Many theories explain the etiology and pathogenesis of BC[2]. In 1936, Yotsuyanagi supposed that BC arouse from inequality in the cellular proliferation of the biliary tract during the early fetal life[23]. Babbitts's theory of the "common channel" (1969) is the most widely accepted in the literature. According to this theory, the common cannel is formed by abnormal pancreaticobiliary junction (APBJ) of the pancreatic and bile ducts outside the ampulla of Vater. This condition leads to pancreaticobiliary reflux and mixing of the pancreatic and biliary juices and activations of pancreatic enzymes, because the maximal pressure within the pancreatic duct is two to three timed higher than within a biliary tract. Activated pancreatic enzymes cause inflammation and deterioration of the bile duct wall that leads to biliary dilatation[24]. A number of studies analyzed the levels of amylase within the bile duct. The higher amylase concentrations have been observed in patients with BC compared to the control groups. Also, association between the amylase level, earlier presentation and dysplasia grade in patients with BC has been reported in the literature[25,26]. Therefore, there is a theory, that the pancreaticobiliary reflux leads to inflammation and dysplasia in patients with BC[2,26-29]. APBJ occurs only in 50%-80% patients with BC. Another counterargument to this hypothesis is a fact, that immature neonatal acini do not produce sufficient pancreatic enzymes to explain antenatal BC[2,30,31]. The counterargument supporting Babbitt's theory is arbitral definition of the long common channel that depends on imaging modality and angles. Therefore, a defined length of a long common channel has been described from 10 mm to 45 mm in the literature. Therefore, APBJ can occur in more patients than radiological investigations show[2]. According to Okada *et al*[32], long common channel as any pancreaticobiliary junction is defined, if it lies outside of the duodenal wall and thus could result in pancreaticobiliary reflux and mixing. APBJ has been divided into three types by Komi *et al*[33]: (1) A right-angled union without an accessory pancreatic duct; (2) An acute-angled union without an accessory pancreatic duct; and (3) A right- or acute-angled union with an accessory pancreatic duct.

Table 1 Types of an anomalous pancreaticobiliary junctions (Komi classification)

Type name	Type description
Type Ⅰ	A narrowed common bile duct joins the pancreatic duct at a right angle
Ⅰ A	A slender common channel
Ⅰ B	A short or long ectatic common channel
Type Ⅱ	A pancreatic duct joins the common bile duct at an acute angle
Ⅱ A	A slender common channel
Ⅱ B	A short or long ectatic common channel
Type Ⅲ	It is complicated by a patent accessory pancreatic
Ⅲ A	A classic pancreas divisum
Ⅲ B	A pancreas divisum without a pancreatic duct
Ⅲ C	A patent accessory pancreatic duct with an intricate network
Ⅲ C1	A tiny communicating duct between the main and accessory ducts
Ⅲ C2	A communicating duct with the same caliber as the main and accessory ducts
Ⅲ C3	A total or partial dilatation of the ductal system

These types are subdivided into subtypes according to the shape of the common channel. The Komi's classification is presented in Table 1. The type of BC and clinical presentation can depend on the type of an angle of the anomalous ductal junction. A right-angled union is associated with cystic dilatation of the common bile duct. In patients with this type of union a palpable mass or jaundice as the main sign of disease are observed. An acute-angled union is associated with fusiform dilatation of the common bile duct. Patients with such dilatation usually complain on abdominal pain, and an erroneous diagnosis of acute pancreatitis is occasionally made. Type Ⅰ B, Ⅱ B, and Ⅲ junctions are associated with a dilated common channel and an accessory pancreatic duct. They are frequently complicated by relapsing pancreatitis leading to chronic pancreatitis[34]. Therefore, it's important to describe the type of APBJ. The type of APBJ is based on a cholangiopancreatographical picture[33-35]. The other theories regarding BC pathogenesis are less popular. According to Singham *et al*[2], biliary dilation can be a result of embryologic overproliferation of epithelial cells within solid bile ducts during the fetal life. According to Davenport and Basu, dilations are due to a lower number of neurons and ganglions in patients with BC that have been recognized pathologically. They suggested that round cysts were congenital with distal obstruction due to agan-

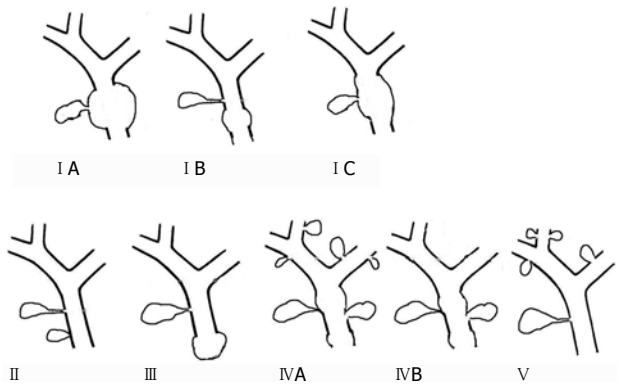

Figure 1 Types of biliary cysts according to Todani classification. Ⅰ: Solitary extrahepatic cyst (40%-85%): Ⅰ A: Common type; Ⅰ B: Segmental extrahepatic duct dilatation; Ⅰ C: Diffuse extrahepatic dilatation; Ⅱ: Extrahepatic diverticulum (2%-3%); Ⅲ: Choledochocele (1.4%-5.6%); ⅣA: Multiple extra- and intrahepatic cysts; ⅣB: Multiple extrahepatic cysts (18%-20%); Ⅴ: Multiple intrahepatic cysts (Caroli's disease) (rare).

glionosis and proximal dilation similarly to Hirschprung's disease. In this theory, chronic inflammation and clinical manifestation are caused by bile stasis within dilated bile ducts[2,31,36].

CLASSIFICATIONS OF BC

The first classification system for BC was proposed by Alonso-LEJ *et al*[37] in 1959. This classification involves three BC types: congenital cystic dilatation (the most common), congenital diverticulum of the common bile duct, and congenital choledochocele[37]. In 1977, Todani *et al*[38,39]modified BC classifications distinguishing five types (Figure 1). The most frequent (more than 90%) is type Ⅰ cyst. The type Ⅰ A cyst involves dilatation of the common bile duct, with marked dilatation of part or all of the extrahepatic bile ducts. The type Ⅰ B cyst involves segmental dilatation of the common bile duct, usually of its most distal part. The type Ⅰ C cyst involves fusiform dilatation of the common bile duct, along with diffuse, cylindric dilatation of the common hepatic duct and common bile duct. In 2011, Michaelides *et al*[40] reported and proposed a new BC variant and called it the Ⅰ D type. In this new variant, apart from the dilatation of the common hepatic and the common bile duct, dilatation of the central portion of the cystic duct was also observed, giving a bicornal configuration to the cyst. The type Ⅱ cyst is a diverticulum of the common bile duct usually arising laterally but may arise in the pancreatic portion. The type Ⅲ cyst (which is called a choledochocele) is a cystic dilatation of the intraduodenal portion of the common bile duct. According to some authors, choledochocele is different from other types of BC. In 2010, Ziegler *et al*[41], compared choledochocele with other types of BC (types Ⅰ, Ⅱ, Ⅳ and Ⅴ according to Todani classification). Based on study including 146 patients with BC (46 patients with choledochoceles), they concluded that classifications of choledochal cysts should not include choledochoceles. They reported that patients with choledochoceles differed from patients with other choledochal cysts with respect to age, gender, presentation, pancreatic ductal anatomy, and their management. Patients with cholechoceles were the most frequently male, older, complained with acute pancreatitis rather than jaundice or cholangitis, and were managed with endoscopic therapy. A pancreas divisum and a low risk of malignancy compared to other BC were observed with patients with choledochoceles. The type Ⅳ cyst involves dilatation of the intrahepatic and extrahepatic bile ducts. In the type ⅣA cyst, both the intrahepatic and extrahepatic bile ducts are dilated. The type ⅣB cyst involves dilatation of multiple segments of the extrahepatic bile ducts. The type Ⅴ cyst (Caroli's disease) involves dilatation of one or several segments of the intrahepatic bile ducts. First, it was described by Todd in 1818, but precise definition of this disorder was constructed by Jaques Caroli in 1958[41-45]. There are two descriptions (Caroli's disease and Caroli's syndrome) in the literature. Caroli's syndrome is the more serious condition compared to Caroli's disease. In Caroli's disease, cholangitis due to bile stasis within dilated intrahepatic bile ducts, is observed. In Caroli's syndrome, recurrent bouts of cholangitis due to bile stasis, hepatolithiasis, gallbladder stones lead to liver fibrosis with portal hypertension and liver failure. Caroli's syndrome can be associated with autosomal recessive polycystic kidney disease caused by a mutation of the *PKHD1* gene[46,47].

BC can be associated with the biliary atresia. Three biliary atresia (BA) types have been distinguished in the literature: 1 BA (atresia of the common bile duct), 2 BA (atresia of the common hepatic duct), and 3 BA (atresia of the porta hepatis)[18]. Muise *et al*[18], concluded that BA associated with BC formed a distinct subtype of BA, characterized by a preponderance of type 1 BA, a relatively good clinical outcome after surgery, and an absence of associated congenital anomalies. In 2004, Visser *et al*[48] proposed modified classification of BC and distinguished the following BC types: choledochal cyst, choledochal diverticulum, choledochocele, and Caroli's disease. All BC classifications are presented in Table 2.

CLINICAL PRESENTATION OF BC

The classic triad of clinical symptoms was described by Alonso-LEJ *et al*[37] and it involves right hypochondriac pain, palpable abdominal mass and jaundice. All clinical signs are observed only in 20%-30% patients[49]. Two of three clinical symptoms occur in 2/3 patients. The most frequently (in 80% of patients) clinical presentation appears before the age of 10 years[44]. Clinical presentation is different and it depends on the patient's age. According to the age, patients are divided into two groups: neonatal patients (under 12 mo) and adults (above 13 mo). Prenatally, BC are diagnosed incidentally during prenatal ultrasonography visualized as an intra-abdominal cystic mass[6,13,14]. In neonatal patients, obstructive jaundice

Table 2 Classifications of biliary cysts

Ref.	Classification
Alonso *et al*[37]	Congenital cystic dilatation
	Congenital diverticulum of the common bile duct
	Congenital choledochocele
Todani *et al*[38,39]	Ⅰ A Common type
	Ⅰ B Segmental extrahepatic duct dilatation
	Ⅰ C Diffuse extrahepatic duct dilatation
	Ⅱ Diverticulum type in the whole extrahepatic duct
	Ⅲ Choledochocele
	ⅣA Multiple cysts of the extra- and intra-hepatic ducts
	ⅣB Multiple cysts of the extrahepatic ducts
	Ⅴ Caroli's disease (intrahepatic bile duct cysts)
Vesser *et al*[48]	Choledochal cyst
	Choledochal diverticulum
	Caroli's disease

and abdominal mass are present the most frequently. Pain, fever and nausea are the most common for adult patients[44]. According to Lopez *et al*[21], pain is the commonest clinical sign in adults. Recurrent cholangitis and pancreatitis are complications of BC due to pancreaticobiliary reflux[49,50]. The other complications observed commonly in adults are the following: cholangiocarcinoma, cholecystolithiasis and cholecystitis, and liver cirrhosis[5]. Cholecystolithiasis and cholecystitis occur due to bile stasis in patients with BC. The secondary liver cirrhosis leads to different complications associated with portal hypertension such as upper gastrointestinal bleeding, splenomegaly and pancytopenia[49]. Portal hypertension can also occur without liver cirrhosis due to mechanical obstruction of the portal vein by the cyst[48]. An spontaneous BC rupture occurs in about 1%-12% of patients. It is presented as abdominal pain, peritonitis signs and sepsis[49,51]. Patients with choledochocele are usually asymptomatic. The Ⅲ BC type can be also presented by gastric outlet obstruction symptoms caused by direct obstruction of the duodenal lumen or intussusceptions[44]. It should be highlighted that BC are premalignant disorder. The overall reported risk of cancer is 10%-30% and it increases with age (from 0% in patients aged < 10 years to 75% in patients aged 70-80 years). Nicholl *et al*[9] reported direct correlation between the patient age and cancer risk: 0 year to 30 years (0%), 31 years to 50 years (19%), and 51 years to 70 years (50%). The histopathological types of cancer are the following: *adenocarcinoma* (73%-84%), *anaplastic carcinoma* (10%), *undifferentiated cancer* (5%-7%), *squamous cell carcinoma* (5%), and others (1.5%). The locations of cancer are the following: the extrahepatic bile duct (50%-62%), gallbladder (38%-46%), intrahepatic bile ducts (2.5%), the liver (0.7%), and the pancreas (0.7%)[49]. Todani *et al*[52] reported that 68% of cancers were associated with type-Ⅰ, 5% type-Ⅱ, 1.6% type-Ⅲ, 21% type-Ⅳ and 6% type-Ⅴ BC. Cholangiocarcinoma occurs as a result of chronic inflammation, cell regeneration and DNA breaks, leading to dysplasia[49,52]. The following molecular lesions have been reported in BC during carcinogenesis: microsatellite instability, k-ras mutations, expression of COX-2 and bcl-2, and increased telomerase activity that occur early and involvement of cyclin D1, beta-catenin, DPC-4/Smad4 and p53 that occur later[7].

DIAGNOSTICS OF BC

Laboratory investigations

Laboratory investigations may demonstrate mildly abnormal liver function and cholestasis tests (serum bilirubin, alkaline phosphatase, γ-glutamyltranspeptidase, alanine and aspartate aminotransferases) or amylase values, but these findings are not specific[34,49-56].

Radiological investigations

Imaging investigations are the most useful in BC diagnosis. The following radiological examinations are performed in order to visualize biliary dilatation: ultrasonography (USG) of the abdominal cavity, computed tomography (CT) of the abdominal cavity, and cholangiography[34,49-56].

USG of abdominal cavity

USG is the initial and easy to perform examination. It allows imaging of intrahepatic and extrahepatic bile ducts with measurement of the diameter of common bile duct or common hepatic duct and BC. It demonstrates (with the exception of type-Ⅲ and type-Ⅴ cysts) a cystic mass in the right upper quadrant (usually at the porta hepatis) separately from the gallbladder[49].

Use of USG in prenatal diagnosis

USG is very useful in prenatal diagnosis of BC. USG shows BC as a round intra-abdominal cystic mass located in the upper abdominal quadrant. Color Doppler USG shows no significant flow within the mass. Differential diagnosis of the cystic mass in prenatal USG should involve simple hepatic cysts, biliary atresia, ovarian, omental or mesenteric cysts, duodenal or gall bladder duplications, adrenal cysts, renal cysts, dilated loop of bowel, hydronephrotic renal pelvis and situs inversus. Proper early differential diagnosis between BC and another biliary disorder such as BA is very important, because BA needs an immediate surgery[6,13,14]. When the differential diagnosis of a cystic mass in the right upper quadrant is difficult to make by conventional USG alone, ultrasound-guided BC aspiration may serve as an alternative to the prenatal diagnosis of BC in the fetus[57,58]. Tanaka *et al*[14] compared imaging (USG and CT) and laboratory investigations in BC and BA in order to differentiate these two pathologies. They concluded that patients with biliary disorder smaller than 21 mm, direct bilirubin level higher than 2.5 mg/dL, and total bile acid level higher than 111 μmol/L in the neonatal period were more likely to have BA than BC and needed a surgery as soon as possible before irreversible liver cirrhosis. Okada *et al*[17] described the differential diagnosis between BC and BA by immunohistological examination using liver biopsy specimens.

They indicated that CD56-positive biliary duct cells were present in prenatally diagnosed type-1 cystic BA.

Cholangiography

Proper diagnosis requires demonstration of continuity of the cyst with the biliary tract, because it allows to differentiate BC from other intrabdominal cysts such as pancreatic pseudocysts, echinococcal cysts or biliary cystadenomas[49]. In order to show it, cholangiography is performed. There are the following methods of cholangiography: endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance-cholangiopancreatography (MRCP), percutaneous transhepatic cholangiography (PTC) and intraoperative cholangiography. These investigations allow to demonstrate the anatomy of biliary tree and define the BC type[49].

ERCP

ERCP is invasive investigation, but it has got therapeutic possibility. It accurately reveals the presence of any associated intraductal pathology or an APBJ. In the a type Ⅲ BC, it allows to perform a therapeutic papillotomy simultaneously[49].

MRCP

MRCP is a non-invasive procedure compared to ERCP. It is a favoured alternative to ERCP, but it has a lower accuracy in the detection of APBDJ and lacks the therapeutic possibility in case of the type Ⅲ BC. MRCP, as a non-invasive procedure, is investigation of choice in preoperative imaging of biliary tree[5,49,54-56]. A gadoxetic acid-enhanced MRCP in order to diagnose the biliopancreatic bile reflux and pancreatico-biliary reflux of pancreatic secretions in patients with anomalous union of the pancreatico-biliary duct has been described in the literature. Gadoxetic acid-enhanced MRCP can visualize the physiology of bile excretion, in contrast to conventional T2-weighted MRC which can visualize fluid filled space by heavily T2-weighted and fat-suppressed images. It is associated with specific properties of the gadoxetic acid which is uptaken by hepatocytes. Gadoxetic acid is excreted into the bile ducts that allows visualization of the bile ducts on hepatobiliary phase T1-weighted images[59].

PTC

Preoperative PTC allows to define the proximal extent of biliary dilatation and to use this information in preoperative resection planning[49]. According to Lipsett *et al*[53], the preoperative placement of a percutaneous ring catheter after cholangiography is useful for the surgeon during the operative procedure and can be used as a stent for the biliary reconstruction.

A technetium-99 HIDA investigation

A technetium-99 HIDA investigation is recommended to visualize the continuity BC with bile ducts. This investigation shows an initial area of photopenia within BC, with subsequent filling and then delayed emptying into the bowel[49].

CT of abdominal cavity

CT is useful in showing continuity of the cyst with the biliary tree, its relation to surrounding structures and the presence and staging of associated malignancy. It is better than USG in visualization of the intrahepatic bile ducts, distal bile duct and pancreatic head. In patients with type-ⅣA cysts and Caroli's disease, it is useful to describe the intrahepatic dilations and the extent of disease (diffuse hepatic or localized segmental involvement). It is important for a surgeon before operation, because localized type-ⅣA BC or Caroli's disease can be treated with segmental lobectomy[49]. Computed tomography cholangiography (CTC) after infusion of meglumine iodoxamate with subsequent 3-dimensional rendering has been described in the literature. Fumino *et al*[60] compared CTC cholangiography with MRCP in visualizing the pancreaticobiliary maljunction in 53 children. They noted superior visualization of the intrahepatic duct and the pancreatic system by MRCP compared with CTC. But the great advantage of CTC was its ability to produce high-quality images without respiratory artifacts in young infants in whom performing a good-quality MRCP is very difficult.

MANAGEMENT IN BC

BC require surgical intervention in order to avoid complications associated with pancreaticobiliary reflux. Management depends on the BC type. Currently, complete cyst excision with cholecystectomy followed by biliary reconstruction using a Roux-en-Y hepatico-jejunostomy is the treatment of choice[53,61,62].

Internal drainage (cystenterostomy) of BC

Currently, this method of treatment has been abandoned due to a high risk of morbidity and malignancy up to 50% following internal biliary drainage. This surgical procedure involved incision of BC and anastomosis it to the duodenum or jejunum depending to its location. Despite relief of clinical symptoms in operated patients, it was associated with a high postoperative mortality rate due to biliary reflux. Reflux of the enteric juice into the retained cyst and biliary tract leaded to recurrent ascending cholangitis. The another complication of this procedure was biliary anastomosis stricture. The most important complication of this treatment method was malignant transformation within the wall of retained BC[62-64]. Therefore, internal drainage is currently not considered to perform and all patients previously operated in this way should be reoperated in order to totally remove the cyst[62,63,65,66].

Total excision of BC with hepaticoenterostomy

Currently, total BC excision is recommended in order to avoid above mentioned complications. Total BC excision

with hepaticoenterostomy separates the biliary tree from the pancreatic duct that ends mixing pancreatic juice with bile. In situations where the intensity of fibrosis precludes safe periductal or pericystic dissection, Lilly's technique is useful. In this technique, the most densely adherent portion of the cyst wall is retained on the hepatoduodenal ligament, removing only the less adherent portion. The mucosal lining of the retained cyst wall should be ablated by diathermy or be stripped or destroyed by abrasion and iodine or alcohol application, because 57% of the bile duct cancer in BC arises from the posterior wall of the cyst[54,63-70].

There are two possible methods of hepaticoenterostomy: hepaticoduodenostomy and Roux-Y hepaticojejunostomy. According to the literature, the success rate of Roux-Y hepaticojejunostomy is 92%, with complication rate of 7%, compared with a complication rate of 42% following hepaticoduodenostomy. Some authors have compared these two reconstructions[63]. Shimotakahara *et al*[71] did not recommend hepaticoduodenostomy for reconstruction after BC excision due to a higher number of complications (33.3%) such as bilious gastritis due to duodenogastric bile reflux and adhesive bowel obstruction and cholangitis. Contrary to this report, Mukhopadhyay *et al*[72] recommended hepaticoduodenostomy as a simple and quick procedure with preservation of normal anatomy and physiology and minimum complications.

Some technical aspects of Roux-Y hepaticojejunostomy should be discussed. According to the literature, the anastomosis should be wide in order to prevent the postoperative stricture and Roux-Y jejunal loop should be 40-50 cm long[66]. Conventionally, an adult's standard of a 40-cm loop is adopted in Roux-Y hepatojejunostomy) also in children, irrespective of patient size. Diao *et al*[73] compared two patients groups according to Roux-loop length: (1) conventional group (n = 108) where a standard 35-40 cm Roux-loop length was used regardless of the child's size, and (2) short Roux-loop group (n = 110) in which the Roux-loop length was based on the distance between hepatic hilum and umbilicus. The mean Roux-loop length in patients in the second group was significantly shorter than in the conventional group. There was no significant difference between both groups in age, operative blood loss, operative time, postoperative hospital stay, and duration of drainage. In the conventional group, 2 of (1.8%) 108 patients developed Roux-loop obstruction was observed in 1.8% patients in 1st group and did not appear in 2nd group. Mild reflux was reported in 2 patients in 1st group and 1 patient of 2nd group. Authors concluded that shorter Roux-Y loop according to patient's size can be safe and effective alternative for biliary reconstruction in children with BC.

Another technical aspect of BC surgery is management with the distal bile duct stump, after cyst excision, which is usually ligated. Diao *et al*[74] compared two patients groups in order to investigate the feasibility of selectively leaving distal stump unligated. In this study, patients were divided into two groups: (1) non-ligation group (n = 207), where the distal stump was stenotic and was left unligated, and (2) ligation group (n = 63), where the distal stump was not stenotic and was ligated. The pancreatic juice leakage rates were compared. Authors concluded that not ligating distal stump is a feasible approach in patients with the stenotic distal common bile duct. In authors' opinion, this management simplifies the operative procedure and may minimize pancreatic duct injury.

Different treatment depending on BC type

Total cyst excision with Roux-Y hepatojejunostomy has been recommended by most authors in the treatment of I and Ⅳ types of BC[62]. The risk of malignancy in type Ⅱ and Ⅲ BC is low. Therefore, complete cyst excision is not necessary. Simple excision of type Ⅱ BC is sufficient. Choledochoceles often just require endoscopic sphincterotomy in order to allow free duodenal drainage of bile and stones. Large choledochoceles should be treated surgically and excised *via* duodenostomy because of biliary, duodenal or gastric outlet obstruction. In some cases of small cysts, endoscopic excision is possible. Type ⅣA BC is treated by surgical cyst excision and a wide hilar hepaticoenterostomy, but clinical symptoms are frequently observed in patients following operation that is caused by the intrahepatic involvement of disease. If the intrahepatic involvement is localized, a segmental hepatectomy can be performed. In case of diffuse disease, a percutaneous hepaticojejunostomy, surgical or endoscopic unroofing of some intrahepatic cysts can be made. Unilobar Caroli's disease can be treated by hepatic lobectomy. Diffuse Caroli's disease with recurrent cholangitis, liver failure and cirrhosis and portal hypertension or malignant disease requires orthotopic liver transplantation[61]. There are a lot reports regarding laparoscopic excision of BC with extracorporeal biliary reconstruction. Total intracorporeal biliary reconstruction has been also described in the literature. This minimally invasive treatment method is safe and effective, and it is associated with earlier postoperative feeding and discharge from hospital[75,76].

The timing of BC surgery

Early surgical treatment in order to prevent further complications is recommended. It has been observed that early diagnosis and surgical treatment was associated with a lower morbidity compared with later diagnosis and treatment. Therefore, prenatal diagnosis is such important[77,78]. Foo *et al*[77] evaluated the clinical outcomes of patients with prenatally diagnosed choledochal cysts compared with those diagnosed after birth and the optimal timing of definitive treatment. The mean age at operation for the prenatally diagnosed group was 4.4 mo. For the postnatal diagnosed group, the mean age at operation was 5.7 years. Based on analysis of 45 patients, they concluded that prenatal diagnosis of BC resulted in earlier

definitive surgery. In patients operated in older age, more adverse complications were observed[77]. Tsai *et al*[79] compared results of surgical treatment according to patients age at the time of surgery. They compared three patients groups that had been operated: < 1 year old (group Ⅰ, n = 26), 1-16 years old (group Ⅱ, n = 48), and > 16 years old (group Ⅲ, n = 33). Group I suffered significantly fewer surgical complications and less severe liver fibrosis compared with groups Ⅱ and Ⅲ. Therefore, authors recommended early surgical treatment. Germani *et al*[80] recommended the surgical treatment after 3 mo of life to increase the success according to the size of the anatomic structure. They recommended the early treatment before 3 mo of life, only in case of severe symptoms.

RESULTS OF THE SURGICAL TREATMENT OF BC

Short-term results and early complications

Surgical treatment of BC is successful in more than 90%. It is associated with a low postoperative morbidity (2.5%-27%) and mortality (0%-6%) rate according to the surgical center and patient's age. The following early complications have been reported in the literature: biliary-enteric anastomosis dehiscence with biliary fistula, intra-abdominal bile collection (biloma) or abscess and acute peritonitis, pancreatic leakage and pancreatic fistula due to injury to the pancreatic duct, acute pancreatitis, acute cholangitis, ileus caused by bowel obstruction due to intussusception or bowel kinking due to manipulation or adhesions, wound infection and wound dehiscence, gastrointestinal bleeding, hepatic failure, and multiple system organ failure[49,54,64,65,67,68,78,81-87].

Long-term results

Late postoperative complications occur in up to 25% patients and they are the following: biliary-enteric anastomosis stricture, peptic ulcer disease, cholangitis, biliary and intrahepatic stones, pancreatitis, liver failure and biliary cancer. Authors recommend to perform a wide bilio-enteric anastomosis in order to prevent its stricture[49,54,64,67,68,77,80-88]. According to the literature, 0%-6% incidence of malignancy occurs following surgery. It is caused by remnant cyst tissue or subclinical malignant disease which had not been detected before surgery. Therefore, some authors recommend intraoperative endoscopic ultrasonography and histopathological investigation of frozen sections to rule out dysplasia, hyperplasia and malignant disease. All patients with BC require long-term follow-up for bile duct cancer, using ultrasonography and laboratory investigations including liver parameters and cancer markers [carcinoembryonic antigen (CEA), CA 19-9, CA-125][49,87-89]. CA 19-9 is the mosts significant, because it is elevated in up to 85% of patients with cholangiocarcinoma. CEA is raised in about 30% of patients and CA-125 in 40%-50% of patients with cholangiocarcinoma. These markers are not specific for bile duct cancer, because their levels are also raised in other neoplasms and inflammatory diseases[90]. Lee *et al*[91] analyzed factors predicting cholangiocarcinoma in patients operated for BC. They pointed the following factors: age > 40 years, the absence of a gallstone, elevated CEA or cancer antigen 19-9 serum level, and the presence of anomalous pancreaticobiliary ductal union in univariate analysis, and an elevated cancer antigen 19-9 level in multivariate analysis. Therefore, laboratory investigations of CEA and CA 19-9 in patients following surgery for BC are useful.

Cytology of bile and bile ducts specimens taken during ERCP ora PTC by brush or needle biopsy play an additional role in cholangiocarcinoma diagnosis. Negative cytology from brushing does not exclude malignancy. Combined brush and biopsy cytology specimens increase sensitivity to 40%-70%[90].

Frequency of follow-up in patients following BC resection has not been clearly established in the literature. In my opinion, laboratory investigations including liver parameters and cancer markers (CA 19-9 and CEA) and ultrasonography should be performed as a screening every 6-12 mo.

In cases of the intrahepatic lithiasis and Caroli's disease, the use of ursodeoxycholic acid (UDCA) in the treatment has been described in the literature. Ros *et al*[92] UDCA observed that therapy with UDCA caused clinical remission, return to normal liver function, and dissolution of intrahepatic stones on USG in all patients. Therefore, litholytic therapy was indicated by authors for intrahepatic stones in Caroli's syndrome. Successful treatment of patients with the hepatilithiasis and Caroli's disease was also described by Guma *et al*[93].

In conclusion, clinical presentation and management of BC depend on the cyst type according to Todani classification. The early and proper treatment allows to avoid serious complications (including bile duct cancer) in patients with BC. The early treatment is also associated with a lower number of complications. In most cases, total cyst excision with Roux-Y hepaticojejunostomy is the treatment of choice. Surgical treatment of BC is associated with low morbidity and mortality. Patients following surgery for BC require permanent and careful postoperative observation because of possibility of biliary anastomosis stricture and biliary cancer in tissue remnant.

Abstract

In this paper, we review the concept of quality of ulcer healing (QOUH) in the gastrointestinal tract and its role in the ulcer recurrence. In the past, peptic ulcer disease (PUD) has been a chronic disease with a cycle of repeated healing/remission and recurrence. The main etiological factor of PUD is *Helicobacter pylori* (*H. pylori*), which is also the cause of ulcer recurrence. However, *H. pylori*-negative ulcers are present in 12%-20% of patients; they also recur and are on occasion intractable. QOUH focuses on the fact that mucosal and submucosal structures within ulcer scars are incompletely regenerated. Within the scars of healed ulcers, regenerated tissue is immature and with distorted architecture, suggesting poor QOUH. The abnormalities in mucosal regeneration can be the basis for ulcer recurrence. Our studies have shown that persistence of macrophages in the regenerated area plays a key role in ulcer recurrence. Our studies in a rat model of ulcer recurrence have indicated that proinflammatory cytokines trigger activation of macrophages, which in turn produce increased amounts of cytokines and chemokines, which attract neutrophils to the regenerated area. Neutrophils release proteolytic enzymes that destroy the tissue, resulting in ulcer recurrence. Another important factor in poor QOUH can be deficiency of endogenous prostaglandins and a deficiency and/or an imbalance of endogenous growth factors. Topically active mucosal protective and antiulcer drugs promote high QOUH and reduce inflammatory cell infiltration in the ulcer scar. In addition to PUD, the concept of QOUH is likely applicable to inflammatory bowel diseases including Crohn's disease and ulcerative colitis.

BIOGRAPHY

Professor Tetsuo Arakawa (Figure 1) received his MD

and PhD degrees from Osaka City University Graduate Medical School, Japan. He was Visiting Research Scholar and Professor at the University of California, Irvine (1990) and the University of Arizona, Tucson, AZ, United States (2000). He is currently Dean and Chairman, Department of Gastroenterology, Osaka City University Graduate School of Medicine, Osaka, Japan. His Curriculum Vitae lists 404 original articles, 421 review articles, 275 book chapters, 24 edited books, prestigious academic awards and honors, and numerous presentations at national and international meetings, including American Gastroenterological Association (AGA), American College of Gastroenterology (ACG), Pasteur Institute and others (over 300 presentations). He has been President/Governor: Japanese Gastroenterological Association, Japanese Society of Gastrointestinal Endoscopy, Japanese Society of Ulcer Research, International Conference on Ulcer Research, Japanese Society of Neurogastroenterology, Japanese Society of Gastroenterological Immunology, and Japanese Society of Capsule Endoscopy chaired numerous sessions during American Gastroenterological Association Meetings and is member of 10 national/international societies, including Fellow of AGA and Fellow of ACG. His research interests cover numerous areas of gastroenterology, endoscopy and pathophysiology; he significantly contributed to the concept of cytoprotection, molecular mechanisms of gastric ulcer healing, mechanisms of anti-ulcer drugs action and translation of basic research to clinical application.

INTRODUCTION

Prior to the introduction of *Helicobacter pylori* (*H. pylori*) eradication treatment, peptic ulcer disease (PUD) had been a chronic disease affecting 5%-10% of the population with a cycle of repeated healing/remission and recurrence. The treatment aimed at eradication of *H. pylori* has changed the life cycle of this disease and the prevalence rate has dramatically decreased. However, the dictum "no *H. pylori*, no ulcer" is over-rated[1]. *H. pylori*-negative PUD exists, similar to PUD in nonusers of nonsteroidal anti-inflammatory drugs (NSAIDs). This PUD is referred to as non-*H. pylori*, non-NSAIDs ulcer or idiopathic PUD (IPUD)[2]. A prevalence rate of IPUD has been reported as 12%-20%, suggesting that IPUD is not rare[2]. A recent report has shown the increase in the prevalence of IPUD[3], however this remains controversial[4].

The recurrence rate of IPUD is higher than *H. pylori* and/or NSAID-associated PUD[5] and their management is more difficult and more costly compared to other ulcers[5]. The recurrence rate of ulcer may be related to quality of ulcer healing (QOUH). The pathogenesis of poor QOUH may be the underlying cause of the refractoriness and ulcer recurrence. In addition to PUD, the concept of QOUH may be applicable to inflammatory bowel disease (IBD), which is also a chronic and recurrent ulcer disease. It is likely that in order to obtain a permanent ulcer healing and remission, the high QOUH is necessary for any type of ulcer disease.

MYSTERY OF ULCER RECURRENCE: PAST HISTORY OF PATHOPHYSIOLOGY

Ulcer recurrence has long been thought to be an unavoidable feature of PUD, and therefore, maintenance treatment has been necessary to prevent recurrence. *H. pylori* is a major cause of both PUD and its recurrence. The bacteria are, however, not the only cause of ulcer recurrence, and still there are a certain number of patients with PUD not related to *H. pylori* and NSAIDs, referred to as IPUD[2,4]. To prevent recurrence of IPUD, the investigations examining the pathophysiology of ulcer recurrence are important.

Oi *et al*[6] have proposed the double-regulation theory to explain why PUD favors the gastric angle. They examined many stomachs with ulcers that had been operated upon, and found that the ulcer site was usually at the interphase of the distal side of the glandular borderline (mucosal rule) and line of distortion of movement (muscular rule). This may be the point of combination of the mechanical tension and exposure to high concentrations of acid in the pyloric gland area. The latter mucosa has a weaker resistance to acid compared to the fundic gland area. This theory may also explain why the ulcer often recurs at the same or neighboring site of a previous ulcer. This theory, however, does not fit with duodenal or gastric ulcer at other sites. Therefore, it is important to determine how the ulcer recurs.

Pan *et al*[7] have reported that the recurrence of healed duodenal ulcer depends on the histological maturity of regenerated mucosa. They have indicated that the cause of ulcer recurrence may be related to the abnormalities of the scar of healed ulcer, leading to the concept of QOUH[7]. Takagi *et al*[8] have developed a chronic gastric ulcer model in rats by topical application of acetic acid from the serosal side of the gastric glandular borderline. This model closely mimics human PUD both in histol-

Table 1 Definition and criteria of quality of ulcer healing

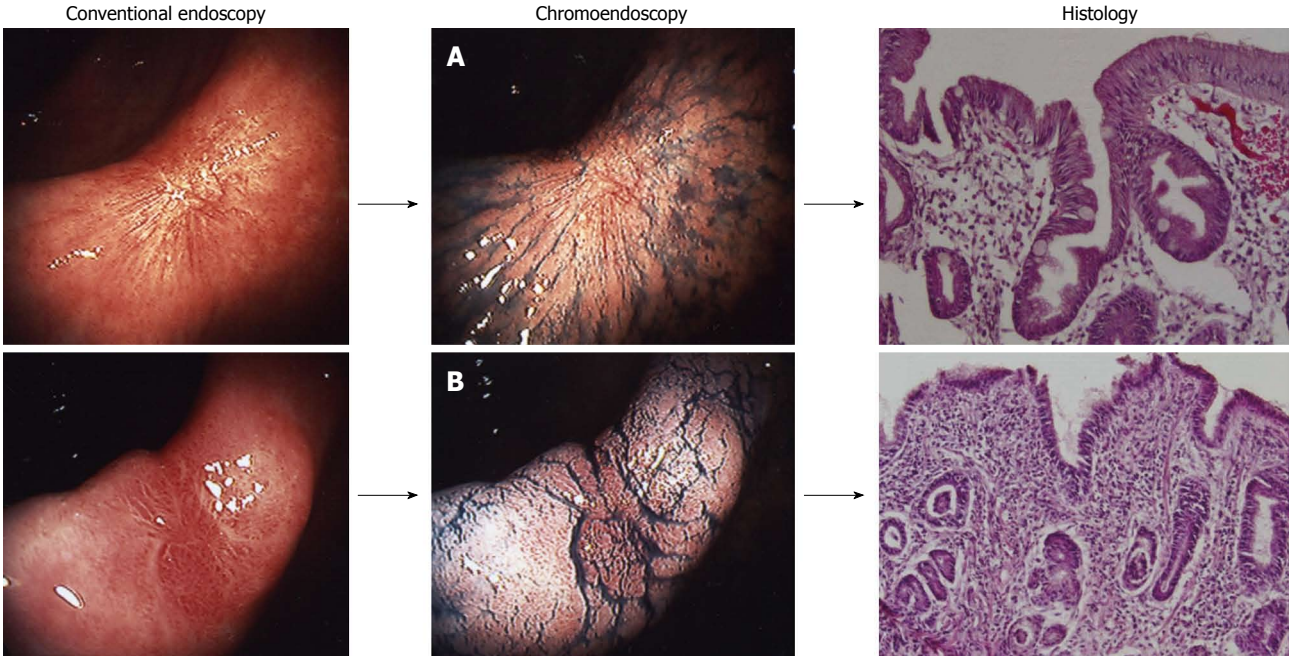
Definition:
QOUH represents histological maturity of healed peptic ulcer; Evaluation of QOUH should be done to assess functional and endoscopic maturity additionally to histological maturity; For a clinical use an endoscopic evaluation of maturity should be the main method
Criteria:
1: Endoscopic evaluation of maturity
Dye-contrast method, magnified endoscopy, endoscopic ultrasonography
2: Histological maturity
Regenerated mucosa: thickness, width, morphological abnormalities of glands, inflammatory cell infiltration
Granulation tissue: angiogenesis, fibroblasts and fibrosis, regeneration of muscularis mucosae, inflammatory cell infiltration
3: Functional evaluation of maturity
Microcirculation, production of mucin, prostanoids, growth factors, cell proliferation, receptor expression, adhesion molecules

Arakawa *et al*[12]. QOUH: Quality of ulcer healing.

ogy and life cycle of ulcer recurrence. Tarnawski *et al*[9] have demonstrated in this rat model that the subepithelial mucosa of macroscopically healed gastric ulcer displays disorganized restoration of glandular and vascular structures and remains histologically and ultrastructurally abnormal. They have concluded that these abnormalities may interfere with oxygenation, nutrient supply, and with mucosal resistance and defense, and therefore could be the basis for ulcer recurrence. They proposed the concept of QOUH based on an experimental ulcer model in 1990[9-11]. In a previous clinical study by our group, we proposed the concept and definition of QOUH in human gastric ulcer in a Japanese journal, which was published in an English journal 18 mo later[12] (Table 1). A flat or non-flat ulcer scar pattern has been defined with chromoendoscopy using indigo carmine, which was not demonstrated with conventional endoscopy (Figure 2). These patterns are compatible with histological maturity of regenerated mucosa of healed gastric ulcer; the flat pattern represents a good QOUH and non-flat represents poor QOUH[13] (Figure 2). The incidence of ulcer recurrence is much higher in a non-flat scar than in a flat scar pattern[13,14] (Figure 3), suggesting that the endoscopically assessed QOUH may detect scars that are predisposed to future ulcer recurrence.

ULCER HEALING AND PROSTAGLANDINS

Prostaglandins (PGs) and the discovery of the phenomenon of cytoprotection by Robert *et al*[15] sparked an enormous interest in the critical role of PGs in mucosal defense and ulcer healing. In humans, "artificial" ulcers in the gastrointestinal tract produced by endoscopic mucosal resection for neoplasm heal rapidly and do not recur. We have shown that the surrounding mucosa of such artificial ulcers synthesizes increased amount of prostaglandin E2 (PGE2) and prostacyclin[16], which may have a crucial role in producing high QOUH. This observation has led to our contention that PUD may be a PG-deficiency disease[17] and that PG deficiency may cause poor QOUH. We have demonstrated that low-dose indomethacin causing PG-insufficiency forms an experimental chronic gastric ulcer with poor QOUH, and that exogenous PGE2 reverses poor QOUH as assessed by recurrence rate after healing, and reduces inflammatory cell infiltration of the ulcer scar[18] (Figure 4). Therefore, PG derivatives and/or PG-inducing drugs such as mucosal protective compounds may promote high QOUH[19,20].



Another important factor in poor QOUH could be a deficiency and/or an imbalance of endogenous growth factors. Jones *et al*[21] have demonstrated that local gene therapy with vascular endothelial growth factor (VEGF) and angiopoietin 1 (Ang1), with limited duration of target gene expression, significantly accelerates experimental gastric ulcer healing in rats. Co-injection of both plasmids encoding rhVEGF 165 and rhAng1 resulted in formation of more mature vessels and more complete restoration of gastric glandular structures within the ulcer scar, reflecting better QOUH. Inhibition of accelerated healing by a neutralizing anti-VEGF antibody indicates an essential role for VEGF and enhanced angiogenesis in ulcer healing.

