown that there were no significant differences in postoperative complications between the patients receiving P^{32}-GMS radiotherapy and the patients without radiotherapy after surgery. No side effects of P^{32}-GMS implantation were observed and no radiation was detected in both blood and urine samples in the patients with P^{32}-GMS treatment. These results further confirmed the safety of local implantation of P^{32}-GMS in the liver.

In conclusion, P^{32}-GMS implantation in the liver after the resection of HCC can significantly decrease the postoperative recurrence of HCC, and improve the overall survival in the patients. This radiotherapy will not cause any side effects and complications, and may provide an innovative method for the prevention of HCC recurrence after hepatectomy.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common malignancies related to a high mortality globally. In recent years, the surgical treatments, including the tumor resection and liver transplantation, offer the only chance for radical treatment of HCC patients. Clinically, the massive HCCs are usually diagnosed at advanced stages, and the prevention of cancer recurrence and metastasis after curative hepatectomy has become a key issue for the improvement of the overall survival of the patients.

Research frontiers

In recent years, nuclide labeled with nontoxic and undegradable micro-carriers such as phosphorus-32 glass microsphere (P^{32}-GMS) has gained much attention as a new radioactive therapy for malignant liver tumors.

Innovations and breakthroughs

Some experimental studies and clinical trials have shown cytocidal effect of local intrahepatic irradiation of P^{32}-GMS in unresectable liver cancers. However, the study of evaluating the preventive effect of the local radiation therapy with P^{32}-GMS in HCC recurrence after radical hepatectomy has not been reported.

Applications

Through evaluating the pharmacology, toxicology and clinical effect, P^{32}-GMS was considered as a helpful therapeutic weapon combined with surgical and other nonsurgical treatment of liver cancer.

Terminology

P^{32}-GMS, which is transformed from nonradioactive P^{31}-GMS by activating the standardized glass microspheres through nuclear-chemical reaction, is the nuclide labeled nontoxic and undegradable micro-carriers. Recently, P^{32}-GMS and yttrium-90 glass microsphere have been successfully developed as a new radioactive medicine for treating malignant liver neoplasms.

Peer review

This report is the first study to evaluate the preventive effect of the local radiation therapy with P^{32}-GMS on HCC recurrence after radical hepatectomy. Although more studies are needed to confirm the safety and effect of the new medicine, it will be beneficial to the prognosis and treatment of HCC patients in the near future.

COLORECTAL CANCER

Hypermethylated *SFRP2* gene in fecal DNA is a high potential biomarker for colorectal cancer noninvasive screening

Abstract

AIM: To investigate the feasibility of detecting hypermethylated secreted frizzled-related protein 2 (*SFRP2*) gene in fecal DNA as a non-invasive screening tool for colorectal cancer (CRC).

METHODS: Fluorescence-based real-time PCR assay (MethyLight) was performed to analyze *SFRP2* gene promoter methylation status in a blinded fashion in tumor tissues and in stool samples taken from 69 CRC patients preoperatively and at the 9th postoperative day, 34 patients with adenoma $\geqslant$ 1 cm, 26 with hyperplastic polyp, and 30 endoscopically normal subjects. Simultaneously the relationship between hypermethylation of *SFRP2* gene and clinicopathological features was analyzed.

RESULTS: *SFRP2* gene was hypermethylated in 91.3% (63/69) CRC, 79.4% (27/34) and 53.8% (14/26) adenoma and hyperplastic polyp tissues, and in 87.0% (60/69), 61.8% (21/34) and 42.3% (11/26) of corresponding fecal samples, respectively. In contrast, no methylated *SFRP2* gene was detected in mucosal tissues of normal controls, while two cases of matched fecal samples from normal controls were detected with hypermethylated *SFRP2*. A significant decrease ($P < 0.001$) in the rate of hypermethylated *SFRP2* gene was detected in the postoperative (8.7%, 6/69) fecal samples as compared with the preoperative fecal samples (87%, 60/69) of CRC patients. Moreover, no significant associations were observed between *SFRP2* hypermethylation and clinicopathological features including sex, age, tumor stage, site, lymph node status and histological grade, *etc.*

CONCLUSION: Hypermethylation of *SFRP2* gene in fecal DNA is a novel molecular biomarker of CRC and carries a high potential for the remote detection of CRC and premalignant lesions as noninvasive screening method.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer worldwide, and is the second major cause of death from cancer in Europe and in the USA[1,2]. Worldwide almost one million new cases occur annually, amounting to 492 000 related deaths[3]. However, the incidence and mortality of CRC have been decreasing over the last decade, and this may be attributable to more effective screening and surveillance[2]. CRC is most effectively treated when diagnosed at an early stage, but the early stage of CRC is mostly symptomless as well as delitescence nature. Approximately 40% of colorectal cancers are diagnosed with localized disease, which have approximately a 90% five-year survival rate after curative surgery. However, the prognosis worsens with advancing stage, and only 5% of patients diagnosed with distant metastases survive 5 years[4]. With the potential of both reducing mortality from CRC as well as enhancing primary prevention through detection and removal of lesions that could potentially develop into cancer, early detection of CRC will increase survival the most[5]. Therefore, the need for early detection is clear, and an effective screening test would have substantial clinical benefits.

A promising noninvasive screening tool for colorectal neoplasia detection is to assay for molecular biomarkers that represent a "specific" or "spectrum" of genetic and/or epigenetic alterations existing in gastrointestinal tumor cells shed into stool[6]. Potentially, both premalignant adenomas and CRC may be detected this way. Epigenetic alterations are defined as heritable signatures of information other than nucleotide sequences. The interest in this field (especially DNA methylation) is immense, and the past several years have seen an explosion in investigations based on the unique differences in methylation patterns between the cancerous and normal-appearing tissues, and this new assay facilitates its use for noninvasive CRC screening[7,8]. However, in contrast to the relatively well accepted mutation-based fecal DNA testing[9], methylation-based testing has been initiated more recently, and is beginning to identify adequate specific markers that are representative of epigenetic "signature" alterations. Methylation analysis of a number of gene promoters in DNA from stool samples has been less comprehensively investigated, but has been suggested to be a sensitive diagnostic tool for colorectal tumor[10-14].

Aberrant Wnt pathway signaling is an early progression event in up to 90% of CRCs[15]. Suzuki *et al*[16-18] have identified frequent promoter hypermethylation and gene silencing of the secreted frizzled-related protein (*SFRP*) genes in CRC, in which *SFRP2* gene at human chromosome 4q31.3 is claimed as a tumor suppressor gene inactivated by the epigenetic CpG hypermethylation in CRC[19]. *SFRP2* is split in three exons of variable size separated by two introns, and have dense CpG islands around its first exons[16]. The CpG islands were closed correlated with DNA methylation of tumor cells. Its expression reportedly is inhibited in CRC specimens by hypermethylation of a CpG island extending from the gene's 5'-flanking region through the first exon[18]. In CRC, *SFRP2* genes have been identified that are commonly unmethylated and expressed in normal colon mucosa but are methylated and silenced in CRC[16-18,20]. Detection of hypermethylation of *SFRP2* genes in human DNA isolated from stools might provide a novel strategy for the detection and investigation of CRC.

In the present study, we analyzed methylation of *SFRP2* in stools taken from CRC patients preoperatively and postoperatively, and from patients with benign colorectal diseases as well as from normal controls, and then evaluated the potential of fecal *SFRP2* gene hypermethylation as a non-invasive screening tool for CRC.

MATERIALS AND METHODS

Patients and collection of tissue and fecal DNA samples

Colorectal tissue samples were routinely collected from 69 patients with sporadic CRC, 60 patients with benign colorectal diseases (34 adenomas and 26 hyperplastic polyps) and 30 macroscopically normal subjects undergoing surgery and endoscopy at the First Affiliated Hospital of Yangzhou university from March 2005 to February 2007. Meanwhile, the matched fecal samples were collected from all CRC patients preoperatively at the time bowel preparation and at the 9th postoperative day, from the patients with benign colorectal diseases and from the endoscopically normal patients, and were kept at 4℃ until being processed. Within 12 h after collection, the samples were washed with 1 × PBS and centrifuged at 1800 r/min for 15 min to pellet the solid stool. The pellet of stool and tissue samples were all stored at -80℃. None of the patients had received chemotherapy or radiation therapy prior to surgery. All patients gave informed consent for their participation in the study which had been approved by the Ethical Committee of our university.

DNA isolation from tissue and fecal samples

Samples were randomly coded before processing to ensure adequate blinding of the clinical information. DNA was isolated from colonic tissues (5-10 mg) by using QIAamp DNA Mini Kit (Qiagen) and from stool samples (250 mg) by using QIAamp DNA Stool Mini Kit (Qiagen) according to the manufacturer's protocol. HE-stained sections from tissue samples were examined by an experienced pathologist to confirm the histological diagnosis.

Bisulfite modification

The DNA was chemically modified by sodium bisulphate to convert all unmethylated cytosines to uracils while leaving methylcytosines unaltered (EpiTect® Bisulfite Kit, Qiagen), and eluted in 50 μL of elution buffer.

Methylation analysis

The bisulfite-modified DNA was used as a template for fluorescence-based real-time PCR (MethyLight) as described previously[21,22]. *SFRP2* gene was examined, and template-free distilled water was included as a negative control for amplification. The sequences of primers reported previously are listed in Table 1[14,23].

For the MethyLight, 3 μL of bisulfite-converted DNA was used in each amplification. PCR was performed in a reaction volume of 25 μL consisting of 17.875 μL of ddH_2O, 2.5 μL of 10 × PCR buffer, 2 μL of dNTP mixture, 0.25 μL of forward primer, 0.25 μL of reverse primer, 2 μL of template, and 0.125 μL of TaKaRa Taq HS (Hot Start) at the following conditions: pre-denaturation at 95℃ for 5 min, followed by 40 amplification cycles of denaturation at 95℃ for 30 s, primer annealing at 50℃ for 30 s (U primer), and extension at 62℃ for 30 s (M primer), and finally a further extension at 72℃ for 5 min. The stain was SYBR green I and PCR was performed in the LightCycle Fluorescent Quantitation PCR Detection System (LightCycler 1.0, Switzerland). A standard curve was created by plotting the logarithmic amount of the standard universal methylated DNA (31.25 pg to 10 ng) against the threshold cycle (CT) value.

Statistical analysis

To compare characteristics of the different groups of patients and biologic samples, two sided Student's *t* test, Chi-square test, and Fisher exact test were used as appropriate. Data were analyzed using SPSS10.0 software. $P < 0.05$ was considered statistically significant.

M1: Hypermethylated SFRP2 in tissue; M2: Hypermethylated SFRP2 in stool. [1]Represents the value of χ^2 and *P vs* normal controls. There were significant differences in prevalence of hypermethylated SFRP2 in tissue and stool between cancer and adenoma (χ^2 = 2.921, *P* = 0.087 and χ^2 = 8.606, *P* = 0.003, respectively) and between cancer and hyperplastic polyp (χ^2 = 17.253, *P* < 0.001 and χ^2 = 19.936, *P* < 0.001, respectively). However, a significant difference was observed in prevalence of hypermethylated SFRP2 between adenoma and hyperplastic polyp only in tissue (χ^2 = 4.450, *P* = 0.035) but not in fecal specimens (χ^2 = 2.241, *P* = 0.134).

RESULTS

Hypermethylation of SFRP2 gene in hyperplastic polyps, advanced adenomas and colorectal cancers

We examined hypermethylation of *SFRP2* gene in DNA from 69 patients with CRC, 34 with advanced adenoma (characterized by size ⩾ 1 cm, villous histology, and high-grade dysplasia) and 26 with hyperplastic polyps. *SFRP2* was hypermethylated in 91.3% (63/69), 79.4% (27/34) and 53.8% (14/26) of the CRCs, advanced adenomas and hyperplastic polyps, respectively. In the colorectal advanced adenomas, the prevalence of hypermethylated *SFRP2* was substantially higher in the tubulovillous and villous adenomas as compared with the tubular adenomas, and was much more in the adenomas accompanying with epithelium dysplasia. The prevalence of hypermethylated *SFRP2* had a gradually increased tendency from hyperplastic polyps to CRCs. In contrast, none of the normal colorectal mucosa of endoscopically normal patients showed any methylated bands (Figures 1-3, Table 2).

The hypermethylation of *SFRP2* gene was significantly different between cancer and normal mucosa ($P < 0.001$), between advanced adenoma and normal mucosa ($P < 0.001$), between hyperplastic polyp and normal mucosa ($P < 0.001$), between cancer and hyperplastic polyp ($P < 0.001$), and between adenoma and hyperplastic polyp ($P = 0.035$); however, no significant difference was found between cancer and adenoma ($P = 0.087$) (Table 2).

Detection of SFRP2 hypermethylation in fecal DNA

Following the performance of the MethyLight assays on the DNA extracted from the tissue samples, we next assessed matched fecal DNA from the corresponding patients to detect *SFRP2* hypermethylation in fecal DNA from individuals with CRC or premalignant lesions. We found that 92.1% (58/63) of CRCs, 66.7% (18/27) of advanced adenomas and 71.4% (10/14) of hyperplastic polyps had concordant hypermethylated *SFRP2* in their tissue DNA and fecal DNA, respectively. Two patients with CRC, 3 with advanced adenoma and 1 with hyperplastic polyp had methylated *SFRP2* only in the fecal DNA, while 5 patients with CRC, 9 with advanced adenoma and 4 with

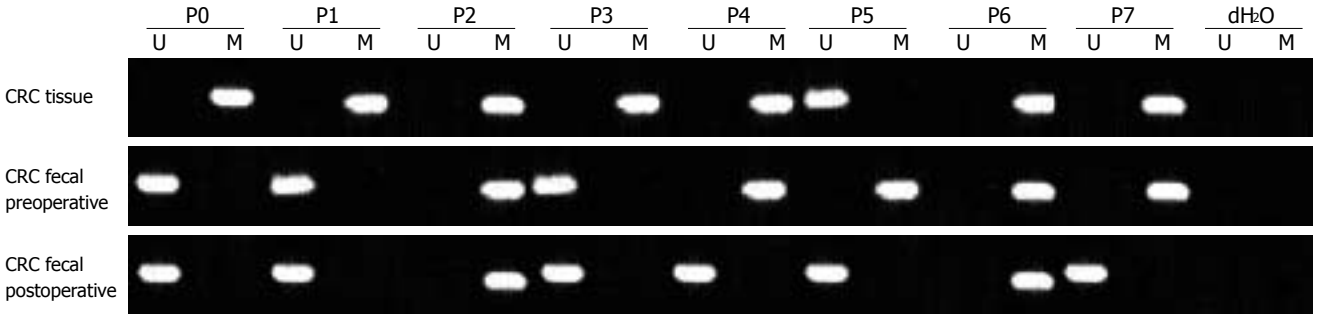

Figure 1 Methylation status of *SFRP2* gene in preoperative and postoperative fecal specimens and in CRC tissues taken from the same patients. P: Patient; M: Methylated; U: Unmethylated.

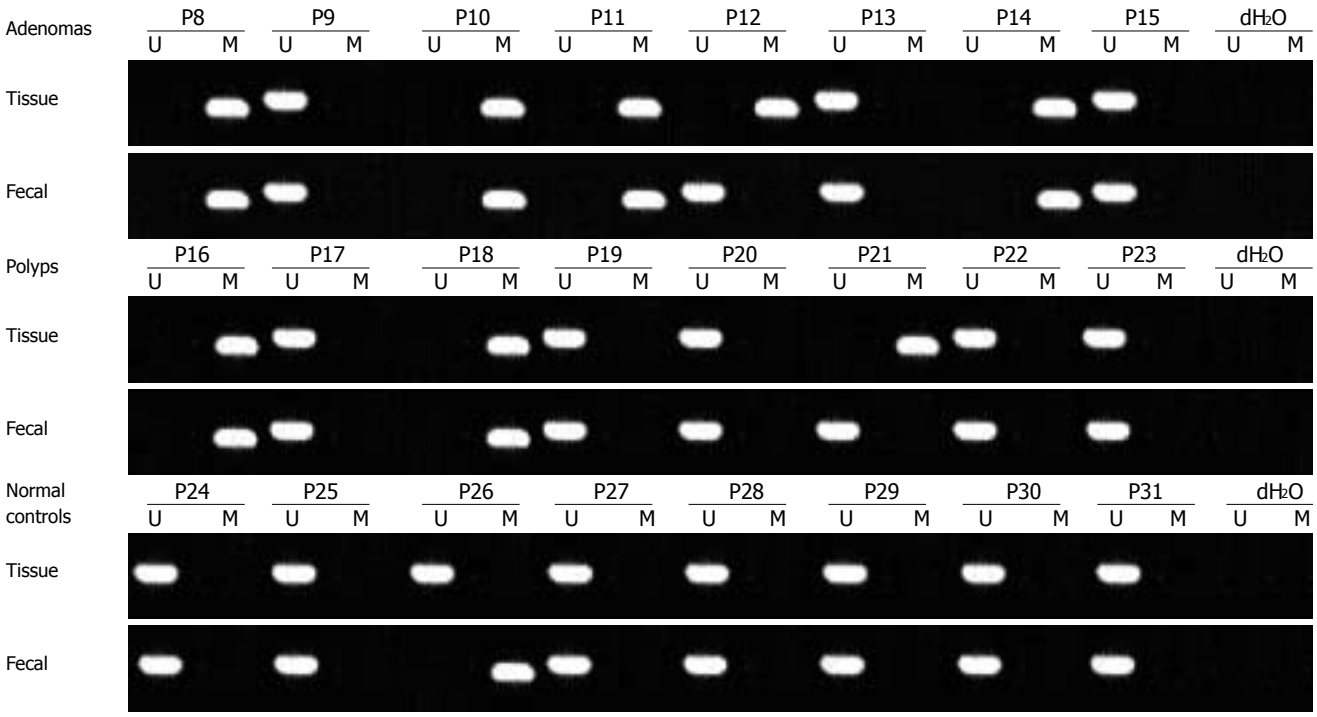

Figure 2 Methylation status of *SFRP2* gene in tissue and feces taken from the same patients with benign colorectal diseases and normal controls.

hyperplastic polyp had methylated *SFRP2* only in the tissue DNA. All of the remaining subjects that had unmethylated *SFRP2* in the tissue DNA showed unmethylated *SFRP2* in their fecal samples (Figures 1-4, Table 2).

Comparison of the performance characteristics of *SFRP2* MethyLight assays showed that the assays could detect 92.1%, 66.7% and 71.4% of individuals with CRC, advanced adenoma and hyperplastic polyp, respectively, that carried hypermethylated *SFRP2*. The clinical sensitivities of *SFRP2* hypermethylation in fecal DNA for detecting the presence of CRC, advanced adenoma and hyperplastic polyp were 87.0% (60/69), 61.8% (21/34) and 42.3% (11/26), respectively. To evaluate the clinical specificity of this assay, we next analyzed fecal DNA of 30 normal control individuals, and found that only 2 (6.7%) samples were positive for hypermethylation of *SFRP2* (Table 2).

Detection of SFRP2 hypermethylation in fecal DNA of CRC patients preoperatively and postoperatively

We compared the *SFRP2* hypermethylation in fecal DNA collected preoperatively and at the 9th postoperative day from CRC patients. Five of the 60 CRC patients whose stool carried hypermethylated *SFRP2* preoperatively had detectable hypermethylated *SFRP2* in their fecal samples postoperatively, showing a significant decrease postoperatively ($P < 0.001$). Only one of the nine CRC patients whose stool carried unmethylated *SFRP2* preoperatively had detectable hypermethylated *SFRP2* in the fecal sample postoperatively. All of the remaining 8 CRC patients with fecal unmethylated *SFRP2* preoperatively showed fecal unmethylated *SFRP2* postoperatively.

Moreover, no significant associations were observed between *SFRP2* gene hypermethylation and clinicopathological features, including sex, age, tumor stage, site, lymph node status and histological grade, etc (Table 2).

DISCUSSION

CRC is a common malignancy that arises from benign

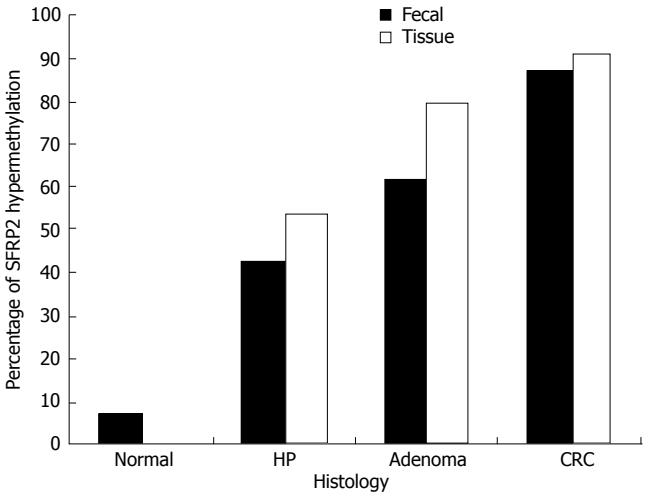

Figure 3 Prevalence of hypermethylated SFRP2 in stool and tissue specimens taken from the subjects with normal colonic mucosa, hyperplastic polyps (HP), adenomas and colorectal cancers (CRCs).

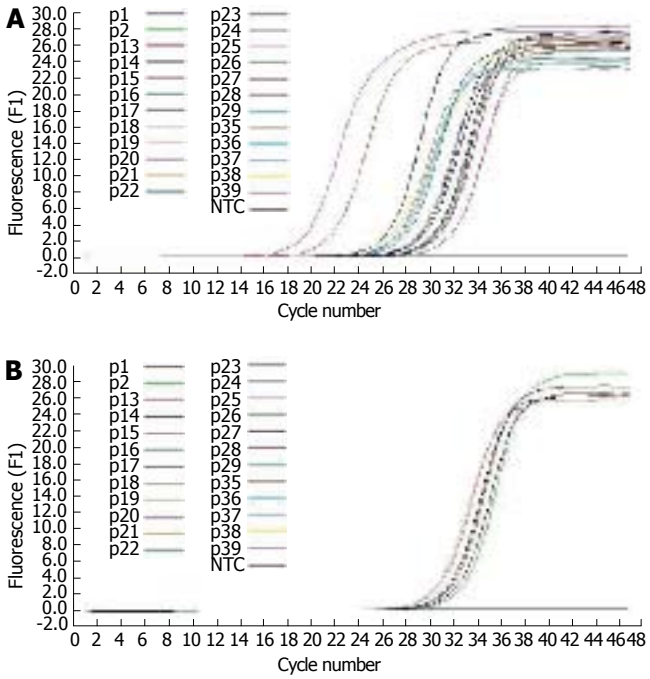

Figure 4 The photofluorogram of hypermethylated *SFRP2* gene in fecal specimen performed by MethyLight. **A**: Photofluorogram of *SFRP2* gene performed in M (methylation) primer and its amplification condition; **B**: Photofluorogram of *SFRP2* gene performed in U (unmethylation) primer and its amplification condition. neoplasms and evolves into adenocarcinomas through a stepwise histological progression sequence, proceeding from either adenomas or hyperplastic polyps/serrated adenomas[24-26]. Genetic alterations have been associated with specific steps in this adenoma-carcinoma sequence and are believed to drive the histological progression of CRC[27]. Recently, epigenetic alterations, especially DNA methylation, have been shown to occur in colorectal polyps, adenomas and CRCs[28-30]. The aberrant methylation of genes appears to act together with genetic alterations to drive the initiation and progression of colorectal polyp and adenoma to CRC[31]. Genetic alterations occur during the adenoma-carcinoma sequence of colorectal cancer formation and drive the initiation and progression of colorectal cancer formation. The aberrant methylation of genes is an alternate, epigenetic mechanism for silencing tumor suppressor genes in colorectal cancer. Thus, the aberrant methylation of genes appears to increase most significantly during the progression of early adenomas to advanced adenomas, and the frequency of specific gene methylation at the different steps of the adenoma-carcinoma progression sequence varies in a gene-specific fashion[28]. DNA methylation changes have been recognized as a key mechanism of colorectal carcinogenesis. Because of the ubiquity of DNA methylation changes and the ability to detect methylated DNA in stool, analysis of aberrantly methylation in stool DNA might provide a novel strategy for noninvasive detection of CRC[7,32-34]. Due to the heterogeneity of tumors, usually multiple markers distributed throughout the human genome need to be analyzed, and this is labor-intensive and does not allow for high throughput screening. Therefore, markers with high sensitivity and good specificity are needed[34]. *SFRP2* is one of the soluble modulators of a putative tumorigenic pathway-the Wnt signaling pathway, and is frequently hypermethylated in colorectal cancer, adenoma and aberrant crypt foci (ACF)[16-18,20,35]. At present, there are only a few researches in literature regarding *SFRP2* hypermethylation in CRC tissue and in stool of CRC patients[14,20,33]. In this study, we assessed the methylation status of *SFRP2* in tissue and matched stool samples from patients with CRC with respect to a series of healthy individuals and patients with benign colorectal diseases, using fluorescence-based real-time PCR assay (MethyLight). Our results suggested *SFRP2* hypermethylation as a highly sensitive and specific independent marker for the fecal screening of CRC.

It has been shown that hypermethylation of *SFRP2* genes, inhibitors of Wnt signaling pathway[16-18,20], is a common early event in the evolution of colorectal tumor, occurring frequently in ACF, hyperplastic polyp and adenoma, which is regarded as the earliest lesion of multistage colorectal carcinogenesis. It appears that hypermethylation of *SFRP2* gene might serve as indicator for early CRC[10,14,33]. We detected hypermethylation of *SFRP2* in tissue and matched fecal samples from the corresponding patients with CRC and premalignant diseases. The results showed that *SFRP2* was hypermethylated in 91.3%, 79.4% and 53.8% of the CRCs, advanced adenomas and hyperplastic polyps, respectively, thereby indicating that hypermethylation of *SFRP2* occurs in hyperplastic polyps and becomes more frequent in advanced adenomas and then in colorectal cancers. Moreover, the clinical sensitivities for detecting the presence of CRC, advanced adenoma and hyperplastic polyp were 87.0%, 61.8% and 42.3%, respectively, and the overall specificity was 76.8%. In addition, there was a trend, although not statistically significant, of *SFRP2* hypermethylation more among the adenomas accompany with epithelium dysplasia. On contrary, hypermethylation of *SFRP2* gene was found in stool of two endoscopically

normal subjects, which might be most likely owing to the *SFRP2* methylation occurring frequently in premalignant aberrant crypt foci (ACF) that is overlooked at colonoscopy[14,16-18]. Polyp and adenoma are the early events of colorectal tumorigenesis, and have a high risk of malignant transformation[28,36]. Our results show that hypermethylated SFRP was detectable not only in stools of patients with CRC, but also in stools of patients with premalignant lesions, such as advanced adenomas, suggesting that hypermethylated SFRP is a sensitive fecal-based molecular marker for screening CRC and premalignant lesions.

At present, there are only two institutions which had studied the methylated *SFRP2* in stool as a molecule marker for CRC screening: Müller *et al*[10] proposed *SFRP2* hypermethylation as a sensitive marker which is able to detect 77%-90% of CRCs; and Huang *et al*[14,33] reported that methylated *SFRP2* occurred in 94.2%, 52.4%, 37.5%, and 16.7% of patients with CRC, adenoma, hyperplastic polyp, and ulcerative colitis, respectively. In this study, we simultaneously detected hypermethylated *SFRP2* in tissue and fecal samples taken from the patients with CRC and benign colorectal diseases and from the healthy individuals. When compared with the two aforementioned researches, our results showed that hypermethylated *SFRP2* in stool had almost the same high sensitivity for detecting CRC, but had significantly higher detection rate for hyperplastic polyp and advanced adenoma. With the same ethnic groups, the discrepancy in performance of our study and that of Huang *et al*[14,33] is likely attributable to the more matched fecal and tissue samples of the same patients, but the use of a more sensitive methylation assay, MethyLight[21,37-39], may also account for the higher sensitivity and lower specificity. Despite of that, the high level of *SFRP2* hypermethylation in patients with hyperplastic polyps is somewhat surprising. There is little evidence that the hyperplastic polyps, which are usually not thought to be premalignant, with methylated DNA would develop into CRC; therefore the hyperplastic polyps will be counted as false positive when using *SFRP2* hypermethylation-based screening strategy. Whether hypermethylation of *SFRP2* gene can really identify this non-malignant diseases is still unclear. As DNA methylation is more common in advanced adenomas and CRC[40], all our findings and that of Huang *et al*[14,33] collectively suggest that *SFRP2* hypermethylation may reflect the malignant potential of these lesions. Because of the nature of CRC evolution (hyperplastic polyp -serrated adenoma-carcinoma sequence), the levels of hypermethylated *SFRP2* in stool of patients with hyperplastic polyps may have substantial clinical benefits through the detection and endoscopic removal of this benign disease, which needs large sample to further study. In short, patients with fecal hypermethylated *SFRP2* may belong to high-risk individuals and need more accurate clinical examinations and follow-up.

Furthermore, we compared the hypermethylated *SFRP2* gene in stool of CRC patients preoperatively and at the 9th postoperative day. The results indicated that the prevalence of hypermethylated *SFRP2* in stool of CRC patients decreased significantly postoperatively, which showed a new evidence that the hypermethylated *SFRP2* gene in stool comes from the CRC tissues and *SFRP2* hypermethylation in stool carries a high potential for the remote detection of CRC as a noninvasive screening method.

At present, there are several methods for detecting of CRC and premalignant lesions[41,42], but none of them is really suitable for screening CRC. Fecal occult blood testing has been shown to reduce CRC-related mortality and is cheap but has low sensitivity. Colonoscopy, with a high sensitivity and specificity for detection of CRC and large adenomas, requires a thorough bowel preparation, causes discomfort and small but non-negligible risk of major complications in patients, and is an invasive procedure. CT colonography[43], also known as virtual colonoscopy, looks promising but so far has been performed unevenly in the hands of community radiologists. However, aberrant methylation in fecal DNA as a molecular marker has developed a new way for screening CRC and premalignant lesions. Our study demonstrated initially that hypermethylated *SFRP2* gene in stool is a promising and noninvasive sensitive marker for screening colorectal neoplasia.

COMMENTS

Background

Silence of secreted frizzled-related protein 2 (*SFRPs*) genes, which are secreted glycoproteins working as inhibitory modulators of the Wnt signaling pathway induced by promoter hypermethylation, plays a key role in colorectal tumorigenesis, and hypermethylation of *SFRPs* genes is a common early event in the evolution of colorectal cancer (CRC). *SFRP2* is one of the *SFRPs* gene family members and is frequently hypermethylated in ACF, adenoma and colorectal cancer. Thus, detection of hypermethylation of *SFRPs* genes in human DNA isolated from stools might provide a novel strategy for the detection and investigation of CRC.

Research frontiers

Epigenetic hypermethylation can result in transcriptional silencing of tumor suppressor genes and is considered to be a key event of sporadic CRC, and gradually become the important areas in the research of CRC. Detection of hypermethylation of *SFRPs* genes in human DNA isolated from stools might provide a novel strategy for the detection and investigation of CRC.

Innovations and breakthroughs

A more sensitive methylation assay (MethyLight) was performed to analyze *SFRP2* gene promoter methylation status in a blinded fashion in tumor tissues and in matched stool samples from the same patients with CRC and colorectal benign diseases. Furthermore, we compared the hypermethylated *SFRP2* gene in stool of patients with CRC preoperatively and at the 9th postoperative day.

Applications

Our study demonstrated initially that hypermethylated *SFRP2* gene in stool is a promising and noninvasive sensitive single marker for screening colorectal neoplasia.

Terminology

Wnt signaling pathway: Signals are transduced by Wnt ligands through frizzled (Fz) membrane receptors by competition with Fzs for Wnt ligands or by direct formation of nonsignaling complexes with Fzs themselves. Secreted frizzled-related proteins (SFRPs): These are secreted proteins of about 36 ku that receive their name by

their structural homology with the extracellular cystein-rich domain (CRD) of frizzled (Fz), a family of developmentally important signaling molecules, and have the ability to bind to both Wnt and Fz proteins. Epigenetic mechanism: Somatic cells acquire changes in gene expression that are transmissible through mitosis but which do not involve any alterations to the DNA sequence. CpG island DNA methylation: The aberrant DNA methylation affects CpG-rich regions, called "CpG islands", in the 5' region of genes and results in transcriptional silencing through complex effects on transcription factor binding and associated changes in chromatin structure.

Peer review

This paper studied the use of hypermethylation of *SFRP2* promoter as a means for diagnosing colorectal cancer. The authors showed that, compared to individuals with normal colon, patients with colon cancer, advanced adenoma and hyperplastic polyps had a high prevalence of *SFRP2* hypermethylation in the tissues and stools. There also appeared to be a significant difference in the methylation patterns in patients with colon cancer before and after surgery. They conclude that hypermethylation of *SFRP2* may be a sensitive diagnostic test for colorectal neoplasm.

Abstract

AIM: To investigate the effect of a vaccine with recombinant adenovirus interleukin-12 (AdVIL-12) transduced dendritic cells (DCs) against colon cancer in mice.

METHODS: DCs and AdVIL-12 were incubated together at different time intervals and at different doses. Supernatant was collected and tested for IL-12 by enzyme-linked immunosorbent assay (ELISA). In order to determine whether tumor cell lysate-pulsed (TP) AdVIL-12/DCs enhance therapeutic potential in the established tumor model, CT26 colon tumor cells were implanted subcutaneously (s.c.) in the midflank of naïve BALB/c mice. Tumor-bearing mice were injected with a vaccination of CT26 TP AdVIL-12/DCs on d 3 and 10. As a protective colon tumor model, naïve BALB/c mice were immunized s.c. in their abdomens with CT26 TP AdVIL-12/DCs twice at seven day intervals. After the immunization on d 7, the mice were challenged with a lethal dose of CT26 tumor cells and survival times were evaluated. Subsequently, cytotoxic T lymphocyte (CTL) activity and interferon gamma (IFNγ) secretion was evaluated in the immunized mice, and assayed CTL *ex vivo*.

RESULTS: Murine DCs were retrovirally transduced with AdVIL-12 efficiency, and the AdVIL-12 transduced DCs secreted a high level of IL-12 (AdVIL-12/DCs, 615.27 ± 42.3 pg/mL *vs* DCs, 46.32 ± 7.29 pg/mL, $P < 0.05$). Vaccination with CT26 TP AdVIL-12/DCs could enhance anti-tumor immunity against CT26 colon tumor in murine therapeutic models (tumor volume on d 19: CT26 TP AdVIL-12/DCs 107 ± 42 mm^3 *vs* CT26 TP DCs 383 ± 65 mm^3, $P < 0.05$) and protective models. Moreover, the CT26 TP AdVIL-12/DC vaccination enhances tumor-specific CTL activity, producing high levels of IFNγ in immunized mice. *Ex vivo* primed T cells with AdVIL-12/DCs were able to induce more effective CTL activity than in primed T cells with CT26 TP/DCs (E:T = 100:1, 69.49% ± 6.11% specific lysis *vs* 37.44% ± 4.32% specific lysis, $P < 0.05$).

CONCLUSION: Vaccination with recombinant AdVIL-12 transduced DC pulsed tumor cell lysate enhance anti-tumor immunity specific to colon cancer in mice.

INTRODUCTION

Colon cancer is one of the most common cancers[1]. Although there has been great progress in colon cancer therapy, it is still difficult to treat advanced colon cancer because it has usually metastasized to lymph glands and other organs. Currently, radical surgery represents the standard method of therapy. Adjuvant therapy such as chemotherapy and radiation therapy have been widely applied, but colon cancer control at the advanced stage remains difficult[2,3]. A new adjuvant therapeutic method is needed in order to improve the 5-year survival rate of patients with colon cancer. Today, tumor immunotherapy for colon cancer is extremely appealing[4,5].

Dendritic cells (DCs) are professional antigen presenting cells (APCs) that both initiate and modulate the immune response[6]. DCs are cells in the pathway of antigen capture and presentation to T cells, with the

unique ability to directly prime naïve $CD4^+$ and $CD8^+$ T cells. They posses the ability to efficiently uptake, process, and present antigens on major histocompatibility complex (MHC) class Ⅰ and Ⅱ molecules, together with co-stimulatory molecules such as B7 and CD40[7]. Therefore, DCs are believed to be essential for stimulating tumor-specific cytotoxic T lymphocytes (CTL) and inducing the protective and therapeutic anti-tumor immunity against cancer cells. There have been attempts to produce vaccines based on DCs, including immunizations by DCs pulsed with tumor lysates or apoptotic tumor cells or tumor RNA. DCs have been fused with tumor cells, transduced with peptides to elicit specific antitumor T cells and enhance anti-tumor immunity[8]. Now, DCs can be pulsed with synthetic peptides or proteins derived from known tumor associated antigens (TAA), such as MUC1, Her-2/neu, tyrosinase, CEA or Melan-A/MART. Primary clinical studies were performed on melanoma patients using DCs pulsed with peptides or loaded with tumor cell lysates[9]. This data revealed that such vaccines could be safely applied without significant side effects and induce antigen-specific CTL responses *in vivo*.

Interleukin (IL)-12 is a heterodimeric, proinflammatory cytokine produced by macrophages, DCs, and B cells, which stimulates T lymphocytes and natural killer cells to release interferon gamma (IFNγ) and promote an anti-tumor response[10,11]. Some studies have shown that IL-12 has powerful adjuvant properties and the immune-modulating characteristics of IL-12 are considered to be responsible for these effects. Therapeutic activity with IL-12 has been observed in various murine tumor models[12,13]. Transduction of vaccine cells with IL-12 genes can substantially improve their immunogenicity[10]. Trials with IL-12 gene-modified melanoma cells have also been initiated in humans[14]. Saika T *et al*[15] reported that DCs engineered to express murine IL-12 and pulsed with a tumor lysate, induce specific T cell responses and anti-tumor immunity against a mouse prostate cancer model. This work suggests that adenovirus-mediated IL-12 gene transduction enhanced the immune responses.

In this study, we demonstrated that vaccination with DCs engineered to express IL-12 by adenovirus-mediated gene transfer and pulsed with CT26 colon tumor cell lysate, enhanced tumor-specific CTL activity and anti-tumor immunity in CT26 colon tumor models, suggesting promising strategy for colon cancer immunotherapy.

MATERIALS AND METHODS

Animals

Female BALB/c ($H\text{-}2^d$) and C57BL/6 ($H\text{-}2^b$) mice (8-10 wk old) were purchased from the Shanghai Experimental Animal Center, Chinese Academy of Sciences (Shanghai, China). All mice were kept under pathogen-free conditions in the animal center of the Shanghai Second Medical University (Shanghai, China).

Cell

CT26 ($H\text{-}2^b$), a mouse colon adenocarcinoma cell line, and SGC-7901 ($H\text{-}2^b$), the gastric cancer cell line were purchased from the Shanghai Cell Biology Institutes, Chinese Academy of Sciences (Shanghai, China). CT26 cell lines grow in BALB/c mice. Both cell lines were cultured in RPMI (Roswell Park Memorial Institute) medium 1640 (GIBCO, USA) containing 10% heat-inactivated fetal calf serum (FCS), 2 mmol/L glutamine, penicillin G (100 U/mL), and streptomycin (100 μg/mL) at 37℃ in a humidified incubator supplemented with 5% CO_2.

Major

Murine granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-4, IL-2, and IL-7 were purchased from Becton Dickinson (New Jersey, USA). Phenotypic analysis, fluorescein isothiocyanate (FITC)- or phycoerythrin (PE)-labeled monoclonal antibodies against murine cell surface molecules, such as MHC Ⅰ ($H\text{-}2K^d$), MHC Ⅱ ($I\text{-}A^b$), CD11b, CD11c, CD40, CD80, CD86, and CD8α, were provided by Pharmigen (CA, USA). Mitomycin C (MMC) was purchased by Jingmei Biothe (Shenzhen, China).

Generation of bone marrow-derived DCs

Primary bone marrow DCs (BM-DCs) was obtained from mouse bone marrow precursor according to a protocol by Zhang *et al*[16]. BALB/c mice bone marrow was obtained from tibia and femurs by flushing with the media. Tissue was minced in a single-cell suspension through a nylon mesh. BALB/c mice bone marrow cells were stained sequentially with biotinylated anti-c-kit MAb and Streptavidm MicroBeads (Dynal, Norway). $c\text{-}kit^+$ hematopoietic progenitor cells were magnetically isolated with a MiniMACS separator (Milteyi Biotec, Auburn, CA) from the of BALB/c mice bone marrow cells. The cells (6×10^6) were cultured for 7 d in fresh RPMI medium 1640 containing 10% FCS, GM-CSF (4 ng/mL), and IL-4 (10 ng/mL).

Immunofluorescence staining

DC immunofluorescence analysis was performed as previously described[16,17]. In brief, DCs prepared and isolated from BALB/c mice, as described above (2×10^5-4×10^5 cells), were incubated with FITC-labeled MAbs against CD40, CD11b, CD11c, or CD80 and PE-labeled MAbs against MHC Ⅰ, MHC Ⅱ, CD86 or CD8α followed by FACScan analysis (Becton Dickinson, USA). Instrument compensation was set in each experiment using two-color stained samples.

Recombinant adenovirus vector

Recombinant adenoviruses IL-12 (AdVIL-12) ecoding the murine IL-12 gene were donated by Dr. Y. Y. Zhang (Health Science Center of Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China). These recombinant adenoviruses were propagated in 293 cells and purified on a CsCl density gradient. Their titres were determined using a plaque assay on 293 cells. Aliquots of the adenovirus solutions were stored at -80℃.

Adenoviral transduction of DCs and secretion of IL-12

DCs generated on d 8 were plated at 2×10^6 cells/well in 1ml of RPMI 1640 medium containing 10% FCS with AdVIL-12 at a multiplicity of infection (MOI) of 100. After 2 h incubation at 37℃ in a humidified incubator

supplemented with 5% CO_2 with gentle agitation every 20 min, the DCs culture medium was replaced with 2 mL of RPMI 1640 medium supplemented with 10% FCS, and the cells were incubated for another 48 h. AdVIL-12 transduced DCs (AdVIL-12/DCs) were harvested, washed twice with PBS, and used for the tumor cell lysate pulsing *in vitro*. Immunofluorescence analysis of AdVIL-12/DCs was performed as described above.

DCs (1×10^6) were infected with AdVIL-12 at MOI 100. Viral supernatant was replaced after 2 h with the cell culture medium. The supernatant was collected and tested for mIL-12 by enzyme-linked immunosorbent assay (ELISA) kit (Rockford, IL, USA) at different time intervals (0, 12, 24, 48, 72, 96 h). Moreover, DCs were infected with AdVIL-12 at different MOI (50, 100, 200, 300, 500). The supernatant was collected 48 h later and tested for mIL-12 by ELISA.

Pulsing DCs with tumor cell lysates

DCs were pulsed with freeze-thawed tumor lysate at a 1:3 DCs: tumor ratio. CT26 tumor (6×10^6) were lysed by rapid freezing (liquid nitrogen) and thawing in a 37℃ bath three times. The AdVIL-12 transduced DCs (AdVIL-12/DCs, 2×10^6 cells/mL) or bone marrow-derived DCs (2×10^6 cells/mL) were incubated in six-well plates in the presence of CT26 tumor lysates (6×10^6 cell equivalents/mL) in RPMI Medium 1640 containing 10% FCS, GM-CSF (4 ng/mL), and IL-4 (10 ng/mL) for one day at 37℃ and 5% CO_2. These CT26 tumor cell lysate-pulsed (TP) AdVIL-12/DCs or DCs were used for vaccination after one day.

Tumor model and DC-based vaccination

In the established tumor model, CT26 tumor cells (5×10^5 cells per mouse) were implanted subcutaneously (s.c.) in the midflank of naïve BALB/c mice (10/each group). Tumor-bearing mice were injected with 1×10^6 DCs vaccination: CT26 TP AdVIL-12/DCs or CT26 TP DCs on d 3 and 10. As a positive control, tumor bearing mice were treated in parallel with unstimulated DCs, CT26 tumor lysate alone, or PBS alone. Tumor growth was assessed by calipers (mean of 2 perpendicular diameters) every 2-3 d. Tumor volume was estimated by the formula $4/3\ \pi r^3$.

In the protective anti-tumor experiment, each group consisting of 10 naïve BALB/c mice were injected s.c. in their abdominal walls with 1×10^6 DCs vaccination: CT26 TP AdVIL-12/DCs or CT26 TP DCs on d 0, 7, and 14. Control mice were injected with unstimulated DCs, CT26 tumor lysate alone, and PBS alone. Each mouse was challenged s.c. with a lethal dose of 2×10^6 CT26 cells on d 21. Survival differences among the groups receiving different vaccinations were evaluated following the primary challenge with CT26 cells.

Assays for cytotoxic T lymphocyte activity and interferon gamma secretion in the immunized mice

To confirm that tumor-specific cytotoxic T lymphocytes (CTLs) had been generated in the immunized mice, splenic $CD3^+$ T cells from tumor-free mice that survived the CT26 tumor challenge through d 61 following DC vaccination, were magnetically isolated using CD3 MicroBeads (Miltenyi Biotech, Bergisch Gladbach, Germany). T cells (1×10^6 cells) from surviving mice were restimulated *ex vivo* by culturing in IMDM containing 10% FCS and MMC-treated CT26 tumor cells (1×10^5). Five days later, the MMC-treated CT26 tumor cells and the T cells were collected for measuring CTL activity and IFNγ secretion. The restimulated effector T cells (2×10^5 in 100 μL per well) were added to the wells containing target CT26 or SGC-7901 tumor cells (5×10^4 in 100 μL per well) in 96-well plates. Supernatant from each well was collected after 20 h and was measured cytolytic activity against target CT26 tumor cells and SGC-7901 tumor cells with a Cytotoxicity Detection Kit (LDH; Boehringer Mannheim, Mannheim, Germany), IFNγ production was determined with the mouse IFNγ ELISA kit (Endogen, Woburn, MA, USA). In some experiments, the target CT26 tumor cells (1.5×10^5) were incubated with a MAb to MHC class I molecules (anti-H2Db/H2Kb; 50 g/mL) or with control antibody (anti-H2Dd; 50 g/mL) at 37℃ for 30 min before the addition of restimulated effector T cells to evaluate the specificity of CTL activity.

Assays for cytotoxic T lymphocyte activity ex vivo

To confirm that tumor-specific cytotoxic T lymphocytes (CTLs) can be generated ex vivo, splenic $CD3^+$ T cells (1×10^6 cells/mL) were magnetically isolated from naïve BALB/c mice using CD3 microBeads. These cells were cultured in RPMI medium 1640 containing 10% FCS, then primed *ex vivo* in the presence of cytokines including IL-2 and IL-7 (5 ng/mL per) at d 0, 7, and 14 with CT26 TP AdVIL-12/DCs or CT26 TP DCs at a 1:20 stimulator to responder cell ratio. Unpulsed DCs and AdVIL-12/DCs were used as controls. Fresh medium containing IL-2 and IL-7 was exchanged every four days. The primed T cells were effector cells, CT26 or SGC-7901 tumor cells were target cells. On d 21, target cell suspension was added into 96 well plates, and effector cells were titrated to the dilutions target cells by serial dilutions (E-T mix, E:T, 1:1, 5:1, 10:1, 20:1, 50:1, 100:1). Supernatant from each well was collected after 20 h in order to measured cytolytic activity against target CT26 and SGC-7901 tumor cells, which was done with a cytotoxicity detection kit as mentioned above.

Statistical analysis

Differences were evaluated using Statistical Package for Social Science 11.0 (SPSS11.0). Statistical analysis was performed using a Student's *t* test. Survival differences among mice groups were evaluated with a log-rank test of the Laplan-Meier survival curves. Statistical tests were two-tailed. P values < 0.05 were considered to be statistically significant.

RESULTS

Phenotypic markers of DC analysis by FACScan

The phenotypic profile of a representative population of bone marrow DCs was first determined. These DCs were expressed in moderate levels of MHC class Ⅰ, CD11b and CD11c, high levels of MHC class Ⅱ, moderate levels of

Table 1 Phenotypic characteristics of AdVIL-12/DCs

DCs[1]	Mean fluorescence intensity							
	MHC Ⅰ	MHC Ⅱ	CD40	CD11b	CD11c	CD80	CD86	CD8α
Nontransduced	35	92	19	48	26	112	69	10
AdVIL-12	49	304[a]	23	56	30	271[a]	229[a]	9

[1]Nontransduced DCs and AdVIL-12 transduced DCs were harvested 6 d after the culture initiation and stained with the listed antibodies. Background intensities = 4-6. [a]$P < 0.05$ *vs* those of nontransduced DCs.

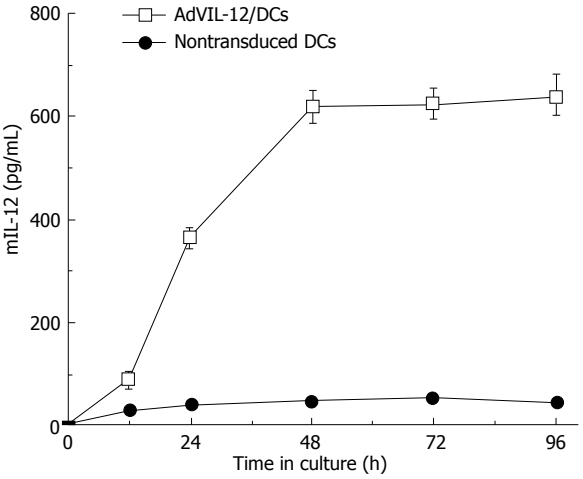

Figure 1 IL-12 production by the DCs transduced with AdVIL-12. DCs and AdVIL-12 were incubated together at different time intervals (0 h, 12 h, 24 h, 48 h, 72 h, 96 h). Supernatant was collected and tested for mIL-12 by ELISA, with nontransduced DCs as control. Data is representative of two independent experiments, with a given as mean ± SE.

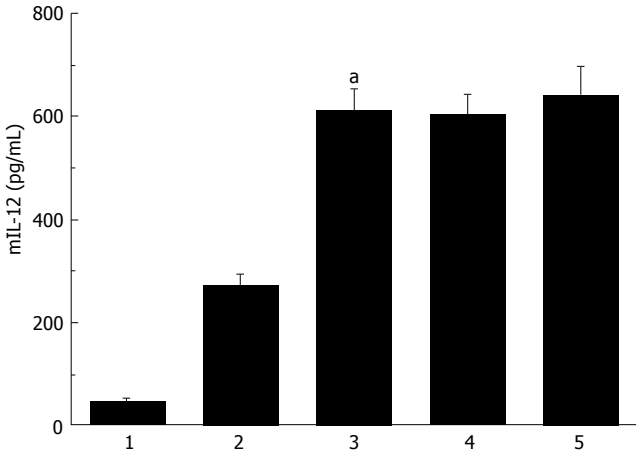

Figure 2 IL-12 production by the DCs transduced with AdVIL-12. BM-DCs was transduced with AdVIL-12 at various doses. DCs supernatant was examined 48 hrs later for the IL-12 production by ELISA, with nontransduced DCs was as control. Statistical analysis used the paired Student's *t* test. Data are given as mean ± SE. [a]$P < 0.05$ AdVIL-12/DCs (MOI 100) compared with nontransduced DCs or AdVIL-12/DCs (MOI 50). 1: Nontransduced DCs. 2: AdVIL-12/DCs (MOI 50). 3: AdVIL-12/DCs (MOI 100). 4: AdVIL-12/DCs (MOI 300). 5: AdVIL-12/DCs (MOI 500).

the co-stimulatory molecules CD40, CD80, and CD86, and very low levels of CD8α. Phenotypic changes within the DCs induced by AdVIL-12 transduction were examined by phenotypic analysis. Expression levels of CD80, CD86, and MHC class Ⅱ were increased in AdVIL-12/DCs compared with the DCs (Table 1).

Secretion of IL-12by transduced DCs in vitro

Secretion analysis of AdVIL-12/DCs, DCs and AdVIL-12 was determined by incubation at different cultured time intervals and at different MOI, and supernatant was collected and tested for mIL-12 by ELISA. Figure 1 illustrated that AdVIL-12/DCs secrete high levels of IL-12 at 48 h intervals. However, the levels of IL-12 did not increase with time. In addition, the DCs transfected with AdVIL-12 at a MOI of 100 showed a significant increase in the IL-12 level against the control DCs. This was statistically significant (AdVIL-12/DCs, 615.27 ± 42.3 pg/mL *vs* DCs, 46.32 ± 7.29 pg/mL, [a]$P < 0.05$, Figure 2).

Vaccination with CT26 TP AdVIL-12/DCs enhances anti-tumor immunity in therapeutic or protective models

In order to determine whether or not CT26 TP AdVIL-12/DCs enhance therapeutic potential in the established tumor model, CT26 tumor cells (1×10^6) were implanted s.c. in the midflank of naïve BALB/c mice (10/each group). Tumor-bearing mice were injected with different vaccinations on d 3 and 10. Figure 3 shows that tumor growth was significantly inhibited in mice vaccinated with CT26 TP AdVIL-12/DCs. Vaccination with CT26 TP AdVIL-12/DCs significantly retarded tumor growth, and exerted a greater anti-tumor effect than CT26 TP DCs (tumor volume on d 19: PBS control 856 ± 95 mm^3, CT26 tumor lysate control 748 ± 67 mm^3, unstimulated DCs control 813 ± 73 mm^3, CT26 TP DCs 383 ± 65 mm^3, and CT26 TP AdVIL-12/DCs 107 ± 42 mm^3, CT26 TP AdVIL-12/DCs *vs* CT26 TP DCs, [a]$P < 0.05$). Differences between CT26 TP AdVIL-12/DCs and CT26 TP DCs were statistically significant.

CT26 TP AdVIL-12/DCs were used in vaccinations to see whether there were increases in anti-tumor immunity. Naïve BALB/c mice were immunized s.c. twice at 7 d intervals in abdominal walls with CT26 TP AdVIL-12/DCs, CT26 TP/DCs, unpulsed DCs, tumor lysates alone, and PBS, respectively. On d 7 after secondary immunization, these mice were challenged with 2×10^6 CT26 tumor cells. All mice vaccinated with unstimulated DCs, tumor lysates alone, and PBS died within 30 d after CT26 tumor cell challenge (Figure 4). However, mice immunized with CT26 TP AdVIL-12/DCs had significantly prolonged survival compared with the control or other vaccination groups. During the 60-d observation period, the mice vaccinated with CT26 TP AdVIL-12/DCs had a 90% survival rate and the mice

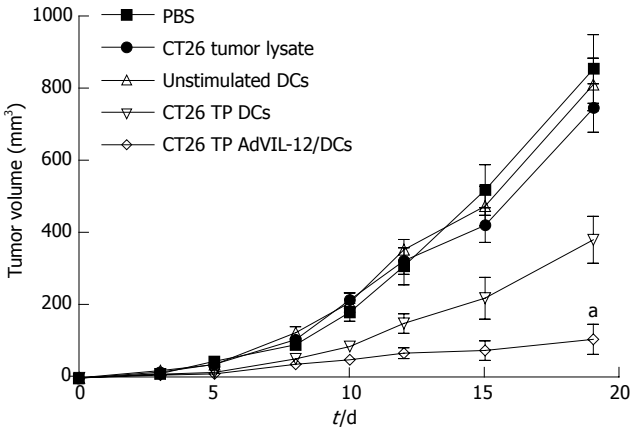

Figure 3 Vaccination with CT26 TP AdVIL-12/DCs enhances anti-tumor immunity in therapeutic tumor models. CT26 tumor cells (5×10^5 cells per mouse) were implanted s.c. in the midflank of naïve BALB/c mice. On d 3 and 10, tumor-bearing mice were injected with 1×10^6 DCs vaccination with CT26 TP AdVIL-12/DCs. As control, tumor bearing mice were treated in parallel with CT26 TP DCs, unstimulated DCs, CT26 tumor lysate alone, or PBS alone. Tumor growth was assessed by calipers every 2-3 d thereafter. Tumor volume was estimated by the formula $4/3\ \pi r^3$. Statistical analysis used the paired Student's *t* test. Data are given as mean ± SE (n = 10 mice in each group). $^aP < 0.05$, CT26 TP AdVIL-12/DCs *vs* CT26 TP DCs or the other control groups (d 19).

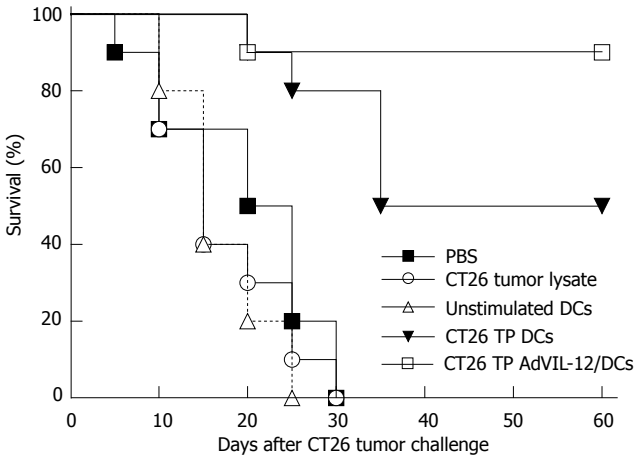

Figure 4 Protective effect of CT26 TP AdVIL-12/DCs in CT26 tumor models. Naïve BALB/c mice were injected s.c. in their abdominal walls on d 0, 7, and 14 with 1×10^6 DCs vaccination: CT26 TP AdVIL-12/DCs or CT26 TP DCs. Mice injected with unstimulated DCs, CT26 tumor lysate alone, and PBS alone were used as controls. On d 21, each mouse was challenged s.c. with a lethal dose of 2×10^6 CT26 cells. Survival was observed after the challenge with tumor cells. Survival rate was compared with a log-rank test of Kaplan-Meier curves. The survival advantage conferred by the CT26 TP AdVIL-12/DC was statistically significant compared with CT26 TP DCs group and other control groups (Kaplan-Meier, $P < 0.05$).

vaccinated with CT26 TP/DCs had a 50% survival rate, respectively, compared with the mice vaccinated with unpulsed DCs (0%), tumor lysates alone (0%), and PBS (0%). Survival advantage of CT26 TP AdVIL-12/DC was statistically significant compared with the CT26 TP DC group or other control groups (Kaplan-Meier, $P < 0.05$).

Enhancement of tumor-specific CTL responses

In order to determine whether vaccination with CT26 TP AdVIL-12/DCs enhances tumor-specific CTL responses and to see if the response was tumor specific, we isolated splentic $CD3^+$ T cells obtained from mice still alive 60 d (in CT26 TP AdVIL-12/DCs or CT26 TP/DCs group) after the CT26 tumor cells challenge. Assayed levels of IFNγ were determined, which is a reflection of immune activation and cytotoxic activity against CT26 tumor cells or SGC-7901 tumor cells. Results demonstrated that the splenic mice $CD3^+$ T cells vaccinated with CT26 TP AdVIL-12/DCs produce higher levels of IFNγ in vitro when stimulated with CT26 tumor cells than T cells obtained from mice vaccinated with CT26 TP/DCs (1685.88 ± 61.54 pg/mL in CT26 TP AdVIL-12/DCs group *vs* 912.58 ± 38.33 pg/mL in CT26 TP DCs, $P < 0.05$, Figure 5A). At the same time they showed substantially enhanced cytotoxic activity (21.86% ± 1.29% specific lysis in CT26 TP AdVIL-12/DCs group *vs* 12.67% ± 0.76% specific lysis in CT26 TP DCs, $P < 0.05$, Figure 5B). In addition, all splenic $CD3^+$ T cells obtained from mice vaccinated with CT26 TP AdVIL-12/DCs and vaccinated with CT26 TP DCs produced high levels of IFNγ and showed specific cytotoxic activity against CT26 tumor cells, but no cytotoxic activity when stimulated with SGC-7901 tumor cells (Figure 5A and B). Furthermore, antibodies to MHC class I molecules abrogated the cytolytic activity against CT26 tumor cells. Vaccination with CT26 TP AdVIL-12/DCs was shown to induce a MHC-I restricted CTL response (Figure 5C).

Finally, vaccination with CT26 TP AdVIL-12/DCs enhances tumor-specific CTL responses *ex vivo*. Naïve mouse splenic T cells were primed ex vivo with CT26 TP AdVIL-12/DCs or CT26 TP/DCs in the presence of IL-2 and IL-7 to elicit cytolytic reactivity against tumor cells. Unpulsed DCs and AdVIL-12/DCs were used as controls. Results demonstrated that primed T cells *in vitro* with AdVIL-12/DCs or CT26 TP/DCs were able to lyse parental CT26 tumor cells specifically, but not SGC-7901 tumor cells. Also, T cells primed with unpulsed DCs or AdVIL-12/DCs did not induce specific CTL against CT26 tumor cells or SGC-7901 tumor cells (Figure 6A and B). Furthermore primed T cells with AdVIL-12/DCs are able to induce effective CTL activity more than primed T cells with CT26 TP/DCs (E:T = 100:1, 69.49% ± 6.11% specific lysis in CT26 TP AdVIL-12/DCs group *vs* 37.44% ± 4.32% specific lysis in CT26 TP DCs, $^aP < 0.05$, Figure 6A). It is possible that a vaccination with CT26 TP AdVIL-12/DCs may enhance the anti-tumor immune response to syngeneic tumor cells.

Together, these results suggest that mice vaccinated with CT26 TP AdVIL-12/DCs, and subjected to CT26 tumor cells, and primed T cells *in vitro* with AdVIL-12/DCs, were more effective in generating generated MHC class I restricted CTLs specific for CT26 tumor cells.

DISCUSSION

In our experiments we showed that murine BM-DCs could be retrovirally transduced with AdVIL-12 efficiency, and the AdVIL-12 transduced DCs could secrete high levels of IL-12. Vaccination with DCs that were engineered to express IL-12 by adenovirus-mediated gene transfer could

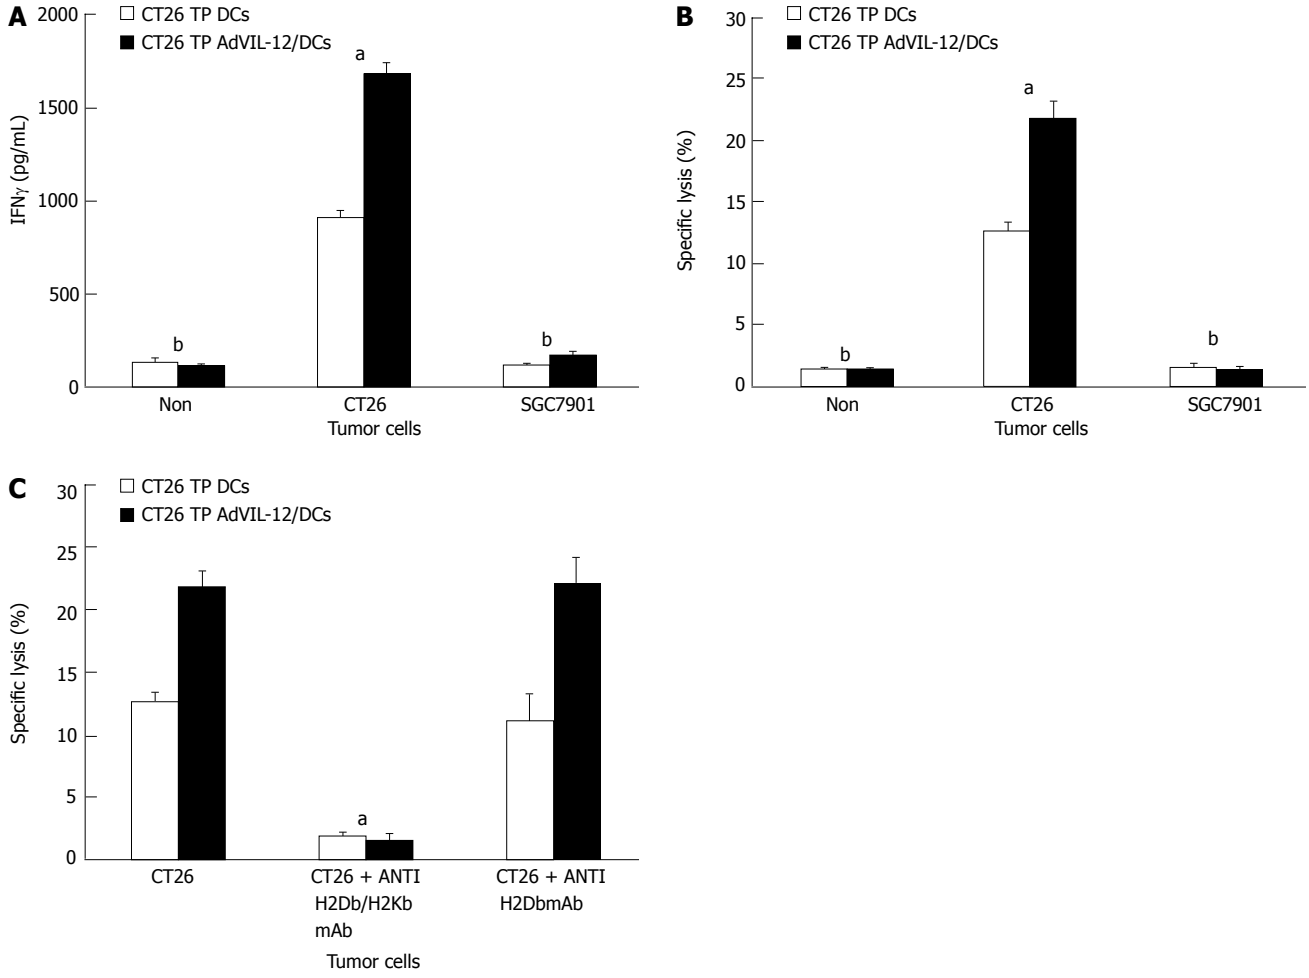

Figure 5 Assays for IFNγ secretion and tumor-specific CTL activity in the immunized mice. Splenic $CD3^+$ T cells from mice that survived the CT26 tumor challenge until d 61 in protective models were magnetically isolated. $CD3^+$ T cells were restimulated *ex vivo* by culturing with the MMC-treated CT26 tumor cells. Then these restimulated effector T cells were added to the wells containing target CT26 or SGC-7901 tumor cells in 96-well plates. After 20 h, supernatant from each well was collected for measuring IFNγ production with the mouse IFNγ ELISA kit (**A**), and for measuring cytolytic activity with a Cytotoxicity Detection Kit (**B**). In some experiments, the target CT26 tumor cells were incubated with a MAb to MHC class I molecules (anti-H2Db/H2Kb) or with control antibody (anti-H2Dd) before the addition of restimulated effector T cells to evaluate the specificity of CTL activity. Statistical analysis used the paired Student's *t* test. Data are given as mean ± SE. A, B $^aP < 0.05$, CT26 TP AdVIL-12/DCs compared with CT26 TP DCs in the CT26 groups, $^bP < 0.01$ CT26 *vs* SGC7901 or Non, respectively. (**C**), $^aP < 0.05$, CT26 + antiH-2kb/DbmAb *vs* CT26 or CT26 + antiH-2DbmAb, respectively.

enhance anti-tumor immunity against CT26 colon tumor in murine therapeutic and protective models. Moreover, in CTL response, vaccination with CT26 TP AdVIL-12/DCs enhanced tumor-specific CTL activity to produced high levels of IFNγ.

Successful genetic modification of murine BM-DCs with retroviral vectors was demonstrated. Previous reports illustrated the feasibility of retroviral gene modification of human DCs by tansduction of $CD34^+$ progenitor cells with the subsequent addition of cytokine to promote differentiation and maturation[18,19]. In this study murine DCs were transduced using cocultivation with retroviral producer cells. The murine BM-DCs transduced with AdVIL-12 at different MOI or different time intervals in culture. DCs transduced with AdVIL-12 at an MOI of 100 shown limited toxicity and maximal production of IL-12, and at 48 h intervals in culture, demonstrate maximal production of IL-12. Phenotypes of DCs retrovirally transduced with IL-12 were evaluated. The experiments demonstrated expression levels of CD80, CD86, and MHC Ⅱ were enhanced in AdVIL-12/DCs compared with the non-transduced DCs, without apparent surface molecules changes. These phenotypic changes could be due in part to the direct effect of IL-12 or, more likely, indirectly through IFNγ production by contaminating T cells or natural killer cells. Grohmann U *et al*[20] reported that IL-12 acts directly on DCs to promote nuclear localization of nuclear factor *k*B and primes DCs for IL-12 production. Suzuki T *et al*[21] also reported that the DCs transduced AdVIL-12 showed increased levels of the costimulatory molecules (CD80 and CD86), MHC Ⅱ molecules, compared with the non-transduced DCs. These changes could explain, in part, why IL-12-transduced DCs are more effective in tumor treatment application.

Tumor immunity induction can be initiated by the effectors of innate immunity and can be further developed by cells of adaptive immunity, with DCs playing a central regulatory role. Several steps are involved including (a) recognition of tumor molecules by DC precursors, (b)

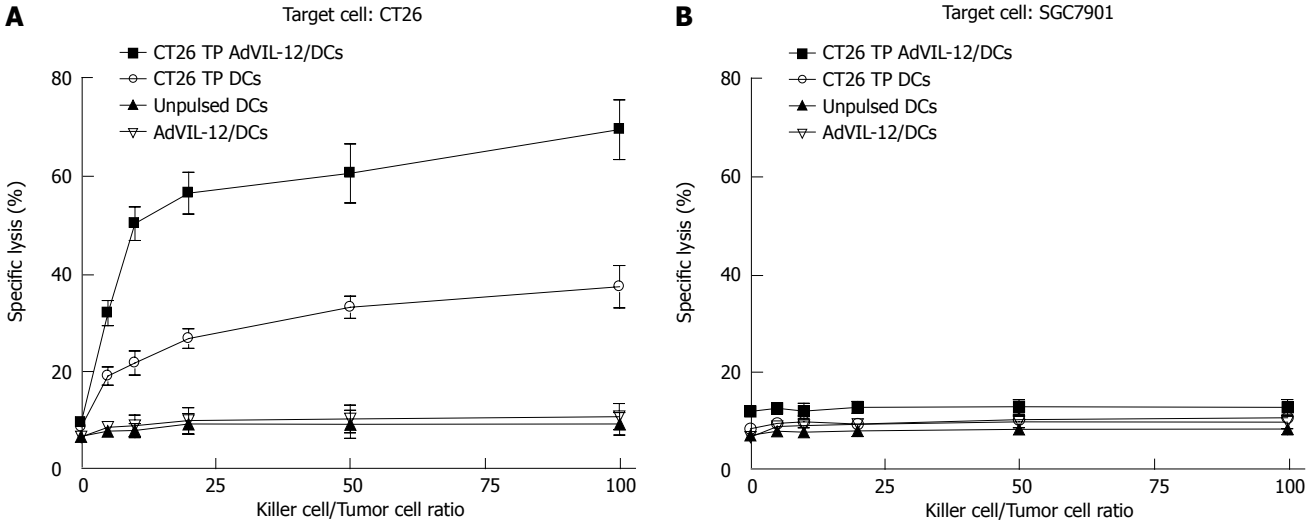

Figure 6 Generation of tumor-specific cytotoxic T cells *ex vivo*. Splenic $CD3^+$ T cells were magnetically isolated from naïve BALB/c mice. These cells were cultured *ex vivo* in the presence of cytokines including IL-2 and IL-7 and with CT26 TP AdVIL-12/DCs or CT26 TP DCs at a stimulator to responder cell ratio of 1:20. The primed T cells were effector cells, CT26 or SGC-7901 tumor cells were target cells. Then these effector T cells were titrated by serial dilution (E-T mix, E:T 1:1, 5:1, 10:1, 25:1, 50:1, 100:1), and their lytic activity against CT26 or SGC-7901 were assayed by a Cytotoxicity Detection Kit. Statistical analysis used the paired Student's *t* test. Data are given as mean ± SE. A $^aP < 0.05$, CT26 TP AdVIL-12/DCs *vs* CT26 TP DCs or other control groups in the CT26 groups.

direct and IFN-γ-mediated killing of transformed cells by NK/NK T cells activated by DCs, (c) capture and cross-presentation of released-tumor-associated Ags (TAAs) by immature DCs, (d) selection and activation of TAA-specific T cells, as well as nonspecific effectors including macrophages and eosinophils, and (e) homing of TAA-specific T cells to the tumor site and recognition elements leading to the elimination of tumor cells[22]. DCs-based vaccination had showed efficiently anti-tumor effective in many tumor models and in the clinical studies. Kono K *et al*[23] reported that tumor vaccination therapy with DCs pulsed with HER-2/neu-peptides may be a potential candidate for the novel treatment of gastric cancer patients. Tumor markers (CEA or CA19-9) were decreased after vaccination in 3 out of 9 patients. Two patients had more than 50% tumor regression, and two presented a mixed response. These studies revealed that such vaccines could be safely applied without significant side effects and induced antigen-specific CTL responses *in vivo*.

Cytokine gene therapy is becoming a promising weapon against cancer[24]. Adenovrial-based cytokine gene therapy has many advantages over other forms of cytokine delivery[25]. Adenoviral vectors allow local, high-efficiency, but transient transgene expression, generating high-level but self-limited cytokine production in treated tumors. Adenoviral vectors are transduction targets in a heterogeneously growing population of tumor cells. Recombinant IL-12 has generated interest as a potential cancer therapeutic agent due to the ability of murine IL-12 to induce tumor regression and to cure in various mouse models of cancer. Studies examining the anti-tumor mechanisms of IL-12 have implicated various cellular mediators including CD8 T cells, NK cells, and NK T cells[26,27]. Taking full advantages of characters of DCs and IL-12 respectively, constitutive production of IL-12 by AdVIL-12/DCs, coupled with their ability to take up and process tumor antigens, migrate to tumor site or lymph nodes can induce an effective immune response. In this study, a DCs-based vaccination transduced with AdVIL-12 was successfully produced using cocultivation methods.

In the experiment *in vivo*, significant anti-tumor effects were observed in therapeutic models or protective models when vaccination with CT26 TP AdVIL-12 transduced DCs were injected. These anti-tumor effects were not observed, however, when nontransduced DCs were injected. Complete tumor eradication was observed in 30%-50% of mice treated with a single injection of CT26 TP AdVIL-12/DCs in therapeutic models. In protective models, the mice immunized with CT26 TP AdVIL-12/DCs had significant survival rates. During the 60-d observation period, mice vaccinated with CT26 TP AdVIL-12/DCs showed 90% survival rate, compared to mice vaccinated with CT26 TP/DCs (50%). These results suggest that overexpression of IL-12 by DCs in the peripheral blood, the tumor site, or in the secondary lymphoid sites, alternatively, could be important for an anti-tumor response in addition to the phenotypic changes in AdVIL-12/DCs. Chemokine (IP-10 and Mig)[28,29] production induced by IL-12, is responsible for these effects, at least in part, through enhanced recruitment of cytolytic effector cells to develop into tumors, plus possibly antiangiogenic effects (Fas/FasL)[30].

Systemic immune responses, as demonstrated by CTL activity and IFNγ production *in vivo* and *ex vivo*, were also significantly higher and tumor specific when AdVIL-12/DCs were used. High cytolytic activity in association with a TH1-type response could possibly contribute to the profound anti-tumor effects that we observed. In contrast, responses induced by nontransduced DCs were far less potent. Tatsumi T *et al*[31] reported that the anti-tumor effect of DCs-based vaccination is dependent on the production of the TH1-type immunostimulatory cytokine such as IFNγ, IL-12. Therefore, the level of IFNγ

production as a result of IL-12 may play an important role in the increased anti-tumor immune responses.

In summary, research data demonstrates that vaccination with recombinant adenoviruses interleukin-12 transduced dendritic cells pulsed tumor cell lysate enhance anti-tumor immunity specific to colon cancer in mice. This approach is superior to that observed by nontransduced DCs. These results suggest that an evaluation of AdVIL-12/DCs in colon cancer patients with is an important next step. A clinical trial evaluating this approach is currently in preparation.

COMMENTS

Background

Dendritic cells (DCs) play a central role in immune responses and may be useful adjuvants for tumor vaccination. Heterodimeric cytokine interleukin (IL)-12 is the key cytokine mediating the generation of a TH1-type cytokine expression pattern in both T lymphocytes and NK cells, resulting in cytotoxic cellular immune responses. IL-12 has been shown to generate powerful anti-tumor responses in many tumor models. IL-12 production by recombinant adenoviruses IL-12 (AdVIL-12) transduced DCs, coupled with their ability to take up and process tumor antigens, induce an effective anti-tumor immune response.

Research frontiers

DCs are believed to be essential for stimulating tumor-specific CTL and inducing the protective and therapeutic anti-tumor immunity against cancer cells. Attempts to produce vaccines based on DCs have been developed including immunizations by DCs pulsed with tumor lysates or apoptotic tumor cells or tumor RNA, fused with tumor cells, transduced with peptides. Now, DCs can be pulsed with synthetic peptides or proteins derived from known tumor associated antigens (TAA) such as MUC1, Her-2/neu, tyrosinase, CEA or Melan-A/MART. Vaccines based on DCs have been safely applied in clinic. Some studies have shown that IL-12 has powerful adjuvant properties and immune-modulating characteristics of IL-12 are considered to be responsible for such adjuvant effects. Therapeutic activity of IL-12 has been observed in various murine tumor models. Transduction of vaccine cells with IL-12 genes can substantially improve their immunogenicity. Trials with IL-12 gene-modified melanoma cells have also been started in humans.

Innovations and breakthroughs

Taking full advantages of characters of DCs and IL-12 respectively, a DCs-based vaccination transduced with AdVIL-12 was successfully produced using cocultivation methods. Vaccination with DC engineered to express IL-12 by adenovirus-mediated gene transfer could enhance anti-tumor immunity in murine therapeutic and protective models. Vaccination can be application for immunotherapy against colon cancer in mice successfully.

Applications

Vaccination with AdVIL-12 transduced DCs pulsed tumor cell lysate enhance anti-tumor immunity specific to colon cancer in mice. These results suggest that an evaluation of AdVIL-12/DCs in colon cancer patients with is an important next step. A clinical application of this approach is currently in preparation.

Terminology

DCs (Dendritic cells), bone marrow DCs (BM-DCs), antigen presenting cells (APCs), Interleukin-12 (IL-12), recombinant adenoviruses interleukin-12 (AdVIL-12), AdVIL-12 transduced DCs (AdVIL-12/DCs), major histocompatibility complex (MHC), cytotoxic T lymphocyte (CTL), interferon gamma (IFNγ),

Peer review

The authors examined that murine BM-DCs could be retrovirally transduced with AdVIL-12 efficiency, and the AdVIL-12 transduced DCs could be secret high levels of IL-12. Vaccination with DC engineered to express IL-12 by adenovirus-mediated gene transfer could enhance anti-tumor immunity against CT26 colon tumor in murine therapeutic and protective models. Moreover, in CTL response vaccination with CT26 TP AdVIL-12/DCs enhanced tumor-specific CTL activity, to produced high levels of IFNγ.

Abstract

AIM: To investigate whether the major kavalactone kavain imposes adverse effects on the liver ultrastructure and function by affecting vascular and microvascular architecture and altering hepatocellular morphology.

METHODS: Kavain solution (10 μg/mL or 43.5 μmol/L) was perfused for 2 h in isolated rat livers. After standard fixation and tissue preparation, the samples were examined by scanning electron microscopy (SEM), transmission electron microscopy (TEM), and light microscopy (LM).

RESULTS: LM, SEM, and TEM examinations indicated kavain-treated rat livers (n = 4) displayed severe vascular and endothelial damage compared to control livers (n = 4).

CONCLUSION: The data so far support the hypothesis that kavain induces adverse effects on liver; additional investigations with other kavalactones and their effects on liver are urgently needed.

INTRODUCTION

Kava-kava, or kava, (*Piper methysticum* Forst.) is a South Pacific plant that has been used by indigenous people as an intoxicating traditional beverage since ancient times[1-4]. Various preparations of kava have been marketed since the 1980s, especially in Europe and North America to manage mild anxiety, tension, and restlessness. Some reports also indicate that kava preparations may have analgesic, spasmolytic, neuroprotective, and antimitotic activities[5-8]. However, a number of case reports have raised serious concerns about kava's safety. These reports suggest that, occasionally, even normal doses (200-300 mg/d standardized to contain 70% kavalactones) of kava can cause severe liver injury[9-13]. On the basis of these reports, regulatory agencies have banned or restricted sale of kava and kava products in many countries.

The main active constituents believed to be responsible for the pharmacological (and perhaps toxicological) effects of *Piper methysticum* are the styryl α-pyrones (called kavapyrones or kavalactones). To date, 18 kavalactones have been identified, among these, six major kavalactones constitute approximately 95% of the lipid extract derived from the dried roots and rhizomes; these are kavain, dihydrokavain, methysticin, dihydromethysticin, yangonin, and desmethoxyyangonin. Figure 1 shows kavain's chemical structure, its molecular formula is $C_{14}H_{14}O_3$, and molecular weight is 230[14-16].

The aim of this study was to investigate whether the major kavalactone, kavain, induces ultrastructural changes and function of the liver instead of biochemical perturbations. This was achieved by examining the vascular, microvascular, and hepatocellular morphological changes that might occur after perfusion of rat livers with kavain. This hypothesis was tested as there are literature evidence that kava might produce general adverse effects on the liver.

MATERIALS AND METHODS

Materials

Kavain (purity 95%) was purchased from ChromaDex, California, USA. Bovine serum albumin (BSA, Fraction V), taurocholic acid, and other chemicals were analytical grade and purchased from Sigma (Sydney, Australia).

Animals

Male Sprague-Dawley rats (Gore Hill, NSW Australia) of about 200 grams were used; prior to the experiments the animals were housed in a 12 h light-dark cycle and

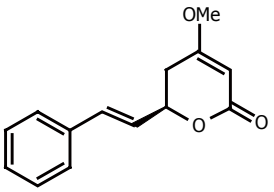

Figure 1 Chemical structure of kavain (KA).

controlled temperature environment with free access to standard laboratory chow and water. The study was approved by the Animal Ethics Committee of The University of Sydney.

Isolated rat liver perfusions with kavain

Rat livers were perfused with 10 μg/mL (43.5 μmol/L) kavain in 100 mL perfusate (1% BSA and 0.1% glucose in Krebs-Henseleit bicarbonate buffer) for 120 min for the kavain treatment groups; livers were perfused only with 100 mL perfusate for 120 min in the control group. The surgical and perfusion techniques have been described previously[17]; briefly this involved *in situ* cannulation of the portal vein and inferior vena cava under barbiturate anaesthesia and harvesting of the liver for recirculating perfusion. Liver viability during the perfusion was assessed by the pH gradient between inflow and outflow perfusate, bile flow rate and the gross appearance of the liver[18]. After 120 min of perfusion, the livers were perfusion fixed with 100 mL of 1.5% glutaraldehyde in 0.12 mol/L cacodylate buffer at pH 6.9 for 7 min. Following this the livers were stored in buffer at 4℃ until preparation for electron microscopic examination.

Liver tissue preparation for light and electron microscopy

Tissue samples were prepared according to standard protocols[19,20]. Briefly, glutaraldehyde perfused-fixed samples were cut into 1 mm^3 blocks in 1.5% glutaraldehyde/0.12 mol/L cacodylate buffer at pH 6.9. Blocks were then submerged in 1% osmium tetroxide/0.1 mol/L cacodylate buffer for 1 h at 4℃, gradually dehydrated in ethanol and embedded in epon. 50-80 nm ultra thin sections were cut, stained first with uranyl acetate and then with lead citrate. Slides were examined in a Philips Zeiss 902 transmission electron microscope at 80 kV.

Semi-thin (1000 nm) sections of TEM embedded liver samples were cut with a glass knife for overall light microscopic observations. Sections were stained with 1% toluidine blue solution prepared in 1% sodium tetraborate buffer, mounted in DePex (Cat. No. RT 13510, Electron Microscopy Science, Hatfield PA, USA) and examined in bright field mode and recorded using a digital CCD camera.