PATHOPHYSIOLOGY OF QOUH

Histological evaluation of scars of healed gastric ulcers shows increased infiltration of regenerated tissue with numerous neutrophils and macrophages in a non-flat scar compared to a flat scar (Figure 5). The persistence of chronic inflammation may be reflected by the finding of a hypoechoic area beneath the ulcer scar with a non-flat pattern, assessed by endoscopic ultrasonography (Figure 6). The number of macrophages infiltrating scar tissue is five times higher than neutrophils in a non-flat scar, suggesting that these macrophages may play a key role in pathophysiology of QOUH, and hence future ulcer recurrence. These macrophages produce increased amounts of interleukin (IL)-1β, tumor necrosis factor (TNF)-α, and monocyte chemotactic protein (MCP)-1 (Figure 7). The proinflammatory cytokines, IL-1β and TNF-α further activate and stimulate macrophages, thus constituting a self-perpetuating circuit. The increased stimulation of production of these cytokines induced by NSAIDs, stress, or *H. pylori* may cause these macrophages to increase cytokine production and/or release, leading in turn to attraction and accumulation of neutrophils. Neutrophils by releasing proteases and active oxygen species damage the scar tissue and induce ulcer recurrence.

MECHANISMS UNDERLYING ULCER RECURRENCE

As mentioned previously, Okabe's rat model of chronic ulcer mimics human peptic ulcer not only morphologi-

Endoscopic pattern	*n*	Regenerated gland index	*P*-value
Flat	10	48.0 ± 2.8	
Non-flat	5	40.2 ± 2.6	< 0.05

Figure 2 Assessment of endoscopic quality of ulcer healing. Flat pattern (A) and non-flat pattern (B) are identified by chromoendoscopy, but not by conventional endoscopy. Flat pattern reflects good quality of healing compared to nodular pattern as assessed by histological maturity (Arakawa *et al*[12]).

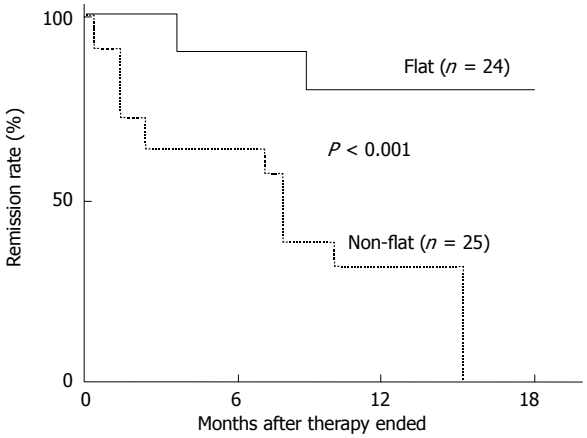


Figure 3 Cumulative remission rates of healed gastric ulcers with flat and non-flat pattern. The incidence of ulcer recurrence is much higher in the ulcer scar with a non-flat than flat pattern (Nebiki *et al*[14]).

cally and histologically but also with regard to the life cycle of spontaneous recurrence. Numerous neutrophils and macrophages persist in and beneath the regenerated epithelium even after ulcer healing. This persistent chronic inflammation may have a key role in causing future ulcer recurrence. Watanabe *et al*[22] have demonstrated that inflammatory cytokines, IL-1β and TNF-α, administered systemically in rats with macroscopically healed gastric ulcer, cause ulcer recurrence at the site of the previous ulcer (Figure 8). In this model of gastric ulcer recurrence that we reported in 1997, we found increased expression of adhesion molecules, intercellular adhesion molecule (ICAM)-1 in endothelial cells and leukocytic β_2 integrins, lymphocyte function-associated antigen (LFA-1; CD11a/CD18) and Mac-1 (CD11b/CD18) in leukocytes, and also of cytokines, IL1β and TNF-α[22], and chemokine, MCP-1[23]. This increase occurred in the regenerated tissue of the healed ulcer site (scar) 12 h after injection of an inflammatory cytokine, and was followed by massive infiltration of macrophages and neutrophils, ultimately resulting in ulcer recurrence. Antineutrophil antiserum prevents ulcer recurrence in this model, suggesting that neutrophils (producing noxious protease and active oxygen species) are the final mediator of tissue injury[22]. This hypothesis is further supported by the demonstration that antibodies against adhesion molecules (ICAM-1 and LFA-1) also inhibit ulcer recurrence[22]. These molecules regulate migration of neutrophils from arterioles into the interstitial space. Antibody against MCP-1 prevents gastric ulcer recurrence in this model[23], suggesting that the overexpression of MCP-1 in resident macrophages accumulated in the interstitial space of the ulcer scar is a first step in the mechanism of ulcer recurrence, because neutrophils and macrophages infiltrate the interstitial space of the ulcer scar only after overexpression of MCP-1[24]. Proton-pump inhibitors (PPIs) prevent gastric ulcer recurrence caused by injection of IL1β[24] and administration of

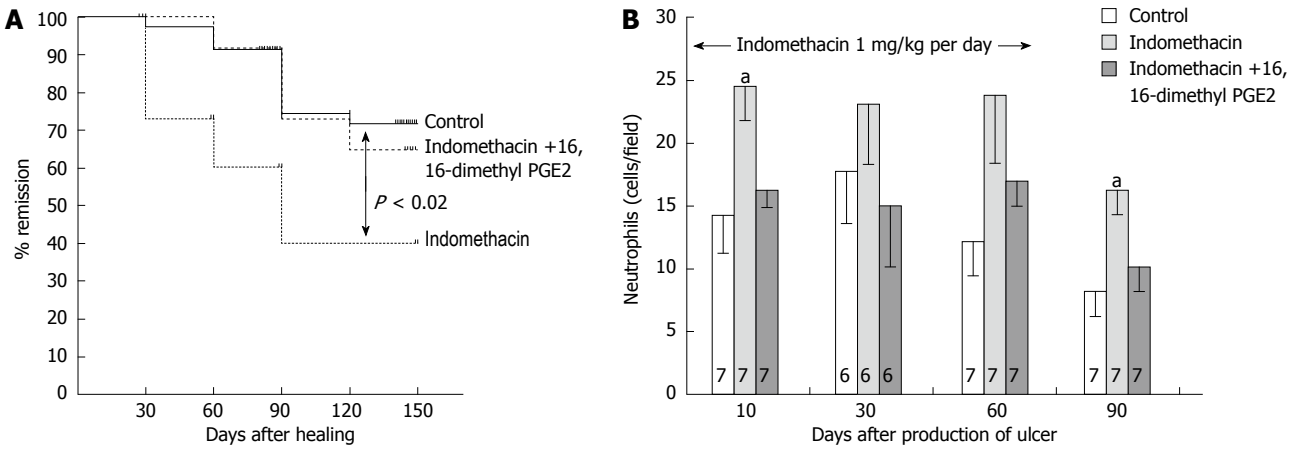

Figure 4 Effect of low-dose indomethacin given during initial period of healing process of gastric ulcer induced by application of acetic acid in rats on cumulative remission rate after healing and on neutrophil infiltration of the interstitial space of the ulcer scar. Indomethacin treatment enhances neutrophil infiltration and this phenomenon persists even after cessation of this drug. Concomitant administration of 16, 16-dimethyl prostaglandin E2 (PGE2) with indomethacin reverses these effects by indomethacin. A: Cumulative remission rate after healing; B: Infiltration with polymorphonuclear cells during and after healing. Control; indomethacin; indomethacin + 16, 16-dimethyl prostaglandin E_2 (Arakawa *et al*[18]). $^aP < 0.05$ *vs* control group.

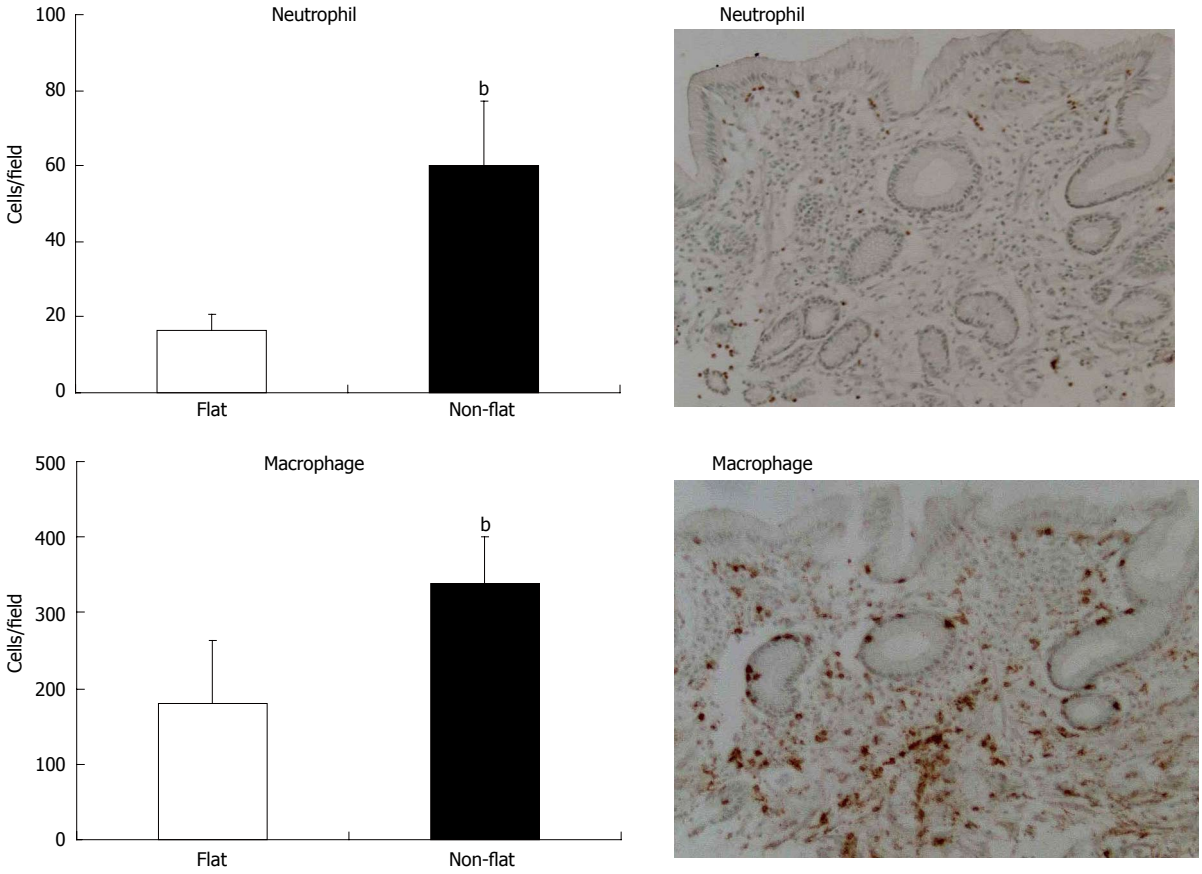

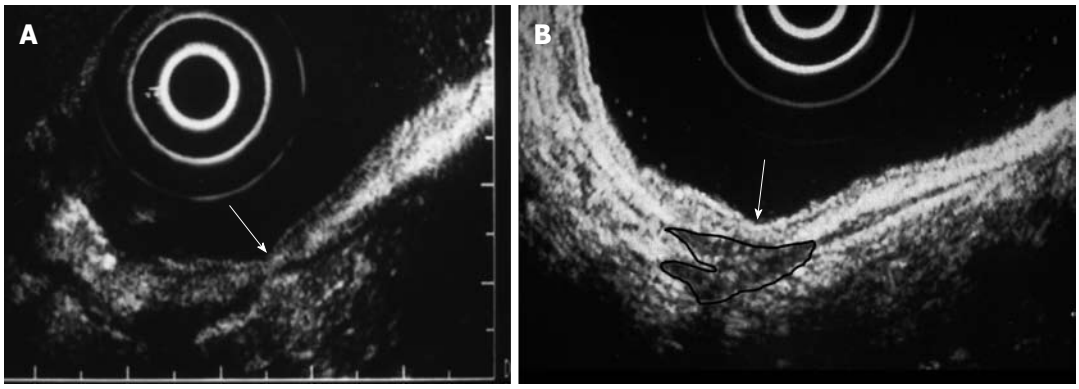

Figure 5 Number of inflammatory cells infiltrating interstitial space of ulcer scar with flat or non-flat pattern assessed by chromoendoscopy in patients with macroscopically healed gastric ulcer. The number of neutrophils and macrophages is much higher in non-flat than in flat pattern. The number of macrophages is increased five times *vs* neutrophils in non-flat scar. $n = 6$, $^bP < 0.01$ *vs* flat group.

exogenous acid reverses the protective action of PPIs on ulcer recurrence, suggesting that presence of acid is necessary to induce ulcer recurrence[24]. Based on these studies, we propose a working hypothesis of gastric ulcer recurrence presented in Figure 9[25].

EFFECT OF ANTIULCER DRUGS ON QOUH

The histological maturity of regenerated mucosa is poor after treatment with H_2-receptor antagonists[26]. This

	Flat	Non-flat	*P*-value
Internal hypoechoic area (+/-)	3/21	16/9	0.0003

Figure 6 Assessment of interstitial space beneath gastric ulcer scar with endoscopic ultrasonography. Hypoechoic area (circle of black line) is clearly seen in non-flat scar (B), but not in flat scar (A). Arrow shows a point of ulcer scar (Nebiki *et al*[14]).

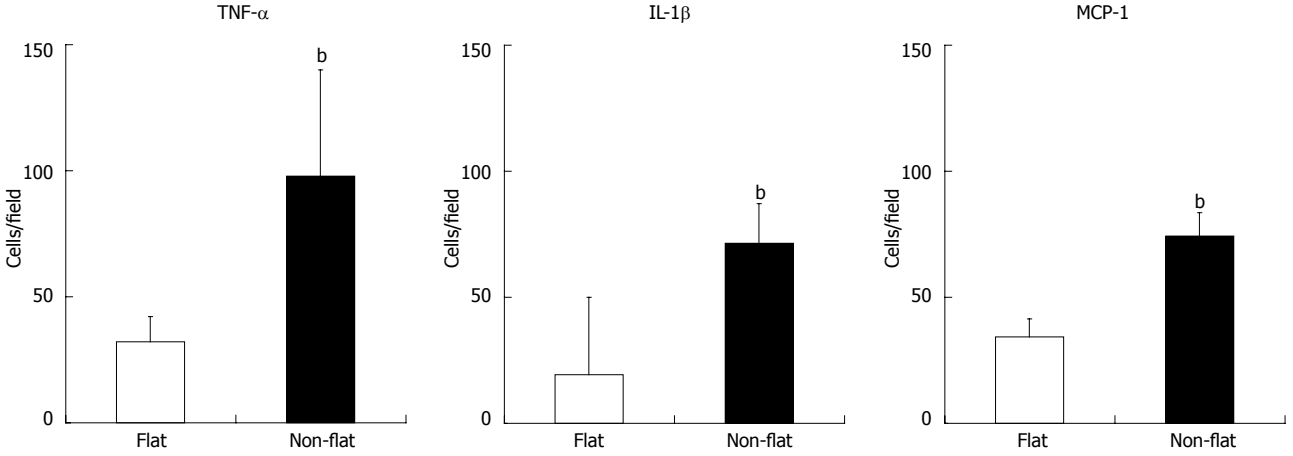

Figure 7 Number of tumor necrosis factor-α-, interleukin-1β-, and monocyte chemotactic protein-1-producing cells in interstitial space of ulcer scar site in patients with gastric ulcer whose ulcer healed with flat *vs* non-flat pattern assessed by chromoendoscopy. $n = 6$, $^{b}P < 0.01$ *vs* flat group. may be related to their action to decrease mucosal PG levels[27]. Rebamipide, a mucosal-protective drug that stimulates synthesis of PGs, accelerates ulcer healing and reduces relapse of acetic-acid-induced gastric ulcer in rats. In contrast, ulcer relapse is not prevented by cimetidine[26]. Similar results regarding improving QOUH by rebamipide have been reported by Qi *et al*[28]. In a clinical setting rebamipide has been shown to improve QOUH of human gastric ulcers, as assessed by chromoendoscopy. Moreover, the ulcer recurrence rate after healing with rebamipide was similar to that found in gastric ulcer patients after *H. pylori* eradication with dual therapy[29]. Rebamipide has been shown to exert anti-inflammatory action, accelerate gastric ulcer healing, and promote high QOUH in both experimental and clinical studies[30,31].

Regarding the action of other drugs related to QOUH, antacid hydrotalcite provides better restoration of glandular structures in the gastric ulcer scar in rats compared to omeprazole[32]. In clinical studies, initial treatment with sucralfate is superior to cimetidine in decreasing recurrence rate of healed duodenal ulcer during maintenance therapy with cimetidine[33]. Direct evidence of promoting better QOUH, as assessed by chromoendoscopy, has been reported with lafutidine in a placebo-controlled trial, and ranitidine compared to famotidine in patients with gastric ulcer[34,35]. Lafutidine is a novel H_2-receptor antagonist developed in Japan. It has the unique property of stimulating capsaicin-sensitive nerves, producing NO, a cytoprotective mediator.

RECENT ADVANCES IN EVALUATION OF QOUH

Recent preliminary findings with magnifying endoscopy and narrow band imaging (NBI) may be useful for a more precise evaluation of QOUH. Magnifying endoscopy shows a fine regular glandular pattern in flat scar

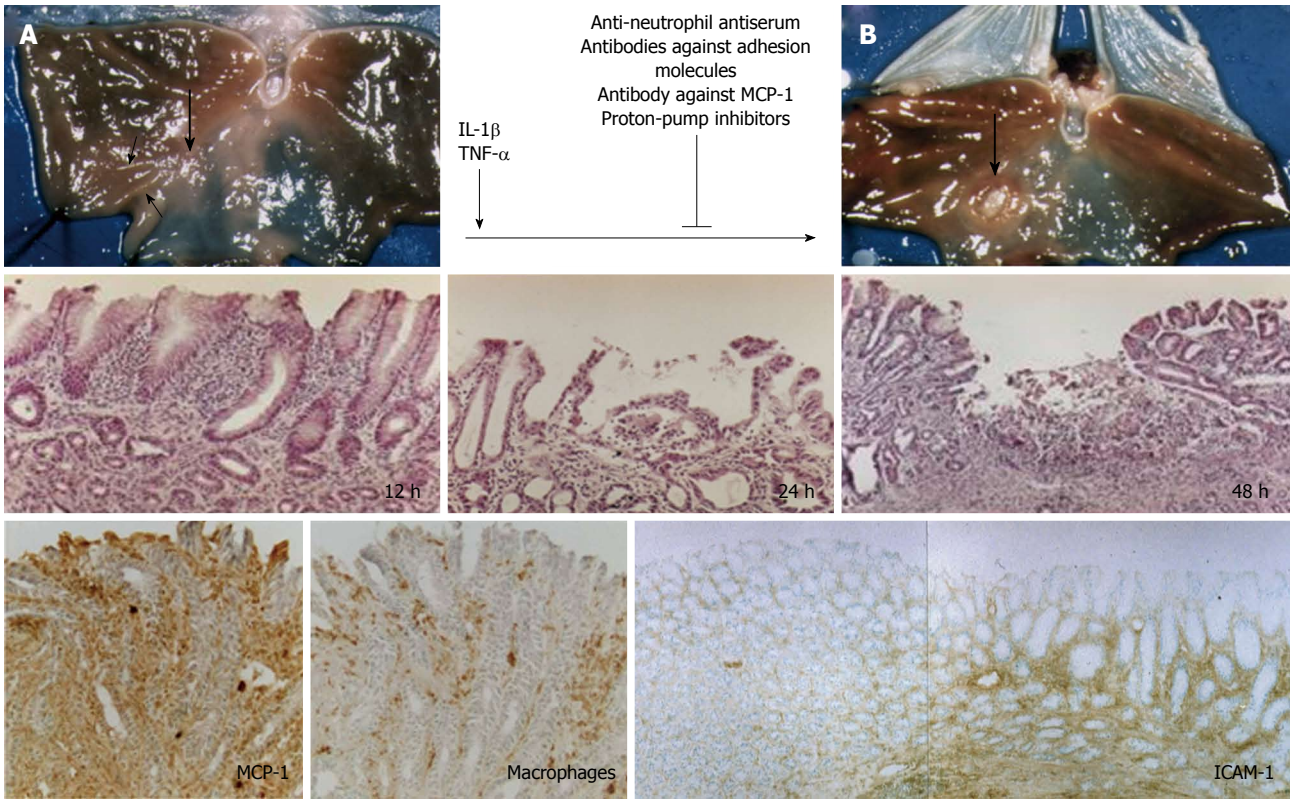

Figure 8 Original rat model of gastric ulcer recurrence. A: Ulcer scar of acetic-acid-induced gastric ulcer healed spontaneously (big arrow) with fold convergence (small arrows); B: Recurrence of ulcer with white coat at the same site as previous ulcer (big arrow). Interleukin-1β (IL-1β) or tumor necrosis factor α (TNF-α) administered systemically causes recurrence of ulcer macroscopically and histologically. Antineutrophil antiserum, antibodies against adhesion molecules, antibody against monocyte chemotactic protein-1 (MCP-1), or proton-pump inhibitors prevent recurrence. MCP-1 is overexpressed in macrophages in the interstitial space of the ulcer scar site at 12 h after administration of IL-1β or TNF-α. Adhesion molecules are overexpressed only at the ulcer scar site (Watanabe *et al*[22-24]). ICAM: Intercellular adhesion molecule.

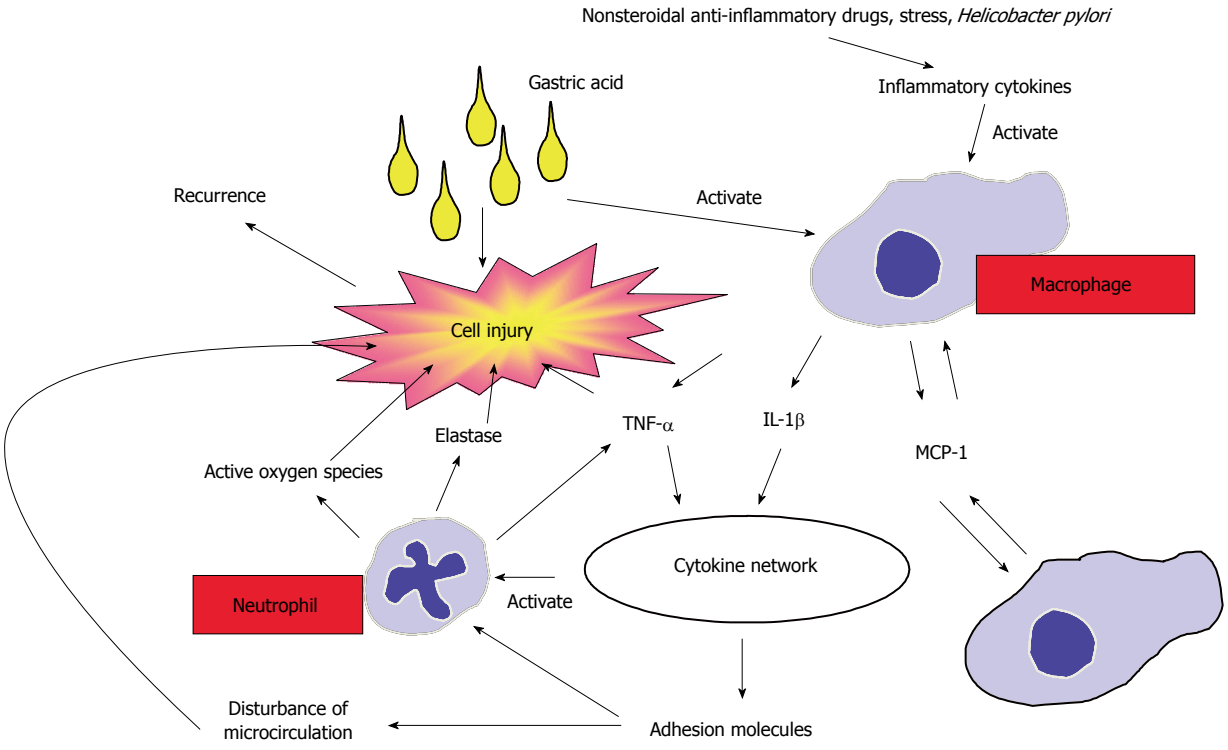

Figure 9 Proposed mechanisms of ulcer recurrence. Ulcerogenic factors such as nonsteroidal anti-inflammatory drugs, stress, and *Helicobacter pylori* stimulate the production of inflammatory cytokines, which activate macrophages under acidic conditions. The activated macrophages produce monocyte chemotactic protein-1 (MCP-1), which accumulates other macrophages. These macrophages all produce a large amount of interleukin-1β (IL-1β) and tumor necrosis factor α (TNF-α), which activate the cytokine network, resulting in activation of adhesion molecules and neutrophils. Activated neutrophils migrate from arterioles to the interstitial space and injure the tissue with noxious substances such as reactive oxygen species and elastase produced by themselves together with gastric acid (Arakawa *et al*[25]).

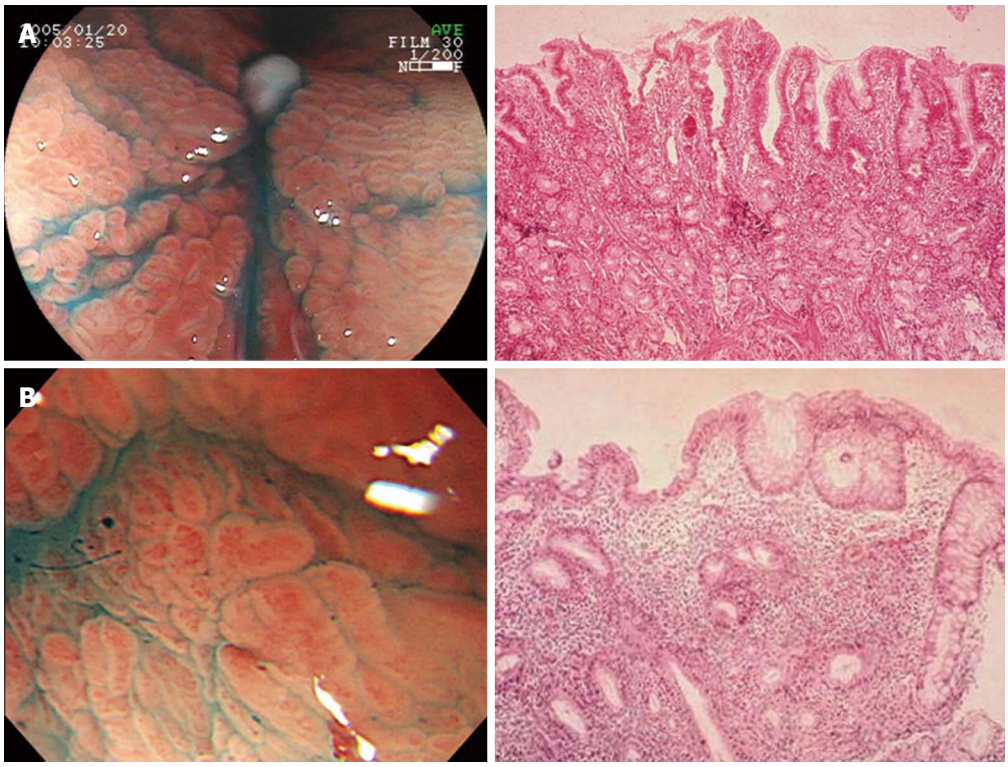

Figure 10 Magnifying chromoendoscopy shows different findings in flat scar as a fine regular pattern (A) and non-flat scar as coarse irregular pattern (B) compatible with histological findings.

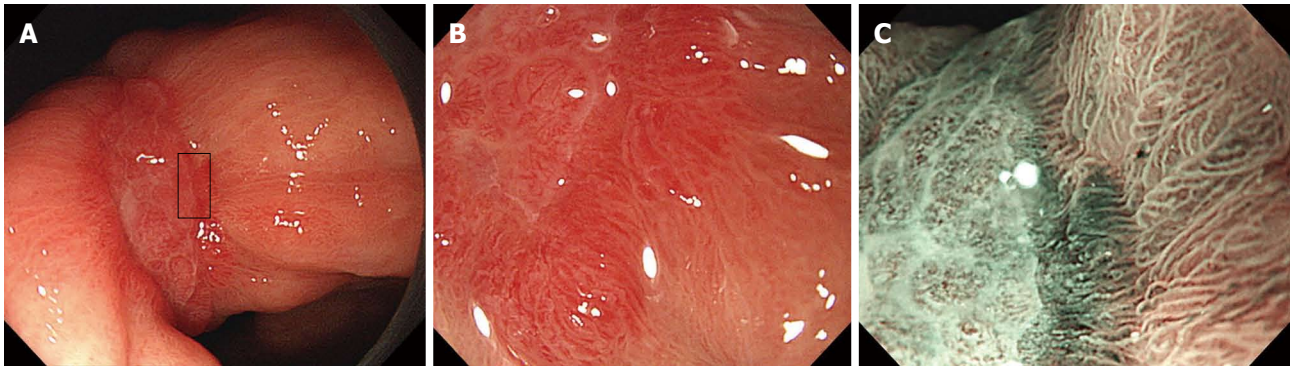

Figure 11 Narrow band imaging with magnification by endoscopy in patients with gastric ulcer shows fine vascular patterns, which may reflect precise quality of ulcer healing. A: Conventional endoscopy; B: Magnifying endoscopy; C: Magnification + narrow band imaging.

and coarse, irregular, and hyperemic glandular pattern in non-flat scar (Figure 10), suggesting that a more precise assessment is possible in the near future. In addition to this procedure, NBI may be the most promising tool to assess QOUH combined with magnification because NBI shows pattern of vessels that may reflect QOUH (Figure 11).

MUCOSAL HEALING IN CROHN'S DISEASE

Biological drugs aimed at TNF-α, such as infliximab (and other related antibodies) as well as thalidomide[36], promote ulcer healing in Crohn's disease resistant to corticosteroids. This action is completely different from the mucosal healing obtained with a PPI for gastric and/or duodenal ulcers, because a PPI inhibits only acid secretion, but may not suppress inflammation. Therefore, PPIs promote rapid healing of acid-related ulcers, but do not improve QOUH, especially in the presence of *H. pylori*. The biological drugs directly suppress inflammation, and thus they may improve QOUH. However, as long as the factor responsible for inflammation is unknown, the efficacy of such drugs may be limited.

Granulomas beneath the regenerated tissue may have an important role in cell-to-cell contact of macrophages with T lymphocytes in Crohn's disease and cause chronic inflammation, and on this background poor QOUH[37,38].

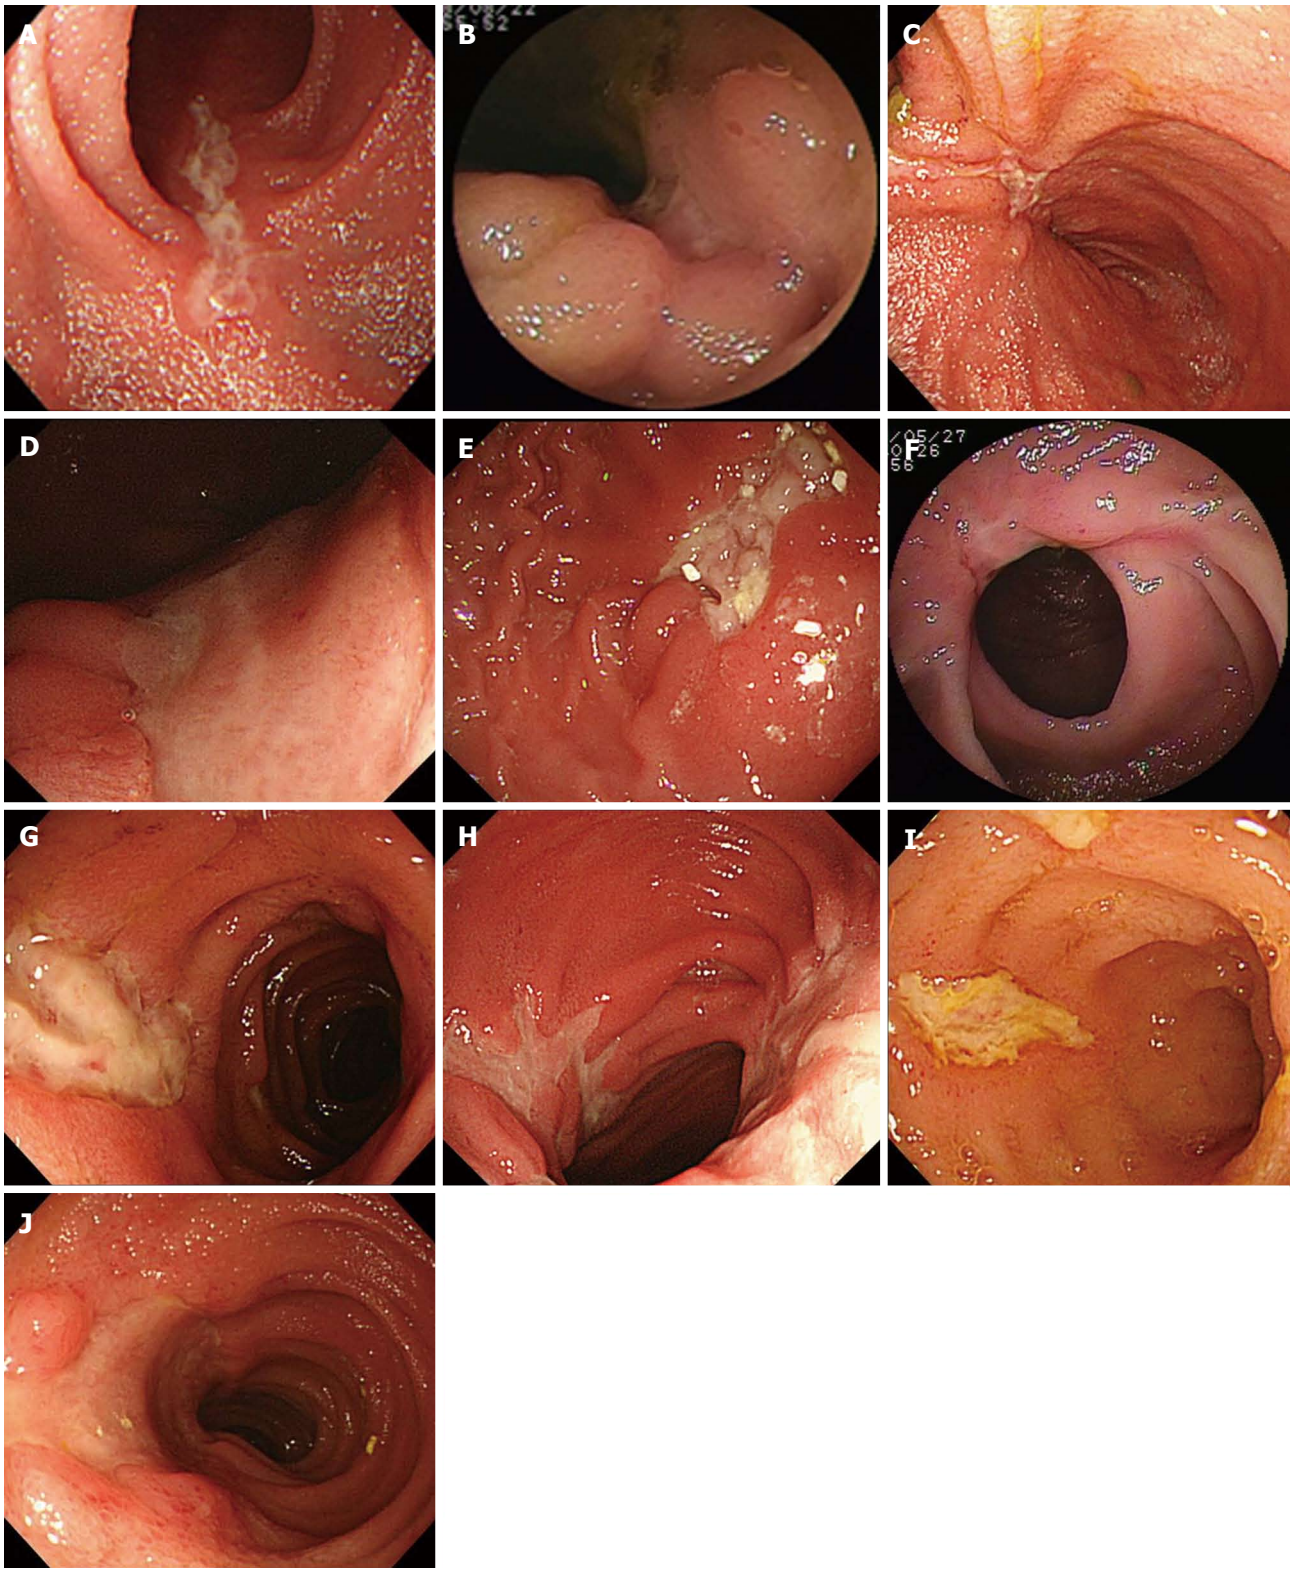

Figure 12 Morphological characteristics of active ulcer in patients with Crohn's disease. Shape of ulcer edge, flat (A) or non-flat (B); fold convergence, negative or positive (C); shape of ulcer base, flat (D) or non-flat (E); stenosis, negative or positive (F); neighboring ulcer, negative (G) or positive (H); width of ulcer, narrow (I) or wide (J).

The inflammation in Crohn's disease in based on Th1 and Th17 reaction[39-41] that is similar to *H. pylori*-associated gastritis[42,43]. Therefore, the inflammation in Crohn's disease may have similar immunopathophysiology to *H. pylori*-associated inflammation, which causes poor QOUH and underlies the ulcer recurrence. The similarity of immunological abnormality in Crohn's disease and *H. pylori*-associated gastritis may also be related to distur-

Table 2 Morphological characteristics of active ulcers in patients with Crohn's disease reflecting possible future mucosal healing after treatment with infliximab

Morphological finding		Mucosal healing

Stenosis	Negative	8	9	
	Positive	2	2	0.99
Neighboring ulcer	Negative	9	4	
	Positive	1	7	0.02
Width of ulcer	Narrow	9	4	
	Wide	1	7	0.02

[1]Fisher's exact test. *P* value indicates the statistical difference in morphological findings between good and poor mucosal healing.

bance of the ghrelin system[44,45].

In our preliminary study of 21 patients with Crohn's disease treated with infliximab, morphological characteristics of active ulcer were defined, namely shape of ulcer edge, flat or non-flat; fold convergence, negative or positive; shape of ulcer base, flat or non-flat; stenosis, negative or positive; neighboring ulcer, negative or positive; width of ulcer, narrow or wide (Figure 12). The incidence of mucosal healing of active ulcer with a flat edge, absence of neighboring ulcer, or a narrow width of ulcer is significantly higher. A negative mucosal fold convergence tends to be more frequent than non-flat ulcer edge, positive fold convergence, positive neighboring ulcer, or wide ulcer (Table 2). The latter type of ulcer may require stronger anti-inflammatory treatment to obtain mucosal healing. These ulcers may need an endoscopic follow-up observation with assessment of mucosal healing after remission. If the ulcer does not recur, the mucosal healing may be high QOUH. Mucosal fold convergence (Figure 12C) may be one of the factors reflecting poor QOUH. Therefore, prevention of the convergence may improve QOUH of Crohn's disease. Stimulation of the local angiotensin Ⅱ system may have a key role in fibrosis, resulting in fold convergence and stricture[46], suggesting that inhibitors on this system such as angiotensin Ⅱ receptor blockers may promote high QOUH in Crohn's disease. However, to identify a causative factor of inflammation in Crohn's disease is the most essential. The responsible antigen needs to be elucidated from candidates such as yeast-like antigen[47], and others. Elimination of the possible antigen may be a powerful tool to obtain high QOUH and permanent remission.

The concept and the paradigm of QOUH may also apply to ulcerative colitis. Tarnawski and coworkers using confocal endomicroscopy and molecular imaging have demonstrated in colonic mucosa of patients with ulcerative colitis in remission impaired crypt regeneration, persistent inflammation, pathological angiogenesis and increased microvascular permeability; all reflecting impaired QOUH. They have found that the underlying mechanisms include dysregulation of survivin, aberrant activation of VEGF gene, and persistent inflammatory cell infiltration[48].

ACKNOWLEDGMENTS

I would like to thank Professor Andrzej S Tarnawski for giving me a valuable advice and correction on this review article and Emilitus Professor Kenzo Kobayashi for his guidance on the concept of QOUH.

GUIDELINES FOR CLINICAL PRACTICE

Use of the tumor necrosis factor-blockers for Crohn's disease

Abstract

The use of anti-tumor necrosis factor-α therapy for inflammatory bowel disease represents the most important advance in the care of these patients since the publication of the National Co-operative Crohn's disease study thirty years ago. The recommendations of numerous consensus groups worldwide are now supported by a wealth of clinical trials and several meta-analyses. In general, it is suggested that tumor necrosis factor-α blockers (TNFBs) are indicated (1) for persons with moderately-severe Crohn's disease or ulcerative colitis (UC) who have failed two or more causes of glucocorticosteroids and an acceptably long cause (8 wk to 12 wk) of an immune modulator such as azathioprine or methotrexate; (2) non-responsive perianal disease; and (3) severe UC not responding to a 3-d to 5-d course of steroids. Once TNFBs have been introduced and the patient is responsive, therapy given by the IV and SC rate must be continued. It remains open to definitive evidence if concomitant immune modulators are required with TNFB maintenance therapy, and when or if TNFB may be weaned and discontinued. The supportive evidence from a single study on the role of early versus later introduction of TNFB in the course of a patient's illness needs to be confirmed. The risk/benefit profile of TNFB appears to be acceptable as long as the patient is immunized and tested for tuberculosis and viral hepatitis before the initiation of TNFB, and as long as the long-term adverse effects on the development of lymphoma and other tumors do not prone to be problematic. Because the rates of benefits to TNFB are modest from a population perspective and the cost of therapy is very high, the ultimate application of use of TNFBs will likely be established by cost/benefit studies.

INTRODUCTION

Crohn's disease (CD) affects about 500 000 persons in North America[1], while the prevalence rates in northern Europe are 27-48 per 105[2]. A selected group of these persons will benefit from the efficacy and safety of tumor necrosis factor-α blockers (TNFBs). This use of TNFB has been reviewed by way of meta-analysis of placebo-controlled trials[3], as well as with recent consensus statements [e.g., Canadian Agency of Drugs and

Technologies in Health (CADTH, 2009)]. The overall view is that TNFBs are superior to placebo for the induction and maintenance of luminal CD or ulcerative colitis (UC). There are insufficient head-to-head studies comparing TNFB with mesalamine [5-aminosalicylic acid (5-ASA)], intermittent use of glucocorticosteroids (GCS), azathioprine (AZA), or methotrexate (MTX). In fistulizing CD, TNFBs other than infliximab (IFX) require further investigation. It remains to be established how early in the course of CD that TNFBs should be started, and what are the factors that predict which patient is most likely to require or to respond to this therapy.

MECHANISMS OF ACTION OF TNFB

There are numerous reviews on the molecule, cellular, physiological and pharmacological properties of TNFB[4-9]. Tumor necrosis factor (TNF) (aka "cachectin") has been called the body's sentinel cytokine or "fire alarm"[10], as it initiates the defence response to local injury. As a result of innate and adaptive immune responses, the level of tumor necrosis factor-α (TNFα) is increased in the serum and mucosa of patients with CD[11-13], and is a trigger for and a mediator of positive and negative feedback loops which influence the chronicity of inflammation.

TNF in the membranes (tmTNF) is a protein which undergoes proteolysis by the protease TNFα converting enzyme, forming a soluble protein, sTNF. Reverse signalling by tmTNFα may alter cellular responses to stimuli such as bacterial lipopolysaccharide[14-16]. The sTNF and the precursor tmTNF bind to the two TNF receptors, TNF receptor 1(TNFR1) (aka pSS or DC120a), and TNFR2 (aka p75 or CD120b)[1]. Binding the TNFR1IR2 to the cleft in the TNF subunits causes activation, and initiates the expression of interleukin (IL)-1, IL-6, interferon-gamma (IFN-γ), cell adhesion molecules (e.g., intracellular adhesion molecule-1), as well as a number other inflammatory molecules[17].

TNFR1 is expressed in all cells, and generates the proinflammatory properties of TNF. TNFR2 is present in immune as well as endothelial cells, and initiates the immunoregulatory properties of TNF[7]. If the TNF/TNFR1 clusters in membrane lipid rafts, it becomes antiapoptotic, whereas if TNF/TNFR1 is internalized within the cell, it becomes proapoptotic. Whether TNFR1 activates apoptosis or not depends upon accessory cell proteins, such as TNA receptor-associated factor 2 (TRAF2). TNFB affects both sTNF-mediated mechanisms, as well as tmTNF-mediated mechanisms[18]. TNFB neutralize sTNF with mean inhibitory concentrations in the nM range. TNFB alter tmTNF interactions with TNFR1 and 2, or as agonists that initiate differential induction of cytokine suppression through reverse signalling, involving signal-peptide-peptidase-like 2a (SPPL2a) and SPPL26. This leads to apoptosis, cell activation, cytokine suppression, induction of the adhesion membrane E-selectin, and resistance to endotoxin[18,19].

Recruitment of Fas-associated death domain binds and activates procaspase-8, which then activates caspase-3, and results in apoptosis. In this way, TRAF2 may lead to apoptosis. Alternatively, TRAF2 may recruit c1 activator-protein-1 (AP-1)-1 and c1AP-2. In turn, c1AP-1/-2 cause nuclear factor κ B (NF-κB) and AP-1 to block apoptosis increase anti-inflammatory proteins, and enhance cell proliferation as well as differentiation. In addition, TNF increases IL-2 receptor, *HLA-DR* antigen gene expression, and I5-A costimulator of IL-2-dependent IFN-γ production.

TNF may be immunostimulatory or immunosuppressive, depending on the genetic background of the patient, the timing and concentration of TNF[17,18], as well as depending on whether TRFR1 or TRFR2 are involved[20]. In clinical situations, TNFB do not likely function as immunosuppressants: TNFB may in fact provide immune enhancements[21], and TNFR may down-regulate some immune reactions that are activated in CD.

Reduced apoptosis in CD may cause inflammation[22], and the death domains in TNFR may induce apoptosis[23]. The tmTNF molecule has a cytoplasmic domain which can induce apoptosis by acting as a ligand for TNFRs, or as a receptor that transmits a reverse signal into the tmTNF-bearing cell[14]. In this way, TNFB may block or induce tmTNFB-mediated apoptosis. TNF-expressing cells such as monocytes, macrophages and T-cells are acted upon either by pathogen-associated molecules which express toll-like receptors (TLRs), or by NF-κB transportation factors which have been stimulated by inflammatory cytokines such as IL-1. The response to TNFB IFX in CD is determined by a single nucleotide polymorphism in the FCGR3A gene encoding for FCjR Ⅲa receptors on NK cells and macrophages[24]. TLR and NF-κB act through p38 MAPK and NF-κB to increase TNF mRNA (gene transcription) and TNF protein (translation).

Both IFX and adalimumab (ADA) induce apoptosis in peripheral blood monocytes as well as in lamina propria T-cells[25,26]. Certolizumab (CER) does not produce apoptosis *via* tmTNF, possibly because it cannot form cross-linkages with tmTNF, or because of its different epitope specificity. The fact that CER does not induce apoptosis and yet is clinically effective in CD provides evidence for mechanisms of action in addition to apoptosis being important in the clinical benefit of TNFBs.

For IFX and ADA, the presence of antibodies to the TNF reduces the serum concentrations and effectiveness of the drugs[27-29]. These antidrug antibodies form multivalent immune complexes with the TNFB, leading to their rapid clearance and therefore to reduced clinical response, as well as to the potential for the development of future infusion reactions.

It is not clear why IFX induces antinuclear, anti-ds DNA and anticardiolipid IgA or IgM antibodies. In reviewing this topic, Tracey *et al*[18] speculated that TNFB either dysregulated apoptosis and release autoimmunogenic plasma nucleosomes from the apoptotic cells, or inhibit some cytotoxic T-lymphocyte response that normally suppresses autoreactive B cells[30].

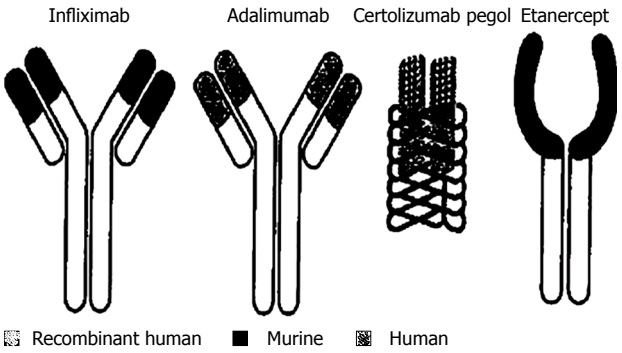

Figure 1 Comparative structures of the anti-tumor necrosis factor agents infliximab, adalimumab, certolizumab pergola and etanercept.

Control of intracellular infections such as Mycobacterium requires macrophages and T-cells in granulomas to come close to bacteria, and then wall them off. Etanercept (ETA) does not show efficacy against granulomutous diseases such as Wegener's granulomatosis and sarcoidosis[18,31]. This is unlikely the main mechanism of clinical benefit of these TNFBs in CD, since ETA is not effective in this disease. Furthermore, ETA, IFX and ADA induce apoptosis, but again ETA is not clinically active in CD. Some other pathway(s) must represent the mechanism of action of IFX, ADA, and CER in CD. IFX, ADA and CER but not ETA almost completely inhibit lipopolysaccharide-stimulated IL-IB release from monocytes, suggesting that inhibition of the production of cytokine may be important in the clinical efficacy of IFX, ADA and CER in CD[32]. Because ETA has not been shown to be clinically effective in the treatment of CD, and will not be discussed further in this paper.

The general comparative structures and individual biological properties of the TNFBs which have been approved in various countries for use in persons with CD are shown in Figure 1, and in Tables 1-3. IFX, ADA and CER are discussed in the order in which they became generally available for clinical use in CD, and the order of presentation does not imply in any way the superiority of one TNFB over another.

Etanercept is a soluble TNF receptor fusion protein (humanized IgG1 Fc fragment fused with two identical humanized p75 TNF receptors) that binds and inactivates soluble, but not membrane-bound TNFα, and although effective for the treatment of rheumatoid arthritis and other forms of inflammatory joint diseases, etanercept failed to demonstrate efficacy at similar doses in a clinical trial for CD.

Biologics other than anti-TNFα agents

Recently, natalizumab, a humanized IgG4 monoclonal antibody that antagonizes integrin heterodimers containing α4-integrin, was approved as a second-line biologic for therapy in the United States for CD patients who failed conventional therapies. Natalizumab inhibits leukocyte trafficking by preventing α4-mediated adhesion of leukocytes to adhesion molecules and transmigration of leukocytes across endothelium into inflamed mucosa[33,34]. Natalizumab is well tolerated, but is associated with an increased risk for infections, acute hypersensitivity reactions, and hepatotoxicity. The primary concern regarding natalizumab therapy has been the reactivation of latent human JC polyomavirus that can lead to a fatal central nervous system infection, progressive multifocal leukoencephalopathy, which has an estimated risk of 1:1000[35]. Therefore, natalizumab use has been restricted to monotherapy, without concomitant immune suppressants, and has a mandated special safety monitoring program and consent that has limited its patient acceptance. Nevertheless, natalizumab remains a viable option for patients who have lost a mechanistic response to anti-TNFα agents.

Table 1 The general biological properties of tumor necrosis factor blockers in clinical practice

Pro- or anti-apoptotic effects[1]
↑ Adhesion molecules on endothelial cells
↑ Epithelial permeability
↑ Antigen-stimulated B-cell proliferation and differentiation
IL-2R production[1]
↑ IL-2 dependent production of IFN-γ
↑ *HLA-DR* gene expression

[1]Represent the data are increased. IFN-γ: Intracellular interferon-γ; IL: Interleukin.

CLINICAL ASSESSMENTS REQUIRED BEFORE THE INITIATION OF TREATMENT WITH TNFBS

Absolute or relative contraindications for use of TNFBs

TNFBs are contraindicated if the CD patient has an abscess, intestinal stricture, a flare of colitis in association with an enteric infection with Clostridium difficile or cytomegalovirus, severe congestive cardiac failure (NYHA Ⅲ or Ⅳ), uncontrolled HIV disease, endemic mycosis, multiple sclerosis, or evidence of tuberculosis (TB) (positive interferon-gamma assay and/or chest X-ray prior to a four weeks course of isoniazid). TNFBs should also be used with caution and balanced consideration in CD persons with neurological disease, chronic liver disease, a history of malignancy (especially lymphoma), and in the woman who is pregnant or plans to begin parenthood (see below).

TFNBs and pregnancy: Lactation and contraception

Because the peak prevalence of inflammatory bowel disease (IBD) is between approximately 20 years to 40 years of age, for the couple where one or both partners have CD or UC, the issues of pregnancy, lactation and contraception are important. These issues need to be discussed proactively and in detail with the patient and their sexual partner.

The American Food and Drug Administration (FDA) classifies IFX and ADA as pregnancy class B agents. So,

Table 2 Individual biological properties of tumor necrosis factor blockers

IFX
High sensitivity and specificity for binding to both sTNF and tmTNF
2-3 IFX molecules bind to each TNF trimer, preventing TNF binding to cellular receptors, and reversing the actions of TNF
The TNF trimer complexes are biologically inactive and are thought to be cleared by the hepatic reticuloendothelial system
Most IFX is in the vascular compartment
No systemic accumulation
Clearance of IFN is slowed by MTX and is ATI
The VOD at steady state is independent of dose
VOD and clearance are not affected by patient age or weight. The effect of liver or kidney disease is unknown
Does not produce a generalized suppression of the body's immune system
Response to IFX is affected by CRP polymorphisms
Linear relationship between dose and serum concentration of IFX
Serum concentration is correlated with clinical response (in at least persons with rheumatoid arthritis)
Reductions in IL-10 levels also correlate with improvement in clinical activity, and FGF and improvement in perianal disease
For the 5 mg/kg dose, the median terminal half-life (t) is 10.9 d[1]
↓ Cells expressing TNF, IL-10, IFN-γ
↓ Cells staining for CD4, CD5, CD6, MMP-9
↓ TNF levels (that are ↑ in serum and diseased mucosa in CD)
↓ ICAM-1
↓ Lamina propria T-lymphocytes and peripheral blood monocytes
↓ Growth hormone resistance
↓ Markers of bone reabsorption, ↑ markers of bone formation
ADA
Forms high molecular weight complexes with human TNF (600-5000 kDa)
Linear relation between dose and serum concentration
Serum concentration is correlated with clinical response
Mean serum t is 10-20 d
Clearance is slowed by MTX, and is accelerated by ATA
Certolizumab pegol
Lacks IgG Fc domain, and thus does not fix lysed cells or complement
The Fab' component of CER contains a free cysteine residue to the hinge region, which provides site-specific attachment of the PEG to the Fab' at a site well removed from the antigen binding site
The retention time of protein conjugates in the blood is increased by pegylation, and immunogenicity is reduced. Pegylation increases in the half-life ($t_{½}$) of the antibody fragment, so dosing may be less frequent
The half-life of CER in healthy volunteers is 313 h
Site-specific pegylation of the Fab' fragment of CER is directed to a site well away from the antigen-binding region. In this way, the conjugate has the same high affinity of the TNF as the tmTNF and sTNF without the pegylation
Does not cause apoptosis of lymphocytes and monocytes, and antibodies to IFX (ATI) do not cross-react with CER
Accumulates preferentially in inflamed rather than in non-inflamed tissue
Has a greater affinity for sTNFs than do IFX or ADA
Has twice the neutralizing potency as IFX or ADA for sTNFα
Has the same neutralizing potency as IFX and ADA for tnTNFα, and occurs through p55/p75 TNFR
Anti-CER antibodies levels are low, and do not affect the efficacy of CER
Does not cross-react with ATI (antibodies to IFX)
Has a linear pharmacokinetic profile
Bioavailability of subcutaneously administered CER is almost 100%
Does not lyse cells, cause compliment-dependant cytotoxicity, antibody-dependant cell-mediated cytotoxicity, apoptosis of activated monocytes or lymphocytes or necrosis of neutrophils

[1]Represent the counts or concentration is decreased. IFX: Infliximab; TNF: Tumor necrosis factor; MTX: Methotrexate; ATI: Accelerated by antibodies to IFX; VOD: Volume of distribution; CRP: C-reactive protein; FGF: Fibroblast growth factor; IFN-γ: Intracellular interferon-γ; IL: Interleukin; MMP-9: Metalloproteinases; ADA: Adalimumab; ATA: Antibodies to ADA; ICAM-1: Intracellular adhesion molecule-1; PEG: Polyethylene glycol; CER: Certolizumab; CD: Crohn's disease; TNFR: TNF receptor.

IFX and ADA may be used during the first two trimesters of pregnancy if clinically indicated, and absolutely necessary[36-38]. There is no detailed published data on the safety of CER in pregnancy. Because clinically significant levels of IFX have been described in the serum of a baby 6 wk after delivery[39], it is recommended for the pregnant IBD mother to stop IFX in the third trimester of her pregnancy. There is no transfer of IFX to mother's breast milk, so the IFX may be restarted shortly after the child has been delivered.

Vaccination

Recommendations have been made for the regular scheduled monitoring of persons on TNFB[40]. When the diagnosis of IBD is initially established, the patient's vaccination status should be reviewed. Unfortunately, the assessment of the IBD patient for vaccine-preventable diseases is not well considered by many healthcare providers[41]. If the vaccination program is not current, then it must be updated before the use of TNFBs. Ideally, vaccinations should be updated before the use of immu-

Table 3 Comparison of *in vitro* properties of different tumor necrosis factor-α blockers in clinical practice for inflammatory bowel disease

Agent	Binds	Mediates		Increases proportion of apoptotic cells	Inhibits cytokine production	Effective in IBD patients

TNF: Tumor necrosis factor; ADCC: Antibody-dependent cell-mediated cytotoxicity; CDC: Complement-dependent cytotoxicity; IBD: Inflammatory bowel disease.

Table 4 Management of hepatitis B virus infection in inflammatory bowel disease patient being considered for tumor necrosis factor-α blockers therapy

Serology	Management
HBsAg+, LE ↑	Treat HBV
HbsAg+, normal LE	Vaccinate for HBV; monitor LE and HBV-DNA
HbsAg-	Vaccinate for HBV
Consider giving a combined vaccination for HAV-HBV	Measure anti-HBs-Ab titer 1 mo after third injection to determine adequacy of response; additional doses may be necessary

LE: Liver enzymes; HBV: Hepatitis B virus; HAV: Hepatitis A virus; HBsAg: Hepatitis B surface antigen.

nosuppressants such as AZA or MTX, or GCS.

Under no circumstance should the patient on TNFB be given live vaccines. To stress, these include vaccines for measles-mumps-rubella, varicella (oral), yellow fever vaccine, or oral polio vaccine. The injectable (non-oral) vaccines for polio and for typhoid are considered to be safe. Live vaccines may be given safely three weeks before or three months after stopping AZA or metronidazole (MTZ), or given at any time to persons on GCS, as long as the dose is below prednisone 20 mg/d. There are no guidelines for the ideal time to vaccinate before or after the use of higher doses of GCS.

In the IBD patient who is hepatitis B virus (HBV) positive (regardless of negative hepatitis B surface antigen, and regardless of elevated or normal liver enzyme test), the HBV must be treated before starting TNFB (Table 4).

The regular travel precautions are taken for malaria. As with all travellers, ciprofloxacin and/or metronidazole should be available to the traveler, in the event that they develop symptoms suggestive of traveller's diarrhea. It is useful if the traveler has a typed copy of their medical records, a copy of their consultant physicians' most recent letter, documentation for custom officials of their prescribed medications, purchase of traveller's insurance without exclusion for pre-existing conditions (i.e., IBD), contact names and numbers of physicians in foreign countries with IBD experience, and contact numbers for care-givers at home. IBD patients with an ileostomy should be aware of the importance of their not becoming dehydrated.

APPROVED INDICATIONS FOR TNFBS IN CD

The approved indications for the use of TNFB vary from country to country. According to the Canadian Association of Gastroenterology, as well as the Canadian Expert Drug Advisory Committee[42,43], IFX is recommended: (1) For patients with moderately to severely active CD who have continuing symptoms despite the use of conventional therapies (5-ASA, antibiotics, GCS, AZA, MTX); (2) For patients with CD who cannot tolerate conventional therapy; (3) For fistulizing CD; and (4) For pediatric CD with inadequate response to conventional therapy.

When to avoid TNFB

There are several situations when TNFB should not be used, or used after full consideration of the consequences and patient awareness and patient awareness and consent.

Narrowing of bowel and TNFB use

Narrowing of bowel and TNFB use: (1) Inflammatory-yes (no pre-stenotic dilation); and (2) Fibrostenotic-no.

Latent infection

Latent infection: (1) TB; (2) HBV; (3) HIV; and (4) Live vaccines within last 3 mo.

Active infection

Active infection: Perianal or intra-abdominal abscess must be drained.

Present malignancy or disorder

Present malignancy or disorder: Present/previous malignancy (other than non-melanoma skin cancer) or lymphoprolifer-ative disorder.

Cautious use in children

Cautious use in children: Because of 48 cases of malignancy, 88% (almost 9 out of 10) of which were while the patient was on both TNFB plus immunomodulators, and half developed lymphoma.

Efficacy of TNFBs

General considerations: There are several goals of therapy in CD (Table 5). It is important to consider a

Table 5 Goals of therapy in Crohn's disease

Induce and maintain remission off steroids
Improve patient's quality of life
Reduced risk of need for surgery or hospitalization
Reduce risk of development of adenocarcinoma/lymphoma
Maintain mucosal healing as a possible predictor or surrogate marker of better future disease outcome
Acceptable efficacy/safety balance

number of factors pertaining to the clinical trials which have been used in meta-analyses to provide therapeutic recommendations for the use of TNFBs for induction and maintenance of CD. What proportion of CD patients will have an initial non-response to IFX (primary non-response), a continued response or remission, and a secondary non-response? The definition of response and remission may vary between studies, the time of assessment of these outcomes may vary, and most studies exclude the primary non-responders at 2 wk. Also, the placebo response rates vary widely, and therefore so too does the therapeutic gain [therapeutic gain (TG); therapeutic minus placebo response]. Some patients may have a short or a long duration of CD before IFX for example was initiated used, and some trial participants were previously or concurrently on GCS, AZA, or MTX, and the dose and duration of use of GCS, AZA and MTX may have varied widely.

About a quarter of persons treated with TNFB will be primary non-responders, i.e., will not respond to an initial dose of TNFB. Because primary non-responders are often excluded from analysis, the response and remission rates in the intention-to-treat group are much lower than the per-protocol group[44]. Patients and physicians must be made aware that some of the published rates of TNFB response (about 2/3 of TNFB users) and remission (about 1/3) are in those persons who responded initially, and do not include the percentages based on all users (i.e., intention-to-treat). The overall desired outcome of TNFB therapy is prolonged steroid-free remission, mucosal healing, good quality of life, and normalization of laboratory markers of inflammation [e.g., C-reactive protein (CRP), erythrocyte sedimentation rate], an acceptably low risk/benefit ratio, and acceptable cost to ensure widespread availability.

There are different ways in which a response to therapy may be defined, and these definitions vary from study to study. In clinical trials of CD, the CD activity index (CDAI) is often used as one of the outcome measures. The CDAI is based on the patient's symptoms, the presence of an abdominal mass, anemia (reduced hematocrit), weight loss, and use of an anti-diarrheal agent. CD is arbitrarily said to be "active" if the CDAI is above 150 points. Clinical response in CD may be a decrease in CDAI of $\geqslant$ 70 points, or a decrease in CDAI of 70 to 100 points plus a 25% improvement from baseline[45]. Clinical remission might be variably defined as a CDAI of $<$ 150, or CDAI $<$ 150 plus a decrease by 50 to 100 points from baseline. Because of these variations in

Table 6 Predictors of good response to tumor necrosis factor-α blockers

Luminal
Short history of CD
Less severe disease
Isolated colonic disease
Inflammatory CD[46-49]
No previous abdominal surgery
Use shortly after ileocolonic resection
CRP > 5 mg/L (76% *vs* 46% response to TNFB), or ↑ CRP returning to normal detectable through serum TNFB (IFX) levels. CRP concentrations are inversely correlated with the rates of placebo response[50]
Non-smoking
Fistulizing
Perhaps for response with rectovaginal fistula

TNFB: Tumor necrosis factor-α blocker; CD: Crohn's disease; CRP: C-reactive protein; IFX: Infliximab.

definition, the results from one study cannot be directly compared with another study. Comparing the placebo responses gives only a very rough approximation of the comparison of the population of patients examined in two studies, because of the very large heterogeneity of CD sufferers. The only totally valid method of comparison of one TNFB to another is a head-to-head randomized controlled trial (RCT). Note that there are no head-to-head comparisons of IFX, ADA, CER. Taking the largest trials into account, and considering all of these previously mentioned cautionary points, it is suggested that there are numerically similar post-induction success rates of clinical remission and fistula closure for IFX, ADA and CER.

Specific considerations: Induction of remission, and primary non-response: Patient selection characteristics and the time in the course of the patients' disease will influence outcomes with TNFB therapy, so there may be large variations in the placebo response in one study *vs* another, and therefore gain achieved with TNFB (Table 6)[46-50]. Careful consideration must be given as when to start TNFB therapy: When to start TNFB depends upon consideration of (1) clinical characteristics (steroid-refractory and steroid-dependent); (2) previous response to treatment; (3) complications and comorbidity; (4) cost/availability; and (5) patient preference and IFX. The 2 wk induction response rates for IFX ranges from 52% to 73% (Table 7). However, the therapeutic gain for single dose IFX for induction of response and remission in CD varies with the time of assessment and dose, and is quite modest, for example, only a 10% to 22% remission rate at week 12. Quoting from the CADTH review[51], "a total of 47 citations reporting 20 RCTs and 17 observational and uncontrolled studies were included. All the RCTs had a parallel group design. Four studies were open-label, single-arm trials. Of the remaining 13 cohort studies, seven studies used a prospective design, and the remaining six studies used a retrospective design. Five cohort studies and one RCT were published as abstracts only. The remaining studies had at least one full peer-

Table 7 Therapeutic gain for single dose infliximab for induction Crohn's disease: Response and remission (%)

reviewed publication. IFX was used as the treatment for patients with CD in eight RCTs (total number of participants 1091; range: 36-335) and 10 observational and uncontrolled studies (total number of participants 1402; range: 12-614), and for patients with UC in six RCTs (total number of participants 1477; range: 299-499) and five observational and uncontrolled studies (total number of participants 157; range: 15-36). One cohort study (10 participants) reported the use of ADA in UC. One RCT of 43 participants evaluated the effects of ENT in patients with CD. Of six which included placebo-controlled trials assessing the effectiveness of IFX in the treatment of CD, three studies used short-term regimens of IFX to induce disease remission, and three RCTs evaluated the effectiveness of long-term IFX in maintenance of remission"[51].

For the treatment of fistulizing CD, reporting on 776 patients in 10 studies, after open-label induction, maintenance trials showed a mean difference of 16% (95%CI: 8%-25%, $P < 0.001$)[3]. Thus, only 11% had induction of remission as compared to placebo, and only 8% maintained their remission for about half a year.

The TG is the treatment response minus placebo response. The TG for significant response at weeks 4, 12, 24, and 30 and 54, a response will be seen in 50% and 37%, 30, 52, and 54 is 48%, 29%, 28%, 23%, 18%, and 22% with TG for remission of 16% and 13%.

In IFX primary non-responders, there is no proven benefit in using ADA. Of those who do respond initially at 2 wk, then after 4 wk of IFX about two-thirds respond (CDAI > 70 point reduction), and about one-third are in remission (CDAI < 150 points)[52]. At 24 wk, 57% will still show a response, but will not be in remission [IFX = placebo (PL), $P = 0.31$][52,53]. At 30 wk and 54 wk, 39% and 28% were in remission[54].

Adalimumab

The two major studies evaluating ADA in CD need to be evaluated separately due to heterogeneity in terms of whether the CD patients were naive to TNFB[51]. Similar to IFX, about 30% of persons with CD given ADA will be primary non-responders. Of those who do respond initially at week 1, about 52% will have responded at 4 wk and 21% will be in remission. The secondary non-response rate to ADA is 23%-48% at 24-26 wk and 23%-59% at 56 wk. The TG (active agent-placebo response) at weeks 4, 26, and 56 was 14%, 23%-25% and 23%-24% (Table 8)[54-56].

Table 8 Comparison of tumor necrosis factor-α blockers for Crohn's disease remission and fistula closure

	IFX (mg/kg)	ADA (mg)	CER (mg)
Remission (26-30 wk)	42	43	48
Fistula closure	36[78]	32	54

CER: Certolizumab; IFX: Infliximab; ADA: Adalimumab.

The Community Economic Development Assistance Corporation recommends ADA for patients with moderate to severely active CD who are "refractory to or who experience contraindication to an adequate course of 5-ASA and corticosteroids and other immunosuppressive therapy"[42]. It is not defined how long the patient must have been on conventional therapies before declaring that they have continuing symptoms, or how minor these continuing symptoms may be before considering adding TNFB therapy. It is not clear whether patient preference represents a "contraindication" to an adequate course of conventional therapy.

The mean percentage of loss of response to ADA among primary responders was 18.2% and the annual risk was 20.3% per patient-year. The mean percentage of patients who required dose intensification among primary responders to ADA was 37% and the annual risk was 24.8% per patient-year. When considering initial responders and patients with primary non-response, the mean percentage of patients who needed an ADA dose escalation was 21.4% and the annual risk was 24.4% per patient-year. Pooled analysis showed that dose escalation permitted response to be regained in 71.4% and remission in 39.9% of patients. Predictors for loss of response or dose escalation were male gender, current/former smoker status, family history of inflammatory bowel disease, isolated colonic disease, extra-intestinal manifestations, 80/40 mg induction therapy, longer disease duration, greater baseline Crohn's Disease Activity Index (Table 9), concomitant corticosteroid use, no deep remission at week 12, low serum trough concentrations of ADA, previous IFX non-response and being previously treated with an anti-tumor necrosis factor agent.

Certolizumab pegol

The Precise 2 trial with CER in CD over 26 wk showed clear superiority to placebo in terms of clinical response and remission[57].

Meta-analysis

There have been five systematic reviews and meta-analyses published on the efficacy of TNFB in inducing remission of active luminal CD[3,58-61], as well as Cochrane review of the efficacy of natalizumab in the same clini-

Table 10 Meta-analysis of efficacy and safety of anti-tumor necrosis factor α antibodies *vs* placebo (4 wk to 12 wk) in inducing remission in active luminal Crohn's disease

Treatment	Outcome (RR of remission not achieving)
All biological *vs* PL	RR = 0.87; 95%CI: 0.80-0.94; NNT = 8 (95%CI: 6-17)
IFX *vs* PL[1]	RR = 0.68; 95%CI: 0.52-0.90, I^2 = 78%, P = 0.01; NNT = 4 (95%CI: 3-7)
ADA *vs* PL	RR = 0.85; 95%CI: 0.79-0.91, I^2 = 0%, P = 0.99; NNT = 7 (95%CI: 5-12.5)
CER *vs* PL	RR = 0.95; 95%CI: 0.90-1.01, I^2 = 0%, P = 0.62
Natalizumab *vs* PL	RR = 0.88; 95%CI: 0.83-0.94, I^2 = 0%, P = 0.72
Adverse effects	
	No statistically significant difference in the incidence of adverse events was detected with TNFB *vs* placebo (RR of experiencing any adverse event, including infusion or injection site reactions = 0.99; 95%CI: 0.90-1.08 With anti-α4-integrin antibodies (natalizumab) *vs* PL, significantly more patients reported headache (compared with placebo: RR = 1.23; 95%CI: 1.03 to 1.47, I^2 = 0%) With NAT there were trends towards more infusion reactions (RR = 1.41; 95%CI: 0.94 to 2.10, I^2 = 0%) and infections (RR = 1.12; 95%CI: 0.97 to 1.30, I^2 = 0%) Number needed to harm with NAT = 17 (95%CI: 9-71)

Independent data extraction was undertaken by two reviewers, and discrepancies checked and resolved intention-to-treat. Analysis and pooled data with a random effects model was used, including the reporting of the search strategy, inclusion criteria, and data extraction processes. [1]Note that when the Sonic trail was excluded from analysis, there was no statistically significant difference between IFX *vs* placebo. RR: Risk ratio; IFX: Infliximab; ADA: Adalimumab; CER: Certolizumab; PL: Placebo; CI: Confidence interval; TNFB: Tumor necrosis factor-α blockers; NAT: Natalizumab; NNT: Needed to treat.

cal setting[62]. The most recent meta-analyses on the therapeutic management of IBD have appeared in the "Red Journal" (Table 10)[61]. Funnel plot asymmetry was considered regarding evidence of publication bias and small study effects, and Cochran Q values for heterogeneity. The criteria for inclusion of studies was stringent, using rigorous and conservative methodologies and these data should be used to better guide and care for patients suffering from CD and UC.

In summary, in persons with active luminal CD who have failed treatment with first and second-line agents or who are corticosteroid dependent, for induction of remission of active luminal CD, "IFX, natalizumab, and ADA appear to have the most evidence for their use, although the latter two therapies performed only moderately in this setting"[61].

Primary non-response

The clinical definition of primary non-response is lack of improvement of clinical signs and symptoms with induction therapy. Definitions and time-frames for the assessment of response and non-response have varied amongst clinical trials for different biological agents; in the original "Targan" study of IFX in refractory CD, response was defined as a 70-point reduction in the CDAI after 4 wk[52].

To a shift in the dominant mechanism of inflammation (loss of the pharmacodynamic effect), increasing symptoms or signs not related to IBD activity (for example, irritable bowel syndrome, concomitant infection, bacterial overgrowth, and so on), or failure to wean off corticosteroids. Loss of response can also imply.

A "relative" term for patients who have shorter durations of response (for example, less than 4 wk for IFX, 1 wk for ADA, or 2 wk for certolizumab) or require dose escalation, which may become economically impractical.

In the Accent I study of IFX, which assessed the maintenance benefits of IFX, the initial response was defined as a 70-point reduction in the CDAI at 2 wk[54]. Most clinicians will consider lack of response after two consecutive infusions of IFX of at least 5 mg/kg body weight and will assess treatment failure at 4 wk[50].

Recent data suggest that patients who initially respond may, more gradually, accrue remissions over time[55].

All three currently approved anti-TNFα biological agents are administered differently and have different pharmacokinetics and dosing intervals, and a reasonable assessment of lack of response to IFX would be after 2 wk, and to ADA and certolizumab pegol would be made after completion of induction therapy at 4 wk and 6 wk.

In approximate terms, 70% of IFX-treated CD patients show a response after 2 wk of treatment. In these primary responders, the secondary non-response rate (i.e.,

Table 11 Mechanisms which are speculated to be the cause of primary non-response

Lack of response may be due to different immunoinflammatory mechanism(s)[63]
A differential role of TNFα in certain stages of disease
Individual differences in drug metabolism and elimination, drug binding in serum or tissues based on disease activity level[27,148]
The presence of innate anti-TNFα antibodies that may exhibit greater neutralizing activity in non-responders[175]
Absence of inflammation accounting for clinical symptoms
Unidentified, genetic or pharmacogenetic or serological backgrounds of individual patients[24,176-179]
Individual differences in bioavailability and pharmacokinetics, leading to inadequate concentrations of a biologic secondary to immunogenicity (neutralizing or non-neutralizing antibodies, or unmeasured or unknown antibody) or other factors that increase drug clearance (decreased circulation half -life and possible high consumption in severe disease)[27,128]

TNFα: Tumor necrosis factor-α.

Table 12 Secondary failure rates

Maintenance of response month (%)	Loss of response (%)	Loss of response per month (%)
13 (64)	36	2.8
55 (63)	37	0.7
28 (78)	22	0.8

In another long-term maintenance study, the percentage of Crohn's disease patients who maintained response declined over time: 30 wk, 83%; 54 wk, 64%; 108 wk, 45%.

Table 13 Therapeutic options for tumor necrosis factor-α blockers secondary non-response

Continue the same TNFB, but use a higher dose at the same time interval
Continue the same TNFB and the same starting dose, but use a shorter interval between doses
Re-induction therapy with another TNFB
Use another therapeutic option (e.g., tacrolimus or cyclophosphamide)
Surgery

TNFBs: Tumor necrosis factor-α blockers.

those who initially respond, but then lose their response) is 40%-50% at 24-30 wk, and 60%-63% at 52-54 wk. At one year, about 30% of the initial responders will still be responding, and about 20% will be in remission.

About 30% of persons given TNFB therapy do not initially respond (primary non-response). The explanation of this is unknown, but it may be speculated that this may be done to the use of too low a dose of IFX (the serum through concentration of TNFB generally correlates with CD response), or the inflammatory process may be independent of TNFα. Of the initial primary non-response responders, about 70% respond and 35% go into remission. Including all persons with active CD, and taking into consideration the initial non-responders, out of 100 CD patients with active disease treated with TNFBs, approximately (100 × 70% = 70, 70 × 70% = 49) will respond and (70 × 30% = 21) will go into remission. These figures are lower than historically reported clinical response and remission rate with conventional (i.e., standard-of-care) management with GCS or, AZA/MTX, however it must be stressed again that because of large differences in study populations and study designs, the clinician must be very caution about accepting comparisons in anything other than direct head-to-lead studies.

There are numerous possible reasons for lack of response (Table 11)[63].

MAINTENANCE OF REMISSION AND SECONDARY FAILURES

Once the CD patient has gone into remission, we wish to prevent relapse. In CD, we lack benefit from 5-ASA/Sulfasalazine (SASP). Antibiotic maintenance has been shown to be significantly better than placebo, but there are insufficient studies for most clinicians to use long-term antibiotics as suppressive therapy. Few clinicians are sufficiently adapt at complex statistical methodology to understand the subtle aspects of whether to believe results reported as risk ratios (RRs) or odds ratio (ORs); immunosuppressives will likely continue to be used for maintenance therapy in CD, at least in the foreseeable future.

About 43% of patients with CD require GCS again within one year of starting GCS. The lifetime need to use GCS is 44%[64]. At 14 wk of use of full therapeutic doses of GCS for moderately active CD, 84% respond and 58% are in remission. At one year 32% are in remission, 28% are still on GCS (steroid-dependent), and 40% have required surgery. It may be speculated that the use of GCS may identify a group of patients who have more aggressive disease, and in whom immunosuppression or TNFB might need to be started early in the course of the disease[65]. AZA/MTX reduce steroid-dependence and maintain disease remission, but do not reduce the need for surgery[66].

Using meta-analysis, Akobeng[67,68] demonstrated that MTX, IFX, ADA, and CER were more effective than placebo for maintaining remission in CD, with number needed to treat (NNT) of 4-6. GCS, 5-ASA, budesonide, cyclosporine, antimicrobials and probiotics did not differ from placebo for maintaining remission at 6-24 mo. Enteral nutrition (EN) was more effective than no EN. Over 50% of CD patients become steroid-dependent or have a surgical resection within one year of starting GCS[64]. The monthly rate of loss of response to TNFB is higher in the shorter than in the longer durations of follow-up, ranging from 2.8% loss of response per month in a 13-mo study, to 0.7%-0.8% loss of response per month for 28- to 55-mo long study (Table 12).

Table 14 Therapeutic gain of infliximab for Crohn's disease maintenance of response and remission (%)

[1]Significant difference. PL: Placebo; IFX: Infliximab.

Those who have initially responded, but then subsequently relapse, are said to be secondary non-responders. In those persons who initially respond to TNFB, and then lose the benefit (CDAI increases, representing active disease; secondary non-response), there are several therapeutic options (Table 13).

IFX

Secondary failures to IFX may be as common as 48% in the first year of anti-TNF therapy, and 66% in the second year[69]. In secondary IFX non-responders, switching to ADA results in a response in 59%-83%, and remission in 29%-50%[70-72].

Secondary non-responders may respond to an increase in IFX dose, or a decrease in dosing interval, or both[73]. In secondary non-responders to IFX, 80%-90% responded to treatment intensification with IFX[54,74]. After two and a half years after an initial response to IFX, about half (54%) of patients require dose intensification[51,75]. Other studies have confirmed the use of dose escalation[76,77]. Dose acceleration helps maintain response: for luminal disease, 90%[74], for fistulising disease, 60%[78]. At 40 wk, 65% were still responding after the last dose intensification over 52 wk[72,73]. The therapeutic gain for IFX maintenance of remission was low, ranging from 14% to 33% at one year (Table 14).

In the Accent I Study[54], dose escalation was needed for persons who initially responded but then worsened at some time during the 54 wk study in 49% of persons on episodic treatment, 30% on 5 mg/kg IFX scheduled treatment, and 26% on 10 mg/kg scheduled treatments (secondary, non-response). Response was re-established with higher doses in 90% of the 5 mg/kg and 80% of the 10 mg/kg scheduled treatment groups treated with higher doses. Most of the cross-overs to higher doses occurred at week 14. In a 40 wk study, 83% of secondary IFX non-responders did respond after the first intensification of IFX, and 65% of patients were still responding after the last intensification dose.

Patients who lost their response to IFX were switched to ADA, and then continued with it for 52 wk. Secondary non-response to ADA was seen in 25%, and therefore, patients required a dose escalation[72]. These response rates are even higher in persons treated with ADA for the first time (i.e., IFX- and ADA-naive CD patients). Two RCTs and four observational and uncontrolled studies assessed the clinical effects of ADA after a loss of response or intolerance to IFX[51]. Re-induction therapy with ADA has a 60% clinical response[79]. Similarly, the Precise Ⅱ study[57] showed a benefit of reinduction in clinical response and remission of CD with CER in those patients who had received IFX in the past .

Long-term maintenance with IFX 3 mg/kg maintains mucosal integrity and avoids CD recurrence one year after surgery[80]. Another study evaluated endoscopic recurrence of CD post-operatively and found the rates to be lower with IFX at one year *vs* placebo (9.1% *vs* 85%)[81]. However, clinical remission was not significant (80% IFX *vs* 53.8% placebo, $P = 0.38$). A recent review of the literature also shows that there is statistical benefit with IFX use within 4 wk of surgery on mucosal healing. But this effect was not statistically significant in reduction of CDAI.

Adalimumab

There are two RCTs[55,56] and four observational and uncontrolled studies[70-72,82,83] assessing the clinical effects of ADA after a loss of response or intolerance to IFX. Blinded clinical trials show that ADA is effective first-line therapy for TNFB-naive CD patients, and is an option for IFX-refractory or-intolerant persons[84]. In the Gain study[55], secondary non-responders to IFX responded better when switched to ADA than when switched to placebo (IFX→ADA *vs* IFX→PL). In an uncontrolled open-label study, the switch from IFX to ADA (IFX→ADA) was associated at week 12 with a 59% clinical response and 29% remission rate[70]. A 50% or greater decrease in the number of draining fistulas was seen in 56%, while 33% had complete absence of fistula. In a second study[82], switching from IFX to ADA (IFX→ADA) gave a partial response in 31% and a complete response in 54%. In a single-arm study[72], 50% of IFX→ADA had a clinical remission at week 52. Four weeks after switching to ADA, 83% had a clinical response and 42% were in remission[72].

In the Crohn's trial of the fully human antibody adalimumab for remission maintenance (CHARM) study[56], there was no statistically significant response to ADA in IFX non-responders (IFX→ADA) or in those who were IFX-naive. When switching from IFX to ADA[56], the response at 26 and 56 wk in the TNFB-naive patients was 47% and 42%, compared to 32% and 31% in the non-responder group. Overall the ADA

[1]Significant difference; [2]40 mg at week 0, 20 mg at week 1; [3]80 mg at week 0, 40 mg at week 2. CDAI: Crohn's disease activity index; PL: Placebo; pts: Points; ADA: Adalimumab; CHARM: Crohn's trial of the fully human antibody adalimumab for remission maintenance.

treated group did better than the placebo group. The ADA group had a higher rate of staying free of steroids for > 90 d and achieved clinical remission at week 26 (19% for 40 mg every other weeks *vs* 15% for 40 mg every week *vs* 3% for placebo, $P < 0.001$). The therapeutic gain of ADA for maintenance of remission ranged from only 25% to 39% (Table 15).

The proportion of ADA-treated patients who required dose escalation and the results of treatment were reported in two RCTs and one small before-after study[51]. In secondary non-responders to ADA, 76% responded to dose escalation and 45% went into remission[55,72,85].