For scanning electron microscopy (SEM), liver tissue samples were prepared according to standard protocols[19,20]. Briefly, liver tissue was glutaraldehyde-prefixed, cut to 1 mm^3 samples and following glutaraldehyde fixation, tissue blocks were postfixed in 1% osmium tetroxide and dehydrated in graded ethanol solutions. The liver tissue was then dried with hexamethyldisilazane and subsequently broken in liquid nitrogen, mounted on stubs and sputter coated with a thin layer of 20 nm gold[21]. SEM-samples were examined in a Philips SEM 505 at 30 kV. Imaging and morphometric analysis was performed on randomly acquired digitized SEM images at magnifications of × 3000, × 5000 or × 20000 as previously described[22]. For light- and electron microscope studies all experiments were repeated at least four times.

RESULTS

Given that there are literature indications that kava affects liver function it was logical to examine with the aid of scanning electron microscopy, the influence of kavain on the surface liver architecture and vasculature in general and on the intactness of the endothelial lining in particular. Under control (no kavain) conditions sinusoids in the liver lobule show an intact endothelial lining, consisting of endothelium with flattened processes perforated by small pores. These pores (i.e., fenestrae) measure about 150-200 nm in diameter and are arranged in groups, also called sieve plates (Figure 2, SEM images). Following kavain treatment the liver tissue displays overall loss of architecture in general; the narrowing of blood vessels, constriction of sinusoidal blood vessels and retraction of the endothelium. Only few intact pores (fenestrae) can be observed since most of the pores are lost, and gaps form in endothelium which are from the dilatation of pores, these gaps can disturb normal liver transportation.

In order to investigate these changes in further detail at overall low versus high magnification light- (Figure 3, LM images) and transmission (Figure 4, TEM images) electron microscopy were applied on sectioned liver tissue, respectively. LM and TEM examination of control tissue shows an intact relationship between the sinusoidal liver vasculature and the neighbouring liver parenchymal cells; i.e., the sinusoid is patent and empty, the wall of the sinusoid is composed of a thin layer of porous (i.e., fenestrated) endothelium, which is covering the space of Disse, filled by microvilli extending from the parenchymal cell surface. These parenchymal cells contain glycogen, a few lipid vesicles, and numerous organelles in their cytoplasm. However, after 120 min of kavain treatment, the LM observations show loss of overall liver architecture; the closed, disrupted endothelium are confirmed, there are no signs of inflammatory reactions (such as platelets and white blood cells or other related cell types); the parenchymal cells of hepatocytes which are lying close to the sinusoidal vasculature are vacuolated, and the vascular bed is constricted, narrowed. The TEM results after kavain treatment confirm the SEM observations; the existence of gaps which indicate disruption of the normal liver architecture, only few pores in endothelial lining were found; and some strong vacuolized hepatocytes surround the blood vessels; finally vascular constriction can be noticed from the images, and it appears that the diameters of the blood vessels are smaller when compared to the control (no kavain) samples. In other words, after kavain treatment the normal hepatic vascular bed is lost. This may cause portal and central pressure perturbations and affect normal physiological liver function.

Noteworthy is that the severe changes in sinusoidal microvasculature and overall loss of the integrity of the liver parenchymal cell architecture was accompanied with striking structural alterations of the liver macrophage population

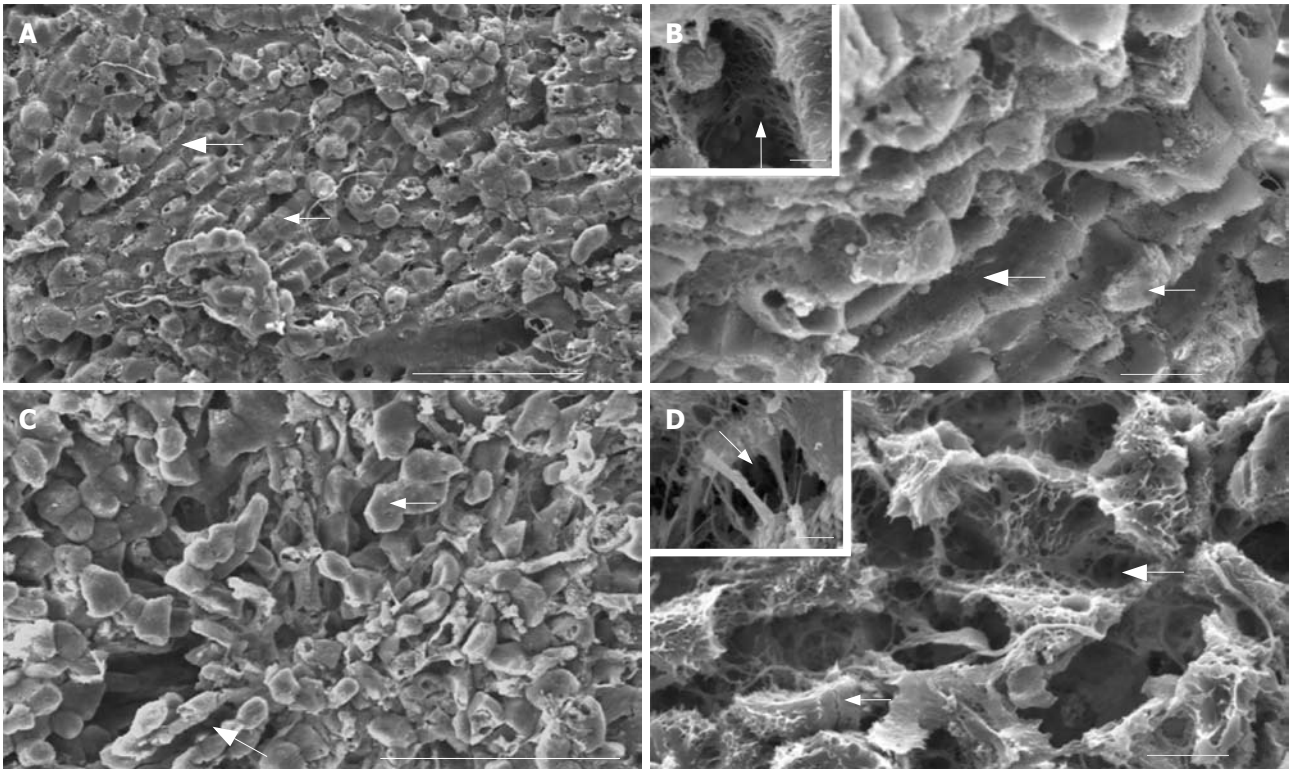

Figure 2 Scanning electron micrographs of control (**A** and **B**) and kavain-treated (**C** and **D**) livers. **A**: Overall low magnification image shows the intact histological relationship between the liver sinusoidal vascular bed (large arrow) and the neighbouring liver parenchymal cells (small arrow) of control liver tissue. Scale bar, 100 micrometer; **B**: Intermediate magnification of control liver tissue reveals the intact hepatic endothelial lining (large arrow) and its relationship with the neighbouring hepatocytes (small arrow). Scale bar, 40 micrometer. Inset depicts the pores or so-called fenestrae (arrow) at high magnification (bar represents 1 micrometer); **C**: Observation of kavain-treated liver tissue at low magnification reveals loss of the normal straight and parallel aligned sinusoidal blood vessels, instead contracted and curly microvessels can be seen (large arrow). Note that the hepatocytes appear to be swollen and have lost their relationship with the bordering endothelial lining (small arrow). Scale bar, 100 micrometer; **D**: When the same tissue is observed at higher magnification the endothelial damage in the form of gaps (large arrow) and the disconnection of the liver parenchymal cells (small arrow) becomes apparent. Scale bar, 40 micrometer. The inset illustrates the severely damaged endothelial lining (arrow, gaps; scale bar 1 micrometer).

(i.e., Kupffer cells) in the sinusoids of kava-treated livers (Figure 5, high magnification TEM images). Close examination by TEM revealed that Kupffer cells appear to be swollen and the presence of large cytoplasmic vacuoles and phagocytosed material is apparent. Furthermore, the cells have lost their typical ruffled cell membrane aspect and concurrently they appear to disengage from the sinusoidal endothelial lining.

DISCUSSION

This study provides LM, TEM and SEM evidence that perfusion of rat liver with kavain (10 μg/mL or 43.5 μmol/L) for 2 h causes severe vascular and endothelial damage manifesting as vasoconstriction, gaps and loss of endothelial and subendothelial liver tissue integrity when compared to control livers. The liver parenchymal tissue looks quite normal except for the cells lying close to the Space of Disse (indicating vacuolization). No other differences were observed between the kavain treated and control livers.

This current study does not allow elucidation of the exact mechanisms by which kavain induces the severe ultrastructural changes in the liver. The severe morphological changes were mainly confined to the sinusoidal vascular bed and the parenchymal liver cells lying close to the Space of Disse. This indicates that kavain either affects the endothelial lining directly resulting in the loss of the integrity of the local sinusoidal liver architecture; or alternatively, kavain might activate the local liver-associated macrophage population (i.e., the Kupffer cells) that in turn release cytotoxic substances which cause the acute endothelial vascular- and parenchymal tissue damage. Consistent with this, it is generally accepted that the increased release of pro-inflammatory mediators and reactive oxygen species by stimulated liver macrophages causes severe and acute liver damage[23,24]. In line with this, we collected fine structural evidence showing the presence of activated liver macrophages in livers exposed to kavain. In addition, these data also support the earlier literature observations of the adverse effects of kava on liver function in general[9-13]. Hence these results open up a new avenue for future research to investigate the cellular adverse effects of kava constituents on isolated liver parenchymal-, endothelial-, and Kupffer cells in mono- or co-cultures by using cytotoxic and functional metabolic assays. Furthermore, additional *in vivo* experiments might address the intriguing question of whether the effects of kavain on liver tissue are reversible, and may in part explain why patients recover from kava intoxication. Mounting literature evidence is available that dysfunction of the hepatic sinusoid can be reversed by modulating the Kupffer cell population[25] or its activation status[26]. On the

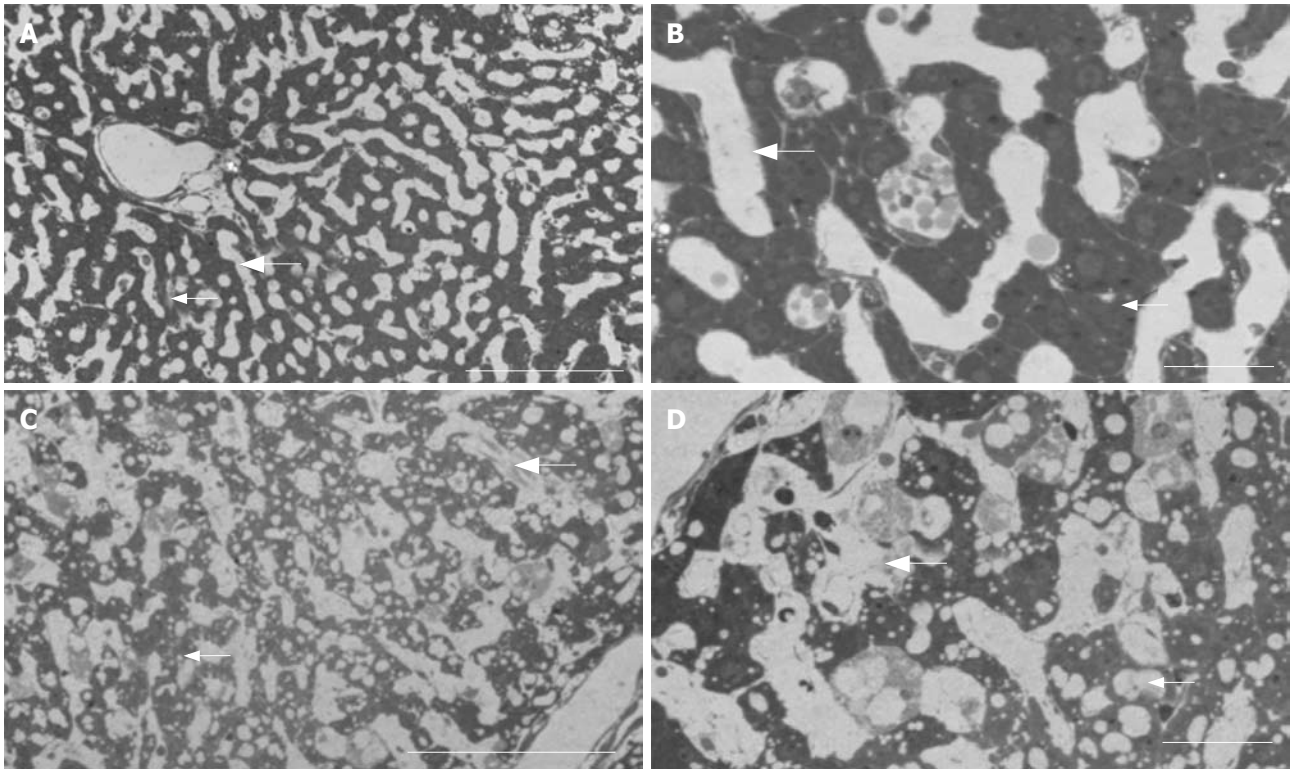

Figure 3 Bright field light optical micrographs of control (**A** and **B**) and kavain-treated livers (**C** and **D**). Note, comparison with the high-magnification TEM data for comparative purposes. **A**: Control liver tissue at low magnification reveals normal histology: i.e., hepatocytes (small arrow) are organized in long cords following the liver sinusoids or microvascular bed (large arrow). Scale bar, 100 micrometer; **B**: Higher magnification of control tissue reveals the patent empty sinusoidal lumen (large arrow) and the relationship with the neighbouring hepatocytes (small arrow). Scale bar 40 micrometer; **C**: In contrast, kavain-treated samples reveal narrowing of the microvessels (large arrow), indicating sinusoidal blood vessel contraction (compare with A). Small arrow, hepatocytes. Scale bar, 100 micrometer; **D**: Intermediate magnification of kavain-treated samples reveal strong vacuolization of the liver parenchymal tissue (small arrow) and loss of normal sinusoidal vasculature (large arrow). Scale bar, 40 micrometer.

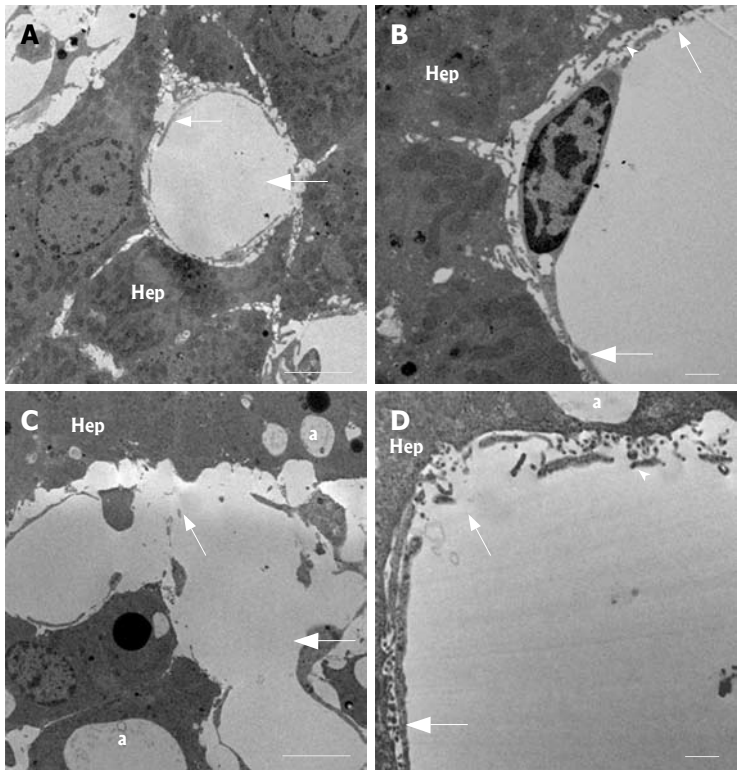

Figure 4 Transmission electron micrographs of control (**A** and **B**) and kavain-treated livers (**C** and **D**). Note, comparisons of these high-resolution TEM data with the corresponding low-magnification light microscopy images. **A**: Intermediate magnification reveals the intact histological relationship between the liver sinusoidal endothelium (small arrow) and the neighbouring liver parenchymal cells (Hep) of control liver tissue. Note the lumen (large arrow) of the small liver capillaries, also called the liver sinusoids. Scale bar, 5 micrometer; **B**: Examination of control samples at higher magnification reveals the intact endothelial lining (large arrow) containing the typical small transportation pores (fenestrae) (small arrow). Hep, hepatocytes; arrowhead, the space of Disse (defined as the space between the endothelial processes and the hepatocytes). Scale bar, 1 micrometer; **C**: Kavain-treated liver tissue samples at intermediate magnification shows strong signs of vacuolization of the hepatic tissue (a), sinusoidal endothelial damage (small arrow). Large arrow, liver sinusoids; Hep, hepatocytes or liver parenchymal cells. Scale bar, 5 micrometer; **D**: High magnification of liver tissue of kavain-treated rats confirm the earlier SEM observations with respect to large gap formation of the endothelial lining (small arrow). Large arrow, sinusoids; arrowhead, space of Disse; asterisk, vacuolization. Scale bar, 1 micrometer.

other hand, it has been recently shown that acute structural and pathophysiological damage of the liver sinusoidal endothelial lining can revert to normal within days[27].

The current study only examined the effects of one kavalactone, kavain on the liver. Hence it is not possible to conclude whether the other five (dihydrokavain,

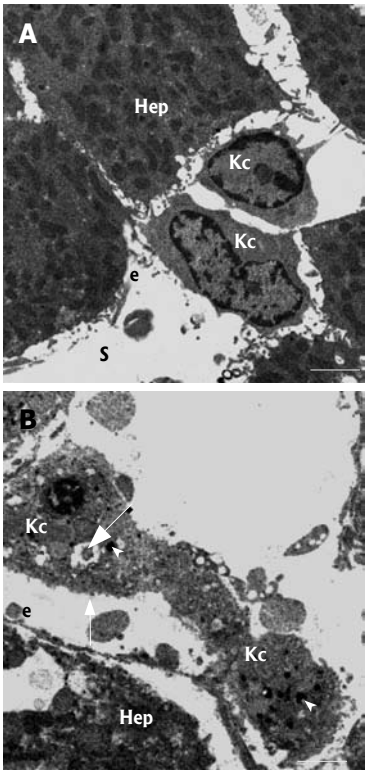

Figure 5 High-magnification transmission electron micrographs of Kupffer cells (Kc) in control (**A**) and kavain-treated livers (**B**). **A**: Kupffer cells are located within the sinusoid (S) and adhere to the endothelial (e) lining by means of multiple cytoplasmic extensions. Note, hepatocytes (Hep); **B**: In kavain-treated livers, Kupffer cells (Kc) show an entire different ultrastructure when compared to control livers (see figure 4A for the difference): i.e., the cells look swollen, contain large amounts of electron dense phagocytosed material (arrowhead), have large vacuoles (large arrow), and have lost their ruffled and microvillous cell surface characteristics (small arrow). Scale bars, 5 micrometer.

methysticin, dihydromethysticin, yangonin, and desmethoxyyangonin) major kavalactones have similar effects individually on the liver. In addition, since kava contains all the six kavalactones in combination, this pilot study has not examined any interactive or synergistic effects of these kavalactones with respect to adverse effects on the liver. It is also not able to be predicted whether kavain and other kavalactones have similar effects on human liver as has been observed here with rat liver.

This study also used only one (10 μg/mL or 43.5 μmol/L) concentration of kavain which was continuously exposed to the livers for 2 h. The choice of this exposure concentration and time was based on literature data. Plasma concentration of total kavalactones was about 33 μg/mL in a fatal human accident subsequent to kava ingestion with alcohol and cannabis[28]. The toxic concentration of kava extracts was 50 μg/mL in rat hepatocytes[29] while kavain toxic concentration (as judged by release of lactate dehydrogenase, LDH) was 125 μg/mL in mouse hepatocytes[30]. Based on this literature data, the kavain concentration in the current study was 10 μg/mL, and the results clearly show liver damage at this concentration. It would therefore be expected that at higher kavain concentrations adverse hepatic effects would be more severe. The exposure time of 2 h reflects literature evidence that livers remain normal during perfusions up to 3 h[18]. The structural changes observed after kavain exposure are therefore genuine as control perfusions revealed normal liver architecture. However, it is not known if the effects of kavain noted here are acute or chronic or if the effects are reversible since the livers were continuously exposed to kavain for 2 h. Since only one kavain concentration was used, it is not known if the effects observed here are concentration-dependent and what the minimum hepatotoxic concentration of kavain is.

COMMENTS

Background

Since the use of kava and kava-containing products were banned in some Western countries due to case report of liver failure, this study was aimed to examine the vascular, microvascular and hepatocellular fine morphological changes that might occur after perfusion of rat livers with major kavalactone kavain.

Research frontiers

This article demonstrates for the first time using light and electron microscopy liver vascular, microvascular architecture and hepatocellular morphologic changes after liver perfusion with kavain perfusate solution.

Innovation and breakthroughs

The isolation perfused rat liver (IPRL) method has been widely used in drug metabolism studies as it closely simulates *in vivo* (whole body) conditions with the advantage that experimental conditions can be precisely controlled, like perfusion time and drug concentration, since high concentrations of drugs would normally be a limitation because of their side effects *in vivo*. Thus IPRL combined with light and electron microscopic techniques increases the chance of determining the exact ultrastructural changes in the liver.

Applications

In this study kavain solution (10 μg/mL) was perfused for 2 h in IPRL, after standard fixation and tissue preparation, the samples were examined by scanning electron microscopy, transmission electron microscopy and light microscopy. Examinations indicated kavain-treated rat livers displayed severe vascular and endothelial damage compared to control livers. The data so far support the hypothesis that kavain induces adverse effects on liver. Further investigations with other major kavalactones and with different kavalactone concentrations to examine their effects on liver are urgently needed.

Terminology

Herb kava-kava (*Piper methysticum* Forst) has been used extensively in the Pacific as a drink for thousands of years. The roots of kava are used to prepare a drink for social and ceremonial occasions, similar to coffee or tea in other cultures. The root is also used for soothing the nerves, inducing relaxation and sleep. Various preparations of kava have also been marketed since 1980s in Europe and North America to manage mild anxiety and insomnia.

Peer review

The authors show that kavain induces adverse effects. The methods and histological examinations are rigid and instructive. The presentation is good. This present study is an interesting trial.

Abstract

AIM: To explore the effects of CO-releasing molecules [tricarbonyldichlororuthenium (Ⅱ) dimer, CORM-2]-liberated CO on attenuation of inflammatory responses in liver of an experimental animal model of thermal injury and to investigate the associated potential mechanisms.

METHODS: Thirty-six mice were assigned to three groups in three respective experiments. In each experiment, mice in sham group (n = 4) received sham thermal injury, whereas mice in burn group (n = 4) received a 15% of total body surface area (TBSA) full-thickness thermal injury, and mice in burn + CORM-2 group (n = 4) received the same thermal injury with immediate administration of CORM-2 (8 mg/kg, iv). Hepatic tissue sections were stained with hematoxylin and eosin and examined under a light microscope. Levels of aminotransferases (ALT and AST) and nitric oxide (NO) were measured by biochemical methods. Tumor necrosis factor-α (TNF-α) and interleukin (IL-1β) activity, and the protein expression of iNOS and HO-1 in serum and tissue homogenates were assessed. In *in vitro* experiments, Kupffer cells were stimulated with LPS (10 μg/mL) for 4 h in the presence or absence of CORM-2 (10-100 μmol/L). Subsequently, the expression levels of TNF-α and NO production were assessed.

RESULTS: Pro-inflammatory mediators (TNF-α, IL-1β, NO) in serum and liver homogenates of thermally injured mice were significantly reduced by CORM-2 administration. This was accompanied by a decrease in the expression of iNOS while an increase in the expression of HO-1 in the liver tissue. In parallel, the concentrations of TNF-α and NO in supernatants of LPS-stimulated Kupffer cells co-incubated with CORM-2 (10-100 μmol/L) were also markedly decreased. Histological examination demonstrated that CORM-2 could attenuate the leukocytes infiltration to the liver tissue.

CONCLUSION: CORM-released CO modulates liver inflammation and significantly protects liver injury in burn mice by inhibiting the expression of iNOS and NO production, down-regulating the expression of pro-inflammatory mediators (TNF-α, IL-1β).

INTRODUCTION

It is well known that endogenous carbon monoxide (CO), a bi-product of inducible heme oxygenase (HO-1), can modulates inflammation. In addition, some experiments have determined that the administration of exogenous CO inhibits lipopolysaccharide (LPS)-induced production of cytokines both *in vivo* and *in vitro*, and consequently exhibits important cytoprotective function and anti-inflammatory properties that are beneficial for the resolution of acute inflammation[1-3].

Recently, transitional metal carbonyls have been identified as potential CO-releasing molecules (CO-RMs) with the potential to facilitate the pharmaceutical use of CO by delivering it to tissues and organs[4]. CO-RMs have been shown to act pharmacologically in rat aortic and cardiac tissue where liberation of CO produced vasorelaxant effects[5-8] and decreased myocardial ischemia-reperfusion damage[9,10], respectively.

Our recent study has confirmed that tricarbonyldichlor oruthenium (Ⅱ) dimer (CORM-2), one of the novel group

of CORMs, inhibited the leukocytes sequestration in liver[11] and down-regulated inflammatory response in the lung[12] of burn-challenged mice. However, the regulating mechanisms of CORM-2 in the inflammatory response in the liver of burn-challenged mice remain unknown. Severe burn injury is a complicated process that involves several host responses, including inflammation, immune response and even systemic inflammatory response syndrome (SIRS). Different cytokines are likely to be produced during these host responses. Some of these cytokines may be produced in response to the thermal injury. Also, the pathophysiological changes seen in SIRS are often not due to the infectious organism itself but instead to the uncontrolled production of pro-inflammatory cytokines and chemokines, including tumor necrosis factor (TNF)-α, interleukin (IL)-1b. Accumulation of these mediators leads to leukocyte recruitment, capillary leak and tissue damage, ultimately producing the lethality of sepsis[13-15].

Based on these preliminary observations, in this study, we employed CORM-2 to determine whether it can exert the potential influence to modulate the important inflammatory mediators (TNF-α, IL-1β and NO) in the liver of thermally injured mice.

MATERIALS AND METHODS

Materials

Tricarbonyldichlororuthenium (Ⅱ) dimer (CORM-2) was obtained from Sigma Aldrich and solubilized in dimethyl sulfoxide (DMSO) to obtain a 10 mmol/L stock. Polyclonal or monoclonal antibodies against HO-1 and iNOS were purchased from Santa Cruz Biotechnology Inc. All other chemicals were of analytical reagent grade and obtained from Sigma-Aldrich (Shanghai Trading Co. Ltd.) unless otherwise stated.

Animal and burn protocol

Thirty-six male C57BL/6 mice, weighing 20 ± 2 g, were fed a standard laboratory diet and water *ad libitum*. Mice were assigned to three groups in three respective experiments. In each experiment, mice in sham group (n = 4) received sham thermal injury, whereas mice in burn group (n = 4) received a 15% of total body surface area (TBSA) full-thickness thermal injury and CORM-2 group (n = 4) received the same thermal injury with immediate administration of CORM-2 (8 mg/kg, iv). The experimental protocol was approved by the Council on Animal Care at Jiangsu University on the protection and the welfare of animals. Under anesthesia with spontaneous inhalation of isoflurane-N_2O (Abbott Laboratories, Missisauga, ON, Canada) in a 60% oxygen-40% nitrogen mixture, the dorsum of each mouse was shaved and the mice were subjected to a 15% of total body surface area (TBSA) full-thickness thermal injury as previously described[16,17]. Sham animals were immersed in a room temperature water bath. All animals were resuscitated with 1.5 mL saline immediately after thermal (or sham) injury. No wound care was required for the burn wounds. This burn method achieves a histologically proven, full-thickness scald injury[18,19]. The animals were sacrificed at 24 h after experimental manipulation.

Histologic studies

The liver specimens harvested from different groups of mice were immersed in 40 mL/L formaldehyde solution after 24 h of the thermal injury. The tissues were embedded in paraffin wax, serially sectioned, and stained with hematoxylin-eosin. Liver morphologic characteristics were evaluated under light microscope.

Isolation and culture of Kupffer cells

In *in vitro* experiment, the effect of CORM-2 on Kupffer cells was studied by isolating Kupffer cells from the normal livers. Liver perfusion was performed using a modification of the two-step collagenase perfusion technique introduced by previous studies[20,21]. Briefly, the liver was perfused through the portal vein with D-Hank's solution until became blood-free, and then with Hank's solution containing 0.5 g/L collagenase Ⅳ. The latter was administered by recirculation until the vessels were digested (up to 20 min). The liver was then scraped using a cell scraper, filtered through a 100-μm filter, and stirred in Hank's solution containing 2.5 g/L pronase and 0.05 g/L Dnase at 37℃ for 20 min. After three times of centrifugation and washing at 300 r/min for 10 min at 4℃ in Gey's balanced salt solution (GBSS), cells were centrifuged in an 180 g/L Nycodenz gradient at 2500 r/min for 20 min. Kupffer cells were carefully sucked by cusp-straws at the pearl layer inderphase. Purified Kupffer cell fractions were then obtained by centrifugal elutriation. The viability of Kupffer cells prepared was more than 95% as determined by trypan blue exclusion. The purity of Kupffer cells was greater than 90% based on a peroxidase activity assay[22].

Kupffer cells were cultured in RPMI 1640 medium containing antibiotics (penicillin 100 U/mL; streptomycin 100 mg/mL), 2 mmol/L glutamine, and 100 mL/L fetal calf serum. The cells at a density of 1×10^6/mL were cultured in 24-well culture plates and co-incubated with LPS (10 μg/mL) and different concentrations of CORM-2 (10, 50, 100 μmol/L) for 4 h. The supernatants were collected and TNF-α and NO concentrations were measured using the methods described below.

Measurement of serum level of transaminases, TNF-α and IL-1β levels in serum, tissue homogenate and cell culture supernatants

Blood samples were obtained by cardiac puncture of the left ventricle. The samples were stored in serum tubes (Capiject, Terumo Medical Corporation, USA) and immediately centrifuged at 6500 r/min for 5 min. Evaluation of hepatocellular injury was performed by determining the enzymatic activity of the alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in serum samples using a commercial kit (Boehringer Manheim, Munich, Germany) according to the manufacturer's instructions. Concentrations of TNF-α and IL-1β levels in serum, tissue homogenate and supernatants of cell culture were assayed by enzyme-linked immunosorbent assay kits (Genzyme, Corp., Cambridge, MA) following the manufacturer's instructions.

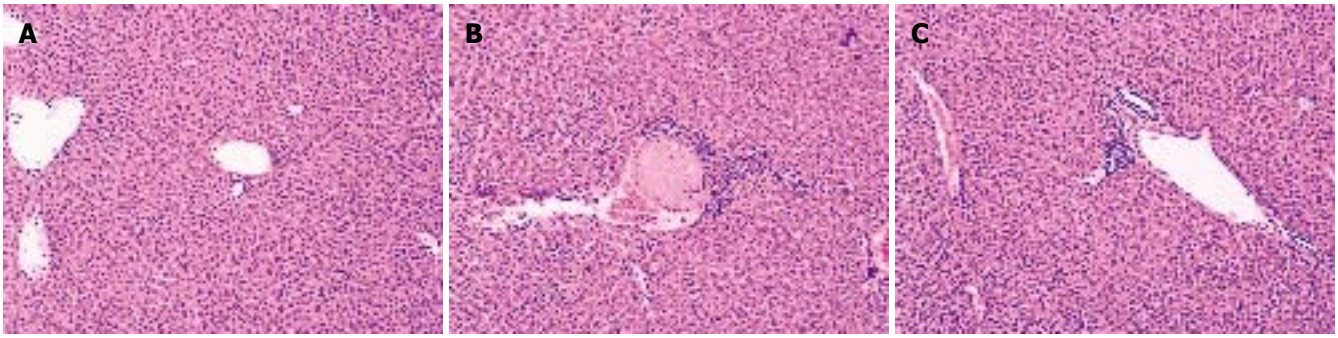

Figure 1 Histologic results of liver tissue after staining with hematoxylin and eosin (HE, × 100). Mice were challenged with thermal injury and immediately intravenously injected with CORM-2 (8 mg/kg). **A**: Sham group; **B**: Burn group; **C**: Burn + CORM-2 group.

Measurement of NO in serum, tissue homogenate and cell culture supernatants

Nitric oxide (NO) was measured by a microplate assay using Griess reagent, which produces a chromophore with the nitrite[23]. Briefly, 100 μL of supernatant was removed and incubated with 100 μL of Griess reagent (10 g/L sulfanilamide and 1 μg/L N-1-naphthylethylenediamine dihydrochloride in 25 mL/L phosphoric acid) in a 96-well plate. The plate was incubated for 10 min at room temperature. Nitrite production was quantified spectrophotometrically using an automated colorimetric procedure. Absorbance at 540 nm (A_{540}) was measured using a microplate reader (Bio-Tek, USA). The nitrite concentration was calculated by comparing samples with standard solutions of sodium nitrite produced in the culture medium. All samples were assayed in triplicate. Results were expressed as μmol/L.

Western blot analysis

Tissues were homogenized for extract preparations in ice-cold mild lysis buffer containing 10 mL/L Nonidet P-40, 0.15 mol/L NaCl, 0.01 mol/L sodium phosphate (pH 7.2), 2 mmol/L EDTA, 50 mmol/L sodium fluoride, 0.2 mmol/L sodium vanadate, and 1 μg/mL aprotinin. The tissue homogenates were centrifuged at 20000 × *g* for 15 min and supernatants were collected. SDS-PAGE was performed on equivalent amounts of protein samples using precast 7% resolving/4% stacking Tris-HCl gels (Bio-Rad, Hercules, CA). Separated proteins were then transferred onto PVDF membranes (Amersham Pharmacia Biotech, Inc., Piscataway, NJ). Membranes were blocked in 50 g/L nonfat milk in TBST (TBS buffer containing 1 g/L Tween 20) for 1 h at room temperature. Blocked membranes were incubated in primary antibodies specific for mouse iNOS (1:2000 dilution) and HO-1 (1:5000 dilution) in TBST overnight at 4℃. Then the membranes were washed and probed with horseradish peroxidase-conjugated secondary antibody (Amersham Pharmacia Biotech, Inc.) for 1 h at room temperature. Chemiluminescence detection was performed with the Amersham enhanced chemiluminescence detection kit according to the manufacturer's instructions. To ensure a similar amount of protein in each sample, the membranes were "stripped off", reprobed with actin, developed with horseradish peroxidase-conjugated secondary antibody, and visualized by enhanced chemiluminescence. The specific bands were quantified by densitometry (Bio-Rad GS-710 Densitometer).

Table 1 Liver injury estimated from serum ALT and AST levels

Groups	*n*	AST (IU/L)	ALT (IU/L)
Sham	6	70.3 ± 6.8	38.5 ± 6.1
Burn	6	345.6 ± 32.7[b]	107.7 ± 16.9[b]
Burn + CORM-2	6	189.9 ± 24.3[a]	58.6 ± 9.7[a]

[b]$P < 0.01$ *vs* sham; [a]$P < 0.05$ *vs* burn.

Statistical analysis

Data were expressed as mean ± SE. Statistical analysis was performed using ANOVA and Student's *t*-test for the comparisons. A P value less than 0.05 was considered statistically significant.

RESULTS

Histology

Histological analysis showed that the liver sections from sham mice demonstrated a normal architecture, while thermal injury induced marked vacuolization and infiltration of the inflammatory cells to the tissue (Figure 1). After *in vivo* administration of CORM-2 (8 mg/kg, iv), granulocyte infiltrations were significantly decreased. However, CORM-2 did not improve the thermal injury-induced congestion in liver sinusoids.

Effect of CORM-2 on transaminases levels in burn-challenged mice serum

Hepatocyte injury was evaluated by determining the serum concentrations of ALT and AST. At 24 h after a 15% TBSA full-thickness thermal injury, serum hepatic transaminases (ALT and AST) were found to be markedly increased in the burn mice as compared to the sham mice ($P < 0.05$), whereas the corresponding values in the burn mice receiving CORM-2 (8 mg/kg, iv) at the beginning of resuscitation were significantly decreased as compared to the burn mice without CORM-2 administration ($P < 0.05$, Table 1).

Effect of CORM-2 on TNF-α and IL-1β levels in serum and tissue homogenates of burn-challenged mice

At 24 h after a 15% TBSA full-thickness thermal injury,

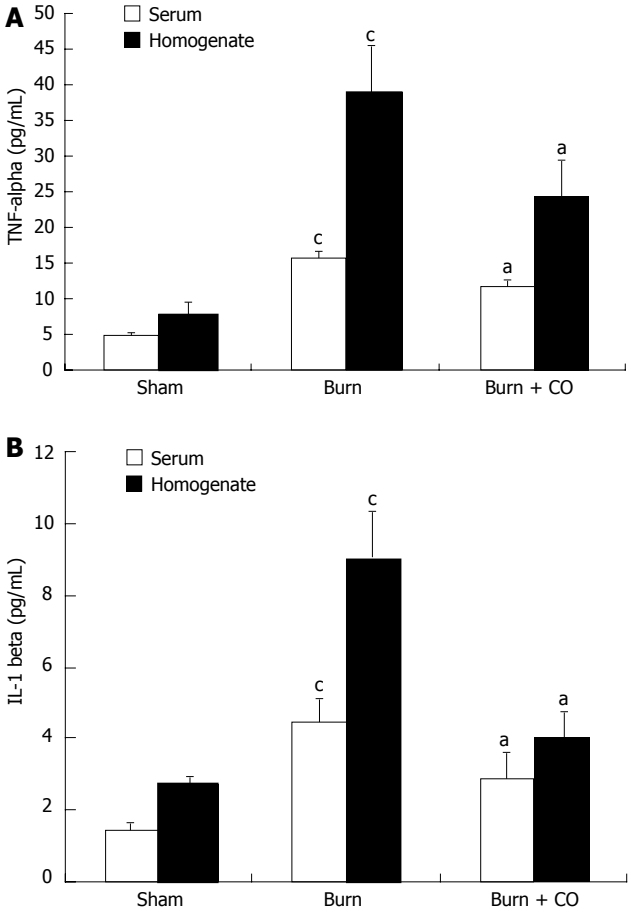

Figure 2 Effect of CORM-2 on TNF-a and IL-1β levels in serum and tissue homogenates of burn-challenged mice. Data are expressed as mean ± SE of three experiments (three mice per group). $^{a}P < 0.05$ *vs* burn group; $^{c}P < 0.05$ *vs* sham group.

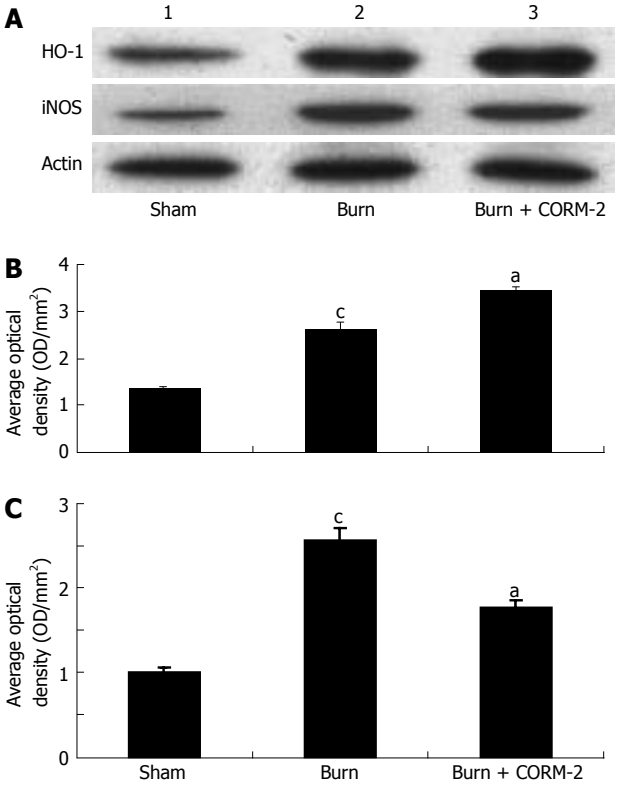

Figure 3 Effects of CORM-2 on protein expression of iNOS and HO-1 in the liver of burn-challenged mice. Protein expressions of iNOS and HO-1 were performed by Western blotting at 24 h after thermal injury. **A**: Representative experiment; **B** and **C**: Quantitative results (average absorbance, A_{540}) of three. $^{a}P < 0.05$ *vs* burn group; $^{c}P < 0.05$ *vs* sham group.

TNF-α and IL-1β levels in serum and tissue homogenates of the burn-challenged mice were markedly increased compared to the sham mice. After administration of CORM-2, the elevation in serum and tissue homogenates levels of TNF-α and IL-1β was significantly abolished (Figure 2A and B).

Effect of CORM-2 on expression of iNOS and HO-1 in the liver of burn-challenged mice

At 24 h after a 15% TBSA full-thickness thermal injury, the expression of iNOS in liver tissue significantly increased compared to the sham mice. *In vivo* administration of CORM-2 (8 mg/kg, iv) resulted in a significant decrease in iNOS expression (Figure 3A and C). HO-1 expression in the liver of burn mice was markedly increased compared to sham mice. Interestingly, HO-1 expression in the liver of burn mice with administration of CORM-2 was more significantly increased as compared to the burn group (Figure 3A and B).

Effect of CORM-2 on NO production in serum and tissue homogenates of burn-challenged mice

As shown in Figure 4, production of NO was low in sham group. After burn challenge, NO levels in serum and tissue homogenates were significantly increased ($P < 0.05$ *vs* sham), whereas administration of CORM-2 significantly decreased the NO levels ($P < 0.05$ *vs* burn group).

Effect of CORM-2 on NO and TNF-α levels in supernatants of Kupffer cells stimulated with LPS

As shown in Figure 5, NO and TNF-α levels were low in controls. After Kupffer cells were stimulated by LPS (10 μg/mL) for 4 h, NO and TNF-α levels in supernatants were significantly increased as compared to controls ($P < 0.05$), while markedly decreased when Kupffer cells were co-incubated with LPS and CORM-2 ($P < 0.05$ *vs* LPS group).

DISCUSSION

Recent studies have demonstrated various physiologic and immunologic alterations in acute inflammations associated with infection, trauma and thermal injury[24-27]. Increasing attention has been directed to the role of cytokines in the mechanisms of such alterations. TNF-α, IL-1β, IL-6, which are pro-inflammatory cytokines, are considered potential mediators of inflammation produced by immunoregulatory cells as well as by a variety of other cell types[28], and play a major role in the regulation of immune response and inflammation[29].

It is well known that heme oxygenase-1 (HO-1), the inducible isoform of heme oxygenase which catalyzes the formation of the endogenous carbon monoxide (CO),

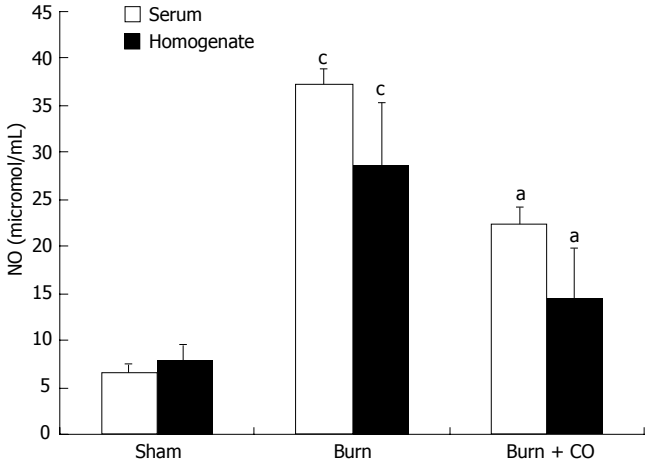

Figure 4 Effects of CORM-2 on NO level in serum and tissue homogenates of burn-challenged mice. Measurement of NO level was performed by a microplate assay using Griess reagent at 24 h after thermal injury. NO levels both in serum and tissue homogenates of thermally injured mice were markedly increased, but significantly inhibited by *in vivo* administration of CORM-2. $^{a}P < 0.05$ *vs* burn group; $^{c}P < 0.05$ *vs* sham group.

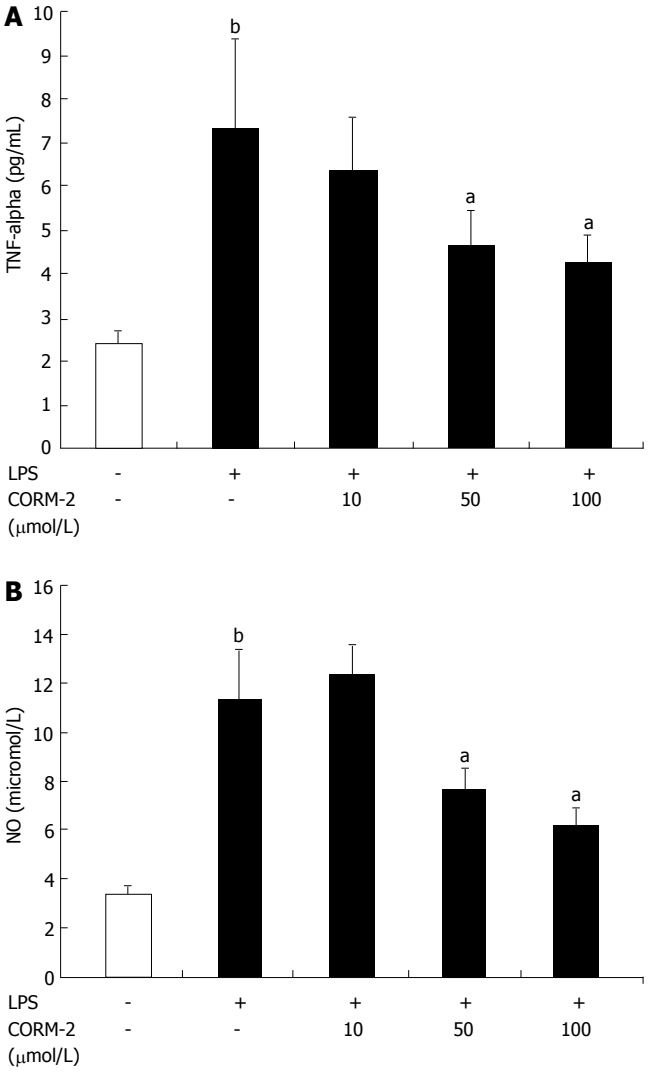

Figure 5 Effect of CORM-2 on levels of NO and TNF-α in supernatants of Kupffer cells stimulated with LPS. Kupffer cells were co-incubated with LPS and different concentrations of CORM-2 (10-100 mmol/L) for 4 h. All values are expressed as means ± SE ($n = 3$). $^{b}P < 0.01$ *vs* control; $^{a}P < 0.05$ *vs* LPS group.

biliverdin/bilirubin and ferrous iron, exhibits important anti-inflammatory properties that are beneficial for the resolution of acute inflammation[30]. Many experimental studies have highlighted the specific and independent role of exogenous CO (i.e. CO gas inhalation) in the modulation of inflammation[31]. Recently some new metal carbonyl-based compounds (CO-releasing molecules, CO-RMs) that have the ability to release CO in biological systems have been identified and synthesized. The vasoactive, antihypertensive and antirejection effects of CO-RMs have been demonstrated to be due to the CO liberated by the compounds. CORM-2, a DMSO-soluble CO-RM, also has exhibited anti-inflammatory actions in an *in vitro* model of LPS-stimulated murine macrophages. Thus, the aim of this study was to shed light on the role of CORM-2, as a exogenous CO, on the local and systemic inflammatory response induced by burn injury.

In this study, we found that HO-1 was significantly up-regulated by thermal injury. Interestingly, HO-1 expression in the liver of thermal injury with administration of CORM-2 was more significantly increased compared to burn mice (Figure 3). This result indicated that not only major burn injury, a severe trauma, might significantly induce HO-1 expression, but also the increase of HO-1 expression can be further enhanced by the *in vivo* administration of CORM-2. Through the by-product (CO, and/or biliverdin), the potent cytoprotective and anti-inflammatory functions were ultimately led to exert.

The data from this study showed that thermal trauma induced hepatocellular injury as evidenced by increased plasma ALT and AST levels. The *in vivo* administration of CORM-2 attenuated post-burn hepatocellular injury (Table 1). In parallel, after application of CORM-2, the elevation both in serum and tissue homogenates levels of TNF-α and IL-1β in burn-challenged mice was abolished (Figure 2). This result suggests that CORM-2 in the prevention of burn-induced liver damage may involve in down-regulation of the production of TNF-α, since TNF-α is an important mediator of hepatic inflammation in burn-induced liver damage. An alternative possibility is that the anti-inflammatory effects of CORM-2 are owing to its potential inhibition of the production and secretion of TNF-α. These data indicated that CORM-2 exhibits, at least partly, an important cytoprotective function during the early period of thermal injury.

Based on current research findings, oxidative stress is believed to be the major causative agent to damage the organs distant from the original burn wound. Nitrosative stress initiates an inflammatory cascade that includes acute phase protein synthesis, up-regulation of inflammatory adhesion molecules, and pro-inflammatory cytokine release[32,33]. Thus, tissue or organ injury after thermal trauma appears to be mediated both by reactive oxygen species (ROS) and reactive nitrogen species (RNS), such as hydroxyl radical, superoxide anion, hydrogen peroxide, and peroxynitrite. It has been demonstrated that burn injury is associated with lipid peroxidation mediated by ROS and is believed to be an important cause of oxidative damage to cellular membranes and, eventually, cell death[34]. Also,

nitric oxide (NO) plays a crucial role in cellular injury in burns. It has been recognized that NO is produced by cNOS and/or iNOS in mice liver[35,36]. In this study, we found that thermal injury produced a significant up-regulation in the inducible nitric oxide synthetase (iNOS) expression (Figure 3), thereby up-regulating iNOS-mediated nitric oxide production. After administration of CORM-2, the iNOS protein expression was significantly decreased, it might effectively decrease the overabundance of NO, which produces significant cellular toxicity *via* several mechanisms[37].

Lipopolysaccharide (LPS), a constituent of the Gram-negative bacterial cell wall, is the leading cause of sepsis, and when administered experimentally to macrophages or mice, mimics the same inflammatory responses. After LPS administration, there is a rapid increase in the pro-inflammatory mediators. The present study showed that the levels of TNF-α and NO in the supernatants of Kupffer cells stimulated by LPS were markedly increased compared to controls, while this increases was down-regulated after the co-incubation with CORM-2 in a concentration-dependent manner (Figure 5). These results are in accordance with our *in vivo* experimental data, which indicated that CORM-2 effectively inhibited TNF-α expression and NO production both in serum and tissue homogenates of experimental models.

In summary, the present study clarifies the anti-inflammatory and cytoprotective role of CORM-2, one of the novel CO-releasing molecules. Application of CORM-2 on thermally injured mice inhibited the expressions of TNF-α and IL-1β both in serum and tissue homogenates of experimental models. Also, iNOS protein expression in liver tissue was effectively inhibited in burn-challenged mice with treatment of CORM-2, this was accompanied by a decrease in NO level. In parallel, TNF-α and NO levels were decreased in LPS-stimulated Kupffer cells treated with CORM-2. Taken together, these findings indicate that CORM-released CO modulates liver inflammation in burn-challenged mice by interfering with TNF-α, IL-1β and NO production, and iNOS and HO-1 protein expressions, thereby suppressing inflammatory response in the liver of experimental models. Further studies are required to understand the detail mechanisms of anti-inflammatory effects mediated by CORMs, and to contribute to the development of a therapeutic approach to protect the liver during severe burn injury.

COMMENTS

Background

Recent studies have shown various physiologic and immunologic alterations in acute inflammations associated with infection, trauma and thermal injury. Increasing attention has been directed to the role of cytokines in the mechanisms of such alterations. TNF-α, IL-1β, IL-6, which are pro-inflammatory cytokines, are considered potential mediators of inflammation produced by immunoregulatory cells as well as by a variety of other cell types, and play a major role in the regulation of immune response and inflammation. In our laboratory, it was confirmed that tricarbonyldichlororuthenium (Ⅱ) dimer (CORM-2), one of the novel group of CORMs, inhibited the leukocytes sequestration in liver and down-regulated inflammatory response in lung of burn-challenged mice. However, the regulating mechanisms of CORM-2 in the inflammatory response in liver of burn-challenged mice remain unknown. Severe burn injury is a complicated process that involves several host responses, including inflammation, immune response and even SIRS. Different cytokines are likely to be produced during these host responses. Some of these cytokines may be produced in response to the thermal injury. Also, the pathophysiological changes seen in SIRS are often not due to the infectious organism itself but instead to the uncontrolled production of pro-inflammatory cytokines and chemokines, including TNF-α, IL-1β.

Research frontiers

Major burn alters immune function, producing an imbalance between pro- and anti-inflammatory cytokine synthesis and increasing susceptibility to post-burn infection and sepsis. Also, severe burn causes damage to multiple organs distant from the original burn wound, leading to multiorgan failure, a serious clinical problem. Liver is one of the most sensitive tissues to ischemia and reperfusion (I/R) injury induced by thermal injury. Different cytokines may be produced in response to the thermal injury. Also, the pathophysiological changes are often not due to the infectious organism itself but instead to the uncontrolled production of pro-inflammatory cytokines and chemokines, including TNF-α, IL-1β. Accumulation of these mediators leads to leukocyte recruitment, capillary leak and tissue damage, ultimately producing the lethality of sepsis.

Innovations and breakthroughs

This is probably the first study which demonstrated CORM-released CO modulates the inflammatory response in the liver of thermally injured mice and the possible associated mechanisms.

Applications

Our research observed that CORM-released CO modulates liver inflammation and significantly protects liver injury in burn mice by inhibiting the expression of iNOS and NO production, down-regulating expression of pro-inflammatory mediators, including TNF-α, IL-1β.

Terminology

Carbon monoxide-releasing molecules (CO-RMs): Transitional metal carbonyls have been identified as potential CO-releasing molecules with the potential to facilitate the pharmaceutical use of CO by delivering it to tissues and organs.

Peer review

This study seems to be well performed, the methods are adequate. The reason for the study seems sound and solid, the conclusions seem to be relevant and the literature covers the subject.

Abstract

AIM: To identify the protein expression differences related to the CagA-induced ERK pathway activation in AGS cells.

METHODS: Human AGS cells transfected with *cagA* and blank vector were treated with specific mitogen-activated protein kinase kinase (MEK) inhibitor. Total cell proteins were combined by strong anion exchange (SAX2) and weak cation exchange (CM10) ProteinChip arrays and analyzed using surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS) proteomics technology. Protein expression profiles were compared with those of inhibitor-untreated *cagA* transfectants. SwissProt/TrEMBL database searching for differentially expressed proteins was carried out using the TagIdent tool with the pI and mass information.

RESULTS: When a total of 16 proteins that showed expression differences in inhibitor-untreated *cagA* transfectants were compared with vector transfectants, three proteins with m/z 4229, 8162 and 9084 were found to have no expression differences after treatment with MEK inhibitor, while the other 13 maintained the same expression differences after inhibitor treatment. Seven pieces of meaningful matching information for the three proteins were obtained from database searching.

CONCLUSION: Biomarkers with m/z 4229, 8162 and 9084 are ERK1/2 phosphorylation dependent, and therefore are the downstream molecules of ERK1/2 in the ERK/MAPK signaling pathway. The three biomarkers may be important cancer-associated proteins according to SwissProt/TrEMBL database information.

INTRODUCTION

H pylori infection, a primary etiological cause leading to gastritis and peptic ulcer[1], is also a high risk factor for gastric cancer, and is classified as a class I carcinogen by the International Research Agency on Cancer (IRAC)[2-6]. Cytotoxin-associated gene A (CagA) protein, which is encoded by cytotoxin-associated gene pathogenicity island, is the major virulence factor of type I *H pylori*. Epidemiological studies indicate that CagA plays an important role in the development of *H pylori*-induced disease, especially in gastric cancer. The CagA antibody titer in gastric cancer patients is higher than in healthy individuals. Similarly, CagA antibody titer is elevated in high-risk populations[7]. Compared with *cagA*-negative *H pylori* strains, *cagA*-positive strains dramatically increased the occurrence of severe gastritis and gastric adenocarcinoma[8-12]. Experimental studies reveal that CagA is translocated into host cells through a type Ⅳ secretion system of *H pylori*[13]. After being tyrosine-phosphorylated at the C-terminal repeat sequence(s) by c-src/Lyn kinase[14,15], CagA strongly stimulates the mitogen-activated protein kinase (MAPK) signaling pathway in host cells, through interaction with SHP-2, a tyrosine phosphatase containing an SH2 homolog, and

results in cell proliferation and differentiation[16]. As one of the major three members of the MAPKs, extracellular signal-regulated kinase (ERK) has been reported to be a key molecule in cell carcinogenesis in various cell types[17-19]. Higashi *et al*[20] have found that ERK is activated by CagA *via* SHP-2 recruitment and activation in AGS cells (human gastric adenocarcinoma epithelial cell line). Our previous research further proved that transformation of immortalized gastric epithelial cells by CagA takes place through the ERK/MAPK pathway[21]. However, the precise mechanism of the interactions between CagA and host cells in associated pathogenesis has not been fully elucidated.

Recently, gene microarrays have been used to establish the global pattern of gene expression in *cagA* gene-transfected AGS cells[22]. Nevertheless, gene and protein expression levels cannot easily be correlated or equated since proteins can exist in different posttranslational functional states. Therefore, it is important to gain an overall view of host response to CagA interference at the protein level. However, to date, few studies that exploit the global protein-expression pattern that can reflect host-cell response to CagA have been reported. Based on surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS) technology, the ProteinChip platform has recently been shown to be valuable in establishing protein expression profiles and discovering new biomarkers[23-25]. ProteinChips, on which proteins from biological samples are selectively retained according to their biochemical properties, are analyzed directly by MS to form peak patterns as protein-expression profiles. The location and intensity of every peak in the pattern reflect the molecular weight and abundance of the corresponding protein. Therefore, the patterns can be used to analyze the protein expression differences under different conditions. This innovative technique has certain advantages over other traditional methods such as two-dimensional gel electrophoresis in its small sample volume, high throughput capability, subfemtomole range sensitivity, high resolution at low mass range, and easy operation, thus it has been successfully applied in new biomarker discovery for early diagnosis of cancer and basic research into disease mechanisms[26-29].

The proteome of AGS cells transfected with *cagA* gene was analyzed using a SELDI-ProteinChip platform in our previous study. Sixteen biomarker proteins involved in CagA induced pathogenesis were identified[30]. In this study, we further investigated the relationship of these protein expression differences and activation of the ERK/MAPK signaling pathway by CagA. Three more pivotal disease-related biomarkers among the 16 were further figured out.

MATERIALS AND METHODS

Expression vectors

Wild-type (WT) *cagA*/pcDNA3.1(+) plasmid (WT-*cagA*) and phosphorylation site mutant *cagA*/pcDNA3.1(+) plasmid (MT-*cagA*) were constructed as previously described[31,32]. Briefly, WT-*cagA* was constructed for encoding CagA proteins containing three tandem Glu-Pro-Ile-Tyr-Ala (EPIYA) motifs, and one repeated EPIYA motif sequence with Asp-Phe-Asp (DFD) in the D2 region. MT-*cagA* was generated from WT-*cagA* by substituting a phenylalanine codon for a tyrosine codon in the repeated EPIYA motif.

Cell culture and transfection

Human gastric adenocarcinoma epithelial AGS cells (ATCC, Rockville, MD, USA) were cultured in RPMI-1640 medium (Gibco, Gaithersburg, MD, USA) supplemented with 10% fetal calf serum (Gibco) in six-well plates. For ERK-associated analysis, cells were transiently transfected with WT-*cagA* or blank vectors. For each well, 4 μg plasmids were transfected into 5.5×10^5 cells by using 6 μL Lipofectamine 2000 reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's protocol. WT-*cagA* transfectants, vector transfectants and untransfected cells were divided into three groups that were respectively treated with the specific mitogen-activated protein kinase kinase (MEK) inhibitor U0126 (Sigma, St. Louis, MO, USA) at 10 μmol/L, DMSO vehicle, or were not treated. Cells were collected after 48 h for protein expression analysis. The transfection efficiency was at least 37%, as determined by the cells transfected with EGFP/pcDNA3.1(+). The expression of *cagA* gene was confirmed by RT-PCR.

Western blot analysis

WT-*cagA* transfectants, vector transfectants and untransfected AGS cells were incubated in 10% FCS for 0, 1 or 3 h following a 24-h serum-starvation period. After washing three times with PBS, cells were harvested and treated with lysis buffer (20 mmol/L Tris-HCl pH 7.4, 150 mmol/L NaCl, 10 mmol/L EDTA, 10 mL/L Triton X-100, 40 g/L SDS, and 100 mL/L glycerol) at 100℃ for 5 min and then centrifuged at 15000 × *g* for 5 min. Western blot analysis was performed with standard techniques, using anti-total ERK1/2 antibody (1:1000; Cell Signaling, Beverly, MA, USA), anti-phospho-ERK1/2 antibody (1:1000; Cell Signaling), followed by an anti-mouse secondary antibody (Beijing Zhongshan Biotechnological, China). Samples were separated on 10% sulfate-polyacrylamide gel and electrotransferred onto nitrocellulose membranes (Amersham Biosciences, USA). Immunoreactive bands were visualized with the ECL detection system (Santa Cruz Biotechnology, Santa Cruz, CA, USA) using Kodak X-ray film.

Preparation of total cell lysates

AGS cells of each group were harvested after PBS washing and resuspended in lysis buffer (8 mol/L urea, 40 g/L CHAPS, 50 mmol/L DTT, 40 mmol/L Tris-HCl) containing protease inhibitor cocktail (Sigma). After 30 min lysis on ice, total cell lysates were obtained by centrifugation at 20000 × *g* for 30 min to remove insoluble debris. Protein concentration was measured using BioRad DC protein assay kit (BioRad, Hercules, CA, USA) and then adjusted to 5 mg/mL for further protein expression analysis.

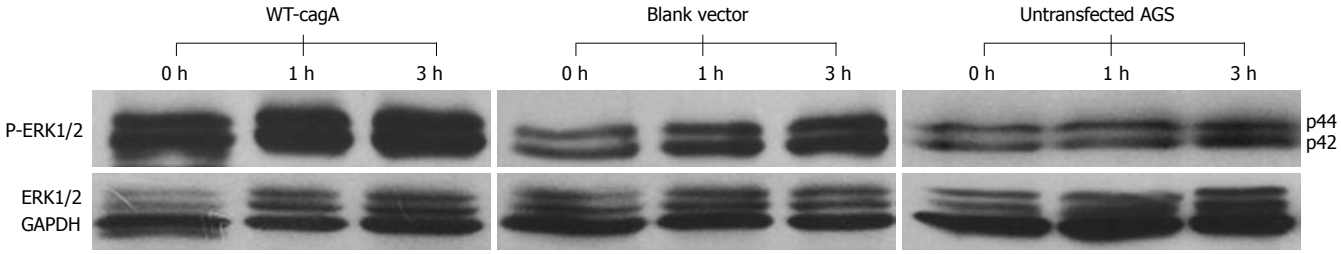

Figure 1 Detection of phosphorylated ERK1/2 in transfected AGS cells. Cells transfected with WT-*cagA* or blank vectors were stimulated with serum by adding fresh medium containing 10% FCS for 0, 1 and 3 h, after 24 h serum starvation, and then harvested for Western blot analysis of total and phosphorylated ERK1/2 (P-ERK1/2). The level of P-ERK1/2 in WT-*cagA* transfectants was significantly higher than that in blank vector transfectants and untransfected AGS cells at all three time points of serum stimulation. No obvious increases in total ERK among the three groups were found. GAPDH level was used as a loading control.

SELDI protein profiling

Expression profiles of each group were obtained by strong anion exchange (SAX2) and weak cation exchange (CM10) ProteinChip Arrays (Ciphergen Biosystems, Fremont, CA, USA) using an "*in situ*" protocol provided by the manual. Before sample loading, each spot of SAX2 and CM10 arrays were equilibrated with 3 μL of binding buffer (50 mmol/L Tris-HCL, pH 9.0 for SAX2 and 50 mmol/L sodium acetate, pH 4.0 for CM10). After 5 min incubation for three consecutive periods, 5 μL total cell lysate (diluted to 1.5 mg/mL in binding buffer) was added for chip binding. All arrays were incubated in a humidity chamber for 1 h and each spot was washed three times with 3 μL binding buffer. After rinsing quickly with HPLC water twice, the arrays were air-dried. One microliter of saturated sinapinic acid (Ciphergen Biosystems) solution in 500 mL/L acetonitrile, in water containing 5 mL/L trifluoroacetic acid, was applied twice, followed by air-drying. Mass accuracy was calibrated using the All-in-1 peptide and All-in-1 protein molecular mass standards (Ciphergen Biosystems). MS analysis of each sample was performed using the ProteinChip Biology System Reader (Model PBS Ⅱ; Ciphergen Biosystems) at a laser intensity of 180 and a detector sensitivity of 7.

Data analysis

Data of every spectrum were collected and analyzed by ProteinChip Software version 3.0 (Ciphergen Biosystems) with integrated Biomarker Wizard software (Ciphergen Biosystems). In brief, baselines were subtracted and normalization was performed by total ion current normalization function, following the software instructions. Biomarker Wizard was then used to identify corresponding peaks in the spectra. Significant differences ($P < 0.05$) in peak intensity of particular proteins between two sample groups were calculated by the software using a Mann-Whitney non-parametrical test.

RESULTS

ERK activity in transfected cells

Western blot results showed that the phosphorylation level of ERK1/2 in WT-*cagA* transfectants was significantly higher than that in vector transfectants and untransfected AGS cells, after serum stimulation at all time points (Figure 1), which indicates that phosphorylated CagA can strongly enhance the phosphorylation level of ERK1/2 in host cells.

Profiling of cell lysates

Protein profiles of cell lysates from each group were obtained from SAX2 (strong anion exchange) and CM10 (weak cation exchange) ProteinChip Arrays. Each type of array surface retains different groups of proteins depending on the surface properties (SAX2 captures proteins with low pIs, while CM10 captures proteins with high pIs), therefore assuring that more host proteins are analyzed. MS analysis was carried out under a laser intensity of 180 and a detector sensitivity of 7.0, which brought out the highest resolution determined by previous experiments. Approximately 200 separate protein peaks with a signal to noise ratio > 5.0 and intensity > 1.0 were obtained in the mass range of 2000-20 000 m/z (mass/charge) in every spectrum, using either CM10 or SAX2 chips.

Biomarker proteins dependent on activation of ERK/MAPK signaling pathway detected by SELDI-TOF-MS

In our previous study[30], we transfected AGS cells with WT-*cagA*, phosphorylation site mutant *cagA*, and blank vector. Protein-expression profiles were analyzed using a SELDI-ProteinChip platform, in order to gain an insight into the effect of CagA and CagA phosphorylation on host protein expression. A total of 16 proteins in AGS cells were found have expression differences under the effect of CagA, and 12 of these were CagA phosphorylation dependent (Figure 2, Table 1). These biomarkers may contribute to the host response to CagA and may be involved in CagA-induced pathogenesis.

According to the previous results, most changes in expression after *cagA* transfection are related to CagA phosphorylation. Phosphorylated CagA can interfere with signal transduction of the ERK/MAPK pathway that plays an important role in CagA-induced cell proliferation and transformation. Various downstream molecules involved in the pathway need to be identified. Thus, our next question is which biomarkers among the 16 are caused by CagA-induced activation of the ERK/MAPK signaling pathway. The results may help us to focus on the most important proteins involved in the host response to CagA. After confirming by Western blotting that WT CagA can significantly increase the activation of ERK1/2, we treated AGS cells with MEK

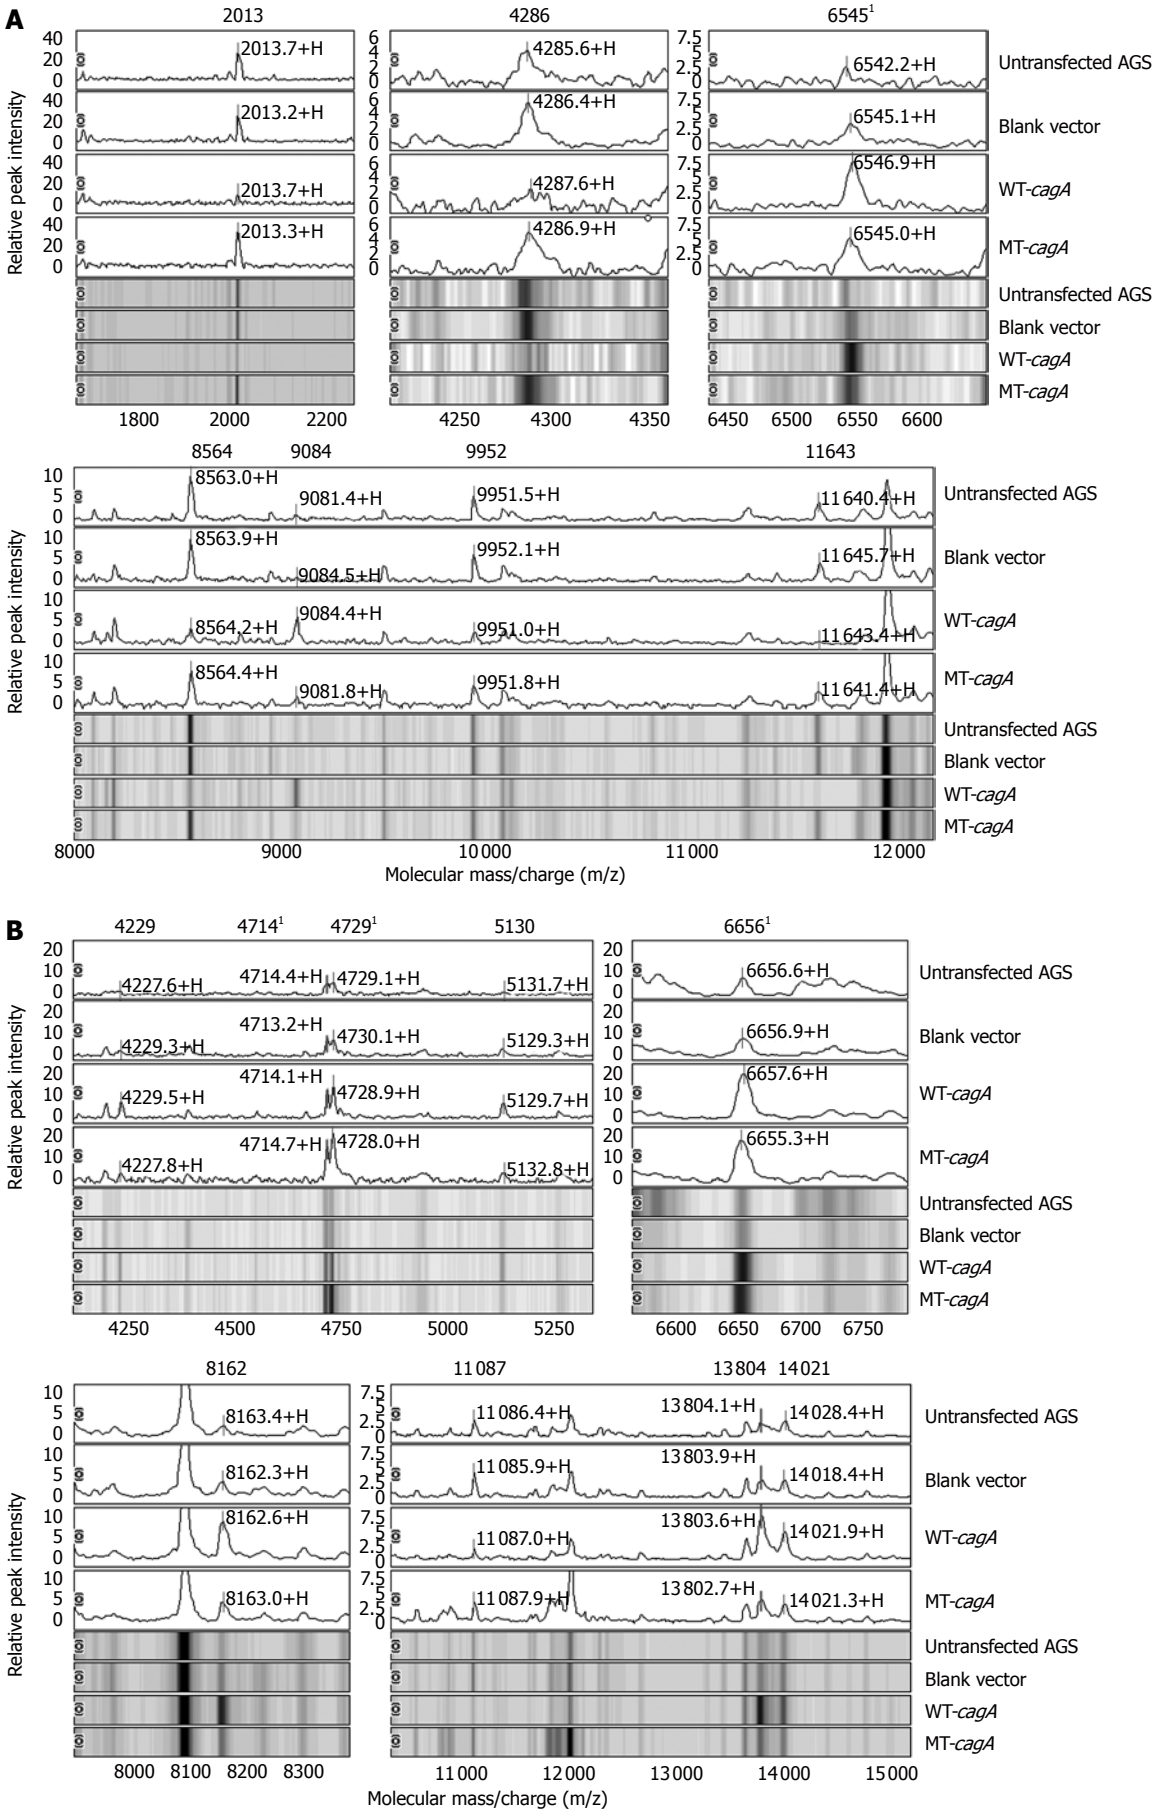

Figure 2 Biomarker proteins with different expression level in WT-*cagA*, phosphorylation site mutant *cagA* (MT-*cagA*) and blank-vector-transfected AGS cells detected by ProteinChip arrays. Cell lysates of each group were analyzed on SAX2 and CM10 Chip surfaces under laser intensity of 180 and sensitivity of 7. One representative spectrum was selected from a quadruplicate set of samples for each group. The top panel in each figure is the spectral view, and the lower panel is the gel view. Peaks with different expression level were marked with m/z values. **A**: Biomarkers detected by SAX2; **B**: Biomarkers detected by CM10. [1]Indicates CagA tyrosine-phosphorylation-independent proteins, which can be induced by both WT CagA and MT CagA (adopted from *Chinese J Cell Biology* 2006; 28: 603-610).

Table 1 Overview of biomarkers' expression level in the 2000-20000 m/z mass range in wild-type *cagA*, phosphorylation site mutant *cagA* and blank vector transfected AGS cells

Array type	m/z	Peak intensity (mean ± SD)			Fold change		Comments

	13804	2.97 ± 0.79	8.66 ± 0.48	4.14 ± 1.23	2.92[a]	1.39	
	14021	3.06 ± 0.24	5.59 ± 0.41	3.66 ± 1.04	1.83[a]	1.20	
SAX2	6545	3.08 ± 0.88	6.95 ± 1.34	5.53 ± 0.69	2.26[a]	1.80[a]	CagA phosphorylation independent
CM10	4714	10.16 ± 1.26	17.95 ± 3.61	17.31 ± 1.41	1.77[a]	1.70[a]	
	4729	11.11 ± 1.75	20.51 ± 4.02	21.92 ± 2.58	1.80[a]	1.97[a]	
	6656	9.67 ± 2.45	22.83 ± 4.27	21.46 ± 1.92	2.36[a]	2.22[a]	

Biomarkers were selected by these criteria: Statistical *P*-value among sample groups less than 0.05; signal to noise ratio higher than 5.0; peak intensity higher than 1.0. The particular fold change in average peak intensity of wild-type *cagA* transfectants (W) or phosphorylation site mutant *cagA* transfectants (M) was calculated compared with the intensity of blank vector transfectants (V). [a]$P < 0.05$. Statistical *P*-value was calculated with a non-parametrical Mann-Whitney test ($n = 4$).

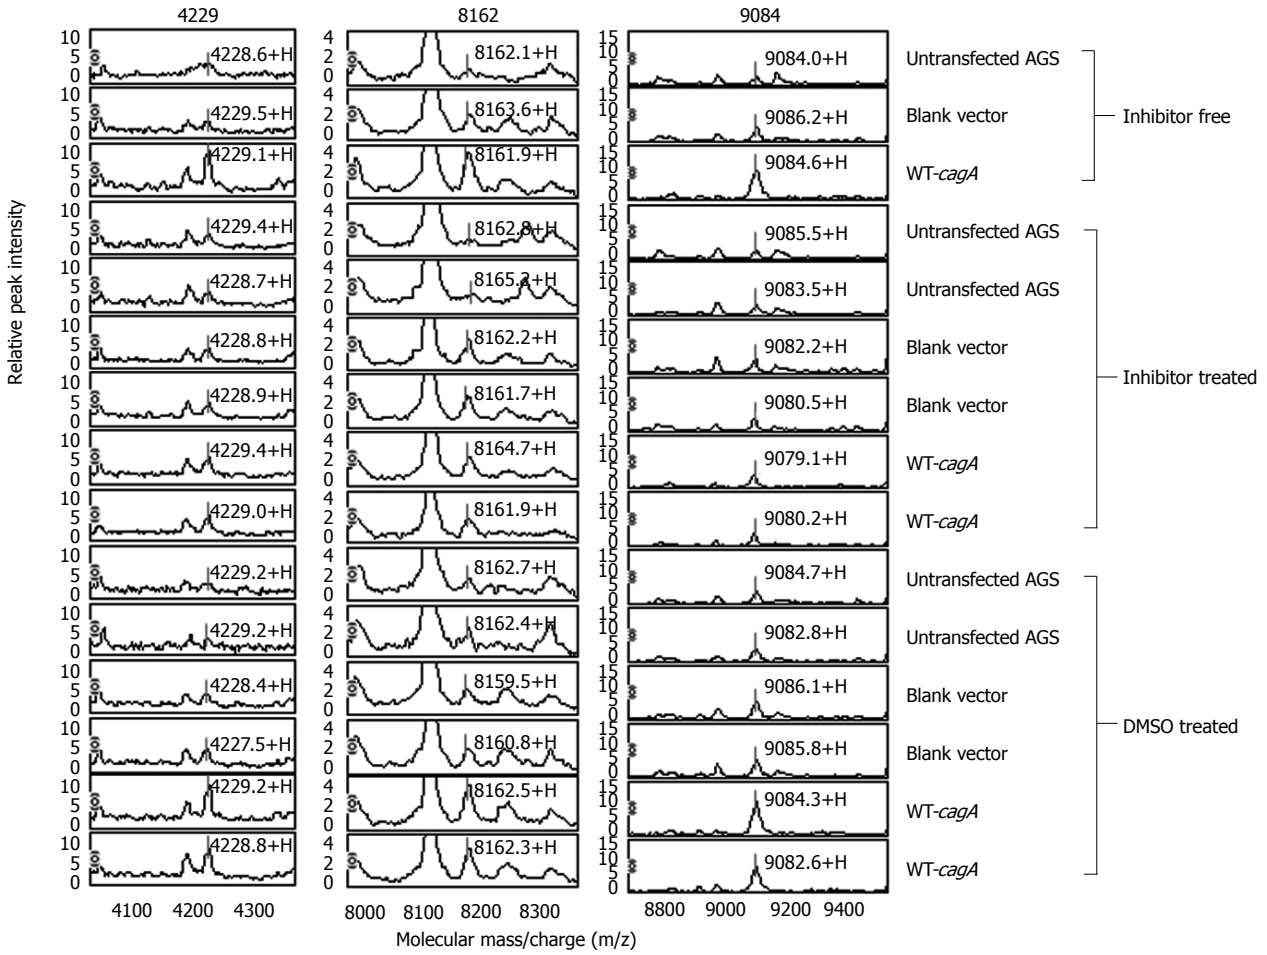

Figure 3 Expression differences of biomarker proteins caused by ERK pathway activation. Cells were transfected with WT-*cagA* or blank vectors with treatment of MEK inhibitor U0126, or its vehicle DMSO. Expression differences of three biomarkers with m/z 4229 (CM10), 8162 (CM10) and 9084 (SAX2) between WT-*cagA* transfectants and vector transfectants appeared under both MEK-inhibitor-free and DMSO-treated conditions, but disappeared under inhibitor-treated conditions.

inhibitor simultaneously to transfection to investigate if the changes in expression of the 16 biomarkers induced by WT-*cagA* disappeared when ERK1/2 was deactivated. The expression levels of three biomarkers with m/z 4229, 8162 and 9084 were found up-regulated significantly in WT-*cagA* transfectants with 2.25-, 1.71- and 1.64-fold changes

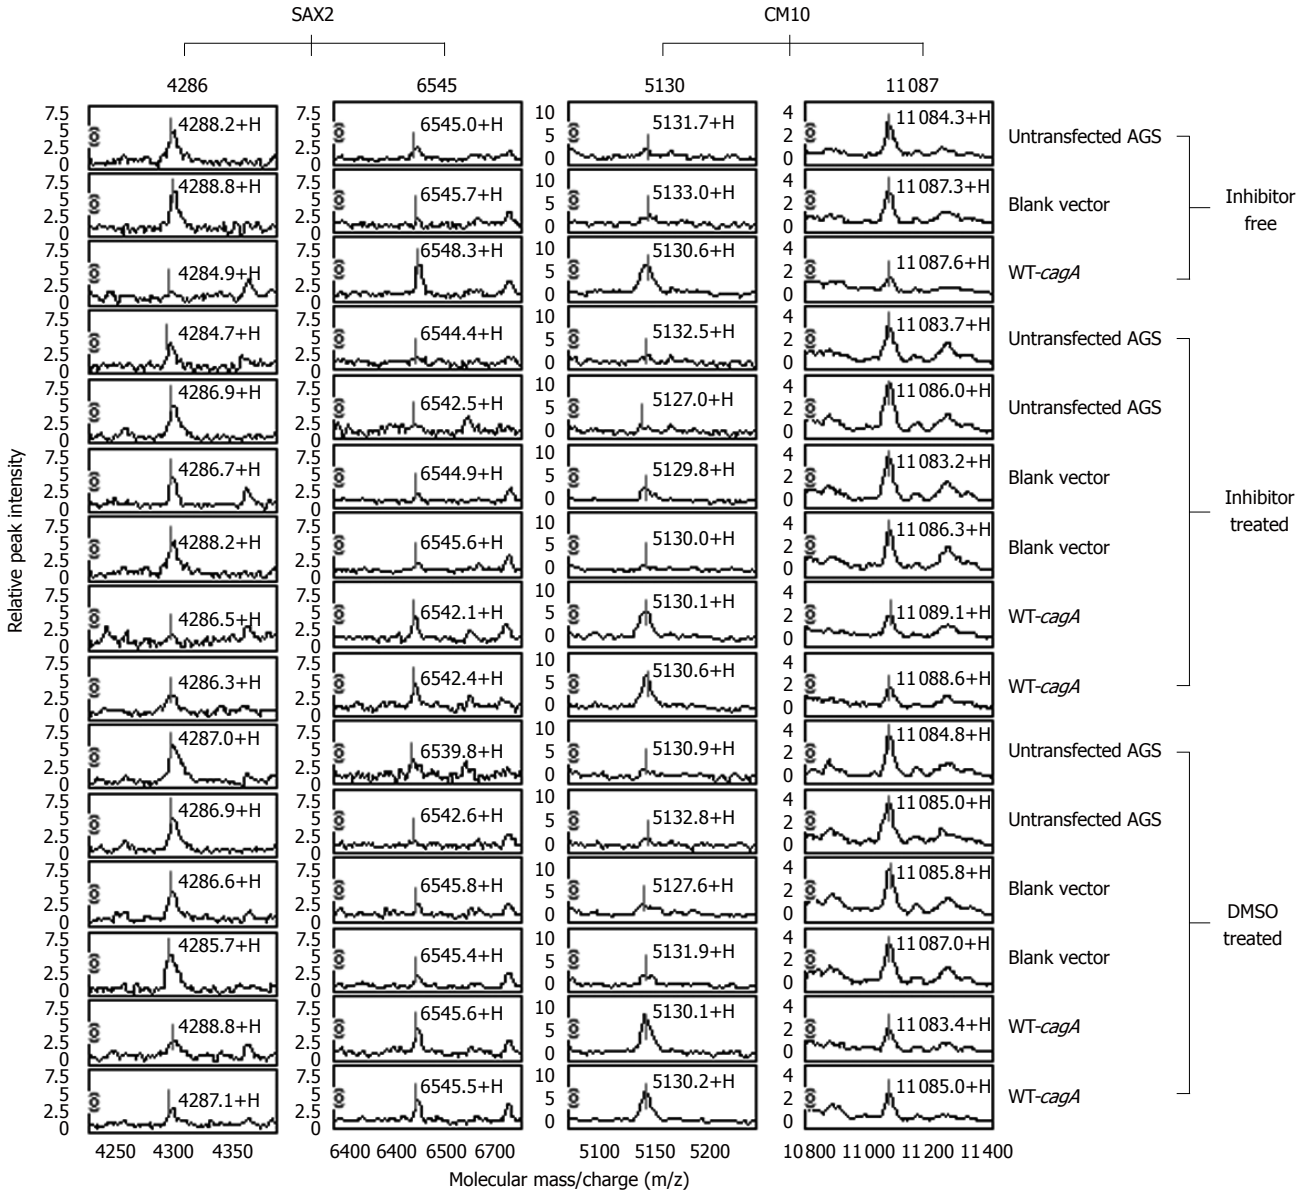

Figure 4 Expression differences of biomarker proteins not caused by ERK pathway activation. Expression differences of the other 13 biomarker proteins between WT-*cagA* transfectants and vector transfectants appeared not only under MEK-inhibitor-free and DMSO-treated conditions, but also under MEK-inhibitor-treated conditions. Spectra of typical biomarker proteins with m/z 4286 (SAX2), 6545 (SAX2), 5130 (CM10) and 11 087 (CM10) are shown in the figure.

compared with vector transfectants under inhibitor-free conditions (Figure 3, panels 1-3). The fold changes were very similar to those in our previous experiment (Figure 2, panels 1-3). In DMSO-treated conditions, they displayed the same expression pattern (Figure 3, panels 10-15) as under inhibitor-free conditions. However, when treated with MEK inhibitor during transfection, the peak intensity of these three proteins in WT-*cagA* transfectants was found not to be significantly different ($P > 0.05$) from that of vector transfectants (Figure 3, panels 4-9). This indicates that the expression differences of biomarkers with m/z 4229, 8162 and 9084 were caused by activation of the ERK/MAPK signaling pathway. The expression differences for the other 13 proteins existed in both ERK1/2-active and -inactive conditions (Figure 4, Table 2). Thus, they were independent of ERK1/2 activation. The biomarkers with m/z 4229, 8162 and 9084 that were identified as ERK1/2 downstream molecules involved in CagA-induced pathogenesis are worthy of further investigation.