There is no data available to assess the effectiveness of using IFX for secondary non-responders of ADA. In the CHARM study[55], 46% of the persons randomized to receive ADA were secondary non-responders. Of those who received dose escalation of ADA, 76% had a no-point response rate and 45% went into clinical remission. In the Classic Ⅱ study[55] (following from the Classic I study), only 5% of patients who completed the 56 wk of treatment needed dose escalation.

Certolizumab pegol

In CD patients who responded to CER induction therapy (Precise 2), and then relapsed during continuous or interrupted maintenance therapy, recapture therapy with CER was provided. The response rates at week 4 were 63%-65%, and 55%-59% at 1 year (Precise 4)[86]. Using Certolizumab pegol maintenance therapy for persons

Table 16 Therapeutic gain of certolizumab Induction of response and remission (%)

[1]Significant difference; [2]The secondary failure rates for CRP were 72% at 26 wk (approximately 10% per month). Precise Ⅰ study (Pegylated Antibody Fragment Evaluation in Crohn's Disease: Safety and Efficacy Ⅰ). PL: Placebo; CRP: C-reactive protein; CER: Certolizumab; TG: Therapeutic gain.

with CD, there was clinically meaningful improvement with the Inflammatory Bowel Disease Questionnaire score (60% *vs* 40%, $P < 0.001$), Short Form 36-Hem Health Survey (SF-36) physical (51% *vs* 34%, $P < 0.001$) and mental component summary responses (44% *vs* 32%, $P = 0.016$), and the proportion of persons living a normal life (21.4% *vs* 12.4%, $P = 0.019$), (57% *vs* 35%, $P = 0.001$). The therapeutic gain of CER for maintenance of remission was at 28% at week 26 (Table 16), similar to the 24 wk and 30 wk result for IFX and ADA. The therapeutic gain of CER varied little between weeks 2 and 12, and with doses of CER 100 mg, 200 mg and 400 mg (Table 17).

In the Precise 2 trial, the 26 wk therapeutic gain in response rates of therapeutic gain with CER were lower in those who had first failed IFX, than in those starting CER and never previously having been on IFX (19% *vs* 29%)[87]. This was also the case with IFX in the Precise 2 study: the response in the IFX-naive group was 69%, compared with 44% ($P < 0.001$) in the non-naive group. Thus, there may be benefit switching from IFX to ADA in the IFX-failure patient. In patients who were treated with IFX and experienced secondary failure, and then were treated with open-label CER, 62% enjoyed a response and 39% remission rate at week 6[88]. When extended to 26 wk, the response and remission rates were 40% and 37%, respectively. CER also improved work productivity during the induction and maintenance components of the Precise study[89].

Also from the Precise 2 study, 58 CD patients with draining fistulas (mostly perianal fistula) who responded initially to CER were continued on CER or placebo[90]. At week 26, 36% on CER had fistula obscure compared with 17% receiving placebo (TG, 19%). Using the definition of ≥ 50% closure at two consecutive post-baseline visits ≥ 3 wk apart, there was only a trend for achieving this end point (54% *vs* 43%, $P = 0.069$).

Table 17 Therapeutic gain of varying doses of certolizumab

Week	Response				Therapeutic gain		
	PL	CER (mg)			CER (mg)		
		100	200	400	100	200	400
2	18	33	19	28	15	1	10
4	19	37[1]	26	33	18[1]	7	11
6	18	36[1]	31	39[1]	18[1]	13	21[1]

[1]Significant difference. PL: Placebo; CER: Certolizumab.

Table 18 Meta-analysis of efficacy and safety of biological therapies (26 wk to 60 wk) *vs* placebo in preventing relapse of disease activity in quiescent luminal Crohn's disease

Treatment	Outcome (RR in preventing relapse)
IFX, ADA, CER	RR = 0.71 (95%CI: 0.65-0.76, I^2 = 5%, P = 0.38); NNT = 4 (95%CI: 3-5)
IFX, CER	Superior to PL
ADA	No statistically significant difference between ADA *vs* PL in preventing relapse
NAT (only one trial)	RR = 0.71; 95%CI: 0.61-0.84
Adverse events	
Any event	RR = 0.93; 95%CI: 0.84–1.03
Infusion or injection site reactions	RR = 0.64; 95%CI: 0.06-6.66; (note that these reactions were actually fewer in those on anti-TNFα therapy, but the difference was not statistically significant)

PL: Placebo; CER: Certolizumab; IFX: Infliximab; ADA: Adalimumab; TNF: Tumor necrosis factor; RR: Risk ratio; CI: Confidence interval; NAT: Natalizumab.

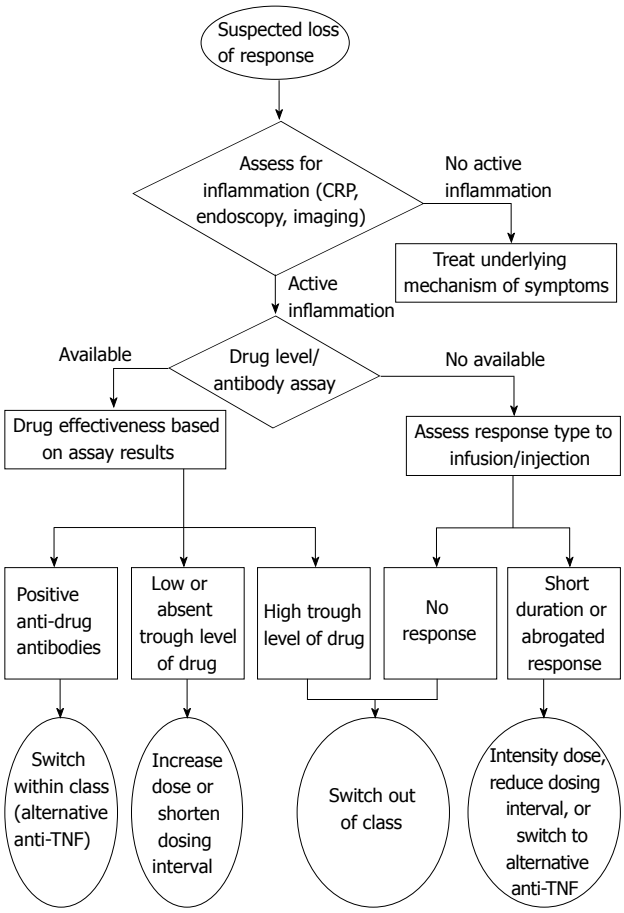

Figure 2 Suggested clinical approach to loss of response to anti-tumor necrosis factor-α therapy. CRP: C-reactive protein; TNF: Tumor necrosis factor.

The maintenance response rate was inversely related to the duration of the patient's history of CD: maintenance of response to CER was present in 90% of patients with a CD diagnosis less than one year, compared with 57% continued response in those with a CD diagnosis ⩾ 5 years[91]. Corresponding remission rates were 68% *vs* 44%. This suggests that there may be improved efficacy of TNFB maintenance therapy when initiated "early" as compared "late" in the history of the patient's disease[92].

Meta-analysis

The results of the most recent vigorous meta-analysis of biological therapies in preventing relapse of disease activity in quiescent luminal CD is shown in Table 18. These authors suggest that the most marked effect of biological therapies was in preventing relapse of luminal CD once remission had been achieved, with a NNT of only 4. This benefit was observes for both IFX and certolizumab, but not for adalimumab[61].

Secondary non-response

About a third of patients treated with anti-TNFα therapy, who meet the criteria for an initial clinical response, eventually lose response, with the magnitude depending on the duration of follow-up on maintenance therapy. Loss of response, also referred to as secondary non-response, is defined as recurrence of disease activity during maintenance therapy after achieving an appropriate induction response. In maintenance trials with IFX and ADA, significant percentages of patients required increased doses (IFX) and or decreased treatment intervals (adalimumab) in order to restore response after interval symptoms developed between dosing[54,56,78,93]. Even after scheduled maintenance therapy and dose adjustments, substantial numbers of patients will still have a poor response[44]. Of the initial responders, 65% need dose escalation, which appears to be successful in approximately 70%, and the probability for dose escalation throughout time is approximately 80% at 120 wk[94].

From the Figure 1, it is apparent that approximately 10% (56%/5 years.) of patients treated with TNFB lose their response each year. If patients who are doing well on IFX + AZA, and the IFX is stopped, 39% relapse within one year[95]. Persons who are likely to relapse when IFX is stopped are those with objective signs of continued inflammatory activity (↑CRP, Crohn's disease endoscopic index of severity ⩾ 2) or low IFX though level. Fortunately, almost all (> 95%) of those who recurred when IFX was stopped respond to IFX retreatment. Presumably a greater proportion relapse as this

interval is followed out beyond one year; it is unknown if those longer term relapsers will continue to have such a favorable response to retreatment with the originally successful TNFB.

How is this loss of response to TNFB managed? A useful suggested clinical approach to loss of response to TNFB therapy has been published (Figure 2). First determine if the patients symptoms might be due to something other than active CA. For example, exclude enteric infection (including *Clostridium difficile*) or small intestinal bacterial overgrowth, bile salt wastage, or adverse reaction to other drugs. What are the options if the CD is active[96]? The initially chosen TNFB is increased in dose, decreased in dosing interval, or both! If there is no response, switch to another TNFB[96].

Suggested clinical approach to loss of response to TNFB (Figure 2), to quote the approach suggested by Yanai *et al*[63]: (1) Confirm that intestinal inflammation is the cause of the "loss of response"; (2) Measure IFX levels at 4 wk after an infusion (therapeutic $\geqslant$ 12 μg/mL); (3) Measure antibodies to IFX (ATI) measurements not available for ADA or CER. The Mayo Clinic group has demonstrated the utility of combining IFX levels and determination of ATI in the clinical management of patients who lose response to IFX[97]; (4) "Patients who lose response to a first agent are more likely to lose response to a second and, similarly, those with toxicity to a first agent are more likely to develop toxicity from a second anti-TNFα agent. This diminishing outcome may, in part, be due to a class effect"; (5) "Patients who lose response to IFX associated with anti-IFX antibodies respond well to switching to adalimumab or certolizumab pegol"; (6) "In the majority of patients, response can be restored by dose and interval adjustments"[44,94]; (7) "Switching between biologics is an important strategy for patients who lose response because of immunogenicity followed by rapid drug clearance or when a significant alternative pathogenic role is suspected. Switching can be within class or with an alternative class"; and (8) "Efficacy of successive agents is decreased compared with the primary agent".

In this situation where there has developed secondary failure, 75% to 78% regain a durable response after dose intensification[73,98,99]. It is recognized that over time after a surgical resection "cure", most CD patients recur endoscopically, and fewer recur symptomatically. In the study by Regueiro *et al*[81], the endoscopic recurrence rate of 85% was reduced to 9% with continued IFX treatment.

TERTIARY FAILURES

If two TNFBs fail, there may be value in switching to a third TNFB[100], with 6 wk response seen in 58%. This, however, needs to be supported by further data[101]. In a European prospective cohort study of 67 adult CD patients who either lost response or developed intolerance to two TNFBs (usually IFX and ADA), treatment with a third TNFB resulted in a 6-wk response and remission rate of 61% and 22%, respectively[100]. "Concomitant therapy with corticosteroids or immunosuppressants order of anti-TNF administration, and prior history of response (i.e., primary non-response, secondary loss response or intolerance) to anti-TNFs did not affect patient's response to the third anti-TNF".

Table 19 Comparative efficacy of infliximab, adalimumab and certolizumab (%)

Induction	Response[1]	Remission[2]		Therapeutic gain
		TNFBs	PL	
Accent I	58	39	21	18
CHARM	58	46	17	29
Precise 2	64	48	29	19

[1]Weeks 2 to 6; [2]Weeks 26 to 30. Remission is often defined by the Crohn's disease activity index, but may also be defined using the Inflammatory Bowel Disease Questionnaire. PL: Placebo; TNFBs: Tumor necrosis factor-α blockers; CHARM: Crohn's trial of the fully human antibody adalimumab for remission maintenance.

The NNT for induction of remission was 9. In maintenance studies, when initial non-responders were excluded, NNT was 4 among responders, but NNT was 9 when including both responders and non-responders[3]. Peyrin-Biroulet *et al*[3] performed a meta-analysis of 14 placebo-controlled trials enrolling 3995 CD patients, of TNFB efficacy and safety in CD. The TNFBs included IFX, ADA, CER, ETA. Quoting directly from their report, "In overall analysis, anti-TNF therapy was effective for induction of remission at week 4 (mean difference, 11%; 95%CI: 6%-16%, $P < 0.001$) and maintenance of remission at weeks 20-30 in patients who responded to induction therapy and in patients randomized before induction (mean difference, 23%; 95%CI: 18%-28% and mean difference, 8%; 95%CI: 3%-12%, respectively; $P < 0.001$, for all comparisons)".

In adult CD patients who either lost response or became intolerant of two TNFBs given at optimal doses, when switched to a third TNFB, 22% achieved full remission and 51% continuing a clinical response to week 20[100].

How long to use TNFB

How long to treat with TNFB? Five observational studies have shown the response to IFX or ADA ranges from 73% to 100% at year one, 65% to 90% at year two, 61% to 68% at year three, and 52% to 58% at year five[102-105]. RCT data is not available yet for more than one year. Clear evidence based guidelines have not been developed as to when to stop TNF therapy, but reasonable empirical suggestions would be with loss of response or severe adverse effects to TNFB. Perhaps after one year TNFB treatment, when the patient is in clinical remission, there are no signs of active inflammation, and perhaps when mucosal healing is achieved, stopping TNFB therapy may be considered and discussed with the patient.

Comparative efficacy of IFX, ADA and CER

There are no head-to-head trials of one TNFB against another. There is heterogeneity in the CD patients recruited for the clinical studies, but interestingly the therapeutic gain for remission at weeks 26 to 30 were close to 18% to 23% (Table 19). It is unfortunate that these rates are so low.

Patient-reported outcome (PRO) instruments are used to provide information about health-related quality of life. The minimal clinically important difference (MCID) and minimal important difference (MID). PRO score changes have been determined from two TNFB clinical trials[106]. The MCID is the smallest difference in a PRO score that is associated with a clinically relevant difference or change[1,107]. The MID is the smallest difference in a PRO score that a patient can perceive as beneficial and would require a change in their treatment. The MCID and MID units are meaningful measures to assess alterations in PRO scores, rather than changes which albeit are statistically significant, are not necessarily useful in a practical sense.

When considering possible advantages of different TNFB, for example, ADA *vs* IFX, ADA has greater ease of administration (subcutaneous, self-administered *vs* infusion facility), no infusion reactions, higher remission rates among secondary non-responders to IFX[72,108], possibly reduced need for dose escalation over time [fewer secondary failures[109], higher later rates of response and remission (maintenance), lower cost [$ incremental cost-utility ratios (ICUR) per quality-adjusted life-year (QALY)][51], and lower risk of developing neutralizing antibodies. Again it must be stressed that there is no head-to-head direct data to allow for a definitive statement to be made about any comparison, including cost and patient preference. These conclusions are based on observations.

In contrast, the possible advantages of IFX *vs* ADA include no injection site reactions or infections, fewer numbers of individual adverse effects, higher early rates (induction) of response and remission, and high rate of fistula improvement or remission with both short- and long-term therapy. IFX also gave higher initial response and remission rates as compared to ADA. Comparatively, the use of ADA led to lower relapse rates, indicating that patients retained longer benefit from ADA *vs* IFX[51].

Continuation of immunosuppression with TNFB therapy

Most guidelines suggest that TNFB therapy be started when immunosuppression alone has failed. The used of TNFB plus immunosuppression is known as concomitant immunosuppression (CI). To understand the subtle aspects of the question about CI use with TNFBs in CD, we need to reflect upon several important studies.

Scheduled maintenance IFX treatment is more effective than episodic treatment (Accent I)[74]; Scheduled maintenance therapy is superior to episodic treatment in terms of the use of steroids or the use of hospitalization and surgery[44]. IFX induction plus azathioprine/6-mercaptopurine (6-MP) is more effective than azathioprine/6-MP alone in AZA-naive patients who are steroid-dependent (GETAID)[53]. Early treatment with IFX in combination with an antimetabolite is more effective than conventional therapy (step-up top-down)[110]. IFX plus azathioprine is significantly better for inducing steroid-free remission and mucosal healing than azathioprine alone in azathioprine-naive patients [study of biologic and immunomodulator naive patients in Crohn's disease (SONIC)][102]. In initial IFX responders, the maintenance of response falls from 83% at 30 wk, to 64% at 54 wk, and to 45% at 108 wk[111].

Table 20 Concurrent immunosuppression with azathioprine plus infliximab *vs* azathioprine alone in Crohn's disease[53] (%)

	Week		
	12	24	52
AZA	38	29	22
AZA + IFX x3	75[1]	57[1]	40
Therapeutic gain	37[1]	28[1]	18

[1]Significant difference. AZA: Azathioprine; IFX: Infliximab.

Scheduled maintenance IFX is more effective than episodic treatment[74]. The standard of care is to use TNFB on a regular and scheduled basis. The benefit of scheduled *vs* episodic use of IFX is related to there being lower levels of antibodies to IFX (ATI), fewer infusion reactions, and fewer hospitalizations and major surgery[54,112,113]. IFX induction plus AZA/6-MP is more effective than AZA/6-MP alone in AZA-naive patients who are steroid-dependent[53]. Early treatment with IFX in combination with an immunosuppressant is more effective than conventional therapy[110]. IFX plus AZA is significantly better for inducing steroid-free remission and mucosal healing, than is AZA alone in AZA-naive patients[114].

There is no additional benefit of adding MTX in the steroid-treated CD patient who is also on IFX[115]. It remains unknown if the continuation of MTX might be useful if the person were just on MTX + TNFB, rather than just being on GCS.

Most current guidelines recommend that AZA/MTX must have been used and be considered to have failed before TNFBs are introduced what should be. The duration of previous use of this immunosuppression and should AZA be continued TNFB once has been started is not known. Some data suggested that continuation of AZA after the introduction of IFX offers no additional benefit beyond 6 mo of combined therapy, as long as the TNFB is used on the basis of a regular schedule, rather than being given episodically. The authors of one trial suggested that "continuation of immunosuppression for more than 6 mo offers no clear benefit over scheduled IFX monotherapy"[116]. IFX monotherapy is superior to IFX plus immunosuppressive therapy after CD induction with IFX. In one study, four times more relapses occur with AZA maintenance after IFX induc-

tion, as compared with IFX induction and placebo maintenance[53]. In a second study, maintenance of remission of CD was no different when AZA plus IFX were given for maintenance, *vs* IFX alone[117].

In the study by Van Assche *et al*[116], at 6 mo in person on IFX in whom AZA had been withdrawn (IFX plus AZA D/C *vs* IFX + AZA), the CRP levels were higher, and IFX levels were significantly lower. Perhaps if the patients had been followed for longer than 6 mo, the AZA discontinuation group might have begun to experience more recurrences. The RAND appropriateness methodology, through a modified Delphi panel approach based on expert interpretation of the available literature, has been used with a "globally diverse panel of 13 gastroenterologists clinically experienced in inflammatory bowel disease"[118]. Using a total of 134 clinical scenarios, concomitant use of immunomodulatory was generally rated inappropriate for young males, and in some scenarios involving uncomplicated disease. However, CI were appropriate for those with extensive disease, shorter duration of disease, perianal involvement, prior surgery, females, and older patients (> 26 years)". In the GETAID study, the IFX + AZA (CI) gave a significant therapeutic gain of clinical remission off steroids, as compared with AZA alone, of 37% and 28% at weeks 12 and 24 respectively. But the benefit was lost at week 18 (Table 20).

Several important aspects to consider when attempting to answer the question of the benefit of using CI with IFX are the duration of follow up, whether the patient is naive to the immunosuppressants or the TNFB, whether the activity of the disease is high as suggested by an elevated surrogate marker such as CRP or mucosal lesions, what is using an endpoint of immunogeneity (such as antibody to TNFB or a disease activity index or QoL score), and whether the question is focused on the CD patient in whom you are trying to achieve induction or maintenance of remission. CI is clearly beneficial when added to IFX regimens which are episodic[112,119], but the controversy about CI comes from studies using regularly scheduled TNFB, the method which is new to the standard of care.

In the SONIC study, CD patients who were naive to both immunosuppression and to TNFB, the rate of clinical remission at week 26 was higher in those given IFX + AZA as compared with IFX alone or AZA alone (57%, 44%, and 31%, respectively)[120]. In a subgroup of patients who initially had both an elevated CRP and mucosal lesions at baseline, the IFX plus AZA + IFX alone values were even higher (69% and 57%, respectively). Since the difference between IFX + AZA was statistically greater than IFX alone, the data may be interpreted to indicate that CI is advisable, at least in the relatively short period of 26 wk, for steroid-free remission. However, the benefit of CI appears to fades after 6 mo to 12 mo[116,121].

In the infliximab maintenance immunosuppression discontinuation study (Van Assche), in CD patients who had been on AZA/MTX before starting IFX, stopping the immunosuppression at 6 mo did not have an adverse effect at 2 years to shorten the interval between IFX infusions, or the time to stopping IFX dosing. The prevalence of antibodies to IFX were similarly low in each group, and CI with IFX + AZA had no different effect in terms of mucosal healing.

The same message comes from the 2-year long COMMIT trial of steroid-requiring CD patients on IFX or IFX + MTX (Feagan 2010): CI does not provide a medium term (2-year) advantage. On the other hand, CI may increase the risk of adverse effects such as non-Hodgkin's lymphoma in adults[122], hepatosplenic lymphomas in children[123], as well as other concerns in children[124]. As well, CI did not benefit the medium term risk of surgery[125]. These individual studies suggest that in many CD patients, CI is "bridge" therapy for 6 mo while the full effect of TNFB is being achieved.

In an observational serial observation of 88 CD patients in remission and on IFX, half had their CI with AZA stopped. The IFX failure free status was 85% at 12 mo, and 41% at 24 mo and 32 mo[126]. This failure rate of IFX maintenance may have been due to the withdrawal of CI with AZA. Failure of CI on AZA-withdrawal was more likely to occur if the initial duration of IFX-AZA therapy was less than 27 mo, if the CRP was greater than 5 mg/L or the platelet count higher than 298 109/L. Until further data becomes available, we can be encouraged by "expert opinion" from the BRIDGE group analysis[118], suggesting that bridging CI may not be necessary such as in young males especially with limited disease, or some case scenarios including uncomplicated CD.

CI[127]treatment also reduces antibody to IFX (ATI) formation [24% *vs* 63%, on CI *vs* not on CI, $P = 0.007$; 43% *vs* 75%, $P < 0.01$]. Former researchers have proposed a time-structural treatment algorithm for moderate CD. This may of course need to be altered in future if "top down" (IFX→AZA→GCS) approaches to CD are shown to be beneficial.

The major role of CI may be in the patient who is on episodic IFX: in these persons, the incidence of ATI was 0% on CI *vs* 60%, not on CI, $P = 0.018$[128]. Comparatively, CI had no relationship on ATIs with scheduled IFX infusions. Combined immunomodulator with TNFB provides small therapeutic gain for 24 wk. Then, it is likely that CI can be abandoned without any detrimental effect of clinical response, and possibly a lower risk of adverse events. In fair balance for the issue of AZA discontinuation in the TNFB-treated patient, the "jury is still out", or as the Scots would say, the case is "not prove". Clearly, more data is needed.

In summary of Combination therapy: (1) In AZA and TNFB naive persons, with ↑ CRP or mucosal lesions on colonoscopy, remission and one year mucosal healing response to combination therapy (SONIC) A AZA = TNFB; (2) Unknown what to do after one year: for IFX alone after successful induction, maintenance for 54 wk gave a therapeutic gain of (28%-14%) 14% and 24% (38%-14%) for 5 mg/kg and 10 mg/kg IFX (Ac-

Table 21 Infliximab for fistulizing Crohn's disease: Induction and maintenance (%)

Study	Week of assessment	Outcome	IFX (mg/kg)		PL	TG
			5	10		
Present *et al*[75]	18	Response	68[1]	56[1]	26	42-30

[1]40 mg at week 0, 20 mg at week 2; [2]80 mg at week 0, 40 mg at week 2; [3]160 mg at week 0, 80 mg at week 2. ADA: Adalimumab; PL: Placebo; TG: Therapeutic gain.

cent Ⅰ). It is unknown what is best to do after one year treatment with IFX; (3) In post hoc analysis of combination therapy of immunomodulators plus IFX/ADA/certolizumab pegol (CZP) *vs* monotherapy with TNFB, there is no benefit in terms of induction synergy; (4) Because of study design, it is not possible to comment whether MTX plus TNFB is superior to TNFB alone; and (5) Not possible yet to predict which patient can be induced with TNFB and maintained on AZA (TNFB as a "bridge").

FISTULIZING DISEASE

Because between 20% to 40% of CD patients will develop fistulas[75,129], and because of the seriousness of perianal fistulas[78,129,130], the improved healing of fistulizing CD with TNFB would be anticipated to reduce the patient's lifetime need for major surgery. The presence of fistulas increases the risk of the need for colectomy[69,82]. Anti-TNF therapy is indicated for use in fistulizing CD. What is the evidence for IFX or ADA in this clinical setting? In the IFX infusion study by Present *et al*[75], IFX was given at 0 wk, 2 wk and 6 wk, and fistula response and complete closure of draining fistulas were assessed at 18 wk. As compared with placebo, IFX 5 mg/kg and 10 mg/kg gave 18-wk fistula response rates of 68% (P = 0.002) and 56% (P = 0.02) *vs* 26%, respectively. The corresponding closure rates were 55% (P = 0.001), 38% (P = 0.040), and 13% at 18 wk. For the 5 mg/kg dose of IFX for fistulising CD, this gave a therapeutic gain of 42% for both fistula response and closure.

Table 23 Adalimumab for fistulizing Crohn's disease maintenance (%)

Study	Assessment week	Combined ADA group[1]	PL	TG
CHARM	Closure			
	26	30	13	17
	56	33	13	20

[1]Statistically significant. Note that the two higher dose regimes of ADA do poorly for induction of fistulizing CD. The TG for IFX and ADA for fistula closure at 54-56 wk is a similar low value of 17%. PL: Placebo; TG: Therapeutic gain; ADA: Adalimumab; CHARM: Crohn's trial of the fully human antibody adalimumab for remission maintenance; IFX: Infliximab; CD: Crohn's disease. 140 mg q0w and 40 mg qw.

Table 24 Meta-analysis of efficacy and safety of biological therapies *vs* placebo (4 wk to 26 wk) in healing of fistulizing Crohn's disease

Treatment	Outcome (RR of fistulas remaining unhealed)
IFX, ADA, CER *vs* PL (4 wk to 26 wk)	RR = 0.88; 95%CI: 0.73-1.05; I^2 = 67%, P = 0.01 (considerable heterogeneity between studies, with no statistically significant difference in fistula healing at 4 wk to 26 wk, compared to placebo, when considering the 3 TNFB)
IFX *vs* PL (one trial)	RR = 0.62; 95%CI: 0.48-0.81
IFX, ADA, CER *vs* PL (excluding 2 trials reporting fistula healing up to only 4 wk)	RR = 0.80; 95%CI: 0.65-0.98; I^2 = 56%, P = 0.08 (heterogeneity between studies remained)
IFX (only 1 trial) *vs* > PL (followed until 54 wk)	RR = 0.81; 95%CI: 0.68-0.96

Adverse events could not be determined from data. CER: Certolizumab; IFX: Infliximab; ADA: Adalimumab; PL: Placebo; RR: Risk ratio; TNFB: TNF-α blockers; CI: Confidence interval.

In the IFX maintenance study by Sands *et al*[130] (Accent Ⅱ), IFX was infused every 8 wk until week 54. As compared with placebo, IFX 5 mg/kg gave 54 wk response rates of 46% *vs* 23% (P = 0.001); and the complete closure rates were 36% *vs* 19% (P = 0.009). This gave a 54 wk therapeutic gain of 23% and 17% for response and closure, respectively. Note the need to caution your CD patient with fistulizing CD: while early TG for response and closure was an encouraging 42%, at one year half this benefit was lost (falling to 23% and 17% at 54 wk)[75,78,129].

The TG in fistula response and closure for IFX (5 mg/kg) at 19 wk was 42% and 42%, respectively, with curiously lower rates of response for the 10 mg/kg IFX dose. At 54 wk, the TG for fistula response and closure was 23% and 17%, respectively. These are low values, but clearly IFX is of considerable benefit to individual patients who may have failed conventional therapy.

The 4-wk fistula response and closure rates for ADA (160 mg at week 0 and 80 mg at week 2) was not statistically different from placebo, but at weeks 26 and 56, the TGs were 17% and 20%, respectively. In the CHARM study, complete healing of fistulas was achieved in 30%

of those receiving ADA either weekly or every other week by week 26. This compared to 13% in the placebo group (P = 0.043). Recall that with fistulizing CD, the early response and closure with IFX was statistically significant, but was not so with ADA. At one year, the fistula response and closure rates were numerically similar for IFX and ADA, but the TGs were small for both TNFBs (Tables 21-23). Therefore, at this time, it is best to use IFX as 1st line to treat fistulising disease. There is insufficient data to recommend the same for CER. Meta-analyses have been performed for biological therapies in healing fistulising CD (Table 24). These authors suggested that "In preventing recrudescence of fistula, there was only one RCT reporting on this end point, which demonstrated that IFX was superior to placebo (Table 24). Although concerns about adverse events arising from the long-term use of these drugs are understandable, the data from the RCTs included in this meta-analysis did not demonstrate any increase in overall adverse events, or serious adverse events, with use for up to 1 year[61]."

In summary of the use of TNFB in fistulising CD "…. there is less evidence for the use of biological therapies, though there was a clear beneficial effect when only IFX was studied, although in one trial, and when only RCTs with follow-up in excess of 4 wk were considered in the analysis. There was also a benefit in favour of biological therapies over placebo when only studies that reported fistula healing in the longer term were included in the analysis."

THERAPEUTIC GAINS

Induction and maintenance, response and remission

At 2 wk and 4 wk after a single dose of IFX (5 mg/kg), the therapeutic gain (TG; IFX response minus the PL response) for clinical response was 56% and 64%, respectively (Table 7), and then fell to 36% at 12 wk[52]. The TG for remission was 36% and 46%, respectively, for weeks 2 and 4. When IFX (5 mg/kg) is given 2, 6 and every 8 wk until week 48[54] or 54[69,82], the week 54 TG for response ranged from 22%[54] to 30%[69,82], and for remission, the TG was 14% for IFX 5 mg/kg and 24% for 10 mg/kg. IFX doses of 10 mg/kg or 20 mg/kg did not give higher therapeutic gains in terms of response.

Thus, after excluding the approximately 30% initial IFX primary non-responders, about the two-thirds will respond and about one-third will go into remission at 4 wk (therapeutic gain). With continued 8-weekly IFX infusion for approximately one year, the TG for response is about one in four, and for remission one in eight. These represent relatively small gains which are not necessarily higher than reported historical figures for conventional therapy induction or maintenance therapy in CD. In children with CD, Kaplan-Meier analysis has shown that the cumulative probability of losing response to IFX after 1 year, 3 years and 5 years is 13%, 40% and 50%[131]. In adults with CD who chose to stop their IFX after achieving remission, 50% relapsed within 477 d after IFX discontinuation[132].

For the currently recommended dose of ADA of 160 mg at weeks 0 and 80 mg at week 2, TGs for response range from 15% to 19% at week 2, and 13% to 25% at week 4 (Sandborn *et al*[93]). The corresponding TGs for remission at 2 wk and 4 wk range from 10% and 14%-24%. The TGs for response at 56 wk range from 7%-25% when ADA is given as 40 mg q every other week, to 15%-33% when ADA is given as 40 mg q weekly[55,56,85,127,133]. The corresponding values for TG for remission at 56 wk range from a low of 4% to a high of 39%[55,56,85,127,133]. The values for the initial TGs in response and remission for induction therapy are numerically slightly lower for ADA; it is slightly higher for ADA for maintenance of response and remission. After two years of maintenance therapy with ADA every other week, 42% were in remission compared to 38% on placebo[134], and 50% with weekly ADA. This study also showed an improvement in IBD QoL questionnaires, suggesting clinical response. There is insufficient evidence at this time to recommend one type of ADA therapy over another.

In addition to therapeutic gains in terms of response and remission rates, other important clinical outcomes include improvements in quality of life, hospitalization and surgery. In patients with RA, combinations of TNFB with low-dose MTX are generally more efficacious than either drug used alone[135], the mechanism of anti-inflammatory properties of this combination is not totally clarified and it is not known if TNFB plus MTX have a synergistic mechanism[136], especially in CD.

Health utilization

Hospitalization: In Canada, about 20% of persons with CD have IBD-associated hospitalizations per year[2]. The proportion of patients who needed hospitalization for IBD were reported in three IFX trials and one ADA trial. Two IFX trials and one ADA trial reported the patients who needed surgery[51]. Overall, CD patients who received IFX maintenance therapy had an approximately 50% reduction in the rate and duration of hospitalization[74,129]. Lower hospitalization rates were also seen with ADA[93]. Infusing IFX on a scheduled *vs* an episodic basis reduces the rate of all-cause hospitalization, as well as IBD-related hospitalization. For example, in Accent I [74,137], the rate of IBD-related hospitalization was 28% in the episodic treatment group *vs* 23% in the IFX 5 mg/kg group (P = 0.047) and 24% in the 10 mg/kg group (P = 0.023). Furthermore, the number and duration of hospitalizations were lower in the scheduled *vs* episodic group (P = 0.018). In Accent II[129], the hospitalization rates were lower with IFX than placebo (14% *vs* 31%, $P < 0.01$), and 11% *vs* 33% in the initial IFX responders *vs* placebo ($P < 0.05$). Also, the mean duration of days in hospital was less with IFX *vs* placebo (0.5 d *vs* 2.5 d, $P < 0.05$).

ers, hospitalizations were higher in the IFX cohort until 18-24 mo after the first IFX prescription, at which point the rate of hospitalization in the IFX group fell to the level of the CD patients treated with AZA or GCS[138]. The likelihood of surgery was similar in IFX and GCS, which was higher than in AZA; even at 3 years post-closing. Overall physician visits were similar between IFX, GCS and AZA. Interestingly, ADA reduced hospitalization rates at 12 mo from 14% with placebo *vs* 10% and 3% with maintenance ADA given every other week and every week ($P = 0.12$ and $P < 0.01$, respectively)[115]. Hospitalizations account for more than 50% of the direct costs of CD[115]. Thus, in responders, TNFB reduced the rate of hospitalization, and this reduction in hospital days carries a major economic impact, which has to be countered against the high cost of maintenance TNFB requiring long-term use of drug, and the cost of management of adverse effects.

Surgery

CD-related surgery was more likely in the episodic *vs* the scheduled treatment groups (9% *vs* 3%, $P = 0.01$)[74], and the mean number of surgeries was higher (118 *vs* 60, $P < 0.01$). As compared with the placebo group, the mean number of surgeries in the IFX group was 13 *vs* 2 per

Table 27 Meta-analysis of efficacy and safety of biological therapies *vs* placebo in inducing remission in moderately to severely active ulcerative colitis[61]

Treatment	Outcome (RR of remission not being achieved)
IFX *vs* PL	RR = 0.72; 95%CI: 0.57-0.91 NNT = 4 (95%CI: 3-8)
Adverse event	
Any adverse event was no higher in IFX *vs* PL, and risk of serious adverse events was lower	RR of serious adverse event = 0.64; 95%CI: 0.41-1.00, $P = 0.05$ NNH = 13 (95%CI: 8-50)

100 in all patients, and from 11 to 11 per 100 in the IFX initial responders[78]. With ADA maintenance, the 12-mo risk of major surgeries was 0.6% *vs* 3.8% in the placebo group ($P = 0.0005$)[115]. Data to date shows that TNFB reduce serious health utilization in persons with IBD.

TNFBS AND THE NATURAL HISTORY OF CD

It is not yet certain whether TNFB will achieve disease modification, or sustained mucosal healing[139]. CD is very heterogenic, and we need much more data on the possibility of patient risk-stratification based on environmental factors, disease phenotype, genotype and disease-initiating and-perpetuating factors (Table 25)[140].

A brief consideration of the use of TNFB in ulcerative colitis

There are many differences between CD and UC (Table 26). Only for purposes of comparison, a very brief overview is provided on IFX use in persons with UC, bearing in mind that these are separate and distinct conditions. About 20% of UC patients on 5-ASA maintenance therapy will have an acute attack each year, and about 10% of those with more severe symptoms will require hospitalization, usually for intravenous (IV) steroid therapy, cyclosporine or TNFB therapy; or surgery. About a third of these will not respond to IV steroids, and may be candidates for colectomy, cyclosporine or IFX.

In the Accent I and 2 studies, approximately half as many of those in the combined IFX group than placebo-treated UC patients required surgery (74% *vs* 8%), and the number of hospitalizations were also lower (18/102 patients *vs* 9/102 patients, $P < 0.01$)[74,115,129]. The colectomy rate in the placebo group is also approximately twice as high as in the IFX group: at 90 d, 67% *vs* 29% ($P = 0.017$)[141], and at 2 years, 76% *vs* 46% ($P < 0.05$)[142]. When IV GCS fail in patients with severe UC admitted to hospital for IFX[143], colectomy rates were as follows: in hospital colectomy, 24%; later colectomy, 14%; no colectomy, 62%. It is not clear how many will eventually require colectomy, whether they will need to

Table 28 Associations of mucosal healing in Crohn's disease

Fewer symptoms	
No previous surgery	
Previous surgery	
Less inflammation at 5 yr requiring steroid use	
Less use of steroids	
Steroid-free remission and no flare at years 3 and 4	Yes (TG, 44%)
Steroid-free remission, no flare and no TNFB at years 3 and 4	Yes (TG, 44%)
No new or persistently active fistulas	No

How do these associations with mucosal healing (MH) in CD compare with UC? About 90% of patients remain asymptomatic after achieving MH on once-a-day 5-aminosalicylic acid (Mezavant®), and after MH, 40% of UC patients remain asymptomatic (TG, 22%). TG: Therapeutic gain; CD: Crohn's disease; UC: Ulcerative colitis; TNFB: Tumor necrosis factor-α blockers (response in active treatment group minus response in placebo group; differences statistically significant).

Table 29 Rates of therapy-associated mucosal healing

Drug	CD		UC	
	Week[1]	MH, %	Week[1]	MH, %

[1]Time for endoscopic assessment of mucosal healing. CD: Crohn's disease; UC: Ulcerative colitis; MH: Mucosal healing; 5-ASA: 5-Aminosalicylic acid; AZA: Azathioprine; MTX: Methotrexate; IFX: Infliximab; ADA: Adalimumab; CER: Certolizumab.

be maintained long-term on IFX, or if they should simply be maintained on AZA or 5-ASA.

Primary non-response has been noted in 22% of UC patients treated with IFX[126]. IFX dose optimization was required in 45%, and colectomy was required in 19%. In a single-centre, prospective out-patient cohort of UC patients, response to induction therapy with IFX was 96% and 80% for ADA[144]. For maintenance therapy response to IFX and ADA, the rates were 78% and 70%. None of these differences was statistically significant.

Recent meta-analysis has considered the efficacy and safety of biological therapies in inducing remission in moderately to severely active UC (Table 27)[61].

The summary points are as follows: (1) No data on the efficacy and safety of biological therapies *vs* placebo in preventing relapse of disease activity in quiescent UC; (2) "IFX was highly effective in inducing remission in patients with moderate to severely active UC who had failed therapy with first and second-line agents, and who had also failed to respond to a course of high-dose corticosteroids, with a NNT of only 4[61]"; (3) IFX for rescue therapy in severe UC, with a therapeutic gain of (71%-33%) 38% (NNT, 3); (4) IFX will induce and maintain clinical remission and mucosal healing in treatment–refractory, moderate/severe UC; (5)Unknown if

[1]Extend: Open-label adalimumab[182]. Of patients with CMH at week 12, 46% of ADA every other weeks had CMH at week 52 *vs* 0% CMH in those receiving only ADA induction. ITT: Intention-to-treat; PP: Per protocol; TG: Therapeutic gain; PL: Placebo; ADA: Adalimumab.

IFX plus AZA is superior to monotherapy with AZA or IFX; (6) Before starting IFX in UC, discuss options of AZA, cyclosporine A (Cy A), and pan proctocolectomy with ileoanal pouch procedure; (7) Unknown comparison of Cy A *vs* TNFB for rescue therapy; (8) Short term: young age, absent pANCA (in CD, presence of pANCA, ASCA, or pANCA + ASCA had no predictive valve); and (9) Long-term (predictors for no colectomy): short term clinical response to CRP < 5 mg/L, no previous treatment with IV steroids or Cy A.

Importance of mucosal healing

There are a number of potential advantages in achieving mucosal healing in CD (Table 28). In both CD and UC, the rates of mucosal healing range widely depending upon the therapeutic agent and the duration of treatment (Table 29).

In clinical trials, there has been no uniform standard for defining mucosal healing (MH), no agreed-upon optimal time for assessing MH. It is not surprising then that the ranges of MH are very wide.

The clinical trials of agents used to treat IBD have used a variety of clinical scores heavily based on symptoms (CDAI), measures of QoL, appearance of the mucosa on diagnostic imaging, endoscopic appearance, or histopathology. Some patients with CD treated with TNFB achieved MH and the question was raised whether MH by itself, independent of patient's symptoms or QoL, was an important outcome variable. MH would be an important outcome if it were to be shown that it was associated with reduced risk of recurrence (i.e., greater likelihood of maintenance of remission), reduced risk of extraintestinal complications, reduced risk of medical treatment-associated complications, long-term risk of hospitalization, surgery or development of colorectal cancer. The risk of development of stricture or fistula in CD increases over time[46,145], so maintaining mucosal healing may decrease these problems. However, there is no evidence to answer the above asked questions.