Database searching for the three ERK-related biomarkers

A search in the SwissProt/TrEMBL database using the TagIdent tool, along with the pI and mass information was performed to get matching proteins for the three biomarkers with m/z 9084, 4229 and 8162. All together, 22 pieces of matching information were obtained from the database. Seven of these were shown to be proteins related to apoptosis, antimicrobial defense, chemotaxis, proliferation, differentiation and carcinogenesis, which may be closely associated with the ERK/MAPK signaling pathway (Table 3). The existence of these proteins was validated at the protein or transcript level in a series of studies. The other 14 were predicted to be proteins or proteins lacking the references providing insightful

Biomarkers listed in top three lanes were identified as biomarkers induced by extracellular signal-regulated kinase 1/2 (ERK1/2) activation. Columns 3, 5, 7 give fold changes in peak intensity in wild-type cagA transfectants (W) compared with vector transfectants (V) as reference under MEK inhibitor U0126 free, MEK inhibitor U0126 treated (I) and DMSO treated (D) conditions. Statistical *P*-value were calculated using a non-parametrical Mann-Whitney test (n = 4).

Table 3 Swiss-Prot and TrEMBL database searching results of the three ERK related biomarkers

Biomarker (Mw)	Meaningful matching information in Swiss-Prot and TrEMBL database			Comments
	Protein Name	Mw	pI	
9084 (SAX2)	BIM-alpha3 (BCL2-like 11 transcript variant 10, chain 1-79)	9081	5.42	Over-expression of BIM-alpha3 results in cell apoptosis
	EP2E (chain 1-80)	9091	7.55	Part of the protein sequences homologous to β-defensins, a family of antimicrobial peptides.
	UPF0197 protein (C11orf10 chain 1-79)	9079	5.58	Expressed in CD34+ hematopoietic stem/progenitor cells
4229 (CM10)	Chromogranin-A Precursor (ER-37, chain 420-456)	4233	4.59	Neuroendocrine and endocrine secretory granules, considered as biomarkers in some human cancers
8162 (CM10)	Small-inducible cytokine B6 Precursor (chain 40-114)	8162	9.74	Functional characterization as chemokines, chemotactic for neutrophil granulocytes
	Putative microRNA host gene protein 1 (chain 1-70)	8163	9.25	Highly expressed in B-cell lymphoma and lung cancer and enhanced cell proliferation
	PNAS-145 (Chain: 1-68)	8161	11.24	Human acute promyelocytic leukemia cell line NB4's apoptosis/differentiation related genes

Searching was carried out using TagIdent tool with mass and the pI information (0-9.0 for SAX2, 4.0-14.0 for CM10).

functional information. Therefore, the three biomarkers with m/z 9084, 4229 and 8162 have great potential to be identified as cancer-associated proteins in future research.

DISCUSSION

Translocation of CagA protein into gastric epithelial cells through the type Ⅳ secretion system is considered to be one of the most important processes in the progression of *H pylori* diseases. In this host-bacterial interaction period, many host proteins and signaling pathways are implicated[33]. In order to gain an overall view into the host response to CagA, the innovative proteomic technology SELDI-ProteinChip platform was employed to investigate the expression changes in gastric epithelial AGS cells. The strongpoint of this technology is that it can detect proteins in fmol quantities, and it allows fast, high-throughput analysis, especially in the low-molecular-weight range, which is essential for biomedical research, and cannot be easily achieved by conventional methods. Following this method, 16 biomarkers have been identified in our previous study as being involved in CagA-host cell interactions, and 12 of these are dependent on CagA phosphorylation. This result provides a primary view of CagA-induced pathological changes at the protein level.

To further investigate the role of CagA-phosphorylation-associated functions in gastric carcinogenesis, we focused our interest on the role of the ERK signaling pathway. It has been verified by clinical pathological tests that the level of phosphorylated ERK in gastric cancer tissue is higher than that in the gastric mucous membrane. The level is also higher in cancer tissue of *H pylori*-positive gastric cancer patients than that in *H pylori*-negative patients[34]. Besides, it has been reported that *cagA*-positive *H pylori* is more powerful than *cagA*-negative strains for ERK activation[35]. Thus, ERK/MAPK pathway activation and subsequent cell proliferation, differentiation, as well as morphological changes, are among the most important pathogenic factors

in CagA-induced diseases. However, this complicated process includes multi-level regulation that has rarely been understood. In the present study, we tried to investigate if the expression changes of the 16 host proteins induced by CagA have some relationship with the activation of the ERK pathway. The phosphorylation level of ERK1/2 in WT-*cagA* transfectants was confirmed to be much higher than that in vector transfectants and blank control cells. MEK inhibitor U0126 that specifically inhibits ERK1/2 phosphorylation was employed to eliminate the changes induced by ERK activation during the transfection of WT-*cagA*. The relationship of the 16 biomarkers and ERK pathway can be determined by comparing their expression levels under ERK-inhibited and ERK-activated conditions. On the other hand, protein profiles indicated that protein expression levels were influenced by DMSO as the solvent of U0126. Therefore, we first compared profiles of WT-*cagA* transfectants and vector transfectants under U0126-free conditions, U0126 treatment, and DMSO treatment. Only the proteins exhibited similar expression differences between WT-*cagA* transfectants and vector transfectants under both U0126 free and DMSO treated conditions, but they exhibited no expression differences under the U0126 treated condition, and thus were considered to be biomarkers that related to ERK activation. In this manner, among the 16 biomarkers, three with m/z 4229, 8162 and 9084 were identified as ERK pathway downstream proteins related to CagA pathogenesis. These three biomarkers will be characterized in our future research.

Most biomarkers discovered so far are peptides or small proteins with low abundance. They are probably metabolic products, abnormally cleaved proteins, modified proteins, neurokinins or cytokines that exist in disease states. The biomarkers detected in our study are also likely small molecules of this kind, which can hardly be detected by traditional methods, but are essential for associated research. While the SELDI-ProteinChip platform is very rapid for protein profiling, it does not allow direct purification and functional identification. A search in the SwissProt/TrEMBL database using the TagIdent tool with pI and mass information was performed to obtain matched information for each biomarker. The search results suggested that these three biomarkers are probably peptides of the following type: β-defensin homologs, which might be involved in host defense to bacterial infection; BCL2-like protein, which might function as an apoptosis inhibitory protein; chemokines; and tumor-related proteins, which might be responsible for cell proliferation and differentiation induced by ERK/MAPK pathway activation, and contribute to CagA-induced carcinogenesis in the gastric epithelium. The matching information provides helpful references for obtaining corresponding antibody which will be employed in future biomarker identification. The biochemical properties provided by the selective ProteinChip surfaces and SELDI-TOF-MS for each biomarker are also useful for the purification process. Further purification and identification will elucidate the function of related small molecules in CagA pathogenesis, and may therefore discover new therapeutic targets.

COMMENTS

Background

H pylori infection is an important causative factor of gastritis, peptic ulcer and gastric cancer. CagA, the major virulence factor of type I *H pylori*, is injected by the bacterium into gastric epithelial cells, and has been shown by epidemiological and experimental studies to be closely associated with the development of *H pylori*-induced diseases, especially gastric cancer. However, the precise role of CagA in cell function after *H pylori* infection remains unclear.

Research frontiers

CagA is translocated into host cells through a type Ⅳ secretion system of *H pylori*. After tyrosine phosphorylation at the C terminus, CagA strongly interferes with signal transduction, which results in cell proliferation and differentiation. Various studies have indicated a relationship between CagA, ERK/MAPK pathway activation and gastric cancer. In this study, a proteomic approach was employed to detect host cell proteins related to CagA-induced ERK pathway activation.

Innovations and breakthroughs

A new proteomic approach based on ProteinChip array and SELDI-TOF-MS was employed to investigate the global protein expression changes in gastric epithelial cells induced by CagA. Three biomarkers were further identified as downstream molecules of ERK1/2 in the ERK/MAPK signaling pathway. Due to the high sensitivity and resolution in the low-molecular-weight range of SELDI-ProteinChip technology, biomarkers discovered in this study are mainly low-mass and/or low-abundance disease-related proteins, which are difficult to detect by traditional methods.

Applications

These results provide new targets for further understanding the biological function and pathogenesis of CagA, as well as new therapeutic targets.

Terminology

CagA: cytotoxin-associated gene A protein encoded by cytotoxin-associated gene pathogenicity island is the major virulence factor of type I *H pylori*. ERK: extracellular signal-regulated kinase. ERK pathway is one of the major three members of the MAPK signaling pathways. ERK has been reported as a key molecule in carcinogenesis in various cell types. ProteinChip array: the surface of array selectively retains proteins from biological samples according to their biochemical properties, and can be analyzed directly by MS. SELDI-TOF-MS: surface-enhanced laser desorption/ionization time-of-flight MS detects proteins in fmol quantities, and allows fast, high-throughput analysis, especially in the low-molecular-weight range.

Peer review

This is a state-of-the-art, well-written paper that has used a proteomic approach to understand CagA protein biology as it relates to gastric cancer.

Abstract

AIM: To investigate the role of artificial neural networks in predicting the presence of thyroid disease in atrophic body gastritis patients.

METHODS: A dataset of 29 input variables of 253 atrophic body gastritis patients was applied to artificial neural networks (ANNs) using a data optimisation procedure (standard ANNs, T&T-IS protocol, TWIST protocol). The target variable was the presence of thyroid disease.

RESULTS: Standard ANNs obtained a mean accuracy of 64.4% with a sensitivity of 69% and a specificity of 59.8% in recognizing atrophic body gastritis patients with thyroid disease. The optimization procedures (T&T-IS and TWIST protocol) improved the performance of the recognition task yielding a mean accuracy, sensitivity and specificity of 74.7% and 75.8%, 78.8% and 81.8%, and 70.5% and 69.9%, respectively. The increase of sensitivity of the TWIST protocol was statistically significant compared to T&T-IS.

CONCLUSION: This study suggests that artificial neural networks may be taken into consideration as a potential clinical decision-support tool for identifying ABG patients at risk for harbouring an unknown thyroid disease and thus requiring diagnostic work-up of their thyroid status.

INTRODUCTION

Atrophic body gastritis (ABG) is characterized by loss of the oxyntic glands and lack of production of chlorhydric acid and intrinsic factor[1], and is epidemiologically and biologically linked to the development of the intestinal-type gastric adenocarcinoma and gastric carcinoid type I [2]. ABG often presents clinically with pernicious anaemia (PA)[3], but may present also with iron deficiency anaemia and/or long-standing dyspepsia[4,5].

The association of ABG with thyroid disorders (TD) has firstly been described about 40 years ago[7-9], and the term "thyrogastric disease" has been used to define the presence of thyroid autoantibodies and/or autoimmune thyroid disease in patients with PA[8,10-12]. These older studies assessed the association between PA and thyroiditis on the basis of gastric and/or thyroid autoantibodies, and found an association ranging from 2.6%-32%[9-12].

Undiagnosed TD may lead to complications related to subclinical hypo- or hyperthyroidism, which may be prevented by an early diagnosis of TD[13]. The diagnosis of TD is generally based on clinical history, assessment of thyroid hormones and autoantibodies as well as ultrasonographic evaluation of the thyroid gland[14]. Albeit, these procedures are non-invasive, a complete diagnostic work-up of TD is time- and cost-consuming. Thus, reliable tools able to select those ABG patients at high risk for harbouring an undiagnosed TD may be useful.

Decision-support systems, based on conventional statistical methods made their entry into medicine several years ago[15], and efforts to improve predictive and prognostic performance of these systems have led to the application of artificial neural networks (ANN) as tools for clinical decision-making[16-18]. ANN are highly flexible

computerized mathematical models for understanding and predicting complex and chaotic dynamics in complex biological systems, and have been effectively used to solve non-linear problems related to diagnostic or prognostic queries[16,19]. Thus, ANN would appear to be a promising tool for clinical decision-making and have been applied in various areas of medical research[20-22]. In particular, this tool has been previously applied with a high accuracy for predicting atrophic body gastritis on the basis of clinical and serological parameters in patients with anaemia and/or dyspepsia[23]. To our knowledge, studies applying advanced statistical methods in patients with ABG and TD have not yet been performed. This study, therefore, aimed to investigate the role of ANN and linear discriminate analyses (LDA) in predicting the presence of TD in ABG patients.

MATERIALS AND METHODS

Patients

This study was carried out using a database comprising data from 253 ABG patients (185 females, median age 54 [17-83] years). Of these ABG patients, 123 (48.6%) had pernicious anaemia. In all patients, the presence or absence of TD was evaluated by biochemistry, ultrasonography and endocrinological evaluation at a single tertiary centre. TD was present in 135 (53.4%), and 118 (46.6%) had a healthy thyroid gland. In detail, of the 135 ABG patients with TD, 102 (75.6%) had an autoimmune TD and the remaining 33 (24.4%) had non-autoimmune thyroid disorders, such as a multinodular goitre (n = 16) or a previously diagnosed subacute thyroiditis (n = 10). In addition, 7 patients had undergone complete thyroidectomy prior to the diagnosis of ABG: 3 for thyroid cancer, 3 for large multinodular goitre and 1 for autoimmune thyroiditis.

For each of these 253 patients at the time of diagnosis of ABG, a structured questionnaire was filled out, composed of 29 items concerning anagraphical, life style, family and clinical history, biochemical and histological variables.

Criteria for the diagnosis of ABG: The diagnosis of ABG was based on the presence of fasting gastrin above upper normal values, and histological confirmation of gastric body mucosal atrophy, as previously described[24, 25]. Briefly, all patients underwent gastroscopy with standardized biopsy sampling from the antrum (n = 3), body (n = 3) for conventional histopathological examination[24,25]. The degree of gastritis was assessed according to the updated Sydney System[26]. Atrophy of the body and antral mucosa was defined as focal or complete replacement of oxyntic or pyloric glands by metaplastic pyloric or intestinal glands, respectively[24,25]. Furthermore, all patients underwent serological studies: fasting gastrin levels were evaluated by means of a specific radioimmunoassay (RIA) using polyclonal antibody No. 4562[24,25]. Pepsinogen I levels were measured using a commercial RIA kit (Pepsik, Sorin, Saluggia, Italy)[25]. Antibodies against anti-parietal cells were assayed using a commercial kit (Autostat, Cogent Diagnostic Ltd, Edinburgh, UK)[24,25].

Criteria for diagnosis of thyroid disease: The thyroid status of ABG patients was evaluated on the basis of clinical history, biochemical and ultrasonographic evaluation. Thyroid hormones and thyroid autoantibodies in serum were determined by commercial kits: free triiodothyronine and free thyroxin levels were assayed by radioimmunoassay (Ares-Serono, Milan, Italy); basal thyrotropin levels were assayed by immunoradiometric assay (Radim Techland, Liege, Belgium); antiperoxidase antibodies were measured by a radioligand assay (Radim Techland, Liege, Belgium)[27]. Thyroid gland size, echogenicity of the parenchyma, and nodular lesions were evaluated by ultrasonographic examination. The diagnosis of autoimmune thyroiditis was based on the presence of antiperoxidase antibodies (antibody titres stably > 200 U/mL in at least two separate measurements performed at least 6 mo apart) and characteristic ultrasound features (i.e. non-homogeneous pattern with diffuse reduction of echogenicity) according to Rago *et al*[14] in presence, but even in absence of mild or overt hypothyroidism[28]. Non-autoimmune thyroid disease (NATD) was assessed on the basis of the presence of ultrasonographic thyroid abnormalities (increased thyroid volume > 25 mL, with the presence of one or more nodules) and the definite absence of antiperoxidase antibodies. Only patients with definite normal morphofunctional and immunological parameters were assumed to have a healthy thyroid gland.

All patients gave written informed consent to the study, which was approved by the local Ethics Committee.

Study design and statistical evaluation

As shown in Table 1, the study was performed on the dataset of 29 input variables of the 253 ABG patients, of which five were continuous, whereas the remaining were dichotomous, as previously described[23]. Biochemical and ultrasonographic data on the diagnosis of TD were not included in the data set. The presence or absence of TD was considered as target variable.

Artificial neural networks (ANN): As shown in Figure 1, the sample of ABG patients was randomly subdivided several times into two equal and balanced sub-samples of subjects with and without TD; one for the training phase (testing) and one for the prediction phase (training). During the training phase, a fixed ANN model is chosen and submitted to the training sub-set in order to learn the linear and non-linear relations existing between all the variables of the original data set and between the input variables and the target variables, performing, in this way, a classification task, i.e., the correct recognition of ABG patients with and without TD. At the end of the training phase, the ANN models showing the best performance on the classification task were submitted to the second sub-sample of patients (the testing set), not previously exposed to the networks, in order to ensure an unbiased evaluation of the classification capability of the ANN. During the so-called "testing phase", the target variable (presence/absence of TD) has been excluded and the networks made its own evaluation, based on the previously carried out training. In the cross validation protocol, the pairs of sub-set are inverted during the elaboration procedure: each sub-set is used once for the

training and once for the testing, this allowing to obtain a non-polarised classification tool.

In order to reduce the number of input variables, selecting those most informative to predict the output, the T&T system, the IS system, as well as the TWIST protocol were used (Table 1). The first system has been developed to solve the problem of establishing the size and assessing the quality of the training and testing sets for a more effective data processing through the ANN models. T&T is a data resampling technique, based on an evolutionary algorithm developed by the Semeion Research Center, the Genetic Doping Algorithm (GenD), able to split the source sample into two or more sub-samples, each one with a similar probability density function. The IS system is an evolutionary wrapper system, also based on the evolutionary algorithm GenD, able to reduce the amount of data, while conserving the largest amount of information available in the dataset. In the TWIST protocol, the T&T and IS systems run in a parallel way to reach a suitable representation of variables and the optimal sample size when dealing with complex and non-linear problems[9]. The software used for the ANN analysis has been developed and were applied by the Semeion Research Center, Rome, Italy.

Linear discriminant analyses (LDA): As shown in Figure 1, the same database was analyzed applying a statistical model based on the assumption of linear correlations between variables, the LDA. In order to optimize the predictive ability, different models were assessed and, as for the ANN procedure, the samples were randomly divided into several sub-samples for the training and testing phases. For the analysis of LDA, the SAS version 6.04 (SAS Institute, Cary, NC, USA) using stepwise procedure was employed. This was performed by the Semeion Research Center, Rome, Italy.

RESULTS

LDA and standard ANN

As shown in Table 2, the predictive performance of LDA in discriminating ABG patients with and without TD reached a mean accuracy of 59%, predicting correctly 61% of the ABG patients with TD (sensitivity) and 58% patients with a healthy thyroid gland (specificity). In this model, 82 out of the 135 ABG patients with TD and 69 of the 118 ABG patients without TD were correctly identified. In contrast, the standard ANN model, which used all the 29 input variables, recognized correctly 93 ABG patients with TD and 70 without TD, yielding a mean accuracy, a sensitivity and a specificity of 64%, 69%, and 60%, respectively. Thus, as far as regards the specificity, the predictive performance of LDA and standard ANN were similar, because LDA missed 49 patients and standard

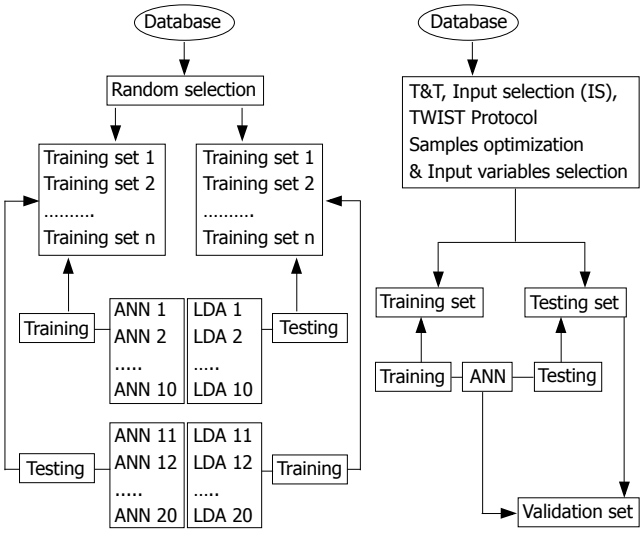

Figure 1 Application protocols of artificial neural networks and linear discriminant analyses.

ANN 48 (P = 1.00). As far as concerns the sensitivity, i.e. the performance in predicting ABG patients with TD, also in this case, the predictive ability of the standard ANN model was similar to that of LDA with 53 and 42 misclassified patients, respectively (P = 0.20).

Data optimization by T&T and IS systems

In a first step of input data optimization, the sequential application of the T&T and IS systems selected as the most informative 24 of the original 29 independent variables (Table 1). The ANN run with these 24 input variables made less classification errors and thus improved the predictive performance compared to the previous ANN performed on all 29 variables, matching correctly 106 ABG patients with TD and 83 without TD and thus yielding a mean predictive accuracy, a sensitivity and a specificity of 75%, 78%, and 70%, respectively (Table 2).

This ANN model with 24 variables misclassified 35 ABG patients without TD, but the statistical significance with respect to LDA and standard ANN was not reached. In contrast, the predictive performance in identifying correctly ABG patients with TD improved significantly by using the optimized ANN model with 24 variables ($P < 0.01$) with respect to LDA, reducing the misclassified ABG patients from 49 (LDA) to 29 (ANN 24 variables).

Data optimization by TWIST protocol

Finally, the application of the TWIST protocol selected as the most informative 16 of the original 29 variables (Table 1). This ANN model reached a better predictive performance compared to the other ANN models, correctly recognizing 82% of the ABG patients with associated TD and 70% of the ABG patients with a healthy thyroid gland; in this case the mean predictive accuracy was 76%, thus outperforming the previous ANN models as well as the traditional linear models in the recognition task. Indeed, the predictive performance in identifying correctly ABG patients with TD improved significantly by using the optimized ANN model with 16 variables ($P < 0.001$) with respect to LDA, reducing the misclassified ABG patients from 49 (LDA) to 25 (ANN 16 variables). On the other hand, with respect to standard ANN, the predictive performance of the optimized ANN model with 16 variables was improved (P = 0.02).

Table 2 Predictive performance of linear discriminant analyses (LDA) and artificial neural networks (ANN) in recognizing atrophic body gastritis patients with and without thyroid disease (%)

	Sensitivity	Specificity	Mean accuracy
LDA	60.8	58.1	59.4
Standard ANN (29 variables)	69.0	59.8	64.4
T&T and IS (24 variables)	78.8[b]	70.5	74.7
TWIST protocol (16 variables)	81.8[d]	69.9	75.8

[b]$P < 0.01$ *vs* LDA; [d]$P < 0.001$ *vs* LDA and *vs* standard ANN $P < 0.05$.

DISCUSSION

The results emerging from this study suggest that artificial neural networks are able to predict, with a good accuracy, the presence of TD in ABG patients, by using clinical and gastric biochemical and histological variables. Indeed, the optimised ANN yielded an accuracy of 76%, correctly identifying 82% of ABG patients with TD.

Indeed, the association between ABG and TD is strong, because, as confirmed by the findings of this study, more than half of patients with ABG have an associated TD. Previous studies found an important association up to 30% between pernicious anaemia and TD on the basis of gastric and/or thyroid autoantibodies[30,31] and a more recent report assessed the coexistence of ABG and TD on more updated diagnostic criteria[27]. Undiagnosed TD may lead to complications related to subclinical hypo- or hyperthyroidism, which may be prevented by an early diagnosis of TD[13]. Albeit, the diagnostic procedures are generally non-invasive[14] and thus easily accepted by the patients, a complete diagnostic work-up of TD is time and cost consuming. Thus, a computer-based decision-support system, able to select, with an acceptable predictive accuracy, those patients with a high probability of having TD, would enable the thyroid investigations to be better addressed.

Generally, the real databases are composed by a large number of variables that, only apparently, provide the largest possible amount of information. In fact, data collection is performed by trying to include in the database all variables that can have a connection with the problem under investigation; but some of these variables may contain redundant information, which is included also in other variables, or confused information (noise), or may not even contain any significant information at all and be completely irrelevant. If inserted into the dataset, these variables can cause a greater difficulty for the ANN to learn data correctly. Indeed, in this study complex "intelligent" data optimization procedures based on evolutionary algorithms were applied, which permitted to reduce the amount of data, while conserving the largest amount of information available in the dataset, to reach a suitable representation of variables and the

optimal sample size when dealing with complex and non-linear problems[29]. This approach, in fact, increased the predictive accuracy as well as the specificity and the sensitivity compared to models performed on non-optimized datasets. Indeed, the reduction in the number of input variables from the initial 29 to 16 led to an increase of the accuracy and the sensitivity of ANN from 64% to 76% and from 69% to 82%, respectively.

It is worthwhile to mention that among the most informative variables for the prediction of TD in ABG patients, Pepsinogen I , parietal cell antibodies, female gender and the type of anaemia were included. This finding is not surprising, because all these features have been reported to be related to ABG[2,13,25]. Among variables with the highest predictive power for the presence of TD in ABG patients, the data optimization procedures selected also the presence of active *H pylori* infection and the positive clinical history for peptic ulcer, which is also related to *H pylori* infection. This finding is quite interesting, since some authors suggest that the coexistence of ABG and TD may be attributable to common organ-specific antigens that occur as a result of these organs sharing common embryonic origin[32]. However, in general, the presence of a statistical relationship between a predictor variable and the outcome alone does not imply causality[33]. This is even more the case for ANNs-based models, which process data in a non-linear way, and the network logic of prediction cannot be broken down into simple elements of clinical reasoning[34,35]. Thus, the variables with the most predictive power selected by the advanced statistical systems should not be viewed as independent predictive variables as perceived by a clinician[33,34].

We are aware that the current study had some limits. For the clinical applicability of computer-based decision support systems and their acceptance by physicians, it is necessary to offer a system which is simple, with entry of data that requires little time, thus using a limited number of variables which are readily available to the clinician. In our final optimized ANN model, 16 input variables were selected as most informative for optimizing the prediction of ABG patients with TD. This large amount of input data may thus be a limit for an eventual clinical applicability of this system since the collection of many input variables may be considered time-consuming and scarcely attractive as a clinical decision tool. In any case, this study did not want to emphasize that advanced statistical decision support systems should replace or substitute experienced clinicians, but to underline that, these systems should be viewed as a potential decision aid in order to better address investigations to save costs and to use resources when effectively necessary, as described in other fields of medical settings[36] .

Moreover, we are aware that external validation has not yet been carried out and that, at this stage, the utility and cost benefit of artificial neural networks in recognizing thyroid disease in ABG, as opposed for example to performing thyroid hormones and thyroid autoantibodies and/or thyroid ultrasonographic evaluation, needs to be determined.

In conclusion, this study suggests that artificial neural networks may be taken into consideration as a potential clinical decision-support tool for identifying those ABG patients at risk for harbouring unknown TD and thus requiring diagnostic work-up of their thyroid status.

COMMENTS

Background

Atrophic body gastritis (ABG) is characterized by loss of the oxyntic glands and lack of production of chlorhydric acid and intrinsic factor. The association of ABG with thyroid disorders (TD) has firstly been described about 40 years ago, and the term "thyrogastric disease" has been used to define the presence of thyroid autoantibodies and/or autoimmune thyroid disease in patients with ABG, for these reasons thyroid evaluation should be considered in these patients.

Research frontiers

Decision-support systems, based on conventional statistical methods made their entry into medicine several years ago, and efforts to improve predictive and prognostic performance of these systems have led to the application of artificial neural networks (ANN) as tools for clinical decision-making. In particular, this tool has been previously applied with a high accuracy for predicting atrophic body gastritis on the basis of clinical and serological parameters in patients with anaemia and/or dyspepsia.

Innovations

In this article, artificial neural networks are used to investigate their ability in predicting the presence of TD in ABG patients and to evaluate their usefulness in selecting atrophic body gastritis at high risk for harbouring an undiagnosed thyroid disease.

Application

This article suggests that artificial neural networks are able to predict, with a good accuracy the presence of TD in ABG patients, by using clinical, and gastric biochemical and histological variables. Indeed, the optimised ANN yielded an accuracy of 76%, correctly identifying 82% of ABG patients with TD.

Peer review

The paper seems innovative since, to our knowledge, studies applying advanced statistical methods in patients with ABG and TD have not yet been performed and the obtained results clearly indicated the potential use of this tool in ABG patients at risk for harbouring an unknown thyroid disease and thus requiring diagnostic work-up of their thyroid status.

Abstract

AIM: To evaluate the yield of brushing biliary strictures and the factors associated with a positive result in biliary strictures.

METHODS: Data on all consecutive patients (01/02 -10/05) who were identified to have a biliary stricture and who underwent biliary brush cytology were collected. The yield of positive biliary brush cytology was evaluated and compared to results with the gold standard for diagnosis (defined as either definitive surgical histology or clinical course). Additionally, associated factors of positive results including stricture location, gender, age, mass size, length of stricture, and dilatation prior to brushing cytology were assessed.

RESULTS: From 199 patients who had brushing cytology samples (10 patients were excluded due to lack of gold standard diagnosis), 77 patients had positive brushing cytology (yield 41%). Variables associated with positive cytology brushing on initial endoscopic retrograde cholangiography were age 1.02 (1.00-1.05), mass size > 1 cm 2.22 (1.01-4.89) and length of stricture > 1 cm 3.49 (1.18-10.2). The sensitivity of biliary brushing was 61%, its specificity 98%, the positive predictive value reached 99%, and the negative predictive value was 57%.

CONCLUSION: Our results revealed a 41% positive yield from brushing cytology. The sensitivity of biliary brushing cytology in our center was 61% and the specificity was 98%. Predictors of positive yield include older age, mass size > 1 cm, and stricture length of > 1 cm.

INTRODUCTION

Biliary duct strictures are most often caused by neoplastic or inflammatory processes involving the biliary tree, pancreas, gallbladder, or ampulla. The use of endobiliary brush cytology to definitively diagnose malignant biliary strictures has been shown to be useful during endoscopic retrograde cholangiography (ERC). However, the diagnostic yield of this technique remains low, ranging from 30% to 80%[1-14] depending on the literature reviewed. Conservative management with biliary drainage is used in many patients with malignant tumors, most of whom are not candidates for curative resection due to locally advanced or metastatic disease. In such patients, an accurate tissue diagnosis may help in developing a concept for further management[3,4,15,16].

Cytological techniques have become the initial diagnostic modality in many cases since biliary lesions are not always readily accessible to biopsy[4,6,7,17]. Percutaneous radiologically guided fine needle aspiration (FNA), although a very accurate technique, is operator dependent and requires a sufficiently distinct mass lesion for targeting. Additionally, in patients who are surgical candidates 'seeding' of the needle tract has been a concern. Brush cytology performed at ERC, in contrast, has a low complication rate and allows sampling from most sites within the biliary duct systems[4,6,7,17].

The objective of this study was to assess the accuracy of brush cytology in biliary strictures and to assess the factors influencing results over a 3.7 years period from January 2002 to September 2005.

MATERIALS AND METHODS

From a total of 2500 endoscopic retrograde cholangiopancreatography performed between January 2002 and September 2005 at our center (St. Paul's Hospital, Vancouver), all biliary brush cytology findings were reviewed. This hospital serves as a tertiary referral center for the management of biliary diseases, and clinicians obtained follow up on all their patients. Two

hundred and ninety nine specimens were received, from one hundred and ninety nine patients in the review period. For inclusion in the study, patients had to have a definite final benign or malignant diagnosis based either on histological or cytological sampling or by clinical outcome. The latter was obtained by case record review. A total of ten patients (3.3%) were excluded from performance characteristics of endoscopic retrograde cholangiopancreatography (ERCP) brush cytology due to lack of gold standard for diagnosis.

Ethics approval for the chart review was performed through St. Paul's Hospital, University of British Columbia, Vancouver, Canada.

The specimens were obtained at ERCP with a Cytomax2, single use, 8 french, 2.5 cm long double lumen Wilson-Cook cytology brush (#4900 Benthania, Station Road, Winston-Salem, NC 27105). Fluoroscopic guidance ensured that the brush was within the stricture. Between ten and fifteen "in and out" passes with the brush was routinely used to ensure an adequate sample, and then the entire brush excised into formalin or saline and sent to the laboratory. Routine cytospin preparations were prepared and stained according to Papanicolaou's method. Samples were classified cytologically as follows: Class 1: Benign; Class 2: Reactive; Class 3: Suspicious for malignancy; Class 4: Cells with cancer morphology recommend biopsy (likely malignant but rarely can be reactive); Class 5: Malignant (equal to tissue diagnosis).

In our study definitively positive biliary brush cytology is defined as class 3 or higher.

Biliary duct stricture location was classified according to one thirds of total biliary duct length and was analyzed *via* two methods (apriori decided), once combining middle and lower common duct and once dividing the duct system to three equal parts. Other factors evaluated include length of stricture, mass size in CT scan/ultrasound, stricture dilation before brushing, age, and gender.

Statistical analysis

Descriptive statistical analysis with the calculation of means and standard deviations of the entire brushings cohort was carried out. Demographic variables were determined a priori as important factors in the outcome of the brushings. For categorical variables, a reference value was selected with the calculated odds ratio relative to the selected reference. Once significant variables were identified by univariate logistic regression analysis, a multivariate logistic regression was carried out. Sensitivity and specificity were calculated based on the gold standard of either surgical resection or clinical follow-up. All statistical analyses were carried out using Stata 8.0 (College station, TX).

RESULTS

Patient characteristics

A total of 199 patients met the inclusion criteria for the study. Ten patients with unknown final diagnoses were excluded. Findings from the remaining 189 patients were analyzed. The mean age was 66.3 (range 21-92) with 51.3% female. One hundred and twenty four patients (62.3%) had malignant and 65 (33%) benign strictures. Seventy seven (40.7%) of the biliary brushings were scored as class 3 or higher (i.e. malignant) and 112 (59.3%) as class 2 or lower (i.e. benign).

Cytological brushing confirmation was obtained in 62% (77/124) of patients with malignant strictures; however in the remaining 48 patients either FNA, surgical specimen or clinical course confirmed the malignant nature of the biliary stricture. Sixty-five patients had pancreatic adenocarcinoma, 10 had hepatic cancer, 16 had distal cholangiocarcinoma, 10 had presumed primary duodenal cancer, 4 had gallbladder cancer, and 3 had Klatskin tumor. The precise type of primary cancer was not identified in 16 patients, however, in all of them it was presumed to be pancreaticobiliary.

There was one non-neoplastic, false positive diagnosis. The patient was an 83-year-old man with a history of primary sclerosing cholangitis who developed a lower common duct stricture. Second brush cytology and ampullary biopsy however, revealed only reactive and inflammatory biliary epithelial changes. This patient was not subjected to surgery and is well 8 years later.

Sixty five patients had benign disease, most commonly strictures secondary to biliary stones (n = 38) and presumed sphincter spasm (n = 7). The rest had variety of benign diagnoses including primary sclerosing cholangitis (n = 4), chronic pancreatitis (n = 5), recurrent pyogenic cholangitis (n = 2), autoimmune liver disease, sarcoidosis, complex benign hilar stricture, leiomyoma, and anastomosis stricture.

Thirty six patients had repeat ERCP and brushing cytology from a period of one to ten months after initial negative cytology result. In 29 patients results of repeat cytology remained negative, however, seven patients were declared to have malignant stricture in repeat cytology. Adding the second cytology result to previous data led to an increase in sensitivity to 67% (83/124).

Overall, there were 76 true positive diagnoses, 64 true negative diagnoses, 48 false negative diagnoses, and one false positive diagnosis. The diagnostic sensitivity, specificity, PPV, and NPV of brush cytology for the series were 61%, 98%, 99%, and 57%, respectively.

Factors associated with positive yield

Among all variables studied including age, gender, location of stricture, CT scan findings, length of stricture, and endoscopic dilation prior to biliary brushing (Table 1), only age, mass size > 1 cm, and stricture longer than 1 cm are associated with positive cytology brushings. Variables associated with positive cytology brushing are illustrated in Table 2.

DISCUSSION

The examination of brush cytology is an established diagnostic technique in the investigation of patients with biliary strictures with suspected pancreatic, bile duct, ampullary, and gallbladder cancers. Acquisition of malignant cells by endoscopic brush cytology during initial ERCP is valuable in planning appropriate therapy and may be important for avoiding additional invasive procedures

Table 1 All variables studied for positive cytology brush

Variable	Value
Age (yr, range)	66.3 (21-92)
Gender (female)	51.30%
Location of stricture	
Lower CD	124
Mid + Upper CD	63

Table 2 Variables associated with positive cytology brushing

Variable	Odds ratio (95% CI)
Age	1.02 (1.00-1.05)
CT scan findings	
Mass < 1 cm	1
Mass 1-3 cm	2.22 (1.01-4.89)
Mass > 3 cm	2.86 (1.07-7.64)
Length of stricture	
Stricture < 1 cm	1
Stricture 1-3 cm	3.49 (1.18-10.2)
Stricture > 3 cm	7.70 (2.15-27.5)

for tissue diagnosis. We have reviewed brush samples from 199 patients during a time period of almost 4 years for yield, sensitivity, and specificity. This is one of the largest series of biliary brush cytology specimens reported and the largest and broadest study looking at factors associated with positive brush result.

The diagnostic sensitivity of biliary brushing has been relatively modest in most studies to date. Stewart and colleagues reviewed 406 patients and found the overall sensitivity to be 59.8%[13]. Similarly, Kurzawinski and colleagues[7,17] reviewed six early series and found the mean sensitivity to be 59%. However, two other large studies on brush cytology have recorded sensitivities of 35%-48% in the patients with pancreatico-biliary malignancy[5,8].

There are very few studies evaluating the factors influencing positive results. McGuire and colleagues have documented the association between the yield of enteropancreatic brush cytology and the location of malignancy, such that strictures of the head and body yielded higher rates of positive cytology compared to the strictures of ampulla, pancreatic genu, and tail regions[9]. DeBellis and colleagues have shown that stricture dilation does not improve the sensitivity of brush cytology for the detection of cancer. However, repeated brushing appears to increase the diagnostic yield[1].

We found that brush cytology accurately identified 76 of 124 (61.2%) neoplasms in our series, a similar result to those of earlier studies reviewed by Stewart and colleagues[13], Kurzawinski and colleagues[7,17], and by Foutch *et al*[3,4,18]. When we consider a second brushing in some patients our sensitivity increases to almost 70%. This is among the highest sensitivity reported in the literature. Other studies such as Lee *et al*[19,20], Ponchon *et al*[21], Longo *et al*[8,22], and Macken *et al*[23] all had lower sensitivities at 37%, 35%, 48%, and 57%, respectively. The reasons for the varied sensitivity are unclear.

Previous studies have shown that a diagnosis of carcinoma on brush cytology is highly specific. The specificity of biliary brush cytology in previous studies has been reported to be between 90%[17] to 100%[3,16,18,24-28]. There was one false positive diagnosis in our study (specificity 98%) in a patient with primary sclerosing cholangitis. Stewart and colleagues also reported three false positives cytological diagnoses among one hundred and sixty patients (specificity 98.1%)[13]. Sturm and colleagues also reported specificity of 97.2% with two false positive cytological diagnoses among 74 patients with benign strictures[30].

It has been suggested in previous studies that the limited sensitivity of brush cytology may be due to an inadequate cellular yield. Theoretically, stricture manipulation may increase exfoliation of tumor cells, making these cells more available for histopathologic evaluation, but DeBellis and colleagues have shown that stricture dilation does not improve the sensitivity of brush cytology for detection of cancer. In their study, brush cytology had a sensitivity of 34.5% before dilation and 31% after dilation ($P = 0.54$)[1]. On the other hand, Mohandas *et al*[31] found that dilation before bile aspiration improved the cancer detection rate of bile cytology. In their series, cytology was positive in 27% of cases without biliary stricture dilation compared to 63% when the stricture was dilated ($P < 0.03$). Use of scraping brush in the series reviewed by Parasher and Huibregtse[16] achieved a sensitivity of 100%. However, stricture dilation did not improve the diagnostic yield of brush cytology specimen in our series of 31 patients who had dilation prior to brush cytology OR 1.18 (0.48-2.85).

We have not routinely performed biliary aspiration or biopsy technique biopsies of the biliary tree; both of which may enhance diagnostic yield. Using a combination of simple biliary brushings occasionally with a second brushing combined with endoscopic ultrasound staging (and biopsy where required) sensitivity reaches more than 90%. Only a small selected group remains undiagnosed through the above two methods, and thus the benefit of other techniques (i.e. aspiration, endoscopic biopsy at ERCP) in increasing the yield is marginal in our hands.

We also analyzed positive yield for multiple factors including age, gender, location of stricture, mass size in CT scan or ultrasound, and the length of stricture. From all the mentioned variables positive brush result was associated with older age: 1.02 (1.00-1.05), mass size of more than 1 cm: 2.22 (1.01-4.89) and stricture longer than 1 cm: 3.49 (1.18-10.2).

In summary, in this study brush cytology identified 76 of 124 (61.2%) of neoplasms in a series of 199 consecutive patients evaluated during a 3.7 years period in our institution. One false positive cytological diagnosis occurred. From all the variables studied only age, length of stricture, and mass size in CT scan or ultrasound were associated with a higher yield. Gender, dilation of stricture prior to cytological sampling, or location of stricture were not found to be associated with a higher yield. Although the limitations of this technique must be recognized,, brush cytology is useful in investigation of patients with suspected biliary neoplasm. The challenge for future developments in this field is to develop strategies to improve lesion targeting facilitating retrieval of cytology specimens with higher quality.

COMMENTS

Background

The usage of biliary brushings has high specificity and moderate sensitivity in the diagnosis of malignant biliary obstruction. Although other methods of diagnosing the etiology of the obstructive lesion have become available we have evaluated our biliary tract brushing results to determine the sensitivity, specificity, and factors that might be associated with a positive result.

Research frontiers

Percutaneous biopsies have the risk of 'needle-track' seeding and thus are discouraged in patients deemed to be surgical candidates. Tissue from biliary/pancreatic lesions is also obtained through endoscopic ultrasound. We have not routinely used biliary aspiration or bile duct biopsies; both of which have a yield that may not be as high as reported in our study with biliary tract brushings.

Innovations and breakthroughs

We found that initial brush cytology accurately identified 76 of 124 (61.2%) patients with malignant biliary strictures. When a second brushing was performed in several patients, we obtained a sensitivity of close to 70%. This is much higher than most studies have reported. Theoretically, stricture manipulation may increase exfoliation of tumor cells, making these cells more available for histopathologic evaluation. Stricture dilation did not increase the yield. We also analyzed positive yield for multiple factors including age, gender, location of stricture, mass size in CT scan or ultrasound, and the length of stricture. From all the mentioned variables positive brush result was associated with older age: 1.02 (1.00-1.05), mass size of more than 1 cm: 2.22 (1.01-4.89), and stricture longer than 1 cm: 3.49 (1.18-10.2).

Applications

In this study, without the use of EUS, we still obtained a sensitivity of malignancy for biliary tract strictures of almost 70%. In this study we used Class 3 as a 'cut-off' for malignancy, however, some studies have used even more stringent criteria. When one then 'adds in' additional cytobiological results obtained with availability of EUS then the need for other methods to diagnose these lesions is limited to a very small group of patients.

Terminology

Biliary brushing: the use of a cytology brush through an endoscope to obtain samples for analysis. Biliary dilation: the use of either a step dilator or a balloon dilator to increase the size of the biliary tree lumen and to allow further intervention or to improve biliary flow.

Peer review

This is an important optimistic report on the diagnostic value of brush cytology in biliary strictures. The diagnostic yield is higher than it was reported in other previous studies. One additional aspect is the evaluation of factors influencing the results.

Abstract

AIM: To analyze the modulation of gene expression profile associated with inhibition of liver regeneration in hepatitis B X (HBx)-expressing transgenic mice.

METHODS: Microarray technology was performed on liver tissue obtained from 4 control (LacZ) and 4 transgenic mice (HBx-LacZ), 48 h after partial hepatectomy. The significance of the normalized log-ratios was assessed for each gene, using robust *t*-tests under an empirical Bayes approach. Microarray hybridization data was verified on selected genes by quantitative PCR.

RESULTS: The comparison of gene expression patterns showed a consistent modulation of the expression of 26 genes, most of which are implicated in liver regeneration. Up-regulated genes included DNA repair proteins (Rad-52, MSH6) and transmembrane proteins (syndecan 4, tetraspanin), while down-regulated genes were connected to the regulation of transcription (histone deacetylase, Zfp90, MyoD1) and were involved in the cholesterol metabolic pathway and isoprenoid biosynthesis (farnesyl diphosphate synthase, Cyp7b1, geranylgeranyl diphosphate synthase, SAA3).

CONCLUSION: Our results provide a novel insight into the biological activities of HBx, implicated in the inhibition of liver regeneration.

INTRODUCTION

The liver has a unique capacity to regenerate after partial hepatectomy (PH) or injury[1]. Experimental evidence has confirmed that hepatocyte proliferation is responsible for liver regeneration following PH, despite the low replication rate of hepatocytes in a normal liver[1]. After a two-third partial hepatectomy, hepatocytes switch from a quiescent state to a proliferative state and re-enter cell cycle division to compensate for the loss of liver mass. Liver regeneration is a multi-step process comprising at least two critical points: the immediate early gene phase (priming) that mediates the transition of the quiescent hepatocytes to the cell cycle (G1), and progression from G1 to S phase. In mice, DNA synthesis peaks at 40-44 h after PH[1].

Numerous growth factors and cytokines regulate the regeneration process by providing stimulatory and inhibitory signals for proliferation. Tumour necrosis factor alpha (TNF-α) and interleukin-6 (Il-6), together with their downstream transcription factors Stat-3 and nuclear factor kappa B (NF-κB), are the most important initiating factors in the regenerative response[1]. TNF-

α-induced hepatocyte proliferation has been shown to involve the small GTPases (Ras and RhoA) necessary for cell cycle progression by stimulating the degradation of Cdk inhibitors ($p21^{Cip}$ and $p27^{Kip1}$)[2]. The initiation factors governing liver regeneration partially overlap with regulators of the hepatic acute phase response (APR), which results in dramatic changes in the expression of acute phase response proteins following PH[3]. Hepatocyte growth factor (HGF) and transforming growth factor alpha (TGFα) further stimulate cell cycle progression, DNA synthesis and cell proliferation. Finally, TGF-β and activin suppress cell growth and terminate liver regeneration at a fixed point[1]. Recently, a large scale gene expression analysis, based on cDNA microarray technology, has provided a unique opportunity to elucidate the expression pattern throughout the course of liver regeneration[4-6], and the priming phase of liver regeneration in mice[7].

In a previous report, we showed that hepatitis B virus (HBV) X protein (HBx) inhibits liver regeneration after PH in HBx-expressing transgenic mice, and also demonstrated a paracrine inhibitory effect of HBx on liver cell proliferation[8]. HBx exhibits pleiotropic effects that modulate cell responses to genotoxic stress, protein degradation, cell viability and signalling pathways[9]. HBx has been shown to enhance transcription in the cytoplasm by activating various signal transduction cascades such as Ras/Raf mitogen-activated protein kinase and Src kinases, as well as in the nucleus through transcription factors like AP-1, AP-2 and NF-κB. Several studies have identified possible cellular targets of HBx, including members of the cyclic-AMP response element binding protein (CREB)/activating transcription factor (ATF) family, the TATA-binding protein, RNA polymerase subunit RPB5, the UV-damaged DNA-binding protein and the replicative senescence $p55^{sen}$[9,10]. HBx has been shown to interact with p53 and inhibit its function, but it may also induce apoptosis *via* p53-dependent and independent mechanisms[9]. Furthermore, it has been demonstrated that mutations identified in HBx-encoding sequences in the tumour cells of HCC can markedly modify the biological activity of HBx, and possibly favour cell transformation[11]. It has been shown that the HBx protein participates in the development of hepatocellular carcinoma (HCC) in HBV infected patients[12]. Indeed, HBx protein can induce HCC in certain transgenic mice and may, under certain conditions, cooperate *in vitro* with Myc or Ras oncogene[13]. However, the mechanisms involved in HBx-mediated HCC remain obscure.

In the present study, we analyzed further the impact of HBx on gene expression profile in the liver of transgenic mice, following PH. For this purpose, we employed HBx-expressing transgenic mice mentioned above, and adopted a transcriptome approach to analyse gene expression modulation, 48 h after PH. We observed that impaired DNA synthesis and reduction in liver mass in HBx-transgenic mice was associated with a weaker expression of genes involved in the cholesterol and nonsterol isoprenoid pathways as well as in impaired expression of serum amyloid A.

MATERIALS AND METHODS

Source of RNA

Two groups of mice (the same as described previously[8]) were used as liver RNA source. HNF1-LacZ transgenic mice carrying the nls-LacZ gene driven by the hepatocyte nuclear factor (HNF-1) promoter acted as controls. Test animals AX16/HNF1-LacZ double transgenic mice, were generated by crossing homozygous AX16 transgenic mice carrying ORF HBx linked to the promoter/enhancer of human anti-thrombin Ⅲ gene, with HNF1-LacZ transgenic mice. PH was performed on 21-35 d old LacZ and HBx-LacZ (with confirmed expression of HBx) transgenic mice. Frozen liver tissue obtained from 4 control (LacZ) and 4 treated (HBx-LacZ) mice was pulverized in liquid nitrogen, 48 h after partial hepatectomy. Total RNA extraction was performed using RNAble (Eurobio), according to the manufacturer's instructions and purified by RNeasy kit (Qiagen) followed by on-column DNase digestion (RNase-free DNase set). Only RNAs with an absorbance ratio of 260/280 over 1.9 and intact ribosomal 28S and 18S rRNA bands, evaluated by 1% agarose gel electrophoresis, were utilized for the microarray study.

Microarray assay

The aminoallyl indirect labelling method was used to obtain Cyanin-3 (Cy-3) or Cy-5 labelled cDNA. Briefly, 20 μg of total RNA and 5 μg of oligo-dT primers were incubated at 70℃ for 10 min and snap-cooled in ice, in order to generate aminoallyl-labelled cDNA. Reverse transcription was then performed by adding 0.5 mmol/L dATP, dCTP, dGTP, 0.3 mmol/L dTTP, 0.2 mmol/L aminoallyl-dUTP (aa-dUTP), 400 U SuperScript Ⅱ, 10 mmol/L DTT, and 1 × first strand buffer. This mixture was incubated at 42℃. After RNA hydrolysis (1 U of RNaseH at 37℃ for 15 min), unincorporated aa-dUTP was removed by the QIAquick PCR purification kit (Qiagen). The resulting aminoallyl -cDNAs were diluted in 0.1 mol/L sodium carbonate (pH 9.0) and coupled with 100 μg of Cy-3 or Cy-5 monoreactive dye (Amersham), prepared in dimethyl sulfoxide (DMSO) for 1 h. Cy3 and Cy5 labelled cDNA targets were concentrated in a Microcon filter device (Millipore) and suspended in 15 μL of hybridization buffer (0.7% SDS, 70% formamide in 3.6 × Denhardt solution). The cDNA microarray consisting of 5376 mice and rat cDNA spotted onto glass slides (Functional Genomic Service, CEA) was prehybridized in buffer containing: 3.5 × sodium chloride-sodium citrate buffer (SSC), 1% Bovine Serum Albumin (BSA) and 0.1% sodium dodecyl sulfate (SDS) for 1 h at 50℃. For each experiment, test cDNA was mixed with control cDNA, labelled with Cy3. Mixed, labelled cDNA, after preheating to 42℃ in hybridization buffer, was overlaid on dried glass cDNA array and incubated overnight at 42℃. After hybridization, the slides were washed once in 2 × SSC/0.2% SDS buffer and twice in 0.2 × SSC buffer, and dried by centrifugation.

Microarray analysis

For each slide, the fluorescent images of hybridized microarray were scanned with a Gene Pix 4000B scanner.

MSH6: DNA mismatch repair protein 6.

Image analysis was performed using a Gene Pix Pro 40054 to quantify the arrays. Spots flagged automatically by Genepix or by visual inspection of the array scans were excluded from the analysis. Global normalization was applied to correct the artefacts caused by different incorporation rates or scanner settings for two dyes. Scatter plots in a log scale were performed to visualize fold changes between two channels by plotting Cy5 intensity against Cy3 intensity. Normalization steps were performed using Bioconductor array packages[14]. After removal of the background, we normalized the log2 of the cy5/cy3 ratio using a print-tip loess approach[15]. For each gene, the average of the normalized log-ratios was computed and the significance was assessed using robust *t*-tests under an empirical Bayes approach[16] as implemented in the limma package. *P*-values were then corrected by the FDR approach[17] to take account of test multiplicity. Differentially expressed genes were considered to be those with a false discovery rate (FDR) of less than 5% and an expression ratio > 1.4.

Real-time PCR

In order to verify microarray hybridization data, real-Time PCR was performed using a Light Cycler rapid thermal system (Roche Diagnostics). Random cDNA was transcribed from 10 μg total RNA with 400 U of Superscript Ⅱ in the presence of 1 μg random primers, according to the manufacturer's instructions. All PCR experiments were carried out on the same cDNA preparation. Reactions were performed according to the manufacturer's instructions in a 20 μL volume containing 2 μL of 10-fold diluted cDNA, 0.5 μmol/L of primers, and an $MgCl_2$ concentration optimized between 2 and 4 mmol/L. A typical protocol included 10 min of initial denaturation followed by 40 cycles of 95℃ denaturation for 20 s, annealing at 53℃-56℃ for 15 s and a 72℃ extension for 5-12 s (depending on the PCR product). For each set of primers, a template without reverse transcription was amplified as a negative control. The details of primer sequences and amplification conditions are summarized in Table 1. The quantification of gene expression was based on a standard curve prepared from gene-specific, purified PCR product (PCR clean-up kit, Macherey-Nagel). The specificity of each PCR product was controlled by a melting curve analysis and subsequent agarose gel electrophoresis of the PCR product. For each experiment, relative concentrations were obtained after normalization with β-actin values. Calculation of the ratio of each mRNA expression was based on the relative concentration of specific cDNA found by RT-PCR in samples originating from control and HBx-expressing livers.

RESULTS

Microarray analysis of gene expression in the liver of HBx-transgenic mice after partial hepatectomy

As previously reported, HBx expression inhibits liver regeneration after PH in AX16/HNF1-LacZ transgenic mice, by a combination of intracellular and paracrine effects[8]. In the present study, we investigated, using microarray analysis consisting of 5376 murine genes, the impact of HBx expression on gene expression profile, 48 h after partial hepatectomy to analyze any changes in gene expression which may be involved in the observed inhibition of liver regeneration in HBx transgenic mice. This time point of gene expression analysis was chosen in order to determine alterations in gene expression associated with the DNA synthesis phase[1]. In addition, BrdU incorporation analysis performed on SCID mice transplanted with HBx-expressing hepatocytes, 48 h after partial hepatectomy, had indicated a marked (5.5-fold) reduction in the cellular DNA synthesis[8].

RNAs isolated from the livers of four HBx-LacZ mice were labelled separately with Cy5, and RNAs from the livers of four LacZ mice were mixed together and labelled with Cy3 as the reference. Thus, the expression profile of each of the four tested RNA was compared with the expression of control RNA by the microarray assay (performed in duplicate). 82% of the clones spotted

Table 2 Upregulated genes in HBx-LacZ transgenic mice 48 h after partial hepatectomy

Gene name (Abbreviation)	Unigene ID	GB Acc.	Fold difference HBx-LacZ/LacZ	*P* value	Function

on the microarray revealed hybridization signals, and the data shown in Tables 2 and 3 was obtained after the elimination of genes that did not comply with the criteria for expression, normalization and statistical analysis (see Material and Methods). In order to validate the microarray analysis, real-time PCR was performed on selected genes for which the expression was found to be up- or down-regulated or unmodified in LacZ-HBx mice when compared with LacZ mice. As shown in Table 4, the RT-PCR results were similar to the data obtained from cDNA microarrays; we therefore did not perform RT-PCR on all the genes listed in Tables 2 and 3.

As shown in Table 2, the majority of the up-regulated genes in HBx-expressed transgenic mice corresponded to the expression of DNA repair and transmembrane proteins. RAD52 is responsible for DNA double-strand break repair and mitotic recombination and MSH6 for DNA mismatch repair[21]. The transmembrane protein genes implicated in focal adhesion (syndecan 4), viral internalization (CD209), transport of protein between the medial-and trans-Golgi compartment (Golgi SNAP receptor) and in interactions with beta-1 integrin (transmembrane 4 superfamily member 2) were found to be up-regulated. In addition, changes in the expression of the epidermal growth factor and Aven, a caspase inhibitor, were also observed.

Genes whose expression was found to be down-regulated in the liver of HBx-expressed transgenic mice (Table 3) consisted of two main classes: those connected to the transcription control, such as Myogenic differentiation1, Zinc finger protein 90 and Histone deacetylase 10 (HDAC 10), and genes involved in cell metabolism, such as serum amyloid A3 (SAA3), creatine kinase, pepsinogen C, aldolase A, glutathione S-transferase and phospholipase A2. A subclass of down-regulated genes, connected with cholesterol metabolism and isoprenoid synthesis, such as farnesyl diphosphate synthase (FPPS), geranylgeranyl diphosphate synthase (GGPPS) and Cyp7 were also observed. In the group of genes that was found to be down-regulated in the liver of HBx-transgenic mice, we observed several genes like SAA3, aldolase A, creatine kinase, phospholipase A2 that have been reported elsewhere as up-regulated during the course of liver regeneration[22-24].

Interestingly, down-regulation of histone deacetylase and up-regulation of DNA repair genes (Rad52 and MSH6)

Table 4 Results from RT-real time PCR 48 h after PH for selected genes

Gene	Mice[1]	RT-real time PCR		Microarrays fold difference HBx-LacZ/LacZ
		Relative value[2]	Fold difference HBx-LacZ/LacZ

SAA3: Serum Amyloid A3; MSH6: DNA mismatch repair protein 6; Rb2: Retinoblastoma like-2. [1]Four animals in control (LacZ) group and four animals in treated (HBx-LacZ) group; [2]for each experiment relative values were obtained after normalization with beta actin expression.

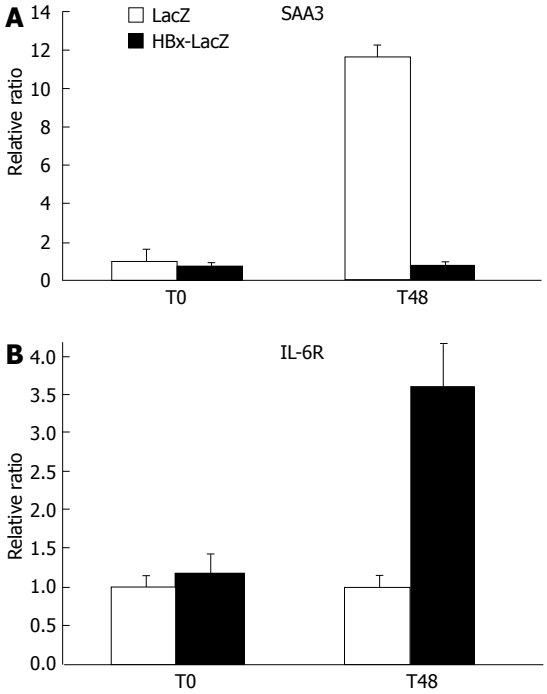

Figure 1 Expression levels of SAA3 (**A**) and IL-6R (**B**) transcripts in livers obtained from LacZ and HBx-LacZ transgenic mice. RNA was isolated before (T0) and 48 h after (T48) partial hepatectomy from the liver of two HBx-expressing (HBx-LacZ) and two control (LacZ) transgenic mice. The level of transcript expression was analyzed by quantitative RT-PCR and expressed as relative ratios after normalization with β actin values. The means of the relative ratio values and standard error were obtained from at least two independent experiments performed in duplicate.

observed in our study in HBx-transgenic mice after PH have, in agreement with other reports, similar effect on the cell cycle by inducing cell cycle arrest[25-28]. Furthermore, it has previously been reported that HBx expression may interfere with nucleotide excision repair mechanisms[29,30] and interact with the DNA repair protein[31,32].

In the next subsections we will focus on selected modulated genes implicated in cholesterol regulation and discuss their possible impact on the inhibition of liver regeneration.

Modulation of serum amyloid A expression and liver regeneration

SAA3 is a multifunctional protein involved in acute phase response, inflammation, and cholesterol transport. However, the precise function of SAA in liver regeneration is unclear. The physiological transient induction of SAA appears to be indispensable for the precise regeneration rate after PH[3]. To investigate whether HBx expression was able to completely or partially inhibit SAA3 expression during PH, real time RT-PCR was performed on liver biopsies obtained at the time of PH (T0) and 48 h later from two LacZ or HBx-LacZ transgenic mice. As expected, in the control LacZ animals, a marked increase in SAA expression (more than 10-fold) was observed 48 h after PH as compared to T0 (Figure 1A). By contrast, in HBx-LacZ mice, PH was not associated with an increase in the expression of SAA3 transcript. Thus, HBx induces complete inhibition of SAA response during PH. This may constitute an important factor involved in the impaired liver regeneration previously observed in these animals.

Regulation of SAA expression during the acute phase response depends on hepatic mitogens (Il-6, IL-1, TNF-α)[3]. As the expression of these cytokines is not significantly modified by HBx 48 h after PH, they are probably not implicated in the observed inhibition of SAA3 transcription in HBx-LacZ transgenic mice. To define whether any modulation of the expression of Il-6 receptor (IL-6R), not incorporated in our microarray, is related to the inhibition of SAA expression in HBx-LacZ mice, we used RT-PCR assay to determine the expression of IL-6R in LacZ and HBx-LacZ transgenic mice, at the time of PH and 48 h later. As shown in Figure 1B, prior to PH, no difference in IL-6R expression was observed in HBx-LacZ mice compared to control mice. By contrast, 48 h after PH there was greater than 3-fold up-regulation in HBx-LacZ mice as compared to controls. These findings suggest that HBx is able to modulate Il-6 receptor expression in association with a factor activated during PH and confirms that the lack of SAA response after PH in HBx-expressing transgenic mice is independent of cytokine activity.

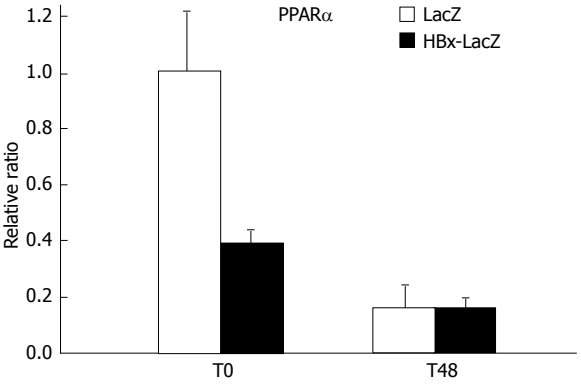

Figure 2 Expression levels of PPARα transcripts in the liver of two HBx-expressing (HBx-LacZ) and two control (LacZ) transgenic mice, before (T0) and 48 h after (T48) partial hepatectomy. The level of transcript expression was analyzed by quantitative RT-PCR and expressed as relative ratios after normalization with β actin values. The means of the relative ratio values and standard error were obtained from at least two independent experiments performed in duplicate.

Impaired expression of isoprenoid pathway and peroxisome proliferator-activated receptor-α

We observed that after PH of HBx-transgenic mice, the expression of enzymes implicated in the isoprenylation biosynthesis (FPPS and GPPS, and to a lesser extent HMG-CoA synthase) was reduced in the liver. Peroxisome proliferator-activated receptor-α (PPARα) is a transcription factor that controls lipid metabolism and glucose homeostasis. PPARα regulates the expression of enzymes implicated in isoprenoid synthesis, and its role in liver regeneration after PH was demonstrated via mechanisms involving prenylation of small GTPases Ras and RhoA independent of TNF-α and IL-6 activation[33-35]. In addition, it was observed that PPARα is involved in the expression of FPPS and HMG-CoA synthase after PH[33]. Thus, we wanted to investigate whether the decrease in the expression of enzymes implicated in isoprenylation observed in HBx-transgenic mice can be explained by a decrease in PPARα expression. We used RT-PCR to assess PPARα expression in LacZ and HBx-LacZ transgenic mice, both at the time of PH and 48 h later. At the time of PH, a 60% decrease in the expression of PPARα gene was observed in HBx-LacZ compared to LacZ transgenic mice (Figure 2). It has been reported that the absence of PPARα expression in mice contributes to impaired liver regeneration[36]. As previously reported, there is a general decrease in PPARα expression after PH[37]. In accordance with the microarray data, there was no difference in PPARα expression between LacZ and HBx-LacZ transgenic mice, 48 h post PH. Thus, the reduced expression of PPARα before PH may be involved in the inhibition of liver regeneration in HBx-LacZ transgenic mice.

DISCUSSION

In the present study, we used liver biopsies of HBx-expressing transgenic mice, 48 h after partial hepatectomy, to assess the factors implicated in the inhibition of liver regeneration in HBx-transgenic mice, by determining the alterations in mRNA profile. By that means, we extended the results obtained in *in vivo* studies, demonstrating inhibition of liver regeneration by HBx-expression in HBx-transgenic mice[8]. The present study demonstrates the influence of altered expression of genes involved in transcription control, DNA reparation, cholesterol metabolic pathway and isoprenoid biosynthesis in the reduction of liver mass observed in HBx-transgenic mice[8].

Although the data is controversial, it has been shown that HBx may up-regulate the expression of $p21^{waf1/cip1}$ and prolong G1→S transition[38,39]. A recent study on liver regeneration performed on transgenic mice showed that HBx can block G1/S transition, and so cause the lower liver mass restoration[40]. In this context, we showed that HBx down-regulated HDAC10 and up-regulated DNA repair gene (Rad52 and MSH6) expression, which may have a similar impact on the cell cycle. Indeed, HDAC inhibition causes cell cycle arrest due to an increase in the expression of p21 WAF1/Cip1 and Rb[25,26,41,42]. Moreover, it has been reported that Rad52 over-expression affects cell cycle regulation by delaying the exit from G1[27], and that MSH6 protein induces apoptosis by activation of p53[28]. Thus, one of the possible mechanisms that has emerged from our study is in accordance with previously reported activity of HBx, inhibition of cell cycle progression throughout the modulation of pathways implicated in DNA repair and transcription control.

During regeneration induced by tissue loss, a complex of growth factors and cytokines induce hepatocyte progression from G0 to cell cycle to restore the original liver mass. At the same time, Il-6, IL-1 and TNF-α, known to be hepatic mitogens, induce the acute-phase response (APR)[3,43]. During APR, the hepatic biosynthesis of SAA is up-regulated by proinflammatory cytokines, and the circulating concentration of SAA can increase up to 1000 fold. SAA is induced transiently and returns to its normal low basal level within 72-96 h of the initial stimulus[44]. It has been reported earlier that the mRNA for APR protein such as serum amyloid A increases dramatically during liver regeneration[45]. When we analyzed the changes in the mRNA profile in liver 48 h after PH we also observed a greater than 10-fold increase in the level of SAA mRNA, but only in the control mice. SAA expression level in HBx-transgenic mice 48 h after PH remained unchanged (even slightly lower) when compared to T0. Although the exact function of SAA is still unclear, the physiologic transient induction of SAA appears to be indispensable for proper regeneration after PH. Thus, the lack of SAA response in HBx-transgenic mice after PH may constitute an alternative factor in the impaired regeneration.

The activity of HMG-CoA synthase, farnesyl pyrophosphate synthase and geranylgeranyl pyrophosphate synthase was found to be indispensable for the isoprenylation process and the subsequent cell cycle progression and cell proliferation[33,34]. Furthermore, FPPS and GGPPS are implicated in cell cycle progression via their association with the isoprenylation process of GTPases Ras and RhoA proteins[33,34,46]. In addition, PPARα plays an important role in regulating lipid homeostasis. Studies of PPARα null mice have revealed the importance of PPARα in the hepatic lipid metabolism and liver regeneration[33,36]. Based on our cDNA microarray

results we determined that after PH of HBx-transgenic mice the expression level of these enzymes in the liver is down-regulated. As shown in previous studies, inhibition of enzymes involved in cholesterol and isoprenoid synthesis leads to the upregulation of cdk inhibitors, reduction in cdk, hypophosphorylation of Rb, followed by cell cycle arrest in G1[47,48]. Thus, the tempered liver regeneration in HBx-transgenic mice can be explained by the inhibition of the isoprenylation process.

Taken together, our microarray experiments performed on HBx-transgenic mice have provided new mechanisms for HBx-mediated inhibition of liver regeneration. The relevance of our results in the context of HBV-dependent cell cycle inhibition, required for an efficient HBV replication, awaits further evaluation.

COMMENTS

Background

The liver has a unique capacity to regenerate after partial hepatectomy (PH) or injury. Experimental evidence supports the hypothesis that proliferation of hepatocytes is responsible for liver regeneration after PH, despite the low replicative rate of hepatocytes in the normal liver. In a previous report we had shown that HBx expression inhibits liver regeneration after PH in HBx expressing transgenic mice. We also demonstrated a paracrine inhibitory effect of HBx on liver cell proliferation. Indeed, transplantation of HBx-expressing liver cells or injection of serum from HBx-transgenic mice into control mice is sufficient to inhibit liver regeneration after PH. Thus, HBx protein may act by combining the intracellular and paracrine effects, and inhibiting the proliferation of both infected and uninfected liver cells in the context of liver regeneration.

Research frontiers

Hepatitis B Virus (HBV) infection is a worldwide health problem. It is estimated that 350 million people are chronic carriers of hepatitis B virus (HBV). According to the WHO, hepatitis B is responsible for 1.2 million deaths each year. Chronic HBV infection is a major risk factor for the development of hepatocellular carcinoma. The HBx protein of HBV exhibits pleiotropic effects, that modulate transcription, cell responses to genotoxic stress, protein degradation, cell viability and signalling pathways. Several studies have suggested that HBx protein of HBV, participates in the development of HCC, although the precise role(s) in this process remain unclear.

Innovations and breakthroughs

In the present report, we examined the impact of HBx on the gene expression profile of liver cells in HBx-expressing transgenic mice, 48 h after partial hepatectomy. We used cDNA microarray containing over 5 thousand mouse and rat cDNA elements to determine genes that are altered in the presence of reduced liver regeneration. By demonstrating molecular mechanisms involved in HBx-mediated inhibition of liver regeneration, the data provides a better understanding of the role of the HBx protein in the physiopathology of chronic liver disease caused by HBV infection.

Applications

Although these observations were made in the specific context of liver regeneration triggered by partial hepatectomy, they may represent an important mechanism of HBV-dependent liver carcinogenesis in chronic hepatitis and the associated stimulation of liver cell proliferation. Thus, this study may contribute to the development of new approaches based on controlling the cellular effects of viral replication and ultimately provide new tools to control HBV-induced liver disease.

Peer review

This is a well written, interesting report on gene modulation associated with inhibition of liver regeneration in hepatitis B x protein transgenic mice.

Abstract

AIM: To investigate the effects of Gli-1 small interference RNA (siRNA) on Huh7 cells, and the change of Bcl-2 expression in Huh7 cells.

METHODS: Human hepatocellular carcinoma cells Huh7 were used. Cell viability was analyzed by 3-(4, 5-Dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide (MTT) assay. The expressions of Gli-1 and Bcl-2 family members were detected by RT-PCR and Western blot. Apoptosis was detected by Flow cytometry using propidium iodide, measured by Hoechst 33258 staining using Advanced Fluorescence Microscopy and caspase-3 enzymatic assay. Cell growth was analyzed after treatment with Gli-1 siRNA and 5-fluorouracil (5-Fu).

RESULTS: Inhibition of Gli-1 mRNA in Huh7 cells through Gli-1 siRNA reduced cell viability. Gli-1 siRNA treatment also induced apoptosis by three criteria, increase in the sub-G1 cell cycle fraction, nuclear condensation, a morphologic change typical of apoptosis, and activation of caspase-3. Gli-1 siRNA was also able to down-regulate Bcl-2. However, Gli-1 siRNA resulted in no significant changes in Bcl-xl, Bax, Bad, and Bid. Furthermore, Gli-1 siRNA increased the cytotoxic effect of 5-Fu on Huh7 cell.

CONCLUSION: Down-regulation of Bcl-2 plays an important role in apoptosis induced by Gli-1 siRNA in HCC cells. Combination Gli-1 siRNA with chemotherapeutic drug could represent a more promising strategy against HCC. The effects of the strategies need further investigation *in vivo* and may have potential clinical application.

INTRODUCTION

Hedgehog (Hh) gene was first identified in a *Drosophila* genetic screen for mutations affecting body patterning[1]. This pathway contains Hh proteins (Sonic Hh, Indian Hh, and Desert Hh), the twelve transmembrane protein Patched (Ptc), the seven transmembrane protein Smoothened (Smo), and the five-zinc finger transcription factor Glis (Gli-1, Gli-2, and Gli-3)[2-4]. When Hh binds to Ptc, Smo is released and the downstream transcription factors such as Gli-1 are activated. Conversely, when Hh unbinds to Ptc, Ptc prevents Smo from activating the pathway[5]. Glis proteins are regarded as nuclear executors of hedgehog signaling[6,7]. Evidence from several groups suggests that Gli-1 and Gli-2 represent the main activators of Hh-target genes, while Gli3 acts mainly as repressor[8,9]. Gli-1 has been demonstrated to represent a direct transcriptional Hh target gene and the marker of Hh pathway activation[10-13].

Constitutive activation of the Hh pathway has been shown to contribute to the growth and maintenance of various cancers[14-21]. We have previously shown that Hh pathway activation was an important event for the development of human hepatocellular carcinoma (HCC)[22]. Our results corroborated and extended the findings of Sicklick *et al*[23] about disregulation of Hh signaling in human hepatocarcinogenesis. The fact that the Hh pathway is active in human HCC suggests a significance of novel targeted strategy for HCC therapy.

Sustained application of specific Hh-pathway inhibitors has been proven effective in preventing growth of many tumors with activating Hh signaling *in vitro* and *in vivo*[21-26], suggesting a promising approach of Hh signaling interference. Current strategies focus on the use of small

molecule inhibitors of Smo. Blocking Smo with antagonist, e.g. cyclopamine or KAAD-cyclopamine[27] is a reasonable yet limited approach, since it is only effective for tumors with Hh pathway activation occurring upstream or at the level of Smo. However, tumors with inactivating mutations in Smo or downstream components will most likely not respond to Smo antagonists[25,28]. It has been reported that Gli-1 is the last and essential step of the pathway and plays a central role in HCC proliferation[24]. Thus, blocking Gli-1 transcription factor would be an ideal strategy to combat HCC. In this paper, we investigated the effects of Gli-1 small interfering RNA (siRNA) on the human liver cancer cells. Our results indicated that Gli-1 siRNA induced apoptosis through down-regulation of Bcl-2 in HCC cells.

MATERIALS AND METHODS

Reagents

The primary goat polyclonal anti-Gli-1 and nonspecific control siRNA were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Rabbit monoclonal anti-Bcl-2, SABC kit, and horseradish peroxidase-conjugated mouse anti-goat/rabbit IgG secondary antibody were obtained from Boster (Wuhan, China). 5-fluorouracil (5-Fu), TRIzol reagent, and propidium iodide (PI) were obtained from Sigma Chemical Co (St. Louis, MO, USA). 5-Fu was dissolved in phosphate buffered solution (PBS).

Cell culture

The human HCC cell line Huh7 and human hepatocyte cell line L02 were kindly donated by professor Guan Xin-yuan (Hong Kong University). Huh7 and L02 cells were cultured in Dulbecco's Modified Eagle Medium (DMEM, Gibco BRL, Grand Island, NY, USA) supplemented with 10% (*v*/*v*) fetal bovine serum (Bio-Whittaker, Walkersville, MD, USA) at 37℃ in a humidified atmosphere with 5% CO_2.

Immunocytochemistry assay

Immunocytochemical staining was performed as described by the manufacturer on cell slides by the streptavidin-biotin-peroxidase complex method using a SABC kit. For negative control, the primary anti-Gli-1 antibody was replaced with PBS.

Treatment with siRNA

The Gli-1 and Bcl-2 siRNA reagent kits were purchased from RiboBio Co. LTD (Guangzhou, China). siRNAs were transfected using the LipofectAMINE 2000 reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions after cells were grown to 50% confluence. Briefly, 1 μL LipofectAMINE was diluted in 50 μL OptiMEMI Reduced Serum Medium (Invitrogen, Carlsbad, CA, USA), mixed gently, and incubated for 5 min at room temperature. Subsequently, a mixture of siRNA was added and incubated for 20 min. The mixture was diluted with medium and the final concentration of siRNA was 100 nmol/L. After treatment for the indicated time period, cells were collected for further investigation.

3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay for cell viability

Cells were seeded onto 96-well plates at 5000 cells/well overnight. After incubating with the test compounds for the indicated time period, 20 μL MTT (5 g/L MTT in PBS) was added to each well and incubated at 37℃ for 4 h. The cells were then centrifuged (700 × *g* for 15 min), and the supernatant was removed. DMSO (200 μL/well) was added to dissolve the cell pellets. Absorbance was measured at a wavelength of 570 nm with enzyme-linked immunity implement (BIO-RAD 2550, USA).

Flow cytometry assay

Huh7 cells were incubated with each experimental treatment. Cells were collected, washed twice with pre-cold PBS, and fixed with 70% ethanol overnight at 4℃. Cell pellets were resuspended in PBS after being washed twice with pre-cold PBS. Then 50 μL of RNase (10 μg/mL) and 25 μL of propidium iodide (1 mg/mL) were added to the cells for 30 min at room temperature, and then flow cytometry (EPICS-XL, Beckman Coulter, Fullerton, USA) analysis was performed. Data were analyzed using CellQuest Software (Becton Dickinson, Mountain View, CA, USA).

Chromatin staining with Hoechst 33258

Apoptosis was observed by chromatin staining with Hoechst 33258 as previously described[29]. In brief, after 48 h transfection with Gli-1 siRNA, Huh7 cells were washed with ice-cold PBS, fixed with 4% paraformaldehyde in PBS for 10 min at room temperature, washed again with PBS, and stained 10 min with Hoechst 33258 (5 mg/L), washed, and observed under an Advanced Fluorescence Microscope (NIKON 80i, Tokyo, Japan) by an observer blind to the cell treatment.

Reverse transcription-polymerase chain reaction (RT-PCR)

Total RNA was isolated from Huh7 cells with TRIzol reagent. First strand cDNA was synthesized using total RNA with the ReverTra Ace system (Toyobo, Tokyo, Japan) according to the manufacturer's instructions. Transcripts of the gene for β-actin were used as an internal control. We used the following primers for PCR: Gli-1 (sense: 5'-ttcctaccagagtcccaagt-3', antisense: 5'-ccctatgtgaagccctattt-3', 185 bp), Shh (sense: 5'-CGCA CGGGGACAGCTCGGAAGT-3', antisense: 5'-CTGC GCGGCCCTCGTAGTGC-3', 476 bp), Ptch (sense: 5' -GTTGGAAGAAAACAAACAGC-3', antisense: 5'-AG CCGTCAGGTAGATGTAGA-3', 277 bp), Smo (sense: 5'-TTACCTTCAGCTGCCACTTCTACG-3', antisense: 5'-GCCTTGGCAATCATCTTGCTCTTC-3', 321 bp); Bcl-2 (sense: 5'-CTGGTGGACAACATCGC-3', antisense: 5'-GGAGAAATCAAACAGAGGC-3', 135 bp), Bcl-xl (sense: 5'-GTAAACTGGGGTCGCATTGT-3', antisense: 5'-TGGATCCAAGGCTCTAGGTG-3', 146 bp), Bax (sense: 5'-CCAGCTGCCTTGGACTGT-3', antisense: 5'-ACCCCCTCAAGACCACTCTT-3', 135 bp), Bad (sense: 5'-AGGGCTGACCCAGATTCC-3', antisense: 5'-GTGACGCAACGGTTAAACCT-3', 178 bp), Bid (sense: 5'-GCTTCCAGTGTAGACGGAGC-3', antisense:

5'-GTGCAGATTCATGTGTGGATG-3', 116 bp)[30] and β-actin (sense: 5'-GTGGACATCCGCAAAGAC-3', antisense: 5'-GAAAGGGTGTAACGCAACT-3', 303 bp). The reactions were carried out in a DNA Thermal Cycler (Perkin-Elmer Corp. Norwalk, Connecticut, USA) with the following cycle conditions: denaturation at 94℃ for 1 min, annealing at respective temperature for 30 s, and extension at 72℃ for 1 min, for 35 cycles.

Western blot analysis

Western blotting was performed as described previously[31,32] with minor modification. Total cell extracts were prepared by lysing cells in RIPA lysis buffer. For gel electrophoresis, equivalent of total protein (40 μg) was loaded on each lane of a 10% sodium dodecyl sulfate-polyacrylamide gel.