It seems self-evident that MH should become an outcome objective of therapy in IBD. However, this needs to be proven. Because the prevalence of MH may decline over time, and the number of the week of study repeating MH varied widely, it is not possible to assert which class of drug has the highest rate of MH (Table 29), nor is it plau-

Table 31 Meta-analysis efficacy of 5-aminosalicylic acid/sulfasalazine to induce remission or to prevent relapse in Crohn's disease

	Induce remission (RR of not being in remission) on active therapy	Prevent relapse (RR of relapse)
CD	SASP (only 2 RCTs) 0.83 (95%CI: 0.69-1.00; trend) 5-ASA 0.91 (95%CI: 0.77-1.06; not significant)	SASP/5-ASA, ITT analysis, no benefit 5-ASA, PP analysis: RR = 0.79 (95%CI: 0.66-0.95; NNT = 13 to prevent relapse)
UC	0.79 (95%CI: 0.73-0.85; NNT = 6)	0.65 (95%CI: 0.55-0.76; NNT = 4 to prevent relapse)

CD: Crohn's disease; ITT: Intention-to-treat; PP: Per protocol; SASP: Sulfasalazine; 5-ASA: 5-Aminosalicylic acid; CI: Confidence interval; UC: Ulcerative colitis; NNT: Needed to treat; RR: Relative risk; RCT: Randomized controlled trial.

sible to compare IFX with ADA or CER. In an open-label study of ADA in which there was a "placebo" (3 doses of ADA for induction), the therapeutic gain in the 12 wk complete mucosal healing (CMH) was 14% in the intention-to-treat analysis (ITT) and 15% in the per-protocol analysis, with 52 wk ITT CMH of 24% (Table 30).

When and how to start TNFB therapy: Start early, vs follow the current guidelines

This question may also be considered as "step-up" *vs* "start high". When considering a comparison in outcomes from a management approach starting early with biological therapy in the patients' lifelong CD course, *vs* the standard of care of step-up therapy, we must reflect the strength of the evidence supporting each of the components of the traditional approach in CD of using 5-ASA products, antibodies, GCS, and the immune suppressants AZA and MTX. The excellent systematic reviews and meta-analyses in the "Red Journal"[61] are very helpful in this regard, and will be reviewed briefly here to demonstrate the potential limitations of the currently accepted standard of care.

5-aminosalicylates therapy: In contrast to the supportive data in UC for the use of 5-ASA to induce remission and to prevent relapse, the data for CD is poor (Table 31)[61]. Thus, for the usually accepted ITT analyses, neither SASP nor 5-ASA can any longer be recommended in persons with CD to induce or maintain remission.

Antibiotic therapy: There is diversity in the design of antibiotic studies in IBD, including which antibiotic, as well as dose and duration of therapy. The antibiotics often used in clinical practice for this indication were metronidazole, cipro', and rifaximin (not yet available in Canada). While taking into account these events, it may surprise some readers that antibiotics are superior to placebo for the induction and maintenance of remission in CD, as well as induction of remission UC (Table 32)[146].

Glucocorticosteroid therapy: Standard GCS remains

Table 32 Efficacy of various antibiotics to induce remission or to prevent relapse in Crohn's disease

		Induce remission (RR of not remission) on active therapy	Prevent relapse (RR of relapse)
CD	Inflammatory disease	0.85 (95%CI: 0.73-0.99, P = 0.03)	0.62 (95%CI: 0.46-0.84)
	Perianal fistula	0.80 (95%CI: 0.66-0.98)	
UC		0.64 (95%CI: 0.43-0.96)	

UC: Ulcerative colitis; CD: Crohn's disease; CI: Confidence interval; RR: Risk ratio.

the standard for inducing remission in moderate-to-severe UC, but must never be used for maintenance of disease because of its lack of efficacy and its high adverse effects risk profile. While the trials of GCS in active CD individually showed efficacy because of heterogeneity between studies (I^2 = 88%, P = 0.004) and the small size of the studies. When the risk difference was used as the summary statistic, the treatment effect became significant, with NNT = 3 (95%CI: 2-11)[61]. Furthermore, systematic review and meta-analysis showed that standard GCS were superior to the locally acting budesonide in achieving remission in active CD (RR = 0.82; 95%CI: 0.68-0.98); oral budesonide itself was superior to placebo for CD remission (RR = 0.73; 95%CI: 0.63-0.84). Oral budesonide used for up to one year delays the time to recurrence of active CD.

Adverse effects of GCS therapy in the setting of treating active CD could not be determined in the studies of Ghosh *et al*[34] and Summers *et al* Standard GCS-related adverse effects were more frequent than with budesonide (RR = 1.64; 95%CI: 1.34-2.00). Thus, GCS and budesonide will continue to be used for short term treatment of active CD, and the choice between standard GCS *vs* budesonide must be made on the trade-off of efficacy, adverse effects and cost.

Immunosuppressive therapy: The meta-analysis of the use of Immunosuppressants in CD was disappointing; example (Table 33), the relative risk of not being in remission for active CD was not different from placebo. However, if OR was used rather than RRs as the summary statistic, then the result was significant, using a random effects model (OR = 0.42; 95%CI: 0.2-0.89). While some clinicians would accept significant ORs of AZA/6-MP/MTX *vs* placebo as reason to use immunosuppression to induce remission of active disease, the onset of biological benefit takes 2-3 mo. While many gastroenterologists use AZA/6-MP/MTX to prevent relapse in CD, this is likely based on the evidence of individual trials or previous meta-analysis. Surprising to some, while immunosuppressant therapy in UC was not significantly superior to placebo to induce remission, azathioprine was efficacious to prevent relapse (Table 33).

In summary then of the standard step-up approach to the care of patients with CD, in the treatment of active disease to achieve remission, the step using 5-ASA/

Table 33 Meta-analysis of efficacy of immunosuppressive therapy to induce remission or to prevent relapse in Crohn's disease and ulcerative colitis

		Induce remission (RR of not being in remission on active therapy)	Prevent relapse (RR of relapse)
CD	AZA/6-MP *vs* placebo/no therapy	0.87 (95%CI: 0.71-1.06)	0.64 (95%CI: 0.34-1.23)
		If OR was used rather than RRs as the summary statistic, then "the result was significant, using a random effects model (OR = 0.42; 95%CI: 0.2-0.89)	There was no statistically significant benefit for continuing AZA to prevent CD relapse (RR = 0.39; 95%CI: 0.21-0.74)
	MTX *vs* placebo	0.82 (95%CI: 0.65-1.03), no statistically significant benefit	IM MTX: 0.57 (95%CI: 0.35-0.94); NNT = 4 (95%CI: 2-25) to prevent one relapse
		If or used, then the result was statistically significant: OR = 0.47; 95%CI: 0.23-0.99	PO MTX to facilitate steroid withdrawal: 0.82 (95%CI: 0.58-1.17)
	Cyclosporine *vs* placebo (only one trial)	0.84 (95%CI: 0.62-1.07; tacrolimus, one study, no improvement: RR = 0.64; 95%CI: 0.44-0.92)	0.96 (95%CI: 0.77-1.20)
UC	AZA *vs* placebo	0.85 (95%CI: 0.71-0.01, *P* = 0.07)	0.60 (95%CI: 0.37-0.95, *P* = 0.03); NNT = 4, 95%CI: 2-10)
	MTX *vs* placebo	0.59 (95%CI: 0.04-7.90)	

UC: Ulcerative colitis; AZA: Azathioprine; MTX: Methotrexate; RR: Risk ratio; OR: Odds ratio; NNT: Needed to treat; CI: Confidence interval; IM: Intramuscular; PO: Oral; CD: Crohn's disease; 6-MP: 6-mercaptopurine.

Table 34 Benefits of mucosal healing in Crohn's disease[183]

Positive: IBSEN, Step-up/top-down, SONIC
IBSEN (Froslie): 5-yr longitudinal study of IBD patients not on TNFB and enjoying mucosal healing
CD: ↓ Inflammation, ↓ Future use of steroids
UC: ↓ Risk of future colectomy
Negative: Music

IBSEN: The inflammatory bowel south-eastern Norway (study group of gastroenterologists); SONIC: Study of biologic and immunomodulator naive patients in Crohn's disease; TNFB: Tumor necrosis factor-α blockers; IBD: Inflammatory bowel disease; CD: Crohn's disease; UC: Ulcerative colitis.

Table 35 SONIC (Crohn's disease diagnosed within 4 years) %

Conventional step-up (steroids→AZA→IFX)	Step-down (IFX x3, with AZA)		
2 yr	30	73	(43)
3-4 yr			
No flare, no steroids, on demand IFX	about 65	about 20	(about 45)
No flare, no steroids, no TNFB	about 60	about 15	(about 45)
New or persistent fistulas	about 2	about 22	(about 20)

IFX: Infliximab; AZA: Azathioprine; TNFB: Tumor necrosis factor-α blockers.

SASP should be removed; the antibiotic and GCS/budesonide steps remain, and the AZA/6-MP/MTX step is rather shaky and quite slow.

In the end, we may believe that early use of biologics is too aggressive a step, which needs to be shored up by more data, but we need to acknowledge that the standard step-up approach is not as good as we used to accept.

The presence of two mutant nucleotide-binding oligomerization domain-containing protein 2 (NOD2) alleles may be quite specific for future complicated disease. Although the sensitivity is poor and the area under the sROC curve is poor, the high degree of specificity may be sufficient to recommend testing for double mutations if we can identify therapies that can truly change the outcomes for this high-risk stratum of patients. Testing for double mutations would likely miss many patients with aggressive disease. However, the presence of double mutations, particularly mutations in P.Leu1007fsX1008, does identify a high risk stratum of reagent-grade patients that should be identified and analyzed as a distinct subgroup in clinical trials. If prospective trials can show a change in outcomes in these patients, this would be a strong justification for targeted top-down therapy in this group of high-risk patients to prevent stricturing or fistulising complications.

The other major finding of this meta-analysis is the lack of prognostic value of the presence of one mutant allele for predicting CD behaviour. Although we specifically studied NOD2 mutations, recent genome-wide association studies have identified numerous other genes that contribute to the susceptibility of developing CD. It is likely that the level at which genetics contributes to phenotypic disease expression is complex and multiple risk alleles contribute to complex interactions. Further studies addressing disease behaviour will likely require large-scale, multicenter trials to obtain sufficient clinical data to accurately ascertain the cumulative risk from clinical, genetic, and environmental factors. Once additional predictive factors are identified and validated, we will be better able to study targeted therapies in high-risk patients.

In a prospective extension of a patient cohort study of 133 newly-diagnosed CD patients recruited from 18 European Centres, half of the patients were initially treated with as "top-down", and the other half as step up[147]. In the 46 persons who had endoscopically proven mucosal healing at two years, ileocolonoscopies were continued at year three and four. The results can be interpreted as being either for or against mucosal healing as an important therapeutic outcome: complete mucosal healing at year two was associated with a greater proportion of steroid-free clinical remissions (71% *vs* 27%, respectively; *P* = 0.036). While MH may be associated with

Table 36 Sonic naive (no azathioprine, no tumor necrosis factor-α blockers) %

	Clinical remission, off steroids		
	AZA	IFX	AZA + IFX
26 wk	30	44	57
50 wk	24	35	46
	17	30	44[1]

[1]AZA + IFX *vs* IFX (P = 0.55) or *vs* AZA ($P \leq 0.001$). IFX: Infliximab; AZA: Azathioprine.

later steroid-free remission, it is not clear if this correlates with fewer adverse effects, or better outcomes such as QoL, hospitalizations or surgery. There are studies in which the support for the benefit of MH is positive, or negative (Table 34). The case remains "unproven" about the long-term importance of mucosal healing rather than symptom relief as the major end point of treatment of CD.

In accordance with recommendations from current guidelines, the TNFBs are usually initiated in the CD patient who has failed the "step up" approach of sequential use of GCS, ASA/MTX. Initial clinical trials of TNFB were designed to take this conventional sequence into account, and to use TNFB as "add-on" therapy. The terms "step-up, step-down" "top-down" and "fast forward" all related to the concept of whether CD patients will do better in the long-term if using TNFBs earlier *vs* relatively later after the diagnosis of CD, in an attempt to possibly alter the course of the disease and to thereby improve patient outcomes.

Is the response to TNFBs greater when used early in the history of the person's CD? Is there benefit of starting recently diagnosed CD patients on IFX or IFX+AZA immediately, i.e., "top down" *vs* the "step-up" of GCS→AZA/MTX→TNFB? In the open label trial of D'Haens *et al*[110], newly diagnosed CD patients were treated either with AZA + IFX, or conventional therapy with GCS, followed by AZA, and then followed by IFX (GCS→AZA→IFX). With the early use of AZA + IFX with GCS (top-down), at week 26 and 52 the proportion who were steroid-free and who had not undergone IBD-related surgery was 60% and 62%, respectively. In the step up group, the corresponding figures were lower at 36% (P = 0.006) and 42%, respectively. Although the top down group achieved remission faster than did the GCS-AZA-IFX group (P = 0.018), at 53 wk a similar percent of patients in each group were in remission (Table 35).

What then is the influence of confounders such as CD duration, or being TNFB- or AZA/MTX naives? In a post-hoc analysis of the use of ADA in the Charm study[57], after adjustment for potential confounders, disease duration had an effect on clinical remission (RR: 0.96, 95%CI: 0.94, P = 0.002). In the Sonic study (REMICADE), patients with CD who had not previously received treatment with anti-TNFBs or immunomodulators (anti-TNF naive as well as anti-AZA/MTX naive) were randomized to IFX, AZA, or IFX + AZA. At 26 wk, the steroid-free remission rate was higher with IFX monotherapy (P = 0.022) or AZA monotherapy (P = 0.009) groups (Table 36).

When IFX was used within one year of the diagnosis of CD, 78% of the early treatment group responded and 76% were in remission, as compared to 47% and 37% (P < 0.001 and P = 0.002, respectively)[51]. This suggests that earlier use of TNFB may be better when looked from the perspective of this relatively short term follow-up. But of course, those persons started earlier on TNFBs might possibly have more total adverse events (AEs), because of their potentially longer duration of total exposure to drug.

Clearly, current guidelines must be respected. More data is necessary, but it looks promising that the early use of TNFBs (or AZA) may provide outcome advantages. If this possibility becomes evidence based, then guidelines and clinical practice will need to change appropriately.

ADVERSE EFFECTS

Anti-IFX antibodies

In some CD patients who develop secondary non-response to TNFB, this may be due to the development of neutralizing antibodies, what proportion of patients on IFX or ADA develop antibodies to IFX (ATIs), or antibodies to ADA [antibodies to adalimumab (ATAs)]? In patients given scheduled IFX 5 mg/kg, 10%-16% develop ATI, whereas ATA occur in 0.04%-2.60%. Infusion reactions with IFX are more common if there are ATI (36%-50% with, and 21%-24% without ATI). Concurrent immunosuppressant (CI) therapy reduces ATI (63%-75% with concurrent AZA/MTX, *vs* 24%-43% with no concurrent AZA/MTX). This beneficial effect of concurrent immunosuppressant on the rate of development of ATI or ATA is most pronounced with episodic rather than with the scheduled use of IFN. This is because the development of ATIs is greater with episodic than with scheduled infusion of 5 mg/kg or 10 mg/kg IFX: 30%, 10%, and 7%, respectively (P < 0.001)[113]; 39% episodic *vs* 16% scheduled (P = 0.036)[128].

The presence of ATI/ATA is of clinical importance. In fact, there is a negative correlation between the concentration of ATIs and the duration of response to IFX (P < 0.001)[112]. Furthermore, the median ATI concentration was 15-fold higher in those with loss of response to IFX than in those who maintained response (P < 0.0001)[148].

The development of ATAs is uncommon: in Classic Ⅰ, the rate of ATA formation at week 4 was 0.04%[149]. In Classic Ⅱ, 2.6% showed ATA[55]. The presence of ATA is also clinically important: there is a significant relationship between the presence of ATAs and non-response to ADA (OR = 12.7, 95%CI: 1.7-92.6, P = 0.05)[83].

Protection against the development of ATIs may be achieved with intravenous hydrocortisone premedication given immediately before each IFX infusion, with lower

Table 37 Adverse effects for infliximab and adalimumab[1]

	IFX	ADA
All AEs	-	-
Serious AEs	-6.6	-4.7[2]
Nausea	+7.9[3]	+2.4
Pharyngitis	+16.1	+3.7[2]
Injection site infection	-	+3.8[2]
Injection site reaction	-	+10.5[2]
Arthralgias	-	+4.3[2]
Urinary tract infections	-	+3.5[2]

[1]The rates are shown as the percentage differences in the rates of AEs in tumor necrosis factor-α blocker minus placebo groups. AEs are shown, with the increased (+) or decreased (-) difference from placebo. Note that the duration of follow-up observation varied between study, and has not been standardized here (e.g., per 100 treatment years); [2]The statistically significant or trends: (1) Note that the rates of all AEs as well as serious AEs were lower than in the placebo groups; and (2) Serious AEs include lymphoma and other cancers; [3]Significant difference. IFX: Infliximab; ADA: Adalimumab; AEs: Adverse effects.

median levels of ATI[150]. However, in this study, even though ATIs were lower, the use of hydrocortisone did not affect the rate of infusion reactions or increase clinical response. As noted previously, the major role of concurrent immunosuppression with maintenance TNFB may be when TNFB is not given in the recommended scheduled manner. Therefore, due to higher rate of ATI with episodic treatment, it is not a recommended route of therapy.

Other adverse effects

When considering the safety of TNFB, it is important to consider whether the TNFB was given with immunosuppressants or steroids, and for how long therapy was undertaken. In one study, steroid use in persons on IFX were the only independent risk factor for infections [or 2.69 (95%CI: 1.18-6.12, $P = 0.018$)][151]. The overall rate of AEs in IFX-treated patients is about 13%[77,111,151,152], which is not statistically significantly different from the 19% AE rate quoted for non-IFX treated patients [OR = 1.33 (95%CI: 0.56-3.00, $P = 0.45$)][151].

In a case-controlled family practice, population-based retrospective study of 15 471 IBD patients followed for an average of 6.4 years, AZA did not increase the risk for solid organ cancer development (OR = 1.04, 95%CI: 0.89-1.21), but the risk of lymphoma was enhanced 3.22-fold[153]. If myelosuppression occurs with AZA in naive CD patients, it does so in the first 6 wk of AZA therapy[154].

AE data has been collected from 10 TNFB randomized controlled trials in IBD [(five IFX[45,52-54,69], four ADA[55,56,85,93] and one with etanercept[31]). More AEs (serious AEs, pharyngitis, urinary tract infection, injection site reaction or infection)] were reported with ADA *vs* placebo than IFX *vs* placebo (Table 37). From four ADA placebo-controlled trials[54-56,93], there was no difference between ADA and placebo in the percentage of persons with overall AEs (77% *vs* 80%, $P = 0.145$). AEs that were more common in the ADA than the placebo group were pharyngitis (10% *vs* 6%, $P = 0.047$), injection site infection (4.9% *vs* 1.1%, $P = 0.005$), injection site reaction (22% *vs* 12%, $P = 0.003$), arthralgia (10.4% *vs* 6.1%, $P = 0.014$) and urinary tract infection (5.0% *vs* 1.5%, $P = 0.017$) (Table 37). Curiously, ADA had significantly fewer serious AEs than did placebo (6% *vs* 10%, $P < 0.001$), and the placebo group from one study had numerically more AEs than another placebo group (11% *vs* 18%, $P = 0.065$).

The medium-term safety of TNFB has been reviewed: In 21 studies enrolling 5356 CD patients, TNFBs did not increase the risk of serious infection malignancy or death[3]. However, as cautioned by these authors, "definitive conclusions cannot be drawn because of methodological limitations (safety analyses satisfied by concomitant therapy were not performed in the individual studies". Fortunately, not all trials reported death as an outcome. In ACCENT I [54], with IFX 5 mg/kg, two patients unfortunately died from sepsis and one from a myocardial infection.

The most common AEs with CER were upper respiratory tract infection (20%), urinary tract infection (7%) and arthralgia (6%)[155]. From five IFX placebo-controlled trials[52-54,78,156], there was no difference between IFX and placebo in the percentage of persons with overall AEs (93% *vs* 95%, $P = 0.355$). The absolute serious AE was 7% higher in IFX *vs* the placebo groups (24% *vs* 17%, $P = 0.019$), and only sinusitis was reported more frequently in UC given IFX *vs* placebo (9% *vs* 5%, $P = 0.04$). Concomitant immunosuppression with maintenance IFX does not significantly extend the duration of clinical response[111]. Nausea was the only AE which was more frequent in IFX than placebo (15% *vs* 7%, $P < 0.031$), with a higher trend for pharyngitis (18.9% *vs* 2.8%, $P = 0.056$). Importantly, the increased role of infections in CD or in CD patients on IFX may be from their concomitant use of GCS[129,151].

Life-threatening side effects occur in 2%-5% of persons on IFX, with twice the rate of sepsis, myelotoxicity or risk of lymphoma as those on thiopurines[157]. However, IFX has been used by approximately one million persons worldwide. As a class, the main complications of TNFBs are infections, lymphoproliferative disorders and malignancy[158]. As well, neurological, dermatological, autoimmune and cardiac complications commonly occur with these agents (Table 37). Deaths have been reported in persons using TNFB. The risk of sepsis, malignancies and myelosuppression is higher if AZA/MTX is given with TNFB. For example[159], the risk of opportunistic infections is increased with TNFB (OR = 4.4), and is increased much more if two or more immunosuppressants and used (OR = 12.9).

It is recommended that the complete blood count (CBC) be performed at 1 wk, 2 wk, 3 wk, 4 wk, 6 wk and 8 wk after starting AZA therapy, and then to continue a monthly CBC thereafter. During the first 8 wk of AZA therapy, the risk of leucopenia (white blood cell, $< 1.0 \times 10^9$/L), neutropenia (platelet-neutrophil complexes, $< 1.0 \times 10^9$/L), and thrombocytopenia (platelet count, $< 20 \times 10^9$/L) were 0.3%, 1.0% and 0.2%, respectively[154]. For

treatment intervals of greater than 26 wk, these hematological risks were 0.2%, 1.1% and 0.1%.

IBD patients, including those on GCS and AZA/MTX, have an increased risk of TB (RR = 2.36, 95%CI: 1.17-4.74). TB reactivation is an accepted risk of TNFBs, with the RR for reactivation 2-20 times that of the general population[160,161]. In high-risk areas, IBD patients who are scheduled to be placed on TNFBs must be screened for histoplasmosis and coccidiomycosis[162].

Some authors suggest that CD itself, in the absence of the use of AZA/MTX/TNFB, does not have an increased risk for the development of lymphoma[163]. Others would argue that CD itself does carry a small increased risk. However, these drugs used to treat CD certainly are associated with as much as a 4-fold increased risk of the development of lymphoma[157]. And yet, in the Treat registry of IBD patients, the incidence of malignancies was 0.53 per 100 patient years in the IFX group and 0.49 in the non-IFX group[164]. A small number of adolescents with CD on IFX and thiopurines have been reported as developing hepatosplenic T-cell lymphoma[165]. This consensus is that the concurrent use of both AZA/MTX plus TNFB should not be used in non-adults.

ECONOMIC EVALUATION

Within the context of an economic evaluation, there are several special considerations: (1) Safety (immunizations complete, no TB, no personal/ or family history or demyelation disorders; (2) Perhaps early after the diagnosis of IBD has been made; (3) Perhaps in those with predictors of likely response to TNFB; (4) About 1/3 of persons treated with IFX, ADA and CZP will have a primary failure; (5) Use same TNFB in higher dose or same dose more frequently or, switch to another TNFB; (6) With a secondary failure, the initial response to another TNFB is lower; and (7) Exclude concurrent infection/abscess as a reason for "failed" effect on luminal inflammation.

Anti-TNF therapy is expensive. While there are reductions in all areas of disease-related resource use following IFX therapy, in the United Kingdom, this was not sufficient to cover the cost of TNFB therapy[166]. Future studies of these pharmacoeconomic issues will also need to include considerations on indirect cost-savings and changes in the quality of life[167]. A cost-utility analysis was determines as a part of the CADTH report, giving cost per QALY. The cost of usual standard of care (SOC) was $17 107, that for ADA was $45 480, and for IFX $54 084. The QALY for SOC was 2.555, and the value for ADA and IFX were only slightly higher at 2.701 and 2.721, respectively. This resulted in ICUR of $193 305 and $222 955 for ADA and IFX, respectively. When comparing IFX with ADA for the ICUR efficiency using a five-year time horizon, the values were $193 305 *vs* $451 165. These cost efficiencies of IFX *vs* ADA were not so much due to variations in the values of their QALY, but rather to higher initial remission and response rates with IFX including with fistulizing CD, lower relapse rates with ADA, and higher remission rates amongst the patients who stopped responding to initial IFX and were switched to ADA[72,108]. It is important to stress that this comment is based on very preliminary data. From an economic perspective, it is preferential to switch an IFX non-responder to ADA, rather to increase the dose from 5 mg/kg to 10 mg/kg. There is insufficient evidence of the use of treating an IFX non-responder to a reduced dose interval. Also, the lower rates of hospitalization and need for IBD-related surgery in the TNFB groups was partly offset by the higher drug costs. The true economic impacts of SOC *vs* TNFBs will depend upon longer term data.

For interest, the cost of usual care for UC patients was $24 268 and the QALY was 2.015. For a strategy of IFX 5 mg/kg every 8 wk for maintenance, and for those who do not respond to IFX or lose the initial benefit, the patient is switched to ADA. This escalated the cost to $82 756 and is associated with a very small increase in QALY from 2.015 to 2.178. For an incremental QALY of 0.163, the ICUR was an astounding $308 088. In contrast, an economic evaluation in the United Kingdom gave a more favourable ICUR for IFX of about $70 000 (using the 2008 currency exchange rate). While there are other economic evaluations of TNFB[168-170], the CADTH study is the first to compare the initiation and maintenance therapy costs of IFX and ADA. The authors of the CADTH review suggested, with regards to the economics of the use of TNFBs, that "...the incremental cost-effectiveness in managing this IBD patient population may not be perceived as favourable for anti-TNFα drugs compared with usual care without these drugs. This finding was supported by deterministic sensitivity analysis and probabilistic sensitivity analysis".

Over the past four years (2006 to 2010), and based on acceptable incidence and prevalence estimates of CD and UC[2], the number of IBD patients has risen by about 5% (1% per year), yet between 2006 to 2008, the annualized increases in public spending on IFX and ADA in IBD have risen 25% and 18%, respectively. There is no evidence that over the past five years there has been a marked increase in the number of IBD sufferers who have suddenly developed severe or non-responsive disease. This 5-fold greater use in TNFBs as compared with the increase in the number of sufferers may reflect the wider dissemination and acceptance of TNFB guidelines, or may be the result of inappropriate over usage.

The economic analysis of the health services impact suggest that "…Adalimumab and IFX for the treatment of IBD may not be perceived to be a cost-effective use of health care resources"[51]. There are no head-to-head trials comparing standard-of-care *vs* anti-TNF therapy. What do TNFBs add to the annual cost of care of every IBD patient in Canada? "Based on trends in expenditures over the past three years, total public expenditures on anti-TNFs for IBD are projected to be $94 832 652 in fiscal year 2010-2011. The estimated annual drug costs for IBD patients who are on maintenance therapy with

Head-to-head trials comparing the effectiveness of IFX, ADA, and CER peg with conventional therapy in refractory CD (other than newly diagnosed and treatment naive patients)
Long-term safety
Evidence for efficacy of switch from ADA → IFX for ADA secondary loss of response
Optimal therapy for anti-TNF therapy primary non-responders
The comparison of standard-of-care *vs* anti-TNF therapy for maintenance therapy in UC
Are physicians correctly distinguishing mild from moderate or severe CD?
What is the profile of the patient who is most likely to respond? Are they genotypic or phenotypic characteristics?
When is the optimal time in the course of the patient's illness to begin anti-TNF therapy?

TNF: Tumor necrosis factor; CD: Crohn's disease; AZA: Azathioprine; MTX: Methotrexate; IFX: Infliximab; ADA: Adalimumab; CER: Certolizumab; UC: Ulcerative colitis.

anti-TNF drugs vary from $23 000 to $38 000[159]. Similar benefits of IFX on rate of hospitalization, surgery and procedures were described in the Accent I and II trails[54,164].

This reduction in health serious utilization could be partially offset by the high cost of biologics, so that cost effectiveness and cost-utility analysis are necessary. A UK cost utility analysis reported that maintenance treatment with IFX every 8 wk was cost-effective for patients with luminal and fistula CD[171]. For example, for luminal CD, an incremental cost per QALY gained for IFX was £26 128 (using the exchange rate at the time of publication of this paper, this equates to approximately $70 000 Cdn). However, the use of QALY for the measurement of cost-effectiveness is of questionable value for diseases such as IBD, which have a young patient base and low mortality rate but high morbidity[167]. Also, indirect costs are high in persons with IBD: In Sweden or Scotland, about two thirds of the costs are indirect[172,173], and in the Accent I trial of IFX, about half the patients at baseline were not employed[54]. Because of this the result of studies of cost-effectiveness and cost-utility need to be challenged, since direct costs are often not taken into consideration[174].

To quote from the report of Canadian Agency of Drugs and Technologies in Health[51], "Using cost-utility analysis cost per QALY allows for the incorporation of quality-of-life impact of clinical effects of CD treatment strategies…" and "allow for comparison with evaluation of disease area that use this outcome." The incremental cost-utility ratio for ADA and IFX, compared with usual care, was $193 305 and $451 165, respectively[51]. "….IFX and ADA have proven clinical benefit when compared to placebo, the primary and secondary non-response rates are high, the therapeutic gain is small, and…"[51] the costs associated with these treatments could be perceived as high. Furthermore, based on incremental cost utility findings from our primary economic evaluations. Adalimumab and IFX for the treatment of IBD may not be perceived to be a cost effective use of health care resources"[51] (Table 38).

CONCLUSION

The results of these and the recent meta-analyses may differ because of ".... a less contemporaneous search data, the inclusion of non-FDA-approved therapies in the analysis, and different time points for data extraction, which were not the primary end points of the included trials"[61].

In persons with luminal CD who have failed treatment with first and second-line agents or who are corticosteroid dependent, for induction of remission of active luminal CD, "IFX, natalizumab, and adalimumab appear to have the most evidence for their use, although the latter two therapies performed only moderately in this setting"[61].

"The most marked effect of biological therapies was in preventing relapse of luminal CD once remission had been achieved, with a NNT of only 4. This benefit was observed for both IFX and certolizumab, but not for adalimumab"[61].

"In terms of fistulizing CD, there is less evidence for the use of biological therapies, though there was a clear beneficial effect when only IFX was studied, although in one trial, and when only RCTs with follow-up in excess of 4 wk were considered in the analysis. There was also a benefit in favour of biological therapies over placebo when only studies that reported fistula healing in the longer term were included in the analysis."

"In preventing recrudescence of fistula, there was only one RCT reporting on this end point, which demonstrated that IFX was superior to placebo. Although concerns about adverse events, arising from the long-term use of these drugs is understandable, the data from the RCTs included in this meta-analysis did not demonstrate any increase in overall adverse events, or serious adverse events, with use for up to 1 year."

"Clinical trials for the three anti-TNFα agents approved for CD or UC have used different end point criteria and response time, in addition to the different modes of administration. Interpretations of these differences and their overall clinical relevance remain contro-

versial."

"The efficacy of anti-TNFα is limited. A total of 20%-30% of patients with refractory CD and roughly 40% of patients with refractory UC do not respond to anti-TNFα treatment and are defined as primary failures."

"Long-term therapy with biologics is associated with significant loss of response (up to 40%)."

"TNFBs represent a major advancement in the management of carefully selected patients with IBD, such as those with active fistulizing CD and active CD not responding to adequate doses of steroids and/or immunosuppressants. It is important to give these agents for an adequate duration before declaring failure of treatment. The specific time period of use is unknown, but it includes side effects to any medications or failure to achieve remission of disease."

It must be appreciated that in most TNFB studies, there is a run-in interval, and the initially approximately 30% non-responsive patients may be excluded from the find reporting of response rates; the methodology for the statistical analysis of each study must be carefully considered.

There is insufficient current evidence to support "top-down" TNFB therapy (starting early in the course of the patient's disease with TNFBs rather than the SOC progression to steroids and immunosuppressants.

The use of mucosal healing as an endpoint of successful therapy, rather than clinical response, has not been proven.

The initial response rate of fistulizing CD for induction may be higher with IFX than ADA, but longer term maintenance with ADA may be superior to IFX.

There are wide ranges in the reported rates of minor or severe adverse effects in short-term users of TNFBs. The increased risk of serious infection, lymphoma and cervical dysplasia may be as much related to the concurrent use of immunosuppressants (AZA/MTX) with TNFBs, as the TNFBs themselves. The longer term risk of TNFBs remains to be established.

It remains controversial whether immunosuppressants (AZA/MTX) should be used concurrently with TNFBs when starting TNFBs for induction therapy or continuing TNFBs for maintenance of remission. For now the international guidelines recommended using both immunomodulators and TNFB for induction of remission and mucosal healing. As well, combination therapy is preferred in moderate to severe CD as data shows reduced efficacy with single agent therapy (immunomodulators or TNFB).

It is unknown if TNFBs change the natural history of IBD.

In the UC patient who is experiencing frequent clinical recurrences while on 5-ASA, AZA or MTZ maintenance therapy, or who is hospitalized for an acute episode of their disease and fail to respond to IV steroids, it remains unclear whether IV cyclosporine followed by colectomy, AZA or IFX maintenance represent optimal therapy.

In persons with chronic continually or intermittently active UC or Crohn's colitis, it is unknown if colonoscopic surveillance protocols need to be changed to offset any potential TNFB-associated alteration in the risk of dysplasia.

When standard methods are used for economic evaluation, it is difficult to justify the use of TNFBs, based on available clinical data.

Given that some persons with IBD require TNFBs because of non-response to conventional therapies SOC, future research must solve the dilemma of predicting who will need TNFBs in the future who will be a TNFB primary or secondary non-responder, and who would benefit from early use of TNFBs. Above all, the pathogenesis of IBD needs to be identified in order than modifiable risk factors may be treated, and the diseases eventually may be prevented and cured.

The estimated 2010 expenditure on TNFBs is over $10 million (CDN), and a per IBD patient TNFB cost of $19 412 is higher than the estimated annual cost for standard of care of $17 107 for CD and $24 268 for UC.

"Making recommendations requiring TNFBs about anti-TNFα therapies based on less-than-conclusive scientific evidence has ethical implications for physicians..." (CADTH, 2009, page 60).

Abstract

Primary biliary cirrhosis (PBC) is a progressive cholestatic liver disease characterized by the immune-mediated destruction of biliary epithelial cells in small intrahepatic bile ducts. The disease is characterized by circulating antimitochondrial antibodies (AMAs) as well as disease-specific antinuclear antibodies, cholestatic liver function tests, and characteristic histological features, including granulomas. A variety of organisms are involved in granuloma formation, of which mycobacteria are the most commonly associated. This has led to the hypothesis that mycobacteria may be involved in the pathogenesis of PBC, along with other infectious agents. Additionally, AMAs are found in a subgroup of patients with mycobacterial infections, such as leprosy and pulmonary tuberculosis. Antibodies against species-specific mycobacterial proteins have been reported in patients with PBC, but it is not clear whether these antibodies are specific for the disease. In addition, data in support of the involvement of the role of molecular mimicry between mycobacterial and human mitochondrial antigens as triggers of cross-reactive immune responses leading to the loss of immunological tolerance, and the induction of pathological features have been published. Thus, antibodies against mycobacterial heat shock protein appear to cross-recognize AMA-specific autoantigens, but it is not clear whether these autoantibodies are mycobacterium-species-specific, and whether they are pathogenic or incidental. The view that mycobacteria are infectious triggers of PBC is intriguing, but the data provided so far are not conclusive.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic, autoimmune liver disease characterized by inflammatory destruction of the small intrahepatic bile ducts, fibrosis progressing to cirrhosis[1-5], and subsequent liver failure[6,7]. PBC primarily affects middle-aged women, with an increased incidence within families[2,8,9]. The prevalence of the disease is estimated to be less than 1/2000[10]. Despite the variance noted amongst countries/ethnic groups, there is a notion that the incidence of the disease is increasing[10-13].

Several autoantibody profiles have been found to be specific for the disease[14], and aid in the diagnostic workup of PBC. These include antimitochondrial antibodies (AMAs)[15-19], and/or disease-specific antinuclear antibodies (ANAs)[20-22], which are found in both symptomatic and asymptomatic patients[23]. Most common symptoms at presentation are nonspecific and include fatigue, pruritus, Sicca symptomatology and arthralgia. In more severe cases, symptoms relate to portal hypertension and hepatic decompensation (jaundice, ascites or variceal bleeding), which may indicate the need for liver transplantation[2,5,24]. The progression of PBC is generally slow and unpredictable[6,24].

The diagnosis of PBC is based on the presence of serum AMA, biochemical markers of cholestasis and histological features on liver biopsy[2]. The diagnosis of PBC is likely when at least two of these criteria are met[2,4]. Biochemical indices of cholestasis include increased levels of alkaline phosphatase and γ glutamyltransferase (GT). The diagnostic hallmark of PBC is the presence of AMA in high titers, with less than 3%-10% of patients with PBC being negative for AMA[23]. Positivity for AMA appears to be predictive of future PBC development in asymptomatic individuals[17,25]. The prevailing notion is that the presence of AMAs and their titers/concentrations do not correlate with the severity of the disease[23]. AMA seropositivity appears unable to identify patients at risk for faster progression of their liver disease compared to the seronegative cases[19,26]. Disease-specific ANAs[27-30] are also found in PBC, to a lesser degree than AMAs (20%-50% *vs* 90%-97%)[31-34], but tend to have elevated titers, and more importantly, appear to characterize patients with a more aggressive form of the disease[35-38]. Levels of IgM are also raised in most cases[2,4]. Histologically, PBC features include destruction of biliary epithelial cells and loss of small bile ducts with portal inflammatory cell infiltration, and granuloma formation (see below)[2,4,5].

The antigenic specificity of AMA[15-19] and ANA[20-22] responses have been extensively studied. PBC-specific ANAs recognize either nuclear body proteins such as the speckled protein 100 and the promyelocytic leukemia protein, or the gp210 and nucleoporin 62 nuclear membrane proteins[28,29,39-41].

AMAs in PBC are directed against the 2-oxo-acid dehydrogenase complex family of enzymes, and in particular the E2 subunits of pyruvate dehydrogenase complex (PDC-E2), branched-chain 2-oxo acid dehydrogenase complex (BCOADC) and 2-oxoglutarate dehydrogenase complex (OGDC)[2,42-44]. PDC-E2 reactivity is found in > 95% of patients with PBC, and 70% recognize BCOADC-E2 and/or OGDC-E2[2]. Reactivity to all three antigens occurs in < 50% of patients[19]. The immunodominant antigenic regions recognized by (CD4 and CD8) T lymphocytes[45-47] on PDC-E2[48-50] comprise a region within the inner lipoyl-binding domain of the subunit, spanning amino acids 212-226 (PDC-E2$_{212-226}$)[51-53]. This region is also the core target of B cell receptors, which are antibodies in their soluble form[54-56].

Medical treatment of PBC includes ursodeoxycholic acid, with the best response seen in patients who initiate treatment early in the disease[2]. These patients often show decreased or even normalized levels of alkaline phosphatase (ALP), γGT and other markers of cholestasis[2,4,6]. Studies reporting findings in large North American and European patient cohorts indicate that the percentage of patients with PBC who require liver transplantation has fallen significantly[2,57].

The cause of PBC remains undetermined[58-61], but it is believed to be the result of a genetic predisposition compounded with several lifetime exposures[62,63], similar to a "multi-hit" model[61,64-67] of disease pathogenesis[50,68,69]. Recent genome-wide association studies[70,71] have identified several HLA[72] and non-HLA[73-76] genes to be associated with PBC. Environmental factors implicated are numerous[77-81], and range from cosmetic products and xenobiotics[82], to estrogen deficiency and infectious organisms[50,58,83-85] including bacteria and viruses[50,54,58,59,63,65,66,68,69]. Mycobacteria have been included in the list of infectious organisms, partially due to the presence of granulomas in the histopathology of PBC, and the association of granulomas with mycobacteria[2,86]. In addition, AMA is found in some patients with mycobacterium-related infections[87,88]. This review will critically analyze the evidence surrounding the role of mycobacteria in the pathogenesis of PBC.

GRANULOMAS IN PBC

Granulomas consist of focal collections of inflammatory cells and cellular debris[89-92]. Their formation occurs when nondegradable products persist, as well as in hypersensitivity reactions or a combination of the two[91]. They form in a complex process involving the interaction of the infectious organism, antigen, macrophages, T cell responses, B cell hyper-reactivity, and circulating media-

PBC: Primary biliary cirrhosis.

tors[91]. T cells involved in granuloma formation may be of the T helper (Th)1 or Th2 type[91]. Several organisms may initiate granuloma formation, including *Mycobacterium*, *Yersinia*, *Toxoplasma gondii* and *Bartonella henselae*[93,94]. Zumla *et al*[91] have noted three categories of granulomatous infections: those due to well recognized organisms; those due to organisms that are detected by molecular techniques but not by conventional microbiological techniques; and those due to organisms that have not been identified, but which are suspected. *Mycobacterium tuberculosis* (*M. tuberculosis*) is the most common organism associated with granulomas, and is histologically characterized by epithelioid cells, lymphocytes, histiocytes, Langerhans giant cells and fibroblasts surrounding a core of necrotic debris[91]. The necrotic core is usually caseating, although non-caseating granulomas may also occur[91,92].

The presence of granulomas in liver biopsies has been well documented, with a prevalence ranging from 2% to 15% in some studies, with geographical differences in prevalence rates (Table 1)[95-99]. A German study conducted by Drebber *et al*[100] examined 12 161 liver biopsies for the presence of granulomas, in addition to determining the etiology of the granuloma through histology, clinicopathological data, and polymerase chain reaction (PCR) for the detection of infectious organisms. Granulomas were found in 442 (3.6%) of the liver biopsies and interestingly, 215 were from PBC patients (1.8% of all biopsies, and 48.7% of all biopsies with granulomas)[100]. PCR demonstrated the presence of infectious organisms in 15 samples (3.4%), with *M. tuberculosis* being detected in three of the 15 (20%). It was not indicated whether any of the samples with positive PCR results came from PBC patients[100]. Although only 1.8% of liver biopsies contained granulomas, nearly half of these were obtained from patients with PBC. However, if mycobacterial infection with associated granuloma formation is a feature of PBC, a much higher percentage of granulomas would be expected. The preponderance of granulomas in liver biopsies from PBC patients has been demonstrated in other studies as well, which show geographical differences in prevalence rates. In a Northern Irish study, 55% of liver biopsies with granulomas were from PBC patients[96], compared to 23.8% in a United Kingdom study[95]. A Greek study indicates an underlying diagnosis of PBC or overlap syndrome in 62% of liver biopsies with granulomas, followed by viral hepatitis in 7.5%, and autoimmune hepatitis (AIH) in 6%[101]. Despite these findings, it should be noted that only a small percentage of granulomas can be attributed to mycobacteria, with the liver disease in these patients being due to infection and not to PBC. Figure 1 illustrates PBC-related liver granulomas contrasted with liver granulomas seen in conditions not directly related to PBC such as sarcoidosis and schistosomiasis.

The predominance of PBC as the underling liver disease in most cases of hepatic granulomas and the association of granulomas with mycobacteria, raise the question as to whether mycobacteria play a role in the pathogenesis of PBC[58,86,102]. If mycobacteria play a role in the pathogenesis of PBC (or at least in some cases of PBC), it would be expected that certain PBC-specific features, such as disease-specific AMA positivity, would also be present in patients with mycobacterial infections. Likewise, evidence of mycobacterial infection would be expected in PBC patients. This evidence may comprise more prevalent immune responses against mycobacterial antigens, or detectable mycobacterial DNA in liver tissues of PBC patients, compared to healthy and pathological controls. If mycobacterial infection plays a role in the pathogenesis of PBC, it is likely that it is limited to a triggering event, because PBC has been known to recur following transplantation[103-106] in up to 35% of patients[107]. The recurrence rate ranges from 21% to 37% at 10 years, to 43% at 15 years[108-111]. Immunosuppression with tacrolimus, as well as warm ischemic time, is associated with an increased risk of recurrence[108-112]. The more aggressive course of recurrent disease suggests that the pathological process involved in the development of PBC persists after transplantation[113]. This does not, however, suggest that the triggers of PBC also persist, and may indicate their transient involvement in the pathogenesis of PBC[113]. Neuberger highlights that hepatitis A virus can trigger autoimmune hepatitis after viral clearance, and also indicates there are several similarities between the recurrence of hepatitis C virus and PBC after transplantation, suggesting a possible infectious trigger of PBC in some individuals[113]. Although these theories are plausible, no conclusive evidence exists to demonstrate an infectious agent (including mycobacteria) as the trigger of PBC.

PBC-specific features in patients with mycobacterial infection

In an analysis of sera from 28 patients with active pul-

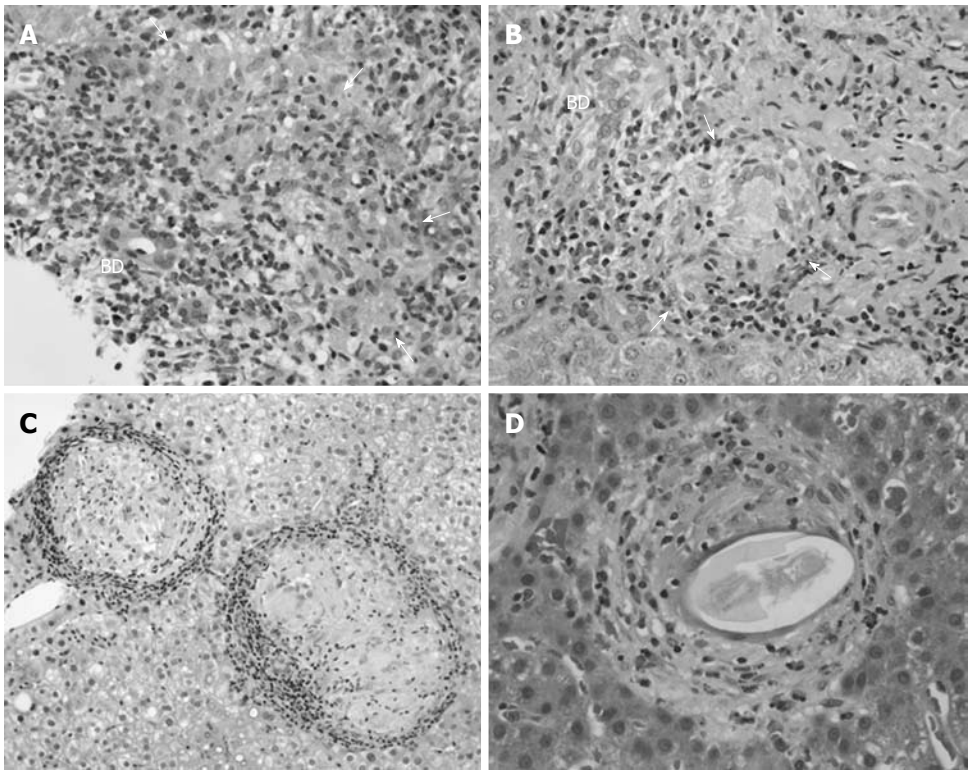

Figure 1 Epithelioid granuloma in liver biopsy. A, B: Liver specimens from patients with primary biliary cirrhosis show granuloma (arrows) close to bile ducts (BD) in portal tracts; C: Granuloma in sarcoidosis is more discrete and large in size; D: Granuloma associated with schistosomiasis contains a large number of eosinophils.

monary tuberculosis (*M. tuberculosis* infection), Klein and colleagues[88] found that 43% of these sera recognized PDC-E2 by immunoblotting based on purified mitochondrial fraction derived from beef heart mitochondria as an antigenic source. Only 2% of sera from individuals with other viral and bacterial infections [including 25 individuals with *Escherichia coli* (*E. coli*)] reacted with PDC-E2, and there was no reaction with sera from healthy controls[88]. The titers of anti-PDC-E2 antibodies were low, with no seropositive cases showing immunofixation of the 70-kDa band corresponding to PDC-E2, at a dilution of < 1/500[88]. Of relevance, none of the anti-PDC-E2 antibody-positive sera (1/10 dilution) gave an immunofluorescent pattern typical of PBC when tested by indirect immunofluorescence based on rat kidney and stomach tissue as substrates[14,16,17,88]. Among the 12 AMA-positive cases with active tuberculosis, six had abnormal levels of γGT and four had slightly elevated levels of alkaline phosphatase; only two of the cases had increased IgM levels[88]. Two of the 12 cases had alcoholic disease and of the remaining 10, none had clinical evidence of chronic liver disease[88].

A variety of autoantibodies have also been reported in the sera of patients with leprosy [caused by *Mycobacterium leprae* (*M. leprae*)], including antibodies against mitochondrial antigens[87,114,115]. In one study, the most common autoantibodies found in leprosy patients were antibodies to SS-B and mitochondria, including cardiolipin[115]. Despite the presence of AMA in the sera of leprosy patients, very few develop liver disease. Gilburd and colleagues[87] screened 69 leprosy patients with no clinical or biochemical evidence of liver disease, for the presence of anti-PDC antibodies. Positive controls consisted of three PBC patients and 18 healthy individuals served as negative controls[87]. Twenty-seven (39%) patients were found to have elevated anti-PDC antibodies by enzyme linked immunosorbent assay, but the absorbance values were relatively low; none of the normal controls had detectable AMA reactivity[87]. By immunoblotting, AMA reactivity was directed against the 54-, 41- and 35-kDa PDC subunits, and only two leprosy patients reacted with PDC-E2[87]. Inhibition studies showed that in contrast to PBC sera, none of the AMA-positive sera gave significant PDC enzyme inhibition; the rate of inhibition being similar to that noted in normal controls. Immunofluorescence testing was not performed[87].

Although AMAs are found in patients infected with mycobacteria, the reactivity patterns observed differ, with *M. tuberculosis*-infected patients showing reactivity to PDC-E2, which has not been observed in those infected with *M. leprae*[87,88]. The source of the AMAs in either case remains unknown. Gilburd *et al*[87] have suggested that the AMAs seen in leprosy patients may arise from the presence of bacterial antigens (such as *M. leprae*), which share sequence homology with the 35-, 41- and 54-kDa subunits. It is not clear whether all bands correspond to PDC subunits (such as PDC-E1 α and β) but may indeed be contaminants of other 2-oxo-acid dehydroge-

nase complexes (formerly known as M2 antigen) such as BCOADC-E2 and OGDC-E2, but reactivity to these antigens has not been tested[87].

Evidence of mycobacterial infection in PBC

In the search for evidence of antimycobacterial antibody reactivity in patients with PBC, Vilagut *et al*[86] investigated a cohort of 19 PBC patients from Spain, using membrane extracts from 10 atypical mycobacteria and found that all cases specifically reacted with *Mycobacterium gordonae* (*M. gordonae*) antigens of approximately 65 kDa and 55 kDa. It remained elusive why the other nine atypical mycobacteria were not targets of antibody responses. The unreactive mycobacterial membranes were those prepared from *Mycobacterium chelonei*, *Mycobacterium flavescens*, *Mycobacterium fortuitum* (*M. fortuitum*), *Mycobacterium intracellulare*, *Mycobacterium kansasii* (*M. kansasii*), *Mycobacterium malmoense* (*M. malmoense*), *Mycobacterium scrofulaceum*, *Mycobacterium xenopi* (*M. xenopi*), and *Mycobacterium terrae*[86]. The extraction of the 10 atypical mycobacterial membranes was performed using the same protocol, therefore, Vilagut *et al*[86] considered that their findings were not a consequence of methodological problems and suggested a biological significance for the role of *M. gordonae* in the pathogenesis of PBC.

This intriguing finding has initiated a series of subsequent studies from the same investigators as well as from independent groups[116-120]. Following the original Spanish report, a study was conducted at King's College Hospital in London investigating reactivity to *M. gordonae* and seven other atypical mycobacteria[119]. O'Donohue *et al*[119] found that 23 of 26 (88%) PBC sera reacted with a 65-kDa protein in extracts of six of the mycobacterial species tested (*M. gordonae*, *M. kansasii*, *M. fortuitum*, *Mycobacterium chelonae*, *Mycobacterium szulgai* and *M. malmoense*). Also, 15 and nine of these samples reacted with the 65-kDa band in membrane extracts of *Mycobacterium avium-intracellulare* and *M. xenopi*, respectively. However, the antibody reactivity to *M. gordonae* or other atypical mycobacteria was not restricted to PBC, but was also present in a similar prevalence in patients with other chronic liver diseases as well as in normal controls[119].

Several studies have attempted to provide evidence of mycobacterial infection in liver tissues from PBC patients. Broomé and colleagues[121] conducted an immunohistochemical study investigating liver biopsy specimens from 10 PBC cases, 13 from primary sclerosing cholangitis, five chronic hepatitis C, four alcoholic liver disease, and six healthy controls. Samples were studied using a monoclonal antibody specific for mycobacterial heat shock protein (hsp) 65. Positive staining was observed in nine of the 10 PBC cases, all primary sclerosing cholangitis, three chronic hepatitis C, and three alcoholic liver disease cases, but in none of the healthy controls[121]. Both interlobular and septal bile duct staining was observed in the PBC cases, with perinuclear staining in all positive interlobular ductal cells, and perinuclear as well as apical staining in the positive septal cells[121].

Direct evidence of microbial products in an affected tissue is best studied at the molecular level using PCR techniques. Vilagut *et al*[116] assessed the presence of *M. gordonae* DNA in liver tissue from PBC patients and controls using PCR based on amplification of a 565-bp fragment of mycobacterial gene coding for 16S rRNA on M. *gordonae*. They detected *M. gordonae* in nine of 11 (82%) PBC liver tissues but in none of the six control livers from patients with other liver diseases[116]. Contradictory results were obtained by O'Donohue *et al*[118] who investigated whether mycobacterial DNA could be detected in archival liver biopsy material from PBC and AIH. Archival material was obtained from 11 PBC and 11 AIH cases, with five lymph nodes from patients with tuberculous lymphadenopathy acting as positive controls[118]. Three of the positive controls also had liver biopsies taken for concurrent tuberculous hepatitis. No mycobacterial DNA was detected in PBC or AIH cases, while four of the five positive controls had detectable mycobacterial DNA[118]. A similar study also utilized a PCR approach for the detection of mycobacterial and other organisms in archived (paraffin embedded) liver tissues from 29 cases of PBC, as well as pathological and healthy controls. Again, no mycobacterial DNA was detected in PBC samples, and only *Helicobacter pylori* DNA was found in one case of PBC[122].

Mycobacteria and PBC: The role of molecular mimicry

The above studies do raise doubt as to whether mycobacteria play a role in PBC, although it is unclear whether a negative detection test only implies that there is no current active infection or can rule out previous infection as well. However, it has been suggested that mycobacteria and other infectious agents may not be actively present in PBC patients, but rather involved in the initiation of autoimmunity by microbial/self immunological cross-reactivity[55,56,123,124]. We and others have studied the role of molecular mimicry[68,69,123,125-128] and immunological cross-reactivity[129-133] as a mechanism responsible for the induction of autoantigen-specific immune responses in viral-hepatitis-triggered autoimmunity and several autoimmune diseases (including those affecting the liver)[134-138] in susceptible individuals[139,140]. Impairments in T-regulatory functions also appear to be a feature[141,142]. Cross-reactivity between PBC-specific mitochondrial antigens and mycobacterial proteins has been investigated by two groups[86,117]. Vilagut *et al*[86] have found that antibody responses to the 65-kDa *M. gordonae* antigen cross-reacted with anti-PDC-E2 antibodies. The same group of investigators went on to demonstrate that the 65-kDa protein was the mycobacterial hsp65, and that preincubation with PBC sera prevented binding of antibodies against hsp65[117]. The apparent cause of this cross-reactivity remained elusive until another group noted a sequence similarity between human PDC-E2 and *M. gordonae* hsp65[120]. These authors have found that the hexameric motif [GDL(IL)AE)] is shared by *M. gordonae* hsp65$_{94\text{-}99}$ and the major PBC-specific mitochondrial autoepitopes,

Table 2 Summary of studies in support or against a role of mycobacteria as triggers of primary biliary cirrhosis

Ref.	Year	Mycobacterium	M2 antigen	In support	Against
Klein *et al*[88]	1993	*M. tuberculosis*	Bovine heart	Anti-M2 AMAs (70 kDa) found in 12/28 (43%) tuberculosis patients	None of the patients had PBC AMA by IIFL were negative Anti-PDC-E2 titers were low
Gilburd *et al*[87]	1994	*M. leprae*	Bovine heart	Anti-M2 against 54-, 41- and 35-kDa bands found in 27/69 (39.1%) leprosy patients	None of the patients had PBC Only 2/27 (1%) sera reacted with the PDC-E2 band Anti-M2 inhibited anti-PDC activity in 19.1%
Vilagut *et al*[86]	1994	*M. gordonae*	Porcine heart	Anti-hsp65 *M. gordonae* antibodies found in 19/19 (100%) of PBC patients. No reactivity to other atypical mycobacteria was found Anti-porcine AMAs (anti-PDC-E2 and BCOADC-E2) cross-reacted with anti-hsp65 *M. gordonae* antibodies and *vice versa*	
O' Donohue *et al*[119]	1994	*M. gordonae*, *M. kansasii*, *M. fortuitum*, *M. chelonae*, *M. szulgai and M. malmoense*, *M. avium-intracellulare and M. xenopi*		23 of 26 (88%) PBC sera reacted with a 65-kDa protein in extracts of six of the mycobacterial species tested Sera from 15 PBC patients reacted with *M. avium-intracellulare* Sera from 9 PBC patients reacted with *M. xenopi*	Reactivity to the atypical mycobacterial mimics was found in non-PBC liver disease patients and controls
Bogdanos *et al*[54]	2004	*M. gordonae*	Primate liver	The motif GDL(IL)AE is shared by *M. gordonae* hsp65$_{94-99}$ and PDC-E2$_{216-221}$	Reactivity to *M. gordonae* hsp65$_{90-104}$ /human PDC-E2$_{212-226}$ seen in Spanish (47.5%), but rarely British patients (4%)
Broome *et al*[121]	1993	-	-	Immunohistochemistry demonstrated positive mycobacterial hsp65 staining in PBC liver tissue	Positive staining was also observed in pathological controls
Vilagut *et al*[116]	1996	*M. gordonae*	-	*M. gordonae* genetic material detected in 9 of 11 (82%) PBC liver tissues	
O'Donohue *et al*[118]	1998	*M. gordonae*	-		Mycobacterial DNA not detected in PBC liver tissues, but was detected in positive controls
Tanaka *et al*[122]	1999	Mycobacterial genus specific primers	-		Mycobacterial DNA not detected in PBC liver tissues

M. tuberculosis: *Mycobacterium tuberculosis*; *M. leprae*: *Mycobacterium leprae*; *M. gordonae*: *Mycobacterium gordonae*; *M. kansasii*: *Mycobacterium kansasii*; *M. fortuitum*: *Mycobacterium fortuitum*; *M. chelonae*: *Mycobacterium chelonae*; *M. szulgai*: *Mycobacterium szulgai*; *M. malmoense*: *Mycobacterium malmoense*; *M. avium-intracellulare*: *Mycobacterium avium-intracellulare*; *M. xenopi*: *Mycobacterium xenopi*; IIFL: Indirect immunofluorescence; PDC: Pyruvate dehydrogenase complex; PBC: Primary biliary cirrhosis; AMAs: Antimitochondrial antibodies; hsp: Heat shock protein.

namely, the inner lipoyl PDC-E2$_{216-221}$ and the outer lipoyl domain human PDC-E2$_{102-107}$[120]. No other sequences were found to be in common with *M. gordonae* hsp65 and human PDC-E2[120]. A database search analysis has found that, among bacteria, the motif SxGDL[IL]AE is virtually unique to mycobacterial hsp, and the only human sequence containing that motif was the inner lipoyl domain of PDC-E2[120]. This excellent and almost unique match between sequences of the dominant epitope of human PDC-E2 and of mycobacterial hsp65 has led the authors to investigate whether the corresponding sequences were targets of immunological cross-reactivity specifically present in patients with PBC. That study involved testing sera from 40 Spanish and 50 British PBC patients, with antibody reactivity to *M. gordonae* hsp 65$_{90-104}$/human PDC-E2$_{212-226}$ being detected in 47.5% of Spanish PBC patients and in only 4% of British PBC patients[120]. No reactivity was observed in controls. Inhibition studies confirmed that the reactivity to the mimics was due to cross-reactivity. In addition, the affinity of anti-*M. gordonae* hsp 65$_{90-104}$ antibodies was higher than that against human PDC-E2$_{212-226}$, raising the possibility that antibody reactivity to the microbe long precedes that against the human homolog[120]. Table 2 provides a summary of the above evidence for and against the role of mycobacteria in PBC.

It remains unclear whether the differing reactivity patterns noted among PBC patients from differing geographical locations (highly prevalent in Spanish PBC cases, practically absent in British PBC cases), could be explained by differing prevalence exposure rates of certain atypical mycobacteria in geographical locations. It should also be noted that multinational epidemiological studies on PBC have not indicated an association with mycobacterial infection, in contrast to what has been reported for *E. coli* or other microbes[77,78,80,81].

CONCLUSION

The presence of granulomas in liver biopsies of PBC patients raises the suspicion that bacterial infections are involved in the pathogenesis of PBC. Although infection with several bacterial species is associated with granulomatous disease, mycobacteria are the most common culprits. It is therefore not surprising that mycobacteria have been added to the list of infectious agents implicated in the pathogenesis of PBC. Furthermore, it has been observed that AMAs, which are characteristic of PBC, are also found in many patients with mycobacterial infections but their titers are low, their epitope specificity differs from that seen in PBC, and they do not appear to be detectable by conventional immunofluorescence. Additionally, mycobacteria have not been found in any significant proportion of hepatic granulomas associated with PBC. When found, the liver disease is often attributed to infection and not PBC.

It is unlikely that ongoing mycobacterial infection is a characteristic of PBC, but an early, transient infection with immunological clearance may be capable of inducing cross-reactivity. Genetic studies on PBC are now demonstrating a genetic susceptibility to the disease, and it is likely that a variety of other factors act in an additive fashion towards PBC development. These factors probably not only vary from patient to patient, but also from one geographical location to the next. A correlation between PBC and certain organisms in the context of their geographical prevalence is warranted. In addition, sequence homology between PDC-E2 and mycobacterial epitopes at the T-cell level has not been fully explored, which is of interest given that differing reactivity patterns have been observed between a variety of mycobacteria and the major mitochondrial epitope of PBC. Experimental studies in animal models of PBC involving mycobacteria may provide useful hints as to whether mycobacteria play a role in the induction of PBC. They may also distinguish between mycobacteria being a trigger of the disease, or being epiphenomena secondary to an increased susceptibility to infection in PBC patients.

Abstract

AIM: To evaluate the effects of indomethacin [dual cyclooxygenase (COX)-1/COX-2 inhibitor] and 3-(3,4-difluorophenyl)-4-(4-(methylsulfonyl) phenyl)-2-(5H)-furanone (MF-tricyclic) (COX-2 selective inhibitor) in a rat experimental model of Barrett's esophagus and esophageal adenocarcinoma.

METHODS: A total of 112 surviving post-surgery rats were randomly divided into three groups: the control group (n = 48), which did not receive any treatment; the indomethacin group (n = 32), which were given 2 mg/kg per day of the COX-1/COX-2 inhibitor; and the MF-tricyclic group (n = 32), which received 10 mg/kg per day of the selective COX-2 inhibitor. Randomly selected rats were killed either 8 wk or 16 wk after surgery. The timing of the deaths was in accordance with a previous study performed in our group. Only rats that were killed at the times designated by the protocol were included in the study. We then assessed the histology and prostaglandin E2 (PGE2) expression levels in the rat esophagi. An additional group of eight animals that did not undergo esophagojejunostomy were included in order to obtain normal esophageal tissue as a control.

RESULTS: Compared to a control group with no treatment (vehicle-treated rats), indomethacin treatment was associated with decreases in ulcerated esophageal mucosa (16% *vs* 35% and 14% *vs* 17%, 2 mo and 4 mo after surgery, respectively; P = 0.021), length of intestinal metaplasia in continuity with anastomosis (2 ± 1.17 mm *vs* 2.29 ± 0.75 mm and 1.25 ± 0.42 mm *vs* 3.5 ± 1.54 mm, 2 mo and 4 mo after surgery, respectively; P = 0.007), presence of intestinal metaplasia beyond anastomosis (20% *vs* 71.4% and 0% *vs* 60%, 2 mo and 4 mo after surgery, respectively; P = 0.009), severity of dysplasia (0% *vs* 71.4% and 20% *vs* 85.7% high-grade dysplasia, 2 mo and 4 mo after surgery, respectively; P = 0.002), and adenocarcinoma incidence (0% *vs* 57.1% and 0% *vs* 60%, 2 mo and 4 mo after surgery, respectively; P < 0.0001). Treatment with the selective COX-2 inhibitor, MF-tricyclic, did not prevent development of intestinal metaplasia or adenocarcinoma. In parallel, we observed a significant decrease in PGE2 levels in indomethacin-treated rats, but not in those treated with MF-tricyclic, at both 2 mo and 4 mo. Compared to control rats that did not undergo surgery

(68 ± 8 ng/g, P = 0.0022 Kruskal-Wallis test) there was a significant increase in PGE2 levels in the esophageal tissue of the rats that underwent surgery either 2 mo (1332 ± 656 ng/g) or 4 mo (1121 ± 1015 ng/g) after esophagojejunostomy. However, no differences were found when esophageal PGE2 levels were compared 2 mo *vs* 4 mo post-esophagojejunostomy. At both the 2- and 4-mo timepoints, we observed a significant decrease in PGE2 levels in indomethacin-treated rat esophagi compared to those in either the control or MF-tricyclic groups (P = 0.049 and P = 0.017, respectively). No differences in PGE2 levels were found when we compared levels in rats treated with MF-tricyclic to not-treated rats.

CONCLUSION: In this rat model of gastrointestinal reflux, indomethacin was associated with a decrease in the severity of esophagitis and reduced development of esophageal intestinal metaplasia and adenocarcinoma.

INTRODUCTION

The incidence of esophageal adenocarcinoma (EA) in the United States and Western Europe has risen dramatically in the last few decades[1-3]. The reasons for this substantial increase are not entirely understood, but it has been linked to an increase in the incidence of gastroesophageal reflux (GERD) and Barrett's esophagus (BE), which is a recognized risk factor for the development of EA. BE is a consequence of chronic GERD, which represents the starting point of the sequence: GERD, inflammation, BE, low-grade dysplasia, high-grade dysplasia, carcinoma *in situ*, and invasive adenocarcinoma[4]. The molecular changes in the progression from GERD to BE and then to EA are not entirely understood[5], but in the last few years, cyclooxygenase-2 (COX-2) has emerged as a key player in carcinogenesis arising from BE; therefore, it is a potential therapeutic target in the sequence leading to EA. Evidence supporting the involvement of COX-2 in this sequence includes epidemiological studies that have demonstrated a protective effect of nonsteroidal antiinflammatory drugs (NSAIDs) against EA and *in vivo* animal studies in experimental models of chronic esophagitis and EA, in which administration of COX-2 inhibitors induced a reduction in the incidence of esophageal cancer. In addition, upregulation of COX-2 has been described at both mRNA and protein levels in humans with GERD, BE, or EA[6]. COX-1, the other cyclooxygenase isoenzyme, was traditionally considered to be a constitutively expressed isoform that generates prostaglandins for normal physiological functions such as platelet aggregation, gastric mucosal protection, and renal electrolyte metabolism; it was thought not be involved in carcinogenesis. Recent evidence, however, has demonstrated that COX-1 may be important in the development of different neoplasias, because elevated levels of COX-1 expression have been found in prostate, breast, and cervical cancers[7]. Furthermore, studies in $Min^{+/-}$ mice showed that homologous disruption of either *COX-2* or *COX-1* genes is followed by a reduction in polyp formation of approximately 80%[7]. In the esophagus, the role of COX-1 in the development of EA has not been investigated extensively. In a previous study, expression of both COX-1 and COX-2 were analyzed at the mRNA level in 123 primary human esophageal adenocarcinomas; mRNA levels of both isoenzymes were increased. Interestingly, RNA expression levels of COX-1 and COX-2 correlated significantly with one other, and expression of both isoenzymes correlated with the expression of vascular endothelial growth factors A and C (VEGF-A and VEGF-C)[8]. Another study reported an increase in COX-1 expression in a rat model of esophagitis induced by acid reflux[9]. Therefore, to analyze the effects of COX inhibitors in the development of EA due to gastrointestinal reflux, we assessed the effect of a dual COX-1/COX-2 inhibitor (indomethacin) in a rat model of esophageal adenocarcinoma induced by gastroesophageal reflux, and compared it with the effect of a selective COX-2 inhibitor (3-(3,4-difluorophenyl)-4-(4-(methylsulfonyl) phenyl)-2-(5H)-furanone) (MF-tricyclic).

MATERIALS AND METHODS

Animals

All of the animal studies were carried out in the Biomedicine and Biomaterials group of the University of Zaragoza, which is officially recorded as a research establishment that practices adequate husbandry and use of all research animals in accordance with Good Laboratory Practices guidelines. All procedures were approved by the in-house Ethics Committee for Animal Experiments from the University of Zaragoza. The care and use of animals were performed according to the Spanish Policy for Animal Protection RD1201/05, which meets the European Union Directive 86/609 on the protection of animals used for experimental and other scientific purposes. Throughout the experiment, all rats were housed

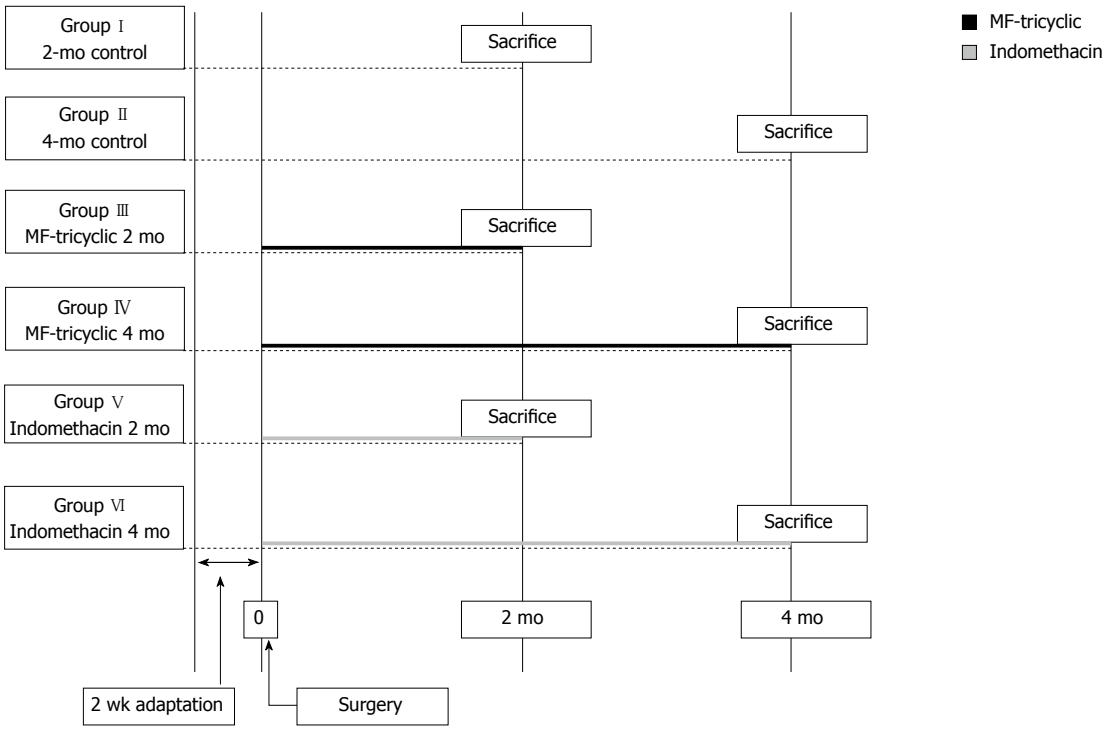

Figure 1 Scheme of the study design.

in specifically designed cages for this type of animal (EU Dim; IFFA Credo) and kept in computer-controlled conditions of light (12-h light/dark cycle), noise (45-50 dB), temperature (21 ± 2 ℃), and humidity (60%-70%). The animals were cared for by veterinary staff. A total of 128 five-week-old female Wistar rats (Harlan, Barcelona, Spain) weighing 220-300 g were used for this study.

Experimental model

Solid food was withdrawn for 24 h and water for 6-8 h before surgery. Anesthesia consisted of 75 mg/kg weight ketamine (50 mg/mL, Ketolar; Parke-Davis, Madrid, Spain) and 0.5 mg/kg weight medetomidine (1 mg/mL, Domtor; Pfizer, Madrid, Spain), which were given as a mixture in a single intramuscular injection. Before surgery, an intramuscular injection of 100 mg/kg weight cefazolin (Kefol; Lilly, Madrid, Spain) was administered as antibiotic prophylaxis. Rats underwent esophagojejunostomy with gastric preservation, allowing the gastroduodenal content to flow back into the esophagus. This surgery was performed according to a previously described protocol[10]. After surgery, the rats were housed in hanging cages to prevent bed ingestion and allowed to drink water *ad libitum*, with fasting until day 3. Water with 0.3 mg/mL buprenorphine (Buprex; Esteve, Barcelona, Spain) was provided during the first 72 postoperative hours. An additional intramuscular injection of cefazolin was administered 24 h after surgery. Rats received 50 mg/kg iron dextran (Difortin; Econatura, Madrid, Spain) intramuscularly once every 4 wk until the end of the experiment. Rats were killed by carbon dioxide inhalation either 2 mo or 4 mo after surgery. A blood sample was obtained for drug analysis from all of the animals immediately before death. Immediately after death, the esophagus was removed and opened longitudinally. Two-thirds of the esophageal specimen was prepared for pathological study. The rest of the esophagus was cut into two slices: the lower and the upper halves of the esophagus. The lower half samples were frozen immediately in liquid nitrogen and then kept at -80 ℃ until biochemical studies were performed.

General design of experiment

Two weeks after surgery, the 112 surviving post-surgery rats were randomly divided into three groups: the control group (n = 48), which did not receive any treatment; the indomethacin group (n = 32), which were given the COX-1/COX-2 inhibitor; and the MF-tricyclic group (n = 32), which received the selective COX-2 inhibitor. Randomly selected rats were killed either 8 or 16 wk after surgery. The timing of the deaths was in accordance with a previous study[10]. Only rats that were killed at the times designated by the protocol were included in the study. A scheme of the study design is shown in Figure 1. An additional group of eight animals that did not undergo esophagojejunostomy were included in order to obtain normal esophageal tissue.

Drug administration and dosage selection

MF-tricyclic was administered at a dose of 10 mg/kg body weight/d. This dose was selected according to a previous study of esophageal adenocarcinoma prevention in the same model[11]. The drug was kindly provided by Merck Frost (Quebec, Canada), which produced a pre-

mixed chow containing the drug. The concentration of MF-tricyclic in the chow was calculated using the average weight of Wistar rats and a daily consumption of 16-20 g of chow/d. This rate of chow consumption was evaluated in previous experiments[10]. Indomethacin (Sigma, Madrid, Spain) was given at a dose of 2 mg/kg body weight/d. This dose was selected according to a previous study of the inhibition of colorectal cancer[12]. The drug was added to drinking water. Indomethacin was replaced on a daily basis and administered in dark bottles in order to avoid light degradation.

Histopathological analysis

Rat esophagi were examined by two independent pathologists who were unaware of the experimental conditions. Changes in the squamous epithelium were classified into the following five categories: (1) Reactive changes: characterized by the presence of basal cell hyperplasia, increased length of papillae, and hyperkeratosis with areas of inflammation and ulceration; (2) Columnar-lined metaplasia (intestinal metaplasia): squamous epithelium was replaced with columnar-lined epithelium comprising occasional and incomplete differentiation of goblet cells; the length of the epithelial transformation was greater than 3 mm starting from the anastomosis site or was intercalated, or it could be seen beyond the surgical anastomosis, and was surrounded by squamous epithelium; (3) Dysplasia: characterized by nuclear atypia, partial loss of mucosecretory function and cell polarity, and an increase in mitotic figures. Dysplasia was classified as low-grade dysplasia (LGD) and high-grade dysplasia (HGD) according to the criteria proposed by Haggitt[13], as previously described in this experimental model[14]. In LGD, the crypt architecture is preserved or minimally distorted; the nuclei may be stratified but without reaching the apical surface of glands, nuclei are enlarged, crowded and hyperchromatic, mitotic figures may be found in the upper portion of the crypt; goblet and columnar cell mucus is usually diminished or absent, but goblet cells in which the mucous droplet does not communicate with the luminal surface may be observed. The abnormalities extend to the mucosal surface. In HGD, distortion of crypt architecture usually is present and may be marked. It is composed of branching and lateral budding of crypts, a villiform configuration of the mucosal surface or intraglandular bridging of epithelium to form a cribriform pattern of "back-to-back" glands. Nuclear abnormalities are present as in LGD, and stratification reaches the crypt luminal surface. There may be a loss of nuclear polarity, and nuclei often vary markedly in size, shape, and staining characteristics. Goblet and columnar cell mucus is usually absent. The abnormalities extend to the mucosal surface; (4) Adenocarcinoma: glandular structures of dysplastic columnar epithelial with stromal invasion and deep infiltration; and (5) Squamous carcinoma: characterized by accumulation of atypical cells with nuclear hyperchromasia, abnormally clumped chromatin, and loss of polarity. The two pathologists showed a high concordance (kappa coefficient > 0.8). However, in cases where there was disagreement, a third pathologist was required to resolve the discrepancy.

Measurement of prostaglandin E2 levels in esophageal mucosa

Prostaglandin E2 (PGE2) analysis was performed in the lower half of the esophagus. Tissue samples were added to 1 mL of cold PBS containing 10 μmol indomethacin. They were then homogenized (DIAX 900, Heidolph, Kelheim, Germany) on ice and centrifuged for 15 min at 1200 rpm (4 ℃). Supernatants were collected in 2 mL tubes. Prostaglandin extraction was performed as previously described by Powell[15]. PGE2 was measured by radioimmunoassay [prostaglandin E2 (I125); Amersham Pharmacia Biotech, Buckinghamshire, United Kingdom].

Plasma drug levels

MF-tricyclic concentration analysis in rat plasma was performed by Merck Frost Canada; the results were disclosed to us after the study was complete. Indomethacin levels were determined as follows: 50 μg (10 μL of a 5 mg/mL methanolic solution) of the internal standard probenecid was added to 1 mL of serum before each analysis. Afterwards, samples were extracted with 2 mL of ethyl acetate and an aliquot of the organic phase was withdrawn, evaporated to dryness under a nitrogen stream at room temperature, and redissolved in 300 μL of methanol. Fifty microliters of these solutions were analyzed by high-performance liquid chromatography (Waters 600 Controller, 996 Photodiode Array Detector). A method capable of quantifying indomethacin was developed using a C-18 column (150 mm × 3.9 mm, 4 μm particle size; Waters, Barcelona, Spain) and probenecid as the internal standard. The column was equilibrated at a flow rate of 1 mL/min with a mobile phase consisting of acetonitrile in water (51:49, v/v) and 0.1% trifluoroacetic acid. The eluate was monitored at 257 nm[16].

Statistical analysis

Data management and statistical analysis were performed using SPSS software. Results from biochemical assays were expressed as mean ± SE. Data were compared between groups by nonparametric tests (Kruskall-Wallis and Mann-Whitney); $P < 0.05$ was considered to be statistically significant. Covariance analysis was used to analyze the quantitative variables of the drug, introducing the number of months as a covariant. Multiple comparisons were corrected by means of the Bonferroni method. Logistic models were adjusted for qualitative variables, evaluating in turn the effect of the drug and the number of months.

RESULTS

Macroscopically, all of the rats that underwent esophagojejunostomy showed dilatation and thickening of the middle and lower esophagus. The distal esophagus

Table 1 Macroscopic results

Squamous adenocarcinoma	1	-	1	1	-	-

showed ulceration. Macroscopically, we did not identify any esophageal tumors. The esophagi of all of the rats that were operated on presented inflammatory infiltrate. In most of the animals, the upper and middle parts of the esophagus showed squamous hyperplasia. The esophagi of all of the rats that were operated had columnar-lined metaplasia in continuity with the jejunal epithelium. Dysplasia had developed in all of the rats that underwent surgery. Neoplastic transformation of the epithelium was always found near the anastomosis, surrounded by columnar epithelium. Histologically, 87.5% of tumors were adenocarcinomas, and 12.5% were squamous carcinoma (Table 1). Microscopically, in some animals, a second type of metaplasia was found far above the anastomosis. This metaplasia contained isolated or grouped goblet cells, which formed authentic mucous glands in some cases. However, in any case, these metaplastic foci progressed to adenocarcinoma.

Effect of treatment on the occurrence of lesions

Inflammation, ulceration, intestinal metaplasia, dysplasia, and neoplasias were present in all of the rats that underwent esophagojejunostomy. When the percentage of ulcerated surface was analyzed, there was a significant decrease in the groups treated with indomethacin compared to the control and MF-tricyclic groups. The indomethacin treatment groups showed a significant reduction in the length of metaplasia; we also observed a significant decrease in the percentage of metaplasia beyond the anastomosis (Figures 2, 3A and B).

Most of the rats developed some degree of dysplasia. When we analyzed the occurrence of low-grade *vs* high-grade dysplasia, we found that the percentage of rats that developed high-grade dysplasia was significantly lower in rats treated with indomethacin compared to the MF-tricyclic and control groups (Figures 3C, D). The absence of neoplasias in the indomethacin-treated group (0% *vs* 36.4% in the MF-tricyclic group and 57.1% in the control group 2 mo after surgery, and 0% *vs* 50% in the MF-tricyclic group and 60% in the control group 4 mo after surgery), did not allow us to estimate the risk effect as odds ratio. Nevertheless, when we applied a log-linear model, we concluded that time was a nonsignificant factor in the presence of neoplasia. When we analyzed the effect of treatment, we observed a lower incidence of neoplasia in the indomethacin group ($P \leqslant 0.001$) (Figure 4).

Prostaglandin E2 levels

There was a significant increase in PGE2 levels in the esophageal tissue of the rats that underwent surgery either 2 mo (1332 ± 656 ng/g) or 4 mo (1121 ± 1 015 ng/g) after esophagojejunostomy compared to control rats that did not undergo surgery (68 ± 8 ng/g; $P = 0.0022$ Kruskal-Wallis test). However, no differences were found when esophageal PGE2 levels were compared 2 mo *vs* 4 mo post-esophagojejunostomy.

At both the 2- and 4-mo timepoints, we observed a significant decrease in PGE2 levels in indomethacin-treated rat esophagi compared to those in either the control or MF-tricyclic groups ($P = 0.049$ and $P = 0.017$, respectively). Rats treated with MF-tricyclic did not show differences in PGE2 levels compared to non-treated animals (Table 2).

Serum drugs levels

All of the rats treated with either MF-tricyclic or indomethacin had detectable levels of the drugs in their plasma. The serum drug concentration in rats receiving 10 mg/kg body weight MF-tricyclic was 1.62 ± 0.19 μg/mL. The rats receiving 2 mg/kg indomethacin had plasma levels of 1.97 ± 0.43 μg/mL. As expected, the rats in the untreated control group did not have detectable MF-tricyclic or indomethacin levels.