Caspase-3 activity detection

After treatment, activation of caspase-3 was detected with 200 μg of cell lysate using the colorimetric protease assay kit (KeyGEN Biotech, Nanjing, China) according to the manufacturer's protocol. The activity of caspase-3 was converted through measurement of absorbance (OD 405 values) using a microplate reader at 405 nm. Non-specific reactions were corrected by subtracting background absorbance readings from the combination of cell lysate and buffer.

Statistical analysis

Values were expressed as mean ± SD from at least three separate experiments. Differences between groups were assessed with one-way ANOVA or Student's *t*-test using SPSS 11.5 for Windows (SPSS Inc, Chicago, IL, USA). Differences were considered significant if $P < 0.05$.

RESULTS

Expression of Hh pathway components in Huh7 cells

To begin to elucidate the effect of Gli-1 on Huh7 cells, we first examined the expressions of Hh pathway components in Huh7 cells and the normal hepatocyte cell line L02 cells. The expressions of Hh pathway components were determined by RT-PCR analyses. The expressions of Gli-1 were also assayed by immunocytochemistry detection. RT-PCR analyses showed that Shh, Smo and Gli-1 were expressed in Huh7 cells, but not in L02 cells (Figure 1A). Ptch was detected in both cells, however, the expressions were elevated in Huh7 cells. To further confirm these findings, we performed immunocytochemistry for Gli-1. Gli-1 protein was present in the cytoplasm of Huh7 cells, but not in L02 cells (Figure 1B). Because Gli-1 is one of the indicators of the Hh pathway activation, our data indicated that Hh pathway is active in Huh7 cells.

Gli-1 siRNA reduced Huh7 cell viability

Since Hh pathway is activated in Huh7 cells, we investigated whether Gli-1 siRNA could kill Huh7 cells. Firstly, we characterized the function of Gli-1 siRNA on Gli-1 mRNA expression. Huh7 cells were transfected with Gli-1 siRNA or nonspecific control siRNA at a concentration of 100 nmol/L. Cells treated with PBS were used as a mock control. Twenty-four hours and forty-eight hours after treatment, the expressions of Gli-1 mRNA were assayed by RT-PCR. The results indicated that Gli-1 siRNA completely blocked Gli-1 expressions in Huh7 cells at two time points (Figure 2A and B). Subsequently, the cell viability was assayed by MTT. The results showed that Gli-1 siRNA decreased cell viability to 88.3% ± 2.3% and 76.8% ± 3.4% after twenty-four hours and forty-eight hours treatment, respectively (Figure 2C).

Gli-1 siRNA induced apoptosis in Huh7 cells

To test whether cell viability decreases by Gli-1 siRNA through apoptosis, we evaluated morphologic and biochemical changes typical of apoptosis. As illustrated in Figure 3A, chromatin condensation was seen by Hoechst 33258 staining forty-eight hours after Huh7 cells treated with 100 nmol/L of Gli-1 siRNA. As apoptosis progresses into the late stage, apoptotic bodies with partially degraded DNA and DNA cleaved at internucleosomal sites appear. These apoptotic bodies were detected as the sub-G1 fraction on propidium iodide fluorescent flow cytometry analysis. Huh7 cells were treated for forty-eight hours with Gli-1 siRNA and subsequently stained with propidium iodide for flow cytometry. The cellular DNA content analysis revealed that Gli-1 siRNA induced more apoptosis than did either control or negative control (Figure 3B). The average percentages of the sub-G1 cells are plotted in Figure 3C. Gli-1 siRNA significantly increased the percentages of the sub-G1 cells by 15.8% ± 2.6%. Caspase-3 is classically regarded as executor. The caspase-3 activities in cell lysates were assayed using a colorimetric assay kit. In accordance with the increase of sub-G1 cells, Gli-1 siRNA increased 2.01-fold caspase-3 activity compared with the activity in untreated control cells (Figure 3D). These results indicated that Gli-1 siRNA reduced Huh7 cell viability through apoptosis induction.

Gli-1 siRNA mediated apoptosis by decreased expressions of the Bcl-2 gene

Several cytoplasmic proteins are critically involved in the regulation of apoptosis, in particular, members of the Bcl-2 family[33-35]. Gli-1 has been shown to up-regulate expressions of the key anti-apoptotic factor Bcl-2 in some malignancies[36,37]. To determine whether Gli-1 siRNA-induced apoptosis in Huh7 cells was associated with change of Bcl-2 family, Bcl-2 family was analyzed after treatment with Gli-1 siRNA. The expressions of Bcl-2 mRNA were remarkably decreased twenty-four hours after treatment with Gli-1 siRNA. In contrast, Bcl-xl, Bax, Bad, and Bid were unchanged (Figure 4A). Consequently, we used western blot to detect Bcl-2 protein. Treatment with Gli-1 siRNA for twenty-four hours resulted in an obvious decrease of Bcl-2 expression. To investigate whether Gli-1 is upstream of Bcl-2, Huh7 cells were treated with Bcl-2 siRNA. The findings showed that the expressions of Gli-1 were unchanged (Figure 4C). These results together with the data presented above indicated that Gli-1 was upstream of Bcl-2 in the hierarchical pathway of apoptosis regulation.

Gli-1 siRNA increased cytotoxic effects of 5-Fu in Huh7 cells

Hedgehog cascades have been proved to be involved in

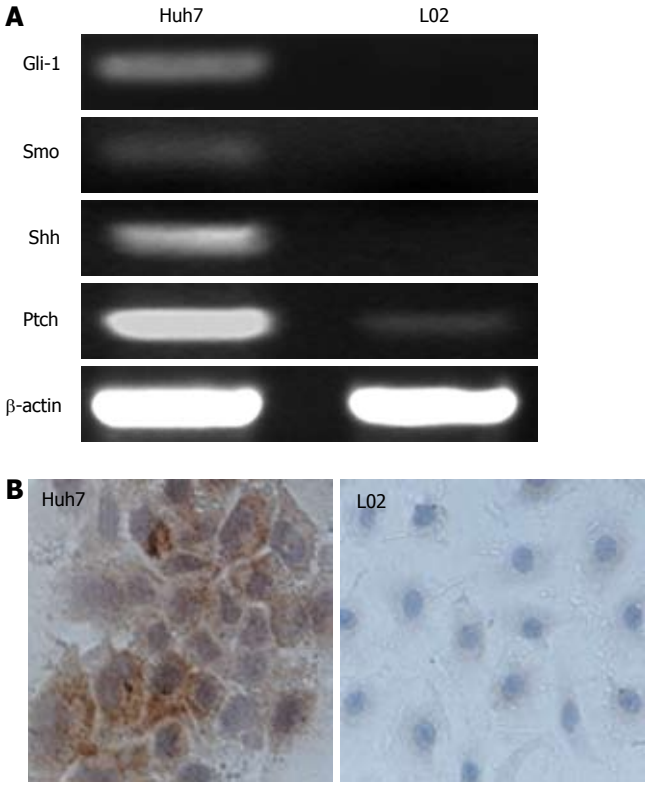

Figure 1 Expressions of Hh pathway components on Huh7 and L02 cells. **A**: The expressions of Gli-1, Smo and Shh mRNA was observed in Huh cells, but not in L02 cells; Ptch mRNA was detected in both cell lines, but the expressions was elevated in Huh7 cells; **B**: Immunocytochemical staining showed Gli-1 protein expression in the cytoplasm of Huh7 cells, but not L02 cells.

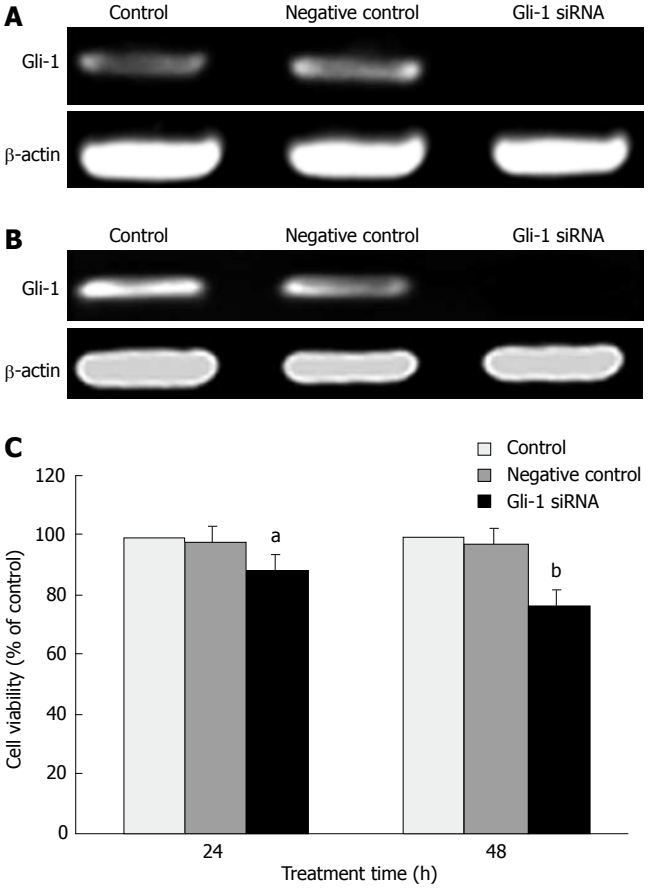

Figure 2 The effect of Gli-1 siRNA on cell viability in Huh7 cells. **A**: The expressions of Gli-1 mRNA 24 h after transfection with Gli-1 siRNA analyzed by RT-PCR. Gli-1 mRNA expressions were significantly down-regulated; **B**: The expressions of Gli-1 mRNA 48 h after transfection with Gli-1 siRNA analyzed by RT-PCR; **C**: The effect of Gli-1 siRNA on Huh7 cell viability by MTT assay. Cells were treated with Gli-1 siRNA for indicated time. Data are expressed as the mean ± SD of 3 independent experiments ($^aP < 0.05$, $^bP < 0.01$ *vs* control).

the resistance to clinical therapies and disease relapse in some cancers[38-40]. We further tested if Gli-1 siRNA could increase the cytotoxic effects of 5-Fu. The results showed that significant increased cytotoxicity effects were observed in Huh7 cells treated with Gli-1 siRNA plus 5-Fu (Figure 5). Moreover, Gli-1 siRNA enhanced 5-Fu-induced apoptosis in Huh7 cells (Table 1).

DISCUSSION

Hedgehog signaling pathway has been found to play a critical role in regulating the growth, proliferation, and apoptosis of several cancers. Various types of cancers contain Hh activation. We have shown previously that hedgehog signaling is activated in HCC[22]. In this study, we found that Hh pathway components including Gli-1, the marker of Hh pathway activation, were expressed in the HCC cell line Huh7 but not in L02 normal liver cells. This provides a target to preferentially kill HCC cells.

Previous studies demonstrated that the naturally occurring plant extract cyclopamine or KAAD-cyclopamine that directly associates with the transmembrane domains of SMO could inhibit proliferation, induce apoptosis in a subset of HCC cell lines[22,24]. These observations suggest a possibility for developing new therapeutic strategies using the Hh pathway inhibitor to kill cancer cells with Hh pathway activation. The Hh pathway can be blocked at several steps, such as blocking Smo with antagonist, e.g. cyclopamine or KAAD-cyclopamine[22-24,41], Shh antibody[17,20] and Gli-1 RNA interference[25]. Blocking Smo with an antagonist can generally inhibit the growth of tumor cells with activated Hh signaling, however, this drug may be less effective in tumors with genetic mutations downstream of SMO[42]. Mutation of Smo was found in human HCC[24]. Effective treatment of Huh7 cells will require identification of novel small molecular weight compounds acting downstream of Smo signaling. Thus, we hypothesized that Gli-1 siRNA that directly inhibit Gli-1 could be effective for Huh7 cells. The present study investigated the effects of Gli-1 siRNA on Huh7 cells. We demonstrated that Gli-1 siRNA down-regulated expression of Gli-1 and significantly decreased cell viabilities in Huh7 cells *via* inducing apoptosis. These findings are consistent and extended with the findings of Chen *et al* regarding induction of apoptosis and decrease of cell proliferation in ovarian carcinoma cells[43] and of Huang *et al* regarding Gli-1 which may be an important regulator in survival of HCC cells[22]. Furthermore, these observations are in agreement with the mechanism of the Hh pathway blockage reported previously. Nevertheless, our findings in this paper are unlike that of Gli-2 in playing a dominant role over Gli-1 in regulating the proliferation of HCC cells[44]. Thus, even in the same cell

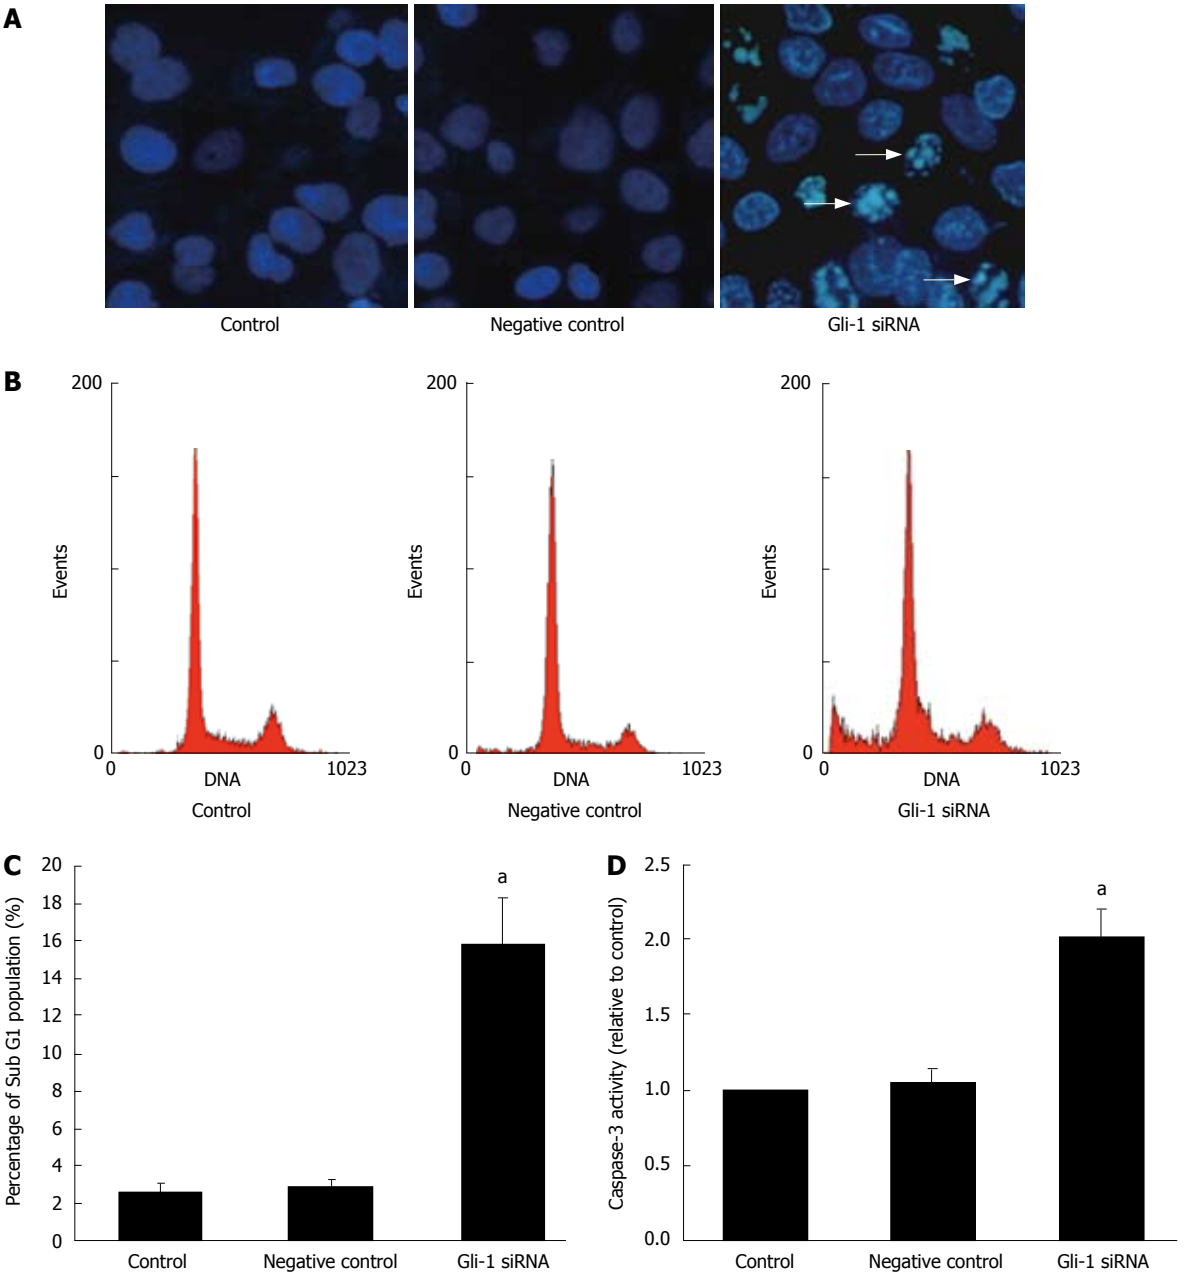

Figure 3 Gli-1 siRNA induced apoptosis in Huh7 cells. Huh7 cells were treated with Gli-1 siRNA for 48 h. **A**: Morphologic changes characteristic of apoptosis. The samples were stained with Hoechst 33 258 (5 mg/L) for 10 min and photographed using fluorescence microscopy; **B**: Gli-1 SiRNA induced apoptosis as measured by propidium iodide using a flow cytometry analysis. After treatment, the nuclei were stained with propidium iodide and analyzed by flow cytometry. Representative frequency distributions of DNA content of cells in the three treatment groups were shown; **C**: The bar chart showed the percentage of cells in the sub-G1 apoptotic fraction. The treatment groups were labeled on the horizontal axis. The error bars represented the standard deviation; **D**: Gli-1 siRNA induced activation of caspase-3. The activity of caspase-3 was assessed by caspase colorimetric assay. The data were showed as mean ± SD of 3 independent experiments. ($^aP < 0.05$ *vs* control).

line, it seems that inhibition of Gli-1 has different effects on cell survival according to the type of knock down method. However, it is still possible that inhibition of Gli-2 may have more cytotoxic effect on HCC cells. It will be worthwhile to further evaluate. On the other hand, the cytotoxic effects of siRNA were moderate. This may be because of autocrine Shh expression in Huh7 cells that continuously drive the expression of Gli-1 to lower the effect of siRNA. Our unpublished data indicate that in low concentration of Gli-1 siRNA-treatment, Gli-1 almost recovers after twenty-four hours of treatment even when Gli-1 is silenced completely at the twelve hour time point. The findings suggest that autocrine Shh have impact on the effect of Gli-1 siRNA. It should be given the rational concentration to exert the best effect of Gli-1 siRNA on HCC.

The Bcl-2 family proteins are important regulators of apoptosis. Among the members of this family, Bcl-2 and Bcl-xl act as inhibitors of apoptosis, whereas Bax and Bak act as promoters of apoptosis. Mitochondrial apoptotic pathway is activated while Bax is over-expressed and transported to the mitochondria. Conversely, Bcl-2 inhibits Bax activity through binding to Bax. Thus, Bcl-2 was thought to be a very important anti-apoptotic protein in cells[34,35]. Several studies showed the increased expression of Bcl-2 in HCC contributed to cell death inhibition[45,46].

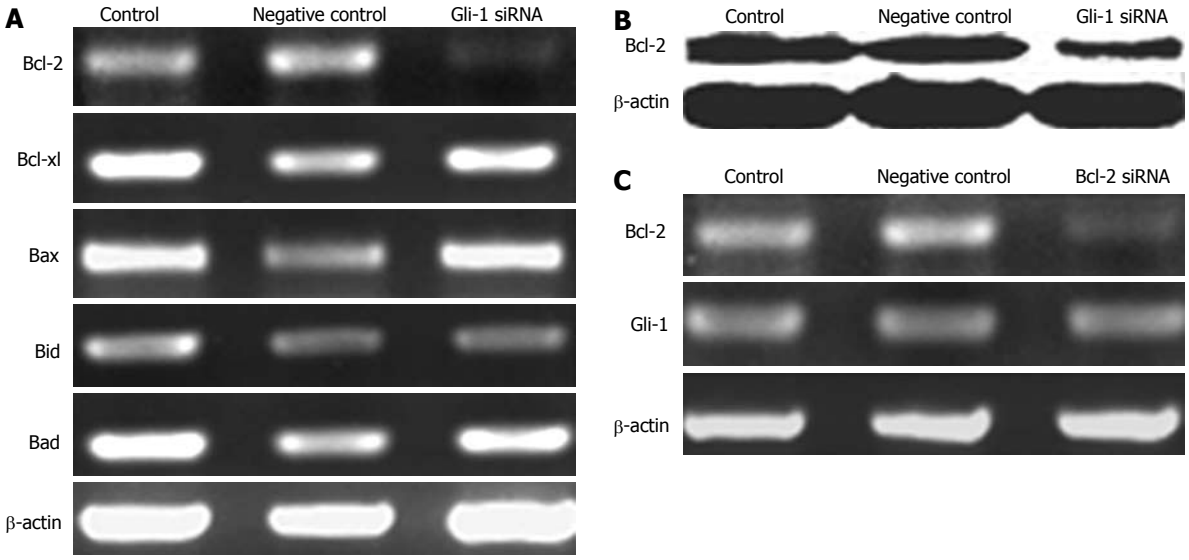

Figure 4 Effects of Gli-1 siRNA on Bcl-2 family member expressions in Huh7 cells. **A**: The expressions of Bcl-2 family member mRNA 24 h after transfection with Gli-1 siRNA analyzed by RT-PCR. The expression of Bcl-2 was remarkably decreased, but no change for other members; **B**: The protein of Bcl-2 was detected by Western blot. The Bcl-2 protein was markedly decreased after 24 h treatment with Gli-1 siRNA; **C**: Bcl-2 siRNA effectively inhibited the expressions of Bcl-2, but the mRNA of Gli-1 was no change after transfection with Bcl-2 siRNA.

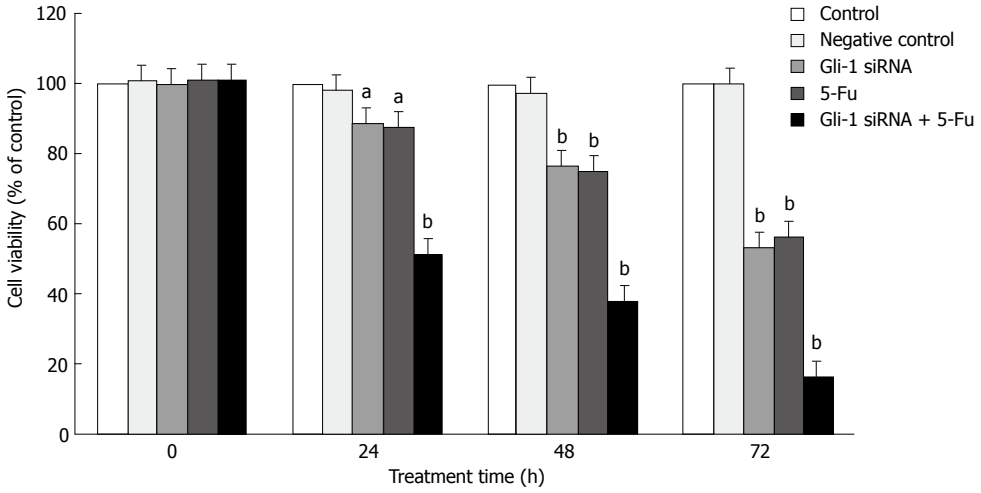

Figure 5 Effect of Gli-1 siRNA combining with 5-Fu on Huh7 cells. The effect of Gli-1 siRNA combining with 5-Fu on Huh7 cell viability was measured by MTT assay. Cells were transfected with Gli-1 siRNA. After 6 h, cells were exposed to 5-Fu (25 μmol/L) or not for the indicated time periods. The bars are grouped according to the treatment time as labeled below the horizontal axis. The treatment groups were as labeled on the color key. Data are expressed as the mean ± SD of 3 independent experiments ($^aP < 0.05$; $^bP < 0.01$ *vs* control or negative control).

It is of interest to establish a direct link between Hh/Gli signaling and Bcl-2 expression. Bigelow *et al* showed that Gli1 was able to stimulate the Bcl-2 promotor[37]. Morton *et al* recently also demonstrated that activation of hedgehog signaling protected tumor cells from apoptosis through the stabilization of Bcl-2 protein[47]. We showed that Gli-1 siRNA induced apoptosis in Huh7 cells. On the basis of the findings reported here it is reasonable to assume that the effect of Gli-1 siRNA would, at least in part, be mediated by the regulation of Bcl-2 expression. In the present study, we showed that Gli-1 siRNA remarkably reduced the level of Bcl-2 mRNA expressions and Bcl-2 protein, but was not effective on other Bcl-2 family members. Moreover, the level of Gli-1 mRNA had no change after transfection with Bcl-2 siRNA in Huh7 cells. These findings suggest that over-expression of Bcl-2 is a consequence of the activation of Gli-1. Thus, silencing Gli-1 would induce apoptosis through down-regulation of Bcl-2 expressions in Huh7 cells. Nevertheless, the involved apoptotic pathway of Gli-1 siRNA-induced apoptosis in Huh7 cells through down-regulation of Bcl-2 remains to be investigated.

5-Fu is the most common chemotherapeutic agent in advanced HCC treatment. However, drug-resistance results in failure of chemotherapy. Loss of apoptosis pathway promoted by Hh signaling activation has been suggested to be the key mechanism by which HCC is resistant to 5-Fu. On the basis of the ability of Gli-1 siRNA to induce apoptosis in Huh7 cells, one would expect that Gli-1 siRNA should increase sensitivity of Huh7 cells to 5-Fu. In fact, the present study showed that Gli-1 siRNA increased chemosensitivity significantly. These results suggest that it is indeed possible to combine Gli-1 siRNA and 5-Fu to overcome drug resistance and enhance therapeutic activity. It would be important to further test the effect of other combinations of Gli-1 down-regulating agents with 5-Fu on a variety of HCC cells. Its potential therapeutic implications seem to justify future research efforts in this area.

In summary, our data provide a potential mechanism

Table 1 Combined effect of Gli-1 siRNA and 5-Fu on apoptosis in Huh7 cells

Group	Percentage of sub G1 population (%)
Control	2.63 ± 0.28
Negative control	2.78 ± 0.39
Gli-1 siRNA	15.8 ± 2.13[a]
5-Fu	27.29 ± 3.14[a]
5-Fu + Gli-1 siRNA	44.25 ± 4.59[a,c]

Huh7 Cells were transfected with Gli-1 siRNA. After 6 h, cells were treated in the presence or absence of 25 μmol/L 5-Fu for 48 h. After treatment, the nuclei were stained with propidium iodide and analyzed by flow cytometry. The percentage of cells in the sub-G1 apoptotic fraction is shown in table. The data shown as mean ± SD were from three independent experiments. ANOVA analysis showed difference between groups was significant ([a]$P < 0.05$ *vs* control or negative control; [c]$P < 0.05$ *vs* other treatment groups).

for Gli-1 siRNA-induced apoptosis. Our findings suggest that combination Gli-1 siRNA with chemotherapeutic drug could represent a more promising strategy against HCC. The effects of the strategies need further investigation in other HCC cell lines and *in vivo*.

COMMENTS

Background

Hedgehog pathway plays an important role in the development and maintenance of human hepatocellular carcinoma (HCC). Thus, there has been increasing interest in the application of specific Hh pathway inhibitors in cancer therapy for many years. Current strategies focus on the use of small molecule inhibitors of Smo. However, tumors with inactivating mutations in Smo or downstream components will most likely not respond to Smo antagonists. Gli-1 is the last and essential step of the pathway and would be the ideal target for HCC therapy. However, the effects of Gli-1 small interfering RNA (siRNA) on the human liver cancer cells remains unclear.

Research frontiers

We demonstrated that Gli-1 siRNA significantly decreased cell viabilities *via* inducing apoptosis through down-regulation of Bcl-2 expression in Huh7 cells. Furthermore, Gli-1 siRNA increased cytotoxic effects of 5-Fu in Huh7 cells.

Innovations and breakthroughs

Our data provide a potential mechanism for Gli-1 siRNA-induced apoptosis. Moreover, our findings show that Gli-1 siRNA significantly increased sensitivity of chemotherapy and suggest that combination Gli-1 siRNA with a chemotherapeutic drug could represent a more promising strategy against HCC. Overcome drug-resistance *via* Hh pathway inhibition will be a big breakthrough in HCC therapy. To our knowledge, this is the first discovery of Gli-1 siRNA causing apoptosis *via* down-regulation of bcl-2.

Applications

Our findings suggest that combination Gli-1 siRNA with chemotherapeutic drug could represent a more promising strategy against HCC. Furthermore, findings of Gli-1 siRNA significantly induced apoptosis through down-regulation of Bcl-2 expression are important in understanding regulation of apoptosis and a rational mechanism-based design of chemotherapy combinations for future clinical testing. Since about 75% of cancer cells of various origins and types are sensitive to drugs with a similar mechanism of action, the findings in this study are highly likely to be applicable to a wide range of cancers. Understanding these molecular mechanisms will allow us to identify novel therapeutic targets and design innovative combination chemotherapy regimens.

Terminology

Gli-1: It is a glioma-associated oncogene homologue 1 gene, Gli-1 is thought to be a direct transcriptional Hh target gene and the marker of Hh pathway activation. Bcl-2: is a family composed of various members, which are generated in mitochondria and key regulators of apoptosis. Bcl-2 is an anti-apoptotic protein and exhibits high expression in a wide range of human cancers including HCC. The increased expression of bcl-2 contributed to cell death inhibition. SiRNA: Small Interfering RNA (siRNA) is a 21-23-nt double-stranded RNA molecule. It guides the cleavage and degradation of its cognate RNA.

Peer review

This paper reports that Gli-1 siRNA induces apoptosis of human hepatocellular carcinoma cells and that this is mediated by down-regulation of Bcl-2. Furthermore, Gli-1 siRNA increased the cytotoxic effect of 5-Fu on Huh7 cells. These results extend the authors' previous observations and in agreement with the mechanism of Hh pathway blockage reported previously. The authors tried to identify novel therapeutic targets and design a more promising strategy based on Hh pathway inhibitor against HCC.

Abstract

AIM: To investigate the protective effect of target suppression of uncoupling protein-2 (UCP-2) on ischemia/reperfusion (I/R) injury in fatty liver in ob/ob mice.

METHODS: Plasmids suppressing UCP-2 expression were constructed, and transfected into fatty liver cells cultured *in vitro* and the ob/ob mouse I/R injury model. Serum tumor necrosis factor (TNF)-α levels, UCP-2 mRNA expression, alanine aminotransferase (ALT) levels in ob/ob mice were tested, and the pathological changes in fatty liver were observed in experimental and control groups.

RESULTS: In ob/ob mouse I/R models, serum TNF-α levels were significantly higher than in normal controls. After the plasmids were transfected into the cultured cells and animal models, expression of UCP-2 mRNA was significantly reduced as compared with that in the control group ($2^{1.56 \pm 0.15}$ *vs* $2^{-0.45 \pm 0.15}$, $P < 0.05$). In ob/ob mouse models, in which expression of UCP-2 was suppressed, serum ALT levels were significantly lower than those of other groups, and pathological analysis revealed that injury of liver tissues was significantly alleviated.

CONCLUSION: The target suppression of UCP-2 expression in fatty liver can alleviate the I/R injury in the ob/ob mice.

INTRODUCTION

It has been reported that primary graft non-function (PNF) occurs in over 25% of donor liver grafts with a lipid volume of > 30%[1,2]. Previous studies have discovered that PNF of fatty liver after liver transplantation is related to liver ischemia/reperfusion (I/R) injury during transplantation[3-5]. Recently, it has been discovered that one kind of mitochondrial protein, uncoupling protein-2 (UCP-2), may play an important role in I/R injury of liver transplantation[6,7]. UCP is a protein of the inner mitochondrial membrane and acts as a proton carrier to allow the dissipation of the proton electrochemical gradient, without phosphorylation of ADP to ATP, which results in the uncoupling of oxidation and ATP synthesis[8-10]. The increased expression of UCP-2 leads to a decrease in ATP in liver mitochondria, therefore, the fatty liver is more susceptible to injury than the normal liver under stress, e.g. transplantation[11]. Previous studies have indicated that polyunsaturated fatty acids can stimulate UCP-2 expression in fatty hepatocytes *via* a peroxisome proliferation activated receptor-α (PPAR-α) mediated pathway[12,13], and reactive oxygen species (ROS) generated intracellularly during lipid metabolism participate in UCP-2 induction[14,15], In addition, tumor necrosis factor (TNF)-α also increases mitochondrial oxidant production and induces expression of UCP-2 in fatty hepatocytes[16,17]. In the previous study by Wan *et al*, caerulomycin (a specific inhibitor of fatty acid synthetase) preconditioning suppressed the expression of UCP-2 in the fatty liver of ob/ob mice, which suggests that preconditioning alleviates the injury of liver cells following transplantation[18]. Caerulomycin cannot be widely used in clinical practice because it leads to metabolic disorders[19,20]. In this study, an antisense technique was used to directly suppress the expression of UCP-2 in fatty liver tissues, and the protective effects of UCP-2 expression inhibition on I/R injury in ob/ob mice was evaluated.

MATERIALS AND METHODS

Materials

Female 4-6-wk-old obesity mice (C57BL ob/ob) and inbred 10-12-wk-old normal mice (C57BL lean) were bought from the Model Animal Research Center of Nanjing University (China). Other reagents and equipment were from the following sources: collagenase Ⅳ (Gibco, USA), Percoll (Second Factory of Shanghai Biochemical Reagents, China), HEPES (Sigma, USA), EGTA (Sigma, USA), Dulbecco's Modified Eagle's Medium (DMEM; Gibco, USA), TNF-α (Sigma, USA), fetal bovine serum (FBS, Shanghai Huamei Bio-engineering Co., China), Ca^{2+}-free Hank's solution and PBS (self prepared), ELISA kit (R&D, USA), TRIzol (Gibco, USA), SYBR Green I fluorescent probe, FTC-200 type real-time fluorescent quantitative PCR instrument and fluorescent quantitative PCR analysis software (Shanghai Fengling Bio-tech, China), CO_2 incubator (Heraeus, USA), UCP-2 primer (Shanghai Bio-engineering), RibocloneR M-MLV(H-) cDNA synthesis system (Promega, USA), eukaryotic expression carrier pEGFP2-C2 (Clontech, USA), restriction endonucleases *Xho* I and *Sal* I , T4 DNA lygase (Huamei Bio-engineering Co), Taq enzyme (Takara, Japan), plasmid extraction purification kit, PCR recycling kit and gel DNA recovery kit (Shanghua Shunhua Bio-engineering, China).

Experimental animals and groupings

There were five *in vitro* experimental groups: normal hepatocyte culture (lean liver cells, A1 group); normal hepatocyte culture + TNF-α (lean liver cells + TNF-α, A2 group); fatty liver cell culture (A3 group); fatty liver cell culture + TNF-α treatment (A4 group); and fatty liver cell culture + TNF-α treatment + UCP-2 inhibition (A5 group). There were three *in vivo* experimental groups ($n = 20$ in each group): normal mouse I/R group (lean mice, B1 group); ob/ob mouse I/R group (obesity mice, B2 group); and ob/ob mouse I/R + UCP-2 inhibition (B3 group).

Mouse I/R model and primary culture of hepatocytes

Under anesthesia, mice were laparotomized, the portal and hepatic veins were ligated by non-invasive vessel clamp for 15 min, then re-opened to establish the I/R model. Hepatocytes were isolated using the collagenase perfusion method[21]. Mice were anesthetized and laparotomized to explore the liver hilus. After intubation of the portal vein, HEPES-buffered Hank's solution (pH 7.4) containing EGTA was perfused into the portal vein at 37℃, and subsequently, the tissues were perfused with collagenase Ⅳ buffer (0.5%) containing Ca^{2+} for digestion. Digested hepatocytes were harvested, re-suspended in culture medium, filtered through a sieve, centrifuged at low speed, and washed with PBS. Non-parenchymal cells were removed with Percoll by centrifugation. Hepatocytes were washed with PBS, centrifuged and stained with Trypan blue to assess cell viability. Hepatocytes were prepared into single cell suspensions and added to a six-well culture plate (1.2×10^6 cells/well) with addition of 2 mL DMEM containing 5% FBS incubated in a 5% CO_2 incubator at 37℃. Eight hours later, the solution was changed, and then changed every 48 h.

Construction and transfection of UCP-2 antisense plasmids

Mouse UCP-2 mRNA was extracted from adipose tissue and a cDNA library. Mouse full-length UCP-2 cDNA was synthesized by the Riboclone M-MLV(H-) cDNA synthesis technique and PCR. The primer was designed according to the Green fluorescent protein (GFP) reading frame of eukaryotic expression carrier pEGFP2-C2, which allowed the coding region reading frame of UCP-2 consistent with that of GFP. Antisense plasmid was constructed with a pair of primers with SalI restriction sites at the 5' end and XhoI restriction sites at the 3' end. Sequences of primers used for construction of UCP-2 fluorescent eukaryotic expression carrier, which was synthesized by Shanghai Bio-engineering was as follows:

P1 *Sal* I 5'-3': 5'-ATGTCGACGTCGGAGATACCAGAG CACT-3';

P2 *Xho* I 5'-3': 5'-TTCTCGAGGTGACCTGC GCTGTG GTACT-3'.

PCR products were cut by *Xho* I and *Sal* I restriction enzymes and linked to the enkaryotic expression carrier pEGFP-C2 (pEGFP-C2-UCP2-antisense). After the construction was identified to be successful, the transfected competent Escherichia coli were cultured and the extracted plasmids were recombined with reverse transcriptional viruses. In B3 group, the mice were transfected with UCP-2 plasmids via the portal vein at the same time as the vessel opening.

Sampling and detection

In all cultured cell groups, cells was added with different concentration of TNF-α (0, 2.5, 5, 10 ng/mL) at 48 h. In A5 group, fatty liver cells were transfected with UCP-2 plasmids after 8 h of culture when the medium were exchanged. Twenty-four hours after TNF-α stimulation, i.e. after 72 h culture, the cells and supernatants were harvested, centrifuged, and stored at -80℃ for later use. In the I/R models, four animals in each group were killed at the time points of reperfusion, at 0.5, 2, 6, 12 and 25 h. Blood was taken from the heart, centrifuged at 3200 r/min for 5 min at room temperature, and the serum was separated, frozen and stored at -80℃ for later detection. Simultaneously, some liver tissues were frozen and stored in liquid nitrogen, and other liver tissues were fixed with 4% paraformaldehyde, embedded with paraffin, stained with HE, and observed pathologically under a light microscope.

The TNF-α levels in the supernatants and serum were determined by ELISA, and each sample was duplicated. The serum levels of alanine aminotransferase (ALT) were tested by the velocity method.

Expression of UCP-2 in the cells and liver tissues was detected by using RT-PCR[22]. In brief, total RNA of each sample was extracted, the purity and concentration were assayed by DNA/Protein Analyzer, and the same total RNA concentration in each group was adjusted. cDNA was prepared by reverse transcription. The primer sequences of UCP-2 for PCR amplification were as follows: F, 5'-ATGGTTGGTTCAAGGCCAC-3'; R, 5'-TCATGAGGTTGGCTTTCAGG-3'[23]. The reaction conditions included: 94℃ for 3 min; 94℃ for 30 s,

Table 1 Serum TNF-α levels in I/R mice (pg/mL) at various time points after reperfusion

Group	Serum TNF-α levels				
	0.5 h	2 h	6 h	12 h	24 h
B1	59 ± 7	81 ± 11	153 ± 23	196 ± 35	278 ± 43
B2	106 ± 16[a]	142 ± 24[a]	231 ± 31[a]	316 ± 47[a]	394 ± 52[a]
B3	97 ± 17[a]	151 ± 21[a]	244 ± 27[a]	332 ± 45[a]	401 ± 48[a]

[a]$P < 0.05$ B2 *vs* B1; and B3 *vs* B1.

and 60℃ for 1 min (45 cycles). The products were electrophoresed with 1.5% agarose gel. The sample expression of mRNA was calculated according to the following formula: Relative value of the detected samples $= 2^{(\Delta Ct_{\text{detected sample}}-\Delta Ct\beta\text{-actin})}$; $\Delta Ct = Ct_{\text{negative control}} - Ct_{\text{detected sample}}$.

Statistical analysis

UCP-2 mRNA, TNF-α and ALT levels were expressed as the mean ± SD and analyzed by using SPSS10.0 software. Comparison of the same index in various groups was performed by using ANOVA and the *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

TNF-α levels in cell culture and I/R model

TNF-α levels in A2, A4 and A5 groups differed significantly. TNF-α levels at the five time points after reperfusion in the B1, B2 and B3 groups are shown in Table 1. Results indicated that TNF-α levels in the B2 and B3 groups were significantly higher than that in the B1 group ($P < 0.05$), but there was no significant difference between the B2 and B3 groups.

Expression levels of UCP-2 in cultured hepatocytes and I/R models

Fluorescent quantitative PCR analysis revealed that in the A1, A2, A3, A4 and A5 groups, expression levels of UCP-2 were 0.125 (0.117-0.134), 1.558 (1.548-1.636), 1.079 (1.007-1.157), 2.949 (2.670-3.278) and 0.732 (0.660-0.812), respectively. It was indicated that in the A2 and A4 groups, the expression levels of UCP-2 were significantly higher than in the corresponding non-stimulated groups ($P < 0.05$). The expression level in the A4 group was significantly higher than in any other group, and in the A5 group, UCP-2 expression was significantly reduced as compared with that in the A4 group ($P < 0.05$). In the B1 group, expression levels of UCP-2 in liver tissues at the five time points after reperfusion were 0.252 (0.248-0.255), 0.287 (0.281-0.293), 0.401 (0.389-0.412), 0.432 (0.427-0.438) and 0.470 (0.438-0.503), respectively; those in the B2 group were 0.940 (0.883-1.000), 1.020 (1.016-1.024), 1.309 (1.241-1.382), 1.469 (1.360-1.587) and 1.629 (1.478-1.796), respectively; and those in the B3 group were 0.320 (0.255-0.402), 0.400 (0.333-0.481), 0.530 (0.467-0.602), 0.570 (0.510-0.638) and 0.621 (0.564-0.682), respectively. The expression level in B3 was significantly lower than in B2, which suggests that the expression of UCP-2 was inhibited (Figures 1 and 2).

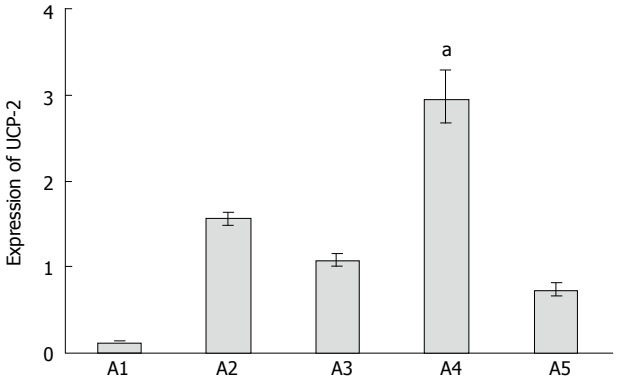

Figure 1 Expression levels of UCP-2 in cell culture. [a]$P < 0.05$ *vs* A5.

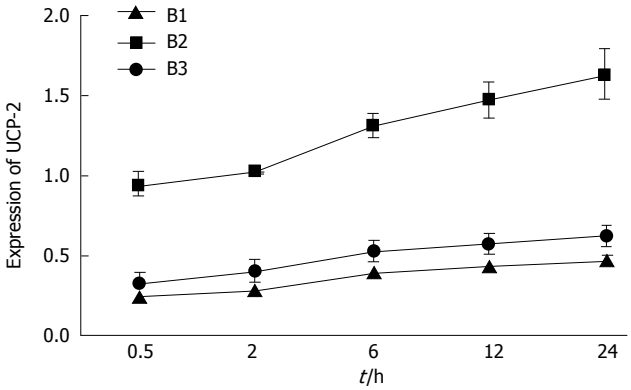

Figure 2 Expression levels of UCP-2 in I/R models.

Serum ALT levels in I/R model mice

In all I/R model mice, serum ALT levels were increased. ALT levels in the B1, B2 and B3 groups were 296 ± 65, 952 ± 147 and 301 ± 74 U/L, respectively. Statistical analysis revealed that ALT levels in the B2 group were significantly higher than those in the other two groups. Among the three groups, B3 had a significantly decreased ALT level after transfection of the plasmids that inhibited expression of UCP-2, which suggests that inhibition of UCP-2 expression can alleviate liver injury.

Pathological examination of liver tissues

In the B1 group, swelling and hydropic degeneration of hepatocytes and hepatic sinusoid endothelial cells, stasis of hepatic sinusoids, and disorder of sinus funiculus were seen. There was exfoliation of partial endothelial cells in the central vein, vacuolar degeneration of hepatocytes on the peripheral zone, and local necrosis in hepatic lobules and at the region adjacent to the portal area. In the B2 group, the above pathological changes were aggravated, and showed multiple local necrosis. However, in the B3 group, the pathological changes in liver tissues were significantly alleviated as compared with those in B2 group (Figure 3).

DISCUSSION

It has been reported that UCP-2 is not expressed in normal liver tissues, but is over-expressed in fatty liver[24].

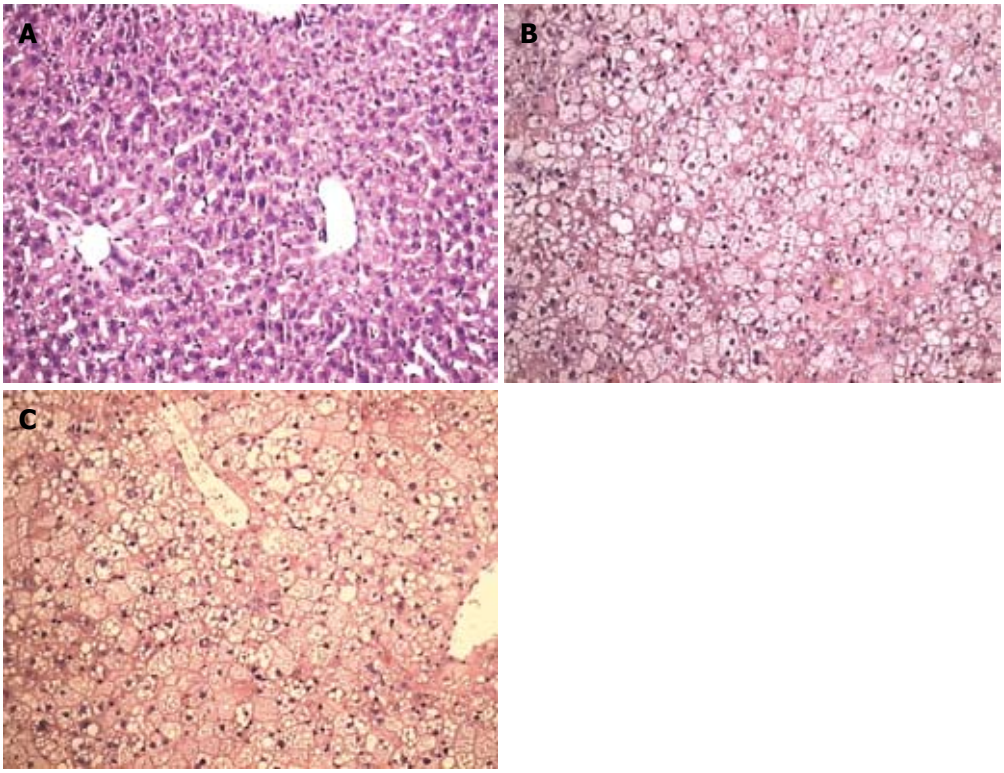

Figure 3 In the B1 group, swelling and hydropic degeneration of hepatocytes and hepatic sinusoid endothelial cells, stasis of hepatic sinusoids, and disorder of sinus funiculus were seen. There was exfoliation of endothelial cells in the central vein, vacuolar degeneration of hepatocytes at the peripheral zone, and local necrosis in hepatic lobules and at the region adjacent to the portal area (HE, × 200); In the B2 group, the pathological changes in Figure 1 were aggravated, showing multiple local necrosis (HE, × 200); In the B3 group, the pathological changes in liver tissues were significantly alleviated as compared with those in B2 (Figure 3B).

Moreover, the abnormal over-expression of UCP-2 in fatty liver can result in a decrease of hepatic ATP content[25,26]. Studies by Chavin *et al* have discovered that in ob/ob mice (approximately 70%-80% of liver lipid content) expression of UCP-2 is four to five times higher than in normal liver tissues, and the ATP content is decreased in mitochondria[27]. In normal conditions, over-expression of UCP-2 does not result in abnormal levels of serum ALT, bile acid metabolites and clotting factors, but under stress conditions, e.g. I/R, over-expressed UCP-2 can lead to severe hepatic cell injury because of ATP reserve deficiency[28,29]. In this study, it was found that in primary culture of fatty liver cells and ob/ob mouse I/R models, expression of UCP-2 was significantly higher than that in normal liver cells and normal mouse I/R models, and TNF-α levels in ob/ob mice were significantly higher than those in normal mice. However, in fatty liver cells stimulated with TNF-α, expression of UCP-2 was significantly higher than that in other cultured cells, which suggests that increased serum TNF-α levels can further enhance the increased expression of UCP-2 in fatty liver tissues. Previous studies have also revealed that TNF-α can induce the expression of UCP-2 in normal hepatocytes and mouse liver tissues, and it is believed that the increased TNF-α is related to lipopolysaccharide (LPS) stimulation[17,30]. Therefore, in I/R, LPS stimulation can result in increased TNF-α levels, which in turn induce higher expression of UCP-2 in fatty liver cells, which causes further decrease of the ATP reserve in hepatocytes, which subsequently aggravates the I/R injury in fatty liver. In this study, the plasmids that inhibited UCP-2 expression were constructed and transfected into hepatocytes and the mouse I/R models, and it was found that expression of UCP-2 mRNA was significantly reduced, which was not related to TNF-α levels. Simultaneously, in the model with transfected mice, serum ALT levels were significantly lower than those in non-transfected mice, and hepatic pathological examination revealed that the I/R injury of liver tissues was alleviated, which suggests that targeting inhibition of UCP-2 expression in fatty liver may protect ob/ob mice from I/R injury. In future studies, the role of UCP-2 expression inhibition in obese mouse liver transplantation will be further investigated.

COMMENTS

Background

Primary graft non-function (PNF) after fatty liver transplantation was related to liver ischemia-reperfusion (I/R) injury during transplantation. Uncoupling protein 2 (UCP-2) has shown a close relationship with I/R injury of fatty liver transplantation by mediating proton leak and interfering with mitochondrial ATP synthesis

Research frontiers

The impact of UCP-2 deficiency during acute liver injury has been investigated recently, and it has been found that lack of UCP-2 reduces Fas-mediated liver injury in ob/ob mice. Although ablation of UCP2 may have no significant impact on steatosis-induced changes in ROS production of Kupffer cells, it alleviates the energy compromise in acutely challenged fatty hepatocytes.

Innovations and breakthroughs

UCP-2 has been reported to be closely related to I/R injury of steatotic liver. However, the direct link between UCP-2 expression and susceptibility of fatty liver to I/R injury is lacking. This study considered UCP-2 as a therapeutic target and investigated its role in fatty liver I/R injury *in vitro* and *in vivo*. The results showed that suppression of UCP-2 expression alleviated I/R injury of fatty liver in mice. This may provide a new gene therapy target.

Applications

The result of this study indicated that UCP-2 could be an effective gene therapy target of fatty liver I/R injury. By suppressing UCP-2 expression, more steatotic liver donors may be used in liver transplantation, and partially alleviate the shortage of donor livers.

Terminology

UCP-2 is an inner mitochondrial membrane carrier. It mediates proton leak and allows the dissipation of the proton electrochemical gradient, which results in the uncoupling of oxidation and ATP synthesis. ROS include superoxide, hydrogen peroxide, and hydroxyl radicals. At low levels, these species may function in cell signaling processes. At higher levels, these species may damage cellular macromolecules.

Peer review

This is a well written and interesting manuscript. The authors demonstrated the alleviation of I/R injury in ob/ob mice by inhibiting UCP-2 expression.

Abstract

AIM: To investigate the changes of methylation state and expression of RASSF1A gene in human gastric cancer cell lines SGC7901 and BGC823 which were treated *in vitro* with demethylating agent 5-Aza-CdR in combination with histone deacetylase inhibitor NaB.

METHODS: After SGC7901 and BGC823 cells were treated with 5-Aza-CdR and/or NaB, the methylation state of RASSF1A gene was detected by methylation-specific PCR, and the changes in expression of mRNA and protein level of RASSF1A gene were observed by RT-PCR and Western-blotting before and after drug treatment.

RESULTS: Hypermethylation was detected in the promoter region of RASSF1A gene in both SGC7901 and BGC823 cells, and there was no expression of this gene at both mRNA and protein level. After treatment with 5-Aza-CdR, demethylation occurred in the promoter region of RASSF1A gene, which subsequently induced re-expression of this gene. The treatment with NaB alone showed no effect on the methylation state and expression of RASSF1A gene. The combined treatment of 5-Aza-CdR and NaB induced complete demethylation of RASSF1A gene, leading to a significantly higher re-expression of the mRNA and protein of RASSF1A than those treated with 5-Aza-CdR alone ($P < 0.05$).

CONCLUSION: Hypermethylation in the promoter region is related to inactivation of RASSF1A gene in human gastric cancer cell lines SGC7901 and BGC823, while demethylating agent 5-Aza-CdR can reverse the methylation state of RASSF1A gene and induce its re-expression. Histone deacetylase inhibitor NaB had a synergistic effect with 5-Aza-CdR in both demethylation and gene transcriptional regulation.

INTRODUCTION

Gastric cancer is a malignant tumor which seriously threatens the human health worldwide. It has been shown that the occurrence of gastric cancer is a multi-gene-involved, multi-stage pathological process under the action of both genetic and epigenetic factors, and that epigenetic mechanism plays an important role in the occurrence and development of gastric cancer[1-4]. Various factors can lead to the loss of function of tumor suppressor genes (TSGs). It has been confirmed that DNA methylation is the third, sometime the only mechanism for the inactivation of TSG, besides gene mutation and deletion[5]. The Ras associated domain family gene 1A (RASSF1A) is an established TSG that can inhibit cell growth, and promote apoptosis and senescence through various ways[6-9]. The methylation in the promoter region of RASSF1A gene can cause depletion of RASSF1A expression, thereby leading to occurrence of tumors, which has been confirmed in human gastric cancer[10,11]. Since the regulation of gene expression by abnormal methylation is reversible, demethylating agents could be used to induce re-expression of the inactivated genes due to methylation[12]. Therefore, changing the CpG island state in the gene promoter region is a potential method for clinical treatment of cancers[13]. The demethylating agent 5-Aza-2'-deoxycytidine (5-Aza-CdR) is a cyto-

sine analogue formed by modified C-5 position of pyrimidine, and used as a DNMT (DNA methyltransferase) inhibitor for the clinical treatment of leukemia[14,15]. Histone acetylation may be related to the occurrence of human gastric cancer[16]. DNA methylation and histone acetylation are associated with each other in the epigenetic regulation of gene expression, and they together play an important role in the occurrence of tumors. They affect each other and likely have the synergistic effect[17]. Therefore, the combined treatment of demethylating agent and histone deacetylase inhibitor can induce the gene demethylation, reverse the transcriptional inhibition, and make the gene re-express, which might be used for the clinical treatment of tumors[18].

In this study, the gastric cancer cell lines were treated *in vitro* with demethylating agent 5-Aza-CdR in combination with histone deacetylase inhibitor NaB (sodium butyrate) so as to investigate the changes in methylation state and expression of RASSF1A gene before and after drug treatment, and to further explore the roles of these two drugs in regulating RASSF1A gene expression. The results will provide the experimental evidences for the clinical therapy.

MATERIALS AND METHODS

Materials

The main materials used included human gastric cancer cell lines SGC7901 and BGC823 (Department of Cell Biology of China Medical University), RPMI 1640 medium (Hyclone), 5-Aza-CdR (Sigma), NaB (Sigma), hydroquinone (Sigma), sodium bisulfite (NaHSO3) (Sigma), Wizard DNA Clean-up (Promega), glycogen (New England Biolabs), SssI (New England Biolabs), Taq enzyme (Takara), dNTPs (Takara), DMSO (Sigma), the RT-PCR Kit (TaKaRa), the sheep anti-human RASSF1A polyclonal antibody (Santa Cruz) and the TRIzol reagent for total RNA extraction (GIBCO BRL).

Methods

Cultivation of human gastric cancer cell lines: BGC823 and SGC7901 cells were grown in RPMI 1640 medium containing 10% fetal bovine serum at 37℃ with 50 mL/L CO_2. At the logarithmic phase of cell growth, with a percentage of viable cells over 95%, the cells were remained hungry for 24 h in the RPMI 1640 medium containing 1% fetal bovine serum, followed by the drug treatment. Cells were transferred every day into the fresh medium containing 5-Aza-CdR or NaB at its experimental dosage. In the fifth day of cultivation, cells were harvested for further analysis. The cells without the intervention of medicine were used as the control group.

Experimental groups: (1) 5-Aza-CdR treatment groups at the dosage of 1.0 or 3.0 μmol/L; (2) NaB treatment groups at the dosage of 1.0 or 3.0 mmol/L; (3) Combined treatment groups: 5-Aza-CdR at 1.0 μmol/L in combination with NaB at 1.0 mmol/L, and 5-Aza-CdR at 3.0 μmol/L in combination with NaB at 3.0 mmol/L. The gastric cancer cells were first treated with 5-Aza-CdR at 1.0 or 3.0 μmol/L for 48 h, followed by washing, and then were treated with NaB at 1.0 or 3.0 mmol/L for 72 h; the cells were then harvested for further analysis.

Detection of methylation state of RASSF1A by MSP: Different groups of BGC823 and SGC7901 cells were harvested after five days treated with different drugs, and cellular DNA was isolated from the harvested cells using phenol-chloroform-isoamyl alcohol assay. The concentration and purity of DNA were detected by the UV spectrophotometry. DNA modification and purification were conducted as described previously[19].

Methylation-specific PCR reaction: Total reaction mixture volume of 25 μL, containing 2 μL DNA, 2.5 μL 10 × PCR buffer, 0.5 μL each of the sense and antisense primers, 2 μL dNTPs, 0.2 μL Taq enzyme, and 17.3 μL double-distilled water. Reaction condition: pre-denatured at 95℃ for 5 min, followed by 35 cycles of 94℃ for 30 s, 58℃ for 45 s, and 72℃ for 30 s, and with a final extension at 72℃ for 10 min. The annealing temperature was 58℃ for the methylated reaction, while 57℃ for the un-methylated reaction. The methyltransferase SssI-treated and untreated peripheral blood cell DNA from the healthy adults were used as the positive and negative controls respectively, while the double-distilled water as the blank control. The 1000 bp DL2000 was used as the molecular weight markers. The sequences of the methylated primers are as follows: the upstream primer 5'-GTGTTAACG CGTTGCGTATC-3' and the downstream primers 5'-A ACCCCGCGAACTAAAAACGA-3', generating a 94 bp PCR product, while the un-methylated primers are: the upstream primer 5'-TTTGGTTGGAGTGTGTTAATG TG-3' and the downstream primers 5'-CAAACCCCACAA ACTAAAAACAA-3', generating a 108 bp PCR product. The PCR products were subjective to the 2% agarose gel electrophoresis at 100 V for 40 min. The gels were photographed using a laser density scanner (Pharmacia LKB Ultroscan) for analysis. Each experiment was repeated five times.

Analysis of mRNA expression of RASSF1A by semi-quantitative RT-PCR: The cellular total RNA was isolated using the Trizol reagent from the harvested cells. The cDNAs were synthesized from the templates in presence of reverse transcriptase and oligo $(dT)_{20}$ primers. The upstream and downstream RASSF1A mRNA primers were 5'-GGC GTCGTGCGCAAAGGCC-3' and 5'-GGGTGGCTTCT TGCTGGAGGG-3' respectively, generating a 330 bp PCR product at the annealing temperature of 67℃. The β-actin was used as the internal control, and its upstream and downstream primers were 5'-GTGGGGCGCCCCAGGC ACCA-3' and 5'-CTCCTTAATGTCACGCACGATTTC-3' respectively, generating a 498 bp PCR product. Twenty-five μL PCR reaction mixture was pre-denatured at 95℃ for 2 min, and 35 cycles of 94℃ for 40 s, 67℃ for 40 s, and 72℃ for 60S were performed with a final extension at 72℃ for 6 min. The RT-PCR products were subjective to the 2% agarose gel electrophoresis. The gels were photographed using an Alpha Image 2000 automatic formatter, and the amount of each PCR product was analyzed using the Fluorchem V 2.0 Stand Alone software. The scanning

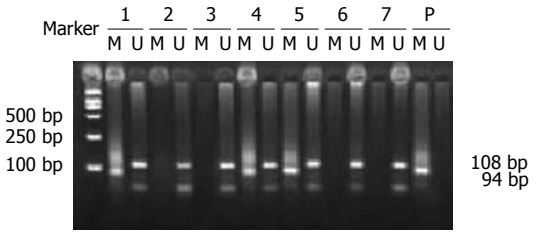

Figure 1 Change in methylation state of RASSF1A gene in gastric cancer cell line SGC7901. Markers: DL2000; 1-7: Control, 5-Aza-CdR at 1.0 μmol/L, 5-Aza-CdR at 3.0 μmol/L, NaB at 1.0 mmol/L, NaB at 3.0 mmol/L, 5-Aza-CdR at 1.0 μmol/L in combination with NaB at 1.0 mmol/L, and 5-Aza-CdR at 3.0 μmol/L in combination with NaB at 3.0 mmol/L; P: Positive control; M: Methylated result; U: Un-methylated result; 1, 4 and 5: Methylation positive, 94 bp; 2, 3, 6 and 7: Methylation negative, 108 bp.

Table 1 mRNA expression of RASSF1A gene in gastric cancer cell lines SGC7901 and BGC823

	1	2	3	4	5	6	7
SGC7901	0	0.29 ± 0.03	0.45 ± 0.05	0	0	0.75 ± 0.04[a]	0.88 ± 0.09[a]
BGC823	0	0.36 ± 0.05	0.64 ± 0.07	0	0	0.82 ± 0.09[a]	0.89 ± 0.05[a]

[a]$P < 0.05$, *vs* groups 2 and 3 ($F_{SGC7901} = 208.83$, $P < 0.001$, $F_{BGC823} = 62.10$, $P < 0.001$).

optical density of each band was taken as the indicator of the gene expression level. Taking the β-actin as the internal control, the ratio of scanning density of RASSF1A gene to that of β-actin was obtained. The ratio values used as the analyzing index were further compared between different experimental groups to investigate the changes in mRNA expression of RASSF1A. Each experiment was repeated five times.

Analysis of protein expression of RASSF1A by Western blotting: 200 μL of cell lysis buffer was mixed with 40 μL harvested cells to isolate the total cellular protein, and then quantitated by the phenol reagent method, 100 μL of the total protein was denaturated for 10 min, and 25 μL was taken for the 10% polyacrylamide gel electrophoresis. The proteins separated by the electrophoresis were then transferred onto the PVDF membrane, and the 10% skim milk used to block the PVDF membrane at room temperature for 1 h. The PVDF membranes were incubated in the 1:200 dilution of the primary antibody at 4℃ overnight, and then in the 1:2000 diluted alkaline phosphatase-labeled secondary antibody solution at 37℃ for 2 h, followed by the DAB coloration. The PVDF membranes were photographed using a ChemiImager 5500 AlPhaInn Ch, and the subsequent data acquisition and mining were conducted with the Fluorchem V2.0 system. Taking the expression level of β-actin protein as the internal control, the ratio of scanning density of RASSF1A protein to that of β-actin was finally calculated and used as the analyzing index to further investigate the changes in protein expression of RASSF1A and compare them between different experimental groups. Each experiment was repeated five times.

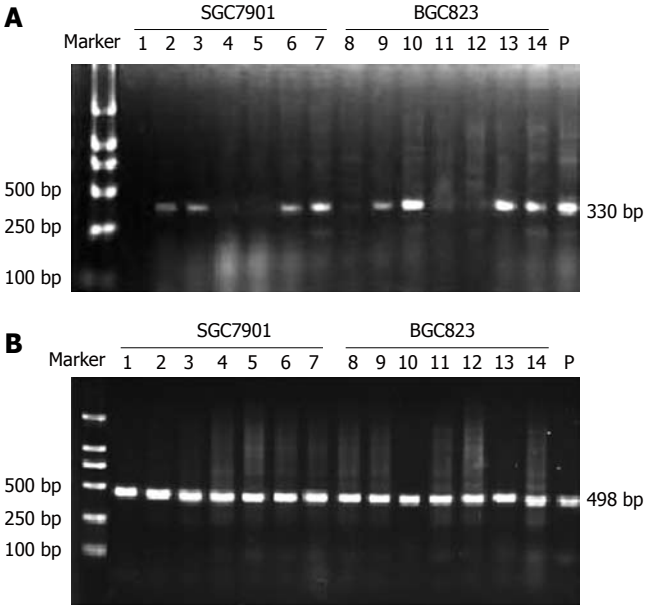

Figure 2 **A**: Change of mRNA expression of RASSF1A gene in gastric cancer cell lines SGC7901 and BGC823. Markers: DL2000; 1-7 and 8-14: Control, 5-Aza-CdR at 1.0 μmol/L, 5-Aza-CdR at 3.0 μmol/L, NaB at 1.0 mmol/L, NaB at 3.0 mmol/L, 5-Aza-CdR at 1.0 μmol/L in combination with NaB at 1.0 mmol/L, and 5-Aza-CdR at 3.0 μmol/L in combination with NaB at 3.0 mmol/L of SGC7901 and BGC823 respectively; P: Positive control, 330 bp; **B**: mRNA expression of β-actin in gastric cancer cell lines SGC7901 and BGC823.

Statistical analysis

Statistical analyses were performed using the SPSS11.5 software package (SPSS, Inc, Chicago, IL). Data were reported as median (minimum-maximum) unless otherwise stated. Continuous variables were compared by the analysis of variance (ANOVA), and multiple comparisons were analyzed by the LSD.

RESULTS

Methylation state of RASSF1A gene

Hypermethylation in the promoter region of RASSF1A gene was detected in gastric cancer cell lines SGC7901 and BGC823, and demethylation appeared after treatment with 5-Aza-CdR for five days, while NaB had no influence on its methylation state. The combined use of 5-Aza-CdR and NaB induced complete demethylation of RASSF1A gene in both SGC7901 and BGC823 cells (Figure 1).

mRNA transcription of RASSF1A gene

There was no mRNA transcription of RASSF1A gene in SGC7901 and BGC823 cells, and it re-expressed after treatment with 5-Aza-CdR for 5 d, while NaB had no influence on its expression. The combined use of 5-Aza-CdR and NaB induced higher re-expression of RASSF1A gene at the mRNA level than the use of 5-Aza-CdR alone ($P < 0.05$) (Figure 2; Table 1).

Protein expression of RASSF1A gene

There was no expression of RASSF1A protein in SGC7901 and BGC823 cells, and it re-expressed after treatment with 5-Aza-CdR for 5 d, while NaB had no

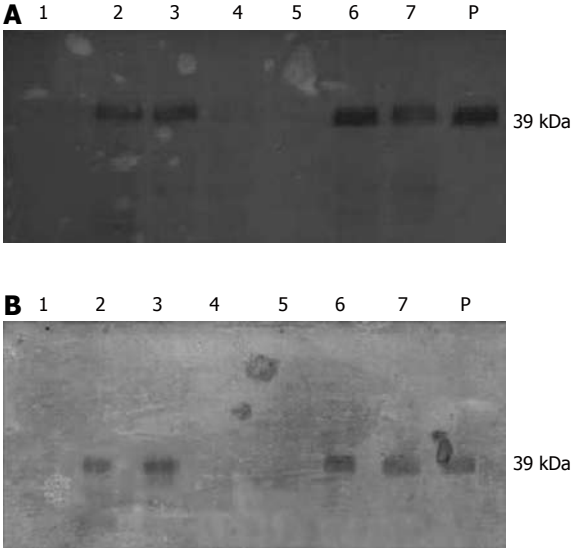

Figure 3 **A**: Change of protein expression of RASSF1A gene in gastric cancer cell line SGC7901; **B:** Change of protein expression of RASSF1A gene in gastric cancer cell line BGC823. 1-7: Control, 5-Aza-CdR at 1.0 μmol/L, 5-Aza-CdR at 3.0 μmol/L, NaB at 1.0 mmol/L, NaB at 3.0 mmol/L, 5-Aza-CdR at 1.0 μmol/L in combination with NaB at 1.0 mmol/L, and 5-Aza-CdR at 3.0 μmol/L in combination with NaB at 3.0 mmol/L; P: Positive control, 39 kDa.

influence on its expression. The combined use of 5-Aza-CdR and NaB induced higher re-expression of the RASSF1A gene at the protein level than the use of 5-Aza-CdR alone ($P < 0.05$) (Figure 3A and B, Table 2).

DISCUSSION

The gene transcriptional regulation in eukaryotes is a complex, multi-step process, and the covalent modification of chromatin participates in the regulation of transcription initiation[20]; it can occur in both DNA and histone. DNA modification is primarily the cytosine methylation, while the covalent modifications of histone include acetylation, phosphorylation, methylation, ubiquitination, and ADP-ribosylation, which thereby constitute the histone code[21]. The occurrence of tumors is a process under the mutual action of genetic and epigenetic mechanisms. The epigenetic molecular mechanisms include DNA methylation, histone modification, chromatin remodeling and RNA interference, all of which play important roles in gene transcriptional regulation[22].

As shown in this study, the action of 5-Aza-CdR on gastric cancer cell lines SGC7901 and BGC823 resulted in the demethylation of RASSF1A gene accompanied by the re-transcription of mRNA and re-expression of protein; this confirmed that 5-Aza-CdR regulated the transcription of RASSF1A gene. DNA methylation regulates gene expression, while the DNA hypomethylation promotes gene expression and DNA hypermethylation inhibits it[5]. 5-Aza-CdR is a cytidine analogue; as a demethylating agent, its mechanism of action is primarily through its covalent bonding to DNMT, which will reduce the biological activity of DNMT, thus lowering the methylation level and regulating gene expression[23]. The demethylation of TSGS by 5-Aza-CdR has been reported[24]. It has been shown recently that the mechanism of action of 5-Aza-CdR is

Table 2 Protein expression of RASSF1A gene in gastric cancer cell lines SGC7901 and BGC823

BGC823	0	0.45 ± 0.03	0.65 ± 0.08	0	0	0.78 ± 0.04[a]	0.83 ± 0.06[a]

[a]$P < 0.05$, compared with groups 2 and 3 ($F_{SGC7901} = 14.41$, $P < 0.001$, $F_{BGC823} = 46.01$, $P < 0.001$).

likely to inhibit the activity of DNMT3a and DNMT3b[25]. After the action of 5-Aza-CdR, the transcription inhibitor MBD brake away from the demethylated DNA or the transcription repression complex that originally bonded to MBD, and then form to its activated conformation of chromatic body[26]. Whether the gene expression is re-activated after the demethylation of this gene by 5-Aza-CdR, depended on the following two factors: (1) whether the hypermethylation of the CpG island in the gene promoter region is reversed; (2) whether there is the simultaneous existence of a transcription activator to activate the specific target promoter[27]. For some of genes, 5-Aza-CdR alone is sufficient to induce the activation and expression, which can be used to explain the reversed expression of RASSF1A gene in the gastric cancer cells, as observed in the present study. This is supported by the report by Byun *et al*[10].

With the action of NaB, there was no change in the methylation state and expression of RASSF1A gene in both SGC7901 and BGC823 cells. In the eukaryotes, histone is an important component of the elementary structure of chromatin-nucleosome, of which the "N" terminal can be covalently modified such as acetylation. The acetylation of histone is a reversible dynamic process; the acetylized chromatin was related to transcriptional activation, while the desacetylizad chromatin was related to transcription inhibition[28]. The common mechanism of action of histone deacetylase inhibitors HDACIs is to inhibit the histone deacetylation so as to enhance the acetylation level of histone, by which the gene expression was up-regulated[29]. Among HDACIs, the NaB is a kind of nontoxic short-chain fatty acid that has been proved to inhibit the proliferation of cancer cells *in vivo* and *in vitro*, to induce the apoptosis, to promote the cell differentiation and to block the cell cycle[30,31]. It has the potential for the clinical therapy of malignant cancers such as breast cancer, colorectal cancer, endometrial cancer[32] and so on. It has been shown that[33] HDACIs can raise the acetylation level of histone, and change the chromatic structure, thereby inducing the transcriptional activity of some genes. Selker *et al*[34] reported that another HDACI-TSA (trichostatin A) could selectively down-regulate the methylation level of some genes in Neurosporae, but the use of NaB alone has no effect on the gene expression of RASSF1A, which was supported by Lynch *et al*[35].

In this study, the up-regulation of RASSF1A gene under the combined treatment of 5-Aza-CdR and NaB was significantly higher than that under the use of 5-Aza-CdR alone, indicating that the demethylating agent 5-Aza-CdR and the deacetylase inhibitor NaB had a synergistic effect in transcriptional regulation; this was consistent

with the results by Egger *et al*[36]. As shown previously, both DNA methylation and histone acetylation were closely related to the regulation of gene expression. DNA methylation could induce the acetylation of the local histone, and could decrease the chromatin acetylation level[5]. The methylated CpG-binding protein MeCP2 bonded to chromatin by a methylation-dependent manner; through its transcriptional repression domain, MeCP2 was closely related to the inhibition complex consisting of the pontine proteins Sin3A and HDAC[37]. The methylation of promoter region and the histone deacetylation are synergistic in the inhibition of gene transcription. However, the inhibitive effect of histone deacetylation on gene transcription relies on the number of methylation sites. If the mCpG in the promoter region is at low density, the pathway of histone deacetylation plays a major role in inhibiting gene transcription. Under the condition that the number of methylation sites in the promoter region increased to the threshold value that is large enough to lead to the extensive silence of gene expression, the pathway of histone deacetylation plays a secondary role in inhibiting gene transcription. Moreover, the pathway of DNA methylation will play the leading role in the gene transcriptional regulation, and it can inhibit the gene transcription by the manner independent of the histone deacetylation[38]. The rational explanation for the mechanism of synergistic action of 5-Aza-CDR and NaB is that NaB promotes the formation of the activated conformation of chromatic body with the action of 5-Aza-CDR[39]. Fahrner *et al*[40] demonstrated that DNA methylation could maintain the inhibition state of the key histones in the hypermethylated promoter regions, directly or indirectly through the transcriptional inhibition. And there is inducible demethylation of hMLH1 gene in the RKO colon cancer cell line 12 h after the 5-Aza-CdR treatment, and reverse of the acetylation state of histone 48 h after the treatment. These also demonstrate the leading role of the DNA methylation in the transcriptional regulation.

The RASSF1A gene can inhibit cell growth, and promote apoptosis and senescence[7]. This study showed that the loss of expression of RASSF1A gene in gastric cancer cell lines SGC7901 and BGC823 was caused by the hypermethylation in the promoter region, the use of 5-Aza-CdR could result in the demethylation and the restoration of transcriptional activity of RASSF1A gene, and that NaB and 5-Aza-CdR were synergic in regulating the expression of RASSF1A gene. Hypermethylation of RASSF1A gene is closely related to the occurrence of gastric cancer. As RASSF1A gene promotes apoptosis and is also likely associated with the resistance to platinum chemotherapy, the effect of 5-Aza-CdR in conjunction with NaB on the regulation of RASSF1A expression is of significant value in clinical practice.

COMMENTS

Background

Epigenetic mechanism plays an important role in the occurrence and development of gastric cancer. As a tumor suppressor gene, the Ras associated domain family gene 1A (RASSF1A) has been reported to be hypermethylated in human gastric cancer, causing depletion of RASSF1A expression and occurrence of tumors. Histone acetylation may be related to the occurrence of human gastric cancer too. Since the regulation of gene expression by abnormal methylation is reversible, and DNA methylation and histone acetylation are associated with each other in the epigenetic regulation of gene expression, the combined treatment of demethylating agent 5-Aza-2'-deoxycytidine (5-Aza-CdR) and histone deacetylase inhibitor NaB (sodium butyrate) can induce the gene demethylation and reverse the transcriptional inhibition, and then cause the re-expression of the gene, including RASSF1A gene, which might be used for the clinical treatment of gastric cancer.

Research frontiers

DNA methylation and histone acetylation have been extensively studied in many aspects, especially the use of their inhibitors in laboratory and clinical trial for the treatment of human cancers. In high-risk myelodysplastic syndrome and chronic myelomonocytic leukemia, decitabine, one of the demethylating agents, was testified whether it can be used in clinical therapy.

Innovations and breakthroughs

In this study, the synergistic effect of demethylation and re-expression of RASSF1A gene was tested in human gastric cancer cell lines SGC7901 and BGC823 under the combined treatment of demethylating agent 5-Aza-CdR and histone deacetylase inhibitor NaB, which has laid an experimental foundation for epigenetic therapy in clinical treatment of human gastric cancer.

Applications

As hypermethylation and abnormal histone acetylation of RASSF1A gene may be related to the occurrence of human gastric cancer, 5-Aza-CdR and NaB might has a potential value in clinical treatment of human gastric cancer.

Terminology

Epigenetics is defined as modifications of the genome, heritable during cell division, that does not involve a change in the DNA sequence. Epigenetics includes DNA methylation, histone modification, chromatin remodeling and RNA interference molecularly, which play important roles in gene expression regulation. DNA methylation and histone acetylation are the two most widely studied epigenetic changes which regulate gene expression. DNA hypomethylation and hyperacetylation can up-regulate gene expression, while DNA hypermethylation and hypoacetylation can down-regulate gene expression. DNA methylation and histone acetylation interact closely.

Peer review

Shen *et al* showed that the treatment of two gatric cancer cell lines with a demethylating agent restored the expression of the tumor suppressor gene RASSF1A which was further enhanced by the addition of a histone deacetylase inhibitor. This effect of 5-Aza-CdR in conjunction with NaB on the regulation of RASSF1A expression may have a potential value in clinical practice.

Abstract

AIM: To determine the clinical, radiographic and pathologic characteristics, diagnostic and treatment modalities in patients with autoimmune pancreatitis (AIP).

METHODS: In this retrospective study, the data of patients with diagnosed chronic pancreatitis (CP) between 1995 and 2006 in Chinese PLA General Hospital were included to screen for the cases with AIP, according to the following diagnostic criteria: (1) diagnostic histopathologic features, and abound IgG4-positive plasma cells on pancreatic tissues; (2) characteristic imaging on computed tomography and pancreatography, together with increased serum IgG, γ-globulin levels or presence of autoantibodies; (3) response to steroid therapy. The clinical, radiographic and pathologic characteristics, diagnostic and treatment modalities, and outcome of AIP cases were reviewed.

RESULTS: Twenty-five (22 male, 3 female; mean age 54 years, 36-76 years) out of 510 CP patients were diagnosed as AIP, which accounted for 49% (21/43) of CP population undergoing surgical treatment in the same period. The main clinical manifestations included intermittent or progressive jaundice in 18 cases (72%), abdominal pain in 11 (44%), weight loss in 10 (40%), and 3 cases had no symptoms. The imaging features consisted of pancreatic enlargement, especially in the head of pancreas (18 cases), strictures of main pancreatic duct and intrapancreatic bile duct. Massive lymphocytes and plasma cells infiltration in pancreatic tissues were showed on pathology, as well as parenchymal fibrosis. Twenty-three patients were misdiagnosed as pancreaticobiliary malignancy, and 21 patients underwent exploratory laparotomy, the remaining 4 patients dramatically responded to steroid therapy. No pancreatic cancer occurred during a mean 46-mo follow-up period.

CONCLUSION: AIP patients always are subjected to mistaken diagnosis of pancreatic cancer and an unnecessary surgical exploration, due to its similarity in clinical features with pancreatic cancer. The differential diagnosis with high index of suspicion of AIP would improve the diagnostic accuracy for AIP.

INTRODUCTION

Autoimmune pancreatitis (AIP) is a unique chronic inflammation of the pancreas in which autoimmune mechanisms are involved in the pathogenesis[1-3]. Since Sarles *et al* first described AIP case in 1961[4], increasing numbers of AIP patients have been diagnosed worldwide[5-9]. Although AIP has distinct characteristics at clinical, radiologic, histologic, and serologic findings[1-3,8], due to the extreme similarity in clinical manifestations of pancreaticobiliary malignancies, the benign condition of AIP has frequently been diagnosed or suspected as pancreatic cancer, especially when clinicians have no awareness of AIP, which consequently impose the patients an unnecessary pancreatic resection[10-12].

The diagnosis of AIP is mainly based on the diagnostic criteria proposed by the Japan Pancreas Society (JPS) in 2002[13]. However, these criteria preclude many problematic cases with clinical findings compatible with AIP, as well as with excellent response to steroids, as a result of failure to fulfill the JPS criteria. Recently, some revised or new diagnostic criteria have been proposed[13-15], including the Mayo Clinic Criteria.

In this study, we reviewed 25 AIP patients from a single institution in China, and analyzed the clinical, radiographic and pathologic characteristics, diagnostic and treatment modalities, outcome, especially the encountered lessons, in order to improve the diagnostic accuracy for patients with AIP.

MATERIALS AND METHODS

Diagnostic algorithm and diagnostic criteria for assessment of AIP

The preliminary screening for AIP patients was carried out among 510 patients who were diagnosed as chronic pancreatitis (CP) between January 1995 and June 2006 in Chinese PLA General Hospital. Those who fit the etiology and diagnostic pictures of alcoholic, gallstone, or other recognized causes of classical CP were excluded initially[16], then the diagnosis of AIP was made in patients with $\geqslant$ 1 of these criteria among the remaining patients: (1) diagnostic histopathologic features, and abound IgG4-positive plasma cells on pancreatic tissues; (2) characteristic imaging on computed tomography and pancreatography, together with increased serum IgG, γ-globulin levels or presence of autoantibodies; (3) response to steroid therapy. Above diagnostic criteria derived from the combination of HISORt (histology, imaging, serology, other organ involvement, and its response to steroid therapy) criteria of Mayo Clinic[15] and other diagnostic criteria[11].

Finally, twenty-five patients met the above criteria for AIP, accounting for 4.9% of CP patients in the same time period.

Patients with AIP

The medical records of the 25 patients (22 males, 3 females; mean age 54 years, range 36-76 years) were reviewed. The mean course of onset of AIP is 2-mo (1-14 mo).

Diagnostic modalities for AIP

Ultrasonography and computerized tomography (CT) scanning were performed for all 25 patients, and endoscopic retrograde cholangiopancreatography (ERCP) was performed in 11 patients, and magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) were done in 7 patients.

Histopathologic examination for AIP

Ultrasound-assisted biopsy specimens of pancreatic lesions were obtained in 6 patients prior to surgery; and intraoperative resected or biopsy specimens of pancreatic lesions were obtained in 21 patients with AIP (2 had both pre- and intra-operative specimens). The specimens were fixed in 10% formaldehyde and embedded in paraffin. The pathologic diagnosis of AIP was made by the hematoxylin and eosin (HE)-stained sections and immunohistochemical staining using CD4, CD8, and IgG4 antibodies.

RESULTS

Clinical manifestations

The main clinical manifestations included intermittent or progressive jaundice in 18 patients (72%), mild epigastric pain or discomfort in 11 (44%), weight loss in 10 (40%), low-grade fever and chronic diarrhea in 2 each. Three patients had no symptoms. Twenty-four percent (6/25) of the AIP patients had a history of autoimmune disease (ulcerative colitis, n = 2; asthma, n = 1; Sjögren's syndrome, n = 1; systemic lupus erythematosus, n = 1; retroperitoneal fibrosis and nephrydrosis, n = 1); other comorbidities included diabetes mellitus (n = 5), chronic acalculous cholecystitis (n = 2), and suspected diagnosis of primary sclerosing cholangitis (n = 2). None of these patients had a history of excess alcohol consumption, or gallstones.

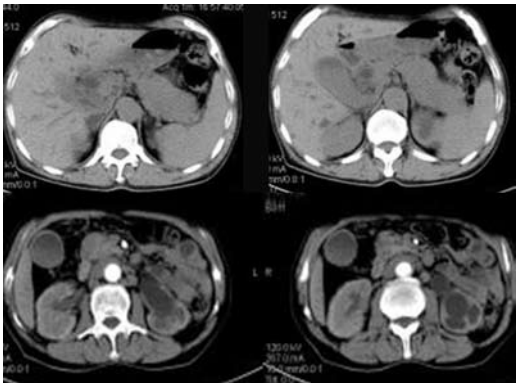

Figure 1 A patient with AIP, CT scan showed a diffusely enlarged pancreas with a sausage-like appearance, together with retroperitoneal fibrosis and nephrydrosis of left kidney.

Laboratory results

Twenty patients (80%) had obstructive jaundice and abnormal serum levels of aminotransferases (ALT and AST) and biliary enzymes (alkaline phosphatase, γ-glutamyltransferase). Hyperglycemia was found in 7 patients (28%), and abnormality of serum CA19-9 level (> 37 U/L) was found in 12 patients (12/19, 63%), among them, the CA19-9 level above 400 U/L in 4 patients. Abnormally elevated levels of serum γ-globulin and IgG were seen in 4 (4/5, 80%). The autoantibodies were determined in 5 patients, only rheumatoid factor, and anti-SSA/-SSB autoantibodies presented in 1 patient each. Mild elevated level of anti-mitochondrial antibody was found in 2. Other antibodies such as antinuclear antibody, antismooth muscle antibody were all negative. No hyperamylasemia was found in all patients.

Imaging features

The results of ultrasonography, CT, and MRI imaging demonstrated that all patients had abnormal alterations in pancreas, massive pancreatic enlargement (sausage-shaped, Figure 1) in 7 patients, and swelling of pancreatic head in 18 patients (Figure 2); the maximal diameter of pancreatic head > 5 cm in 6, and dilation of biliary trees in 18, and thickening of extra-hepatic biliary (Figure 3) or gallbladder walls in 8, retroperitoneal fibrosis and nephrydrosis in 1 (Figure 1).

Ultrasonography revealed a suspected pancreatic cancer in 18 cases (72%), and biliary cancer in 4 cases (16%), and CP was considered in 3. CT scanning showed pancreatic cancer in 15 (60%), and cholangiocarcinoma in 8 (32%), and CP was suspected in 2, for whom, pancreaticobiliary malignancy was not excluded. ERCP and MRI/MRCP

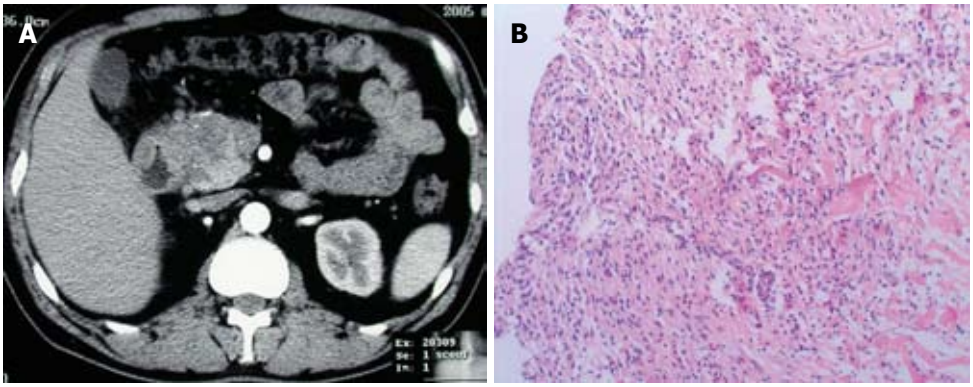

Figure 2 An asymptomatic patient with AIP, CT scan showed an enlarged head of pancreas (**A**), the diagnosis of AIP was confirmed by histologic findings of the pancreatic biopsy specimen: diffuse lymphoplasmacytic infiltration, obliterative phlebitis, dense parenchymal fibrosis and loss of acinar cells (HE, × 100) (**B**). He underwent radiofrequency ablation for the enlarged pancreatic head.

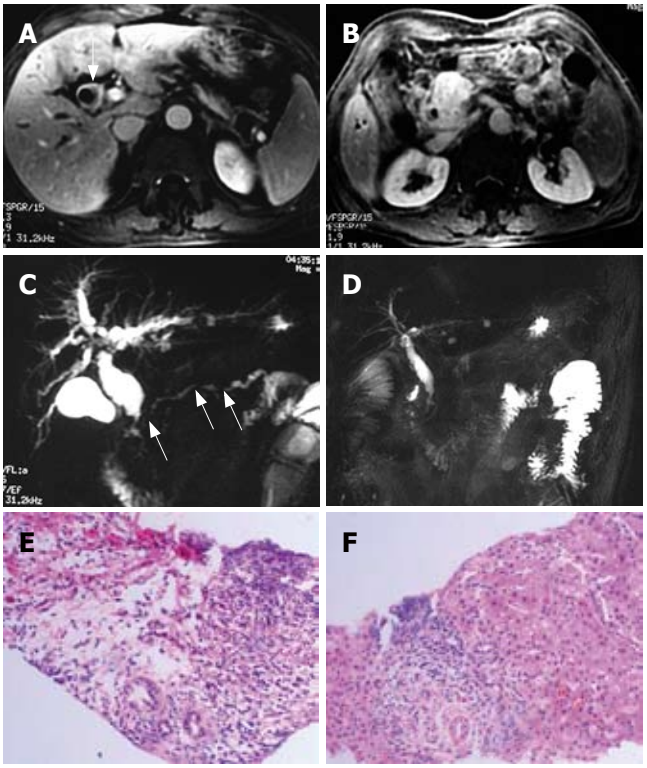

Figure 3 A patient with AIP, MRI imaging before treatment showed dilation of extrahepatic biliary ducts, thickening of hilar biliary wall (arrow) (**A**); and an enlarged mass in the head of pancreas (**B**); MRCP showed dilation of intra- and extra-hepatic biliary ducts, stricture of intrapancreatic and hilar bile duct, and segmental narrowing of main pancreatic duct (arrow) (**C**); after 1 mo of steroid therapy, the radiologic abnormalities resolved (**D**); The histologic findings of the pancreatic biopsy specimen include: dense fibrosis, diffusely lymphoplasmacytic infiltration, and acinar atrophy (HE, × 100) (**E**); the liver biopsy tissue also showed lymphoplasmacytic infiltration, cholestasis, and cloudy swelling of hepatocytes, especially at the portal area (HE, × 200) (**F**).

were detected in 11 cases and 7 cases, respectively, all revealed a stricture of intra-pancreatic common bile duct (CBD) with dilation of upstream biliary trees, focal stricture of hilar duct in 5; multiple stricture of main pancreatic duct (MPD) in 8, and segmental strictures of MPD with minimal upstream dilation in 6 (Figure 3), near-normal configuration of MPD in 2, and poor visualization of MPD in 2.

Based on the clinical and imaging features, a diagnosis or suspected diagnosis of pancreatic cancer and biliary cancer were made in 15 and 8 cases, respectively, and with a 92 percent of misdiagnosing rate at admission.

Histopathologic findings

During surgery, the pancreas was "rock-hard" or firm at palpation, as well as peripancreatic inflammatory adhesion, for whom pancreatic cancer was not ruled out. No calcification, mucoprotein plugs, or pseudocysts was exhibited.

Histological examinations show a significant presence of lymphocytes, plasma cell infiltration surrounding medium and large interlobular ducts, obliterative phlebitis, and scattered eosinophils, as well as acinar atrophy and dense fibrosis in all specimens (Figures 2 and 3). In specimens of 8 cases, dense fibrosis completely replaced the acinar cells and islets, with loss of figuration of pancreatic tissue. Immunohistochemical staining revealed a predominance of CD8+ and CD4+ T lymphocytes, with few B lymphocytes, as well as abundant IgG4-positive plasma cells.

Above-mentioned pathologic features are also present in biliary duct, gallbladder, and liver (Figure 3). In the liver specimens, cholestasis, diffusely cloudy swelling of hepatocytes, and prominent lymphoplasmacytic infiltration are detected, especially at the portal area.

Surgical procedures

Twenty-one patients with AIP underwent 22 sessions of exploratory laparotomy, accounting for 49% (21/43) of the patients with diagnosed CP who undergoing laparotomy: 4 cases underwent pancreaticoduodenectomy (PD) owing to suspicion of pancreatic cancer; 14 cases underwent choledochojejunostomy, among them, 1 case performed 2 sessions of laparotomy (the first laparotomy at a local hospital revealed a firm palpation of pancreatic head and portal vein encasement, and a presumptive diagnosis of advanced pancreatic cancer was made, together with a biliary external drainage; 4 mo later choledochojejunostomy was performed in our hospital after pathologic diagnosis of AIP); for the 3 asymptomic patients, 1 with preoperative diagnosis of AIP insisted on surgery and thus radiofrequency ablation for the enlarged pancreatic head was performed, another 2 only performed intraoperative biopsy of pancreatic tissues. Nineteen of 20 patients with obstructive jaundice underwent surgery, because of the mistaken diagnosis of pancreaticobiliary cancer. Four patients with pathologic diagnosis of AIP through ultrasound-guided percutaneous pancreatic biopsy did not undergo laparotomy.

Treatment and follow-up results

Four patients take oral prednisolone, and repeated

CT and/or MRI revealed improvement of pancreatic imaging 1 mo after steroid therapy (Figure 3), the clinical manifestation and serum levels of γ-globulin, IgG, and CA19-9 restored normally. Furthermore, the effective response to steroid therapy confirmed the diagnosis of AIP for the suspected cases. After steroid therapy, the abnormality of biliary duct and pancreatic duct normalized, and the nephrydrosis improved significantly, but not the retroperitoneal fibrosis.

All the patients with AIP were followed-up, with a mean period of 46 mo (12-142 mo), and no pancreaticobiliary cancers were progressed, nor the symptoms of jaundice, abdominal pain, or acute episode of acute pancreatitis.

DISCUSSION

Autoimmune pancreatitis (AIP) is a distinct subtype of CP. AIP occurs in the absence of gallstones, pancreas divisum, alcohol abuse, or other factors commonly associated with CP. AIP is characterized histologically by a diffuse lymphoplasmacytic infiltration and dense fibrosis. AIP was first described in 1961 by Sarles *et al*[4], who reported 2 patients with hypergammaglobulinemia. The concept of AIP was first proposed by Yoshida *et al* in 1995[1]. Hereafter, the concept of AIP has been widely accepted, and its clinical, histologic, radiographic, and serologic features have been characterized[5-12]. The cellular mechanisms and genetic factors contributing to AIP are also investigated[17-19].

The following characteristics of AIP have been noted[5-12]: (1) predominance of elder male, with mean age of 55-63 years; (2) nonspecific abdominal pain, painless jaundice (> 60%), and, rarely, acute attack of pancreatitis; (3) dense fibrosis with prominent lymphoplasmacytic infiltration in pancreatic lesions; (4) diffuse or focal irregular narrowing of the MPD on ERCP, together with stricture of intrapancreatic common bile duct and dilation of the bile duct upstream; (5) diffuse or focal enlargement of the pancreas; (6) increased serum γ-globulin or IgG or IG4 levels; (7) the presence of autoantibodies; (8) frequent presence of cholestatic liver dysfunction, hyperbilirubinemia, and elevated CA19-9 level; (9) usually absence of pancreatic calcification and cysts; (10) extra-pancreatic organs involvement in autoimmune diseases, such as ulcerative colitis, Sjögren's syndrome, sclerosing cholangitis; and (11) effectiveness of steroid therapy. Sometimes, AIP patients presented with nephrydrosis or upper gastrointestinal bleeding[20].

Nevertheless, the clinical manifestations of AIP are nonspecific, which makes it difficult to differentiate AIP from pancreaticobiliary cancer. Therefore, a significant number of patients with AIP receive operative treatment for an inflammatory mass suspicious of pancreatic cancer. The incidence of AIP ranges 1.86%-6.6% of CP[21], however, the AIP patients undergoing PD due to a clinical suspicion of a malignancy ranges 21%-28% of CP patients receiving surgery[10,22,23], the AIP lesions sometimes have been identified as unresectable tumor because of vessel infiltration.

In China, few cases with AIP have been reported[9]. In our experience, the AIP patients accounted for 5% of CP population; however, 84% (23/25) of the AIP patients was diagnosed or suspected of pancreaticobiliary malignancy, which resulted in 22 episodes of laparotomy for 21 AIP cases, accounting for 49% (21/43) of CP patients receiving surgical treatment.

The pathological features of lymphoplasmacytic infiltration and fibrosis, acinar atrophy are often used as the gold standard for the diagnosis of AIP[11,24-26]. However, the diagnosis made on pancreatic biopsy specimens may be inconclusive (false negative) or suggestive, because of small sample size and sampling error[26,27]. For those with suspected pancreatic cancer, the role of needle or core biopsy specimen is primarily to exclude malignancy[24]. Although studies have revealed that IgG4-positive plasma cells may be a useful marker for the diagnosis of AIP[28-32], whether IgG4-positive staining can diagnose AIP with certainty needs further investigation[30-33].

Abdominal CT findings include a focally or diffusely pancreatic involvement, especially in the head of pancreas, with low-attenuation or an isoattenuation. Thus, the differential diagnosis of focal AIP from pancreatic cancer is difficult on CT findings only. On CT and MRI, the diffusely enlarged pancreas shows a sausage-like appearance, as well as a peripheral rim of the hypointense "halo". The hallmark findings on ERCP are focal, segmental or diffuse irregular narrowing of the MPD, the upstream duct is minimally dilated. Occasionally, a double duct sign (concomitant presence of distal CBD and distal pancreatic duct stricture, suggesting a tumor in the head of pancreas) may be present. Endoscopic ultrasound in the diagnosis of AIP has not been well characterized; however, endoscopic ultrasound guided fine needle aspiration biopsy is beneficial to establish a diagnosis of AIP and exclude cancer[34].

MRCP poorly shows pancreatic duct strictures[35], but it can well demonstrate stricture of the intrapancreatic bile duct, and dilatation of the upper biliary tract. Sclerosing changes of the extrapancreatic bile ducts similar to PSC are sometimes observed. Steroid therapy is effective for changes of the biliary and pancreatic ducts. In view of its above-mentioned advantages and its noninvasiveness, MRCP can partially replace the role of ERCP in diagnosing of AIP[9].

AIP patients frequently exhibit positive serologic antibodies, and elevated levels of γ-globulin or IgG. It has reported that elevated levels of the IgG4 were a sensitive and specific marker of AIP[36,37]; however, elevated level of IgG4 seems nonspecific for AIP[13,38] and its role requires further study. In China, the determination of serum IgG4 level is still unavailable for most of hospitals, so we did not use it in our diagnostic criteria.

Current diagnostic criteria include the JPS criteria[13,39], the Kim criteria[14], the HISORt criteria of Mayo Clinic[15], and the Italian criteria[13]. This absence of integrated criteria makes it difficult to compare studies from different centers. The problem of JPS criteria is that the cases showing an excellent response to steroids may yet fail to fulfill the JPS criteria[13,39,40]. Thus other 3 criteria include the criterion "response to steroid therapy"[8,13-15]. The dramatic effectiveness of steroid for the suspected AIP cases strongly supports the diagnosis, thus avoiding unnecessary surgery.

Steroid therapy is effective for AIP. The initial dose of prednisone should be 30-40 mg daily for a week, followed

by a taper of the daily dose by 2.5-5 mg per week. The response to steroids is often dramatic[13-15,39]. During the first 2-4 wk of therapy, CT or MRI/MRCP should be used to monitor the response. Laboratory, and functional abnormalities may also show improvement with steroid therapy[13-15,39,41]. A poor response to 1-2 wk of steroid therapy should raise the question of pancreatic cancer or other forms of CP. Surgery is preserved for those in whom the pancreaticobiliary malignancy could not be excluded or who complicated with infection of biliary tract.

In summary, the establishment of diagnosis of AIP should rely on combinations of the clinical, radiographic, histologic and serologic evidence, and a response to steroids. AIP is frequently misdiagnosed as pancreatic cancer, because of the clinical similarity with cancer. In order to improve the diagnostic accuracy for AIP, the clinicians must have a high index of suspicion of AIP and be conversant with its manifestations.

COMMENTS

Background

Autoimmune pancreatitis (AIP) is a unique chronic inflammation of the pancreas. AIP has distinct characteristics at clinical, radiologic, histologic, and serologic findings. However, due to the extreme similarity in clinical manifestations of pancreaticobiliary tumors, the patients with AIP frequently were misdiagnosed as pancreatic cancer, and were imposed an unnecessary pancreatic resection.

Research frontiers

The establishment of reasonable diagnostic criteria compatible with all AIP patients is the major area of research, because the criteria can spare the AIP patients unnecessary pancreatic resection.

Innovations and breakthroughs

Although presence of established diagnostic criteria, that clinicians have the knowledge of AIP and with a high index of suspicion is the prerequisite for accurate diagnosis of AIP. In this retrospective study, we demonstrated that there is a terrible frequency of misdiagnosis and unnecessary surgery in AIP patients if the clinicians have no awareness of AIP.

Applications

The diagnostic accuracy for AIP will be improved, if the clinicians have a high index of suspicion of AIP and are conversant with its manifestations. The accurate diagnosis is mainly based on clinical, radiologic and histologic findings, sometimes together with excellent response to steroid therapy.

Terminology

AIP is a type of chronic pancreatitis characterized by an autoimmune inflammatory process in which prominent lymphoplasmacytic infiltration and fibrosis of the pancreas.

Peer review

This is the first English literature reporting AIP patients from China, most of the AIP patients in China were misdiagnosed and experienced subjected to unnecessary surgery, as their Western counterparts before the entity of AIP was not recognized widely. The diagnostic criteria used in this study are practical for AIP patients from developing countries, where the determination of serum IgG4 is unavailable.

Abstract

AIM: To study the expression of suppressor of cytokine signaling-1 (SOCS-1) in the liver tissues of chronic hepatitis B (CHB) and the clinical significance of this expression.

METHODS: The expression of SOCS-1 in liver tissues of 45 cases of CHB was investigated by immunohistochemical staining, and its correlations with inflammation grades and fibrosis stage were analyzed by SPSS statistics software.

RESULTS: The result showed SOCS-1 expressing could be observed in the liver tissue of CHB. The expression of SOCS-1 was mainly distributed near the portal area in the liver tissue of mild inflammation CHB group, and was diffusely distributed in the liver tissue of moderate and severe inflammation groups. SOCS-1 positive stains mainly appear in the hepatocytes, only a few of liver interstitial cells were involved. Inside the hepatocyte, SOCS-1 positive stains are mainly distributed in the plasma. Some of the staining was observed on the membrane. The inclusion bodies in the plasma of hepatocytes were observed occasionally. There were both obvious correlations between the expression of SOCS-1 and the inflammatory grade, and that between the expression of SOCS-1 and the fibrosis stage.

CONCLUSION: The distribution of SOCS-1 in the liver tissue of CHB is variable. This expression was correlated with the inflammation grade and fibrosis stage.

INTRODUCTION

Hepatitis B virus (HBV) infection is a leading cause of chronic liver diseases globally. The exact mechanism by which HBV induces liver damage is still unknown. The suppressor of cytokine signaling (SOCS) family, which consists of SOCS-1 to 7 and cytokine-inducible SH2-containing protein (CIS), has been proved in the negative feedback regulation of janus kinase-signal transducer and activator of transcription (JAK/STAT) signal transduction pathway, which is induced by cytokine signaling[1-4]. SOCS-1 has been implied in the inhibition of inflammation of human body[5-8]. It also influences the inflammation and fibrosis of liver[9-11]. The recent research data also showed that SOCS-1 negatively regulated the response of chronic hepatitis C (CHC) to a-interferon (IFN-α)[12,13]. Methylation of SOCS-1 is implicated to be correlated with carcinoma, including hepatocarcinoma, pancreatic cancer, multiple myeloma and myeloid leukemia[14-19]. Expression of SOCS-1 was regulated by many factors. Cytokines induced by inflammation upgrade the expression of SOCS-1[20-23]. Recent research data showed that, SOCS-1 transcripts in the livers of CHC were significantly higher than controls[12]. Therefore the objective of this study was to explore weather and how SOCS-1 expression in the liver tissues of chronic hepatitis B (CHB) patients and its relationship with inflammation grade and fibrosis stage of the livers.

MATERIALS AND METHODS

Production of the specimen

Biopsied liver specimens were obtained from 45 CHB patients (44 males and 1 females) hospitalized in the infectious department of the third affiliated hospital of Sun Yat-San University to accept liver biopsy from August 2005 to November 2006. All cases were stratified into 3 groups (G2 to G4, 15 cases each group) according to the modified criteria for grading and staging of chronic hepatitis from hepatitis meeting consensus in 2000 of china.

All cases were HBsAg positive. Patients with infection of hepatitis virus of A, C, D, E, malignancy or antivirus therapeutic history were excluded.

Reagent and antibodies

Rabbit anti-human SOCS-1 monoclonal antibody (sc7006) was purchased from Santa Cruz Biotechnology. Diaminobenzidine (DAB) and Streptavidin Biotin Complex (SABC) were purchased from BOSTER Biotechnology in Wuhan.

Collections of clinical data

The clinical data including age, gender, clinical history, liver function tests results done from 3 d before to 3 d after the biopsy and the evaluation results of liver pathology accorded to the modified criteria for grading and staging of chronic hepatitis were collected for analysis.

Immunohistochemistry

The routine paraffin-embedded liver tissue specimens were used. Antigen retrieval was performed by microwaving for 10 min at 90℃ using Dako target retrieval solution (Dako, Carpinteria, CA, USA)[24]. The immunohistochemistry associated with anti-SOCS-1 was performed as described previously[25]. For a negative control, the primary antibody was replaced with non-immune normal mouse IgG.

Evaluation of the positive results of immunohistochemistry staining

The immunohistochemistry staining was evaluated by the staining area and density as described previously[26]. For the staining area, specimens without staining area score 0. Specimens with staining area smaller than 1/3 of the area observed score 1. The one larger than 2/3 scores 3. That from 1/3 to 2/3 score 2. For the staining density, light staining ones score 1, dark staining ones scored 2. The final score was the sum of area score and density score.

Statistical analysis

The SPSS 13.0 was used for the statistical analysis. Rank test was used to analyze the category rank data. Spearman non-parameter correlation analysis was used to analyze the rank associated data. Probabilities of $P < 0.05$ were assumed as statistically significant.

RESULTS

The distributing mode of SOCS-1 in hepatic acinus

Under microscope, the positive staining for SOCS-1 was observed focally distributed. In the liver tissue of mild CHB group, the positive staining is mainly distributed near the portal area (Figure 1A). In the moderate and severe group, the positive staining is diffusely distributed (Figure 1B).

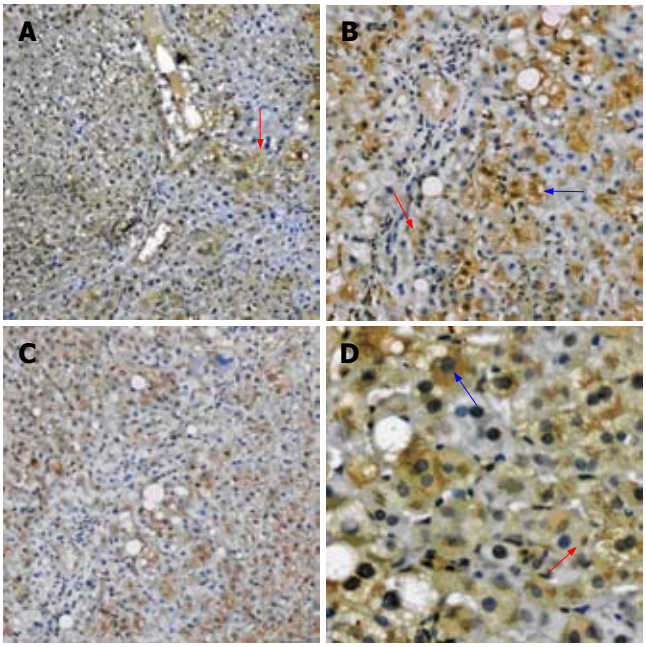

Figure 1 **A**: The liver tissue of mild CHB show the positive staining mainly distributed near the portal area (red arrow); **B**: The liver tissue of severe CHB show the positive staining is diffusely distributed; **C**: The positive staining mainly involves the hepatocytes (blue arrow), only a few of liver interstitial cells are involved (red arrow); **D**: The positive staining is mainly distributed in the plasma (blue arrow), some on the membrane. occasionally in the inclusion bodies (red arrow). (**A**, **B**: Immunohistochemistry SABC × 100; **C**: Immunohistochemistry SABC × 200; **D**: Immunohistochemistry SABC × 400).

Table 1 Evaluation of immunohistochemistry with SOCS-1 in the livers of CHB

		Evaluation of immunohistochemistry					
		0	2	3	4	5	Up
Group	G2	2	2	5	6	0	15
	G3	0	1	8	3	3	15
	G4	0	0	2	7	6	15
	Up	2	3	15	16	9	45

The expression mode of SOCS-1 in liver cell

The positive staining for SOCS-1 mainly involves the hepatocytes, only a few of liver interstitial cells are involved (Figure 1C). The positive staining for SOCS-1 observed in the involved cell is mainly distributed in the plasma. Some of the staining was observed on the membrane. The inclusion bodies in the plasma of hepatocytes were observed occasionally (Figure 1D).

The expression extent of SOCS-1 in hepatic tissue of CHB

Evaluation of the staining for SOCS-1 in the mild hepatitis B group shows that 2 cases scored 0, 2 cases scored 2, 5 cases scored 3 and 6 cases scored 4. Evaluation of the staining for SOCS-1 in the moderate hepatitis B group shows that 1 case scored 2, 8 cases scored 3, 3 cases scored

Table 2 Correlation between the expression of SOCS-1 and liver pathology

		Grade	Stage
SOCS-1 scores	Correlation	0.493	0.308
	P value	0.001	0.04
	n	45	45

4, 3 cases scored 5. Evaluation of the staining for SOCS-1 in the severe hepatitis B group shows that 2 cases scored 3, 7 cases scored 4, 6 cases scored 5 (Table 1).

The correlation between the expression of SOCS-1 and liver pathology

The Spearman correlation analysis was used to analyze the relationship between the expression of SOCS-1 and the pathologic degree. The result showed that the expression of SOCS-1 is positive correlated with the inflammatory degree and extent of the fibrosis stage ($P = 0.001$ and $P = 0.04$) (Table 2).

The correlation between the expression of SOCS-1 and the liver function tests results

The correlation between the expression of SOCS-1 and the liver function tests was analyzed by Spearman correlation analysis. The results showed that no correlation was observed (Table 3).

DISCUSSION

The exact mechanism of CHB has not been clarified completely. By far, we have known that both the replication of HBV and the immune response of the host play important roles in hepatitis B. SOCS-1 is an important suppressor of cytokine signaling pathway in the serial reactions of immune response of host. SOCS-1 transcripts have been found in thymus cells, lung, liver, spleen, testis, and peripheral blood monocytes of mouse and human being by polymerase chain reaction (PCR)[12,21,27].

Imanaka K compared the expression of SOCS-1 in the liver tissues of 21 cases of CHC patients and 9 control patients by quantitative reverse transcription-polymerase chain reaction (RT-PCR), and found that the transcripts of SOCS-1 in the liver tissues of CHC were significantly higher than controls[12]. The expression of SOCS-1 in the livers of CHC patients implied that it might associate with the inflammation and fibrosis of the livers, yet little has been known about whether and how it expresses in the liver tissues of CHB patients and its relationship with the mechanism of CHB.

The findings herein showed that there were variable expressions of SOCS-1 in the liver tissue of CHB. The expression of SOCS-1 was focally distributed. It was mainly distributed near the portal area in the livers of mild inflammatory CHB patients, and was diffusely distributed in the moderate and severe ones. As we know, inflammatory injure of the livers of CHB patients was mainly distributed near the portal area in the livers of mild inflammatory CHB patients, and was diffusely distributed in the moderate and severe inflammatory CHB patients. The findings suggested that expression of SOCS-1 in the livers of CHB patients accorded with the inflammation of the livers. This indicated that the expression of SOCS-1 was more or less correlated with the inflammation.

Research showed that SOCS-1 is expressed mainly in the hepatocytes and rarely in the interstitial cell. It may be due to the fact that inflammation in the livers of CHB patients mainly involves the hepatocytes. The signaling pathway in the hepatocytes was especially active, so that the expression of SOCS-1 in these cells was elevated. This finding showed that distribution of SOCS-1 in the livers of CHB patients was mainly in hepatocytes due to the influences of inflammation.

The molecular biological data shows that SOCS-1 is synthesized and executes its biological function in the cell plasma. Our results showed that no SOCS-1 was found in the nucleolus and the positive staining mainly seen in hepatocytes plasma. This indicated our findings complied with the previous reports.

Large amount of experiments show that SOCS-1 was an important inhibitor of inflammation. It inhibits the signaling pathway of many cytokines such as interleukin-2 (IL-2), IL-3, IL-4, IL-6, IFN-α, IFN-β, IFN-γ, tumor necrosis factor-α (TNF-α) and so on[21-23].

Naka *et al* found that mice lacking SOCS-1 would die within 3 wk of birth with extensive fatty degeneration of the liver and monocytic infiltration of several organs. His experiment demonstrated that SOCS-1 inhibited the inflammation[28].The new born mice with injection of large amount of IFN-γ showed the same phenotype with mice lacking SOCS-1, which could be contradicted by injection of anti-IFN-γ antibody. It suggested that the hypersensitivity of the mice to IFN-γ caused that inflammatory syndrome. SOCS-1 was a key negative regulator of gamma interferon action *in vivo*[29] and can inhibited the extent of inflammation.

The recent finding also showed that SOCS-1 protected oligodendrocytes from demyelination effects of interferon-gamma[30].

On the other hand, expression of SOCS-1 has been demonstrated to be induced by IFN-γ, Erythropoietin (EPO), Granulocyte Colony Stimulating Factor (G-CSF), Granulocyte-macrophage colony stimulating factor (GM-CSF), IL-2, IL-3, IL-4, IL-6, Leukemia inhibitor factor

(LIF), growth hormone (GH), prolactin (PRL) and so on[20-23]. It referred to that inflammation could induce expression of SOCS-1.

The finding herein showed that expression of SOCS-1 was correlated with the inflammation grade of CHB patients. The reason might be that the inflammatory injure in the livers of the CHB patient induced the expression of SOCS-1. While SOCS-1 was not large enough to inhibit the inflammatory injure that have been occurred. But no significant relation between the expression of SOCS-1 and the liver function tests was observed. It may due to that liver function didn't always accord with the pathological changes.

There were some reports that SOCS-1 can also inhibit liver fibrosis of the CHB patients. Yoshida examined SOCS-1 gene methylation in more than 200 cases of patients with chronic liver diseases and found that the severity of liver fibrosis is strongly correlated with SOCS-1 gene methylation[10]. Our finding showed that expression of SOCS-1 was correlated with the fibrosis stage of CHB patients. But the correlation is low and it is not easy to tell if it affects the progression of fibrosis directly or indirectly through negatively inhibiting the extent of inflammation by our results. Further research is needed to concern the relation between SOCS-1 expression and liver fibrosis.

COMMENTS

Background

Hepatitis B virus (HBV) infection is a leading cause of chronic liver diseases globally. The exact mechanism by which HBV induces liver damages is still unknown. The suppressor of cytokine signaling (SOCS) family, which consists of SOCS-1 to 7 and cytokine-inducible SH2-containing protein (CIS), has been proved in the negative feedback regulation of JAK/STAT signal transduction pathway, which is induced by cytokine. SOCS-1 was discovered by three different groups in 1997. It was named according to its feedback regulation of the cytokine signaling pathway. The former studies showed that SOCS-1 inhibited inflammation, fibrosis and carcinoma, and negatively regulated the response of chronic hepatitis C to IFN-α. It can be upgraded by cytokines induced by inflammation. But little has been known about whether and how SOCS-1 expresses in the liver tissues of CHB patients and its relationship with the mechanism of chronic hepatitis B (CHB).

Research frontiers

There has been a considerable interest over recent years in the significance of SOCS-1 in signaling pathway. The interactions between SOCS-1 and some cytokines have been well explored. And the effect of SOCS-1 on inflammation and malignancy were the hotspots.

Innovations and breakthroughs

We described the distribution of SOCS-1 in the liver tissue of CHB by immunohistochemistry and performed correlation analysis on the expression of SOCS-1 with the inflammatory grade as well as the fibrosis stage and found positive correlation in both for the first time.

Applications

The research stated the distribution of SOCS-1 in the liver tissue of CHB. It is significant for the further statement of the mechanism of CHB and helpful for improvement of the management of CHB.

Terminology

SOCS-1: SOCS-1 was discovered by three different groups in 1997. It was named according to its feedback regulation of the cytokine signaling pathway; 2. JAK/STAT signal transduction pathway: JAK/STAT signal transduction pathway is a signaling conduction pathway. It consisted of JAK and STAT. The mechanism includes phosphorylation of JAK, activation and aggregation of STAT.

Peer review

The paper seems innovative. Zhao *et al* investigated the expression of SOCS-1 in the liver of patients chronically infected with HBV by immunohistochemistry and performed correlation analysis on the expression of SOCS-1 with the inflammatory grade as well as the fibrosis stage and found positive correlation for the first time. The experiment was well designed and plentitude of clinical data. Some interesting observations were obtained. All of these are significant for the further statement of the mechanism of CHB.

Abstract

AIM: To investigate the quality of care for a hospital based-cohort of patients with inflammatory bowel disease (IBD) from East China according to the current practice guidelines.

METHODS: A retrospective review was conducted, involving 177 patients with IBD admitted to Sir Run Run Shaw Hospital, College of Medicine, Zhejiang University between June 2000 and June 2006. Data regarding demographic and clinical characteristics as well as medical therapy including use of oral aminosalicylates, topical therapy, corticosteroid agents, immunomodulatory agents (such as azathioprine) at admission and outpatient clinic visit were analyzed.

RESULTS: A total of 177 eligible patients were evaluated in this study, including 71 patients with Crohn's disease (CD) and 106 with ulcerative colitis (UC). All were the Han nationality Chinese with active disease at baseline. All the 106 patients with ulcerative colitis received optimal doses of aminosalicylate while 27 of 68 (39.7%) patients with ileal or colonic CD received the suboptimal doses of aminosalicylate. The incidence of suboptimal dose of aminosalicylate was significantly higher in CD patients with small intestine involvement only (52.8% *vs* 25.0%, $P = 0.019$). Thirty-one (54.4%) patients with active distal or left-sided ulcerative colitis received topical therapy, and 27.8% of patients suffering from severe inflammatory bowel disease did not receive oral or intravenous steroid therapy. Among the 51 patients for whom thiopurine was indicated, only 10 (19.6%) received immunomodulatory agents, and more than half of the 8 patients received a suboptimal dose of azathiopurine with no attempt to increase its dosage.

CONCLUSION: The quality of care for IBD patients can be further improved. A suboptimal dose of aminosalicylate is used in treatment of patients with CD, especially in those with small intestine involved only. Topical mesalazine is inadequately used in patients with distal or left-sided colitis. Oral or intravenous steroid therapy is not used in some patients with severe IBD. Use of immunomodulatory medication is limited. Larger prospective studies are needed to investigate the quality of care for patients with IBD to establish our own evidence-based guidelines.

INTRODUCTION

Inflammatory bowel disease (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), is a chronic disorder of the gastrointestinal tract. The prevalence of IBD is about 1.0/1000 in Western countries[1]. No large scale epidemiological investigation is available on the incidence and prevalence of IBD in China so far, but the diagnosed IBD in China has increased obviously in the past ten years[2].

A number of national and international practice guidelines for management of inflammatory bowel disease are available[3-5]. However, the essentials in a step-up treatment have not changed significantly. These practice guidelines are means of bringing evidence-based medicine into full play to improve IBD patient care. However, such

guidelines can improve the care of IBD patients only when they succeed in moving the actual clinical practice closer to the recommended practice.

The Sir Run Run Shaw Hospital is a teaching hospital affiliated to Zhejiang University, China. Together with 12 other large hospitals and numerous smaller district hospitals, it provides health care to 48 million people living in Zhejiang Province of East China. Our group has carried out a retrospective study to assess the demographic and clinical characteristics of IBD in Chinese patients[2]. This study was to investigate the impact of such guidelines and the quality of care for a hospital based cohort of patients with IBD from East China.

MATERIALS AND METHODS

Subjects

IBD patients admitted to Sir Run Run Shaw Hospital, College of Medicine, Zhejiang University, between June 2000 and June 2006, were consecutively enrolled in this study. The diagnosis of IBD was confirmed by the criteria established by Chinese Society of Gastroenterology[6] in 2000 and the guidelines issued by the Clinical Services Committee of the British Society of Gastroenterology (BSG)[3] in 2004. The patients not under the care of a gastroenterologist were excluded.

Data collection

A retrospective review was performed. Clinical data on demographic information, clinical characteristics of IBD patients, as well as endoscopic, radiologic, surgical and pathological records, confirmed diagnoses, duration and severity of disease, medical therapy, were collected from the inpatient and follow-up clinic visit records and input into an IBD database. Medical therapy included use of oral aminosalicylate, topical therapy, corticosteroid agents, and use of immunomodulatory agents at admission and outpatient clinic visit.

Statistical analysis

Variables were expressed as mean, while categorical data such as proportion of patients receiving particular therapies and dose of medications were expressed as percentage. Association of patient gender, age, location and severity of disease with suboptimal therapy was analyzed by χ^2 test. $P < 0.05$ was considered statistically significant. All statistical analyses were carried out with the SPSS v. 13.0.

RESULTS

Patient characteristics

A total of 177 eligible patients were evaluated in this study, including 71 patients with CD and 106 with UC. All the patients were the Han nationality Chinese. Disease activity was assessed using the Harvey-Bradshaw index (HBI) for CD and the Sutherland index for UC. Active disease was defined as a HBI value $\geqslant 5$ or a Sutherland index $\geqslant 3$. All the eligible patients had active disease at admission. Severity was broadly divided into mild, moderate or severe according to the Truelove & Witts' criteria for UC and the criteria established by Chinese Society of Gastroenterology for CD[6]. Mild CD was defined when the patient had no fever, abdominal tenderness, abdominal mass and obstruction, while severe CD was defined when the patient had persistent high fever, weight loss, nausea, vomiting, abdominal pain, diarrhea, anemia and complications. The characteristics of the patients and the information about the location of disease are given in Tables 1 and 2, respectively. Twenty-one gastroenterologists were involved in the treatment of the patients.

Table 1 Characteristics of patients with CD or UC

Characteristics	CD (n = 71)	UC (n = 106)
Sex (male/female)	41/30	56/50
Age (yr) [mean (range)]	35 (13-70)	45 (15-80)
Disease duration (yr) [mean (range)]	5.3 (0.5-14)	5.8 (0.5-23)
Smoker/non-smoker	17/54	26/80
Disease severity		
Mild	13	53
Moderate	38	37
Severe	20	16
Previous surgery	34	4

Table 2 Distribution of CD and UC

Disease location	n

Ulcerative colitis (106)	
Distal colitis	35
Left-sided colitis	22
Extensive colitis	47
Missing information	2

Medical therapy

Medical therapy for the patients including use of aminosalicylate, topical therapy, corticosteroids and immunomodulatory agents was analyzed, and the results are listed in Table 3.

Overall, 175 of 177 patients received oral aminosalisylate. Among them, 145 received mesalazine and 30 received sulphasalazine (SASP) (69/71 with CD, 106/106 with UC). The remaining 2 patients who did not receive oral aminosalicylate, had a history of adverse events, and therefore, received oral corticosteroids. A suboptimal dose of mesalazine or SASP was defined as a dose less than 4.0 g/d in patients with ileal or colonic CD or a dose less than 3.0 g/d in patients with UC. Among the 69 CD patients who received aminosalicylate, one had stomach involvement. Among the remaining 68 CD patients, 27 (39.7%) had a suboptimal dose. In contrast, all the 106 patients with UC were treated with an optimal dose. A further analysis was performed to elucidate factors associated with suboptimal doses of such medications. The variables were gender, age, location of disease, and severity of disease. It revealed no association other than a significantly higher incidence of

Table 3 Suboptimal dose used in treatment of CD and UC

Clinical parameters	Proportion (%)
Suboptimal dose of aminosalicylate	
Crohn's disease	27/68 (39.7)
Ulcerative colitis	0/106 (0.00)
Failure to use topical therapy	26/57 (45.6)
Failure to use corticosteroid	10/36 (27.8)
Failure to use immunomodulatory agents	41/51 (80.4)
Suboptimal dose of AZA	4/7 (57.1)

Table 4 Suboptimal dose of aminosalicylate and location of CD

Location of CD	Suboptimal dose (*n*)	Optimal dose (*n*)
Small intestine[a]	19	17
Colon	2	4
Ileocolon	6	20

[a]$P = 0.019$: A significantly higher incidence of suboptimal dose in CD patients with small intestine involved only.

suboptimal dose in CD patients with small intestine involved only ($P = 0.019$) (Table 4).

Of the 57 patients suffering from active distal (applies to colitis confined to the rectum or rectum and sigmoid colon) or left-sided (applies to colitis extending proximal to the sigmoid descending junction up to the splenic flexure) ulcerative colitis, 31 (54.4%) received topical therapy. Medications used in topical therapy included mesalazine ($n = 5$), corticosteroids ($n = 22$), antibiotics ($n = 12$) as well as traditional medications ($n = 15$).

Oral corticosteroid use was also assessed. Of the 177 patients (29/71 with CD, 31/106 with UC), 60 were treated with corticosteroids. No significantly different doses were applied in patients with mild to moderate disease or severe disease ($P = 0.391$) (mild to moderate disease: mean dose 35.4 mg/d, range 10-60 mg/d; severe disease: mean dose 38.7 mg/d, range 10-75 mg/d). Of the 36 patients with severe inflammatory bowel disease, 10 (27.8%) did not receive oral or intravenous steroid therapy.

Of the 177 patients, 51 were thiopurine indicated. Among these 51 patients, 23 were steroid-dependent (refers to a relapse when the steroid dose is reduced below 10 mg/d, or within 6 wk of stopping steroids), 4 were steroid-refractory (refers to active disease in spite of an adequate dose and duration of prednisolone > 20 mg/d for > 2 wk) and 24 had postoperative fistulation CD. However, only 10 (19.6%) patients received immunomodulatory agents (8 received oral azathioprine AZA, 2 received oral cyclosporine). The mean AZA dose used in the 8 patients was 1.52 mg/kg per day, ranging from 0.83 to 2.22 mg/kg per day. A suboptimal dose of AZA was defined as a dose less than 1.5 mg/kg in the absence of leukopenia or hepatotoxicity. Based on such criteria, one patient developed myelotoxicity and tolerated a lower dose. Of the remaining 7 patients receiving AZA, 4 (57.1%) received a suboptimal dose with no attempt to increase the dose. None of the patients was treated with methotrexate or inflixmab.

DISCUSSION

IBD, including UC and CD, is a complex disorder characterized by a wide range of variations in clinical practice. As the evidence is changing and rapidly growing, national and international societies are continuously updating the current diagnostic and treatment guidelines, for the sake of avoiding variations in clinical practice, and offering strategies for their effective implementation. Ultimately, the success of practice guidelines is determined by the physicians' acceptance, and perceived usefulness of the guidelines and their impact on patient care. Reddy *et al*[7] have investigated whether patients with IBD receive optimal therapy in America according to the practice guidelines. Since general information about the quality of care for patients with IBD in China is lacking, we conducted this study to examine the quality of care for IBD patients in our hospital.

Abundant evidence suggested that higher doses of aminosalicylates (4 g/day) are more effective for inducing remission in UC or CD. A dose-response trend for aminosalicylates was also observed[8]. Clinical improvement (but not necessarily remission) in ulcerative colitis is associated with the dose of aminosalicylate ($\geqslant$ 3 g/d)[8]. Although the role of aminosalicylate in the management of CD is less clear, it was reported that its higher doses ($\geqslant$ 4 g/d) are effective on active CD of the ileum and colon[9-11]. Compared with sulphasalazine (SASP), mesalazine is not significantly better, but has lower side effects[12]. In our hospital, SASP is still widely used to induce and maintain remission of mild to moderate UC and CD, because of its comparatively lower price. Besides, the incidence of UC is relatively higher and the adverse events of SASP seem lower in China than those in Western countries. The mainstay of treatment, however, has shifted towards the use of mesalazine. In our study, all the patients with UC received the optimal doses of aminosalicylate, while 39.7% patients with CD received its suboptimal doses. Furthermore, a significantly higher incidence of suboptimal dose was found in CD patients with small intestine involved only. This phenomenon may be explained by the relatively lower incidence of CD than that of UC in China and therefore the less understanding of this disease.

Topical therapy allows direct delivery of the active drugs to the site of inflammation, limiting systemic absorption and potential side effects. Topical therapy is the most effective approach, provided that the formulation reaches the disease. It also plays an important role in the maintenance of remission. Oral therapy combined with topical therapy is superior to a single agent[13-15]. Furthermore, meta-analysis has shown that aminosalicylate is significantly better than topical steroids in inducing clinical remission[16,17]. However, in our study, only 31 (54.4%) patients with distal or left-sided colitis received topical therapy, and topical mesalazine was only used in 5 patients. There is a tendency that topical therapy is thought to be less effective in clinical practice, quite reverse to the evidence. Actually, its lower efficacy may be due to the lack of preparations such as liquid enemas, foams, gels and suppositories, rather than due to the medication itself.

Corticosteroids can effectively induce remission of UC and CD. Oral or intravenous corticosteroids are recommended for severe UC and CD[3,4]. In our study, more than a quarter of patients suffering from severe inflammatory bowel disease did not receive oral or intravenous steroid therapy, possibly due to the lack of comprehensive evaluation of the patients' baseline states and reevaluation when exacerbations occurred. In addition, the patients' and even some physicians' fear of adverse effect played a part role. There is evidence that side effects of corticosteroid therapy are related to the dosage used and its duration. Short-term corticosteroid therapy is relatively safe.

Although corticosteroids are effective in inducing remission of CD and UC. More than 20% of patients may be steroid-refractory or become steroid dependent. Meta-analyses have shown that corticosteroids are not effective in maintaining medically or surgically induced remission of IBD. The frequency and severity of well recognized adverse effects also preclude their long term use. Immunomodulatory agents such as azathioprine (AZA) and mercaptopurine (MP) can induce and maintain remission of CD and UC and have steroid sparing effects in patients with steroid dependent or refractory IBD[21,22]. Although lower doses had been favored in early clinical trials, a meta-analysis demonstrated greater efficacy of higher doses[23,24]. In our study, the use of immunomodulatory agents was restricted to a minority of IBD patients (19.6%), which is distinctly less frequent compared with that in Western countries. Furthermore, more than half of the patients received a suboptimal dose of AZA with no attempt to increase its dosage. Biological agents such as infliximab have not been registered for the treatment of CD in our region, and their effect on CD in Han nationality Chinese needs to be further investigated.

The limited use of immulomodulatory medications may be due to the lack of evidence and limited experience with these drugs in Han nationality Chinese with IBD. Uncertainty regarding the risk for neutropenia deters some physicians from using AZA at effective doses and longer treatment with it. Experience abroad has shown that AZA can be safely used in treatment of CD and UC[25-27]. Recently, thiopurine methyltransferase (TPMT) and its genotype have been applied in predicting the myelotoxicity and reducing the incidence of leucopenia in Europe and North America[28-30].

In contrast, the data available on the management of IBD in China are rather limited. Guidelines published by the Chinese Society of Gastroenterology adhere mainly to the international ones. The lack of evidence holds back the use of these medications and therefore affects the quality of care for IBD patients. As the incidence of IBD has been increasing in China, it may be of interest to follow the temporal epidemiological trends and treatment policy for IBD in China.

Several factors limit the interpretation of our data. Firstly, we did not determine the duration or the frequency of visits. A longer period or more frequent contacts may provide more opportunities to achieve better care for IBD patients. Secondly, the patients' perspective and preference were not taken into account, which may affect the decision. Finally, we did not study the association of the reported quality of care with patient outcomes.

In conclusion, the quality of care for IBD patients can be improved. suboptimal doses of 5-ASA was used in treatment of patients with Crohn's disease, especially those with small intestine involved only and Topical mesalazine is inadequately used in treatment of patients with distal or left-sided colitis. Oral or intravenous steroid therapy is not used in treatment of certain patients with severe IBD. Use of Immunomodulatory agents is limited. Larger prospective studies are needed to investigate the quality of care for patients with IBD and to establish our own evidence-based guidelines.

ACKNOWLEDGMENTS

The authors thank the patients for their participation in this study, and acknowledge the contribution of all the doctors and nurses in the GI Unit of Sir Run Run Shaw Hospital for collecting the data.

COMMENTS

Background

As the evidence is changing and rapidly growing, a number of national and international practice guidelines for management of inflammatory bowel disease (IBD) are available, for the sake of avoiding variations in clinical practice and offering strategies for their effective implementation. However, guidelines for IBD treatment can improve patients' care only when they succeed in moving actual clinical practice closer to recommended practice.

Research frontiers

Reddy *et al* have investigated the quality of care for patients with IBD in America, and suggested that patients often do not receive optimal treatment of IBD, despite the availability of practice guidelines.

Innovations and breakthroughs

Although the incidence of IBD has been increasing in China, general information about the quality of care for patients with IBD in China is lacking. We investigated the impact of guidelines and the quality of care for IBD patients from East China.

Applications

The results of this study suggest that the quality of care for IBD patients can be improved. Larger prospective studies are needed to investigate the quality of care for patients with IBD and to establish our own evidence-based guidelines.

Peer review

This is an interesting paper addressing an important issue in Chinese IBD patients. The paper is well written.

Abstract

AIM: To correlate the polymorphisms in the 5'-untranslated region with thymidylate synthase (TS) protein expression in Han Chinese colonic neoplasms.

METHODS: Adenocarcinoma samples were from 68 patients who received no treatment before surgery. Tandem repeat length of TS gene was determined by PCR amplification of genomic DNA. Intratumoral TS protein expression was studied immunohistochemically in corresponding sections from paraffin-embedded primary foci. Immunoreactivity was semiquantitatively evaluated by immunoreactivity score (IRS).

RESULTS: Double-(2R) and triple-repeated (3R) sequences of the TS gene were found in the cancer tissues. Three genotypes of TS were found: 2R/2R (n = 6), 2R/3R (n = 22) and 3R/3R (n = 40). Patients who were homozygous for triple-repeated (3R/3R) sequences showed significantly higher IRS of TS than patients who were homozygous for double-repeated (2R/2R) sequences or heterozygous patients (2R/3R): 5.73 ± 3.25 *vs* 2.17 ± 1.47 or 3.77 ± 2.64, P = 0.008 or P = 0.015. But no statistical significance of IRS in cancer tissues was observed between 2R/3R genotype and 2R/2R genotype.

CONCLUSION: There is a relationship between TS genotype and TS protein expression in clinical specimens. The data might offer an advantage for selection of Chinese cancer patients to receive fluoropyrimidines treatment.

INTRODUCTION

Thymidylate synthase (TS) catalyses deoxyuridine-5' -monophosphate (dUMP) to 2'-deoxythymydine-5' -monophosphate (dTMP). This is the only *de novo* source of thymidylate, an essential precursor of DNA biosynthesis[1,2]. The critical role of TS in nucleotide metabolism has made it an important target for cancer chemotherapeutic drugs such as 5-fluorouracil (5-FU), whose mechanism of action is primarily mediated through competitive TS inhibition[3-5].

Several studies have suggested that intratumoral TS protein expression before the chemoradiation treatment was inversely correlated with response to 5-FU chemotherapy. Patients with low TS levels have better clinical outcome than those with high TS levels[6-13].

TS expression is a tightly controlled process regulated by the proliferative status of the cell. Special 28-base pair-sized, unique tandem repeated sequences have been descried in the 5-untranslated region of TS gene[14-16], and this polymorphism is identified to be various ethnically[17-20]. There are three predominant genotypes of TS: (1) homozygous with two tandem repeats (2R/2R); (2) homozygous with three tandem repeats (3R/3R); (3) heterozygous with both alleles (2R/3R). It was reported that TS genes with the triple repeats have higher expression activity than those with double repeats *in vitro* and *in vivo*[15,21,22]. In this study, we investigated the association of TS genotype with its protein expression in clinical specimens of colon adenocarcinoma.

MATERIALS AND METHODS

Materials

Sixty-eight tumor samples obtained by surgical resection in patients (Han Chinese) who received no treatment before surgery were studied. The tumor tissue (1 g) from primary foci was obtained and frozen immediately in liquid

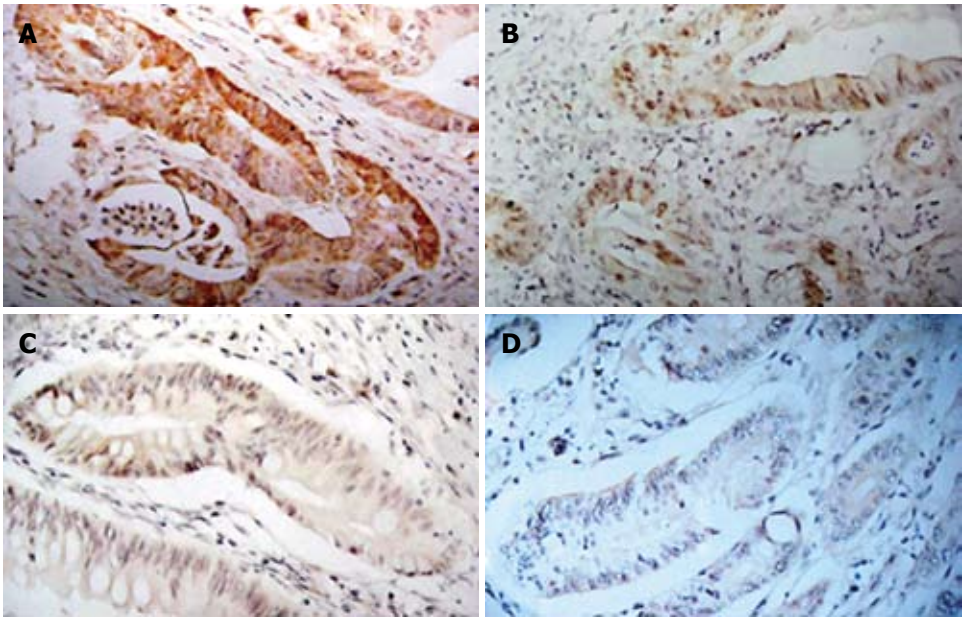

Figure 1 Immunohistochemical detection of TS staining intensity on paraffin sections of colorectal carcinoma. **A**: Strong; **B**: moderate; **C**: Weak; **D**: Absent (× 200).

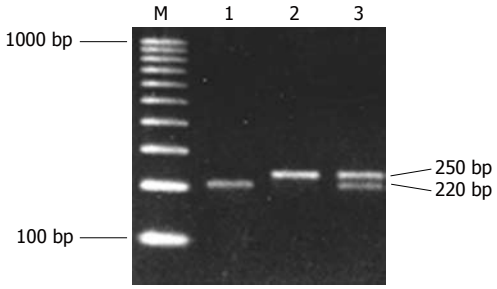

Figure 2 Electrophoresis of amplified products of patients with different TS TR genotypes: 220 bp (2R/2R), 248 bp (3R/3R) or both (2R/3R). Lane 1: 220 bp (2R/2R); Lane 2: 248 bp (3R/3R); Lane 3: 220 bp and 248 bp (2R/3R); M: molecular weight marker, a 100 bp ladder.

nitrogen until molecular analysis. The paraffin-embedded, formalin-fixed specimens from corresponding tumor were analyzed by immunohistochemistry.

Immunohistochemical evaluation

The monoclonal antibody TS 106[23] was used to detect TS. The standard Streptavidin-Peroxidase complex (Maixin-Bio, Fuzhou) technique was used. Immunoreactivity was evaluated semiquantitatively: labeling intensity (absent, weak, moderate, strong; Figure 1) × percentage of cells in each of the four intensity categories (0%-1%, 1%-25%, 26%-50%, 51%-75% and 76%-100%). In order to analyze the individual immunostaining result, integer values were assigned to the intensity scores (0-3) and the proportion of cells stained (0-4). These values were multiplied to provide a single integrated immunoreactivity score (IRS) for TS. All slides were randomly allocated for independent assessment by two observers, blinded to marker status. The agreement of IRS reached by two independent observers was > 90%. If there was disagreement, IRS was determined by consensus.

DNA extraction

DNA was extracted from the samples which were stored immediately at -80℃. After overnight incubation in 100 ng/mL Proteinase K (Promega, Southampton, UK) in 50 mmol/L TrisHCL (pH 7.5) and $CaCl_2$ 5 mmol/L solution at 37℃, DNA was extracted by the phenol-chloroform method.

Polymerase chain reaction (PCR)

The sequences of the primers used were TS12 5'-GTGG CTCCTGCGTTTCCCCC-3' (sense) and TS18 5'-GCTCC GAGCCGGCCACAGGCATGGCGCGG-3' (antisense). PCR analysis was performed in a total volume of 25 μL: 1.5 μL DNA, 1 μL (10 μmol/L) antisense and sense mixed primer, 0.25 μL (5 U/μL) Taq DNA polymerase (TaKaRa LA Taq LotE5801-7, code RR002A), 12.5 μL of 2 × GC buffer, 4 μL of 2.5 mmol/L mix of dNTP, and 5.75 μL DDW on Gene Amp PCR System 9700 (Perkin Elmer, Foster city, Norwalk, CT). All PCR reagents were obtained from TaKaRa Biomedicals (Otsu, Shiga, Japan). After 30 cycles of amplification (denaturation at 94℃ for 30 s, annealing at 70℃ for 30 s, extension at 72℃ for 30 s), the amplified products were electrophoresed in 2% agarose gel. Products of 220 bp (2R/2R), 248 bp (3R/3R) or both of these products (2R/3R) were obtained based on the TS TR genotype (Figure 2).

Cloning and sequencing of PCR products

PCR products were subcloned using the pGEM-T Vector System (Promega, Madison, WI). Subsequently the cloned PCR products were sequenced with a Thermo Sequenase Cy5.5 Terminator Sequencing kit (Amersham-Pharmacia, Piscataway, NJ). For confirmation of the sequence, at least five clones were analyzed.

RESULTS

TS polymorphisms: distribution among samples

In the studied samples, the following frequencies of TS genotypes were detected: 2R/2R in 6 patients (9%), 3R/3R in 40 patients (59%), and 2R/3R in 22 patients (32%) (Figure 3). Tandem repeated sequences in TS DNA:

TS genotype and IRS of TS

Cancer tissues with 3R/3R genotype showed significantly higher IRS of TS than those with 2R/3R genotype (5.73 ± 3.25 *vs* 3.77 ± 2.64, $P = 0.015$). Similarly, IRS of TS in 3R/3R genotype tissues was higher than that in 2R/2R genotype (5.73 ± 3.25 *vs* 2.17 ± 1.47, $P = 0.008$). But there was no statistical significance of IRS in cancer tissues between 2R/3R genotype and 2R/2R genotype (Figure 4).

DISCUSSION

There is an increasing need for defining new factors that may be used to effectively forecast the clinical response of colon cancer to a particular chemotherapy. Measurements of TS in colon cancer have been shown to be of interest because of the possible role of this enzyme in the clinical prognostic value to 5-FU-based chemotherapy[6,8,9,13,24-28]. However, the classical assay for TS-activity determination (high-performance liquid chromatography with output monitored by radioactive flow detector) is tedious and expensive. Edler *et al*[29] and Van Triest *et al*[30] compared the TS enzyme activity of lysates from frozen-stored colorectal cancer specimens with TS staining intensity using the monoclonal antibody TS106, and found a statistically significant correlation between the peak enzyme activity values and the TS staining intensity of respective colorectal cancer samples. IRS of TS in the paraffin-embedded specimen, a semiquantitative analysis of the individual immunostaining results, seems to be a good alternative to evaluate the intratumoral TS enzyme activity. Therefore, our observation of the link between TS genotype and IRS of TS suggested that TS genotype can be a genetic factor which can be used to predict the patient's response to 5-FU-based chemotherapy.

The present investigation demonstrated that there was a correlation between TS genotype and IRS of TS. Patients with the 3R/3R genotype showed significantly higher intratumoral IRS of TS compared to those with the 2R/3R genotype. Similarly, intratumoral IRS of TS in 3R/3R genotype tissues was higher than that in 2R/2R genotype. But no statistical significance of IRS was observed between 2R/3R genotype and 2R/2R genotype. Our results support the previous observation that the expression activity of the TS gene with the triple repeats is higher than that with the double repeats in a transient expression assay[15]. One of the mechanisms by which the repeat length of the TS gene influences its protein expression is that the three-repeat sequence has greater translation efficiency than that with two-repeat sequence[22].

Ethnic variations of the TS genotype have been reported in the literature[17-20]. The frequency for homozygous triple repeats arranged from 30% to 54% in the Caucasian population. In the Latino population, TS genotype distribution has been reported to be 16% in the 2R/2R group, 42% in the 2R/3R group, and 42% in the 3R/3R group. In the present study with Han population, the allelic frequency of triple repeats was 75%. According to Luo *et al*[31], the frequency of allele 3 varied from 62% to 95% in different Chinese populations.

In conclusion, our results support the previous *in vitro* expression study and suggest the association between TS genotype and TS protein expression in clinical specimens. These data are important for pharmacogenomics analysis in 5-FU-based chemotherapy. Prospective, large-scale trials are needed to confirm that the TS polymorphism is a useful molecular tool for optimizing drug therapy for the cancer patients.

COMMENTS

Background

As a pyrimidine analog, 5-fluorouracil (5-FU) exerts its antitumor effect through competitive thymidylate synthase (TS) inhibition. It was noted that the outcomes differed greatly among patients who received 5-FU-based adjuvant chemotherapy, whose efficacy seem to be affected by the intratumoral TS level. Polymorphism in 5'-untranslated region of TS gene influences the efficacy of TS expression, and this polymorphism was identified to be various ethnically. In this experiment, association of TS genotype with its protein expression in clinical specimens of Han Chinese with colon adenocarcinoma was observed.

Research frontiers

To associate the presence of the tandem repeat sequences within the 5'UTR of the TS gene with intratumoral TS expression, the TS expression was assessed by the immunoreactivity score (IRS). However, there has been no report about the relationship between TS gene polymorphisms and TS protein expression in Han Chinese patients.

Innovations and breakthroughs

Immunoreactivity score was applied to evaluate the TS expression level semiquantitatively to improve the study efficiency.

Applications

Prospective, large-scale trials are needed to confirm our results and to establish the advantages of the TS polymorphism as a useful molecular tool for optimizing fluoropyrimidine-based therapy in Han Chinese cancer patients.

Terminology

Thymidylate synthase (TS) is the key enzyme that catalyzes methylation of fluorodeoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), which is an important step in the process of DNA synthesis.

Peer review

This study associated the presence of the 3R/3R tandem repeat sequence within the 5'UTR of the thymidylate synthase gene with increased tumor TS expression as assessed by IHC. The study was conducted in a cohort of 68 Han Chinese patients with colon cancer. It was relatively well performed and appropriate conclusions have been drawn.

Abstract

AIM: To test the clinical significance of antineutrophil cytoplasmic antibody (ANCA) in evaluation of adult Henoch-Schönlein purpura (HSP) patients presenting mainly with abdominal symptoms.

METHODS: Twenty-eight consecutive HSP patients who presented predominantly with abdominal symptoms were enrolled in this study. Control subjects included 27 age- and sex-matched patients with peptic ulcer disease, colon cancer, acute gastroenteritis, irritable bowel syndrome and colonic polyps. ANCA was measured by indirect immunofluorescence (IIF) in all patients, and follow-up ELISA was performed in patients with positive IIF tests.

RESULTS: ANCA was detected in 9 HSP patients by IIF (2 were positive for c-ANCA and 7 were positive for p-ANCA). No ANCA was found in the control group. The sensitivity and specificity of a positive ANCA test (either c- or p-ANCA) were 32.1% and 100% respectively. Only one out of the 9 patients with positive ANCA by IIF had positive ANCA by ELISA and the antigen was myeloperoxidase (MPO). The patients positive for ANCA had higher HSP clinical scores, and were more likely to have renal function impairment. Patients with late purpura development were also associated with more severe clinical manifestations.

CONCLUSION: A positive ANCA test is associated with more severe symptoms in HSP. After inflammatory bowel disease is excluded, a positive ANCA test provides a clue to the diagnosis of HSP presenting predominantly with abdominal symptoms.

INTRODUCTION

Abdominal pain, diarrhea, hematochezia are the common symptoms seen in clinical gastroenterology. The underlying causes may not always be clear. Henoch-Schönlein purpura (HSP) is one of the uncommon causes and can be a challenging clinical problem[1]. Among the presenting symptoms, gastrointestinal (GI) complains occur in 50% to 85% of patients[2]. Some HSP patients may develop serious GI complications, such as intussusception, obstruction and perforation, which may require surgical intervention on rare occasions[3-5]. Early diagnosis of HSP presenting mainly with acute abdominal symptoms in adults remains a challenge to both gastroenterologists and general surgeons, particularly if the abdominal symptoms precede the typical skin rash. Although HSP is more common in children, it has also been documented in adults[6]. In comparison to children, adult patients have more atypical symptoms and a poorer prognosis and need more intensive care[7]. Although lots of efforts have been made, the mortality in adults with HSP is still higher than that in children. Doctors are eager to find a more effective therapy for the disease.

Since antineutrophil cytoplasmic antibody (ANCA) was reported in 1982 by Bavis, many studies have shown that ANCA is a useful tool for the diagnosis of systemic

vasculitis, especially for the diagnosis and follow-up of microscopic polyangiitis and Wegener's granulomatosis[8,9]. It was reported that ANCA is also detectable in patients with HSP. However, the prevalence of HSP remains controversial, ranging 0%-79%[10-13]. It has been shown that the positive ANCA rate is as high as 82.3%[14], suggesting that ANCA can be used to confirm the diagnosis of HSP in children. In addition, some reports indicate that ANCA is also related to the severity of autoimmunological diseases, such as Wegener's granulomatosis[15], systemic vasculitis[16,17]. However, the relationship between ANCA and the severity of HSP has not been extensively investigated.

Till now, most studies were confined to children, only a few studies have been done in adults[12,13] and no reports on adult HSP patients presenting mainly with gastrointestinal symptoms are available. The aim of this study was to evaluate the clinical significance of ANCA in adult HSP patients who presented mainly with gastrointestinal symptoms and its role in the diagnosis of HSP and its relationship to the disease severity.

MATERIALS AND METHODS

Patient selection

From February 2003 to March 2006, all adult HSP patients (age > 20 years) with prominent gastrointestinal symptoms, admitted to West China Hospital of Sichuan University, were enrolled in the study. All the patients fulfilled the HSP diagnostic criteria[18]. During the same period, non-HSP inpatients with similar gastrointestinal symptoms served as the control group. Only patients without preexisting medical comorbidity were included in this study. Patients with known inflammatory bowel disease or autoimmune diseases were excluded from the study.

ANCA detection by indirect immunofluorescence (IIF)

The method is commercially established and provided by EUROIMMU Company (Germany). Briefly, serum samples were diluted at 1:3.2 in a phosphate- buffered solution (PBS), then 25 μL was applied to slides, and incubated at room temperature for 30 min. After the slides were washed with PBS, 20 μL FITC-labeled affinity-purified goat anti-human IgG (EUROIMMU Company, Germany) was applied to the slides and incubated at room temperature for 30 min. Fluorescence microscopy was performed and the results were interpreted as negative for lack of fluorescence and positive for the presence of moderate or intense fluorescence.

ANCA detection by ELISA for PR-3, MPO, EL, Cath-G, LF and BPI

The ELISA kit from EUROIMMU Company (Germany) was used. Briefly, 100 μL of patient serum diluted at 1:100, positive and negative controls were put in 96-well plates (coated with PR-3, MPO, EL, Cath-G, LF or BPI) and incubated at room temperature for 30 min. After washed with PBS, 100 μL enzyme-labeled rabbit antihuman IgG (EUROIMMU Company, Germany) was added to the wells and incubated for 30 min. After washing, 100 μL enzyme substrate (TMB/H_2O_2) was added to the wells, and incubated for 15 min. The reaction was then terminated by adding 100 μL sulfuric acid (0.5 mol/L). The absorbance was read at 450 nm with an automated plate reader. The result was expressed as (serum sample OD-OD of negative control)/[(C-blank OD) × 0.2)]. A value < 0.1 was regarded as negative and ⩾ 0.1 as positive.

Table 1 Clinical scores for HSP

Symptom	Score
Purpura	
below the umbilicus	1^+
above the umbilicus	2^+
Abdominal pain	
Stool occult blood < 2^+	1^+
Stool occult blood > 2^+	2^+
Joint pain	1^+
Renal involvement	
Urinary occult blood 1^+	1^+
Urinary occult blood 2^+	2^+
Urinary occult blood 3^+	3^+

Other biochemical examinations

Twenty four-hour urinary protein, urinalysis, kidney function and antinuclear antibody (ANA) test and rheumatoid factor (RF) were performed in the clinical laboratory of the hospital.

HSP clinical score

To stratify patients according to the disease severity, the clinical scoring system of was used as previously described Table 1[19].

Statistical analysis

Results were given as mean ± SD and percentage. For statistical analysis, Student *t* test (for age, clinical scores, blood creatine, 24 h urinary protein) and χ^2 test (for sex and clinical symptom percentages) were used. $P < 0.05$ was considered statistically significant.

RESULTS

Twenty-eight patients with a final diagnosis of HSP who presented mainly with gastrointestinal symptoms were included in the study. All HSP patients eventually developed typical purpura lesions. The average clinical score was 5.32 ± 0.92. Twenty-seven patients with peptic ulcer ($n = 10$), colon cancer ($n = 1$), acute gastroenteritis ($n = 6$), irritable bowel syndrome ($n = 6$), and colonic polyps ($n = 4$) served as controls. Age and sex distribution were comparable between the two groups ($P > 0.05$). The demographics, symptom percentages in both groups are listed in Table 2.

All the patients were negative for ANA. Only one HSP patient was found to have a positive RF test. Of the 23 patients who could recall the occurring time of their symptoms, 5 complained of GI symptoms preceding purpura while 18 complained of purpura preceding the GI symptoms.

ANCA was detected in 9 HSP patients. Of them, 2 had

Table 2 Comparison of demographic data between HSP patients and controls

	HSP	Control	*P* value
n	28	27	NS[1]
Gender (male/female)	15/13	11/16	NS
Age (yr) (mean ± SD)	29.8 ± 8.1	30.1 ± 8.6	NS
Age range (yr)	20-46	22-52	
Symptoms			
Abdominal pain (%)	53.6	59.8	NS
Hematochezia (%)	46.4	51.2	NS
Diarrhea (%)	21.4	32.1	NS
Vomiting (%)	10.7	14.8	NS

[1]NS denotes no significance.

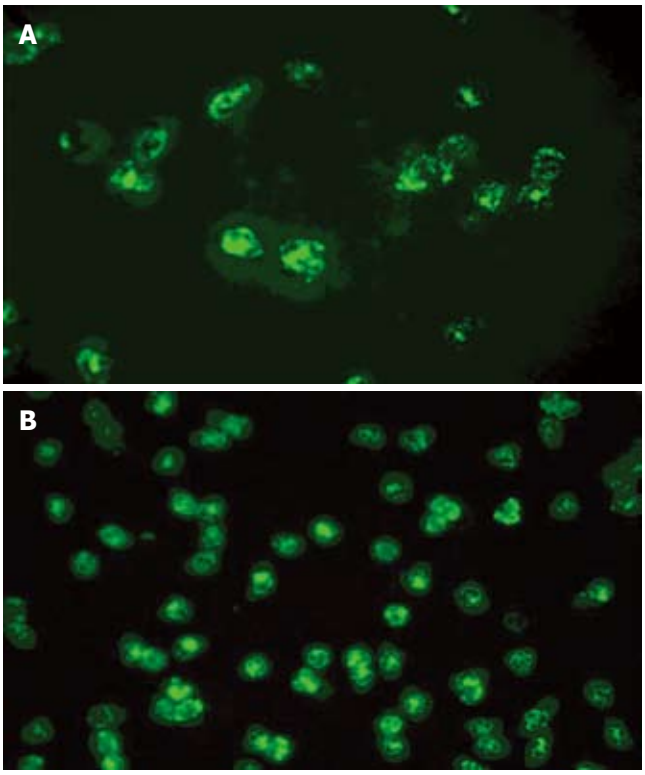

Figure 1 Strong cytoplasmic (**A**) and nuclear (**B**) staining patterns of ANCA (C-ANCA and P-ANCA) detected by indirect IIF. Serum samples from patients were diluted and incubated with primary antibody, then with FITC-labeled affinity-purified goat anti-human IgG. The results were observed under fluorescence microscope.

C-ANCA (Figure 1A) and 7 had P-ANCA (Figure 1B). No ANCA was detected in the controls (Table 3). The sensitivity and specificity of positive ANCA were 32.1% and 100% respectively. ELISA was performed for the 9 patients with positive ANCA detected by indirect IIF. Only one patient was positive for ANCA and the antigen was myeloperoxidase (MPO).

HSP patients who were positive for ANCA had higher clinical scores (6.79 ± 0.72 *vs* 4.12 ± 0.63, $P = 0.02$), and a higher rate for renal involvement as indicated by serum creatine level and 24 h urinary protein at the time of diagnosis (Table 4). Baseline kidney function tests were not available for most patients. However, given the lack of preexisting medical conditions, HSP was the most likely culprit for renal impairment in these patients.

Table 3 ANCA detected by IIF in HSP patients and controls

	+ANCA by IIF	- ANCA by IIF
HSP	9	19
control	0	27

Table 4 Blood creatine and 24 h urinary protein in HSP patients (mean ± SD)

	Blood creatine (μmol/L)	24 h urinary protein (g/L)
ANCA (+)	320 ± 22 (3.64 ± 0.25 mg/dL)	1.78 ± 0.12
ANCA (-)	104 ± 15[b] (1.19 ± 0.16 mg/dL)	0.78 ± 0.32[c]

[b]$P = 0.01$, [c]$P = 0.03$.

Table 5 Characteristics of the two groups

Symptom sequence	Positive ANCA (%)	HSP score	Abdominal pain (%)	Diarrhea (%)	Hematochezia (%)
Purpura before abdominal symptoms	33.3	5.02 ± 1.23	55.6	22.2	38.9
Purpura after abdominal symptoms	40.0	6.23 ± 1.08	60.0	40.0	60.0

HSP clinical scores and ANCA positive rates in patients with early and late purpura were also analyzed (Table 5). The latter was associated with a higher clinical score, but the GI symptoms and ANCA positive rate were similar in the two groups.

Typical case presentation

Case 1: A 28-year-old male was admitted for vomiting and diarrhea for 5 d and oliguria for 1 d. Physical examination on admission showed mild tenderness in the mid upper abdomen. Stool analysis showed white blood cells (+) and red blood cells (+). Renal function test showed moderately elevated blood BUN and creatine. Urinary analysis showed occult blood (++). "Acute gastroenteritis and acute renal function failure" were the initial diagnosis on admission. Infusion of 2 liters of intravenous fluid did not result in any clinical improvement. Serum ANCA test was positive. Three days later, typical purpura appeared on his lower extremities and HSP was thus diagnosed. The symptoms disappeared after one-month intravenous cyclosporine therapy.

Case 2: A 26-year-old male was admitted for abdominal pain and hematochezia for 4 d, and hematuria for 1 d. Physical examination was normal. Blood examination showed moderate anemia. Urinalysis showed red blood cells (++). Renal ultrasound was normal. An upper endoscopy showed edema and congestion in the pyloric region (Figure 2A). Colonoscopy showed several petechiae scattering throughout the colon (Figure 2B). ANCA test was positive. Four days later, typical purpura appeared in his hips and lower extremities. All symptoms disappeared three weeks after treatment with prednisone.

DISCUSSION

HSP is an immune-complex mediated vasculitis, affecting small vessels in skin, gut and glomeruli[20] and is characterized by polymorphonuclear leukocytic infiltration of the vessel wall. Mucosal lesions of HSP can occur anywhere in the GI tract, and the small intestine is unfortunately the most commonly affected[21,22]. In 10%-15% HSP patients, gastrointestinal symptoms precede the cutaneous lesions[23]. The GI manifestation in these patients is usually severe and sometimes requires laparotomy. Our study also showed that the patients with GI symptoms preceding the purpura had higher clinical scores, but unfortunately their GI symptoms were nonspecific.

ANCA is an auto-antibody existing in peripheral blood, and has a high specificity for and sensitivity to certain vasculitis. Saulsbury tested ANCA in 29 HSP patients and none was positive[10], suggesting that ANCA is not a useful diagnostic tool for HSP. Renato and Robson *et al*[11,12] have also found a low prevalence of ANCA in HSP, indicating that ANCA is not related to HSP. On the contrary, it was reported the prevalence (79%) of ANCA is high in HSP patients[13,24]. Faith *et al*[14] also showed that IgA ANCA is 82.3% in children with HSP, demonstrating that ANCA is a useful test to confirm the diagnosis of HSP in children. In our study, the specificity and sensitivity of ANCA were 100% and 32.1%, respectively. Due to its high specificity, a positive test result can be very helpful in making the early diagnosis of HSP before cutaneous lesions occur. However, our study excluded ulcerative colitis (UC) patients. According to recent studies, ANCA is recorded in 50%-70% of patients with UC[25]. Because UC has its own characteristic clinical manifestations, especially specific colonoscopic manifestation, it is very easy for GI doctors to differentiate UC from HSP.

The reasons why the reported results are different may be as follows. (1) IIF is a crude test method its results may be affected by many factors such as RF and fibronectin, and interfered with the different process and conditions of the study. In our study, RF was found only 1 patient, suggesting that it is not the reason why ANCA test was positive in our study. (2) Specific antigens are insufficient. The main target antigens of ANCA lay in the azurophil granules of neutrophils. Only five specific antigens have been identified so far for ANCA, including proteinase 3 (PR-3), myeloperoxidase (MPO), leukocyte elastase (EL), cathepsin G (CG), lactoferrin (LF)[26]. In our study, we tested the binding of the five antigens to ANCA by ELISA. The result showed that only one HSP serum sample had reactivity against anti-MPO, which is in agreement with previous reports, indicating that the five antigens are not specific antigens for ANCA. However, little is known about the specific antigens for ANCA. Ronda *et al*[13] analyzed the target antigen by Western blot using four strongest ANCA positive serum samples and found that a 51-kDa protein can be recognized in the neutrophil extract, indicating that the target antigens of ANCA may be different in patients with HSP and vasculitis. Discovery of more specific antigens for ANCA is needed to improve its value for clinical utilization. (3) It also may be related to the selection bias of cases. Some studies showed that different expressions of HLA are interfered with the expression of ANCA.

Our results show that a positive ANCA test was associated with a higher HSP score and a higher rate for renal dysfunction and urinary abnormality, which is consistent with the data reported by Shaw and Esnault[27,28], who found that patients with worse kidney function and higher urinary protein level have a higher ANCA titer, showing that ANCA is related to the activity of HSP. These findings suggest that ANCA may take part in the pathogenesis of HSP. The presence of ANCA in the sera of patients may exert both stimulatory and inhibitory effects on neutrophil and monocyte functions. It can stimulate the oxidative burst and degranulation, leading to the release of reactive oxygen intermediates. Enzymes from granules may directly damage the target tissues, inhibit the microbicidal activity of polymorphonuclears, thus aggravating the neutrophil/macrophage dysfunction by inadequate elimination of the infectious agents[29]. This may lead to the Th1/Th2 lymphocyte imbalance, leading to tissue damage and perpetuation of chronic inflammation. In addition, ANCA may influence the process of physiologic cell death. It was reported that ANCA can induce apoptosis of neutrophils, phagocytosis of apoptotic neutrophils opsonized by ANCA induces oxidative metabolism of monocytes, and defective apoptosis of neutrophils may thus exacerbate the tissue damage[30].

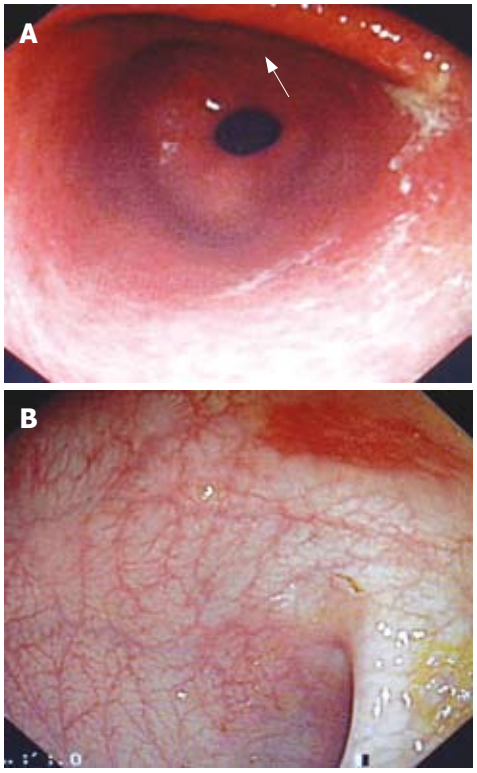

Figure 2 Gastroendoscopy showing edema and congestion in the pyloric region (**A**) and several petechiae scattering throughout the colon (**B**).

In conclusion, after exclusion of UC, a positive ANCA test in patients presenting mainly with GI symptoms can provide a clue to the diagnosis of HSP. Patients with a positive ANCA develop more severe symptoms and are more likely to have their kidneys involved. HSP patients with positive ANCA initially presenting with only GI symptoms should receive a more aggressive therapy. Since our sample was small, further studies are needed to find the exact antigens for ANCA in HSP patients.

COMMENTS

Background

Gastrointestinal symptoms are the common symptoms of Henoch-Schönlein purpura (HSP). Early diagnosis of HSP with gastrointestinal symptoms is difficult and some patients even undergo unnecessary laparotomy. Improving the early diagnosis of HSP still remains a challenge to both gastroenterologists and general surgeons.

Research frontiers

Antineutrophil cytoplasmic antibody (ANCA) is a useful tool for the diagnosis of systemic vasculitis. Recent studies indicate that ANCA is also detected in patients with HSP. However, its prevalence remains controversial. In addition, it was reported that ANCA is also related to the severity of many autoimmunological diseases, but the relationship between ANCA and the severity of HSP has not been extensively investigated.

Innovations and breakthrough

Most studies on HSP have been confined to children and no reports are available on adult HSP patients presenting mainly with gastrointestinal symptoms. In the present study, the authors found that ANCA positive test had a high specificity in HSP patients with gastrointestinal symptoms and HSP patients with ANCA positive had a higher clinical score.

Applications

ANCA may be a useful marker for the diagnosis of HSP with gastrointestinal symptoms.

Peer review

This paper investigated the significance of ANCA in HSP patients presenting with gastrointestinal symptoms. The authors concluded that a positive ANCA test could diagnose HSP in adult patients. HSP patients with positive ANCA have more serious symptoms.

Abstract

AIM: To investigate genistein-induced apoptosis of implanted tumors of SG7901 cells in nude mice, and the relationship between this apoptosis and expression of Bcl-2 and Bax.