DISCUSSION

In the present study, we have used an enteroesophageal reflux model in rats to evaluate the impact of dual COX-1/COX-2 *vs* selective COX-2 inhibition in the neoplastic transformation of esophageal epithelium. Although in this experimental model the pH of the refluxate increases with increasing distance from the stomach to the anastomosis, non-acidic refluxate has been shown to enhance the occurrence of intestinal metaplasia with dysplasia and esophageal adenocarcinoma[17]. In addition, these models are widely used because they reproduce the sequence of histological changes that take place in human esophageal adenocarcinogenesis and show morphological and phenotypic characteristics similar to those observed in human Barrett's esophagus and associated

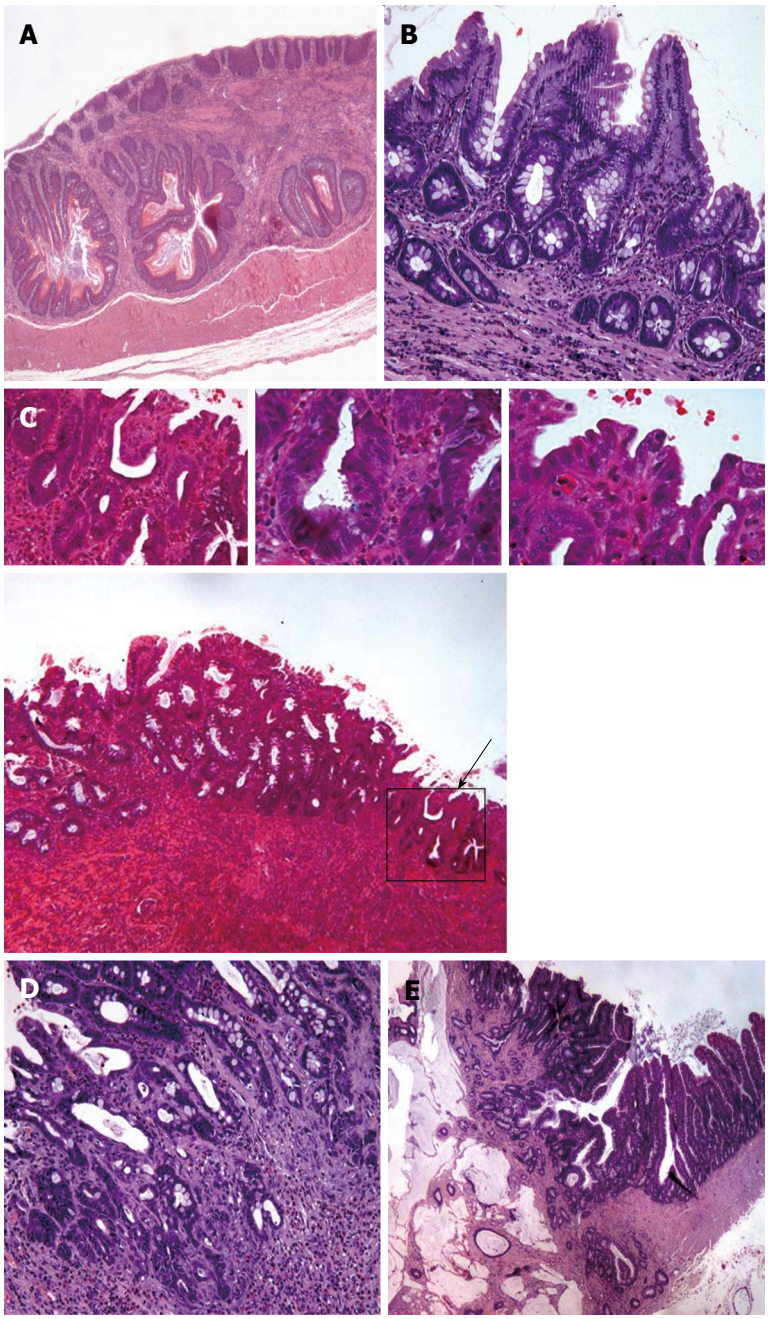

Figure 2 Pathological findings in the esophagus of rats with esophagojejunostomy. A: Hyperplasia of squamous epithelium in a control rat esophagus; B: Hematoxylin and eosin (HE) staining (× 100) showing an area of intestinal metaplasia without dysplasia. The top picture shows in more detail a gland (× 400); C: Indomethacin-treated rat. HE staining (× 40) of an area of intestinal metaplasia showing a focus with low-grade dysplasia (black arrow). The top pictures show in more detail the area with low grade dysplasia (× 200; × 400). Glands conserve their architecture. Nuclear pseudostratification can be seen, nuclear size is also increased but nuclei do not reach the lumen; D: HE staining of an area of intestinal metaplasia showing high grade dysplasia. Magnification × 100; the top picture illustrates at higher magnification (× 400), some glands with high grade dysplasia, characterized by loss of nuclear polarity and atypia; E: Photomicrograph shows an adenocarcinoma developed inside the intestinal metaplasia of the esophagus near the jejunum epithelium in a rat that had undergone an esophagojejunostomy. HE staining shows that the esophageal adenocarcinoma consists of dilated, cystic glands with abundant mucin secretion and epithelial dysplasia. (Magnification × 40; the top picture shows the same fields at × 100 magnification).

adenocarcinoma, including mucin features and expression of differentiation markers and markers of neoplastic progression[14,18].

Our results showed that treatment with the dual COX-1/COX-2 inhibitor indomethacin induced a significant reduction in the area of ulcerated mucosa, the length of metaplasia in continuity with anastomosis, the incidence of metaplasia beyond the anastomosis, the severity of dysplasia, and the incidence of adenocarcinoma in this rat model of chronic gastrointestinal reflux. In contrast, treatment with the selective COX-2 inhibitor, MF-tricyclic, did not prevent the development of these lesions in this model. Our results are consistent with those reported by Heath *et al*[19] in a human clinical trial, in which treatment with 200 mg/d of celecoxib, another selective inhibitor of COX-2, did not prevent the progression of Barrett's dysplasia to cancer. In parallel with our histopathological results, we found a significant decrease in PGE2 levels in indomethacin-treated rats, but not in the MF-tricyclic group, which suggests that PGE2 inhibition is also linked to the effect observed with these two agents. Increased levels of PGE2 during chronic inflammation were previously correlated with carcinogenesis. In an esophagitis rabbit model, Lanas *et al*[20] observed high PGE2 levels associated with increased activity of both COX-1 and COX-2. The levels decreased when rabbits were treated with the nonselective COX inhibitor, indomethacin.

In an experimental model, Buttar *et al*[11] showed that treatment with sulindac had a preventive effect against EA. In contrast with our findings, they observed a similar, although numerically lower, beneficial effect with MF-

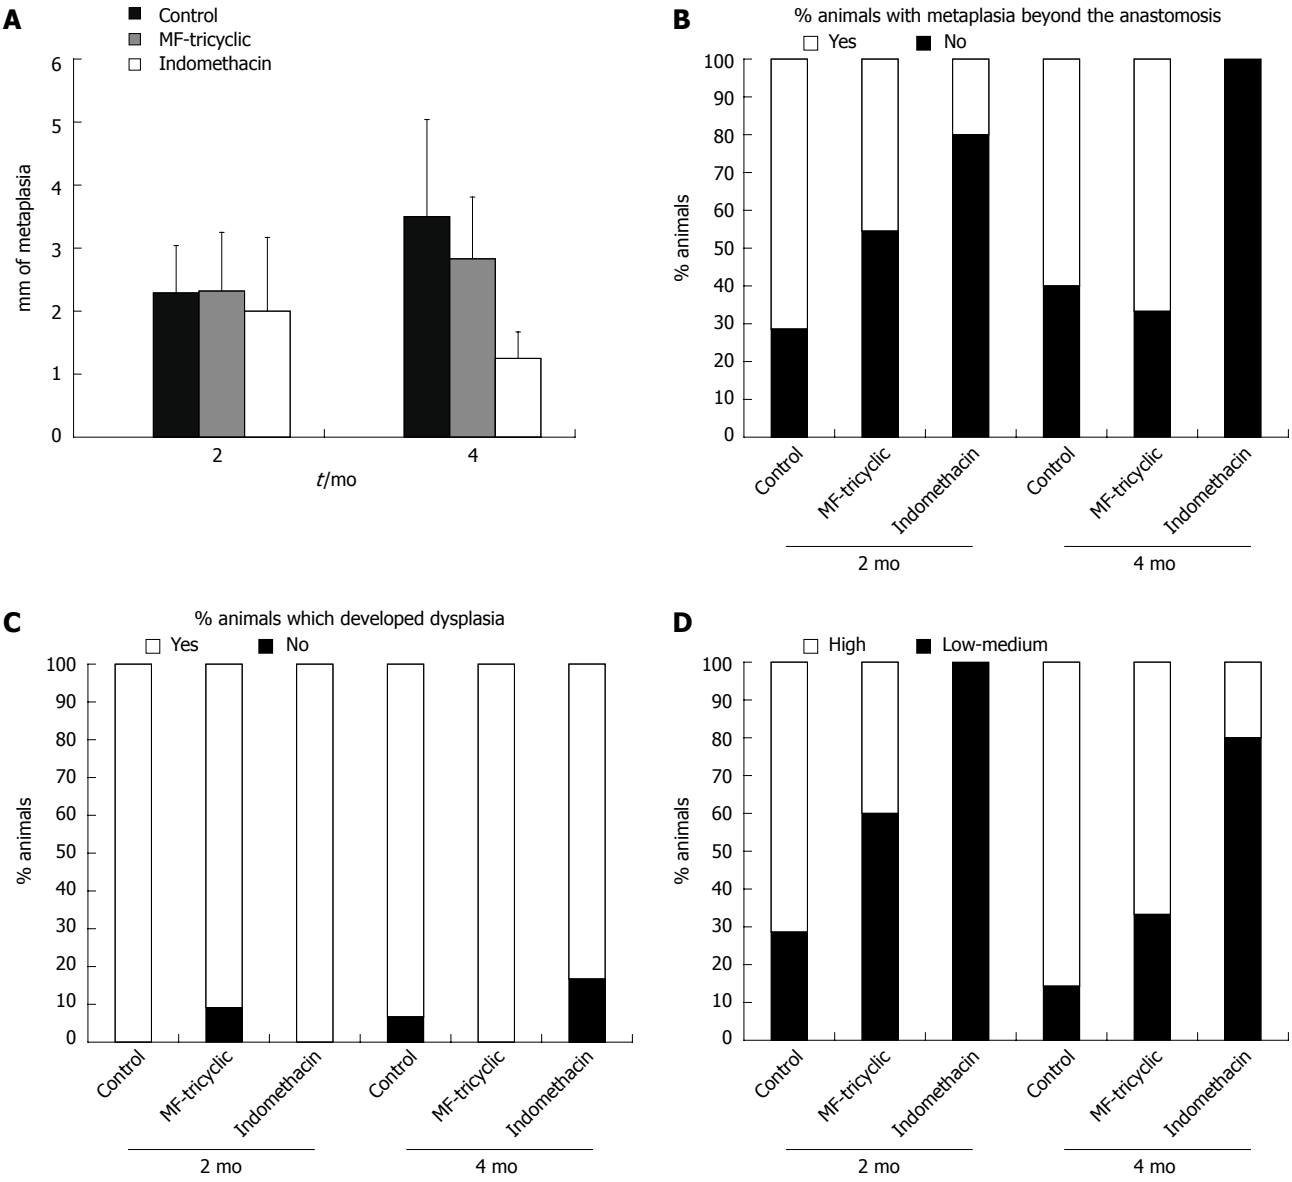

Figure 3 Macroscopic findings. A: Effect of treatment on metaplasia in continuity length. A significant decrease was observed in indomethacin-treated groups compared to control groups (P = 0.007); B: Treatment effect on the percentage of animals that developed metaplasia beyond the anastomosis. Percentage of animals that developed metaplasia beyond the anastomosis was significantly higher in both control and MF-tricyclic groups (P = 0.009 and P = 0.036, respectively); C: Percentage of animals that developed dysplasia; D: Because most animals developed dysplasia, low-to-medium grade *vs* high-grade dysplasia was analyzed. Percentage of rats that developed high-grade dysplasia was significantly lower in indomethacin groups compared to control groups (P = 0.002). When we analyzed the effect of treatment, we observed lower incidence of neoplasia in the indomethacin group (P = 0.000). MF-tricyclic: 3-(3, 4-difluorophenyl)-4-(4-(methylsulfonyl)phenyl)-2-(5H)-furanone.

tricyclic, although they also did not see significant mucosal PGE2 inhibition with this agent. In our study, we used the same dose of MF-tricyclic as that reported in Buttar's experiment, but the serum drug levels found in our rats were higher. Therefore, we suggest that the apparent differences between these results could be due to the different experimental periods of treatment (28 and 16 wk in Buttar's and our study, respectively). In a 40-wk experimental study, Oyama *et al*[21] showed that pathological changes associated with accelerated cell proliferation, such as regenerative thickening and basal cell hyperplasia, were significantly suppressed in the treated group (celecoxib 500 ppm, 100 mg/kg/d) throughout the experiment. However, the incidence of columnar lined epithelium and EA were significantly suppressed only at the end of the study (40 wk). Similarly, Chen *et al*[22] showed beneficial effects in animals treated with celecoxib over a 40-wk experimental period. We selected the endpoint of the present study according to previous research performed in our group, in which rats under esophagojejunostomy showed a high incidence of esophageal adenocarcinoma and intestinal metaplasia 4 mo after surgery. It is possible that this period of time is sufficient to see a positive effect with profound inhibition of both types of COX activity as with indomethacin, but is not long enough to see the results of weaker or partial COX inhibition with a selective COX-2 agent.

Most studies, including ours, showed a greater decr-

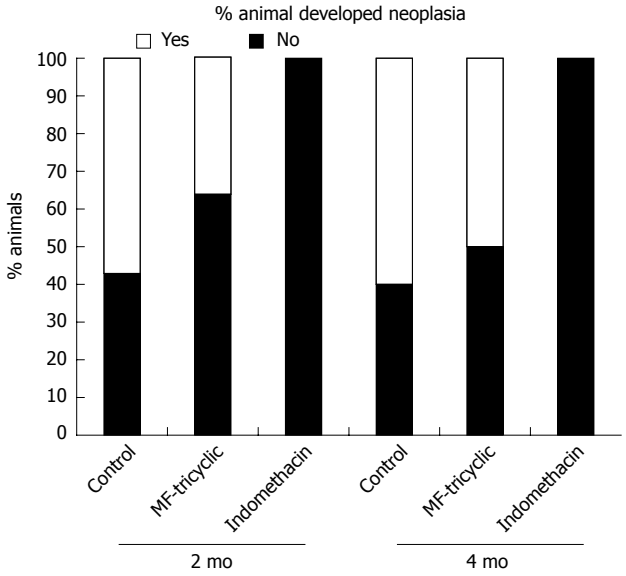

Figure 4 Percentage of animals that developed neoplasia.

ease in tissue PGE2 levels with a nonselective COX inhibitor compared to COX-2 selective inhibitors[11,20,23]. This effect suggests that PGE2-derived COX-1 inhibition may play a role in the progression from gastrointestinal reflux to EA. In addition, additional mechanisms not linked to either COX-1 or COX-2 inhibition may be involved in this process. Orido *et al*[24] observed that treatment with indomethacin, but not sulindac, decreases arachidonic acid uptake in a human colorectal cell line. They suggested that the anticancer effect of indomethacin could be independent of COX-2 inhibition. Moreover, Kim *et al*[25] evaluated the induction of NAG-1 and apoptosis by various NSAIDs, such indomethacin, sulindac, and diclofenac. Indomethacin was the most potent inducer of both NAG-1 expression ($P < 0.05$) and apoptosis ($P < 0.05$). Kopp *et al*[26] and Castro *et al*[27] reported that sodium salicylate, acetylsalicylic acid, and indomethacin inhibit activation of NF-κB[26,27]. Hanif *et al*[28] observed that NSAIDs inhibit the proliferation rate of two colon cancer cell lines independent of their ability to inhibit prostaglandin synthesis.

In addition to the above observations, it is important to note that much higher doses of NSAIDs are required for inhibition of proliferation and angiogenesis and induction of apoptosis, some of the mechanisms that have been suggested to contribute to antitumor activity, than for inhibition of prostaglandin synthesis[29].

In conclusion, treatment with indomethacin, a dual COX-1/COX-2 inhibitor, in our experimental model of EA, prevented the development of intestinal metaplasia and esophageal adenocarcinoma and reduced PGE2 production. In contrast, treatment with MF-tricyclic, a selective COX-2 inhibitor, was not associated with these effects. The profound inhibition of mucosal PGE2 with indomethacin, but not with MF-tricyclic, might partly explain the different effects, but other reasons, such as the length of therapy, activity of COX-1, and involvement of COX-independent mechanisms, could also explain the results, and deserve further investigation.

Table 2 Esophageal prostaglandin E2 levels in rats at 2 mo and 4 mo (mean ± SE, ng/g)

	2 mo	4 mo
Without treatment	1332.7 ± 656.7	1121.6 ± 1015.6
MF-tricyclic	1776.8 ± 1403.3	1914.9 ± 1905.5
Indomethacin	480.3 ± 333.4	243.9 ± 85.7

MF-tricyclic: 3-(3,4-difluorophenyl)-4-(4-(methylsulfonyl)phenyl)-2-(5H)-furanone.

COMMENTS

Background

Over the last decades, the incidence of esophageal adenocarcinoma in the United States and Western Europe has dramatically risen. Epidemiological studies have reported that consumption of cyclooxygenase (COX) inhibitors leads to a decrease in the chance of developing esophageal cancer.

Research frontiers

COX-2 has become a target for the prevention of esophageal adenocarcinoma. There are several studies in which administration of COX-2 inhibitors showed a reduction in the incidence of esophageal adenocarcinoma in rat reflux-induced models. In contrast to previous studies, the research showed no effect when a selective COX-2 inhibitor was administered, while a non-selective COX inhibitor, indomethacin, inhibited the complete carcinogenic sequence in the rat esophagus.

Innovations and breakthroughs

Recent evidence has demonstrated that COX-1 may be important in the development of different neoplasias, because elevated levels of COX-1 expression were found in prostate, breast, and cervical cancers. In the study, treatment with indomethacin, a dual COX-1/COX-2 inhibitor, prevented the development of intestinal metaplasia and esophageal adenocarcinoma and reduced prostaglandin E2 (PGE2) production. In contrast, treatment with 3-(3, 4-difluorophenyl)-4-(4-(methylsulfonyl)phenyl)-2-(5H)-furanone (MF-tricyclic), a selective COX-2 inhibitor, was not associated with these effects. These results suggest that COX-1 also plays an important role in the development of esophageal adenocarcinoma.

Applications

The inhibitory effect of the complete carcinogenic sequence observed with indomethacin in this study suggests two new aspects that should be further investigated; firstly, the potential role of COX-1 in esophageal adenocarcinogenesis and secondly, the involvement of cyclooxygenase-independent anticancer actions of indomethacin.

Peer review

The authors evaluated the effect of indomethacin, a COX non-selective inhibitor, and MF-tricyclic, a COX-2 selective inhibitor, in an experimental model of Barrett's esophagus and EA in rats. The study showed that indomethacin but not MF-tricyclic prevented the development of intestinal metaplasia and esophageal adenocarcinoma and reduced PGE2 production. The results suggest that COX-1 plays an important role in the development of esophageal adenocarcinoma.

Abstract

AIM: To investigate the effect of Tangweian Jianji (TWAJJ) on the biomechanical and morphometrical remodeling of the upper gastrointestinal tract in diabetic rats.

METHODS: Diabetes was induced in 27 rats by injecting streptozotocin (40 mg/kg body weight), the animals were then divided into three groups (n = 9 in each group), i.e., diabetic control (DM); high dose (10 g/kg, T1) and low dose (5 g/kg, T2). Another 10 rats acted as normal controls (Control). TWAJJ was administered by gavage once daily. Blood glucose and serum insulin levels were measured. Circumferential length, wall thickness and opening angle were measured from esophageal, duodenal, jejunal and ileal ring segments. The residual strain was calculated from the morphometric data. Step-wise distension was carried out on esophageal and jejunal segments. The obtained data on the length, diameter and pressure changes were then used to calculate the circumferential and longitudinal stresses and strains. Real-time reverse transcription polymerase chain reaction was used to detect the receptor of advanced glycation end-products (RAGE) mRNA level in jejunal tissues.

RESULTS: At the end of the experiment, the blood glucose level was significantly higher and the serum insulin level was significantly lower in DM, T1 and T2 groups than in the control group (Glucose: 30.23 ± 0.41 mmol/L, 27.48 ± 0.27 mmol/L and 27.84 ± 0.29 mmol/L *vs* 5.05 ± 0.04 mmol/L, $P = 1.65 \times 10^{-16}$, $P = 5.89 \times 10^{-19}$ and $P = 1.63 \times 10^{-18}$, respectively; Insulin: 1.47 ± 0.32 μg/L, 2.66 ± 0.44 μg/L, 2.03 ± 0.29 μg/L and 4.17 ± 0.54 μg/L, $P = 0.0001$, $P = 0.029$ and $P = 0.025$, respectively). However, these levels did not differ among the DM, T1 and T2 groups. The wet weight per unit length, wall thickness and opening angle of esophageal and intestinal segments in the DM group were significantly higher than those in the control group (from $P = 0.009$ to $P = 0.004$). These parameters in the T1 group were significantly lower than those in the DM group (wet weight, duodenum: 0.147 ± 0.003 g/cm *vs* 0.158 ± 0.001 g/cm, $P = 0.047$; jejunum, 0.127 ± 0.003 g/cm *vs* 0.151 ± 0.002 g/cm, $P = 0.017$; ileum, 0.127 ± 0.004 g/cm *vs* 0.139 ± 0.003 g/cm, $P = 0.046$; wall thickness, esophagus: 0.84 ± 0.03 mm *vs* 0.94 ± 0.02 mm, $P = 0.014$; duodenum: 1.27 ± 0.06 mm *vs* 1.39 ± 0.05 mm, $P = 0.031$; jejunum: 1.19 ± 0.07

mm *vs* 1.34 ± 0.04 mm, *P* = 0.047; ileum: 1.09 ± 0.04 mm *vs* 1.15 ± 0.03 mm, *P* = 0.049; opening angle, esophagus: 112.2 ± 13.2° *vs* 134.7 ± 14.7°, *P* = 0.027; duodenum: 105.9 ± 12.3° *vs* 123.1 ± 13.1°, *P* = 0.046; jejunum: 90.1 ± 15.4° *vs* 115.5 ± 13.3°, *P* = 0.044; ileum: 112.9 ± 13.4° *vs* 136.1 ± 17.1°, *P* = 0.035). In the esophageal and jejunal segments, the inner residual stain was significantly smaller and the outer residual strain was larger in the DM group than in the control group (*P* = 0.022 and *P* = 0.035). T1 treatment significantly restored this biomechanical alteration (*P* = 0.011 and *P* = 0.019), but T2 treatment did not. Furthermore, the circumferential and longitudinal stiffness of the esophageal and jejunal wall increased in the DM group compared with those in the control group. T1, but not T2 treatment, significantly decreased the circumferential wall stiffness in the jejunal segment (*P* = 0.012) and longitudinal wall stiffness in the esophageal segment (*P* = 0.023). The mRNA level of RAGE was significantly decreased in the T1 group compared to that in the DM group (*P* = 0.0069).

CONCLUSION: TWAJJ (high dose) treatment partly restored the morphometric and biomechanical remodeling of the upper gastrointestinal tract in diabetic rats.

INTRODUCTION

Diabetic gastrointestinal disorder (DGID) is a common complication of diabetes. Up to 76% of diabetic patients express gastrointestinal symptoms including dysphagia, early satiety, reflux, constipation, abdominal pain, nausea, vomiting and diarrhea[1,2]. Duration of the disease and poor glycemic control seem to be associated with the severity of gastrointestinal (GI) problems. In general, the pathogenesis of DGID includes high blood glucose level, smooth muscle degeneration, abnormal autonomic neuropathy, gastrointestinal hormone secretion disorders and oxidative stress[3,4].

The GI tract is functionally subjected to dimensional changes. Hence, biomechanical properties such as the stress-strain relationships are of particular importance[5]. These properties are remodeled in response to growth[6], fasting[7] and disease[8]. The biomechanical properties are crucial for GI motor function because peristaltic motion which propels the food through the GI tract is a result of an interaction between the passive and active tissue forces and the hydrodynamic forces in the food bolus. Remodeling of the mechanical properties reflects the changes in the tissue structure that determine a specific motor dysfunction. During the past few years, several studies have demonstrated that experimental diabetes induces GI morphological and biomechanical remodeling[9-13]. Following the development of diabetes, the GI wall becomes thicker and stiffer in a time-dependent manner. Therefore, diabetic gastrointestinal morphological and biomechanical remodeling play an important role in DGID and has become the new perspective of diabetic gastrointestinal pathogenesis[11].

Some studies on diabetic arteries have demonstrated that non-enzymatic glycation of arterial wall tissues is associated with remodeling of the wall[14,15]. We believe that the same applies to the diabetic GI wall. Advanced glycation end-products (AGEs) may contribute to diabetic GI morphological and biomechanical remodeling by two major mechanisms. The first is receptor-independent alteration of the extracellular matrix architecture by non-enzymatic glycation and the formation of protein cross-links. The second mechanism is receptor-dependent and consists of modulation of cellular functions through ligation of specific cell surface receptors[16-18].

Western medical treatment of DGID is mainly focused on symptomatic control with improvement of gastric motility, using promoting agents and supportive measures based on blood glucose control[2]. Although these therapies can partially improve the clinical symptoms, they do not fundamentally reverse the diabetes-induced changes and result in a very high relapse rate. In clinics it was shown that Tangweian Jianji (TWAJJ) significantly improved DGID with a low relapse rate, however, the mechanism involved in this improvement is not fully understood. Therefore, the aim of the present study was to investigate whether TWAJJ treatment can improve the morphometric and biomechanical remodeling of the GI tract in streptozotocin (STZ)-induced diabetic rats. Furthermore, the receptor of advanced glycation end-products (RAGE) mRNA level in the jejunal tissues was also investigated to explore the possible mechanism of TWAJJ in the treatment of DGID.

MATERIALS AND METHODS

Animal model and groups

Forty male SD rats weighing 220-250 g were included in this study. Diabetes was induced in 30 rats by a single tail vein injection of 40 mg/kg body weight of strepto-

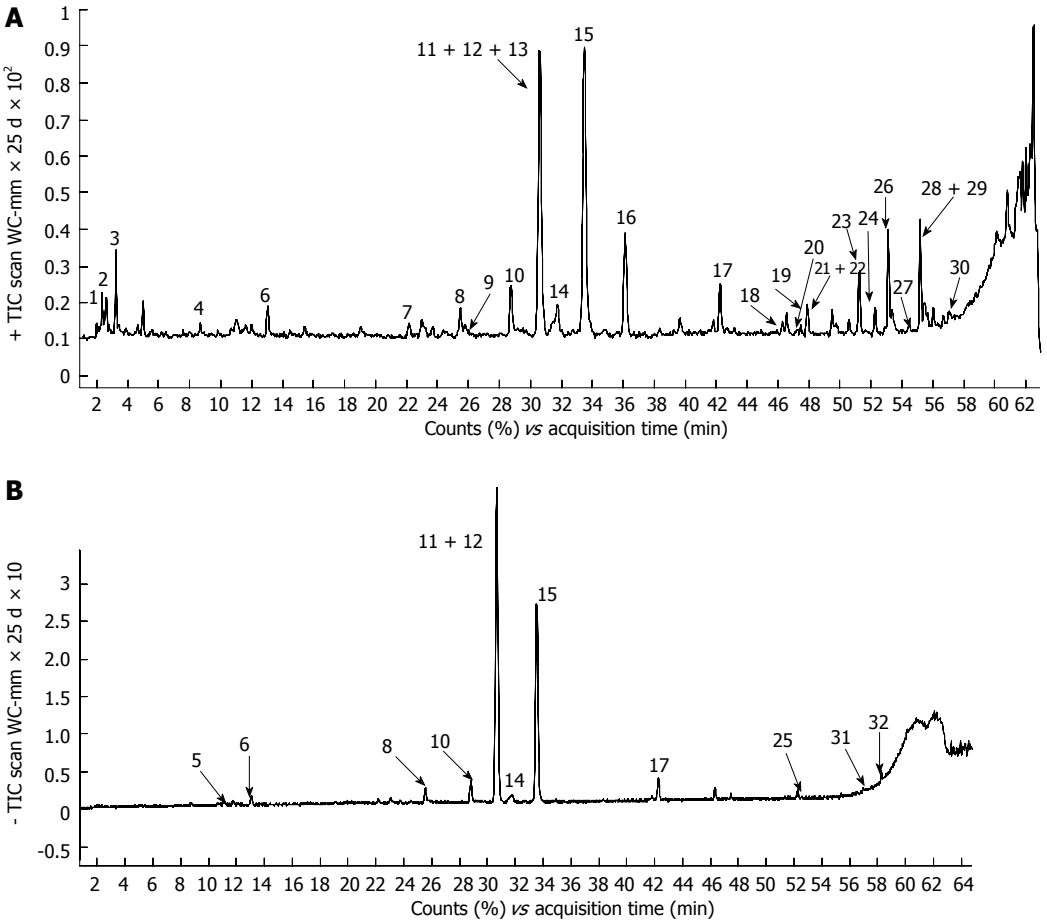

Figure 1 High pressure liquid chromatograph/mass spectrometry analysis of Tangweian Jianji extract. A: Representative total ion current (TIC) chromatograms of the Tangweian Jianji (TWAJJ) extract were obtained in positive ion electrospray; B: TIC chromatograms of the TWAJJ extract was obtained in negative ion electrospray. Visual inspection of the two TIC plots shows that the two modes of ionization generate different constituent information based on the ionizability differences of the components in TWAJJ. A total of 32 peaks were observed. The most abundant compounds identified are Naringin (peak 12), Neohesperidin (peak 15), Lobetyolin (peak 16), Atractylenolide (peak 26) and Emodin (peak 23). WC: Wave chromatogram.

zotocin (STZ, Sigma-Aldrich, China). This dose of STZ resulted in a random blood glucose level ⩾ 16.7 mmoL/L in 90% of rats 7 d after the injection. The remaining 10% of rats were excluded from this study. Twenty-seven STZ-induced diabetic rats were subdivided into three groups (n = 9 in each group), i.e., diabetic control group (DM); high dose of TWAJJ group (T1) and low dose of TWAJJ group (T2). Another 10 rats of similar age and body weight from the same vendor were used as a non-diabetic control group (Control).

Drugs and administration methods

TWAJJ is composed of Citrus aurantium, Codonopsis, fried Atractylodes and wine Rhubarb and was provided by Guang'anmen Hospital, China Academy of Chinese Medical Sciences. The medicine was administered by gavage which passed though the esophagus and reached the stomach lumen. The drug was perfused directly into the stomach once daily from the beginning of the experiment. The dosage was 10 g/kg for T1 and 5 g/kg for T2, respectively. The rats in the DM and control groups were perfused with physiological saline.

Chemical analysis of TWAJJ

The formulation of TWAJJ was prepared according to the corresponding monograph in the 2005 Edition of Chinese Pharmacopoeia. There were quantitative control limits for the raw herbs (for example, the content of Naringin in Citrus aurantium was not less than 4.0% and Neohesperidin was not less than 3.0%) and for the final drug product. The chemical composition of TWAJJ was determined by using an ultra-fast high performance liquid chromatography-electrospray-ionization-quadrupole time-of-flight mass spectrometry method. An example chromatographic fingerprint is shown in Figure 1. The major compounds in the final dosage form were identified as Naringin, Neohesperidin, Lobetyolin, Atractylenolide and Emodin. These compounds were used as the quality control markers in the final TWAJJ formulation.

Experimental procedures

Weight and blood glucose levels were measured at 2-wk intervals after initiating the experiment. For blood glucose measurement, one drop of blood was obtained from rat tail vein and blood glucose was measured by a John-

son and Johnson One Touch Ultra Blood Glucose Meter. For insulin measurement, blood was obtained from the abdominal aorta and 0.2 mL serum was separated. The serum insulin was measured by radioimmunoassay (rat insulin radioimmunoassay kit, Linco Company, United States) at the end of the experiment.

The experimental period was 60 d. At the end of the experiment, the rats were fasted overnight and anesthetized with 4% Chloral hydrate (10 mL/kg, *ip*). Following laparotomy, the whole esophagus and ten centimeters of duodenum, jejunum and ileum were harvested. The duodenum was taken from the descending section, 1 cm down from the pylorus; the jejunum from 5 cm distal to the ligament of Treitz, and the ileum from 5 cm proximal to the ileo-cecal valve. After gently cleaning the lumen of the segments with saline, the length and wet weight were measured.

The esophageal and jejunal segments were divided into three sections, the proximal 1 cm segment was immediately stored at -70 ℃ for protein and RAGE mRNA detection. The adjacent 1 cm long segment was used for the zero-stress state experiment. The remaining section was used for the distension test. The duodenal and ileal segments were divided into two and used for protein and mRNA detection and the zero-stress state experiment. In this experiment, RAGE mRNA detection was performed only on the jejunal segments.

Zero-stress state experiment

To obtain data on the zero-stress state, three 1-2 mm wide esophageal and intestinal rings were cut and placed in Krebs solution at room temperature. The composition of Krebs solution (mmol/L) was: NaCl, 118; KCl, 4.7; $NaHCO_3$, 25; NaH_2PO_4, 1.0; $MgCl_2$, 1.2; and ascorbic acid, 0.11. A photograph was taken of the cross-section of the rings using a Canon camera (Canon, Japan) and was presented as the no-load state. Each ring-shaped segment was then cut radially from the opposite mesentery site and the photographs were taken about 60 min after the radial cutting to allow viscoelastic creep to take place. This is presented as the zero-stress state.

Distension test

The distal end of the remaining esophageal and jejunal segments was tied with a suture and the proximal end was cannulated with a tube for the distension experiment. After preconditioning of the segments, they were inflated with Krebs solution using a step-wise distension protocol from 0 cm to 20 cm H_2O (0 cm, 1 cm, 2 cm, 3 cm, 5 cm, 10 cm, 15 cm and 20 cm H_2O) for the esophageal segment and from 0 cm to 10 cm H_2O (0 cm, 0.5 cm, 1 cm, 2 cm, 4 cm, 6 cm, 8 cm and 10 cm H_2O) for the jejunal segment. The segments conformed to a cylindrical geometry during the distensions. Each pressure lasted for 2 min and then the outer diameter and length of the segments were photographed (Canon, Japan).

Mechanical data analysis

The morphometric data were obtained from digitized images of the segments in the zero-stress, no-load and pressurised states. Measurements were undertaken using image analysis software (Sigmascan ver. 4.0, Sigma Corp., San Rafael, CA, United States). The following data were measured from each specimen: the circumferential length (C), the wall thickness (h), the wall area (A), and the opening angle at zero-stress state (α). The subscripts i, o, n, z and p refer to the inner (mucosal) surface, outer (serosal) surface, no-load state, zero-stress state and pressurised condition. The opening angle α was defined as the angle subtended by two radii drawn from the midpoint of the inner wall to the inner tips of two ends of the specimen. Furthermore, the outer diameter (D) and the length (L_p) were measured from the images of the pressurised segments.

The measured data were used for the calculation of biomechanical parameters defined as:

Residual Green's strain at the mucosal surface:

$$E_i = \frac{(\frac{C_{i-n}}{C_{i-z}})^2 - 1}{2} \quad (1)$$

Residual Green's strain at the serosal surface:

$$E_o = \frac{(\frac{C_{o-n}}{C_{o-z}})^2 - 1}{2} \quad (2)$$

The stress and strain of the esophageal and intestinal segments in the pressurised state were determined under the assumptions that the wall was homogenous and the organ shape was cylindrical. Calculations were performed knowing the no-load state dimensions, the outer diameters and lengths of the specimens at varying pressures, and assuming incompressibility of the wall. The longitudinal stretch ratio, $\lambda_\varphi = \frac{L_p}{L_z}$;

the luminal radius, $r_{i-p} = \sqrt{r_{o-p}^2 - \frac{A_n}{\pi\lambda_\varphi}}$;

the wall thickness, $h_p = r_{o-p} - r_{i-p}$; the mucosal circumferential length, $C_{i-p} = 2 \times \pi \times r_{i-p}$; the serosal circumferential length, $C_{o-p} = 2 \times \pi \times r_{o-p}$; the mid-wall circumferential length, $C_{m-p} = \frac{C_{i-p} + C_{o-p}}{2}$;

the circumferential stretch ratio, $\lambda_\theta = \frac{C_{m-p}}{C_{m-z}}$

(where the middle-wall circumferential length at zero-stress state, $C_{m-z} = \frac{C_{i-z}}{C_{o-z}}$) were calculated.

Then the Kirchhoff's stress and Green's strain in a wall at a given pressure were calculated according to the following equations:

Circumferential Kirchhoff's stress: $S_\theta = \frac{\Delta P r_{i-p}}{h_p \lambda_\theta^2}$ (3)

Longitudinal Kirchhoff's stress: $S_\varphi = \frac{\Delta P r_{i-p}^2}{h_p \lambda_\varphi^2 (r_{o-p} + r_{i-p})}$ (4)

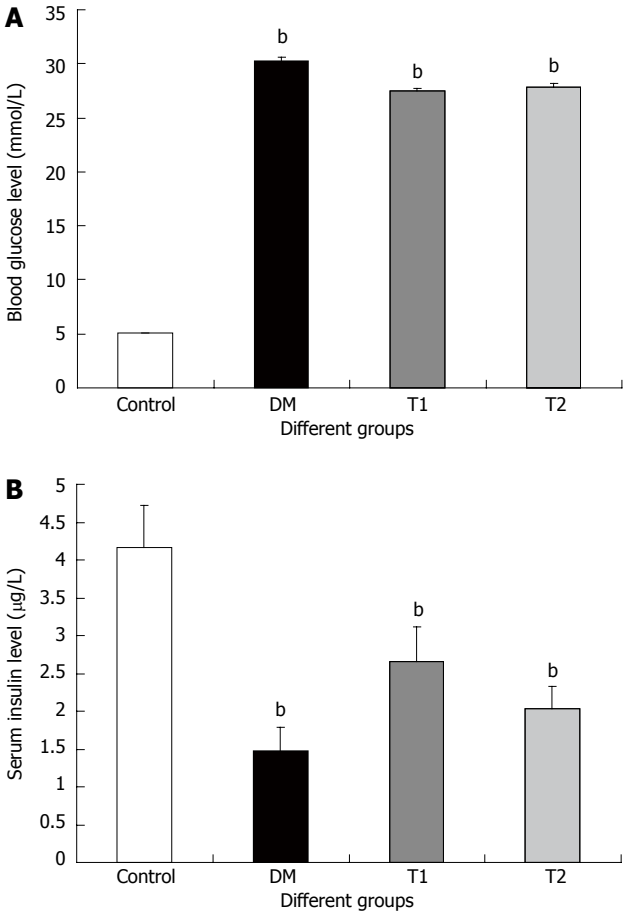

Figure 2 Blood glucose levels and serum insulin levels in the different groups. A: Blood glucose levels; B: Serum insulin level. DM, T1 and T2 groups compared with the control group. $^{b}P < 0.01$ *vs* control group. DM: Diabetic control; T1: High dose; T2: Low dose.

$$\text{Circumferential mid-wall Green's strain: } E_{\theta} = \frac{\lambda_{\theta}^{2} - 1}{2} \quad (5)$$

$$\text{Longitudinal Green's strain: } E_{\varphi} = \frac{\lambda_{\varphi}^{2} - 1}{2} \quad (6)$$

ΔP is the transmural pressure difference. The longitudinal mid-wall stretch ratio was referenced to the no-load state because tissue strips could not be cut to obtain the zero-stress state in the longitudinal direction. However, the longitudinal mid-wall length in rat intestine does not differ between the no-load and zero-stress states[19].

Receptor of advanced glycation end-products mRNA detection

Real-time polymerase chain reaction (RT-PCR) was used to detect RAGE mRNA level in the jejunal tissues. Total RNA was isolated from 100 mg tissue of each specimen using ultra-pure Trizol reagent according to the procedure described by the manufacturer (Invitrogen, United States). RNA concentration was determined when equal amounts of total RNA (3 μg) were used in the reverse transcription with the iScript cDNA synthesis kit (Bio-Rad Laboratories, Hercules, CA, United States). RT-PCR was used to quantify the mRNA expression of RAGE. Amplification was performed using iQ Supermix with the iCycler iQ Real-Time Detection System according to the manufacturer's instructions (Applied Biosystems). A standard curve was generated for each primer pair and a probe to determine PCR efficiency. Mean threshold cycle (Ct) values for each sample were normalized to β-actin and calibrated to the control group to obtain the threshold cycle difference (ΔΔCt) with 2-ΔΔCt being the fold change relative to the control group. The probes and primer sequences used were as follows: RAGE: Sense: 5'-TCT CAG AAG CCC AAG GAA GAG T-3'; Antisense: 5'-CCT AGG TCT GAA GGC CCT GAG T-3', amplified cDNA length: 173 bp; β-actin: Sense: 5'-AGA TCC ACA ACG GAT ACA TT-3'; Antisense: 5'-TCC CTC AAG ATT GTC AGC AA-3', amplified cDNA length: 309 bp.

Statistical analysis

The data were representative of a normal distribution and accordingly the results were expressed as mean ± SE. The stress-strain curve for each direction was fitted using the exponential function equation $S = (S^* + \beta)\, e^{\alpha (E-E^*)} - \beta$.S* and E* are the stress and strain at a physiological reference level[5]. The constants α and β from the above exponential function were used for the statistical evaluation of the stress-strain data. Analysis of variance was used to detect differences in the parameters and groups (Sigmastat 2.0™). The results were regarded as significant when $P < 0.05$.

RESULTS

Blood glucose and serum insulin levels

Blood glucose and serum insulin levels at the end of the experiment are shown in Figure 2. The blood glucose level was 4-fold higher in the DM group compared with the control group (Figure 2A, $P < 0.01$). The serum insulin level was significantly lower in the DM group compared with the control group (Figure 2B, $P < 0.01$). Compared with the DM group, the blood glucose and insulin levels did not significantly change in the T1 and T2 groups.

The weight/cm, wall thickness and wall area

The wet weight per unit length (Figure 3A), no-load wall thickness (Figure 3B) and cross-sectional wall area (Figure 3C) of the esophageal and intestinal segments increased in the DM group compared with the control group ($P < 0.01$, $P < 0.05$). After treatment with T1, the wall thickness decreased in all segments (Figure 3B, $P < 0.05$), whereas the wet weight and wall area decreased in the duodenal, jejunal and ileal segments (Figure 3A, D, $P < 0.01$, $P < 0.05$), but not in the esophageal segment ($P = 0.12$). All the above parameters did not change significantly in the T2 group.