METHODS: Establishing a transplanted tumor model by injecting human SG7901 cells into subcutaneous tissue of nude mice. Genistein (0.5, 1 and 1.5 mg/kg) was directly injected adjacent to the tumor, six times at 2-d intervals. Then, changes in tumor volume were measured continuously and tumor inhibition rate of each group was calculated. We observed the morphological alterations by transmission electron microscopy (TEM), measured the apoptotic rate by the TUNEL staining method, and detected the expression of apoptosis-regulated gene Bcl-2 and bax by immunohistochemical staining and RT-PCR.

RESULTS: Genistein 0.5, 1 and 1.5 mg/kg significantly inhibited carcinoma growth when it was injected near the tumor by 10.8%, 29.9% and 39.6%, respectively. Genistein induced implanted tumor cells to undergo apoptosis, with apoptotic characteristics seen by TEM. The apoptosis index was increased progressively with increasing genistein dose (28.9% ± 1.2%, 33.8% ± 1.6% and 37.7% ± 1.2%). The positive rate of Bcl-2 protein was decreased progressively (11.9% ± 0.9%, 5.9% ± 0.7% and 4.2% ± 0.6%), and the positive rate of bax protein was increased progressively (0.9% ± 1.7%, 24.9% ± 0.8% and 29.6% ± 1.7%) by immunohistochemical staining, with increasing dose of genistein. The density of Bcl-2 mRNA decreased progressively and the density of bax mRNA increased progressively with elongation of time by RT-PCR.

CONCLUSION: Genistein was able to induce apoptosis of transplanted tumor cells. This apoptosis may be mediated by down-regulation of the apoptosis-regulated gene Bcl-2 and up-regulation of apoptosis-regulated gene bax.

INTRODUCTION

The Bcl-2 family plays a crucial role in the control of apoptosis. The family includes a number of proteins which have homologous amino acid sequences, including anti-apoptotic members such as Bcl-2 and Bcl-xl, as well as pro-apoptotic members including Bax and Bad[1-4]. In *in vitro* experiments, overexpression of Bcl-2 has been shown to inhibit apoptosis[5-9], but overexpression of Bax has been shown to promote apoptosis[10-14].

Genistein has estrogenic properties in receptor binding assays[15,16], cell culture[17,18], and uterine weight assays[19-21]. Genistein inhibits microsomal lipid peroxidation[22] and angiogenesis[23]. Genistein exhibits antioxidant properties[24-26] and has been reported to induce differentiation of numerous cell types[27-29]. Moreover, a recent report has shown that genistein is a potent cancer chemopreventive agent[30-32]. The anti-tumor activity of genistein might be related to the induction of apoptosis of tumor cells but the precise mechanism of its antitumor activity is not well understood.

This study investigated genistein-induced apoptosis of implanted tumors of SG7901 cells in nude mice, the relationship between this apoptosis and expression of Bcl-2 and bax *in vivo*, and the theoretical and methodological basis of the clinical application of genistein.

MATERIALS AND METHODS

Materials

Genistein was obtained from Sigma and dissolved in dimethylsulfoxide (DMSO). In situ cell detection kit, anti-Bcl-2 monoclonal antibody and anti-Bax monoclonal antibody were purchased from Beijing Zhongshan Biotechnology. Female Balb/C nude mice (4 wk old, 16-18 g) were obtained from Chinese Academy of Medical Science.

Cell culture

Fresh samples from a patient with low-differentiation gastric cancer were obtained in the operating room. A single-cell suspension of tumor cells with a concentration of 5×10^5/mL was prepared for seeding. SG7901 cells were artificially purified after culture by pancreatic proteinase.

Tumor implantation into nude mice

A transplanted tumor model was established by injecting 1×10^9 human SG7901 cells/L into the subcutaneous tissue of nude mice. After 10 d, 25 nude mice were randomly divided into five groups, and 0.2 mL normal saline solution, 1.5 mg/kg DMSO, or 0.5, 1 or 1.5 mg/kg genistein was directly injected adjacent to the tumor, six times at 2-d intervals. Changes in tumor volume [$V = (\pi/6) \times abc$] were measured at 11 d after drug treatment and the tumor inhibition rate of each group was calculated.

$$\text{Inhibitory rate (IR) of tumor growth} = \frac{C(V_1 - V_0) - T(V_1 - V_0)}{C(V_1 - V_0)}$$

where C is the control group; T is the treated group; V_1 the volume before treatment (mm^3); and V_0 the volume after treatment (mm^3).

Transmission electron microscopy (TEM)

The tumor samples were cut into 1 mm^3 blocks and fixed in 4% glutaraldehyde and immersed in Epon 821, and embedded for 72 h at 60℃. The cells were cut into ultrathin section (60 nm) and stained with uranyl acetate and lead citrate. Cell morphology was observed by TEM. made in Japan.

TUNEL assay

The tumor samples were cryopreserved in liquid nitrogen and cut into 8-μm-thick slices. Slices were fixed in ice-cold 80% ethanol for up to 24 h, treated with proteinase K and 0.3% H_2O_2, and labeled with fluorescein dUTP in a humid box for 1 h at 37℃. Slices were then combined with POD-horseradish peroxidase, stained with DAB, and counterstained with methyl green. Controls were treated the same except for labeling with fluorescein dUTP. Cells were examined by light microscopy. The apoptotic index (AI) was calculated as follows: AI = (number of apoptotic cells/total number of cells) × 100%.

Immunohistochemical staining

The tumor samples were cryopreserved in liquid nitrogen and cut into 8-μm-thick slices and fixed in acetone. After washing in PBS, slices were incubated in 0.3% H_2O_2 solution at room temperature for 5 min. Slices were then incubated with anti-Bcl-2 or anti-Bax monoclonal antibody at a 1:300 dilution at 4℃ overnight. After washing in PBS, the second antibody, biotinylated anti-rat IgG, was added and the cells were incubated at room temperature for 1 h. After washing in PBS, ABC compound was added and then incubated at room temperature for 10 min. DAB was used as the chromogen. After 10 min, the brown color signifying the presence of antigen bound to antibodies was detected by light microscopy. Controls were prepared in the same manner as the experimental group, except for incubation with the primary antibody. The positive rate (PR) was calculated as follows: PR = (number of positive cells/total number of cells) × 100%.

Table 1 Inhibition effect of genistein on implanted tumors in nude mice (mean ± SD)

Groups dosage	Number of animals		Volume of tumors (mm^3)		Inhibition rate (%)
	Beginning	Ending	Beginning	Ending	
Control group					
0.2 mL saline	5	5	20.6 ± 1.1	499.8 ± 11.8	
DMSO					
1.5 mg/kg	5	5	20.6 ± 1.3	509.4 ± 8.6	
Genistein					
1.5 mg/kg	5	5	20.3 ± 1.6	458.2 ± 6.7	10.8[a]
1.0 mg/kg	5	5	21.6 ± 1.6	359.7 ± 6.4	29.9[a]
1.5 mg/kg	5	5	21.5 ± 1.6	319.5 ± 10.6	39.6[a]

[a]$P < 0.05$ *vs* the control group.

RT-PCR

The tumor samples were cryopreserved in liquid nitrogen and total RNA was extracted. The concentration of RNA was determined by absorption at 260 nm. The primers for Bcl-2, bax and β-actin were as follows: β-actin (500 bp) 5'-GTGGGGCGCCCCAGGCACCA-3', 5'-CTCCTTAATGTCACGCACGATTTC-3'; Bcl-2 (716 bp) 5'-GGAAATATGGCGCACGCT-3', 5'-TCACTTGTGGCCCAGAT-3'; bax (508 bp) 5'-CCAGCTCTGAGCAGATCAT-3', 5'-TATCAGCCCATCTTCTTCC-3'. PCRs were performed in a 50 μL reaction volume. RT-PCR reaction was run as follows: 94℃ for 7 min, one cycle; 94℃ for 1 min, 72℃ for 1 min, 30 cycles; 72℃ for 7 min, one cycle. Ten microliters PCR product was placed on to 15 g/L agarose gel and observed by ethidium bromide staining using a Gel-Pro analyzer.

Statistical analysis

Datas were analyzed by analysis of variance, and statistical significance was considered at $P < 0.05$.

RESULTS

Inhibitory rate of tumor growth

An inhibitory effect was observed in all therapeutic groups, and the IR for 0.5, 1 and 1.5 mg/kg genistein was 10.8%, 29.9% and 39.6%, respectively (Table 1).

Morphological changes

Control cells had a normal structure, but some cells in the therapeutic groups had apoptotic characteristics, including chromatin condensation, appearance of chromatin

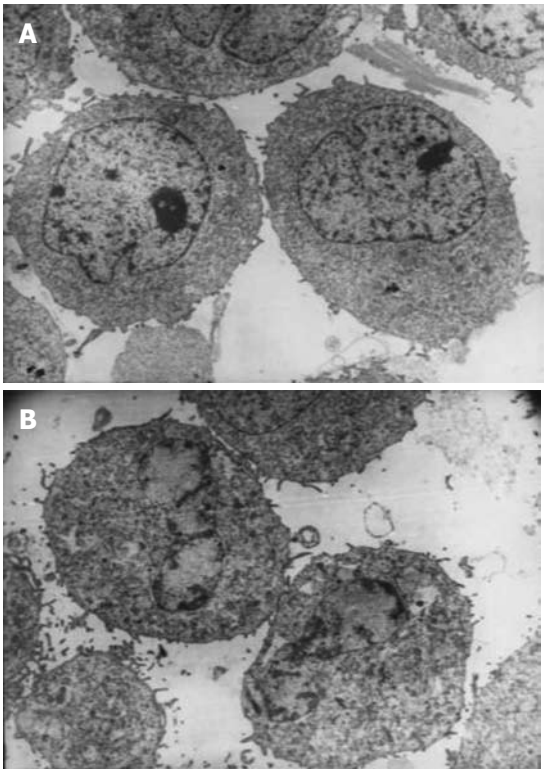

Figure 1 **A:** Ultrastructure of transplanted tumor cells (× 4800); **B:** Ultrastructure of apoptotic transplanted tumor cells induced by genistein (× 4800).

crescents, and nucleus fragmentation, which were seen by TEM (Figure 1A and B) .

TUNEL assay

Positive staining was located in the nucleus. The AI for 0.2 mL normal saline solution, 1.5 mg/kg DMSO, and 0.5, 1 and 1.5 mg/kg genistein was 12.6% ± 0.6%, 13.4% ± 0.7%, 28.9% ± 1.2%, 33.8% ± 1.6% and 37.7% ± 1.2%, respectively (Table 2) .

Expression of Bcl-2 proteins

Positive staining was located in the cytoplasm. The PR for Bcl-2 protein for 0.2 mL normal saline solution, 1.5 mg/kg DMSO, and 0.5, 1 and 1.5 mg/kg genistein was 18.4% ± 1.6%, 17.9% ± 0.7%, 11.9% ± 0.9%, 5.9% ± 0.7 and 4.2% ± 0.6%, respectively by immunohistochemical staining (Table 3) .

Expression of Bax proteins

Positive staining was located in the cytoplasm. PR for bax protein for 0.2 mL normal saline solution, 1.5 mg/kg DMSO, and 0.5, 1 and 1.5 mg/kg genistein was 11.2% ± 0.8%, 11.9% ± 0.5%, 20.9% ± 1.7%, 24.9% ± 0.8% and 29.6% ± 1.7%, respectively (Table 3).

RT-PCR

The density of Bcl-2 mRNA for 0.2 mL normal saline solution, 1.5 mg/kg DMSO, and 0.5, 1 and 1.5 mg/kg genistein decreased progressively, and the density of bax mRNA for 0.2 mL normal saline solution, 1.5 mg/kg DMSO, and 0.5, 1 and 1.5 mg/kg genistein increased progressively, with elongation of time by RT-PCR.

Table 2 Apoptotic index (AI) of implanted tumors in nude mice (%)

	AI

1.5 mg/kg	4.2 ± 0.6	29.6 ± 1.7

DISCUSSION

Currently, only a few chemotherapeutic drugs are effective for the treatment of human primary gastric carcinoma, and there is a clear need to look for new anti-gastric carcinoma drugs. Genistein is a planar molecule with an aromatic A-ring, has a second oxygen atom from that in the A ring, and has a molecular mass similar to those of the steroidal estrogens. It has estrogenic properties in receptor binding assays[15,16], cell culture[17,18], and uterine weight assays[19-21]. Genistein inhibits topoisomerase Ⅱ[33], platelet-activating factor- and epidermal growth factor-induced expression of c-fos[34], diacylglycerol synthesis[35], and tyrosine kinases[36]. It also inhibits microsomal lipid peroxidation[22] and angiogenesis[23]. Genistein exhibits antioxidant properties[24-26] and has been reported to induce differentiation of numerous cell types[27-29]. Moreover, a recent report has shown that genistein is a potent cancer chemopreventive agent[30-32].

The Bcl-2 family plays a crucial role in the control of apoptosis. The family includes a number of proteins that have homologous amino acid sequences, including anti-apoptotic members such as Bcl-2 and Bcl-xL, as well as pro-apoptotic members including Bax and Bad[1-4]. Overexpression of Bax has the effect of promoting cell death[10-14]. Conversely, overexpression of anti-apoptotic proteins such as Bcl-2 represses the function of Bax[5-9]. Thus, the ratio of Bcl-2/Bax appears to be a critical determinant of a cell's threshold for undergoing apoptosis[37].

We found that genistein was able to induce apoptosis in SG7901 cells *in vitro*. This apoptosis might have been mediated by down-regulating the expression of the apoptosis-regulated gene Bcl-2 and up-regulating the

expression of apoptosis-regulated gene Bax. In this study, we evaluated the effectiveness of the gastric carcinoma apoptosis induced by genistein *in vivo*, and investigated the molecular mechanisms involved, and the theoretical and methodological basis for the clinical application of genistein, by using an animal model.

We demonstrated that inhibition was induced in all therapeutic groups. Control cells appeared normal in structure, but some cells in the therapeutic groups showed apoptotic characteristics. The AI of 0.5, 1 and 1.5 mg/kg genistein increased with the dose of genistein. Expression of Bcl-2 in the presence of genistein was decreased, but expression of bax was increased. The density of Bcl-2 mRNA decreased progressively with 0.5, 1 and 1.5 mg/kg genistein, and the density of bax mRNA increased progressively. The ratio of Bcl-2/Bax was decreased and triggered apoptosis of transplanted tumor cells. Our results demonstrated that genistein was able to induce apoptosis of transplanted tumor cells in nude mice. The apoptosis may have been mediated by down-regulating expression of apoptosis-regulated gene Bcl-2 and up-regulating expression of apoptosis-regulated gene Bax. Genistein may be potentially used as a chemotherapeutic drug in the anti-gastric carcinoma chemotherapy.

COMMENTS

Background

A recent study has shown that genistein is a potent cancer chemopreventive agent. The anti-tumor activity of genistein might be related to induction of apoptosis of tumor cells, but the precise mechanism of its anti-tumor activity is not well understood. This study investigated the genistein-induced apoptosis of implanted tumors of SG7901 cells in nude mice, the relationship between this apoptosis and expression of Bcl-2 and bax *in vivo*, and the theoretical and methodological basis for the clinical application of genistein.

Research frontiers

Our results demonstrated that genistein was able to induce apoptosis of transplanted tumor cells in nude mice. The apoptosis may have been mediated by down-regulating expression of apoptosis-regulated gene Bcl-2 and up-regulating expression of apoptosis-regulated gene Bax.

Related publications

For more information about each section, please refer to the studies cited in the reference list.

Innovations and breakthroughs

Genistein was able to induce the apoptosis of transplanted tumor cells in nude mice. The apoptosis may have been mediated by down-regulating expression of apoptosis-regulated gene Bcl-2 and up-regulating expression of apoptosis-regulated gene Bax. To the best of our knowledge, no similar studies are available at present.

Applications

According to the results of this study, genistein may potentially be used as a chemotherapeutic drug for gastric carcinoma.

Terminology

Bcl-2: This is a large family composed of various members that are key regulators of apoptosis. High levels and aberrant patterns of Bcl-2 expression have been reported in a wide variety of human caners. Bax: This is a pro-apoptotic member of the Bcl-2 family, which is thought to induce apoptosis. Loss of Bax in genetically engineered mice results in increased tumor incidence, which suggests that Bax may play a role in suppressing tumor growth *in vivo*.

Peer review

The study demonstrated that genistein was able to induce apoptosis of transplanted tumor cells in nude mice. The apoptosis may have been mediated by down-regulating expression of apoptosis -regulated gene Bcl-2 and up-regulating expression of apoptosis-regulated gene Bax. The authors conclude that genistein may potentially be used as a chemotherapeutic drug for gastric carcinoma.

Abstract

AIM: To carry out a hospital-based case-control study to investigate risk factors for intrahepatic cholangiocarcinoma (ICC) in China.

METHODS: A total of 312 ICC cases and 438 matched controls were included in the study. The presence of diabetes mellitus, hypertension, hepatolithiasis, primary sclerosing cholangitis, liver fluke infection (*Clonorchis sinensis*), was investigated through clinical records. Blood from all participants was tested for hepatitis B surface antigen (HBsAg) and anti-HCV antibodies. Odds ratios (OR) and 95% confidence intervals (95% CI) were estimated using conditional logistic regression.

RESULTS: Compared with controls, ICC patients had a higher prevalence of HBsAg seropositivity (48.4% *vs* 9.6%, $P < 0.000$), and hepatolithiasis (5.4% *vs* 1.1%, $P = 0.001$). By multivariate analysis, the significant risk factors for development of ICC were HBsAg seropositivity (adjusted OR, 8.876, 95% CI, 5.973-13.192), and hepatolithiasis (adjusted OR, 5.765, 95% CI, 1.972-16.851). The prevalence of anti-HCV seropositivity, diabetes mellitus, hypertension, cigarette smoking, and alcohol consumption were not significantly different between cases and controls.

CONCLUSION: These findings suggest that HBV infection and hepatolithiasis are strong risk factors for development of ICC in China.

Key words: Intrahepatic cholangiocarcinoma; Hepatitis B virus; Hepatitis C virus; Risk factors

INTRODUCTION

Intrahepatic cholangiocarcinoma (ICC), a rare malignant tumor arising from the ductular epithelium of the biliary tree within the liver, is the second most common malignancy after hepatocellular carcinoma (HCC) among the primary liver cancers[1]. It is one of the most biologically virulent malignancies and has a dismal prognosis because of its late diagnosis and absence of effective treatment. There is a marked regional variation in the incidence of ICC, linked strongly to the distribution of risk factors[2]. Therefore, identifying risk factors may lead to prevention and control of this disease. Liver fluke infection (*Clonorchis sinensis* or *Opisthorchi viverrini*)[3,4], primary sclerosing cholangitis (PSC)[5,6], and hepatolithiasis are thought to be the risk factors for ICC[7,8]. Recently, several studies have suggested that HBV and HCV infections, the major risk factors for the development of HCC, also increase the risk of ICC[3,9-13]. However, to the best of our knowledge, no study of ICC and risk factors has yet been conducted in China.

We therefore conducted a hospital-based case-control study to investigate risk factors for ICC in China, a country endemic for HBV infection.

MATERIALS AND METHODS

Subjects

This study consisted of 312 patients with ICC who underwent surgical resection at the Eastern Hepatobiliary Surgery Hospital, Second Military Medical University, Shanghai, China, between February 2004 and May 2006. Controls were selected from patients who were unaffected by liver diseases in the Changhai Hospital of the Second

Table 1 Characteristics of cases and controls

Characteristics	ICC (n = 312)	Control (n = 438)	P value
Mean age (SD)	53.2 ± 10.4	54.8 ± 11.8	> 0.05
Gender			> 0.05
Male	207 (66%)	276 (63%)	
Female	105 (34%)	162 (37%)	

Military Medical University, and were matched to cases in terms of age (± 5 years), sex, and date of hospital admission. The control group consisted of 438 patients admitted to the Departments of Gastroenterology, Urology, Ophthalmology, Neurology and Cardiology. All the specimens from ICC were diagnosed by pathological examination.

For both cases and controls, ever having smoked cigarettes was defined as having smoked cigarettes ⩾ 4 d/wk for ⩾ 6 mo, and ever having drunk alcohol as having consumed alcoholic beverages ⩾ 1 d/wk for ⩾ 6 mo.

The presence of diabetes mellitus, hypertention, hepatolithiasis, PSC, liver fluke infection (*C. sinensis*), was investigated through clinical records.

Laboratory tests

Blood samples were taken from all patients on the first morning of hospital admission, and tested for HBsAg and anti-HCV using a commercial ELISA (Abbott Laboratories, North Chicago, IL, USA). The project was approved by the ethics committee at the two hospitals.

Statistical analysis

Categorical variables were compared using the χ^2 test and continuous variables were compared using Student's t test. Odds ratio (OR) and 95% confidence intervals (CI) were calculated using a conditional multiple logistic regression model. The model was constructed using a forward selection process. $P < 0.05$ was considered statistically significant. These analyses were performed using SPSS 11.0 software (SPSS, Chicago, IL, USA).

RESULTS

No differences were found between patients with ICC and controls according to age and gender (Table 1). Table 2 shows the results of univariate analysis on the risk factors for ICC. The prevalence of anti-HCV seropositivity, diabetes mellitus, hypertension, cigarette smoking and alcohol consumption were not significantly different between the patient and control groups. Compared with the controls, ICC patients had a higher prevalence of HBsAg seropositivity (48.4% *vs* 9.6%, $P < 0.000$), and hepatolithiasis (5.4% *vs* 1.1%, $P = 0.001$). None of the patients had PSC. Liver fluke infection was found in 11 ICC cases (3.5%). However, it is difficult to obtain accurate diagnostic evidence for liver fluke infection and PSC in control groups. Thus, we could not compare these two variables between the patients and controls.

All variables in the univariate analysis were further evaluated by multivariate logistic regression analysis. The

Table 2 Risk factors for ICC by multivariate logistic regression analysis

Variables	ICC Cases n=312 (%)	Controls n = 438 (%)	OR (95% CI)
HBV			8.876 (5.973-13.192)
HBsAg+	151 (48.4)	42 (9.6)	
HBsAg–	161 (51.6)	396 (90.4)	
HCV			0.933 (0.281-3.1)
Anti-HCV+	9 (2.9)	6 (1.4)	
Anti-HCV–	303 (97.1)	432 (98.6)	
Diabetes mellitus			1.505 (0.597- 3.796)
Yes	13 (4.2)	11 (2.5)	
No	299 (95.8)	427 (97.5)	
Hypertension			1.492 (0.867-2.570)
Yes	34 (10.9)	38 (8.7)	
No	278 (89.1)	400 (91.3)	
Hepatolithiasis			5.765 (1.972-16.851)
Yes	17 (5.4)	5 (1.1)	
No	295 (94.5)	433 (98.9)	
Cigarette smoking			1.237 (0.7-2.188)
Yes	43 (13.8)	67 (15.3)	
No	269 (86.2)	371 (84.7)	
Alcohol consumption			0.809 (0.487-1.345)
Yes	39 (12.5)	41 (9.4)	
No	273 (87.5)	397 (90.6)	

significant independent risk factors for development of ICC were HBsAg seropositivity (adjusted OR, 8.876, 95% CI, 5.973-13.192) and hepatolithiasis (adjusted OR, 5.765, 95% CI, 1.972-16.851). Other variables were not significant risk factors by multivariate logistic regression analysis.

The mean age was significantly younger in the HBsAg-positive ICC group (50.8 ± 10.4 years) compared with the HBsAg-negative group (55.5 ± 9.9 years).There were more men among HBsAg-positive ICC patients compared with the HBsAg-negative group [76.8% (116/151) *vs* 56.5% (91/161); $P < 0.001$]. Among ICC patients, cirrhosis was found in 69 who were HBsAg-positive (45.7%), and in six who were HBsAg-negative (3.7%).

DISCUSSION

Recently, infection with HCV or HBV has been suggested as a risk factor for ICC[3,9-13]. A case-control (41 cases and 406 controls) study from Korea reported that the prevalence of anti-HCV and HBsAg positivity was 12.5% and 13.8%, respectively, in patients compared with 3.5% and 2.3% in controls. Multivariate analysis found anti-HCV positivity to be associated with ICC (OR, 3.9) but not with HBsAg positivity (OR, 1.3)[3]. A prospective cohort study from Japan showed that 2.3% of 600 patients with HCV-related cirrhosis developed ICC during a mean follow-up of 7.2 years. The risk of developing ICC among patients with HCV-related cirrhosis was 1000 times higher than that in the general population[9]. A case-control study from Italy that compared 26 patients with ICC with 824 controls found that seropositivity for anti-HCV and HBsAg was 25 and 13% in ICC cases and 5.8 and 6.7% in controls, respectively. A statistically significant increase in the OR was observed for anti-HCV (OR, 9.7), whereas a weaker, non-significant association was found with HBsAg (OR, 2.7)[10]. Similarly, according to a case-control study

that involved 625 cases and 90 834 controls from the United States, the prevalence of anti-HCV and HBsAg was 5.6 and 0.2% in ICC cases and 1 and 0.2% in controls, respectively. The adjusted OR for ICC was 6.1 for anti-HCV, whereas no association was found with HBsAg (OR, 0.8)[11]. Another hospital-based case-control study from Japan showed that HCV seropositivity was detected in 36% of ICC patients and 3% of controls, and the adjusted OR for ICC development was 6.02 for anti-HCV[12]. Overall, these studies suggest that HCV infection may play a role in ICC development, whereas HBV infection does not seem to be a relevant risk factor for the disease. Only sporadic cases of ICC have been reported with HBV infection[13]. In the current study, seropositivity for HBsAg and anti-HCV were found in 48.4 and 2.9% of ICC cases, and in 9.6 and 1.4% of controls, respectively. This indicates that HBV, but not HCV infection is a strong risk factor for development of ICC. These findings differed markedly from the results of previous studies[3,9-12]. ICC is characterized by wide variability in incidence and risk factors. HCV seems to be associated with ICC in regions with relatively low prevalence of HBV infection, such as Japan and the United States[9,11]. China, a highly endemic area for HBV infection, has an HBsAg-positive rate of 9.09% in the general population[14], but a low incidence of HCV infection (0.42%-2.1%)[15,16]. Therefore, the difference in etiological factors associated with ICC can be explained by the type of endemic hepatitis virus. Thus, screening and vaccination for hepatitis B may be a useful strategy to decrease the high rate of ICC in China. It is noteworthy that the prevalence of HBV or HCV infection in our controls is compatible with the figure observed in the general population in China, which suggests no relevant selection bias in our controls.

The precise mechanism of HBV infection in the carcinogenesis of ICC is still unknown. Integration of the HBV sequence into the human genome is one of the most important steps in HBV-related carcinogenesis[17]. HBV sequences are found in human[18] and duck[19] bile duct epithelial cells by *in situ* hybridization. HBV sequence integration is suggested to have a direct oncogenic effect by modulating the expression of neighboring cellular genes involved in the regulation of cell proliferation and apoptosis. HBV X gene-encoded protein (HBX) acts as a transactivator of various cellular genes and plays a crucial role in the pathogenesis of HCC[17,20]. Wang *et al*[21] has observed frequent, strong HBX immunochemical staining in bile duct cells of cancerous and surrounding hepatic tissues, in some HBV-infected ICC specimens, and has suggested that HBX may contribute to the pathogenesis of ICC. Furthermore, it has been shown that HBX may activate the transcriptional expression of human telomerase reverse transcriptase, which leads to tumorigenesis in cholangiocytes[22]. Further studies are required to investigate the cellular transformation mechanisms of ICC induced by HBV infection.

Cirrhosis, such as alcoholic cirrhosis and HCV-related cirrhosis, has also been associated with ICC[9,10]. HBV infection may result in chronic hepatitis, followed by liver cirrhosis. Our data showed that cirrhosis was found in 69 HBsAg-positive ICC cases (45.7%). This finding suggests that HBV-related cirrhosis may be an essential stage in the development of ICC, as it is for HCC in China.

Hepatolithiasis was another independent risk factor for ICC development in our study. This result was compatible with several previous studies[7,8,23,24]. The carcinogenesis associated with hepatolithiasis may be a multi-step process in which there are changes from hyperplasia to dysplasia, and finally to adenocarcinoma[25]. Recent studies have demonstrated that several cancer-related genes, including those of *p16*, cyclooxygenase-2, prostaglandin E2, c-met, and caudal-related homeobox gene 2, play an important role in the development and progression of ICC arising in hepatolithiasis[26-30].

In conclusion, this study showed that HBV, but not HCV infection and hepatolithiasis, are strong risk factors for development of ICC in China.

COMMENTS

Background

Intrahepatic cholangiocarcinoma (ICC) is one of the most biologically virulent malignancies and has a dismal prognosis because of its late diagnosis and absence of effective treatment. There is a marked regional variation in the incidence of ICC, linked strongly to the distribution of risk factors[2]. Therefore, identifying risk factors may lead to prevention and control of this disease. HBV and HCV infections have been suggested as risk factors for ICC[3,9-13]. However, no study of ICC and risk factors has yet been conducted in the China, a country endemic for HBV infection.

Research frontiers

We carried out a hospital-based case-control study to investigate risk factors for ICC in China. A total of 312 ICC cases and 438 matched controls were included in the study.

Innovations and breakthroughs

We found that HBV, but not HCV infection and hepatolithiasis were strong risk factors for development of ICC in China.

Applications

Screening and vaccination for hepatitis B may be a useful strategy to decrease the high rate of ICC in China.

Peer review

This is a well performed study that shows that HBV, but not HCV infection and hepatolithiasis are strong risk factors for development of ICC in China. The discussion is well balanced.

Abstract

We present an unusual case of corrosive esophageal injury following liquid glue ingestion. The endoscopic findings were tissue sloughing and blackened appearance of the esophagogastric junction, due to caustic esophageal injuries following ingestion of glue containing toluene.

INTRODUCTION

Toluene is an aromatic hydrocarbon commonly used as an industrial solvent for the manufacturing of paints, chemicals, pharmaceuticals and rubber. It is commonly found as a glue in the household. It can be swallowed accidentally, can create a burning sensation, and cause gastrointestinal symptoms such as abdominal pain, nausea, vomiting and hematemesis. Their effect on the mouth, pharynx, larynx, esophagus and the rest of gastrointestinal system is unknown. However, no cases have been reported so far in English-language literature.

CASE REPORT

A 37-year-old man was brought to the surgical emergency department of our institution, reporting that he had been threatened by unknown persons 6 h earlier and forced to ingest liquid household glue (containing toluene) mixed with numerous coins and pins. The patient's main complaints were vague: epigastric pain, nausea and vomiting. He was hemodynamically stable, but uncooperative. He did not smoke, nor was he an alcoholic or a drug addict. There were no signs of trauma or burns on the head and neck, except for a slight excoriation on the neck consistent with attempted strangulation, which proved to be self-inflicted. Chest and abdominal physical examinations were normal, except for moderate tenderness in the upper abdomen, without guarding. Laboratory tests were normal. Plain abdominal radiography revealed multiple sharp opacities in the stomach; in addition to these, an image of some pins was detected in a region consistent with the right lower quadrant (Figure 1). We performed upper gastrointestinal (GI) flexible endoscopy (Figure 2). The endoscopic findings were tissue sloughing and blackened appearance of the esophagogastric junction, due to caustic esophageal injuries, following liquid glue ingestion. An attempt was made to remove the foreign body endoscopically, but without success. The patient was scheduled for emergency surgical exploration.

DISCUSSION

Halogenated hydrocarbons, such as the solvent trichloroethane and methylene chloride, are known to produce hepatic and renal toxicity following chronic exposure, as well as central nervous system (CNS) effects with acute exposure[1], but corrosive GI injury has been never reported up to now. Endoscopic investigation furthermore showed metal pins and coins in the stomach. When approaching intestinal foreign body cases, location of the foreign body is of great importance in terms of management. The choice between outpatient treatment and surgical intervention will depend upon the localization and shape of the object. Although sharp objects pass through the gastrointestinal tract without difficulty in 90% of the cases, they may also be removed using fiberoptic gastroscopy without waiting. Early endoscopy is recommended in cases with objects wider than 2 cm and longer than 6 cm, since their

Figure 1 Gastric overt dense opacities on plain abdominal film.

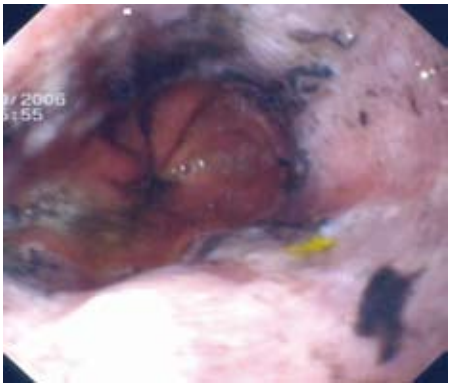

Figure 2 Tissue sloughing and blackened appearance of the oesophagogastric junction.

passage through the pylorus and duodenum might become difficult. Sharp and pointed foreign bodies, as well as elongated foreign bodies, can be very challenging and difficult to manage. It is important to be extremely careful not to make this situation worse or to cause a complication, such as a perforated esophagus, that can be fatal. It should not be considered a defeat to have to remove a foreign body surgically, for this is sometimes the safest means [2]. In this case, the stomach was opened by longitudinal gastrotomy in the greater curvature and the foreign bodies were removed. The next day, on the basis of visual and auditive hallucinations, the patient left the surgical unit, refusing any treatment. A psychotic illness was diagnosed and mandatory treatment was given. The patient was referred for a psychiatric consultation and after one month of follow-up showed a satisfactory recovery.

Abstract

Intussusception is rare in adults. We describe a 47-year-old man with ileal schwannoma that led to ileocolic intussusception. Abdominal ultrasonography, abdominal CT scan and barium enema confirmed an ileal tumor. Colonoscopy revealed a peduncular submucosal tumor (SMT) 75 mm long with an ulcerated apex at the ascending colon. The provisional diagnosis was a gastrointestinal stromal tumor of the terminal ileum. Ileocecal resection was carried out and the tumor was histologically diagnosed as schwannoma. Abdominal pain resolved postoperatively. This case reminds us that ileal schwannoma should be included in the differential diagnosis of intussusception caused by an SMT in the intestine.

INTRODUCTION

Ileal schwannoma is an extremely rare disease, even among small intestine tumors. In Japan, there have been no more than eight cases reported in the literature[1,2]. There have been no reports describing adult cases of ileocolic intussusception due to ileal schwannoma. Here, we describe a rare case of ileal schwannoma that led to ileocolic intussusception.

CASE REPORT

The patient was a 47-year-old Japanese man. He was admitted to our hospital complaining of intermittent abdominal pain of several months' duration that was increasing in both magnitude and frequency. He had not had previous abdominal surgery and had been in good health. No specific family history was identified. His body temperature was 36.4℃, blood pressure was 126/78 mmHg, and radial pulse rate was 66 beats/min and regular. He had neither anemia nor jaundice. A neurological examination revealed no abnormal findings and there was no lymphadenopathy. Routine hematological examination and biochemical tests were within normal limits. Abdominal CT scan revealed a large, comparatively well-defined mass in the colon and intussusception (Figure 1). An air contrast barium enema also showed a large elevated mass 7 cm × 4 cm in diameter with a smooth surface in the ascending colon, which suggested a submucosal tumor (SMT). Colonoscopy revealed a large SMT with an ulcerated apex in the ascending colon (Figure 2). The SMT was peduncular, covered with normal ileal mucosa, and prolapsed from the ileocecal valve to the ascending colon. A biopsy specimen obtained from the lesion showed spindle-like cells. Based on these findings, the patient was diagnosed with intussusception due to intestinal SMT, which suggested a gastrointestinal stromal tumor (GIST). The patient underwent an urgent laparotomy (ileocecal resection) because of the increased frequency of abdominal pain after colonoscopy. The resected tumor, 75 mm × 43 mm × 34 mm in size, was covered with normal ileal mucosa (Figure 3). Histological examination of the resected specimen revealed interlaced bundles of large, bizarre, spindle-like tumor cells without mitotic figures (Figure 4). No fission images were evident. Immunohistological findings were negative for CD34 and α-smooth muscle actin (SMA), and positive for S-100 protein (Figure 4). Based on the above findings, this tumor was diagnosed as ileal schwannoma. The postoperative course was uneventful. No additional therapy was performed. As a result of this treatment, the patient's abdominal pain resolved postoperatively.

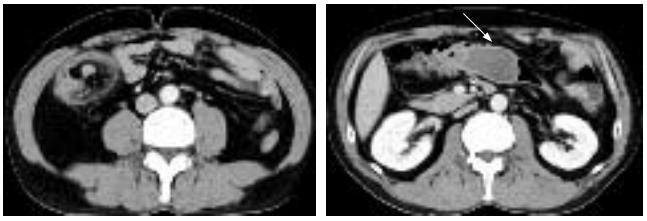

Figure 1 CT revealed a large, comparatively well-defined mass in the colon (arrow), and intussusception.

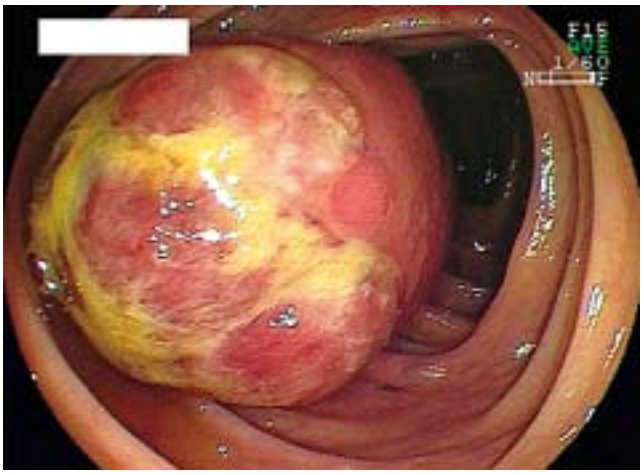

Figure 2 Colonoscopy revealed a large SMT, with an ulcerated apex covered with normal ileal mucosa, in the ascending colon.

Figure 3 Macroscopic findings of the tumor. A 75 mm × 43 mm × 34 mm pedunculated SMT arising from the ileum was observed.

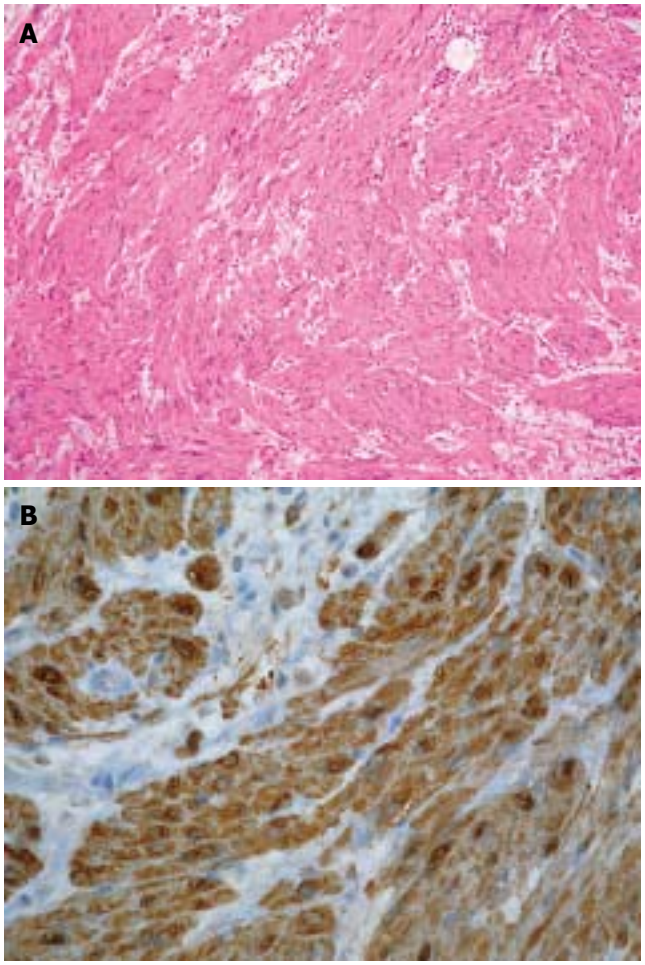

Figure 4 Histological findings of the tumor. **A**: Proliferation of bizarre spindle-like tumor cells without mitotic figures (HE, × 20); **B**: Tumor cells were positive for S-100 protein.

DISCUSSION

Schwannomas are tumors derived from Schwann cells. These tumors are prone to occur peripherally in the head and limbs, and cause radiating pain or sensory paralysis[3]. Although schwannoma rarely occurs on the trunk, even a small one in the brain or spinal cord causes serious neurological symptoms. Manifestations in the gastrointestinal tract are rare, but when they do occur, the incidence is high in the stomach; a schwannoma originating in the small intestine is rare[4]. According to Nozu *et al*[1] and Nagai *et al*[2], a review of the Japanese literature has revealed only eight cases of ileal schwannoma in Japan up to 2003. Common symptoms are abdominal pain and melena[1,2,5,6]; intestinal obstruction or intussusception is rare. In contrast with intussusception in children, nearly all adult cases have primary causes such as a polyp, an SMT or a malignant tumor that needs to be resected[7]. In the present case, the tumor prolapsed to the ascending colon due to intussusception.

The preoperative diagnosis of schwannoma appears to be difficult. According to Nagai *et al*[2], none of the reported cases of ileal schwannoma in Japan had been correctly diagnosed preoperatively. For preoperative diagnosis, CT, ultrasound (US), MRI, and angiography are useful for locating the tumor site. CT depicts the tumor growing outside the wall, and displays a high shadow effect[8]. Imaging of the small intestine shows findings suggestive of an SMT, such as extramural pressure or tumor shadow loss[9]. Angiography of the superior mesenteric artery shows hypervascular tumor vessels[10]. In the present case, CT, US and barium enema images were compatible with schwannoma. However, the diagnosis could not be confirmed despite endoscopy. Because of the increased frequency of abdominal pain after colonoscopy, the patient underwent urgent laparotomy;

thus, angiography and MRI were not performed in the present case.

This disease is treated in principle by surgical resection. It is not possible to differentiate benign from malignant schwannoma confidently with imaging alone. Ileal benign schwannoma is not fatal and patients remain asymptomatic in their daily lives, except for bowel intussusception or obstruction; therefore, it is likely that there are patients with latent small bowel schwannoma, which may be incidentally discovered in the future as a result of advances in diagnostic imaging, such as improved CT and MRI.

In conclusion, we have reported a very rare case of ileal schwannoma that led to ileocolic intussusception. Thus, it is necessary to be aware that an ileal schwannoma may cause ileocolic intussusception and should be suspected in a patient with chronic atypical abdominal pain.

Abstract

Combined duplication of the colon and vermiform appendix is one of the rare congenital anomalities of the alimentary tract. Only a few cases have been reported in the adult population. A 28-year-old man presented to the clinic with a mass in the right flank. Imaging showed only a hydronephrotic atrophic kidney. The final diagnosis was only available at exploration. Combined duplication of the tubular colon and vermiform appendix was confirmed histopathologically. The patient was treated with nephrectomy and complete resection of the duplicated colon and vermiform appendix. The patient recovered uneventfully, and has done well for the past year. This is believed to be one of the first reports of combined duplication of the tubular colon and vermiform appendix as a cause of hydronephrotic atrophic kidney in an adult patient.

INTRODUCTION

Gastrointestinal duplication is rare, although it may be observed throughout the alimentary tract. Most duplication is located in the ileum and the presenting symptoms are bowel obstruction, intestinal bleeding and/or even perforation. Apart from ileal duplication, colon duplication is a rare congenital anomaly[1-4]. We present a case of combined duplication of the colon and appendix vermiformis, which led to hydronephrotic atrophy of the kidney.

CASE REPORT

A 28-yr-old man with fever (38.9℃) and intermittent right flank pain was referred to the clinic. Anorexia, nausea and vomiting were also noted. Physical examination revealed a palpable mass in the right flank. No sign of peritoneal irritation was noted. He had no history of surgery, urinary tract infection and/or calculi. Leukocytosis and urine infection were only the findings upon blood and urine analysis.

Ultrasonography (US) revealed a heterogeneous and hyperechoic pararenal mass and grade 3 to 4 hydronephrosis. Intravenous pyelography (IVP) was diagnostic for a non-functional right kidney. ^{99m}Tc-diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) and ^{99m}Tc-dimercaptosuccinic acid (^{99m}Tc-DMSA) nephrograms confirmed decreased right renal function. CT showed hydronephrosis in the right kidney, with a mass adjacent to the right renal pelvis. A continuum of the mass with the colon was noted. Colonoscopy was not diagnostic for intraluminal pathology.

During exploration, a severely scarred and inflamed mass at the inferior medial pole of right kidney was observed, which caused hydronephrosis and atrophy of the right kidney. Nephrectomy was undertaken. The continuum of the mass was followed during dissection. A precast peritoneal window and connection of the mass to the patent cecum was observed. There were two tubular lumens at the base of the cecum. Resection of the mass was completed with careful dissection to spare the normal adjacent structures. Cecal opening at the connection of the mass was closed with simple saturation, and a formal appendectomy was performed. The patient recovered steadily and was discharged from the hospital after 10 d, and he progressed well over the next year.

Gross pathological examination revealed a combined

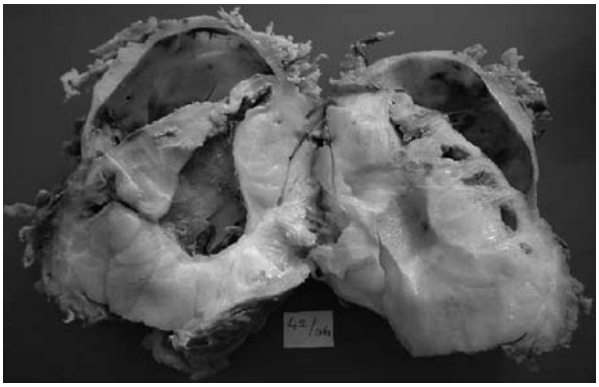

Figure 1 Macroscopic view of the duplicated colon and appendix vermiformis.

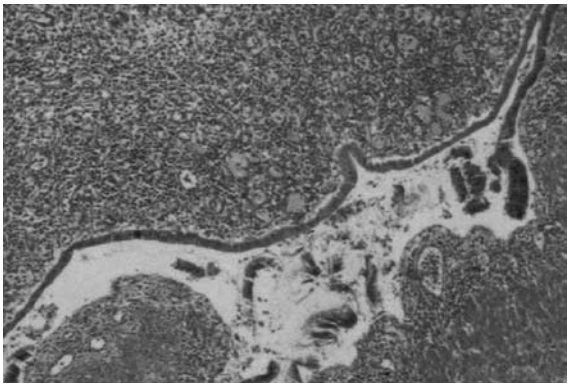

Figure 2 Histological appearance of the duplicated colon and appendix vermiformis.

tubular structure with fecal material inside, and an appendix-like extra tubular structure with an obstructing fecalith in its lumen (Figure 1). This duplicated appendix was not perforated. Histologically, a colonic mucosa layer with accumulation of infiltrating lymphocyte nests, and a duplicated appendix was confirmed. Pathological examination revealed no evidence of malignancy (Figure 2).

DISCUSSION

Gastrointestinal duplication, which may occur throughout the alimentary tract, is a rare congenital anomaly[1]. More than 80% of the cases present before the age of 2 years, as acute abdomen or bowel obstruction[1,2]. Most duplication is located in the ileum and presenting symptoms are bowel obstruction, intestinal bleeding and/or even perforation[3,4]. Apart from ileal duplication, colonic duplication is a rare abnormality. A thorough review of the international literature since 1950 has revealed 83 cases of colonic duplication to date, and only 4%-18% of all gastrointestinal duplications have been reported in the cecum[5-7].

Inclusion of the urogenital tract by an intestinal duplication has been reported in two cases[8,9]. Duplication of the tubular colon and vermiform appendix causing hydronephrotic atrophic kidney in adults has not previously been reported.

Preoperative diagnosis of colon duplication is often difficult. Symptoms usually include abdominal pain, nausea and/or vomiting, palpable mass, weight loss, and bleeding, which often confuses colon duplication with other more common diagnoses. The pathogenesis of these lesions has not yet been well characterized. One of the most widely accepted theories is an abnormality of the embryonic gut that results in the formation of a diverticulum, a cyst, or twinning of a bowel segment[10]. Environmental factors such as trauma or hypoxia during early fetal development have also been suggested to play a role[11]. Although intestinal duplication is considered to be a benign lesion and mostly asymptomatic, they may result in significant morbidity and mortality if left untreated[12]. Indications for surgical intervention often arise in an acute setting, in the form of complications. Specifically, patients with previously undetected duplication may present with bowel obstruction or severe gastrointestinal hemorrhage (i.e., ulcerating gastric mucosa within a duplication cyst)[5]. If encountered incidentally, these lesions should be surgically addressed to avoid any future complication, including the possibility of malignant degeneration within the duplication cyst[5,12].

Duplication of the vermiform appendix is extremely rare. It is found in only 1/25 000 patients (0.004%) operated on for acute appendicitis[13]. The clinical presentation can vary depending on the location of the appendices in the colon. Cave and Wallbridge have classified the observed variants into several types: type A has incomplete duplication with both appendices having a common base; type B has complete duplication with the first appendix arising from its usual location at the confluence of the teniae coli, and the second appendix is located at various sites along the colon; and type C has complete duplication of the cecum, with each part having its own appendix[14,15]. Our case was diagnosed as type B.

Although preoperative diagnosis has been made with the aid of radiological studies such as a barium enema, the majority of cases have been diagnosed at surgery or upon pathological examination. Barium enema studies are considered essential for the diagnosis of tubular colonic duplication, with opacification of two colons being the diagnostic sign. However, in certain cases, barium enema apparently does not show positive findings. A case has been reported in which a barium follow-through study established a complete diagnosis of duplication of the colon and terminal ileum. The findings were confirmed by laparotomy. Although the diagnosis of appendix duplication is a rarity, surgeons should be aware of the possibility, especially when clinical signs and symptoms point to appendicitis, although at laparotomy the appendix looks normal. Routine exploration for a second appendix is definitely not indicated because of its rarity and increased complication rate.

Although duplication of the alimentary tract is rare, the possibility of congenital lesions of the alimentary tract should not be overlooked, even in adults presenting with vague or no gastrointestinal symptoms.

Abstract

Gastrointestinal duplications are an uncommon congenital abnormality that manifest before the age of two in 80% of cases. Ileal duplication is the most common while colonic duplication, either cystic or tubular, occurs in 10%-15% of cases and remains asymptomatic and undiagnosed in most cases. Mostly occurring in pediatric patients, colonic duplication is encountered in adults in only a few cases. The most common clinical manifestations are abdominal pain and intestinal obstruction. Rarely, duplications present with signs of acute abdomen or acute bleeding. This study reports a case of colonic duplication in an adult who presented with chronic constipation. Complete diagnostic workup was made on several occasions during the previous eight year period, but no pathology was found and chronic constipation was attributed to hypothyroidism caused by long standing Hashimoto thyroiditis. Multislice CT, performed because of abdominal distension, defined colonic pathology but the definite diagnosis of duplication of the transversal colon was made at operation. The cystic duplication and the adjacent part of the ascending and transversal colon were excised en-block. This study implies that colonic duplication, though uncommon, should be included in the differential diagnosis of chronic constipation even when precipitating factors for constipation, such as hypothyroidism are present.

INTRODUCTION

Duplications are rare congenital cystic or tubular abnormalities of the gastrointestinal tract that occur anywhere from the mouth to the anus. Despite a variety of early descriptions, Ladd coined the term alimentary tract duplications in 1937, which described the clinical and pathologic aspects of these lesions more effectively[1]. Their etiology is of embryonic origin and several theories have been proposed. However, none of these theories alone is able to explain the full diversity of these lesions. Although they can present at any age, more than 80% of the cases present before the age of two as an acute abdomen or bowel obstruction[2]. Colorectal duplications occur in 13% of these cases[3]. If encountered incidentally, these lesions should be surgically addressed to avoid any future complications[4,5].

We report a case of colonic duplication in an adult woman who presented with distended abdomen and chronic constipation that was attributed to long standing hypothyroidism.

CASE REPORT

A 42-year-old woman was admitted to the division of gastroenterology with symptoms of significant abdominal distension and chronic constipation. The patient had a medical history of chronic constipation from the early childhood which was not striking until 1991 when, during gestation, significant gaseous bowel distention was found. Complete diagnostic workup was made to find the cause of the constipation but all findings were normal. The constipation was attributed to hypothyroidism caused by long standing Hashimoto thyroiditis treated with thyroid hormone replacement. In 1999 the symptoms progressed and again complete diagnostic workup was made. The diagnosis was elongated colon (dolichocolon). During these eight years the patient used cathartics, different types of tea and manual stool evacuation. There were periods of seven days without stool evacuation. The patient got

Figure 1 Plain X-ray of the abdomen showing a dilated intestinal loop occupying more than half of the abdominal cavity filled with fecal masses.

Figure 2 Abdominal CT showing a dilated intestine from the diaphargm to the pelvis, measuring 36 cm in length with a diameter of 11 cm dislocating normal intestine laterally.

Figure 3 Operative view of normal transversal colon and the distended tubular colonic duplication.

Figure 4 Surgical specimen showing part of the normal ascending and transversal colon together with a tubular duplication with all layers of the colonic wall dividing these structures.

used to irregular bowel habits and after 1999 did not go to regular controls. Finally in the last few months in 2006 she noticed significant abdominal distension and consulted the gastroenterologist. Complete laboratory findings, including proteins, albumins, IgA, IgM, IgG, T3, T4 and TSH were normal. ECG and esophagogastroduodenoscopy were normal. Plain X-rays of the abdomen showed an extremely dilated intestinal loop, presumably colon with fecal masses without signs of obstruction (Figure 1). Colonoscopy revealed normal mucosa with few biopsies showing chronic nonspecific colitis. Anal manometry showed: lower mean resting pressure (50 mmHg), normal squeeze pressure (200 mmHg), normal rectal sensation, rectal compliance and recto-anal inhibitory reflex. The conclusion was that there were no elements for Hirschsprung's disease and that the internal anal sphincter showed slight hypofunction. Multislice CT with peroral contrast showed an enormously dilated intestinal loop from diaphragm to pelvis, measuring 36 cm in length with the diameter of 11 cm occupying the complete abdominal cavity in the midline (Figure 2). The stomach, rectum and genitourinary tract were normal. There were no enlarged lymph nodes. The patient was transferred to the department of surgery and the exploratory laparotomy revealed colonic duplication of the transversal colon with no other intra-abdominal pathology (Figure 3). Duplication was separated by a sharp dissection from the left half of the transversal colon but shared common wall with the right half of the transversal colon. The duplication ended blindly at the splenic flexure and had an opening that communicated with the normal colon at the hepatic flexure (Figure 4). Finally, right hemicolectomy was performed. The patient functioned well postoperatively and a few months after the procedure did not have any stool evacuation difficulties as encountered preoperatively.

DISCUSSION

Gastrointestinal duplications are rare congenital anomalies which in 80% of cases are detected prenatally or in the first two years of life, although they can remain undetected until older age[6]. The clinical picture varies according to their location, size, and other factors such as the presence of ectopic mucosa within the duplication, communication with adjacent bowel, or inflammation. The duplications are classified according to their location (ileum 30%, ileocecal valve 30%, duodenum 10%, stomach 8%, jejunum 8%, colon 7%, rectum 5%), shape: cystic ($\geqslant$ 80%) or tubular[7]. The most common clinical manifestations are abdominal pain and intestinal obstruction. Rarely, such duplications present with signs of acute abdomen or acute bleeding[8]. Pyloric and duodenal duplications can mimic hypertrophic pyloric stenosis or a choledochal cyst[5,9,10]. An ovarian cyst should be considered in female patients, and adolescent patients can sometimes have a presumptive diagnosis of Crohn's disease. Ultrasound is the imaging modality of choice for the evaluation of an abdominal mass in the neonate. Approximately 30% of the intestinal duplications

are diagnosed prenatally[11]. Additional imaging procedures are often required: barium enema, CT scan, radionuclide scan (HIDA scan for choledochal cyst and pertechnetate scan for Meckel's diverticulum). However, gastric, duodenal, and rectal duplications can lead to a diagnostic dilemma.

Chronic constipation as a presenting symptom of intestinal duplication in adults present specific diagnostic problems because of a wide variety of etiologic factors. The cause of constipation is usually multifactorial. Secondary constipation could be caused by low fibre diet, anal fissures, thrombosed hemorrhoids, strictures, and tumors, hypercalcemia, hypokalemia, hypothyroidism, diabetes mellitus, pregnancy, stroke, Hirschsprung disease, Parkinson's disease, multiple sclerosis, spinal cord lesion, Chagas disease, familial dysautonomia, scleroderma, amyloidosis, mixed connective-tissue disease and use of different drugs. Functional constipation could be caused by repressed defecatory urge, irritable bowel syndrome, idiopathic megacolon or megarectum, idiopathic slow transit constipation, chronic intestinal obstruction, anismus, solitary rectal ulcer, intussusception, descending perineum, rectocele or ineffective straining.

Intestinal duplications often require urgent surgical intervention. Secretion of ectopic gastric mucosa causes ulceration of the intestinal mucosa, which can lead to massive bleeding or bowel perforation[12]. Gastric mucosa was found in 50.8% of cystic duplications and was present in all locations, including the colon and rectum with somewhat lower frequency of 33%[3].

Colorectal duplications represent 13% of all duplications[3]. Tubular duplications of the colon, may appear in a double-barreled or Y-shaped form[13,14]. These congenital anomalies have a double muscular layer and epithelium similar to the rest of the colon[13,15]. The clinical signs include constipation, vomiting, volvulus, perforation, and, most commonly, intestinal obstruction owing to the blind end of the duplication compressing the normal bowel[13,14,16]. If there are no other associated malformations, tubular duplications of the colon are often not discovered until there is surgical treatment for the complications.

Most authors recommend that once the diagnosis is made, an elective surgical procedure should be performed to avoid complications and to perform the procedure in an optimal state of the patient, but few think that only symptomatic duplications should be surgically treated. The recommended surgical procedure is excision of the duplication. Intestinal duplications are located on the mesenteric side adjacent to normal bowel. Some duplications and the adjacent normal bowel share part of the muscular coat and the intestinal straight arteries. Thus, resection of both normal and duplicated bowels with intestinal anastomosis is a usual surgical treatment[17]. Sometimes it is possible to resect them without compromising the adjacent bowel vascularization. Although there have been some malignant changes reported in adults[18], colorectal duplications are in themselves benign lesions. For this reason, surgical excision should not be radical but should involve complete resection of the duplication along with the relevant part of the colon[4]. Although rare, colorectal duplications are one possible cause of chronic constipation and, when discovered, should be treated surgically before complications arise. According to previous studies, surgical resection should extend at least 2 cm from the opening of the duplication; because substantial fibrotic changes near the opening of the duplication have been found[4,13]. Prognosis is good because of localized disease and the benign nature of the disease[4].

Abstract

This paper described a rare case of adenomyoma of common bile duct. The case is a 51-year-old man who was hospitalized for yellow color skin and sclera and itching for 2 mo without abdominal pain. Nothing special was found in physical examination except yellowish skin and sclera. The clinical presentation and Contrast-enhanced magnetic resonance imaging (MRI), Magnetic resonance cholangiopancreatography (MRCP), and ultrasonography suspected a tumor of the distal bile duct. The patient was treated successfully by pancreaticoduodenectomy. Histologically, the lesion consisted of adenoid and myofibrous tissue and moderate atypia. The immunophenotype of the epithelial component was cytokeratin 7+/cytokeratin 20-. The patient has been well without any evidence of recurrence for 12 mo since his operation.

INTRODUCTION

The benign biliary tract tumor is rarely found in clinical practice. It is only 0.1% among the total biliary tract operations and 6% of extrahepatic biliary tract tumors reported at home and abroad. Till the year 2000, less than 200 cases of benign biliary tract tumor had been reported in English literatures[1], including polyps, adenomatoid papilloma and adenoma, while adenomyoma was seldem found. One patient with biliary tract adenomyoma was admitted to our hospital and reported below.

CASE REPORT

The patient is a 51-year-old man admitted to our hospital in August 2005, who was presented with yellow color skin and sclera and complained of itching for 2 mo. He suffered from anorexia and occasional nausea and deep tea color urine, yellowish white feces and weight loss of 2.5 kg were found, but without vomiting, chill, fever, abdominal pain and distension. Nothing special was found in physical examination except yellowish skin and sclera.

On admission, blood biochemical examination showed: alanine aminotransferase (ALT) 250 U/L, aspartate aminotransferase (AST) 102 U/L, alkaline phosphatase (ALP) 641 U/L, γ-glutamyltranspeptidase (γ-GT) 854 U/L, total bilirubin 32.9 μmol/L; direct bilirubin 22.8 μmol/L; Glucose 4.29 mmol/L, blood urea nitrogen (BUN) 6.56 mmol/L, creatinine (Cr) 67 μmol/L, carbohydrate antigen19-9 42.9 U/mL; carbohydrate antigen-50 57.86 U/mL; carcinoembryonic antigen (CEA) 6.8 ng/mL and γ-GT isoenzyme(-). α-fetal protein (AFP) 6.21 ng/mL, AFU 563 μmol/L.H, ferritin (Fer) 500 μg/L. Contrast-enhanced MRI revealed dilatation of the bile duct and pancreatic duct, eccentric stricture of the distal bile duct and multiple cysts of liver (Figure 1). Magnetic resonance cholangiopancreatograph (MRCP) showed dilatation of the bile duct and pancreas duct, irregular stricture of the bile duct (Figure 2). Ultrasonography showed distension of intrahepatic bile duct (0.32 cm), increase of gallbladder volume (11.1 cm × 4.4 cm) with smooth wall (0.3 cm thick), distension of common bile duct (1.27 cm) but stricture (0.4 cm) at pancreatic segment and a mass (1.6 cm × 0.27 cm) at the lumen of this segment (Figure 3).

Gross observation revealed the tumor was a cord-like mass with smooth surface, white color in resecting surface, wide and immovable base (Figures 4 and 5). Pathological examination demonstrated that the tumor epithelium was adenomyomatosis with adenoid and myofibrous tissue and moderate atypia (Figure 6). Glandular epithelial component expressed cytokeratin 7 (Figure 7) but did not express cytokeratin 20. The stomach, intestine and pancreas were negative after surgery and lymphnodes aside the bile duct and in the hepatoduodenal ligament presented inflammatory hyperplasia. The digestive tract was reconstructed with Child operation. The patient has been well without any evidence of recurrence for 12 mo since his operation.

Figure 1 Contrast-enhanced MRI showing distension of gallbladder, dilatation of the intra and extrahepatic bile duct and eccentric stricture of the distal bile duct, and a mass (arrow) at the lumen of the duct.

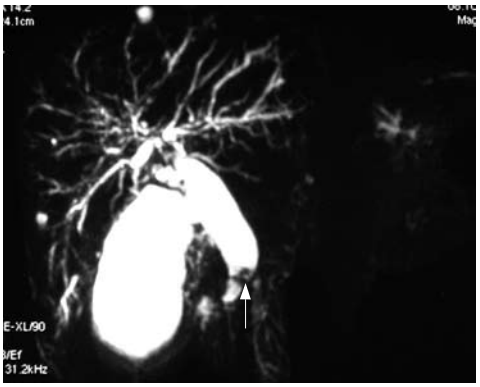

Figure 2 MRCP showing irregular stricture of the distal bile duct and a mass (arrow) at the lumen of the common bile duct.

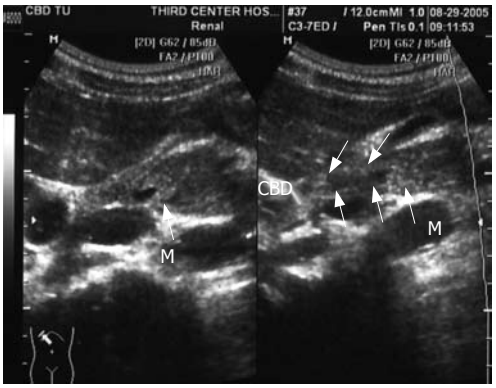

Figure 3 Ultrasonography showing a mass at the lumen of the common bile duct. M: Mass; CBD: Common bile duct.

DISCUSSION

In the year 2000, Beazley and Blumgart[1] reviewed a total of 115 patients with benign polyps, adenomas or cystadenomas. The anatomical distribution of papillomas or adenomas was as follows: most tumors were located in the ampulla or close proximity of the Vaterian system (47%), followed by common bile duct (27%), common hepatic duct (15%), right and left hepatic duct (8%) and cholecyst duct (3%) in frequency. Adenomyoma of the

Figure 4 Gross examination showing a cord-like mass with smooth surface (arrow) and dilatation of proximal part of the common bile duct (a), duodenum (b) and pancreas (c).

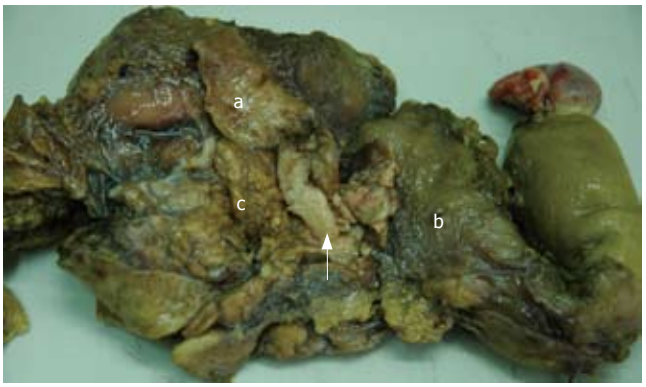

Figure 5 Gross examination of the mass: white color in resecting surface, wide and immovable base (arrow). a: Dilatation of proximal part of the common bile duct; b: Duodenum; c: Pancreas.

biliary tract is a rare nonneoplastic lesion. Abdulkadir Bedirli and his colleagues[2] reviewed the literature from 1964 to 2000, and retrieved a total of 49 articles. Most were case reports of biliary tract adenomyoma. The lesions were located in the gallbladder (n = 35), extrahepatic biliary tree (n = 11), ampulla of Vater (n = 9) and duodenum (n = 4). Histology showed multiple glandular structures surrounded by a fibroblastic/myofibroblastic proliferation[3], and the immunophenotype of the epithelial component was cytokeratin 7+/cytokeratin 20-. The tumor in our case was developed in pancreatic segment of common bile duct, and the immunophenotype of the epithelial cells was cytokeratin 7+/cytokeratin 20-.

It is demonstrated that the adenomyoma is difficult to diagnose preoperatively. The ERCP image can be a useful diagnostic approach as it allows the inspection of the periampullary region and visualization of the bile duct and pancreatic duct. Moreover, a biopsy could be taken from the adenomyoma for further histopathological examination. However, the definite diagnosis is not easy to confirm before operation. Menzel and colleagues[4] showed that the overall accuracy for preoperative histopathological diagnosis was 62% for tumors in ampulla of Vater. The endoscopic retrograde cholangiopancreatography (ERCP) could not be performed in the patient because the mass was invisible in the duodenum[5].

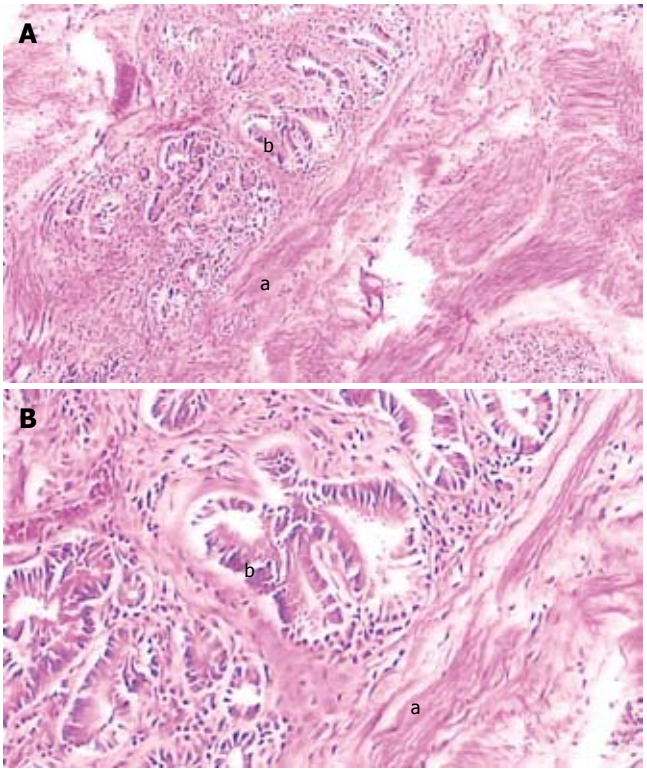

Figure 6 Pathological examination demonstrating the tumor epithelium is adenomyomatosis with adenoid (b) and myofibrous tissues (a) and moderate atypia (b). A: HE, × 100; B: HE, × 400.

Positron emission tomography with [^{18}F] fluoro-2-deoxy-D-glucose was applied to diagnose bile duct cancer[6], and the median standard uptake value (SUV) was 3.8 [confidence interval (CI 3.56-5.01)] for the malignant lesions, 2.9 (CI 2.42-3.22) for the benign lesions, the sensitivity and specificity were 92.3% and 92.9%, respectively.

The adenomas are generally soft, hardly palpable and present little or no resistance in exploring ductal probes, thus being difficult to detect during the operation. They are more frequently detected by intraoperative cholangiography, ultrasonography or choledochoscopy. In the year 2000, Seo[7] reviewed 111 patients with benign or malignant bile duct tumors, analyzed the results of cholangioscopy examinations and classified the findings according to histology of the tumor. Since bile duct tumors exhibit characteristic cholangioscopic findings, cholangioscopy seems to be useful for differential diagnosis.

In a review[8] of 406 cases, brush cytology was used to assess the pancreatico-biliary stricture. There are three adenomas identified on brush cytology but could not be distinguished from adenocarcinoma morphologically.

Intraoperative frozen section from the mass may differentiate whether the lesion is benign or malignant[9,10]. Sato *et al*[11] defined the importance of intraoperative frozen section, Imai *et al*[12] stated that final histological examination should be required to confirm the definite diagnosis.

Therefore, according to the clinical presentation, biochemical, radiographic[13], and endoscopic investigations, and intraoperative frozen section may not be able to confirm whether the tumor is benign or malignant, pancreaticoduodenectomy was sometimes necessary[2,14-16].

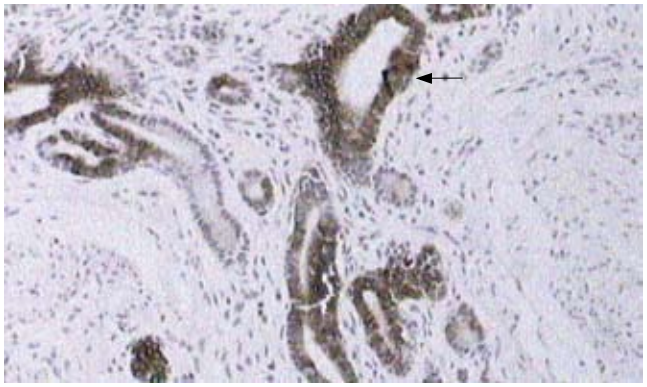

Figure 7 Immunohistochemical features demonstrated that cytokeratin 7 was strongly expressed in the epithelial cells of glandular structures (arrow).

In conclusion, preoperative endoscopic and radiological evaluations, and intraoperative section biopsies are insufficient for differentiating adenomyoma from other malignant tumors. Therefore, extensive surgery has to be performed for some non-neoplastic lesions which are suspected to be malignant.

Abstract

The definition of large stones is not clear ranging from 10 mm to 15 mm and does not include the lower common bile duct (CBD) diameter. Three hundred and four patients who underwent endoscopic retrograde cholangiopancreatography and stone extraction were retrospectively analyzed over a 1-year period. Sixteen patients were different from others in that 10 patients with large stones had stone extraction with a wire basket or a balloon catheter and 6 patients with small stones had stone extraction with mechanical lithotripsy. The definition of large stones should include diameter of the lower CBD and any stone exceeding 2 mm than the lower CBD diameter should be called large stone irrespective of the size of the stone.

Sharma SS, Jain P. Should we redefine large common bile duct stone? *World J Gastroenterol* 2008; 14(4): 651-652 Available from: URL: http://www.wjgnet.com/1007-9327/14/651.asp DOI: http://dx.doi.org/10.3748/wjg.14.651

LETTER TO THE EDITOR

We read with great interest in the article "Small sphincterotomy combined with papillary dilation with large balloon permits retrieval of large stones without mechanical lithotripsy" by Minami *et al* in *World journal of Gastroenterology* published in April 21, 2007[1]. We agree that the size and number of common bile duct (CBD) stones are still a concern in endoscopic sphincterotomy (ES). Balloon dilatation is not suitable for removal of large stones (> 1 cm in diameter) without sphincterotomy[2]. The successful removal of a CBD stone with a maximal diameter with conventional methods depends on the diameter of the distal CBD and the size of the sphincterotomy[3]. In general, common bile duct stones smaller than 1 cm in diameter may be extracted after sphincterotomy using retrieval balloons or baskets, whereas most of the larger stones require lithotripsy prior to their removal. The definition of large stones is not clear ranging from 10 mm to 15 mm[4] and does not include the lower CBD diameter[3].

We retrospectively analyzed patients admitted to our gastroenterology ward in SMS Hospital, Jaipur, between June 2006 and June 2007 who underwent endoscopic retrograde cholangiopancreatography (ERCP) for CBD stones (Table 1). Out of the 304 patients who underwent ES and stone extraction, 16 were different from others in that 10 patients with large stones had stone extraction with a wire basket or a balloon catheter and 6 with small stones had stone extraction with mechanical lithotripsy. The CBD stones were classified into 2 groups according to their size, lower CBD diameter and possible extraction with a wire basket, occlusion balloon or need for mechanical lithotripsy. The patients were divided into two groups: group A with their CBD stones > 10 mm in maximum diameter[2] and dilated CBD, group B with their CBD stones < 10 mm in diameter and their lower CBD diameter being 2-4 mm. We excluded patients with longitudinal stones (longest dimension in the axis of CBD) with their transverse diameter within 3 mm of the lower CBD diameter. All patients underwent ES with their CBD stones extracted using a wire basket or an occlusion balloon. The size of CBD stones was measured by comparing the diameter of the stones with the tip of endoscope, as on the cholangiogram. CBD stones were found in 16 patients with a male: female ratio of 5:11 with a mean age 42.8 years (range 27-58 years). Sixteen patients had abdominal pain, 14 had jaundice, and 5 had cholangitis.

The first group consisted of 10 patients (4 males, 6 females) with a mean age of 44.4 years (range 34-58 years). The median CBD stone diameter was 15.5 mm (range 15-20 mm), the median lower CBD diameter was 16 mm (range 13-24 mm). Eight patients had abdominal pain, 8 had jaundice and 2 had cholangitis. No patient had periampullary diverticula. All patients underwent successful stone removal with a wire basket after undergoing ES. A repeat cholangiography showed no residual stone in the CBD. There was no post procedure complication.

The second group was comprised of 6 patients (2 males, 4 females), with a mean age of 40 years (range 27-48 years).

Table 1 Clinical features, endoscopic retrograde cholangiopancreatography findings and management of common bile duct stone

Number of patients	Age (yr)	Sex	CBD diameter (mm)	Lower CBD diameter (mm)	Abdominal pain	Jaundice	cholangitis	Management
1	37	M	15	16	+	+	-	Stone extraction with basket
2	52	F	20	24	+	-	-	Stone extraction with basket
3	42	F	16	18	+	+	+	Stone extraction with basket
4	58	M	18	15	+	+	-	Stone extraction with basket
5	46	M	15	13	+	+	-	Stone extraction with basket
6	34	F	14	16	+	+	-	Stone extraction with basket
7	40	F	15	18	+	+	-	Stone extraction with basket
8	54	M	17	20	+	-	-	Stone extraction with basket
9	50	F	18	22	+	+	+	Stone extraction with basket
10	33	F	13	14	+	+	-	Stone extraction with basket
11	27	F	8	3	+	+	+	Biliary stent followed by mechanical lithotripsy
12	41	M	8	3	+	+	+	Biliary stent followed by mechanical lithotripsy
13	46	F	8	4	+	+	-	Mechanical lithotripsy
14	42	F	7	3	+	+	+	Biliary stent followed by mechanical lithotripsy
15	35	F	8	3	+	+	-	Mechanical lithotripsy
16	48	F	9	3	+	+	-	Biliary stent followed by mechanical lithotripsy

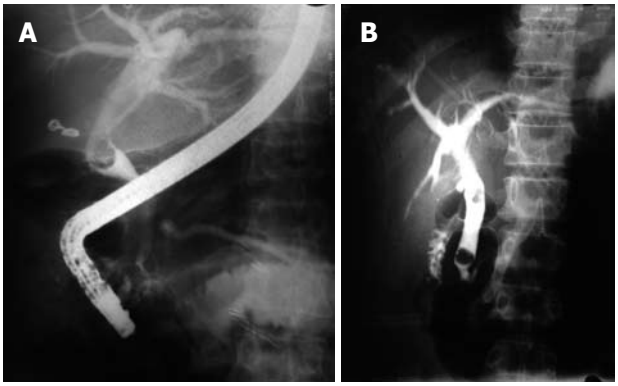

Figure 1 Cholangiogram showing a 8 mm common bile duct (CBD) calculus and a 4 mm lower CBD diameter and intrahepatic biliary radical dilation (**A**), and a 9mm CBD calculus and a 3 mm lower CBD diameter and intrahepatic biliary radicals dilation (**B**).

Six patients had abdominal pain and jaundice, 3 patients had cholangitis. The median CBD stone diameter was 8 mm (range 7-9 mm), the median lower CBD diameter was 3 mm (range 3-4 mm) and all patients had a single stone (Figure 1). No CBD stones were found in any of the patients due to the smaller diameter of the lower CBD. A 7F double pig tail biliary stent was placed followed by mechanical lithotripsy (n = 4) or mechanical lithotripsy (n = 2). One patient had mild post-ERCP pancreatitis which was recovered in 3 d.

In the first group, the overall successful bile duct stone retrieval rate was 100% in the dilated lower CBD. Each patient required one session of ERCP since all of our patients had a single CBD stone.

In the second group, we were not able to remove the CBD stones as their size was disproportionate to the lower CBD diameter. The CBD is a pliable structure but dilates gradually. This is why obstruction occurs even after impaction of stones in lower CBD dilatation. Acute dilatation can only occur after balloon dilatation where the force is transmitted from inside to outward rapidly over a considerable length of the duct, while in removal of CBD stones, the force is exerted on CBD from downward. So, expansion is not expected and will result in injury or avulsion of the CBD and excessive force should not be applied to the stone.

Possible benign stricture was ruled out in all the 6 patients in the second group based on the following points. (a) The patients were asymptomatic with no recurrence of CBD stones during a mean follow-up period of 10 mo (range 6-15 mo). (b) The serum alkaline phosphatase was normal in all the six patients. (c) The common bile duct diameter was normal. Jakobs *et al*[5] reported that patients with a bile duct stenosis have a significantly elevated risk for stone recurrence. This might be explained by bile stasis proximal to the lesion, favoring stone formation. In our study, none of the patients had bile duct stenosis.

In conclusion, the definition of large stones should include diameter of the lower CBD and any stone exceeding 2 mm than the lower CBD diameter should be called large stone irrespective of the size of the stone.

Meetings

Events Calendar 2008-2009

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008
Istanbul

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327/ CN 14-1219/R) is a weekly journal of with a circulation of more than 15707, published on the 7th, 14th, 21st and 28th of every month. *WJG* is a peer-reviewed journal. The number of overseas users with an independent IP address was 15600, representing 123 countries worldwide. Original research, reviews, comments, and case reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously or submitted elsewhere simultaneously.

Publication model

WJG is a journal with a so-called public beneficial publication model, which consists of an Open Access and the commercialized publication model (i.e. payment by the third party). This publication model has been proven very effective and produced fruitful outcome. By 21st December 2007, the number of visit hits to the *WJG* website has reached 21350084. *WJG* advocates the tenet that the research funding granted to scientists be used to serve scientists, by which high quality scientific articles can be published.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from the organization in which the author(s) works should be provided with the contributed article to warrant not give away any secret and if the contributed article is completed in cooperation by authors from different organizations, a letter of recommendation from each of the organizations should be provided to ensure not given away any secret.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained in the mailing process.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381901-600. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. font with ample margins. The preferred font is Book Antiqua. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, author contributions; disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analysed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend. Otherwise, article is rejected. Reviewers are acknowledged in the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou Univerisity, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, that reflect the content of the study.

Text
For articles of these sections, original articles, rapid communicatin and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. As require, figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. The examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is nessesary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to make out the high resolution-figures of E-version or the printed one.

Tables
Three-line tables should be numbered 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate that already contained in the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "Fom references [19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement
PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement
A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. World J Gastroenterol 2007; 13(48): 6458-6464

The accuracy of the information of the journal citations is very important. We will interlink all references with DOI in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter and responses, to reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a CAF from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After the manuscript goes online, links to PDF edition of submitted manuscript, peer-reviewers' report and revised manuscript will be created. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors could benefit from the feedbacks and revise the manuscript according to the comments in real time.

Science news releases

Authors of accepted manuscripts are suggested to write science news to their articles as both following guidelines and samples, and the news will be released soon at EurekAlert/AAAS --http://www.eurekalert.org. The title for news is less than 90 characters. The summary for news is less than 75 words, and main body less than 500 words. The science news should be lawful, ethical, and tightly based on your original contents with attractive title and amusing pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Insulinomas continue to pose a diagnostic challenge to physicians, surgeons and radiologists alike. Most are intrapancreatic, benign and solitary. Biochemical diagnosis is obtained and imaging techniques to localize lesions continue to evolve. Surgical resection is the treatment of choice. Despite all efforts, an occult insulinoma (occult insulinoma refers to a biochemically proven tumor with indeterminate anatomical site before operation) may still be encountered. New localization preoperative techniques decreases occult cases and the knowledge of the site of the mass before surgery allows to determine whether enucleation of the tumor or pancreatic resection is likely to be required and whether the tumor is amenable to removal *via* a laparoscopic approach. In absence of preoperative localization and intraoperative detection of an insulinoma, blind pancreatic resection is not recommended.

INTRODUCTION

Although rare, insulinomas are the most common functioning islet cell tumor of the pancreas. Recognition of the key neuroglycopenic symptoms should trigger the initial investigation. Biochemical proof of endogenous hyperinsulinemic hypoglycemia establishes the diagnosis. Several options are available for imaging and localizing these tumors. The tumors are usually small, single, benign, well-circumscribed, and evenly distributed throughout the pancreas. This tumor may be a part of the multiple endocrine neoplasia type 1 (MEN-1) syndrome. Surgical treatment is the only curative method. Patients are almost invariably cured lifelong with complete excision of a benign insulinoma[1-10]. Medical therapy can control hypoglycemic symptoms in approximately 50%-60% of patients with insulinoma, but operation remains the only curative treatment. The urgency of surgery is related to the severity of symptoms and the ability to manage them medically. In general, if hypoglycemia can be managed medically, there is less immediate pressure on the surgeon to find and remove the tumor. However, if symptoms are poorly controlled with medical management, the operation must be successful[5].

Most of the time it is easy to diagnose, localize and remove insulinoma, allowing complete alleviation of the dramatic, and sometimes life-threatening, symptoms of neuroglycopenia. Sometimes, however, this may not be so; despite adequate knowledge of its size and location, an insulinoma may be "occult" (occult insulinoma refers to a biochemically proven tumor with indeterminate anatomical site before operation) and difficult to localize[11-14]. What is (are) the technique(s) of choice to localize insulinoma? What surgical approach will be adopted in case of occult insulinoma? To respond to this important issue, we must discuss the different localization studies with operative procedure options.

EPIDEMIOLOGY OF INSULINOMA

Insulinoma are rare and small neuroendocrine tumors with an incidence of approximately one to four per million per year. It is the most common pancreatic islet cell tumor (25% of endocrine pancreatic tumors) and is malignant in only 5%-11% of cases. Virtually all insulinomas are intrapancreatic in location[1,3,5]. Extrapancreatic insulinomas with symptoms of hypoglycaemia are extremely rare (2%) and are most commonly found in the duodenal wall. In its sporadic form (90%) tumors are generally solitary, whereas in its familial form (5%-10%), they are multiple, especially in the setting of the multiple endocrine neoplasia (MEN) type 1 syndrome. Approximately 80%-90% of insulinomas are less than 2 cm in size and the lesions are distributed equally throughout the head, body and tail of

the pancreas. Most insulinomas are benign (90% of cases). Two per cent of patients have diffuse islet cell hyperplasia, microadenomatosis, or adult nesidiblastosis. Although insulinoma may occur throughout life, the mean age at presentation is 45 (range 8-82) years, and there is a female preponderance (female to male ratio 1.4:1). In MEN 1 the mean age at presentation is younger, at 25 years or less[1-5].

CLINICAL PRESENTATION

Almost all patients with an insulinoma present with symptoms of hypoglycemia secondary to excessive and uncontrolled secretion of insulin[11]. In the case of an insulinoma, symptoms are typically evident in the morning after an overnight fast, and are often precipitated by exercise[15]. Patients learned to avoid symptoms by eating frequent small meals and sugary snacks, with resultant weight gain. Symptoms are often misinterpreted, non-specific, episodic, vary among individuals and can differ from time to time in the same individual. So it is important to obtain a plasma glucose level during symptoms because a normal value in this case rules out the possibility of an insulinoma[5]. Hypoglycemic symptoms can be divided into two categories: neuroglycopenic and neurogenic symptoms[16,17]. Neuroglycopenic symptoms are due to central nervous system neuronal glucose deprivation. They include behavioral changes, confusion, lethargy, weakness, transient motor deficits, difficulty awakening, visual changes, fatigue, seizures and loss of consciousness[18-20]. If hypoglycemia is severe and prolonged, death may result. Neurogenic symptoms are are due to autonomic nervous system discharge caused by hypoglycemia. This results in cholinergic symptoms including hunger, sweating and parasthesia, and adrenergic symptoms including anxiety, tremor and palpitations. Erroneous psychiatric or neurological diagnoses are common in such situations and, on average, it takes up to 2 years before the correct diagnosis is made[5].

CLINICAL EVALUATION

In general, venous plasma glucose levels higher than 3.9 mmol/L after an overnight fast are normal; levels between 2.8 mmol/L and 3.9 mmol/L suggest hypoglycemia and lower than 2.8 mmol/L indicates hypoglycemia. Accurate diagnosis relies upon demonstration of symptomatic hypoglycemia with objective biochemical evidence of cell hypersecretion in the absence of factitious use of an insulin secretagogue. Whipple originally proposed the diagnostic triad of symptomatic hypoglcemia induced by fasting, a blood glucose level below 2.48 mmol/L (0.45 g/L), and prompt relief of symptoms following administration of glucose[5]. A corresponding rise in C-peptide is crucial to verify that insulin secretion is endogenous and to exclude factitia, i.e. self administration of insulin or peroral antidiabetic medication, claimed to be more common than insulinoma. Undetectable C-peptide in a hypoglycemic patient with an elevated insulin level would indicate exogenous insulin administration. Proinsulin levels in normal individuals are usually < 20% of total immunoreactive insulin but tend to be higher in patients with insulinoma. Proinsulin/insulin ratio > 50% may indicate malignant insulinoma, but occurs also with 25% of benign insulinomas. Oral sulphonylurea antidiabetics may cause hypoglycaemia with rise in insulin, C-peptide and proinsulin, and should be excluded by plasma measurement. The use of a ratio of insulin to glucose to aid in the diagnosis has been advocated by some authors but have evidence that they may be misleading. In one series, 34% of patients with excised insulinomas had insulin to glucose ratio > 0.30, demonstrating the fallibility of this ratio. The absolute values of glucose and insulin are the keys: when the glucose level drops to 0.45 g/L, any measurable insulin is abnormal[5,21-23]. A supervised 72 h fast forms the basis for the diagnosis of endogenous hyperinsulinemia[24,25]. The critical pathophysiological feature is failure of insulin secretion to fall to very low rates during episodes of hypoglycemia. From published reports, symptoms develop in 35% of patients within 12 h, 75% within 24 h, 92% within 48 h and 99% within 72 h[22]. The presence of hypoglycemic symptoms with fulfillment of the following criteria is diagnostic of insulinoma: blood glucose level 2.5 mmol/L or lower, insulin level 6 units/mL or higher, C-peptide level 0.2 nmol/L or higher, plasma proinsulin level 0.5 nmol/L or higher, plasma beta-hydroxybutyrate 2.7 mmol/L or lower, change in blood glucose of 0.25 g/L or higher at 30 min after 1 mg intravenous glucagon, and a negative sulphonylurea screen in the plasma and/or urine[21].

DIFFERENTIAL DIAGNOSIS

Hypoglycemia due to excessive endogenous insulin secretion can be caused by a primary pancreatic beta cell disorder including an insulinoma, beta cell hyperplasia or nesidioblastosis (presence of diffuse microadenomatosis, in which multiple small non-encapsulated tumors or nodules are distributed throughout the pancreas), a beta cell secretagogue including a sulphonylurea or a beta cell-stimulating antibody, or an antibody to insulin[20,26-29]. The differential diagnosis of hypoglycaemia includes hormonal deficiencies, hepatic insufficiency, exogenous hyperinsulinism, medication, drugs and enzyme defects. Occasionally differentiating insulinoma from these other causes of hypoglycaemia can be quite difficult. Hypoglycemia was reported in the setting of some tumors and of advanced gastrointestinal stromal tumors. Patients with multiple myeloma or systemic lupus erythematosus (SLE) and hypoglycaemia may have anti-insulin antibodies. These antibodies bind and release insulin in an unregulated manner, resulting in hypoglycaemia. These patients can be distinguished from patients with insulinoma by an anti-insulin antibody test[20,30-32].

LOCALIZATION STUDIES

The localization of small functioning islet cell tumors has proved a challenge to endocrinologists, surgeons and radiologists for several decades. No single imaging test has

emerged as being clearly superior. Imaging to localize insulinomas should only take place once the diagnosis has been confirmed biochemically. The role of imaging is not to diagnose insulinomas, but to identify and localize the tumor. Because virtually all insulinomas are found in the pancreas, it should be the focus of attention; no ectopic insulinomas have been encountered throughout the Mayo Clinic experience[3]. A number of techniques are available to localize an insulinoma, including transabdominal ultrasonography, abdominal computed tomography (CT), magnetic resonance imaging (MRI), arteriography, endoscopic ultrasonography (EUS), transhepatic portal venous sampling, selective arterial calcium stimulation with heptic venous sampling, 111 In-labelled octreotide scan with single photon emission tomography, intraoperative ultrasonography and intraoperative palpation.

Conventional preoperative techniques

Conventional imaging studies such as ultrasonography, computed tomography, and magnetic resonance imaging fail to reveal the majority of insulinomas[5,33-36]. The reported sensitivity of conventional CT scan, MRI, and ultrasonography for detection of pancreatic insulinoma ranges from about 30% to 66%, 37% to 71%, and 9.6% to 61% respectively. Combined Conventional CT scan, MRI and ultrasonography identify 17% to 66% of insulinoma[5,36-39]. With these conventional preoperative techniques, occult insulinoma was present in 31% to 52% of cases in some series[12,13]. The incidence of patients with occult insulinomas seen at the national institutes of health, increased from 16% to 52%[13].

Arteriography was considered the 'gold standard' for insulinoma localization. However, reported sensitivities of 29%-64%, combined with improved non invasive imaging modalities, have decreased its use[33-35,40,41].

Intraoperative techniques

Because of the inability of conventional preoperative studies to localize an insulinoma accurately, some have recommended surgical exploration with intraoperative ultrasonography (IOUS), thereby avoiding other costly preoperative imaging techniques. The most effective method for localizing an insulinoma at surgery is intraoperative ultrasonography[42-48]. Combining many of the attributes of preoperative ultrasonography but also enhanced by the ability to image the pancreas directly without the interference of overlying organs or gas, IOUS has been highly useful in localizing these small tumors. However, it is labour intensive, extremely operator dependent, and, without any definite preoperative localization, obviously focuses the immediate pressure to localize the tumor on the shoulders of the radiologist and ultimately the surgeon. Relevant operative anatomy can be examined to determine the optimal resection method with respect to proximity of the tumor to the main pancreatic duct, combined with colour flow Doppler assessment of adjacent major vessels. It can guide the safest approach to a tumor and facilitate dissection from the pancreatic duct, and also reveal tumor bilobation that has to be appreciated at enucleation. Sensitivities of up to 95% are reported in the detection of pancreatic insulinomas especially useful for tumors in the thicker pancreatic head. Islet cell tumors appear as well-defined, hypoechoic lesions on ultrasonography. The insulinoma is seen as a sonolucent and discrete mass. IOUS is now considered a necessary prerequisite for insulinoma operation together with complete pancreatic exploration and palpation at surgery. The IOUS should be done by an experienced investigator, and can identify tumors larger than 2-3 mm.

Most insulinomas are intraoperatively palpable as a firmer nodule with sensitivity of 90%. Tumors deep within the pancreatic head and in the uncinate process are difficult to palpate, and any lesion is difficult to detect in patients with previous pancreatitis. Combination of IOUS and palpation increases the sensitivity of insulinoma detection to nearly 100%, but requires complete surgical exploration. The head of the pancreas is delivered by the Kocher manoeuvre, with the uncinate process carefully dissected towards the porto-mesenteric vein. The pancreatic tail is mobilized to the mesenteric vein, allowing bidigital palpation and IOUS investigation from both dorsal and ventral surfaces[43,45,48].

Intraoperative laparoscopic ultrasonography greatly facilitates tumor localization and is valuable in guiding the site of pancreatic transection or enucleation especially with respect to the pancreatic ducts. It also defines the relationship of the tumor to the mesenteric vessels and confirms the adequacy of resection. Additionally, it readily demonstrates the relevant operative anatomy, defining the relationship of the tumor to the pancreatic and bile duct, and adjacent blood vessels[49-52].

New preoperative techniques

Transabdominal ultrasonography with frequency probes of 7.5-12 MHz allows higher image resolution. The advent of helical CT scanning has improved the detection of insulinomas compared with conventional CT[5,53-56]. Much investigation has gone into determining the optimal phase for detection and the consensus shows that the use of CT in the early phases is the most sensitive. Diagnostic sensitivity was 94% for dual-phase thin-section multidetector CT, 56% for dual-phase multidetector CT without thin sections and 29% for sequential CT. MR imaging is usually reserved for the detection of small and non-organ-deforming pancreatic tumors, including the functional islet-cell tumors. In current practice MRI is a second-line investigation, but potentially could take over from CT in the future as it becomes more widely available and expertise improves. For some authors, magnetic resonance imaging enables localization of small pancreatic insulinomas[57-62]. For others, while tumor detection increases with tumor size, MRI has been shown to be more accurate than CT, especially for the detection of smaller tumors. Multiple lesions are more difficult to detect using either modality. Current studies still emphasize that MRI is more sensitive for tumor detection. Nevertheless, in many institutions worldwide, CT remains the main imaging method for assessment of pancreatic disease, due largely

to its wide availability.

EUS appears to be emerging as one of the best preoperative studies to identify insulinoma. However, it requires considerable specialized expertise, is observer dependant and is not available in all centers. Sensitivities of up to 94% (range 57%-94%) are reported[63-65]. It has a specificity of 95% for identifying intrapancreatic insulinomas. The combination of biphasic thin-section helical CT and EUS resulted in an overall diagnostic sensitivity of 100%[66]. The EUS appearances of insulinoma are characteristic and include homogenous hypoechoic, rounded lesions with distinct margins. The availability of linear and curvilinear array EUS has broadened its applicability, with the ability to perform fine-needle aspiration cytology of suspicious lesions, contrast-enhanced EUS using Levovist and preoperative marking of lesions to facilitate surgical excision[67-72]. EUS can reveal important relation to the pancreatic duct, and if introduced in the horizontal duodenum allows visualization also of the uncinate process; some of the equipment may be used for tumor biopsy. It has appeared as the most efficient method for preoperative localization, although some isoechoic (6%) or pedunculated tumors may fail to be visualized. Other limitations of EUS include poor evaluation of lesions in the distal body or pancreatic tail[73,74]. Detection rates of 83%-100% of head and body lesions are reported compared with 37%-60% for pancreatic tails lesions[5]. Intraduct ultrasonography has been used to identify small islet cell tumors, and shows promise in differentiating benign from malignant causes of localized stenosis of the main pancreatic duct. It has a reported detection rate of over 90% in the diagnosis of 1-3-mm diameter lesions. However, it is not widely available, requires specialist skills to perform and interpret, and will probably remain confined to selected centres[75,76].

Transhepatic portal venous sampling and selective arterial calcium stimulation with hepatic venous sampling have been proposed as the most sensitive preoperative localization techniques by some authors[77-84]. Selective arterial calcium stimulation with hepatic venous sampling is a more sensitive and specific provocative test, and has largely replaced transhepatic portal venous sampling. This technique has a reported sensitivity of over 90% (range 87.5%-100%) in the accurate localization of pancreatic insulinomas. Although selective arterial calcium stimulation with hepatic venous sampling has a high detection rate, it is not used routinely in most centers as it is invasive, technically demanding and expensive. It may be appropriate when an insulinoma is strongly suspected but all non-invasive imaging tests are negative.

Insulinomas have a low density of somatostatin receptor in only 50% of tumors[85]. Consequently, somatostatin receptor scintigraphy has a limited role in the evaluation of primary insulinomas. Evolving techniques include peptide receptor scintigraphy combined with anatomic imaging methods such as CT or positron emission tomography[57,65]. In tumors that express somatostatin receptor, this can be determined along with detailed axial imaging. This technique has a role in tumor localization, and also for follow-up after treatment with peptide receptor radionuclide therapy[86-93].

PREOPERATIVE LOCALIZATION IS NECESSARY?

Avoiding all efforts at preoperative localization has been espoused by some because a relatively high percentage of insulinomas can be identified intraoperatively in the hands of experienced surgeons. However, reports of insulinomas that remain undetected range from 10% to 27% in several series and preoperative localization was considered essential to successful surgical treatment' in 15 of 41 (37%) patients at one major medical centre with a highly experienced endocrine surgeon. There is absolutely no question that positive localization is required prior to reoperative insulinomas. Preoperative localization is very helpful in planning the operation and certainly offers a measure of comfort to both the surgeon and patient prior to entering the operating room. However, preoperative imaging enables more accurate surgery, which may spare the patient an unnecessary total pancreatectomy and its associated morbidities, and facilitates the detection of metastases. Furthermore, it avoids prolonging the duration of surgery and potential intra-operative damage to major structures such as the splenic vein. It is agreed by the majority, however, that knowledge of the site of the tumor before surgery is helpful in that it allows one to determine not only whether enucleation of the neoplasm or pancreatic resection is likely to be required but also whether the tumor is amenable to removal *via* a laparoscopic approach. It should also mean that the operation itself can be performed more rapidly, thereby reducing its reported morbidity and mortality. Many surgeons emphasize the importance of preoperative localization of insulinomas, because 10%-20% of these lesions cannot be identified during surgical exploration. With recent advances in non-invasive imaging giving a detection rate fast approaching that of intra-operative imaging, the present consensus is generally that preoperative localization is worthwhile. The combination of biphasic thin-section helical CT and EUS resulted in an overall diagnostic sensitivity of 100%[66] and constituted the preoperative localization study of choice.

OPERATIVE MANAGEMENT

Surgical resection is the treatment of choice and offers the only chance of cure. Overall cure rates of 75%-98% are reported after surgery, with prognosis dependant on the stage at presentation and whether complete resection was achieved[94-98]. The surgery may use laparoscopic or open techniques, and includes enucleation, and/or resection. With advances in laparoscopic techniques, both laparoscopic enucleation and resection of pancreatic insulinoma have been performed successfully in many centers, and can be associated with markedly reduced hospital stay and increased patient comfort[99-124]. The operation is facilitated by laparoscopic ultrasonography, but may be complicated-especially in the case of pancreatic head tumors-by higher risk of pancreatic effusion (20%-40%). This operation can be chosen for carefully

selected lesions and should be performed by expert laparoscopists. Enucleation is indicated for small, benign tumors at least 2-3 mm from the main pancreatic duct. Intraoperative ultrasonography can be used to measure the distance between the tumor margin and the main pancreatic duct. Macroscopically, lesions appear reddish-brown in colour in contrast to the surrounding yellowish pancreatic parenchyma, and possess a pseudocapsule with a clear plane of dissection between the tumor and the surrounding soft pancreatic parenchyma. Recent guidelines suggest enucleation is enough if the lesion is clearly localized before surgery, near or at the pancreatic surface, and easily defined intraoperatively. Histologic confirmation of complete excision and the benign nature of the insulinoma are essential[66]. Resection is indicated when the tumor abuts the pancreatic duct or major vessels, or where malignancy is suspected with a hard, infiltrating tumor and puckering of the surrounding soft tissue, distal dilatation of the pancreatic duct or lymph node involvement[102]. Resection options include distal pancreatectomy (with or without splenectomy), pylorous-preserving Whipple procedure, or mid-body pancreatectomy, depending on the site of insulinoma. To determine completeness of tumor excision, a perioperative insulin assay is valuable[125-127]. Intraoperative frozen section can provide information regarding the nature of the tissue, but is often non-diagnostic and cannot assess features of malignancy accurately. Completeness of excision is assessed by gross pathological appearance and should be confirmed by formal histological examination[102]. In 80% of patients with MEN 1 who have endogenous hyperinsulinemia, there are multiple pancreatic tumors. In these patients, an 80%-85% subtotal pancreatectomy to the level of the portal vein with enucleation of lesions in the head of the gland is recommended to reduce the risk of exocrine and endocrine insufficiency. After successful surgical excision, overall 5-year survival has been 97% (5.96); the long-term survival is 88% at 10 years with a higher risk of recurrence in patients with MEN 1[5]. After resection, the risk of recurrence is greater in patients with MEN 1 (21% at 20 years) than those without MEN 1 (5% at 10 years and 7% at 20 years).

OCCULT INSULINOMA

Insulinomas continue to pose a diagnostic challenge to physicians, surgeons and radiologists alike. With the new preoperative localization techniques, especially the combination of biphasic thin-section helical CT and EUS resulted in an overall diagnostic sensitivity of 100%, very few cases of occult insulinoma may still be encountered. In the past, different strategies have been used to deal with this problem. Blind distal pancreatectomy, progressive pancreatectomy and subtotal pancreatectomy with intraoperative glucose monitoring have hitherto been recommended. Blind distal and progressive pancreatectomy are no longer indicated if no insulinoma is found, since recent studies indicate that occult tumors are more commonly located within the pancreatic head[13,42,43,100]. As insulinomas are small and the pancreatic head parenchyma is thick, most non-palpable tumors are in the pancreatic head. Intraoperative ultrasonography can play a critical role in the identification of non-palpable lesions. In a series by Norton[43], only 33% of insulinomas in the pancreatic head were palpable. However, intraoperative ultrasonography correctly identified 100% of them. Still, it is difficult to advocate performing a Whipple procedure on the basis of circumstantial evidence that the tumor may be present in the pancreatic head. If the tumor is not identified despite a careful exploration with intraoperative ultrasonography, termination of the operation without blind resection is recommended. In such cases the surgical procedure should be terminated, the abdomen should be closed, the patient referred to a specialist centre[13,42-44], and subjected to further investigation to verify the biochemical diagnosis and exclude factitious insulin administration. A repeat 72 h fast may be necessary to be certain of the diagnosis. A trial of the best current medical therapy to stabilize the patient on a short-term basis allows time for more extensive localization procedures applied before reoperation, often including the SAS intra-arterial calcium injection test[13,100], a technique that is useful in localizing the region of the pancreas containing the tumor. At re-exploration, if still no tumor is identified, the area of the pancreas suggested by the calcium angiogram should be removed. One might call this an enlightened resection rather than a blind resection.

MEDICAL MANAGEMENT

Medical management of insulinoma is generally restricted to high-risk candidates for surgery, those not suitable for resection or in those who have undergone an unsuccessful operation with persistent symptoms. Options include dietary management, diazoxide, calcium channel blockers and somatostatin analogues. Patients are advised to avoid prolonged fasting and to take frequent meals and snacks, including complex carbohydrates. The recommended daily dose of diazoxide is 200-600 mg orally. Good symptom control is achieved in about 50% of patients. However significant side effects of edema, weight gain, hirsutism and nausea are common. The calcium channel blocker, verapamil, has also been used with some success[102]. Octreotide, a synthetic somatostatin analogue results in only temporary and modest symptom relief. It can worsen hypoglycemic symptoms owing to a grater suppressive effect on growth hormone and glucagon secretion than on insulin. A satisfactory response is reported in only 50% of patients[5,128,129].

CONCLUSION

Insulinomas are uncommon tumors. Most are intra-pancreatic, benign and solitary. A biochemical diagnosis obtained during a supervised 72 h fast followed by high quality dual phase thin section multidetector CT of the pancreas and endoscopic ultrasound confirms the diagnosis and localize the insulinoma in the majority of patients and few cases of occult insulioma may persist. Intraoperative palpation and ultrasonography should enable accurate tumor localization if preoperative studies

fail to localize insulinoma. If the tumor still occult, blind pancreatic resection is not recommended. Laparoscopic treatment is increasingly performed, and leads to long term cure if the tumor is benign.

Abstract

Opisthorchiasis caused by *Opisthorchis viverrini* remains a major public health problem in many parts of Southeast Asia, including Thailand, Lao PDR, Vietnam and Cambodia. The infection is associated with a number of hepatobiliary diseases, including cholangitis, obstructive jaundice, hepatomegaly, cholecystitis and cholelithiasis. Multi-factorial etiology of cholangiocarcinoma, mechanical damage, parasite secretions, and immunopathology may enhance cholangiocarcinogenesis. Moreover, both experimental and epidemiological evidences strongly implicate liver fluke infection as the major risk factor in cholangiocarcinoma, cancer of the bile ducts. The liver fluke infection is induced by eating raw or uncooked fish products that is the tradition and popular in the northeastern and northern region, particularly in rural areas, of Thailand. The health education programs to prevent and control opisthorchiasis are still required in the high-risk areas.

Key words: *Opisthorchis viverrini*; Carcinogenic; Liver fluke; High-risk areas

INTRODUCTION

History of Opisthorchis viverrini

Liver flukes are platyhelminth parasites of the class trematoda, and *Opisthorchis viverrini* (*O viverrini*) is a member of the family *Opisthorchiidae*. *Opisthorchis spp.* are prevalent human parasites particularly in the Far East and South East Asia. *O viverrini* is highly prevalent in Thailand and Laos while C. *sinensis* is endemic in South China, Japan, Korea and Taiwan, *O felineus* is the prominent fluke in Eastern Europe[1]. *O viverrini* was first described in the post-mortem examination of two prisoners from a jail in Chiengmai, northern Thailand, in 1911 by Leiper[2] who obtained specimens from Kerr. Kerr[3] reported that 39 of 230 (17%) adult male prisoners examined in a prison in Chiengmai were infected with *O felineus*. In 1927, Prommas[4] identified the worms found at an autopsy of a 17-year-old Thai male residing in Roi-et, northeast Thailand, as *O felineus*. Sadun EH[5] commented that the liver fluke infection in Thailand was caused by *O viverrini*, not by *O felineus*[5], and this was confirmed later in 1965 by Wykoff *et al*[6].

Life cycle of O viverrini

Fish-borne trematodes have a complicated life cycle with two intermediate hosts (Figure 1). Starting from a human host, the adult worms deposit fully developed eggs that are passed in the feces, the eggs from adult flukes are passed out with the faeces. The eggs must get into water in order to hatch and be able to infect their first intermediate host, a freshwater snail. After being ingested by a suitable snail, the eggs release miracidia which undergo in the snail several developmental stages: sporocysts, rediae, cercariae. The snail intermediate hosts are *Bithynia goniompharus, B funiculata and B siamensis*[6,7]. Cercariae are released from the snail and then penetrate freshwater fish that are the second intermediate host (*Cyclocheilichthys spp.*, *Puntius spp.*, *Hampala dispa*), encysting as metacercariae in the muscles or under the scales. Cats, dogs, and various fish-eating mammals including humans are the definitive host[8]. They become infected by ingesting undercooked fish containing infective metacercariae. In infected definitive host, the metacercaria excyst in the duodenum and ascend through the ampulla of Vater into the biliary ducts, where they attach and develop to adults, which lay eggs after 3 to 4

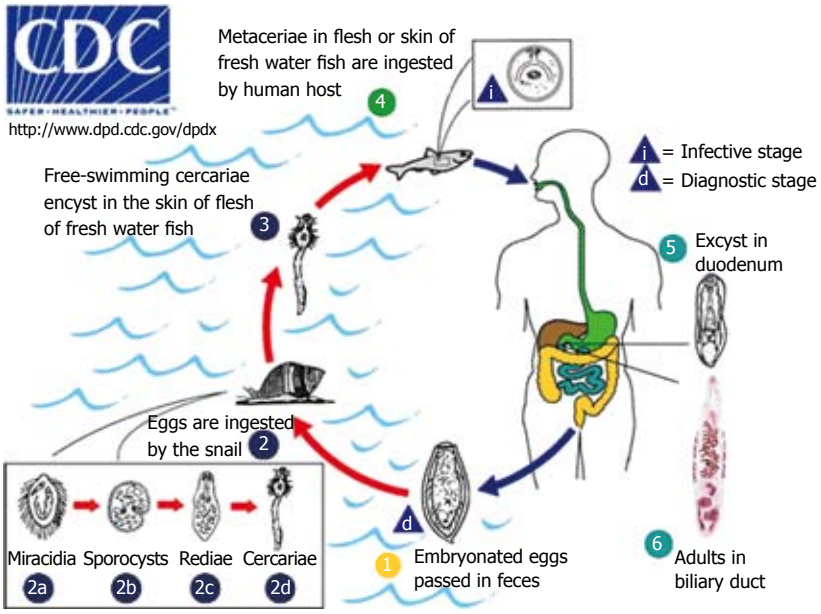

Figure 1 Life cycle of *O viverrini*. Embryonated eggs are discharged in the biliary ducts and in the stool (1). Eggs are ingested by a suitable snail intermediate host (2). Each egg releases a miracidia (2a), sporocysts (2b), rediae (2c), and cercariae (2d). The cercaria is released from the snail and after a short period of free-swimming time in water, it penetrates the flesh of a freshwater fish, where it encysts as a metacercaria (3). Humans are infected through ingestion of undercooked or raw freshwater fishes (4). The metacercaria excysts in the duodenum (5) and ascends the biliary tract through the ampulla of Vater. Maturation to adulthood takes approximately one month (6). (Adapted from: http://www.dpd.cdc.gov/DPDx/HTML/Opisthorchiasis.htm).

Figure 2 Adult worm of human liver flukes: a: *O viverrini*; b: *O felineus*; c: *C sinensis*. The average size of *O viverrini* worm is 7.0 (5.4-10.2) x 1.5 (0.8-1.9) mm[8]. (Adapted from Ash, 1997).

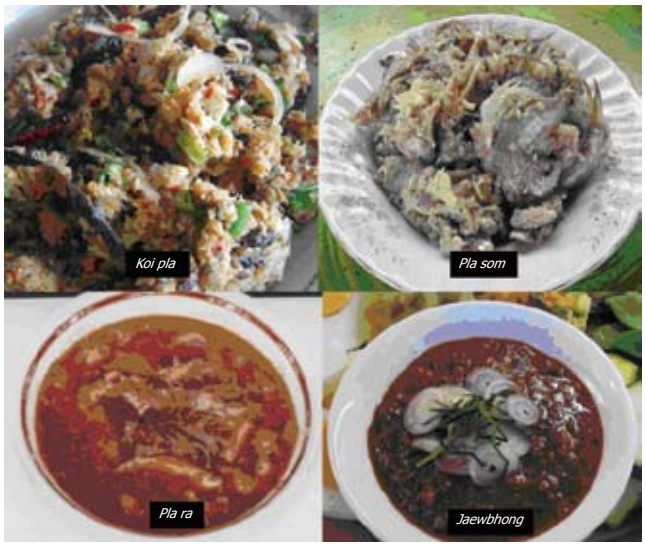

Figure 3 Preparation of *koi pla*, *pla som*, *pla ra* and *jaewbhong*. *koi pla* is prepared with the fish-based meals with local herbs, spices, condiments, rice, and vegetables. *Pla som* is moderately fermented or stored for a few days to weeks. *Pla ra* is fermented fish sauce, popular in Northeastern Thai cuisine. It is made by combining fish, salt, and roasted rice, fermenting in a pot for one to three months. *jaewbhong* is made by combining *pla ra* and chili.

wk. The adult worms reside in the biliary system of the mammalian host, where they attach to the mucosa. The life span of *O viverrini* in human is not known, however, it may be over 25 years as recorded in *C sinensis*.

Morphology of O viverrini

The *O viverrini* are dorso-ventrally flattened, lancet-shaped, thin and transparent. The adult worms are monoecious and the average size is 7.0 (5.4-10.2) × 1.5 (0.8-1.9) mm. The oral sucker is subterminal and the ventral sucker at approximately anterior one-fifth of the body length. Two testes are deeply lobed, diagonal, situated near the posterior extremity (Figure 2)[9]. *O viverrini* is morphologically similar to *C sinensis* but it is slightly smaller in size, the main difference from *C sinensis*. The long, slightly coiled seminal vesicle terminates in the ejaculatory duct, which opens through the genital pore immediately in front of the ventral sucker. Cirrus sac and cirrus are absent. The multilobated ovary is in front of the anterior testes and nearby is the seminal receptacle and Laurer's canal. The vitellaria consist of numerous follicles disposed as several columnous groups in the lateral fields between ventral sucker and testes. Excretory bladder is long, sac-like tubed, S-shaped and runs between the two testes[8].

Epidemiology of O viverrini

In Thailand, at least 15 species of cyprinoides' fish, the freshwater fish, are able to serve as intermediate hosts of *O viverini* metacercariae. The tradition of eating raw or uncooked fish products is the main reason that liver fluke is a problem in Thailand. This is very popular in the northeastern and northern region, particularly in rural areas. In the northeast, three types of preparations contain uncooked, small and medium-sized, fish: (1) *koi pla* which is eaten soon after preparation; (2) moderately fermented

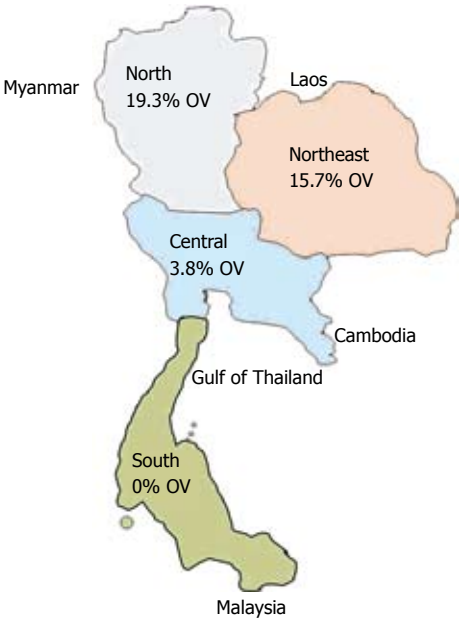

Figure 4 Prevalence of *O viverrini* infection in Thailand[15], OV: Percentage of *O viverrini* infection.

pla som which is stored for a few days to weeks; and (3) *pla ra* which is extensively fermented, highly salted fish, and stored for at least 2-3 mo[5,10] (Figure 3). The consumption frequency of *koi pla* in the population of some communities who ate it every week was approximately 80%[11]. Studies found the highest prevalence of liver fluke infection in the northeasterners who ate *koi pla*[12,13]. The frequencies of *koi pla* consumption have declined and are generally confined to special social occasions, while other under-cooked fish preparations like *pla som* and other moderately preserved fish are generally eaten several times a week[10]. *Pla ra* and *jaewbhong*, fully preserved fishes, are an important staple food and consumed daily by 60%-98% of northeasterners and lowland Laotians[11,14]. Studies have reported that *Koi pla* is probably the most infective, followed by the fish preserved for < 7 d, then *pla ra* and *jaewbhong* in which viable metacercaria are rare[10].

A small scale helminthiasis control program started in 1950 included the opisthorchiasis control in some high-risk areas. Following a number of studies and trial projects of the Faculty of Tropical Medicine, Mahidol University, the National Liver Fluke Control Program has been developed and operated under several National Public Health Development Plans. Presently, the program is being operated in some provinces of the Central, and all provinces of the northeast and north of Thailand[15]. The main liver fluke control strategies comprise of three interrelated approaches, namely stool examinations and treatment of positive cases with praziquantel for eliminating human host reservoir; health education for promotion of cooked fish consumption to prevent infection; and the improvement of hygienic defecation for the interruption of disease transmission[15]. The prevalences of *O viverrini* infection in the north (19.3%), the northeast (15.7%), the central (3.8%) and the south (0%) have recently been reported (Figure 4)[5,15]. The decline in the northeast from 34.6% in 1981 to current level[16,17] is attributed to intensive and continuous control activities[15]. Sithithaworn *et al*[10] performed a cross-sectional survey of intestinal helminthes infections by examining the fecal samples collected from 332 rural northeast Thais from 3 communities during October-November 2000, and they found that the average prevalence of *O viverrini* infection was 14.2% (range 8.6%-19.4%)[10]. Similarly, the prevalence of *O viverrini* infection in Khon Kaen Province, northeast Thailand was found to be 24.5%, which was rather higher in men (27.6%) than in women (21.4%)[18]. A total of 479 stool specimens were collected from rural communities of Ubon Ratchathani Province, Thailand and examined by using two techniques: the modified Kato thick smear and the direct smear. The prevalence of *O viverrini* was 14.8%, being much higher than other intestinal parasite infections[19]. *O viverrini* is still prevalent and a serious health problem in some parts of Thailand. Therefore, the health education and promotion is still more required.

Pathology and pathogenesis of O vivierrini

Most *O viverrini* infection is asymptomatic. Mild symptoms include dyspepsia, abdominal pain, constipation or diarrhea. With chronic infection, the symptoms can be more severe, and hepatomegaly and malnutrition may be present. In rare cases, cholangitis, cholecystitis, and cholangiocarcinoma (CCA) may develop. The severity of the pathology appears to be associated with both intensity and duration of infection. In humans, *O viverrini* inhabits mainly in the intra- and extrahepatic bile ducts and, rarely, in the gall bladder and pancreatic duct. The infection can induce several pathologic changes in the liver, gall bladder and extrahepatic bile ducts. Its infection can enlarge the liver and the weight of the liver may be more than the normal up to 3000-3500 g or more in heavily infected cases. The subcapsular bile ducts of heavily infected patients are usually dilated and show prominent fibrotic wall[20-22]. Microscopically, the intrahepatic lesions of opisthorchiasis are confined to the biliary tree, particularly to the large and medium-sized bile ducts where the flukes are harboured[21]. The typical histologic changes of intrahepatic bile ducts in liver fluke infection include inflammation, epithelial desquamation, goblet cell metaplasia, epithelial and adenomatous hyperplasia and periductal fibrosis[20-23].

Periportal and periductal fibrosis appeared as the most prominent histologic feature in chronic *O viverrini* infection in hamster. This fibrosis correlates with the marked increase in synthesis of hepatic content of type I and, particularly, type Ⅲ collagen as demonstrated in long-term *O viverrini* infected hamsters. Periductal inflammatory cell infiltration of lymphocytes, monocytes, macrophages, eosinophils and plasma cells was also seen both in infected hamsters[24,25] and in human[21]. Granulomatous inflammation in response to the entrap parasite eggs in the periductal tissue and liver parenchyma was occasionally observed in human[26] but frequently seen in animal model[24]. Histologically, the changes seen in the gall bladder and extrahepatic bile duct in opisthorchiasis are adenomatous hyperplasia, epithelial hyperplasia and chronic inflammation[21,27,28]. However, the studies of 189 cholecystectomy specimens in Khon Kaen revealed that

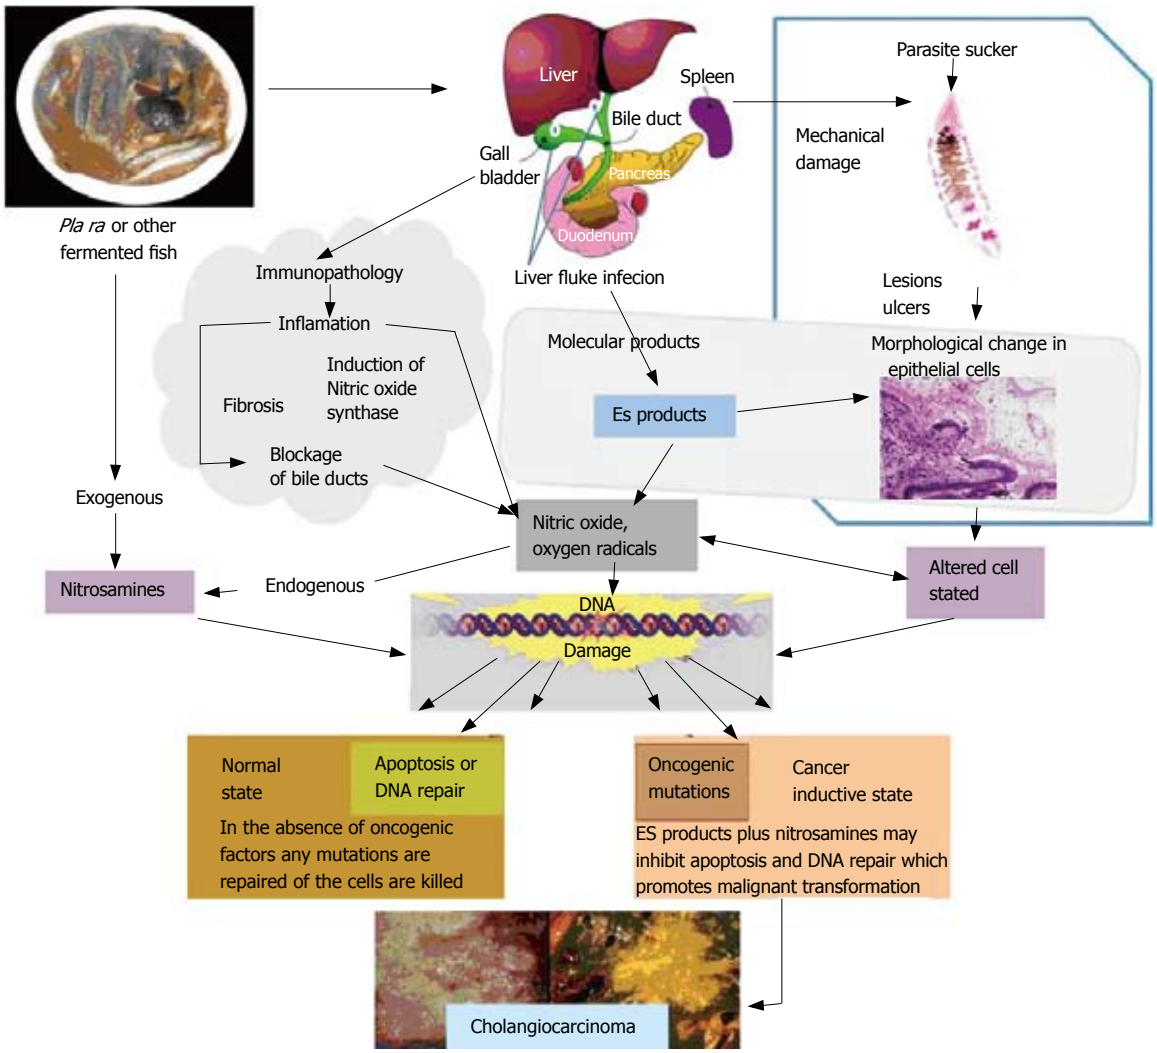

Figure 5 Proposed mechanisms of *Opisthorchis-derived* CCA initiation. (Adapted from Sripa *et al*[30]).

fibrosis of the gall bladder wall the most common finding, among several other histopathologic features, associated with opisthorchiasis as evidenced by parasite-specific antibody. For the extrahepatic bile duct, thickened cystic duct has been noted in autopsies with opisthorchiasis. Hamsters infected with *O viverrini* also showed heavy inflammatory cell infiltration and periductal fibrosis[29].

Multi-factorial etiology of CCA, mechanical damage, parasite secretions, and immunopathology may enhance cholangiocarcinogenesis (Figure 5)[30,31]. The pathogenesis of *O viverrini*-mediated hepatobiliary changes may be due to mechanical irritation caused by the liver fluke suckers and/or its metabolic products[18,24]. However, several authors suggest that immunopathological process may contribute to the hepatobiliary inflamation and damage[22,24,26,27]. Many pathological features in the hamster model reveal evidence of such mechanism, e.g. periportal infiltration of lymphocytes and macrophages. Acute damage may be induced by parasite factors, but the progressive changes are consistent with immunopathologic mechanisms[22]. During liver fluke infection, inflammation, periductal fibrosis, and proliferative responses, including epithelial hyperplasia, goblet cell metaplasia, and adenomatous hyperplasia, may represent predisposing lesions that enhance susceptibility of DNA to carcinogens[32-35]. Several *N*-nitroso compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste, *pla ra*, a condiment that is a ubiquitous component of the cuisine of northeastern Thailand and Laos[30]. Some authors hypothesised that *N*-nitroso compounds are a primary carcinogen leading to CCA in humans in northeastern region[36,37]. Jinawath *et al*[38] showed the selective up-regulation of genes involved in xenobiotic metabolism in Thai patients with CCA, implying that these genes may be involved in the detoxification of possible carcinogens, such as nitrosamines. In hamster experimentally infected with *O viverrini,* CCA was induced by exposure of sub-carcinogenic doses of nitrosamine[34]. Liver fluke infection can induce the endogenous nitrosation both in humans and experimental animals. Infected hamster showed nitric oxide synthase (NOS) expression by immune effector cells in the inflamed areas and increased endogenous nitrosation of thiazolidine-4-carboxylic acid (thioproline)[39]. In human studies, infected cases showed a higher endogenous

nitrosation than uninfected cases[40,41]. Infected cases had increased levels of plasma and urinary nitrate and nitrite compared to the uninfected cases[39]. Praziquantel treatment and co-administration of ascorbic acid with proline showed enhanced immune responses to *O viverrini* and an increase of endogenous nitrosation[42]. Thus the aforementioned findings clearly demonstrate both exogenous and endogenous nitrosation may lead to DNA alkylation and deamination in predisposed and inflamed tissues[43-45].

Molecular biology of O viverrini

Information regarding the molecular biology of *O viverrini* is limited in comparison of other known trematode parasites. The ribosomal DNA of *O viverrini* has been identified, showing the total length of approximately 13 kb consisting of 4.2 kb of large subunit rDNA, 2.0 kb of small subunit rDNA, 1.0 kb of transcribed spacer DNA and 5.8 kb of non-transcribed + external transcribed spacer DNA. The rDNA units represent 6.1% of the total genomic DNA. The small subunit gene is 1992 nucleotides long and has a G + C content of 50.94%. The use of the rRNA gene sequence comparison for determination of phylogenetic classification of *O viverrini* is comparable to conventional taxonomic classification[46,47]. The mitochondrial cytochrome c oxidase subunit I (CO I) gene and the second internal transcribed spacer region (ITS Ⅱ) gene of *O viverrini* were compared among *O viverrini* from various areas in northeast Thailand. In the nucleotide sequences of partial CO I gene (417 bp), the intraspecific variations were classified into 5 patterns but no area-specific pattern was observed. Nucleotide sequences of a region of the *O viverrini* ITS Ⅱ gene (296 bp) from different areas were different from those of *C sinensis*, *Haplorchis taichui, H pumilio, F gigantica, Echinostoma malayanum and Centrocestus sp*[48]. DNA methylation and demethylation processes are thought be taken place in *O viverrini*. The *O viverrini* genome contains a highly repeated DNA element which is very specific to the organism[49]. The construction of DNA probe to detect genomic DNA of the parasite, for diagnosis of suspected patients or identification of parasites in suspected specimens from endemic areas was developed. The construction of specific DNA probe *O viverrini* was achieved using a unit of highly repeated DNA element (334 base pairs)[50]. The specific DNA probe was characterized and used for detecting the presence of eggs DNA in stool samples[51,52]. Specific primers were designed and used for PCR-based detection. The PCR detection was highly specific and 100% positive. Further studies on molecular biology of *O viverrini* are needed to better understanding of the parasite and host-trematode relationship. Several other molecular studies of *O viverrini* have been reported, including cloning and expression of glutathione S-transferase genes[53,54].

Laha *et al*[55] reported the gene discovery effort for *O viverrini* that should expedite molecular studies of cholangiocarcinogenesis and accelerate research focused on developing new interventions, drugs and vaccines, to control *O viverrini* and related flukes. Approximately 5000 randomly selected cDNAs from the adult stage of *O viverrini* were characterized and accounted for 1932 contigs, representing about 14% of the entire transcriptome, and, presently, the largest sequence dataset for any species of liver fluke. Twenty percent of contigs were assigned GO classifications. Abundantly represented protein families included those involved in physiological functions that are essential to parasitism, such as anaerobic respiration, reproduction, detoxification, surface maintenance and feeding. A total of 164 *O viverrini* contigs contained ORFs with signal sequences, many of which were platyhelminth-specific, such as convergent evolution between host and parasite secreted/membrane proteins identified were homologues of vaccine antigens from other helminths. Finally, ORFs representing secreted proteins with known roles in tumorigenesis were identified, and these might play roles in the pathogenesis of *O viverrini*-induced CCA[55]. One of candidate gene, cysteine protease was studied by Kaewpitoon *et al* (unpublished data). By using specific fluorogenic substrates, majority of *O viverrini* protease was cysteine protease cathepsin L whereas serine and aspartic protease showed very low activities. Molecular cloning of cysteine protease encoding gene by RACE-PCR using degenerated oligonucleotide primers derived from conserved active site obtained a full-length mRNA of 981 bp encoding for 326 amino acids (GenBank, accession number AY821800). The cDNA of the novel *O viverrini* cysteine protease was designated *Ov*-cp-1. Sequence analysis showed high homologies with cysteine proteases of other trematodes, such as *Clonorchis sinensis* (85%) and *Paragonimus westermani* (55%). *Ov*-cp-1 cDNA expression was observed in various developmental stages of *O viverrini* including the metacercariae, juvenile (1, 2, 3 wk), adult worms, and eggs. Polyclonal antibody to *Ov*-CP-1, expressed protein, showed strong reaction with the gut epithelium, testes, vitelline glands and eggs in the uterus of the adult worm. Further functional study revealed that *Ov*-CP-1 could digest human hemoglobin and the activity was inhibited by the addition of E-64. The results suggest that the recombinant *Opisthorchis* cysteine protease *Ov*-CP-1 is potential for development of host-parasite relationship.

Immunity to O viverrini infection

O viverrini infection can induce both cellular and humoral host immune responses. Humoral immune response has been reported in both humans and animal model. The parasite antigens were detected in the epithelial lining of intrahepatic and extrahepatic bile ducts as early as d 3 after hamsters were infected with *O viverrini* and stimulated the host immune system[25]. The antibody levels in the patients with severe opisthorchiasis were significantly higher than those with mild infection. The infected hamster serum contained a component, possibly specific immunoglobulin(s) capable of reacting with adult, juvenile, excretory-secretory (Es) and egg antigens[56-61]. Antibody response to both somatic and Es antigens were detected[60,62]. The antibody responses in hamsters were first detected as early as 7-14 d post-infection. During early infection, hamsters infected with 50 or 100 metacercariae (Mc) showed higher antibody levels than those infected with 25 Mc. Then, the antibody level increased rapidly to a plateau at approximately 2 mo. The antibody levels to egg and somatic, but not to Es antigens, were significantly higher in the hamsters infected with 25 Mc than in those

infected with 50 or 100 Mc. These antibody responses, particularly to egg and Es antigens, did not correlate with worm burden or egg output[59]. Secretory IgA antibody reacted with both egg and Es antigens also appeared in the bile of infected hamsters. IgG, IgA and IgE antibodies in serum and bile have been reported in patients with opisthorchiasis[61-64]. Analysis of bile and serum from individual patients showed that while IgG was the predominant in the serum of all patients, IgA was present at approximately the same level as IgG or higher in the bile, while IgE antibody could be detected in 50% of the bile samples[64]. The IgG levels to the somatic antigen were most markedly elevated in disease cases and were closely associated with gall bladder size and dysfunction, and also significantly correlated with opisthorchis egg counts[32]. The antibody response to *O viverrini* decreased after treatment[65,66]. Immunoblot analysis revealed a 91/93-ku metacercaria homogenate doublet which was recognized only in sera of individuals with severe liver disease on ultrasound findings, including cholangiocarcinoma[64,67,68].

Cell-mediated immune responses (CMIR) to *O viverrini* infection have been demonstrated. Granulomatous inflamatory response to adult flukes and eggs during chronic infection is one of the typical CMIR. The inflammatory granuloma is surrounded by eosinophilic precipitates, neutrophils, eosinophils, mononuclear cells and macrophages after 6 wk of infection[24]. Similarly, patients infected with *C sinensis* exhibited egg-induced granuloma, both in the gall bladder and in the liver portal area[69,70]. Although both cellular and humoral immunity to *O viverrini* have been reported, there exists a striking difference in the antigenic recognition pattern of T and B cells which may be important for selecting antigen molecules for immunological studies of this trematode infection in man[71]. The molecular weight of the main immunogenic fractions for T cells ranged from 28 to 46 ku, whereas those recognized by antibodies were 45, 52, 56, 59, 65, 69, 75 and 81 ku. The exposure to *O viverrini* depressed the egg and egg reduction could be due to biliary obstruction and not necessarily to immunological damage of the reproductive system of the flukes. Biliary obstruction is unlikely to be the major factor as it is known to be uncommon in experimental opisthorchiasis[24,72]. Infection of hamsters with *O viverrini*, whether or not eliminated with praziquantel before the time of the re-challenge, failed to confer any protective immunity to reinfection[73].

An attempt to potentiate acquired immunity in hamsters with prior infection by immunizing them with aqueous somatic extract of adult worms resulted in a 30% reduction of worm[74]. IgG, IgA and IgM were found significantly higher levels to adult worm homogenate and metacercaria homogenate in stool of the egg-negative residents in the *O viverrini*-endemic area comparing to stool of the egg-positive group, thereby indicating some protective evidence of opisthorchiasis[75]. The lack of protective immunity is perhaps due to suppression of both cellular and humoral immune responses to unrelated antigens by *O viverrini* as shown by reduced phytohemagglutinin-induced lymphoproliferation and response to sheep red blood cell stimulation[68,75]. Moreover, when specific antibody was measured in the infected animals, the titer was found to be depressed during the late stage of infection, particularly in heavily infected group[77]. The parasites may be resistant to immune damage or able to evade the defense system of the host. The inability to kill the worms by serum from infected animals or from patients with opisthorchiasis, and the resistance to immune damage may be related to tegumental shedding and repair[68,76]. The role of T cells and cytokines in protective immunity and pathogenesis of opisthorchiasis is also unclear. The set of cytokines produced by these different T helper responses, in turn, can exert opposing effects on the parasite, resulting in either control of infection or promotion of disease. *O viverrini* may induce the Th2 response as found with other flukes, such as *Schistosoma mansoni*. However, information regarding the significance of immune responses generated during liver fluke infections is limited[68].

Diagnosis of O viverrini infection

Diagnosis of the infection is basically based on the standard fecal examination of the fluke's eggs. However, in cases with bile duct obstruction or in a light infection, eggs may not be detected in the feces[77]. Detection of fecal *Opisthorchis* antigen has been reported[78,79], though it is not so convenient. There is a need for a reliable diagnostic tool to solve the clinical and parasitological diagnosis problems in opisthorchiasis. Immunodiagnostic method is one of highly sensitive techniques in diagnosis of *O viverrini* infection. Several serologic tests for the diagnosis of opisthorchiasis have been reported[58,65,78-83]. However, some cross-reactions with other parasitic infection are still a problem. The recombinant cysteine proteinase-based ELISA was used to diagnose the infected hamsters and humans. The use of *Ov*-CP-1 as antigens showed that humoral immune responses in hamsters infected with 50 Metaceriae of *O viverrini* occured as early as d 15 post-infection and rapidly increased at one month before reaching a plateau at mo 2, which is in agreement with that reported by using *O viverrini*-somatic extract, excretory-secretory product or egg antigens[58]. In human cases, the *Ov*-CP-1-based ELISA did not cross-react with sera from patients with hookworm, minute intestinal fluke, *S stercoralis, Taenia sp., G lamblia* and *E. coli* infection. The sensitivity and specificity of the test were 94.66% and 95.55%, respectively. This is even higher than conventional indirect ELISA using *O viverrini* somatic extracts or excretory-secretory product antigen[63,64,79,81]. The sensitivity and specificity are similar to other studies using ELISA based on recombinant trematode cysteine protease, such as *C sinensis* (sensitivity: 81.3%-96%; specificity: 92.6%-96.2%)[84,85] and *P. westermani* (sensitivity: 86.2%-93%; specificity: 93%-98%)[86,87]. It seems that the more specific purified antigen used, the more sensitivity and specificity obtained. Recently, Ruangsittichai *et al*[54] reported a high sensitivity and specificity of a recombinant eggshell protein (ESP) as a potential serodiagnosis of human opisthorchiasis. However, detection of *O viverrini* DNA is expensive and requires skillful professional personnel. This overall result suggests that *Ov*-CP-1 has potential as an antigen for ELISA-based immunodiagnosis of opisthorchiasis.

PCR-based amplification of parasite DNA from stools has been documented for its high specificity. Compared with that of formalin-ether and Stoll's egg count, the sensitivity of the PCR was found to be 100%, 68.2%, and 50% in the fecal specimens containing > 1000, 200-1000, and < 200 eggs per gram of feces, respectively. Human fecal materials showed a strong reduction in PCR sensitivity of detection[51,52]. Recently, an adult stage *O viverrini* cDNA library was constructed and was isolated a glutathione S-transferase (GST) cDNA. The cDNA has a size of 893 bp and encodes a GST of 213 amino acids (OV28GST). The OV28GST RNA was detected in the parenchymal cells of adult parasites. Both purified recombinant and purified native OV28GST were resolved as 28-ku proteins. Molecular analysis of OV28GST is helpful in ongoing development of diagnostic applications for *O viverrini*[54].

O viverrini is a medically important food-borne trematode in some part of Southeast Asian countries, including Thailand. The opisthorchiasis has been studied for more than 50 years, a major break through in pathology and pathogenesis of opisthorchiasis was the discovery of *Opisthorchis* antigens in the biliary epithelium and its associated intense inflammatory response in certain infected animals[25]. The infection is associated with cholangiocarcinoma and other hepatobiliary diseases. The epidemiology is found in some rural areas because of the tradition of eating raw or uncooked fish products. The health education programs to prevent and control opisthorchiasis are still required in the high-risk areas.

Abstract

Approximately 20% of patients with acute pancreatitis develop a severe disease associated with complications and high risk of mortality. The purpose of this study is to review pathogenesis and prognostic factors of severe acute pancreatitis (SAP). An extensive medline search was undertaken with focusing on pathogenesis, complications and prognostic evaluation of SAP. Cytokines and other inflammatory markers play a major role in the pathogenesis and course of SAP and can be used as prognostic markers in its early phase. Other markers such as simple prognostic scores have been found to be as effective as multifactorial scoring systems (MFSS) at 48 h with the advantage of simplicity, efficacy, low cost, accuracy and early prediction of SAP. Recently, several laboratory markers including hematocrit, blood urea nitrogen (BUN), creatinine, matrix metalloproteinase-9 (MMP-9) and serum amyloid A (SAA) have been used as early predictors of severity within the first 24 h. The last few years have witnessed a tremendous progress in understanding the pathogenesis and predicting the outcome of SAP. In this review we classified the prognostic markers into predictors of severity, pancreatic necrosis (PN), infected PN (IPN) and mortality.

INTRODUCTION

Acute pancreatitis (AP) remains a serious disease. It is defined as an inflammatory process of the pancreas with possible peripancreatic tissue and multi-organ involvement inducing multi-organ dysfunction syndrome (MODS) with an increased mortality rate[1]. The majority of patients present with a mild disease, however approximately 20% run a severe course and require appropriate management in an intensive care unit. According to the Atlanta classification, severe acute pancreatitis (SAP) is defined as an AP associated with local and/or systemic complications. Atlanta classification is a clinically-based classification defining AP, severity and complications. This classification has been proposed in the international symposium on AP, Atlanta, 1992 by 40 international authorities from 15 countries and six medical disciplines[1]. Development of organ dysfunction within 72 h of symptom onset is defined as early severe acute pancreatitis (ESAP). Early severe acute pancreatitis is characterized by a short course, progressive MODS, early hypoxemia, high computed tomography (CT) score, increased incidence of necrosis infection and abdominal compartment syndrome (ACS)[2,3].

Multi-organ dysfunction syndrome, the extent of pancreatic necrosis, infection and sepsis are the major determinants of mortality in AP[4-6]. Pancreatic necrosis is considered as a potential risk for infection, which represents the primary cause of late mortality. Occurrence of acute respiratory (ARF), cardiovascular (CVF) and renal failures (RF) can predict the fetal outcome in SAP[7]. A wide range of mortality (20%-60%) has been reported in SAP[8,9]. Early diagnosis and prognostic evaluation are extremely important and may reduce the morbidity and mortality associated with SAP.

PATHOGENESIS

Inappropriate intracellular activation of proteolytic enzymes induces pancreatic tissue damage in the presence of intracellular lysozyme enzymes and activation of trypsinogen to trypsin. Trypsin in turn activates a cascade of phospholipases, elastases and other mediators with increased neutrophil migration to the pancreas. Consequently a variety of inflammatory cytokines including interleukin-1 (IL-1), interleukin-6 (IL-6), interleukin-8 (IL-8), platelets activating factor (PAF) and tumor necrosis factor (TNF) are released[10]. Apparently proinflammatory cytokines play a pivotal role in the pathogenesis of AP and its systemic complications[11]. IL-1 and TNF induce the release of IL-6 and IL-8[12,13] The presence of high C-reactive protein (CRP) and serum amyloid A (SAA) strongly suggests their major role in

the pathogenesis of AP[14]. Metalloproteinase-9 (MMP-9) may alter the permeability by disruption of the basement membranes of the vascular endothelial barrier[15,16]. Additionally, in experimental pancreatitis activation of mast cells has contributed to the intra and extrapancreatic endothelial barrier dysfunction and may partly contribute to the development of MODS[17]. The endothelial barrier damage in various organs including the pancreas, lungs, kidneys and intestine is associated with an increased permeability and consequent passage of blood constituents to various tissues[18-20]. Lung involvement with development of pleura effusion indicates systemic involvement with an increased mortality risk[21]. In addition, inflammatory mediators may also affect intestinal microcirculation leading to damage of microvilli allowing endotoxine and bacterial translocation (BT) into the systemic circulation and hence increase the risk of pancreatic infection[22,23]. Hyperstimulation of the immune system determines the immunosuppression and the increased mortality risk in the course of acute necrotizing pancreatitis. In the early stage of AP, cytokinemia and the oxidative stress are responsible for the inadequate immune response[24,25]. The inflammatory process is associated with acinar cell damage and an inadequate immune response mediated mainly by monocytes, macrophages, polymorphonuclear cells (PMNs), lymphocytes, mast cells and endothelial cells[26,27]. In SAP the inflammatory process is amplified by the release of cytokines and reactive oxygen species (ROS)[28]. The intensity of oxidative stress correlates well with the severity of AP[24,25]. Antioxidants such as glutathione peroxidase (GPx) play a pivotal role in the process of defense especially, where ROS contribute significantly to the disease etiology[29,30]. Glutathione peroxidase activity is selenium-dependent and is lowered in states associated with selenium deficiency[28]. In the presence of cytokines and ROS, nuclear factor-κB (NF-κB) is activated. It links the inflammatory response and regulates several forms of proinflammatory gene expressions including TNF-α, IL-1, IL-8, chemokines, selectin-E and intracellular adhesion molecule-1 (ICAM-1)[31,32].

During infection, the liver produces large amounts of SAA and other inflammatory markers. Serum amyloid A plays an important role in the activation of PMNs and chemotaxis of PMNs, monocytes and T-lymphocytes and release of proinflammatory mediators such as TNF-α, IL-b and IL-8 from PMNs[33,34]. Neutrophils are also activated by MMP-9, which promotes their endothelial cell adhesion and migration into the inflamed tissue[35]. Proteolytic activity of MMP-9 may further mediate pathological inflammation[36]. TNF-α, IL-1b and IL-8 can stimulate the release of MMP-9, which damage basement membranes and alter permeability[15,16].

Several recent studies have emphasized the role of genetic polymorphism in the predisposition to immune response variations and severe clinical course of AP. This supports the knowledge of genetic and environmental factors as severity modifiers of the disease and helps to provide prophylactic and therapeutic strategies that minimize the morbidity and mortality of SAP. For instance, monocyte chemotactic protein-1 (MCP-1) is increased in the early course of AP and can therefore accurately predict the severity and mortality[37]. Oxidative stress may also contribute to the pathogenesis of SAP. Glutathione-s-transferase (GST) genetic polymorphism also enhances the inflammatory response to pancreatic injury and promotes the progression of mild acute pancreatitis (MAP) to SAP due to the oxidative stress-induced glutathione depletion[38]. In contrast, TNF-α polymorphism has had no relation to severity of pancreatitis, but there has been a strong association with severity of sepsis complicating SAP[39]. However, in another study TNF-α and heat shock protein (HSP-70-2) polymorphism has been associated with risk of SAP[40].

Pancreatic necrosis (PN)

Approximately 20% of patients with AP develop PN. Various factors including ischemia, lysozyme enzymes, vasoactive mediators and ROS are responsible for the development of PN. It is assumed that the lysozomal protease, that activates trypsinogen in the presence of intracinar colocalisation of digestive and lysozyme enzymes, is responsible for the acinar necrosis[41]. Other vasoactive mediators that contribute to the development of PN include endothelin-1[42], phospholipase A2 (PL-A2)[43] and bradykinin inhibition[44]. Phospholipase-A2 also mediates the development of PN and strongly correlates with severity of AP as well as with occurrence of pulmonary and renal complications. Severe AP is associated with microvasculature damage, compromise of the microcirculation and release of ROS from leukocytes and macrophages[45]. Chronic alcohol consumption constitutes a strong risk factor for PN as has been shown in a recent two-arm study[46]. Alcohol, whether acute intake or chronic consumption, increases monocyte response to inflammatory signals and may enhance the inflammatory process in pancreatitis[47]. It is assumed that the most significant determinant prognostic factor of AP is development of PN with subsequent complications[48]. Acute necrotizing pancreatitis consists of an early phase during the first two weeks characterized by a sterile PN and systemic inflammatory response syndrome (SIRS) and a second phase with infection of the PN, septic complications and MODS[49].

Infected pancreatic necrosis (IPN)

The presence of bacteria in focal or diffuse areas of intra- or extrapancreatic tissue is defined according to the Atlanta definition as IPN[1]. The gut represents the main source of pancreatic contamination and related septic complications[49]. The mechanism of pancreatic infection is not yet fully explored. However, recent investigations have focused on the bacterial translocation (BT) from the intestine. Systemic inflammatory response syndrome associated ischemia, release of ROS and acidification are responsible for the mucosal dysfunction in patients with SAP[50]. Transmural[51], hematogenous[52] and lymphogenous[53] spread are the major pathways of BT. Several factors including altered gut motility, immunosuppression, bacterial overgrowth and damaged mucosal barrier promote BT and hence pancreatic contamination with septic complications and increased mortality rate[54]. Acute pancreatitis by itself

may promote BT with subsequent pancreatic infection and related complications[55]. Experimental studies have suggested BT *via* a damaged intestinal barrier[45] and immunosuppression[56] as the two important key factors of pancreatic contamination.

The incidence of infection in AP usually does not exceed 10%[57], however it approaches 80% in NP with increased morbidity and mortality rates[58,59]. The risk of infection is correlated with the extension of necrosis. It occurs in 30%-40% of patients with ⩾ 30% necrosis. Aggravation of abdominal pain, fever, leukocytosis, although not specific, may indicate infection of pancreatic necrosis. However, a definite diagnosis is established only by US- or CT-guided fine needle aspiration (FNA)[60,61]. Currently, FNA and culture of the aspirate are recommended to confirm IPN in patients with sepsis[62]. The mortality rate in IPN is around 25% compared to 10% in sterile necrosis and no mortality in MAP[63]. Infection and septic complications account for 60%-80% of mortality in AP[64,65].

Multi-organ dysfunction syndrome (MODS)

Several factors are thought to contribute through their injurious effect on the endothelial barrier to the pathogenesis of MODS. These factors include cytokines[66], ROS[67], PL-A2, elastases[68] and calcium flux[69]. In SAP the development of MODS is a result of hemodynamic abnormalities possibly secondary to activation of kinin and other vasoactive peptides[70]. Reactive oxygen species originate from various sources including xanthin oxidases, mitochondrial cytochrome oxidases, arachidonic acid metabolism and PMNs[71,72]. In SAP, the microcirculatory dysfunction is apparently mediated by ROS, leukotriens, PAF, interleukins and other proinflammatory mediators[73]. Proinflammatory cytokines (TNF-α, IL-1b and IL-6) play a significant role in the pathogenesis of AP and may mediate systemic complications[11]. These complications may result from an exaggerated and uncontrollable host response leading to SIRS[74]. Multi-organ dysfunction syndrome is apparently induced by cytokines, and inflammatory mediators released in a state of SIRS[2,75] which occurs in 72%-90% of patients with SAP. Single organ failure (SOF) accounts for 25%-37% and multi-organ failure (MOF) accounts for 35%-66% of MODS. The most commonly encountered SOF has been respiratory, cardiovascular, hepatic and renal failure in 39.1%-63%, 23%-37.7%, 20.7% and 5.8%-13% of patients, respectively[76-78]. In a similar study, 61.7% have had MOF and 26.6 SOF mainly respiratory (35.1%), cardiovascular (22.3%), GI (19.1%), hepatic (15.9%) and renal (14.9%) in origin[7]. Development of MODS is considered a major risk of mortality[11,79].

Abdominal compartment syndrome (ACS)

The combination of intra-abdominal hypertension (IAHT) and end-organ dysfunction has been described as ACS. It is determined by measurement of abdominal pressure[80]. The diagnosis of ACS is established when intra-abdominal pressure exceeds 15 mmHg (2 kPa) associated with low cardiac output, progressive oliguria and hypoxia[2]. Abdominal compartment syndrome is associated with a high mortality rate correlated with sepsis and MODS. Recent reports have described the association of ACS with SAP. Approximately 11% of patients with SAP develop ACS with a higher incidence in fulminant AP, higher mortality[81-83] and organ failure rates in the majority of patients[84]. More frequently, IAHT has occurred in association with ESAP. Approximately 78% of patients with ESAP have had IAHT[2]. Abdominal compartment syndrome may develop in association with an aggressive fluid replacement[85] and during the infection and SIRS stages[86]. It is mainly correlated with uncontrolled and sustained IAHT and characterized by a severely distended abdomen and MODS. Anuria and IAHT are the most important determinants of mortality[87].

Mortality

Several authors have reported various rates of mortality varying according to the stage and severity of AP. While MAP has no mortality, the rate amounts to 10% in NP and 25% in IPN[63]. Higher rates ranging from 20%-60%[8,9] and 30%-90% in fulminant pancreatitis[88] have been reported. There are two peaks of mortality in SAP. The early phase mortality, mostly due to SIRS and MODS, occurs within the first few days and the second peak induced by PN, IPN and MODS occurs after the second week[79]. Approximately 23% of the early mortality has occurred within the first 3 d and 53% within the first week[3]. Another study has reported early mortality in 51% within the first two weeks primarily due to MODS and later 49% mainly due to IPN[89]. Sepsis and MODS may complicate pancreatic contamination contributing to > 80% of mortality[65]. Early diagnosis and appropriate management are important to decrease morbidity and mortality. A delay of transfer to ICU > 24 h after admission is associated with a four fold increased mortality risk[90]. Several factors such as etiology, age, gender, race, genetic makeup, severity on admission, the extent and infection of PN have been reported to influence the mortality[77]. On the contrary, other authors have reported a correlation between the mortality and the severity of the attack but no correlation with the cause of AP[88]. The persistence of organ failure is a strong marker of poor outcome and mortality[91]. PN, IPN and MODS are the major determinants of mortality[6,58]. The majority of deaths are due to MODS[6,92]. In a multivariate logistic analysis ARF,CVF and RF have been the independent prognostic factors of mortality[7] and IPN and MODS are the most significant causes of hospital mortality[93,94]. Other authors have reported ARF and RF as the main cause of mortality and no influence of PN on mortality in SAP[95]. Despite improvement in diagnostic and therapeutic modalities, SAP remains associated with a high mortality rate[96] ranging from 15%-20%[88] and may be as high as 40%[97]. While some authors have reported a persistence of the mortality rate for the last decades[96,98], others have reported a significant decline[79,99].

PROGNOSTIC EVALUATION

SAP is associated with a high early mortality rate (30%-50%) mostly as a result of MODS[100,101]; hence early diagnosis and appropriate management are essential. However, identification of severe cases during the first

Table 1 Predictors of severity of acute pancreatitis

Severity predictor	Reference
Multifactorial scoring system	
Ranson, Imrie, APACHE II	[14]
Clinical data	
Age	[108]
Etiology	[108]
Obesity	[63,109]
Simple prognostic scores	
BUN (=/> 25 mg/dL), LDH (=/> 900 IU/L) and PN on CE-CT	[104]
Age, highest serum creatinine (within 72 h), chronic health status and requirement for mechanical ventilation	[119]

PL-A2, CRP	[64]
PMN-elastase	[122]
TAP	[123]
PCT	[124]
CT-scoring index (CTSI)	[140]

PN: Pancreatic necrosis; CE-CT: Contrast enhanced computed tomography; IL-6: Interleukin-6; IL-8: Interleukin-8; PL-A2: Pancreatic phospholipase A2; TAP: Trypsinogen activation peptide; CRP: C-rective protein; PTC: procalcitonin; PMN: Polymorphonuclear cells; LDH: Lactate dehydrogenase.

Table 2 Early predictors of severity

Marker		Period	Reference
Clinical:	Obesity	on admission	[111,112]
Radiological:	Abnormal chest radiograph	within 24 h	[21]
Laboratory:	Serum BUN	within the 1st 24 h	[104]
	Serum creatinine	within the 1st 24 h	[21]
	Hematocrit	on admission	[133]
	Proteinuria	2nd d of admission	[111]
	CRP	24-48 h	[129]
	MMP-9	1-48 h of admission	[132]
	SAA	within the 1st 24 h	[43]
	IL-6, IL-8	within the 1st 24 h	[10]
	IL-18	within the 1st 48 h	[28]
	Trypsinogen-2	on admission	[131]
	Trypsin-2 AAT	on admission	[131]
Factors (in biliary pancreatitis) predicting need for ICU:			
	Heart rate, Glucose, BUN, WBC&CRP	on admission	[136]

CRP: C-reactive protein, MMP-9: Matrix metalloproteinase-9; SAA: Serum amyloid A; IL-6, 8, 18: Interleukins 6, 8 and 18; BUN: Blood urea nitrogen; WBC: White blood cell count, trypsin-2; AAT: Trypsin-2-alpha-1-antitrypsin.

2-3 d of symptoms onset, where MODS takes place, is difficult[102,103]. The best predictors include clinical features, markers of pancreatic injuries and markers of inflammatory response[63].

Currently, several markers are used for prognostic evaluation of different stages in the course of AP and development of complications. They can be classified as markers of severity, early prediction, PN, IPN and mortality (Tables 1-5).

Markers of severity

Multifactorial scoring systems (MFSS): All MFSS such as Ranson, Glascow, Imrie, APATCHE Ⅱ and clinicobiochemical systems have a similar accuracy after 48 h of admission[14]. They are good predictors of severity and PN[104]; however they have insignificant value for prediction of infection in patients with SIRS[105,106]. MFSS are complex, consist of several criteria[104] and are less accurate than the calcitonin precursor in the prediction of infection in patients with SIRS[107] and consume 48 h.

Table 3 Predictors of pancreatic necrosis

Marker	Reference
1 C-reactive protein (CRP)	[48,148]
2 Serum lactate dehydrogenase (LDH)	[153]

8 Interleukin-6 (IL-6)	[90]
9 Reactive nitrogen intermediates (RNIs)	[58,156]

Clinical data: Some recent reports have discussed the predictive value of clinical data such as age, etiology[108] and obesity[63,109]. Obese individuals have had a worse prognostic score on admission and have developed significantly more complications compared to non-obese patients. For instance, respiratory failure has occurred more frequently in obese subjects[109]. Also the rates of infective complications such as IPN, sepsis and pancreatic abscess have been higher in obese patients[109,110]. Generally, obesity is more frequently associated with SAP, local and systemic complications and mortality; hence it should be used routinely in the initial assessment of severity[111,112]. Obesity increases the risk for SAP by enhancing the immune response to pancreatic injury[113]. Body mass index (BMI) > 30 kg/m^2 is a reliable predictor of severity[63,114]. However, another study has found no effect of BMI on pro- or anti-inflammatory cytokines levels in early pancreatitis[115].

While some studies have not found a correlation between etiology on one hand, course and outcome of AP on the other hand[88,116], others have reported the highest mortality rate in patients with idiopathic pancreatitis[117,118].

Laboratory markers: Current prognostic markers of severity are valuable, but immediate evaluation is difficult to establish[109]. However, Simple prognostic score (SPS), consisting of blood urea nitrogen (BUN) ⩾ 25 g/dL, serum lactate dehydrogenase (LDH) ⩾ 900 U/L and presence of PN on contrast enhanced-CT (CE-CT), is comparable with MFSS with the advantage of simple prediction of SAP on admission[104]. Another SPS constituting four variables including age, highest serum creatinine within three days of primary admission, chronic health status and mechanical ventilation requirement have had a similar predictive performance as APACHE Ⅱ[119].

Inflammatory markers: Cytokines have a central role in the pathogenesis of SAP. The proinflammatory cytokine response is reflected by an increased IL-6 level and release of anti-inflammatory mediators. Elevated levels of pro- and anti-inflammatory cytokines occur early, persist for several days in systemic circulation and are independent of sepsis. By univariate analysis an IL-6 level > 1000 pg/mL is associated with an increased risk of mortality at day one[90]. Inflammatory markers such as IL-6, TNF-α, PL-A2 and CRP are good predictors of severity, however, their role in identifying those at risk to develop IPN is not determined yet[64]. Significantly higher levels of IL-6, IL-8 and TNF-α differentiate independently MAP from SAP. TNF-α is difficult to measure compared to IL-6 and IL-8[10]. IL-ra and IL-15 are useful predictors of complications, especially MODS[120,121] and mortality[121].

Other markers such as PMN-elastase[122], trypsinogen activation peptide (TAP)[123] and procalcitonin (PCT)[124] are elevated in SAP and can be used for severity assessment. They are able to predict the severity, but they are not widely available. Currently, CRP is the only marker applied routinely in clinical use[125]. It is considered as the standard severity and prognostic serum marker in SAP[126]. The levels of CRP in SAP have differed from control and MAP after 48 h of symptom onset. In contrast, SAA plasma level has differed significantly ($P < 0.001$) in SAP from MAP and control and can predict severity earlier and better than CRP[14]. In SAP CRP and SAA levels are significantly higher than other acute phase proteins[127].

Early markers for prediction of severity

Various markers including IL-6, IL-8[119,128], TNF-α, PMN-elastase[129], TAP[130], PLA-2[43] can be used as early predictors of SAP, however they need to be made clinically applicable[63]. CRP is the widely used and clinically applied marker of severity 48 h after the onset of symptoms[129]. Other early predictors of severity include a marked decrease of GPx and selenium serum concentration, which reflect the significance of oxidative stress, are associated with a marked increase of IL-18 during the first two days of admission in patients with SAP. Hence, GPx and IL-18 may be used as predictors of severity[28]. Trypsinogen-2 and trypsin-2-alpha-1-antitrypsin (trypsin-2 AAT) have been reported as early accurate markers of severity already at admission, therefore, they are considered as useful markers for clinical use[131].

In addition, MMP-9, a Zn^{2+} containing enzyme[132] has been reported as a valuable early predictor of severity. It significantly degrades the basement membrane components in the inflammatory process and is involved in the deterioration of SAP. In comparison to normal subjects and those with MAP, it increases significantly one hour after admission, decreases after 48 h and is able to differentiate SAP from MAP already one hour after admission. It also correlates well with CRP and TNF-α levels and APACHE Ⅱ in patients with SAP[98].

BUN, a marker of hypovolemia and catabolism has been suggested as the most useful prognostic predictor in the first 24 h of SAP onset[104]. In addition, serum creatinine level exceeding 2 mg/dL (> 176.8 μmol/L) and the presence of pleura effusion or parenchymal densification on chest radiography identify within 24 h of admission those with a severe or adverse clinical course[21]. The presence of pleural effusion particularly, left-sided or bilateral, has an excellent predictive value[99]. Furthermore, patients with SAP commonly develop proteinuria, which can discriminate on the second day of admission SAP from MAP[111].

Hematocrit (Hct) has also been reported as an early, reliable, easily obtainable and cheap marker. Its prognostic value on admission is comparable to MFSS after 48 h of admission. It limits the requirement of CE-CT to those who do not improve[133]. On the contrary, other authors have not found a significant difference in the decrease of the 24 h Hct concentration in MAP and SAP[134] and hemoconcentration has recently been reported as a poor predictor of PN[135]. In patients with biliary pancreatitis serum glucose, BUN, WBC, tachycardia and APACHE Ⅱ scores independently predict patients requiring intensive care management[136].

Early localization of PN by CE-CT can predict the outcome in SAP. Necrosis of the head or the entire pancreas is associated with high risk complications compared to the distal part[137]. The accuracy is enhanced by additional use of Hong-Kong simple biochemical criteria (BUN and glucose)[138]. Additionally the presence of extrapancreatic collection and non-visualization of portal and splenic veins on CT predicts complicated outcome in SAP[139]. Balthazar CT-severity index (CTSI) ⩾ 5 is an accurate tool for assessing the severity and outcome of AP. It has been superior to Ranson's criteria and APACHE Ⅱ in predicting outcome of AP[140].

Lipid peroxidation products, which suggest a pivotal role of oxidative burst, may help to predict the prognosis in SAP[141]. Also plasma alph2-macroglobulin proteolysis, which induces local and distant tissue injuries and has been associated with increased MMP-2, MMP-9 and serine proteinase plasma levels can be used as a prognostic marker of severity in SAP[142]. Further, recently reported prognostic markers include SAA and neopterin. Serum amyloid A is a sensitive marker of inflammation and tissue injury. It predicts early severity and it has been superior to CRP within the first 24 h of symptom onset[43]. Neopterin, a marker of macrophage activation along with IL-6 serum

levels reflect pancreatitis severity and therefore it may act as a predictor of severity within the first week of AP onset[143]. While PCT has been reported to be of limited additional clinical value in the early assessment of AP[144], it has been found to be an early predictor of severity and can be used to monitor the clinical prognosis[145]. In addition, a more recent prospective international multicenter study has reported PCT as an early and reliable marker of clinically relevant pancreatic infections and the overall prognosis in SAP[146]. The initial data of a recent study has also suggested serum proteomic profile as a predictor of severity that differentiates SAP from MAP[147].

Markers of PN

PN usually develops within the first three days of SAP onset. Several markers are implicated in the prognostic evaluation of PN. These include IL-6[78], TNF[134], CRP, PMN-elastase[148], TAP[149] and SAA[14]. Among these markers CRP is the only available marker in clinical laboratories[59]. CRP is produced in the liver cells under stimulation by IL-1 and IL-6. Although the peak serum concentration is reached after 72 h[150], it is able to differentiate SAP from interstitial pancreatitis within 24 h. CRP with a cut-off level of 110 mg/L has a highest sensitivity and negative predictive value for PN[48]. Its predictive value for PN has been higher than those of PCT and IL-8. The area under the curve (AUC) of ROC has been 0.92, 0.79 and 0.52 respectively[151]. CRP concentration rises significantly in early stages of PN with a high sensitivity and negative predictive value (NPV) of approximately 95%. In a multivariate analysis serum macrophage migration inhibitory factor (MIF) has recently been reported to be an independent predictor of PN[152]. CE-CT is a valuable diagnostic modality for PN with almost 100% sensitivity between 4 and 10 d. It is the gold standard method that confirms the diagnosis of PN; however CRP and LDH, a marker of tissue damage, are routinely utilized as markers of PN[153].

Markers of IPN

The incidence of IPN is influenced by the extent of necrosis and is associated with a prolonged hospital stay and increased rates of morbidity[154] and mortality[155]. In the early stages of the disease there has been no significant difference in the median CRP concentration between IPN and sterile pancreatic necrosis (SPN). Univariate and multivariate regression analysis have shown a correlation between CRP concentration and secondary pancreatic contamination and therefore it has been suggested as a marker to differentiate preoperatively IPN from SPN[64]. Procalcitonin serum level is markedly higher in IPN compared to SPN during the first week. Compared to CRP and IL-6, PCT at a cut-off value of 1.8 ng/mL is closely correlated with the presence and intensity of necrosis infection. On the other hand, a combination of PCT < 2 ng/L and IL-6 < 400 pg/L has been the best to identify patients not at risk of secondary pancreatic contamination. PCT is suggested as a potential and accurate new marker for prediction of IPN[64]. It is a nonspecific marker of infection and sepsis, posses the same diagnostic accuracy of FNA and it correlates well with the presence and severity of infection[64,124].

IL-6 is increased for several days in both infected as well as sterile necrosis, however with significantly higher levels in IPN. Also IL-8 is elevated for a few days in both types of necrosis with markedly higher levels in IPN[64].

IL-8, a potent PMN activating cytokine, is a good indicator of septic MODS in patients with SAP. Other inflammatory cytokine levels for instance, sICAM[58] and nitric oxide in the form of reactive nitrogen intermediates (RNIs)[155] are elevated in both sterile and infected necrosis. Higher levels of NO are associated with an increased risk of sepsis and mortality[156].The gold standard for an accurate and early diagnosis of IPN is the US- or CT-guided FNA with an approximately 90% sensitivity and specifity[14].

Predictors of mortality

Recently, nonenhanced CT has been found to be a valuable predictor of mortality[157]. A novel model for prediction of mortality consisting of four variables: age, highest serum creatinine level within 60-72 h from primary admission, requirement for mechanical ventilation and chronic health status with at least a similar predictive performance of APACHE Ⅱ can predict fetal outcome in the early stage of SAP[119]. ARF, CVF and RF predict mortality in patients with SAP[7]. Systemic complications especially ARF and RF are the main causes of mortality in SAP[95]. Also the presence of chronic renal failure (CRF) worsens the prognosis of AP and is associated with high morbidity and mortality[158]. In a univariate analysis, an IL-6 concentration > 1000 pg/mL has been associated with an increased risk of the first 24 h mortality[90]. Also IL-ra and IL-15 are useful predictors of mortality[120,121].

The mortality risk is correlated with higher serum NO concentration[58]. A serum creatinine level > 2 mg/dL and an abnormal chest radiograph together and isolated are significantly associated with a high mortality risk at 90% sensitivity and 76% specifity[21].

The persistence of organ failure is a strong marker of poor outcome and mortality[91]. PN, IPN and MODS are the major determinants of mortality[6,92].

CONCLUSION

The intracellular presence of inappropriately activated proteolytic enzymes is responsible for the damage of pancreatic tissue. Trypsin in turn activates a cascade of inflammatory markers, which are together with ROS responsible for the development of acute pancreatitis and its complications. Early diagnosis and prognostic evaluation may reduce morbidity and mortality. Prognostic predictors of severity, PN, IPN and mortality are summarized: (1) early severity predictors: obesity, abnormal chest radiograph, serum BUN, creatinine, proteinuria, hematocrit, CRP, MMP-9, SAA, IL-6, IL-8, and IL-18, trypsinogen-2 and trypsinogen-2 AAT, (2) prognostic predictors of necrosis include CE-CT, LDH, CRP, PCT, IL-6, SAA and MIF, (3) prognostic predictors of IPN: CRP, PCT and ultrasound or CT-guided FNA, (4) prognostic predictors of mortality: obesity, pleural effusion on chest radiograph, IL-6, RNIs, PN, IPN, and MODS.