Opening angle and residual strain

At the end of the experiment, the opening angle of all three intestinal segments was significantly increased in

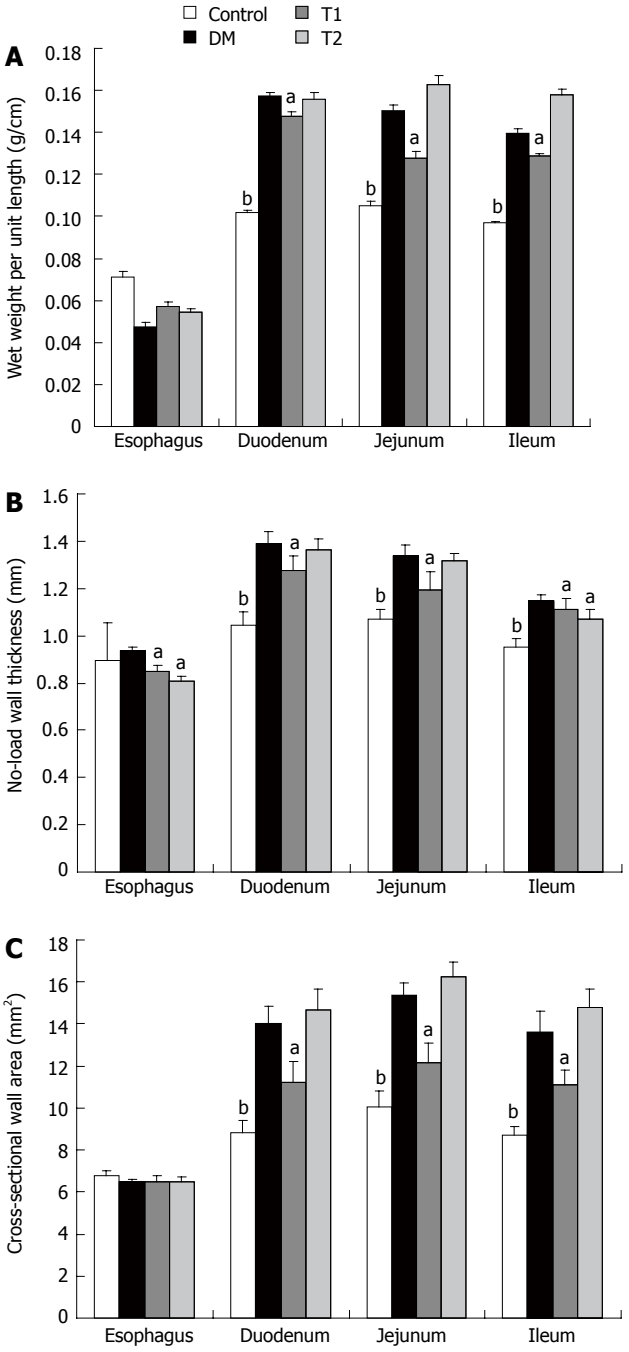

Figure 3 Wet weight per unit length, wall thickness and wall area in different segments of the different groups. A: Wet weight per unit length; B: Wall thickness; C: Wall area. [a]*P* < 0.05, [b]*P* < 0.01 *vs* DM group. DM: Diabetic control; T1: High dose; T2: Low dose.

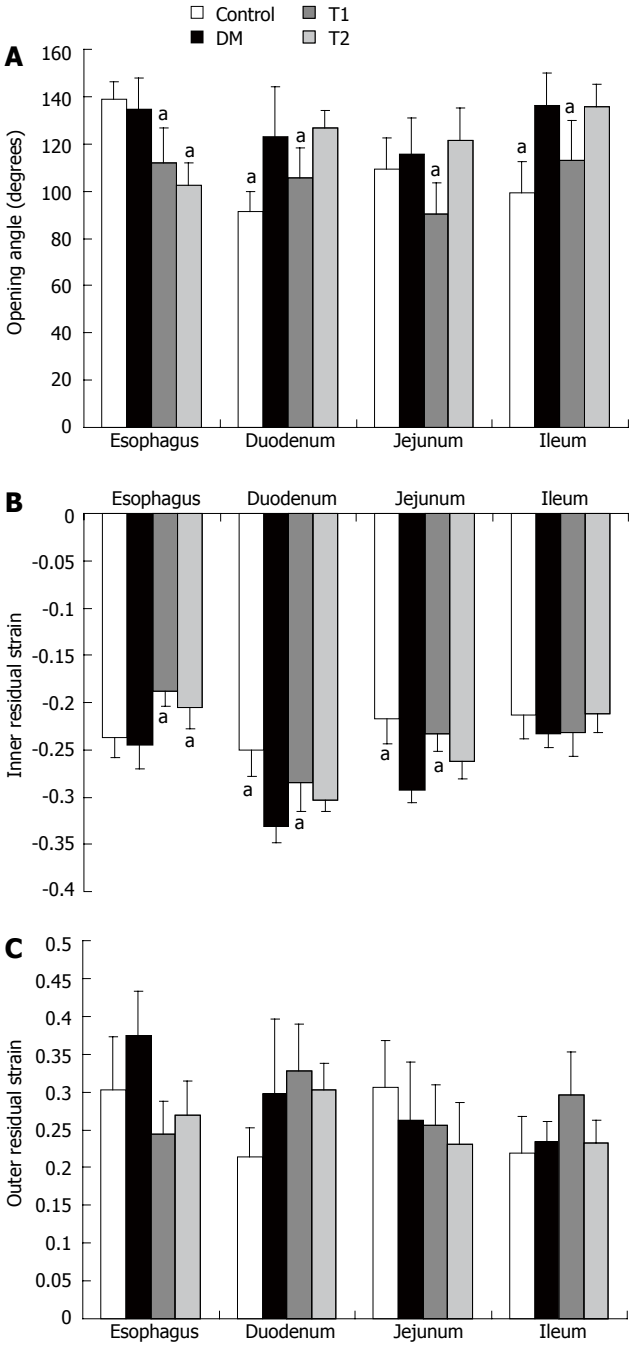

Figure 4 Opening angle, inner residual strain and outer residual strain in different segments of the groups. A: Opening angle; B: Inner residual strain; C: Outer residual strain. [a]*P* < 0.05 *vs* DM group. DM: Diabetic control; T1: High dose; T2: Low dose.

the DM group compared with the control group (Figure 4A, $P < 0.05$). However, the opening angle in the esophageal segment did not change. Treatment with high dose TWAJJ decreased the opening angle in all segments studied (Figure 4A, $P < 0.05$). Interestingly, the opening angle of the esophageal segment was also decreased in the T2 group ($P < 0.05$).

A similar pattern to that found in the opening angle was found in the inner residual strain for all segments and groups, with the exception of the ileal segment (Figure 4B), where no difference was found between the different groups ($P > 0.05$). The outer residual strain did not differ between the groups and segments (Figure 4C).

Stress-strain distribution

At the end of the experiment, the stress-strain analysis showed that the circumferential stress-strain curves of esophageal and jejunal segments (Figure 5A, C), and the longitudinal stress-strain curve of the esophageal segment (Figure 5B) in the DM group shifted to the left

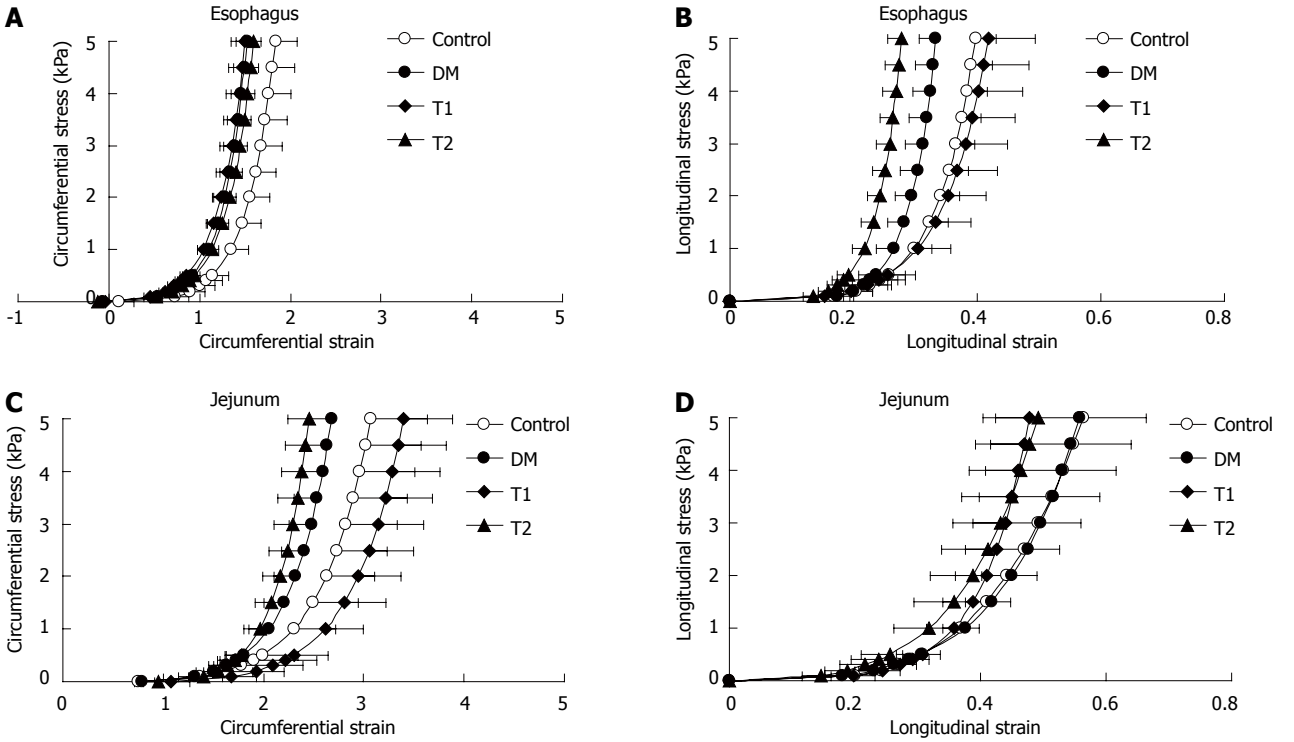

Figure 5 Circumferential and longitudinal stress-strain curves of esophageal and jejunal segments in the different groups. DM: Diabetic control; T1: High dose; T2: Low dose.

Table 1 Comparison of constant a among the different groups

	Circumferential direction		Longitudinal direction	
	Esophagus	Jejunum	Esophagus	Jejunum
Control (n = 10)	3.56 ± 0.35	2.65 ± 0.37	18.33 ± 2.36	13.51 ± 3.66
DM (n = 9)	4.59 ± 0.79[a]	3.81 ± 0.31[a]	27.62 ± 3.93[a]	14.79 ± 2.26
T1 (n = 9)	3.77 ± 0.39	2.55 ± 0.51[c]	19.43 ± 4.13[c]	14.67 ± 1.56
T2 (n = 9)	3.84 ± 0.44	4.02 ± 0.71[a]	27.82 ± 1.74[a]	15.41 ± 4.36

[a]$P < 0.05$ *vs* control group; [c]$P < 0.05$ *vs* DM group. DM: Diabetic control; T1: High dose; T2: Low dose.

compared with those in the control group, indicating that the diabetic esophageal and intestinal wall became stiffer. Calculation of the mechanical constants demonstrated a difference between the DM group and the control group ($P < 0.05$, Table 1). However, the longitudinal stress-strain distribution of the jejunal segment did not differ between the DM and control groups ($P > 0.05$, Figure 5D). High dose TWAJJ (T1) decreased the stiffness of the esophageal wall in the longitudinal direction (Figure 5B and Table 1, $P < 0.05$) and the intestinal wall in the circumferential direction (Figure 5C and Table 1, $P < 0.05$). Low dose TWAJJ did not improve the stiffening of the esophageal and jejunal wall caused by diabetes ($P > 0.05$, Figure 5 and Table 1).

Receptor of advanced glycation end-products mRNA level

RAGE mRNA level of the jejunal segment increased in the DM group compared to the control group (Figure 6, $P < 0.01$). T1 treatment reduced the RAGE mRNA level (Figure 6, $P < 0.01$). We did not observe a significant difference between the T2 group and the DM group (Figure 6, $P > 0.05$).

DISCUSSION

Diabetes mellitus is a pandemic disease. According to WHO´s statistical report; 370 million diabetic patients are expected by 2030. The serious impact caused by diabetes and its complications does not only affect patients but is also a heavy financial burden to the health care system and on families[20]. DGID is a common complication of diabetes. A previous study showed that prominent proliferations of the GI wall, especially the small intestine and esophagus mucosae, occur in experimental diabetes[21]. Other studies demonstrated morphological and biomechanical remodeling of the upper GI tract in diabetes[9-10,22], which may be caused by over-expression of AGE and RAGE in the diabetic GI tract. Furthermore, a linear association between the glucose level and morphometric and biomechanical remodeling was observed[23].

In the view of traditional Chinese medicine, DGID is in the category of fullness, epigastric pain, vomiting, diarrhea, and constipation concurrent with diabetes. The major syndrome of DGID includes spleen deficiency and qi stagnation. Therefore, the principal treatment is to strengthen the spleen and remove stagnation. TWAJJ is a practical Chinese medicinal compound for DGID[24-26] and is composed of several herbs. Atractylodes mac-

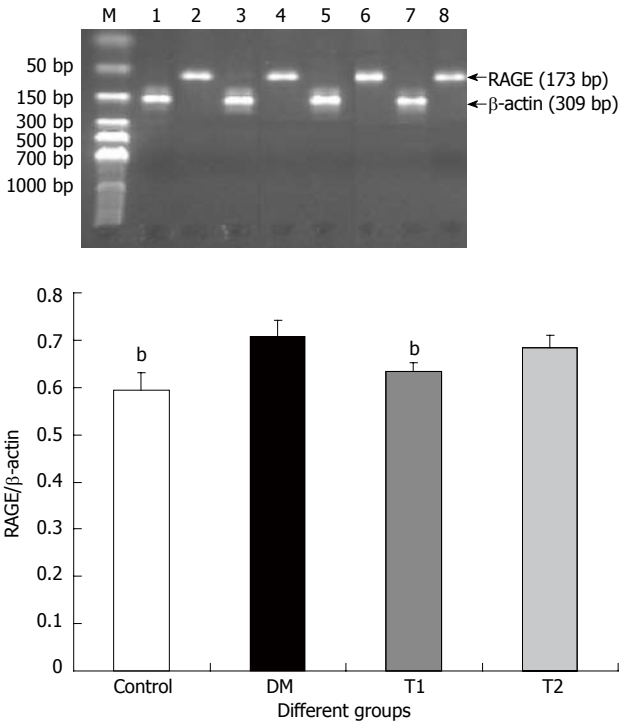

Figure 6 Receptor of advanced glycation end-products mRNA level of the jejunal segment in the different groups. $^{b}P < 0.01$ *vs* DM group. M: Ladder marker; 1, 3, 5, 7: β-actin; 2, 4, 6, 8: RAGE; 1, 2: Control; 3, 4: DM; 5, 6: T1; 7, 8: T2. DM: Diabetic control; T1: High dose; T2: Low dose; RAGE: Receptor of advanced glycation end-products.

rocephala can strengthen the spleen, harmonize the stomach, regulate GI motility and protect the gastric mucosa[27]. Citrus aurantium and wine rhubarb move qi and accumulation. Pinellia downbears counterflow and inhibits vomiting. Ginseng tones qi and has a beneficial affect on body fluid. Citrus aurantium has a non-competitive antagonist effect on acetylcholine and histamine in intestinal smooth muscle contraction, possibly by influencing Ca^{2+} channels. Its total alkaloid level can prevent vomiting and can promote GI tract movement in rats[28-30]. The active ingredients of ginseng ginsenosides can reduce blood sugar by stimulating insulin secretion and anti-apoptosis of pancreatic β-cells[31,32]. Furthermore, the results of a retrospective clinical study on TWAJJ treatment in DGID patients have been reported[24,25]. After treatment with TWAJJ, symptoms such as fullness, eructation, nausea (vomiting) and constipation were significantly improved. Although the fasting blood glucose tended to decrease after treatment, this decrease was not statistically significant. However, clarification of the clinical validity of TWAJJ in randomized controlled clinical trials is necessary. In this study, we also found that TWAJJ had a tendency to decrease blood glucose and increase serum insulin, however, statistical significance was not reached. Therefore, we consider that the functional mechanism of TWAJJ in DGID is through other pathways rather than through blood glucose regulation.

The esophagus and small intestine are tubular organs. One important function is transportation of food by wall movement; therefore the biomechanical properties of the wall are important for this function[8]. The biomechanical properties of the esophagus and small intestine depend on their structure and can be evaluated by the opening angle, residual stress and strain, and stress-strain relationship[11]. Previous studies have demonstrated that the esophageal wall[12,33,34] and intestinal wall[9-11] were remodeled during the development of diabetes. Therefore, it is important to determine whether TWAJJ can improve DGID through a pathway involved in changing the biomechanical properties of the GI tract.

The present study confirmed previous findings that morphometric and biomechanical remodeling of the esophageal and intestinal wall occur in STZ-induced diabetic rats. Although the treatment with TWAJJ did not significantly change the blood glucose and serum insulin levels, high dose TWAJJ, to a large extent, improved the morphometric and biomechanical remodeling caused by diabetes. The improvement in morphometric remodeling was expressed as reduced wall thickness and area. Improvements in biomechanical remodeling were expressed as reduced opening angle, reduced absolute value of residual strain and decreased wall stiffness. The present study indicated that the effect of TWAJJ on improvements in DGID in the clinic may be partially associated with improvements in biomechanical remodeling of the GI wall. Due to the complex geometry of the stomach[22,35], we did not focus on the biomechanical parameters of the gastric wall in the present study. Future studies may focus on the effect of TWAJJ on the stomach due to the importance of stomach function in diabetic patients.

The alterations in residual strain and wall stiffness in diabetes will change the tension and stress distribution in the location of mechanosensitive afferents in the GI tract[36,37]. Therefore, biomechanical remodeling of the diabetic GI wall indirectly affects GI motor function. High dose TWAJJ partially restored the changes in biomechanical properties caused by diabetes. This may be associated with improved motor and sensory function of the diabetic GI tract.

AGEs is a heterogeneous group of macromolecules formed by the non-enzymatic glycation of proteins, lipids and nucleic acids[38]. Endogenous AGEs are generated at higher rates in diabetes due to abnormal glucose metabolism. Chronic high blood glucose can cause excessive glycoprotein accumulation in the body including the GI tract causing GI wall stiffening[8]. There is growing evidence to show that AGEs and RAGE are implicated in various disorders. AGE levels in serum and tissues are associated with chronic complications of DM including DGID. Furthermore, RAGE is involved in signal transduction of AGEs in a variety of cells[39]. Our previous studies showed that AGE and RAGE were over-expressed in diabetic GI tissues[40]. In the present study, we found that the RAGE mRNA level in the jejunal segment increased in diabetic rats compared with normal rats. Following high dose TWAJJ administration, this alternation was reversed to the normal state. Therefore, the observed

improvement in the mechanical factors due to TWAJJ treatment in DGID may be through the inhibition of AGEs accumulation. However, in future studies we need to clarify this mechanism by immunohistochemistry of RAGE to demonstrate whether the change in mRNA expression actually translates to protein expression. Furthermore, it is also important to study whether specific knockdown of RAGE in the GI mucosa can improve biomechanical remodeling of the GI tract in diabetes and reverse DGID.

In conclusion, high dose TWAJJ treatment improves biomechanical and morphometric remodeling of the diabetic esophageal and intestinal wall. The mechanism may, at least partly, be explained by decreased RAGE mRNA levels in STZ-induced diabetic rats. Therefore, it seems feasible to develop Chinese herbs, such as TWAJJ, to improve the morphometric and biomechanical remodeling caused by diabetes. This may have an impact on GI dysfunction in diabetes and be used in clinical practice.

COMMENTS

Background

Diabetic gastrointestinal disorder (DGID) is a common complication of diabetes. However, neither the pathophysiology nor the pathogenesis of patients' gastrointestinal (GI) symptoms associated with diabetes are well understood. Furthermore, many patients with DGID do not receive appropriate treatment. Although Western medicine can partially improve the clinical symptoms, it does not fundamentally reverse the diabetes-induced changes and results in a very high relapse rate. In the clinic, it was shown that Tangweian Jianji (TWAJJ) significantly improved DGID with a low relapse rate, however, the mechanism involved in this improvement is not fully understood.

Research frontiers

The GI tract is functionally subjected to dimensional changes. Hence, biomechanical properties such as the stress-strain relationship are of particular importance. Several studies have demonstrated that diabetes induces GI morphological and biomechanical remodeling. The non-enzymatic glycation of the intestinal wall in diabetes is associated with remodeling. Therefore, the present study investigated whether TWAJJ treatment can improve morphometric and biomechanical remodeling of the GI tract in streptozotocin (STZ)-induced diabetic rats. Furthermore, the receptor of advanced glycation end-products (RAGE) mRNA level in the jejunal tissues was also investigated to explore the possible mechanism of TWAJJ in the treatment of DGID.

Innovations and breakthroughs

Compared with previous studies, this study is the first to use biomechanical test methods combined with RAGE detection to investigate the mechanism of the effect of the Chinese medicine, TWAJJ, on diabetic GI dysfunction. We showed that high dose TWAJJ improves the biomechanical and morphometric remodeling of the diabetic esophageal and intestinal walls. The mechanism may, at least partly, be related to the decreased RAGE mRNA levels in STZ-induced diabetic rats. As knowledge of GI biomechanics is new and was only recently developed and the non-enzymatic glycation of the GI tract is closely related to its biomechanical properties, determination of biomechanical properties and expression of advanced glycation end products and their receptor (AGE/RAGE) may be useful tools to investigate the mechanism of TWAJJ in DGID.

Applications

The findings of this study suggest that it seems feasible to develop Chinese herbs, such as TWAJJ, to improve the morphometric and biomechanical remodeling caused by diabetes. This may have an impact on GI dysfunction in diabetes and be used in clinical practice.

Terminology

DGID is a common complication of diabetes related to the GI tract. Up to 76% of diabetic patients express GI symptoms including dysphagia, early satiety, reflux, constipation, abdominal pain, nausea, vomiting and diarrhea; GI biomechanical properties are used to define the GI wall deformation (strain) and force (stress), which can be described by the opening angle, residual stress and strain, stress-strain relationship, stress relaxation and creep; TWAJJ is a practical Chinese medicinal compound for diabetic gastrointestinal dysfunction and is composed of several herbs including Citrus aurantium, Codonopsis, fried Atractylodes and wine Rhubarb.

Peer review

This is an interesting article. DGID is clearly a big topic especially in developed countries, thus this topic is interesting. Further, it was also fascinating to see that high dose TWAJJ was able to "treat" DGID without treating hyperglycemia. The manuscript is well written, the experiments are well planned, methods are adequately described and suitable to achieve the goals and results are appropriately described.

Abstract

AIM: To investigate usefulness of adherence to gastro-esophageal reflux disease (GERD) guideline established by the Spanish Association of Gastroenterology.

METHODS: Prospective, observational and multicentre study of 301 patients with typical symptoms of GERD who should be managed in accordance with guidelines and were attended by gastroenterologists in daily practice. Patients (aged > 18 years) were eligible for inclusion if they had typical symptoms of GERD (heartburn and/or acid regurgitation) as the major complaint in the presence or absence of accompanying atypical symptoms, such as dyspeptic symptoms and/or supraesophageal symptoms. Diagnostic and therapeutic decisions should be made based on specific recommendations of the Spanish clinical practice guideline for GERD which is a widely disseminated and well known instrument among Spanish in digestive disease specialists.

RESULTS: Endoscopy was indicated in 123 (41%) patients: 50 with alarm symptoms, 32 with age > 50 years without alarm symptom. Seventy-two patients (58.5%) had esophagitis (grade A, 23, grade B, 28, grade C, 18, grade D, 3). In the presence of alarm symptoms, endoscopy was indicated consistently with recommendations in 98% of cases. However, in the absence of alarm symptoms, endoscopy was indicated in 33% of patients > 50 years (not recommended by the guideline). Adherence for proton pump inhibitors (PPIs) therapy was 80%, but doses prescribed were lower (half) in 5% of cases and higher (double) in 15%. Adherence regarding duration of PPI therapy was 69%; duration was shorter than recommended in 1% (4 wk in esophagitis grades C-D) or longer in 30% (8 wk in esophagitis grades A-B or in patients without endoscopy). Treatment response was higher when PPI doses were consistent with guidelines, although differences were not significant (95% *vs* 85%).

CONCLUSION: GERD guideline compliance was quite good although endoscopy was over indicated in patients > 50 years without alarm symptoms; PPIs were prescribed at higher doses and longer duration.

INTRODUCTION

Gastro-esophageal reflux disease (GERD) is one of the most prevalent gastrointestinal disorders in the general population[1]. GERD diagnosis is made mainly according to the presence of symptoms. Patients with heartburn and/or regurgitation (typical GERD symptoms) received the diagnosis. Typical symptoms of GERD are experienced by 25% of people at least once a month, 12% at least once per week, and 5% describe daily symptoms[2]. The prevalence of GERD among the Spanish population is 15%, with 33% and 22% of subjects reporting monthly episodes of heartburn and regurgitation, respectively[3]. Reported consultation rates range from 5% to 56%[4].

GERD is perceived as a benign disease but the spectrum of chronicity and severity of upper gastrointestinal symptoms frequently affects health-related quality of life (HRQoL)[5]. The wide-ranging effects of GERD on health and well-being can have consequences for the work productivity, psychological and social performance of affected individuals, particularly in patients with severe symptoms or night time acid reflux and sleep disturbance[5-8]. In some respects the HRQoL burden of these patients is similar to or greater than that observed in patients with conditions such as diabetes, hypertension or coronary heart disease[9,10].

Although treatment with proton pump inhibitors (PPIs) is satisfactory in many cases and results in cicatrisation of esophagitis when esophagitis is present, complete disappearance of symptoms is difficult to achieve[11]. Nevertheless, in many cases PPI therapy leads to rapid symptom improvement that is associated with a better HRQoL. For example, in a large Italian study, 96% of patients were satisfied with the results of 4 wk of PPI therapy and the average HRQoL score improved significantly during this period[12]. An effective management strategy is particularly important because, as mentioned, GERD imposes a significant burden of illness[13,14]. For that purpose several clinical practice guidelines have been developed by different medical societies and expert consensus meetings[15-19]. However, although many national and international guidelines are currently available, the impact of these recommendations on the behaviour of physicians has generally been limited[20-25]. Only in some disease states guidelines have been shown to influence physician behaviour, which depends on the prevalence of the disorder and access to the guidelines among other factors[26-28].

The objective of this study was to assess the level of adherence of gastroenterologists to the Spanish clinical guidelines for GERD and the results obtained in the care of patients with typical symptoms of GERD attended in daily practice.

MATERIALS AND METHODS

Study design

This multicentre and observational study was prospectively designed with two purposes: (1) to investigate whether patients with typical GERD symptoms seeking consultation from a specialist in gastroenterology were managed in accordance with the clinical practice guideline for GERD developed by the Spanish Association of Gastroenterology, the Spanish Society of Family and Community Medicine and the Iberoamerican Cochrane Center[15]; and (2) to assess the results obtained. The study was focused on the "acute phase" of GERD (4-8 wk after diagnosis) and not on the long-term; therefore, evaluation of maintenance treatment was not done. Thirty-three gastroenterologist from 33 different medical centers throughout Spain participated in the study, that was conducted under routine clinical practice conditions. Gastroenterologists participating in the study were not aware they were included in an adherence study. Consecutive patients were recruited between December 12, 2007 and November 5, 2008. All patients provided written informed consent. The protocol was approved by the Ethics Committees of the participating centers.

Inclusion and exclusion criteria

Consecutive patients (aged > 18 years) attending to gastroenterologists offices were eligible for inclusion if they had typical symptoms of GERD (heartburn and/or acid regurgitation) more than twice a week for at least 2 mo as the major complaint, in the presence or absence of accompanying atypical symptoms, such as dyspeptic symptoms and/or supraesophageal symptoms. All enrolled patients were required to sign the informed consent. Patients who had taken drug treatment for GERD within 2 mo prior to the study were excluded. Also, patients were not eligible they were currently taking non-steroidal anti-inflammatory drugs or platelet antiaggregant agents as well as if previous treatment with PPIs had been unsuccessful. Patients with history of esophageal or gastric surgery except for suture repair of a perforated gastric ulcer were excluded.

Study procedures

The study protocol included a baseline visit and a final visit, which was scheduled after 4 wk or 8 wk. At the baseline visit, eligibility criteria were assessed and the following data were recorded: demographic and anthropometric variables, and GERD-related symptoms including

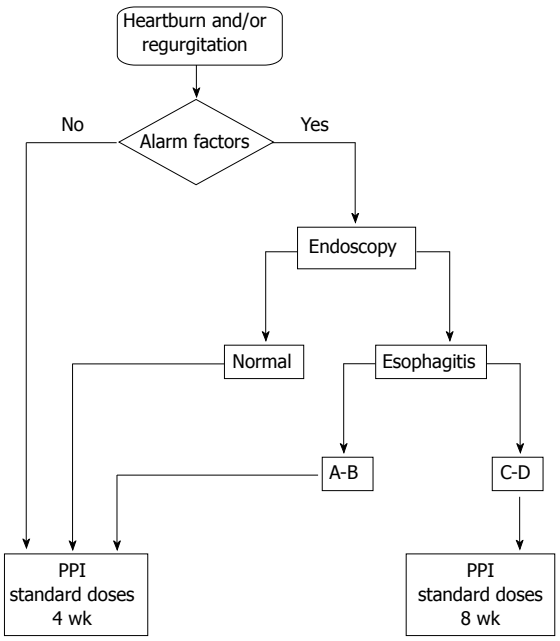

Figure 1 Management algorithm of patients with heartburn or regurgitation that should be used according to recommendations of the Spanish Clinical Practice Guideline. PPI: Proton pump inhibitor.

duration of symptoms, previous drug treatment, and frequency and intensity of typical symptoms. The frequency of each symptom was graded as 0 = absent or present less than 2 d per month, 1 = present more than 2 d per month, 2 = present weekly less than 3 d, and 3 = present 3 or more days per week. Intensity was graded as 0 = none, 1 = awareness of symptom but easily tolerated, 2 = discomfort sufficient to cause interference with normal activities, and 3 = incapacitating, with inability to perform normal activities. The product of frequency and intensity was used to define the severity of each symptom, which was expressed as the absolute number (0-1 = absent or irrelevant, 2 = mild, 3-4 = moderate, 6 = severe, and 9 = very severe).

Diagnostic and therapeutic decisions should be made based on specific recommendations of the Spanish clinical practice guideline for GERD[15], which is a widely disseminated and apparently well known instrument among specialists in digestive disease. The algorithm for the diagnosis and treatment of patients with GERD is summarized in the Figure 1. When upper gastrointestinal endoscopy was indicated, reasons and endoscopic findings should be recorded. The presence and severity of erosive esophagitis were determined using the Los Angeles classification[29]. According to the guideline, in the absence of erosive esophagitis or mild esophagitis (Los Angeles grade A or B) the duration of treatment was 4 wk but in the presence of esophagitis grades C and D, the duration of treatment was 8 wk. Treatment-related data included prescription of PPI, dose and duration of treatment (4 wk or 8 wk), and non-pharmacological measures (acid reflux diet, elevated position of the bed). The PPI selection (omeprazole, lansoprazole, pantoprazole, rabeprazole or esomeprazole) was made by individual medical preference.

Assessments at the end of treatment (4 wk or 8 wk) included frequency and intensity of symptoms to quantify the severity of disease after PPI treatment. Response to treatment was considered when patients became asymptomatic, that is, in the category of "absent or irrelevant". Patients were interviewed regarding their compliance with treatment, which was classified as excellent (> 95%), very good (> 90%), good (> 80%), fair (≥ 70%), bad (< 70%) and very bad (< 50%).

Statistical analysis

Sample size calculation was based on proportion of symptomatic treatment response after 4-8 wk. Considering a treatment response around 58%, with a ± 6% deviation, the needed sample size was 260 patients. Expecting a 15% lost during follow-up the final calculated sample size was 306 patients.

Categorical data are expressed as absolute number and percentages, and continuous data as mean and standard deviation. Response to PPI therapy according to adherence to guidelines in the doses prescribed was analyzed with the χ^2 test or fisher exact test. All analyses were performed using SAS 8.2 (SAS Institute, Cary, NC). A P value of less than 0.05 was considered statistically significant.

RESULTS

A total of 306 patients were recruited and 301 patients (58.5% men; age of 45 ± 14 years) fulfilled the inclusion criteria and were included in the study. All of them completed follow-up. The remaining 5 patients were excluded because of refusal to take part in the study (n = 2) and lack of fulfilment of the inclusion/exclusion criteria (n = 3). Mean time from the onset of GERD symptoms was 4.5 ± 6.3 years. Previous pharmacological treatment for GERD (not within 2 mo prior to the study) was recorded in 156 patients (51.9%), 87 of which had been treated with PPIs. Presenting complaints were heartburn in 99% of cases (nocturnal heartburn in 78%), regurgitation in 86%, and both heartburn and regurgitation in 85%. Only 3 patients complained of regurgitation only. A total of 273 patients (90.7%) presented dyspeptic symptoms and 174 (57.8%) supraesophageal symptoms. Distribution of heartburn, nocturnal heartburn and regurgitation according to severity of symptoms is shown in Figure 2. Symptoms were rated as severe or very severe in 56% of cases for heartburn, 34% for nocturnal heartburn and 35% for regurgitation.

Upper gastrointestinal endoscopy was performed in 123 patients (40.8%). According to participating gastroenterologists opinion indication of endoscopy was justified because of alarm symptoms in 50 patients and age over 50 years in 32. Adherence to the guidelines in relation to indication of upper gastrointestinal endoscopy

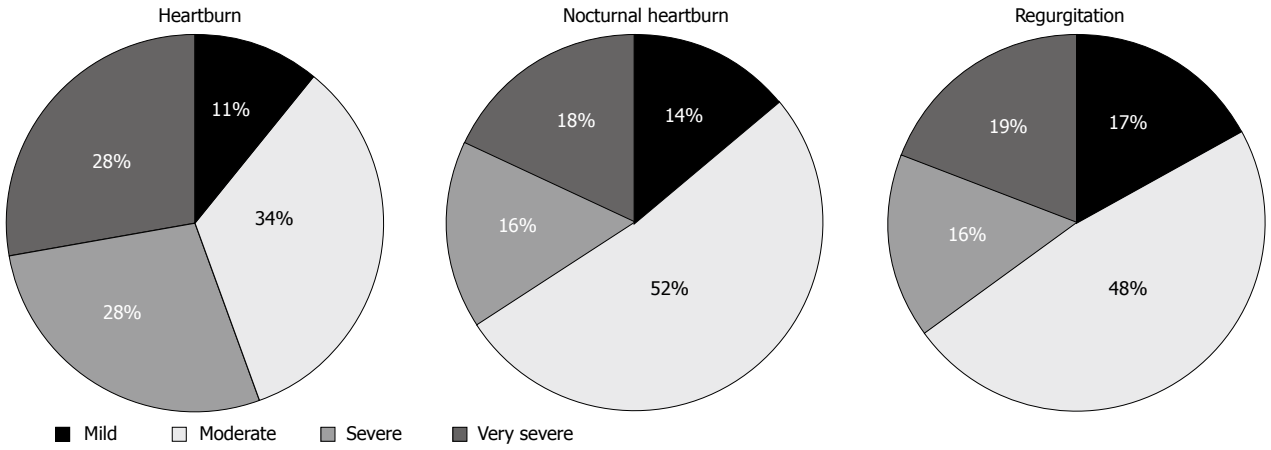

Figure 2 Distribution of typical gastro-esophageal reflux disease symptoms according to severity.

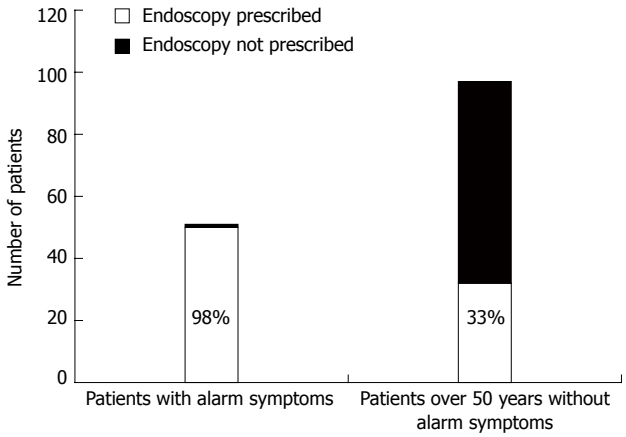

Figure 3 Upper gastrointestinal endoscopy was prescribed in 98% of patients with alarm symptoms (in accordance with the guideline) and in 33% of patients older than 50 years of age without alarm symptoms (not in accordance with the guideline).

was good due to the presence of alarm symptoms in 98% of cases. On the other hand, endoscopy was performed in 32 of 97 patients (33%) older than 50 years of age without alarm symptoms (Figure 3).

Esophagitis was diagnosed in 72 (58.3%) patients (grade A, 23, grade B, 28, grade C, 18, grade D, 3). Metaplastic changes of the esophageal mucosa suggestive of Barrett's oesophagus were documented in 9 patients and peptic stenosis in 1. Hiatal hernia was reported in 37 patients and Schatzki ring in 5.

Treatment with PPIs was prescribed to 298 patients (99%). In most cases (80%), there was adherence to the guidelines as the recommended dose of PPI was prescribed. However, doses prescribed were lower (half) in 4.8% of cases and higher (double) in 14.7%. The duration of PPI therapy was 4 wk in 63% of cases and 8 wk in 37%. In respect to duration of PPI therapy, adherence to guidelines was shown in 69% of cases (62% for the indication of 4 wk and 7% for 8 wk). Lack of adherence (31% of cases) included duration of treatment of 4 wk in patients with esophagitis grades C-D (0.7%) or 8 wk in patients esophagitis grades A-B (7.8%) or in patients without endoscopic studies (22.8%).

Compliance with pharmacological treatment was excellent in 58% of cases, very good in 30%, good in 8%, fair in 3% and bad or very bad in 1%. Acid reflux disease diet was recommended in 79% of patients and raising the bed position in 34%.

Response to PPI therapy was higher among patients who received PPI doses recommended by the guidelines as compared with patients treated with lower doses (95% *vs* 85%), although differences were not statistically significant ($P = 0.2$). Treatment response was similar in patients in which adherence to guidelines regarding duration of treatment was good or poor (95% *vs* 93%; $P = 0.5$).

Symptomatic response to treatment according to esophagitis grade was 87% in grade A, 89% in grade B and 100% in grades C and D. The indication to perform an upper gastrointestinal endoscopy had no effect on the rate of response to PPI treatment ($P = 0.9$) or whether there was good or poor adherence to the guidelines in terms of indication of the endoscopic study ($P = 0.7$).

DISCUSSION

GERD is a chronic condition in many cases and frequently requires prolonged therapy. Although complications are infrequent, the symptoms of reflux disease have a profound effect on quality of life and work performance, making GERD an expensive disease to manage. When different management strategies are compared, the cost of each strategy must be balanced against its effectiveness. For that purpose, various clinical practice guidelines have been developed based on the scientific evidence and recommendations made by experts[15-19]. In 2007, the Spanish Association of Gastroenterology, the Spanish Society of Family and Community Medicine and the Iberoamerican Cochrane Center developed a clinical practice guideline for GERD, in which two of the authors have collaborated (FM, JP), which was distributed throughout Spain both in printed version and through

the Internet[15]. Afterwards, it was investigated whether the GERD guideline had a practical impact through the Spanish gastroenterologists in the care of patients with GERD in routine daily practice.

The main findings of this study can be summarized as follows: (1) upper gastrointestinal endoscopy was requested in 41% of patients, mainly because of the presence of alarm symptoms but also because of age over 50 years without alarm symptoms; (2) severe esophagitis was infrequently diagnosed even though patients were selected for endoscopy; (3) in almost all cases (99%), treatment with PPIs was prescribed, in the majority of cases (80%) in accordance with doses recommended in the guidelines (lower doses were prescribed in only 5% of cases and higher doses in 15%); (4) adherence regarding duration of PPIs therapy was lower (69%) and most non-compliant behaviours were related to prolonged duration of treatment in patients with mild esophagitis or in those in which endoscopy was not performed; and (5) response to PPI treatment was higher in patients treated with doses of PPIs recommended in the clinical practice guidelines as compared with patients receiving other doses, although the difference was not statistically significant (95% *vs* 85%).

It is to note that, although GERD guideline compliance was quite good, endoscopy was overindicated. Thus, it was prescribed in 32 out of 97 patients (33%) older than 50 years of age without alarm symptoms. We have to emphasize here that not in the Spanish guideline neither in other very prestigious ones[30,31] is endoscopy recommended in patients with typical GERD symptoms (heartburn and/or regurgitation) older than 50 years and no alarm symptoms.

GERD is a very frequent cause of consultation in specialized gastroenterology practices as well as in the primary care setting. Consultation for GERD is associated with increased symptom severity and frequency, interference with social activities, sleep disturbance, higher levels of comorbidity, and psychological distress. Patients are less likely to consult if they feel that their doctor would trivialise their symptoms[4]. GERD has a negative impact on HRQoL being involved factors such as female gender, increased body mass index and nocturnal symptoms[5]. Nevertheless, when symptoms are properly treated, HRQoL improves in most of the cases. Thus, in a 5-year follow-up study of a large GERD population under routine care only a small minority of patients reported a clinically relevant decrease in HRQoL[32].

Although several clinical practice guidelines for GERD have been developed and published, to our knowledge, their clinical impact on gastroenterologists practice has not been evaluated. On the other hand, it is known that current GERD guidelines are infrequently used by primary care physicians. It has been shown that among 352 practitioners from 17 countries only 33% used an international and 14% used a national guideline in managing GERD patients[33]. However, in a retrospective Australian study it was shown a significant improvements in the diagnosis and management of GERD after a clinical guideline distribution and a 3-year self-audit process revealed a decrease in use of endoscopy, improved identification of risk factors, increase in recommendations for patient weight loss and reduction in use of medications that may exacerbate reflux symptoms[34]. Regarding antisecretory therapy it is well accepted that these medication are frequently overprescribed; when concordance between use of PPIs and prescribing guidelines was evaluated drug utilisation data indicated widespread use of PPIs outside current prescribing guidelines[35]. Another study tried to evaluate variability in dyspepsia management among Italian general practitioners; it was found that 44% of endoscopies prescribed for uninvestigated patients (more than half complaining of GERD symptoms) did not comply with the European Society for Primary