Abstract

Surgeons may be severely criticized from the perspective of evidence-based medicine because the majority of surgical publications appear not to be convincing. In the top nine surgical journals in 1996, half of the 175 publications refer to pilot studies lacking a control group, 18% to animal experiments, and only 5% to randomized controlled trials (RCT). There are five levels of clinical evidence: level 1 (randomized controlled trial), level 2 (prospective concurrent cohort study), level 3 (retrospective historical cohort study), level 4 (pre-post study), and level 5 (case report). Recently, a Japanese evidence-based guideline for the surgical treatment of hepatocellular carcinoma (HCC) was made by a committee (Chairman, Professor Makuuchi and five members). We searched the literature using the Medline Dialog System with four keywords: HCC, surgery, English papers, in the last 20 years. A total of 915 publications were identified systematically reviewed. At the first selection (in which surgery-dominant papers were selected), 478 papers survived. In the second selection (clearly concluded papers), 181 papers survived. In the final selection (clinically significant papers), 100 papers survived. The evidence level of the 100 surviving papers is shown here: level-1 papers (13%), level-2 papers (11%), level-3 papers (52%), and level-4 papers (24%); therefore, there were 24% prospective papers and 76% retrospective papers. Here, we present a part of the guideline on the five main surgical issues: indication to operation, operative procedure, peri-operative care, prognostic factor, and post-operative adjuvant therapy.

INTRODUCTION

Surgeons may be severely criticized from the perspective of evidence-based medicine because the majority of surgical publications appear to not to be convincing[1]. In the top nine surgical journals in 1996, half of the 175 publications refer to pilot studies lacking a control group, 18% to animal experiments, and only 5% to randomized controlled trials (RCTs).

There are five levels of clinical evidence[2]: level 1 (randomized controlled trial), level 2 (prospective concurrent cohort study), level 3 (retrospective historical cohort study), level 4 (pre-post study), and level 5 (case report).

Recently, a Japanese evidence-based guideline for the surgical treatment of hepatocellular carcinoma (HCC) was made by a committee (Chairman, Professor Makuuchi and five members). We searched the literature using the Medline Dialog System with four keywords: HCC, surgery, English papers, in the last 20 years. A total of 915 publications were identified and systematically reviewed (Figure 1). At the first selection (in which surgery-dominant papers were selected), 478 papers survived. In the second selection (clearly concluded papers), 181 papers survived. In the final selection (clinically significant papers), 100 papers survived. The evidence level of the 100 surviving papers is shown here: level-1 papers (13%), level-2 papers (11%), level-3 papers (52%), and level-4 papers (24%); therefore, there were 24% prospective papers and 76% retrospective papers.

Here, we present a part of the guideline on the five main surgical issues: indication to operation, operative procedure, peri-operative care, prognostic factor, and post-operative adjuvant therapy.

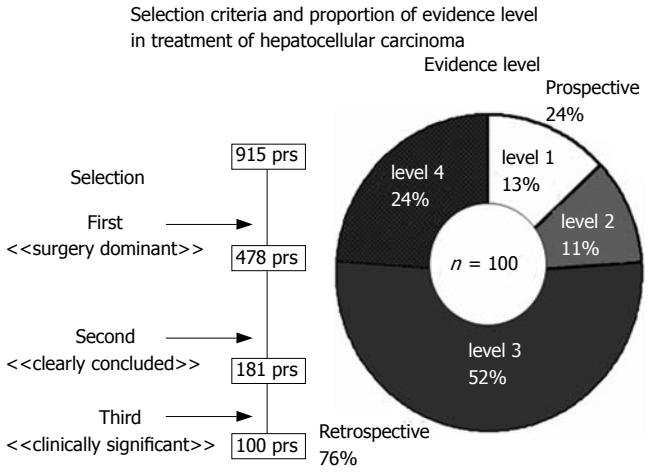

Figure 1 Selection criteria and proportion of evidence level in surgical treatment of hepatocellular carcinoma. We searched the literature using the Medline Dialog System with four keywords: HCC, surgery, English papers, in the last 20 years. The 915 publications were systematically reviewed by 3 steps. Almost all publications were retrospective (76%), there were only 24 (24%) with a high level evidence.

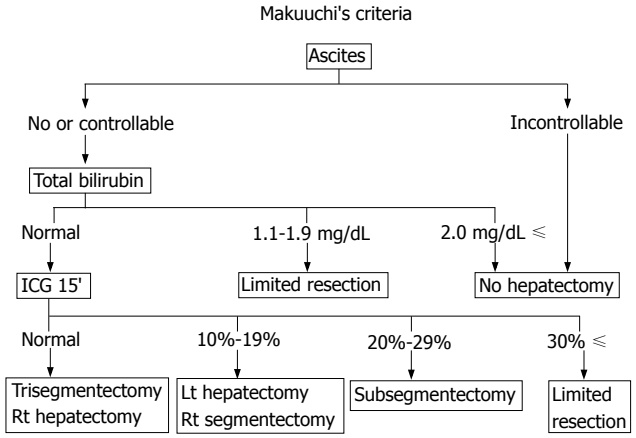

Figure 2 Algorithm before proceeding to safety hepatectomy for HCC with cirrhotic liver. Makuuchi's criteria include three factors: ascites, total serum bilirubin, and the ICG-R15: indocyanine green 15 min retention rate. This algorithm shows the maximal area for which an operation can be performed safely.

GUIDELINE 1: OPERATIVE INDICATION FOR HCC

Selection criteria in primary HCC

The selection of appropriate candidates for hepatectomy depends on careful assessment of the tumor status and liver function reserve. In order to evaluate tumor status, careful assessment of the liver function reserve is critical in patient selection for hepatectomy to avoid post-operative morbidity and mortality[3,4]. As selection criteria for operative procedures in patients with HCC and liver cirrhosis, Makuuchi's criteria have been used widely in Japan[5] (Figure 2). Criteria comprise ascites, total serum bilirubin, and the indocyanine green (ICG) K disappearance rate. In patients without ascites and with total bilirubin of < 2 mg, hepatectomy is indicated. The ICG rate indicates the upper limit of the hepatectomy procedure.

Table 1 The outcome of hepatectomy in major institutions

Author	Criteria	Morbidity (%)	Mortality (%)	5-yr Survival (%)
Blumgart[22]	Child	45	4.5	39
Bismuth H[7]	Child	40	10.0	48
Belghiti[8]	Child	31	6.4	37
Gozzetti[9]	Child	36	3.5	43
Bruix[10]	Child	-	3.9	51
Fan[6]	ICG15	38	2.5	49
Wu CC[11]	ICG15	11	2.3	51
Makuuchi[7]	ICG15	26	0.0	53

The Child classification is usually used by Western surgeons, while Eastern surgeons rely on the ICG-R15 retention rate to determine the liver function of patients. Operative morbidity rates were similar, but operative mortality rates were lower in the East, and five-year survival rates were higher in the East.

The clinical significance of the ICG clearance test was reported by Lau *et al*[6]. A prospective study was performed to identify the best test for assessing the adequacy of hepatic functional reserve in patients with HCC before hepatectomy. Each patient was evaluated before operation with regard to the ICG clearance test, the aminopyrine breath test, and the amino acid clearance test. ICG retention at 15 min was significantly associated to whether the patient survived or died.

As shown in Table 1, Eastern surgeons use the Child class and ICG test, while some Western centres rely on liver biochemistry and Child's classification alone to determine the liver function of patients. Operative morbidity rates were similar, but operative mortality rates were lower in the East, and five-year survival rates were higher in the East[7-11].

In fact, by refining pre-operative and post-operative care and surgical skills, liver resection mortality can be reduced to zero. There were 1056 hepatectomies without operative mortality and less than 3% major postoperative complications in HCC in the last eight years[12]. Liver resection can be performed without mortality provided that it is carried out in a high-volume centre and the surgeon pays sufficient attention to the liver functional reserve and the volume of liver to be removed. Thus, Makuuchi's criteria and the ICG clearance test are simple and reliable.

Early HCC

Early HCC is a well-differentiated cancer with no substantial destruction of the preexisting hepatic framework[13]. We performed a prospective study of surgical treatment for stage I HCCs to assess the therapeutic impact of hepatectomy. Stage I HCC was divided into two groups: microscopically early HCCs and others. The rate of microscopic regional spread, the time to recurrence, local recurrence, overall survival, and recurrence-free survival is significantly higher in early HCCs. This study shows that early HCC is a clinical entity with a high rate of surgical cure[14].

Portal vein tumor thrombus

The presence of portal vein tumor thrombus in a patient with hepatocellular carcinoma is one of the most significant factors for a poor prognosis[15-18]. In patients with portal vein tumor thrombus (PVTT), the median

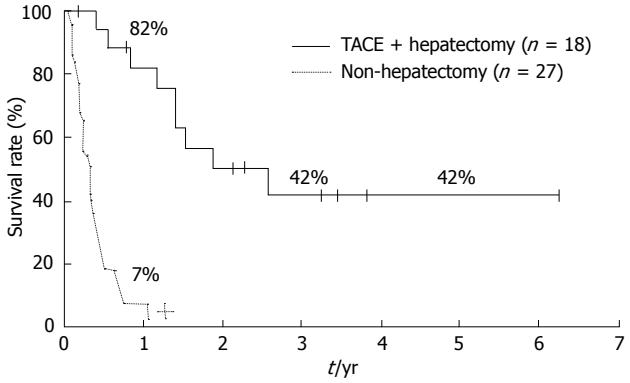

Figure 3 Treatment for HCC with portal vein tumor thrombus. Patient survival can be improved by TACE plus hepatectomy, when the number of primary nodules is not greater than two, the portal trunk is not occluded by tumor thrombus, and the indocyanine green retention rate at 15 min is > 20%. Minagawa *et al*. Ann Surg. 2001.

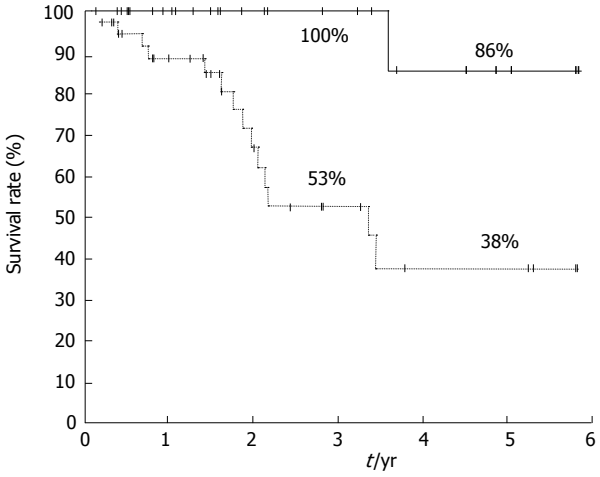

Figure 4 The result of repeat hepatic resection. Repeat hepatic resection is a satisfactory result in patients previously having undergone resection of a single HCC at primary resection and in whom recurrence developed after a disease-free interval of one year or more and the recurrent tumor had no portal invasion. Minagawa *et al*. Ann Surg. 2003.

survival was reported to be 2.7 mo, whereas survival in those without PVTT was 24.4 mo. Minagawa *et al*[19] reported that hepatic resection followed by pre-operative transarterial chemoembolization (TACE) leads to long-term survival in selected patients (Figure 3). The purpose of pre-operative transcatheter arterial embolization for patients with growth of PVTT is to interrupt the rapid growth of PVTT. They suggest that patient survival can be improved by this combination therapy, when the number of primary nodules is not higher than two, the portal trunk is not occluded by tumor thrombus, and the indocyanine green retention rate at 15 min is > 20%.

Repeat hepatic resection

The cumulative five-year recurrence rates after curative resection for HCC range from 77% to 100% according to the hepatitis virus and the main cause of late death. Some studies have demonstrated that repeat hepatectomy is effective for treating intrahepatic recurrent HCC in selected patients[20,21]. Using multivariate analysis, the authors showed that repeat hepatic resection is the treatment of choice for patients who have previously undergone resection of a single HCC at primary resection and in whom recurrence developed after a disease-free interval of one year or more and the recurrent tumor had no portal invasion[22] (Figure 4). For these reasons, repeat resection has been selected as the primary treatment for recurrent HCC under the same indications as for the first hepatectomy.

Transplantation

Liver transplantation is the best option for small HCC in patients presenting with severe deterioration of liver function. Currently, liver transplantation is considered to be the standard treatment for small HCC in patients with cirrhosis or advanced liver disease[23,24]. Optimal candidates for liver transplantation were identified in the '90 s: patients with single HCC of < 5 cm or with three or less nodules of 3 cm, without extrahepatic or vascular spread[25]. Liver transplantation eliminates or decreases significantly the risk of developing HCC, and it can prolong the life expectancy of the patient. In Japan, the scarcity of donor organs and the waiting time is too long, but living donor-related liver transplantation is rapidly becoming accepted. Moreover, cost-effectiveness analyses have shown that the benefits of living donor liver transplantation are achieved when the waiting time exceeds seven months.

Liver transplantation for HCC of < 5 cm in diameter has been shown to produce favorable survival results, but to extend the patient selection criteria for HCC, further evidence is required.

GUIDELINE 2: OPERATIVE PROCEDURE FOR HCC

Inflow vascular occlusion technique

Minimization of intraoperative blood loss is a widely accepted goal since the amount of blood loss and blood transfusion have been shown to adversely affect patient outcome[26,27]. Inflow occlusion techniques such as Pringle's maneuver and the hemihepatic vascular occlusion technique have been reported to decrease bleeding during transection of the liver parenchyma without causing damage to the remaining liver, and are widely accepted in conventional hepatectomy[28].

Makuuchi *et al* reported that by using the hemihepatic vascular occlusion technique, the amount of blood loss was markedly decreased[29]. The mean blood loss fell below 1000 mL, and the proportion of non-transfused patients reached 86.9% by 1986. This technique was followed by a prospective study[30] and RCT[31]. Man *et al* evaluated whether vascular inflow occlusion by the Pringle maneuver during hepatectomy is safe and effective in reducing blood loss by RCT[32]. The findings show a significant effect in less blood loss and better preservation of liver function during liver transection.

Anatomical resection

In 1985, Makuuchi devised "ultrasonically-guided

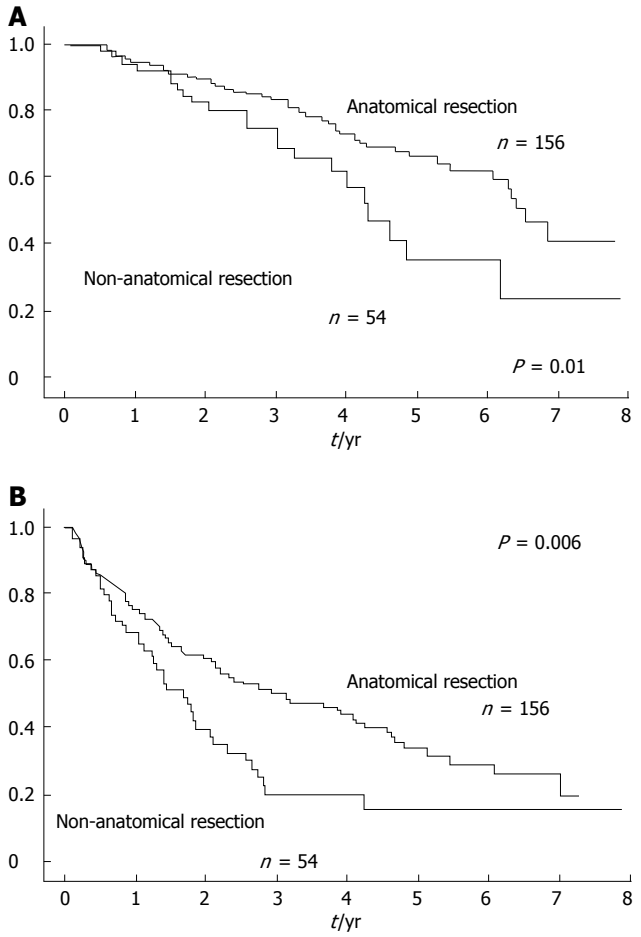

Figure 5 Anatomical resection in HCC. Overall (**A**) and disease-free (**B**) survival in anatomical and non-anatomical resection for single HCC. Both the five-year overall survival and disease-free survival rates in the anatomic resection group were significantly better than those in the non-anatomic resection group. Hasegawa *et al*. Ann Surg. 2003.

systematic segmentectomy," by which every Couinaud's segment could be removed completely[33]. This technique has been widely used around the world and is an essential technique in hepatic resection[34-40].

Anatomical resection is theoretically effective for eradicating the intrahepatic metastases of HCC with preference for eradicating portal venous tumor extension and intrahepatic metastases. This method is thought to have a beneficial effect on recurrence-free survival after hepatectomy for HCC. In the tumor enucleation group, the five-year survival rate was 35%, and in the segmentectomy group the five-year survival rate was 66% (group difference was significant). The relative risk of death in the segmentectomy group was 0.51, and segmentectomy appears thus to be the better option. The findings are supported by other retrospective studies[39-41].

Recently, Makuuchi's group showed that anatomic resection is a reasonable treatment option for HCC[42]. Both the five-year overall survival and disease-free survival rates in the anatomic resection group were significantly better than those in the non-anatomic resection group (Figure 5). Anatomical resection appeared to have a beneficial effect on recurrence-free survival after hepatectomy for HCC. Thus, systematic anatomical resection is the reasonable option of choice.

GUIDELINE 3: PERI-OPERATIVE CARE FOR HCC

Peri-operative nutritional support

Fan *et al* assessed by RCT whether peri-operative nutritional support improved the outcome in patients undergoing major hepatectomy for HCC associated with cirrhosis[43]. There was a reduction in the overall post-operative morbidity rate in the peri-operative nutrition group as compared with the control group. The operative morbidity rate was significantly lower in the supporting than in the control group (34% *vs* 55%).

Hemihepatic occlusion technique

Intermittent occlusion of hepatic blood inflow by means of the hemihepatic or total hepatic occlusion technique is essential for reducing operative blood loss, especially in cirrhotic patients[26-32]. Wu *et al* performed RCT to compare total versus hemihepatic vascular occlusion[44] (Table 2). There was no difference between the amount of blood loss during liver parenchymal transaction between total and hemihepatic vascular occlusion. However, the blood loss in the declamping period was significantly smaller in the hemihepatic vascular occlusion group due to the difference in operative blood loss and the incidence of blood transfusion. These findings indicate that hemi-hepatic clamping can be recommended for complex central liver resections in cirrhotic patients when the area of transaction is wide.

Blood transfusion

There are frequent recurrences of HCC after resection, especially in patients with cirrhosis. Dr. Yamamoto assessed retrospectively the effect of blood transfusion on HCC recurrence[45] (Figure 6). Recurrence-free survival was significantly better in the non-transfused than in the transfused group. Multivariate analysis showed that pre-operative blood transfusion was a significant predictor for accelerated recurrence of HCC after hepatectomy ($P = 0.003$). Thus, blood transfusion is avoided as far as possible[46,47].

Portal vein embolization

Portal vein embolization (PVE) before hepatectomy is intended to induce atrophy of the embolized lobe to be resected, with a compensatory hypertrophy of the counterlobe to be preserved[48]. To assess whether PVE is clinically useful, we determined the clinical outcome with PVE in 51 HCC patients[49]. After right lobe PVE, the mean ICG-R15 values rose by 4.3%, and the mean increase of the left lobe was 8%. All patients tolerated PVE well, and hepatic functional data returned to the baseline levels within one week. As a whole, the operative morbidity and mortality rates were the same as in the non-PVE hepatectomy group. The cumulative five-year survival rates were 44% in patients with HCC. PVE is a useful procedure for selected patients who may need extensive hepatectomy for diseased liver.

Table 2 The effect of hemihepatic occlusion in hepatectomy with cirrhotic patients (mean ± SE)

	Total inflow occlusion group (n = 28)	Hemihepatic occlusion group (n = 30)	P value
Resected liver weight (g)	443.9 ± 10.7 (150-1670)	422.7 ± 17.4 (180-1320)	0.29
Overall ischemic time (min)	96.0 ±10.9 (62-196)	94.2 ±9.9 (64.5-188)	0.28
Liver transection time (min)	86.4 ± 5.3 (64-171)	84.4 ± 5.2 (62-174.5)	0.54
Area of liver cut surface (cm^2)	103.1 ± 8.7 (62-208)	101.2 ± 6.9 (64-204)	0.86
Overall operative blood loss (mL)	6.82 ± 0.32 (3.8-11.5)	6.65 ± 0.26 (3.9-10.8)	0.37
Blood loss during parenchymal transection (mL)	1685 ± 170 (500-4800)	1159 ± 221 (400-4200)	0.049
Blood loss in declamping period (mL)	1015 ± 112 (400-4300)	974 ± 101 (300-4200)	0.51
Need for blood transfusion (n)	379 ± 12 (50-890)	179 ± 18 (50-460)	0.03
	12	5	0.04

Hemihepatic clamping is recommended for complex central liver resections when the area of transaction is wide. Wu *et al*. Arch Surg. 2002.

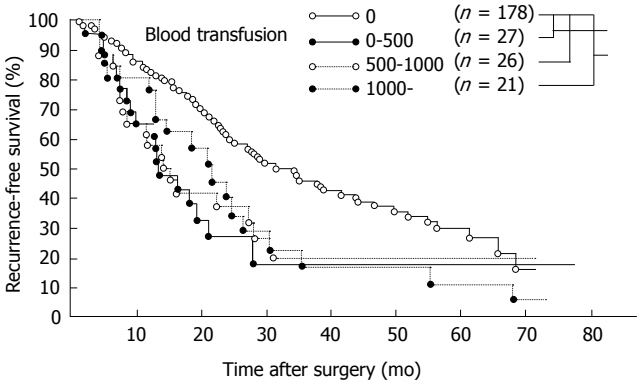

Figure 6 The relation between blood transfusion and recurrence. A close relationship between blood transfusion and recurrence-free survival was shown. Yamamoto *et al* . surgery 1994.

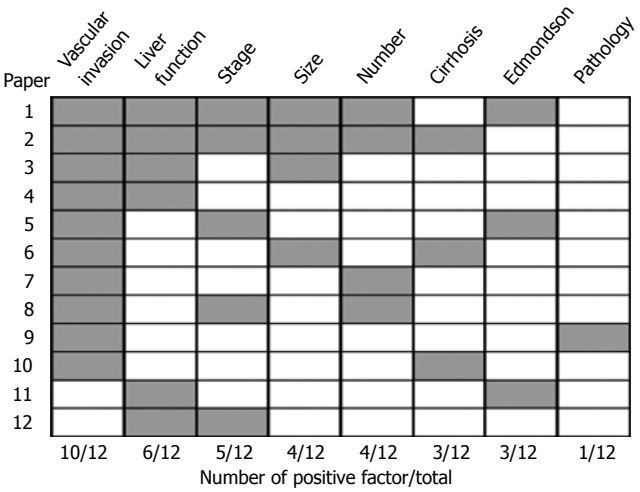

Figure 7 Prognostic factors in HCC. The eight main prognostic factors (vascular invasion, liver function, the stage of TNM classification, tumor diameter, number of tumor, degree of cirrhosis, Edmondson classification, and pathological type) were identified in twelve major publications. Vascular invasion, pTNM stage, and liver function are the most powerful prognostic factors.

GUIDELINE 4: PROGNOSTIC FACTORS IN HCC

There are many reports on prognostic factors in HCC after hepatectomy. We found 12 publications that focused on prognostic factors in HCC. Shown in Figure 7 are the eight prognostic factors identified: vascular invasion, liver function, pTNM stage, tumor size, number of tumor, degree of cirrhosis, Edmondson's classification, and pathological findings. Vascular invasion was a significant factor in multivariate analysis in ten of twelve publications. Liver function was significant in six publications, tumor stage in five, tumor size and number in four.

Vascular invasion has a high probability in recurrence-free survival, while tumor size is a controversial factor. Three factors, namely vascular invasion, pTNM stage, and liver function are the most powerful prognostic factors.

In a single HCC of < 2 cm in diameter, pathological early HCC showed a lower relative risk of recurrence (0.31) and death (0.26).

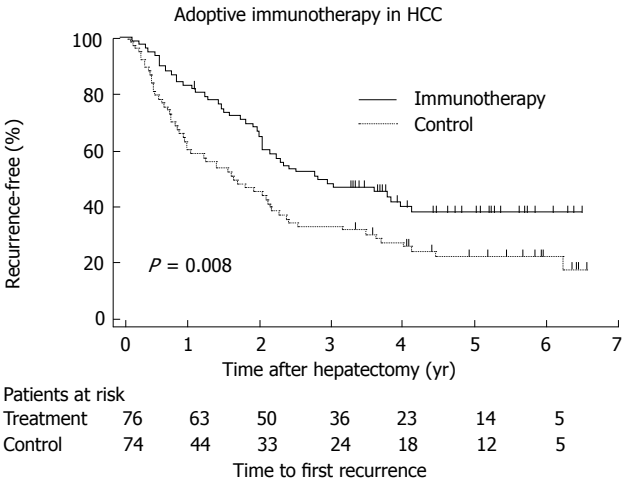

Figure 8 Adoptive immunotherapy in HCC. Autologous lymphocytes activated in vitro with recombinant interleukin-2 and infused five times during the first month. Adoptive immunotherapy reduces recurrence and improves recurrence-free survival after surgery for HCC. Takayama *et al*. Lancet 2000.

GUIDELINE 5: POSTOPERATIVE ADJUVANT THERAPY IN HCC

Resection of hepatocellular carcinoma is potentially curative, but local recurrence is common. In order to reduce the recurrence rate of HCC, effective adjutant therapy is needed. We found ten publications on RCT in adjuvant therapy[50-59]. Interventions included transarterial chemoembolization, retinoid therapy, immunotherapy (Figure 8), and interferon treatment[50-52]. However,

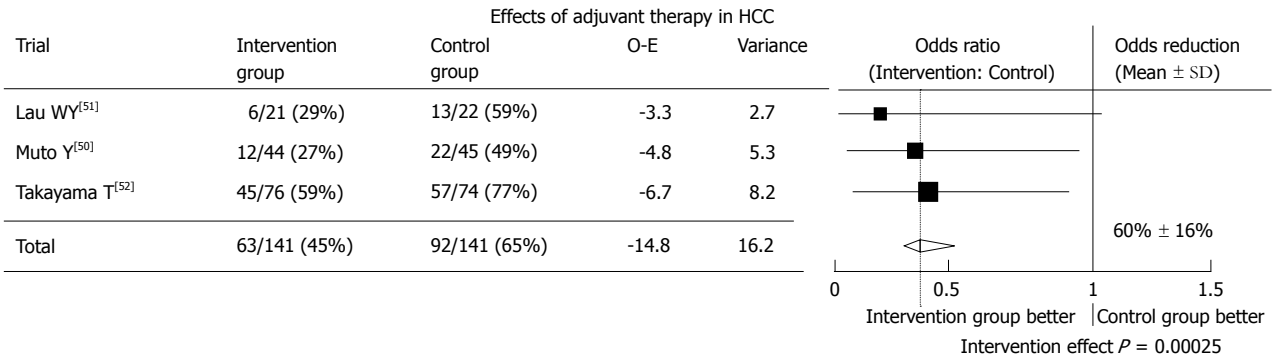

Figure 9 Effects of adjuvant therapy in HCC. Relative risk of recurrence in three RCTs by meta-analysis. The boxes show the relative risk, and the lines indicate 95% CI. A significant relative risk reduction was seen for recurrence (60%, SD 16%). O-E: observed-expected difference by Peto's method. Takayama *et al*. Cancer Reviews 2003.

the sample size was calculated only in three reports[60] (Figure 9). Eight reports showed positive results, but the quality of these RCTs are different.

Retinoid therapy

Muto *et al* reported that the oral intake of retinoid improves recurrence-free survival[50]. Cox proportional-hazards analysis demonstrated that, as an independent factor, polyprenoic acid reduced recurrence (relative risk, 0.31; 95% confidence interval, 0.12 to 0.78). Treatment with polyprenoic acid significantly reduced the incidence of recurrence after hepatectomy of the primary HCC as did a percutaneous injection of ethanol.

Intra-arterial ^{131}I-lipiodol injection

Lau *et al* reported a prospective randomized trial in which they aimed to determine whether one dose of postoperative adjuvant intra-arterial iodine-131-labeled lipiodol reduced the rate of local recurrence and increased disease-free and overall survival[51]. Patients who underwent curative resection for HCC and recovered within six weeks were given curative resection intra-arterial ^{131}I-lipiodol treatment. The median disease-free survival in the treatment and control groups was 57.2 (0.4-69.7) and 13.6 (2.1-68.3) mo, respectively (P = 0.037). Three-year overall survival in the treatment and control groups was 86.4% and 46.3%, respectively (P = 0.039). ^{131}I-lipiodol had no significant toxic effect, and this treatment decreases the rate of recurrence and increases disease-free and overall survival.

Adoptive immunotherapy

We used adoptive immunotherapy. From an HCC patient, peripheral blood was taken and lymphocytes were cultured in the presence of interleukin-2 for two weeks before assay-activated autologous T-cells were transferred back to the same patient[52]. Before the start of this RCT, we calculated the sample size of 143 patients to detect 20% improvement of recurrence-free survival at 5% significance and 80% power. After a median follow-up of five years, adoptive immunotherapy improved recurrence-free survival (Figure 8). On multivariate analysis, the relative risk of recurrence was 0.60.

CONCLUSION

Operative procedures are selected by precise pre-operative evaluation of hepatic functional reserve; thus, we rely on the algorithm (Figure 2) for decision making in surgical treatment. The overall five-year survival after resection of HCC in a high-volume centre is around 50%. However, the disease-free survival after partial hepatectomy is unsatisfactory because of the high incidence of intrahepatic recurrence. As there is no established adjuvant therapy that is proven to be effective in prevention of recurrence, aggressive management of recurrence using various modalities including surgical resection, transarterial chemoembolization, and local ablation is currently the most practical measure in prolonging survival after resection of HCC.

Liver transplantation offers the dual advantages of eradicating the tumor and replacing the diseased liver. This modality has become the treatment of choice, especially for patients with end-stage liver disease, whereby LDLT is a promising treatment for HCC in Japan.

We here presented part of the Japanese guideline, showing that surgery is the primary option of choice for HCC. However, the guideline should be refined using high-level evidence as it becomes available.

Abstract

AIM: To investigate the expression of multiple genes in Chinese jianpi herbal recipe Wei Chang An (WCA) in human gastric cancer cell line SGC-7901.

METHODS: A human gastric adenocarcinoma cell line SGC-7901 grafted onto nude mice was used as the animal model. The mice were randomly divided into 3 groups, one control and the two representing experimental conditions. Animals in the two experimental groups received either WCA over a 34-d period or 5-fluorouracil (5-FU) over 6-d period starting at 8th d after grafting. Control animals received saline on an identical schedule. Animals were killed 41 d after being grafted. The expression profiles in paired WCA treated gastric cancer samples and the N.S. control samples were studied by using a cDNA array representing 14181 cDNA clusters. The alterations in gene expression levels were confirmed by Real-time Quantitative polymerase chain reaction (qPCR).

RESULTS: When compared with controls, the average tumor inhibitory rate in WCA group was 44.32% ± 5.67% and 5-FU 47.04% ± 11.33% ($P < 0.01$, respectively). The average labeling index (LI) for PCNA in WCA group and 5-FU group was significantly decreased compared with the control group. Apoptotic index (AI) was significantly increased to 9.72% ± 4.51% using the terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) method in WCA group compared with the controls 2.45% ± 1.37%. 5-FU group was also found to have a significantly increased AI compared with the controls. The expression of cleaved Caspase-3 in WCA group and 5-FU group was significantly increased compared with the control group respectively. There were 45 different expressed sequence tags (ESTs) among the control sample pool and WCA sample pool. There were 24 ESTs up-regulated in WCA samples and 21 ESTs down-regulated. By using qPCR, the expression level of Stat3, rap2 interacting protein x (RIPX), regulator of differentiation 1 (ROD1) and Bcl-2 was lower in WCA group than that in control group respectively. By using SP immunohistochemical method the expression of Phospho-Stat3 (Tyr705) and Bcl-2 in WCA group and 5-FU group was significantly decreased compared with the control group respectively.

CONCLUSION: WCA could inhibit gastric cancer cell SGC-7901 growth *in vivo*. WCA could induce gastric cancer cell apoptosis and suppress proliferation. Its mechanisms might be involved in the down-regulation of Stat3, RIPX, ROD1 and Bcl-2 gene.

INTRODUCTION

Gastric cancer, despite its declining incidence, remains one of the most common causes of cancer-related death worldwide. Overall, 5-year survival after the diagnosis of gastric cancer is 10%-21%[1]. Surgery is the main method of treatment. Patients who undergo a potentially curative resection have a better prognosis, but even with curative resection, gastric cancer still has a high risk of relapse.

Although various chemotherapeutic agents have been reported for use in patients with gastric cancer, the median prognosis for survival in patients with advanced gastric cancer remains less then 7-12 mo at present[2-5].

We developed a Chinese jianpi herbal recipe Wei Chang An (WCA) to improve survival of gastric cancer patients. Previous clinical paired comparative studies have indicated patients with gastric carcinoma will benefit from WCA treatment[6,7]. Clinical data have shown that WCA can increase the 3-year survival rate of advanced gastric cancer. Another clinical study of 208 patients with gastric adenocarcinoma has suggested interaction between TNM stage (P = 0.000), radical resection (P = 0.000), chemotherapy (P = 0.002) and WCA (P = 0.000) in their effect on long-term survival. Patients who have received WCA have better prognosis on multivariate analysis, independent of other prognostic factors. The odds ratios of WCA was 0.315 (95% CI 0.204-0.486)[8].

In an animal model of human gastric cancer cell line SGC-7901 subcutaneously grafted onto nude mice, we have found tumor growth is significantly inhibited by treatment with WCA. Immunohistochemical staining for Ki-67 has shown WCA inhibits cell proliferation. The terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) method, flow cytometry and electron microscopy have clarified that WCA also enhances apoptosis[9]. In the orthotopic implanted model, inhibition of tumor growth and metastasis has also been verified, and higher activity of NK cells has been found in WCA-treated animals compared with the control group[10-12]. Based on previous studies, we inferred that the tumor suppressive effect of WCA involves multiple biological processes and mechanisms. This study was designed to investigate the underlying mechanism of WCA in treatment of gastric cancer, using the cDNA array technique, real-time quantitative PCR and immunohistochemical techniques.

MATERIALS AND METHODS

Drugs

The composition of WCA includes *Atractylodes macrocephala* koidz., *Poria cocos* (Schw.) Wolf, *Glycyrrhiza uralensis* Fisch., Rehd. Et Wils., and *Prunella vulgaris* L. The preparation of WCA decoction has been described previously[8,9] and the concentration of the decoction was 120 g/L. High Performance Liquid Chromatography (HPLC) was used for monitoring the stability of the decoction. Lichrospher-C18 column at 25℃ was used. The mobile phase consisted of methyl alcohol/water with a linear gradient as follows: methyl alcohol, 5, 5, 70, 100, 100%; water, 95, 95, 30, 0, 0%; at 0, 5, 15, 35 and 40 min, respectively, and the flow rate was 1 mL/min. The detection was performed at UV 280 nm (Figure 1). 5-fluorouracil (5-FU) was purchased from Xudong-Haipu (Shanghai) Pharma, China (Lot 030601).

Cell line, animal model and experimental schedule

A human gastric adenocarcinoma cell line SGC-7901 and 73 6-7-wk-old male BALB/C-nu/nu mice (weight 18-22 g) were obtained from Shanghai Tumor Institute [No. SCXK (Shanghai) 2002-0001; Shanghai, China]. The animal experiment was repeated three times. The mice were divided into three groups in every test, one control and two experimental. Animals in the two experimental groups received either WCA 0.5 mL/d by gastric perfusion over a 34 d period or 5-FU 20 mg/kg per day i.p., over a 6-d period starting on day 8 after grafting. Control animals received saline 0.5 mL/d by gastric perfusion on an identical schedule. Animals were killed 41 d after being grafted. Tumor weight was determined immediately by electron balance after the animals were killed. Tumor tissue was obtained within 2 min after removal from the animal. Each block was cut into three pieces, one for routine pathological diagnosis and immunohistochemical staining, and the others for molecular analysis. The latter samples were frozen immediately in liquid nitrogen and stored at -260℃.

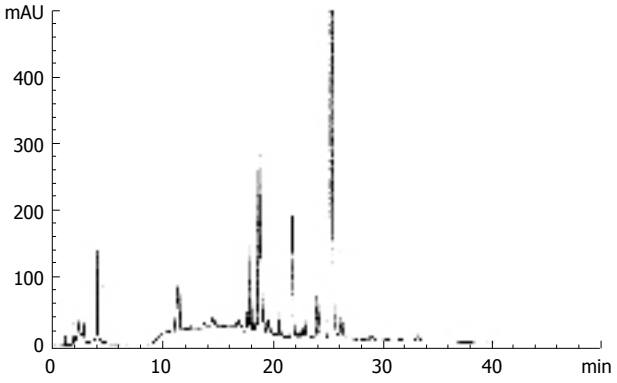

Figure 1 HPLC print of 120 mg/mL WCA. HPLC: High Performance Liquid Chromatography; WCA: Wei Chang An.

Cell proliferation and apoptosis

Cell proliferation: The streptavidin peroxidase (SP) immunohistochemical method was used to detect the expression of proliferating cell nuclear antigen (PCNA) in xenografts. The dilution of PCNA mouse monoclonal antibody (Shanghai Changdao Biotech, Shanghai, China; Cat. No. M-0437, Lot 0509) was 1:150. The procedure was performed according to the manufacturer's instructions. The positive cells were identified, counted and analyzed under the light microscope. Non-necrotic zones were selected in the tissue section. Five images (× 400) of at least 1000 cells were selected on the screen and analyzed. PCNA is predominantly localized in the nuclei.

Apoptosis: Apoptotic index (AI) was examined by TUNEL method (Roche Diagnostics, GmbH, Mannheim, Germany; Cat. No. 11 684 817 910, Lot 12 067 000). The procedure was carried out according to the kit protocol. The positive cells were identified, counted and analyzed under the light microscope. Non-necrotic zones were selected in the tissue sections. Five images of at least 1000 cells were selected on the screen and analyzed.

chemistry was also used to detect cleaved caspase-3. The dilution of cleaved caspase-3 (Asp175) antibody (Cell Signaling Technology, Beverly, MA, USA; Cat. No. 9661, Lot 15) was 1:200. Cleaved caspase-3 was predominantly localized in the cytoplasm and perinuclear region in apoptotic cells.

cDNA microarray

The expression profiles in paired WCA-treated gastric cancer and control samples were studied by using a cDNA array (Casarray, Shanghai, China) representing 14 181 cDNA clusters.

Membranes were exposed to a phosphor screen overnight and scanned using a FLA-3000A fluorescent image analyzer (Fuji Photo Film, Tokyo, Japan). After subtracting the background selected from an area in which no PCR product was spotted, clones with an intensity density over 10 were considered as positive signals. Hybridization data were considered invalid if there was a difference of over 1.5-fold in the intensity of any of the 12 control spots for the same control cDNA between arrays.

The hybridization intensity of corresponding dots in control and WCA groups was compared. If the difference in spot intensity in these two groups was more than twofold higher or lower, the corresponding genes were considered as being differentially expressed.

Real-time quantitative PCR

According to the result of cDNA array analysis, 19 genes related to regulation of cell proliferation, differentiation and apoptosis were selected for investigation. Quantification of gene expression levels were confirmed by real-time quantitative PCR. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal standard. Sequences of the primers used for RT-PCR analysis are described in Table 1. Primers were designed by Primer Express 2.0 and synthesized by TaKaRa Biotechnology (Dalian), China. Total cellular RNA was isolated from tumor tissues using Trizol (Gibco/BRL, Carisbad, USA). The RNA extracted from each sample was qualified by agarose gel electrophoresis and ethidium bromide staining and the A: 260/280 ratio was determined by electrophotometry. The extracted RNA was converted to first strand cDNA with AMV reverse transcriptase (Reverse Transcription System, Promega, Madison, USA). Nineteen genes and GAPDH were amplified using a sequence detection system (ABI PRISM® 7900HT; ABI, Foster City, CA, USA). Each cDNA sample was placed in three different wells (triple-offset). The PCR reaction consisted of stage 1, 50℃ for 2 min; stage 2, 95℃ for 15 min; stage 3, 40 cycles of 94℃ for 15 s, 55℃ for 30 s, and 72℃ for 30 s; stage 4, 95℃ for 15 s, 60℃ for 15 s and 95℃ for 15 s. Each reaction tube contained: 10 μmol/L primer (a pair) 0.5 μL + SYBR 2.5 μL + ROX 0.1 μL + cDNA 1 μL + ddH_2O 0.9 μL (Platinum®SYBR® Green qPCR SuperMix UDG (Invitrogen, Carlsbad, CA, USA; Cat. No. 11733-038). Relative gene expression was analyzed using the $2^{-\Delta\Delta CT}$ method[13].

Immunohistochemical assay

The SP immunohistochemical method was used to detect Phospho-Stat3 and Bcl-2 expression in tumor cells. The dilution of Phospho-Stat3 (Tyr705) antibody (Cell Signaling Technology; Cat. No. 9131, Lot 5) was 1:100 and Bcl-2 (Shanghai Changdao Biotech; Cat. No. M-0025, Lot 51806) was 1:50. Phospho-Stat3 was predominantly localized in the nucleus. Bcl-2 was predominantly localized in the cytoplasm and nuclear membrane.

Statistical analysis

Statistical analysis was performed using SPSS ver. 11.0 (SPSS, Chicago, IL, USA). The results were expressed as mean ± SD and significant difference was assessed by Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

WCA-induced effects on tumor growth

When compared with controls, tumor growth was significantly inhibited by treatment with WCA or 5-FU ($P < 0.01$). The average tumor inhibition rate in the WCA group was 44.32% + 5.67% and 47.04% ± 11.33% in the 5-FU group (Table 1).

Cell proliferation and apoptosis

The average labeling index for PCNA in the WCA and 5-FU groups was significantly decreased compared with that in the control group (Table 2, Figure 2). AI of human gastric cancer xenografts in nude mice was significantly increased to 9.72% ± 4.51% in the WCA group compared with that in the control group (2.45% ± 1.37%). The 5-FU group also had a significantly increased AI compared with the controls (Table 2, Figure 2). The expression of cleaved caspase-3

in the WCA and 5-FU group was significantly increased compared with that in the control group (Table 2, Figure 3).

Confirmation of cDNA array findings

There were 45 different expressed sequence tags (ESTs) among the control and WCA samples. There were 24 ESTs up-regulated and 21 down-regulated in the WCA samples. These 45 ESTs contained 35 cloned genes and 11 unknown ESTs. According to the results of cDNA array analysis, 19 genes related to regulation of cell proliferation, differentiation and apoptosis were selected for investigation. Quantification of gene expression levels was confirmed by real-time quantitative PCR. The expression level of *stat3* ($2^{-\Delta\Delta CT} = 0.16$), rap 2 interacting protein x (RIPX) ($2^{-\Delta\Delta CT} = 0.18$), regulator of differentiation 1 (ROD1) ($2^{-\Delta\Delta CT} = 0.23$) and *bcl-2* ($2^{-\Delta\Delta CT} = 0.10$) was

lower in the WCA group than that in the control group. The expression level of another 15 genes did not differ between the two groups (Table 3).

Expression of Phospho-Stat3 (Tyr705) and Bcl-2

We performed immunohistochemistry to confirm our data at the protein level. Expression of Phospho-Stat3 (Tyr705) and Bcl-2 was significantly decreased in the WCA and 5-FU group compared with that in the control group (Table 4, Figure 4).

DISCUSSION

Gastric cancer is the second most common cancer worldwide. Its poor outcome is due to the fact that 75% of patients are considered incurable at diagnosis (advanced

disease), therefore, its treatment remains a great challenge. The Chinese jianpi herbal recipe WCA has been developed to improve survival of gastric cancer patients. Previous studies have shown the tumor suppressive effect of WCA involved multiple biological processes and mechanisms, including enhanced apoptosis and inhibition of proliferation. However, further mechanisms are not fully understood[9-12].

In the present study, tumor growth was significantly inhibited by treatment with WCA at a concentration of 120 g/L in the animal model of human gastric cancer cell line SGC-7901 grafted onto nude mice ($P < 0.01$). The average tumor inhibitory rate in the WCA group was 44.32% ± 5.67%. The TUNEL method was used to detect apoptotic cells. AI of cancer cells was significantly increased in the WCA group compared with that in the control group. The 5-FU group also showed a significantly increased AI compared with that in the control group. Caspase-3 is one of the key executioners of apoptosis, which is either partially or totally responsible for proteolytic cleavage of many key proteins, such as the nuclear enzyme poly ADP-ribose polymerase. Activation of caspase-3 requires proteolytic processing of its inactive zymogen into activated p17 and p12 subunits. Cleavage of caspase-3 requires aspartic acid at the P1 position[14,15]. Cleaved caspase-3 (Asp175) antibody detects endogenous levels of the large fragment (17/19 kDa) of activated caspase-3, which results from cleavage adjacent to Asp175. It does not recognize full-length caspase-3 or other cleaved caspases. The expression of cleaved caspase-3 in the WCA and 5-FU groups was significantly increased compared with that in the control group. This result clarifies that WCA enhances apoptosis.

Immunohistochemical staining for PCNA also showed WCA inhibited cell proliferation. These results were consistent with our previous studies[9].

Carcinogenesis and the progression of carcinoma are thought to develop from multistage activation of oncogenes and loss of suppressor genes. In trying to understand the mechanism of WCA at the RNA expression level, we used cDNA microarray and real-time quantitative PCR techniques. The expression profiles in paired WCA-treated gastric cancer and control samples were screened by cDNA array analysis, which represented 14181 cDNA clusters, and verified by real-time quantitative PCR and immunohistochemistry. There were 24 ESTs up-regulated and 21 ESTs down-regulated in WCA samples. These 45 ESTs contains 35 cloned genes and 11 unknown ESTs. According to the result of cDNA microarray analysis, 19 genes related to the regulation of cell proliferation, differentiation and apoptosis were selected for investigation. The expression level of Stat3 ($2^{-\Delta\Delta CT} = 0.16$), RIPX ($2^{-\Delta\Delta CT} = 0.18$), ROD1 ($2^{-\Delta\Delta CT} = 0.23$) and Bcl-2 ($2^{-\Delta\Delta CT} = 0.10$) was lower in the WCA group than that in the control group. The expression level of another 15 genes did not differ between these two groups. Moreover, we performed immunohistochemistry to confirm these data at the protein level. The expression of Phospho-Stat3 (Tyr705) and Bcl-2 in the WCA and 5-FU groups was significantly decreased compared with that in the control group.

Jak-Stat pathways play important roles in oncogenesis, tumor progression, angiogenesis, cell motility, immune responses and stem cell differentiation[16]. Stat3 is a key signaling molecule for many cytokines and growth-factor receptors, and is required for murine fetal development. In addition, Stat3 is constitutively activated in a number of human tumors and possesses oncogenic potential and anti-apoptotic activity[17,18]. Stat3 is activated by tyrosine phosphorylation at Tyr705, which induces dimerization, nuclear translation and DNA binding. Stat3 isoform expression appears to reflect biological function. The relative expression levels of Stat3 α (86 kDa) and Stat3 β (79 kDa) depends on cell type, ligand exposure or maturation stage of the cells. Phospho-Stat3 (Tyr705) antibody detects endogenous levels of Stat3 only when phosphorylated at Tyr705. Activated forms of Stat3 and Phospho-Stat3 (Tyr705) were found in the nucleus of cancer cells in 30% of human gastric cancer specimens, which suggests that constitutively activated Stat3 signaling supports gastric cancer cell survival in association with survivin expression[19]. Stat3 regulates multiple genes important for apoptosis, cellular proliferation and angiogenesis in gastric cancer, therefore its activation may play an important role in gastric cancer development and progression[20]. The expression level of *stat3* mRNA and Phospho-Stat3 protein was lower in the WCA group than that in the control group, which suggests WCA may regulate human gastric cancer cell SGC-7901 apoptosis and/or proliferation through the Stat3 pathway.

The expression level of *bcl-2* mRNA was also decreased in the WCA group, as was that of its encoded protein. Bcl-2 is one of the Bcl-2 family that is important in regulation of apoptosis. Previous studies have demonstrated Stat3 regulates Bcl-2 expresssion[21], therefore, we inferred that the decrease in Bcl-2 expression in the WCA group was related to the mechanism of action of WCA, and may be correlated with lower Stat3 expression.

Other two genes: ROD1 (Hs.269988) or RIPX (Hs.7927) we found decreased expressing in WCA group had been seldom studied in solid tumor. In the fission yeast *Schizosaccharomyces pombe*, the *N*-arginine dibasic convertase 1 (NRD1) gene that encodes an RNA-binding protein negatively regulates the onset of differentiation. The mammalian homologue of NRD1 is ROD1, which encodes a protein with four repeats of typical RNA-binding domains. When expressed in fission yeast, ROD1 protein functions are similar to those of Nrd1. ROD1 is highly expressed in adult and embryo hematopoietic cells or organs. Overexpression of ROD1 effectively blocks the differentiation of human leukemia cells, without affecting their proliferative ability, which suggests ROD1 plays a critical role in controlling differentiation in mammalian cells[22,23]. Andoh *et al* have reported interaction of Rod1 and Rsp5 may be important for drug resistance[24]. However, the role of ROD1 in the development of human gastric cancer is not clear.

Another name for RIPX is kIAA0871, which is a member of the KIAA gene family[25]. In the progress of

the human gene project, KIAA genes have been found continuously. These genes are newly identified long cDNAs that encode large proteins. The large proteins play important roles in biological processes. Further physiological, developmental and genetic studies are necessary[26].

In conclusion, genes involved in the mechanism of WCA are Stat3, Bcl-2, RIPX and ROD1. WCA down-regulates the expression of several genes. How WCA affects the expression of these genes and the roles of these genes themselves need to be explored.

COMMENTS

Background

Previous clinical paired comparative studies have indicated patients with gastric carcinoma will benefit from treatment with the Chinese Jianpi herbal recipe Wei Chang An (WCA).

Research frontiers

This study was designed to investigate the underlying mechanism of WCA in treatment of gastric cancer by cDNA microarray analysis and real-time quantitative polymerase chain reaction.

Applications

Gastric cancer, despite its declining incidence, remains one of the most common causes of cancer-related death throughout the world. The poor outcome is due to the fact that 75% of patients are considered incurable at diagnosis (advanced disease), and therefore, its treatment remains a great challenge. Previous research has shown the tumor suppressive effect of WCA involves multiple biological processes and mechanisms, including enhanced apoptosis and inhibition of proliferation. To understand the further mechanisms of WCA is of benefit to developing a new therapeutic method.

Terminology

WCA is composed of *Atractylodes macrocephala* koidz., *Poria cocos* (Schw.) Wolf, *Sargentodoxa cuneata* (Oliv.) Rehd. Et Wils. and *Prunella vulgaris* L. The concentration of the decoction was 120 g/L. High Performance Liquid Chromatography was used for monitoring the stability of WCA.

Peer review

This is an interesting study. The authors investigated the expression of multiple genes in nude mice grafted with human gastric cancer cell line SGC-7901 and treated with WCA. It was demonstrated that WCA inhibited gastric cancer cell growth *in vivo*. WCA can induce gastric cancer cell apoptosis and suppress proliferation.

Abstract

AIM: To elucidate the influence of quasispecies on virological response and disease severity in patients with chronic hepatitis C.

METHODS: Forty seven patients with hepatitis C [32 with chronic active hepatitis (CAH), 9 with cirrhosis, and 6 with hepatocellular carcinoma (HCC)] were screened for the presence of quasispecies by single stranded conformational polymorphism (SSCP) analysis in the hypervariable region (HVR) and non-structural 5B (NS5B) viral genes of hepatitis C virus. The 41 patients excluding those with HCC were on therapy and followed up for a year with the determination of virological response and disease severity. Virus isolated from twenty three randomly selected patients (11 non-responders and 12 showing a sustained virological response) was sequenced for the assessment of mutations.

RESULTS: The occurrence of quasispecies was proportionately higher in patients with HCC and cirrhosis than in those with CAH, revealing a significant correlation between the molecular evolution of quasispecies and the severity of disease in patients with hepatitis C. The occurrence of complex quasispecies has a significant association ($P < 0.05$) with the non-responders, and leads to persistence of infection. Significant differences ($P < 0.05$) in viral load (log_{10} IU/mL) were observed among patients infected with complex quasispecies (CQS), those infected with simple quasispecies (SQS) and those with no quasispecies (NQS), after 12 wk (CQS-5.2 ± 2.3, SQS-3.2 ± 1.9, NQS-2.8 ± 2.4) and 24 wk (CQS-3.9 ± 2.2, SQS-3.0 ± 2.2, NQS-2.1 ± 2.3) in the HVR region. However, a statistically significant difference ($P < 0.05$) was observed between the viral loads of patients infected with CQS and those infected with NQS in NS5B viral gene after 24 wk (CQS-3.9 ± 2.2, SQS-3.0 ± 2.2, and NQS-2.1 ± 2.3) and 48 wk (CQS-3.1 ± 2.7, SQS-2.3 ± 2.4, NQS-2.0 ± 2.3) of therapy. Disease severity was significantly associated with viral load during therapy. The strains isolated from non-responders showed close pairing on phylogeny based on the NS5B gene, but dissimilar HVR regions. This revealed the possibility of the selection of resistant strains during the evolution of quasispecies in NS5B.

CONCLUSION: Viral quasispecies may be an important predictor of virological responses to combination therapy in patients with chronic hepatitis C. Complex quasispecies and resistant strains may lead to high viral loads during therapy, with a concerted effect on disease severity.

INTRODUCTION

Hepatitis C is a noncytopathic hepatotrophic virus having a single stranded, positive sense linear -9.5 kb RNA genome. Hepatitis C virus infection is the leading cause of acute, chronic, liver cirrhosis and hepatocellular carcinoma. Chronic infection due to hepatitis C virus (HCV) occurs in 170-200 million people worldwide[1,2]. In India, 15%-20% of all patients with chronic liver disease and 5%-10% of hepatocellular carcinoma patients are infected with hepatitis C[3]. The HCV continues to persist, unless the patients are put on interferon therapy. Treatment with interferon-based

therapy and error-prone replication of the genome *via* RNA-dependent RNA polymerase (RDRP) accelerates the evolution of HCV variants during the course of infection[2]. The origination of highly heterogeneous population in hepatitis C infected patients closely related to HCV genome because of interferon therapy, immune pressure and replication strategy called quasispecies[4].

The hypervariable region 1 (HVR-1) is located at the 5'-end of the E2 envelope glycoprotein, and variations occur in this region in association with persistence of viral infection[5]. Significant mutations in HVR-1 arise due to the presence of a specific anti-E2 humoral immune response. It is emerging that genetic heterogeneity extends throughout the entire HCV genome, and that this allows HCV infection to persist. Anti-HCV-specific T cell responses efficiently clear viruses during the acute phase of infection[6]. HVR quasispecies may have important biological consequences for the persistence of hepatitis C viral infection and the severity of liver disease[5,7].

HCV quasispecies populations result from the error rate (misincorporation frequencies averaging from about 10^{-4} to 10^{-5} per base) and the absence of proof-reading by RDRP. Most mutant particles cannot replicate, but the fittest infectious particles are selected on the basis of their replication capacities and selective pressure exerted by their interaction with host cell proteins and by the immune response[8]. Adaptive mutations in NS4B, NS5A or NS5B strongly enhance replication, but are incompatible to each other, whereas adaptive mutations in NS3 tend to be weak and cooperatively enhance replication when combined with strongly adaptive mutations[8,9]. The adaptive mutations in NS3 and NS5B map to surface residues distant from the enzyme active site, suggesting that these changes are likely to affect the interaction between non-structural protein and cellular factors[8].

Hepatitis C viral quasispecies can be detected by cloning of reverse transcription - polymerase chain reaction products, but sequencing of 15-20 independent clones is expensive and laborious, and so is not practical for a large number of clinical samples. For large numbers of clinical samples, faster methodologies like single-strand conformational polymorphism (SSCP), heteroduplex analysis (HDA) and gel shift assay (GSA) have been developed based on the differential migration of amplified DNA in acrylamide gel electrophoresis. In the present study, we used the established and reliable method of SSCP to detect quasispecies[10-13]. The mobility of mutated DNA fragments is affected by particular changes in the single-strand DNA structure; therefore, every variant migrates in a different way.

In controlled trials on the effect of interferon and ribavirin combination therapy, the independent predictive influence of virological parameters on patients with sustained virological response (SVR) raised questions about the intrinsic properties of HCV strains, like genotype and quasispecies and their effect on sensitivity and resistance to combination therapy[14-16]. The influence of viral quasispecies with variations in the hypervariable region (HVR) and NS5A ISDR (interferon-sensitivity determining region) genes on the effectiveness of interferon has been explored world wide[14,17-20]. These studies paid special attention to the importance of quasispecies as independent predictor of SVR. The cause and mechanism of HCV resistance to interferon needs to be well understood and several viral proteins may influence the therapy outcome. Gupta R *et al* reported HCV mutations in the 5' untranslated region, ISDR and PePHD region, and their influence on therapy responses in a South-Indian population. However, the influence of quasispecies in the HVR and NS5B regions on the persistence of infection and disease severity in chronic hepatitis C patients needs to be explored.

MATERIALS AND METHODS

Study design

This study enrolled 47 patients with chronic liver disease [32 with chronic active hepatitis (CAH), 9 with cirrhosis and 6 with hepatocellular carcinoma (HCC)] verified by histological examination, Child-Pugh score, and FNAC (fine needle aspiration cytology) wherever applicable, who attended medical outpatient departments (OPDs) and wards of Lok Nayak Hospital, New Delhi, India between 2003 to 2005, on the basis of pre designed performa, with all relevant information about possible risk factors, symptoms, clinical examination, detailed biochemical investigation and serology. They had a mean age of 48.4 ± 14.5 years, a male:female ratio of 25:22 and an alanine aminotransferase (ALT) value (mean ± SD) of 79.6 ± 44.6 (26-296) IU/L. Out of 47 patients, 34 (24 with CAH, 6 with cirrhosis, and 4 with HCC) were infected with virus strain of genotype 3, 11 (7 with CAH, 2 with cirrhosis, and 2 with HCC) with virus of genotype 1 and 2 (1 with CAH and 1 with cirrhosis) with virus of mixed genotype (1 + 3). The most probable risk factor for transmission was transfusion of infected blood and contaminated blood products, in 63.8% (30/47) of the patients. Out of 47 patients, 41 (32 with CAH and 9 with cirrhosis) were on combination therapy, 30 (73.17%) attained sustained virological responses and 11 (26.83%) were non-responders. However, the 6 HCC patients were not on therapy. The 41 chronic hepatitis C (CH-C) patients (32 with chronic active hepatitis and 9 with cirrhosis) were on medication (interferon-α2b 3 MU + 1000 mg ribavarin daily), having ALT $\geqslant$ 60 IU/L and HAI score $\geqslant$ 3 at baseline. The severity of liver disease was determined by histopathological grading according to the modified Knodell Score for the CAH patients and by Child-Pugh score for the cirrhosis patients[21-23]. These 41 patients were put on 48 wk of therapy or follow up. The viral load was estimated after 0 d, 4, 8, 12, 24 and 48 wk of the therapy. Patients without any detectable HCV viremia ($\leqslant \log_{10}$ 1 IU/mL) after stopping the therapy, and even after 6 mo of therapy withdrawal, were defined as responders, and, if these patients were found to show positivity 6 mo after withdrawal of therapy, they were defined as relapsers. However, the patients with detectable HCV viremia after the end of wk 48 of therapy were defined as non-responders. Liver biopsies of CAH patients and Child-Pugh scoring in cirrhosis patients were performed at baseline, and after 24 and 48 wk of therapy. The SSCP analysis of the HVR and NS5B regions was performed in all sera samples before the initiation of treatment and after 24 wk of therapy. Genotypes were also studied by RFLP for genotypic classification of these

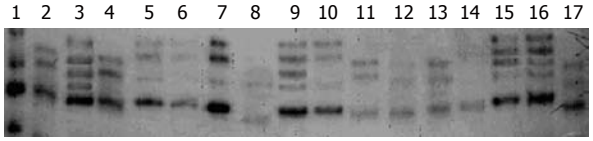

Figure 1 Representative autoradiograph of SSCP analysis of HCV RNA-positive samples showing the development of quasispecies in samples 1, 2, 3, 4, 5, 6, 7, 9, 10, 11, 12, 13, 15, 16 and 17.

patients (data not shown). Patients with > 4 SSCP bands were considered to have complex quasispecies (CQS) of HCV. However, the patients with 3 or 4 bands in the SSCP gel were considered to have simple quasispecies (SQS) and those with 2 bands were considered to have no quasispecies (NQS). The patients were grouped based on the number of bands in the SSCP gel (Figure 1) to study the influence of quasispecies on virological responses and disease severity. RNA extracted from sera samples (11 non-responders and 12 responders) was amplified by RT-PCR using primers specific for the HVR and NS5B genes, and the products were sequenced (Macrogen Inc, Korea) on a commercial basis at three different time (0 d, 24 wk and 48 wk) intervals during therapy in non-responders and two times (0 d and last sample before the clearance of HCV infection) in responders. Sequencing results at baseline were submitted to the GenBank database and also used for phylogeny. A phylogenetic tree was drawn to analyze the distance matrix between the SVR and non-responder (NR) patients on the basis of sequences derived from the HVR and NS5B genes, using the Bio Edit program for sequence analysis.

Biochemistry and serology

Biochemical investigations, including routine and specific liver function tests, were carried out in all cases. Serological tests were performed using commercially available ELISA kits, according to the manufacturer's instructions. Sera samples of all 47 patients were screened for HBsAg using a 3rd generation ELISA kit from Biokit, Spain; IgG HBc and HBeAg were screened using an ELISA kit from RADIM SpA, Italy; and anti-HCV antibody using a 3rd generation ELISA kit (General Biological Corporation, Taiwan). Exclusively anti-HCV-positive patients' sera were used for the detection of HCV RNA.

Reverse-transcription PCR of HVR and NS5B region

Total RNA was isolated using Tri Reagent (Sigma-Aldrich) according to the manufacturer's instructions and amplified by reverse transcription-PCR. For reverse transcription, 5 μL of extracted template RNA was added to 20 μL of reaction master mix containing reaction buffer, dNTPs, RNAsin (10 U), M-MuLV reverse transcriptase (40 units) and outer antisense primer, and incubated at 42℃ for one hour for cDNA synthesis. First-round PCR amplification was carried out using outer sense and antisense primers, 2 μL of cDNA template, reaction buffer containing magnesium, dNTPs, and Taq DNA polymerase (1 unit), in a 25-μL reaction, by denaturing at 94℃ for 5 min and 35 cycles with 60 s each of denaturation at 94℃, annealing at 55℃ and extension at 72℃, in a DNA thermal cycler (M.J. Research, USA). After the last cycle, the extension was prolonged for 8 min at 72℃. Second-round PCR was performed using 2 μL of the first PCR product as template, which was amplified with the second PCR mix containing inner primers (Table 1). The reagent composition and temperature profile were the same as those for the first PCR. Both positive and negative controls were run in parallel with the test samples. The expected PCR products for HVR and NS5B were 403 and 293 bp, respectively; these were detected in ethidium bromide-stained 30 g/L Nusieve agarose gels in a UV Transilluminator.

Single-strand conformational polymorphism

Briefly, single-strand conformational polymorphism (SSCP) was performed by radiolabelling the PCR products for an additional 10 cycles where dCTP was replaced with (α-p^{32}) dCTP (specific activity, 4000 CI/nmol) in the PCR mix. One μL of radiolabelled PCR product was diluted with 9 volumes (10 times) of denaturing solution (950 g/L formamide, 20 mmol/L EDTA pH 8.0, 0.5 g/L xylene cyanol and 0.5 g/L bromophenol blue), heat-denatured for 5 min at 95℃, and chilled on ice for 3 min; 3 μL of this diluted radiolabel product was subjected to non-denaturing electrophoresis in a 60 g/L polyacrylamide gel containing 100 mL/L glycerol. Gels were run in 1 × TBE for 16 h at 250 V in a DNA sequencing apparatus, at 17 ± 1℃, dried on a gel drier, and exposed to X-ray film with an intensifying screen at -20℃. Electrophoretic mobility shifts of single-strand DNA bands were analyzed following development of the X-ray film.

Hepatitis C viral quantitation by real time PCR

Total RNA was used for real time quantification. The RealArt HCV PCR Reagents constitute a ready-to use system for PCR amplification and the detection of HCV RNA on the Light Cycler instrument (Rotor Gene 3000, Corbett Research Inc.). The RealArt HCV PCR master mixture contains reagents and enzymes for the amplification of a 240-bp region of the HCV genome with the parallel detection (A.Ch 1-FAM) and quantification of the amplified PCR products in comparison to five standard samples diluted 10-fold, which were used to generate the standard curve.

Statistical analysis

Statistical analysis was performed using the Student's *t*-test, ANOVA, Chi-square, and Fischer's exact test, wherever applicable, using the software EPISTAT and SPSS. Statistical analysis was performed by comparisons of two groups descriptively. Patients were classified as being infected with complex quasispecies (CQS), simple quasispecies (SQS) and no quasispecies (NQS) on the basis of their SSCP pattern, representing the level of HCV quasispecies variations. The results are expressed as means ± SD. $P < 0.05$ was considered significant.

RESULTS

Quasispecies

Patients were screened for the presence of quasispecies by SSCP analysis, on the basis of differential migration in PAGE

Table 1 Primers used for reverse transcription-PCR of the HVR and NS5B genes of HCV

Region/Nucleotide position	Primer set	Forward/Reverse	Sequence (5'-3')	Amplicon size (bp)

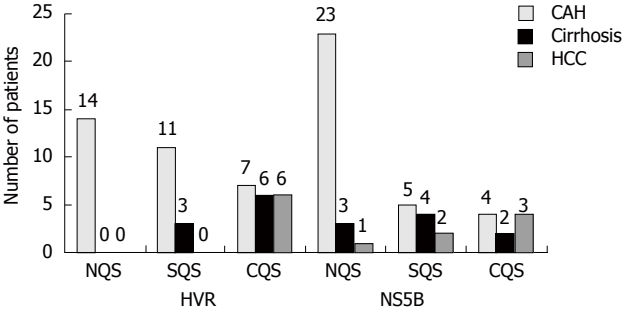

Figure 2 Patients with chronic active hepatitis, cirrhosis and HCC with different degrees of quasispecies with variations in the HVR and NS5B genes of HCV, observed by SSCP.

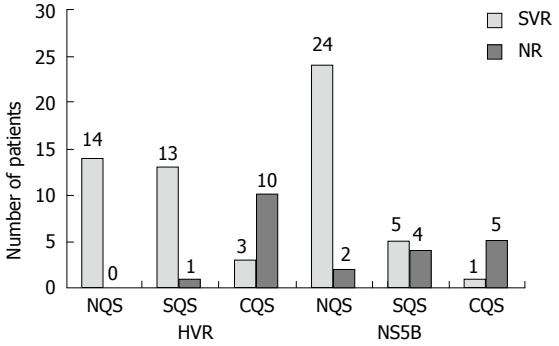

Figure 3 Virological responses in patients with different degrees of quasispecies with variations in the HVR and NS5B genes of HCV, observed by SSCP.

denaturing gels. The appearance of more than 2 bands in gels is associated with the presence of quasispecies. Patients with more than 4 bands in SSCP gels were infected with complex quasispecies (CQS). Complex quasispecies were detected both in the NS5B and HVR regions of HCV, but were relatively more abundant in the HVR (n = 19) than the NS5B (n = 9) region. Among the 32 patients with chronic active hepatitis, 18 (56.3%) showed presence of quasispecies (CQS-7, SQS-11, NQS-14) when the HVR gene was used for the analysis, while 9 (28.2%) showed presence of quasispecies (CQS-4, SQS-5, NQS-23) when the NS5B gene was used for the analysis. All 9 cirrhosis patients showed presence of quasispecies (CQS-6, SQS-3) when the HVR gene was used for the analysis, while only 6 (66.7%) showed presence of quasispecies (CQS-2, SQS-4, NQS-3) when the NS5B gene was used (Figure 2). It was interesting to note that all 6 HCC patients were positive for complex quasispecies when the HVR was used for the analysis, while 5 out of the 6 (83.3%) showed presence of quasispecies (CQS-3, SQS-2, NQS-1) on the basis of the NS5B gene (Figure 2). These results showed the influence of the occurrence of HVR quasispecies on the disease severity in hepatitis C infected patients as all cirrhosis and HCC patients showed evolution of quasispecies in this region. However, NS5B quasispecies also showed their influence on disease severity. No difference was observed in the SSCP band patterns of the patients after 24 wk of therapy, confirming the accuracy of the PCR reaction and SSCP profiles. The genotypic classification of quasispecies was not feasible from this data due to sample size. However, the occurrence of quasispecies in both the genotypes (genotypes 1 and 3) was observed.

Virological responses

Among the 41 patients on therapy, 30 had sustained virological responses, whereas 11 were non-responders. HVR quasispecies were detected in 27 out of 41 (65.9%) patients (CQS-13, SQS-14, NQS-14), while NS5B quasispecies were detected in 15 out of 41 (36.6%) (CQS-6, SQS-9, NQS-26) (Figure 3). Out of the 11 non-responders, 10 were infected with complex quasispecies (> 4 bands in the SSCP) and 1 was infected with simple quasispecies, based on analysis of the HVR gene; when the NS5B gene was analyzed, among the 11 non-responders, 5 were infected with complex quasispecies, 4 with simple quasispecies and 2 with no quasispecies. Among the 30 SVR patients, 16 (53.3%) were infected with HVR quasispecies (CQS-3, SQS-13, NQS-14), whereas 6 (20.0%) were infected with NS5B quasispecies (CQS-1, SQS-5, NQS-24) (Figure 3). These results suggest that the presence of complex quasispecies with variations in the HVR gene has an impact on virological response, as 90.9% (10/11) of patients infected with complex quasispecies with variations in this region did not respond to combination therapy, whereas only 10.0% (3/30) of patients infected with complex quasispecies were responders.

Correlation of viral kinetics with quasispecies

Out of 41 patients on therapy, HVR quasispecies were seen in 27 patients. No statistical difference was observed in viral load of patients with CQS, SQS and NQS (mean ± SD $\log_{10}$ IU/mL) from baseline (CQS-6.9 ± 0.29, SQS-6.8 ± 0.26, and NQS-6.9 ± 0.22) to 8 wk (CQS-4.3 ± 1.05, SQS-4.5 ± 1.2, NQS-4.1 ± 1.1) of combination therapy with minimum standard error. A statistically significant

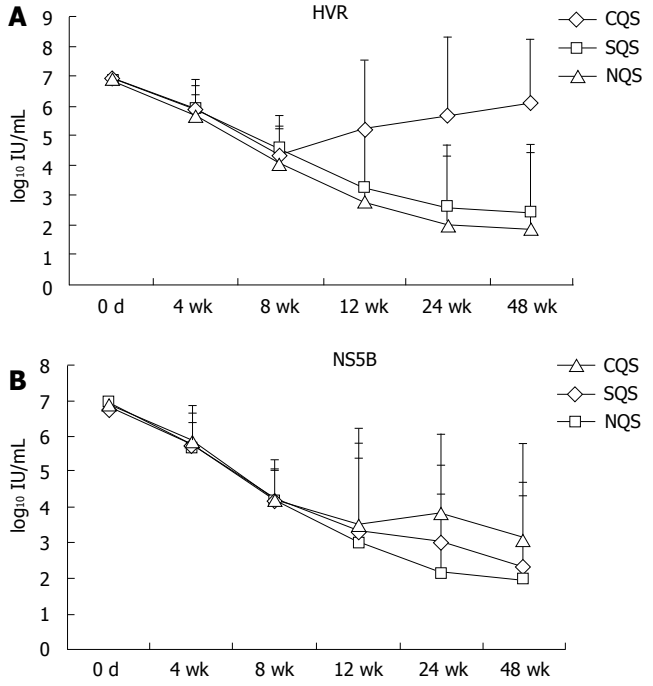

Figure 4 Viral load (mean ± SD) at different phases during 48 wk of therapy in patients grouped on the basis of the number of bands observed in the selected region. **A**: Viral kinetics of patients grouped on the basis of quasispecies in the HVR region (CQS-13, SQS-14, NQS-14); **B**: Viral kinetics of the patients grouped on the basis of quasispecies in the NS5B region (CQS-6, SQS-9, NQS-26) by SSCP analysis.

difference in the viral load ($P < 0.05$; CQS *vs* SQS, NQS) was observed after 12 wk (CQS-5.2 ± 2.3, SQS-3.2 ± 1.9, NQS-2.8 ± 2.4) of therapy in patients with HVR region quasispecies of HCV. A statistically significant difference in viral load ($P < 0.05$) with high standard error was observed in comparisons of CQS with SQS and NQS after 24 wk (CQS-5.7 ± 2.6, SQS-2.6 ± 2.1, NQS-2.0 ± 2.33) and 48 wk (CQS-6.1 ± 2.1, SQS-2.4 ± 2.3, NQS-1.9 ± 2.5) of therapy (Figure 4A). No significant difference ($P > 0.05$) was observed in the mean viral load (log_{10} IU/mL) from baseline (CQS-6.9 ± 0.29, SQS-6.8 ± 0.3, NQS-6.94 ± 0.22) to 12 wk (CQS-3.5 ± 2.7, SQS-3.3 ± 2.5, NQS-3 ± 2.4) in comparisons of patients with different levels quasispecies (CQS, SQS and NQS) in NS5B region. However, the standard error was almost negligible at baseline, but an increased standard error in viral load was observed after 12 wk of therapy. A statistically significant difference ($P < 0.05$) with high standard error was observed between the mean viral loads of patients infected with CQS and those infected with NQS after 24 wk (CQS-3.9 ± 2.2, SQS-3.0 ± 2.2, and NQS-2.1 ± 2.3) and 48 wk (CQS-3.1 ± 2.7, SQS-2.3 ± 2.4, NQS-2.0 ± 2.3) of therapy (Figure 4B). A continuous decline in mean viral load was observed in patients without complex quasispecies infection, suggestive of an influence of the presence of quasispecies on viral kinetics and therapeutic outcome during combination therapy.

Correlation of disease severity with the presence of quasispecies

The histological activity index (HAI) score is an important factor for the assessment of disease severity in CAH patients. It was interesting to note that mean HAI scoring (mean ± SD) was comparable among groups based on the degree of quasispecies diversity in the HVR at baseline (CQS-6.64 ± 2.9, SQS-6.72 ± 1.2, NQS-6.9 ± 0.22). Patients grouped on the basis of genetic variability in the NS5B gene showed a statistically significant difference (CQS *vs* NQS) in the mean HAI scores at baseline (CQS-7.6 ± 3.3, SQS-6.7 ± 2.2, NQS-5.86 ± 2.08). An improvement in the severity of disease was observed in 80.0% (24/30) of the SVR (sustained virological response) patients. Bridging of fibrosis was observed in all NR (non-responders) and 13.3% (4/30) of the SVR patients. No statistical significant difference in the results of liver function tests was observed among patients with different degrees of HVR and NS5B quasispecies, at baseline and on follow-up every 4 wk until 48 wk.

Quasispecies and phylogeny

Amino acid variation in the NS5B gene plays a major role in the replication of the virus and may be important for the virological response during combination therapy. It was interesting to note that the number of mutations was higher in genotype 1 as compared to genotype 3 in the HVR region, suggesting an influence of genotype on the rate of mutations in the selected region of HCV and on the evolution of quasispecies. Amino acid variations in the HVR and NS5B regions of different genotypes among patients (n = 23, Genotype 1 = 5, Genotype 3 = 18) during different phases of therapy are suggestive of the occurrence of mutations during the course of therapy. The sequences of virus strains during the course of therapy showed 2-5 amino acid substitutions and synonymous mutations at the nucleotide level in both HVR and NS5B regions, compared with the sequences of virus strains before therapy (data not shown as no specific mutation was observed to be responsible for the persistence of infection during therapy). Phylogenetic analysis of sequenced virus isolated from patient samples showed different distance patterns between responders and non-responders in HVR and NS5B regions, as shown in Figures 5 and 6. The non-responders were on a different branch, suggestive of no close pairing between these non-responder strains of genotype 3 in the HVR region. However, closing pairing was observed between non-responder strains of genotype 3 in the NS5B region: 5 non responder patients were on the same branch and 3 patients were on the other branch. However, all four non-responder were on the same branch in patients of genotype 1. Strains appearing on the same branch (close pairing) during phylogenetic tree analysis possess significant homology in their nucleotide sequences. These results suggest that either the selection of resistant strains or the development of quasispecies may be the cause of unresponsiveness to combination therapy in HCV patients; however, these mechanisms require further analysis.

DISCUSSION

Diversifications in the HCV genome are the results of viral RNA polymerase infidelity, immune-driven selection and exertion of therapy pressure or a combination of these processes. PCR-SSCP analysis is a well established

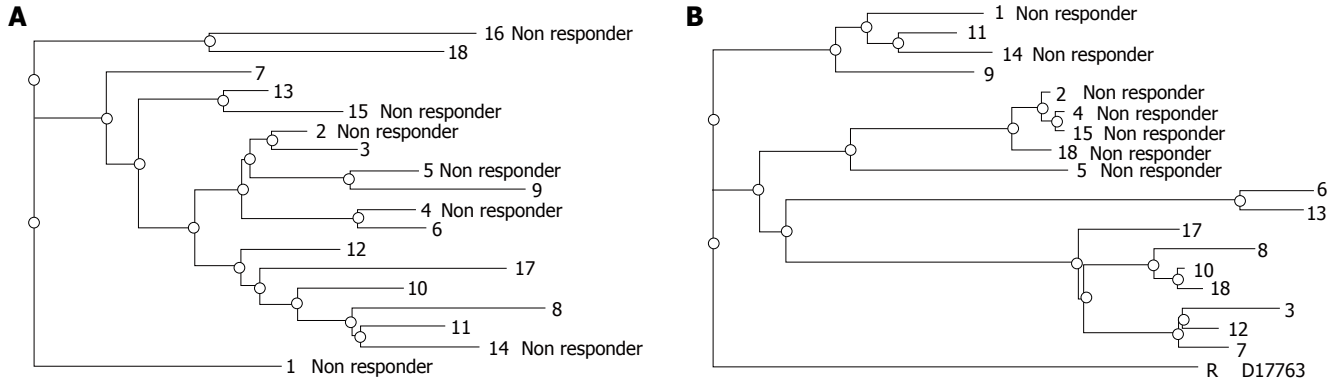

Figure 5 Phylogenetic analysis of the 18 (7 NR and 11 SVR) patients infected with HCV of genotype 3 by the neighbor-joining method in order to draw a distance matrix of the sequences. **A**: HVR, the accession numbers of the HVR genes in patients 1-18 are EF015726 to EF015743 in order; **B**: NS5B region, the accession numbers of the NS5B regions in patients 1-18 are EF015699 to EF015716 in order.

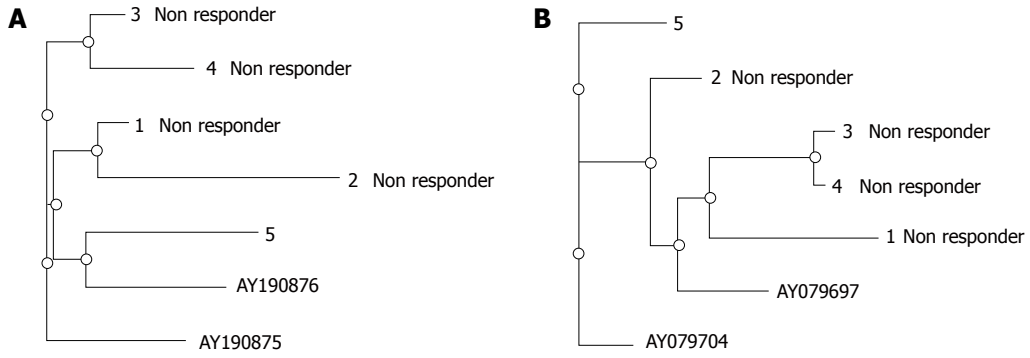

Figure 6 Phylogenetic analysis of the 5 (4 NR and 1 SVR) patients infected with HCV of genotype 1 by the neighbor-joining method, in order to draw a distance matrix of the sequences. **A**: HVR, the accession numbers of the HVR gene in patients 1-5 are EF015744 to EF015748 in order; **B**: NS5B region, the accession numbers of the NS5B region in patients 1-5 are EF015721 to EF015725 in order.

technique to study genetic variability, including the presence of mutations and quasispecies[10-13]. Millions of viruses are produced *via* replication and eliminated each day due to exertion of immune pressure and interferon therapy[16]. Ribavirin does not have any effect on the viremia level of HCV-infected patients, but it reduces the ALT level, increases the likelihood of sustained virological response and reduces the probability of relapse[16].

The HVR and NS5B genes were selected in the present study because the persistence of infection may be associated with positive selection of HVR quasispecies by the host immune system and because of the major role of NS5B in the replication of hepatitis C. Factors like age, sex and duration of infection may be possible causes of the occurrence of quasispecies; in this study, we studied virological responses in patients infected with quasispecies before the initiation of therapy and looked for alterations in the SSCP patterns during therapy. Several conflicting reports about a possible correlation of therapy response and disease severity with the presence of quasispecies have been published[15,20,24-27]. The genes encoding HVR protein exhibit a high degree of variability, giving rise to differing phenotypic traits, including alterations in receptor-binding affinity and escape from immune recognition[28]. Substitutions in the NS5B gene of HCV may correlate with the virological response to interferon-based therapy[29-31].

The occurrence of quasispecies was proportionately higher in patients with HCC and cirrhosis than in CAH patients, revealing a significant correlation between the molecular evolution of quasispecies and the severity of disease in hepatitis C patients in this study. The genetic diversity at baseline can be predictive of distinct virological behavior during the course of combination therapy. Among the 13 patients infected with complex quasispecies with variations in the HVR gene, 10 were non-responders at baseline. This correlates significantly with the persistent of infection as the response rate against interferon may be due to two mutually compatible approaches; the infecting virus might have become naturally resistant to interferon or the virus could have evolved into quasispecies. The non-responders had normal signal transduction pathways required for the intracellular activity of interferon[32]. The recognition of the HVR epitope (envelope) by immune cells and the exertion of interferon-based therapy play a major role in the evolution of quasispecies.

Several studies have shown an association of epidemiological factors and treatment regime with the presence of quasispecies[13,14,19,33]. Complex quasispecies with variations in the HVR and NS5B genes of HCV were significantly associated with virological response during wk 48 of therapy. Virus quasispecies evolution within patients increases the pathogenicity of HCV. The resulting viral quasispecies are heterogeneous and sensitive to selection pressures. Complex variants escape from immune pressure and the antiviral spectrum of the combination therapy[34]. No mutant strains have the capacity for replication, but only selective mutants can replicate, which may be responsible for persistence of infection. The circulating viremia in blood and liver cells is significantly associated with disease prognosis[35]. There was no statistically significance difference in the HAI scores among patients with different degrees of HVR quasispecies at baseline. However, there was a

significant difference in the HAI scores at baseline between patients infected with different genetic variants (CQS *vs* NQS) of the NS5B gene. Selective adaptive mutations in the resistant strains occurring during replication influence the RDRP activity and lead to increases in viremia level and HAI scoring[7-9]. These results suggest the significance of evolution of quasispecies on virological responses and disease severity.
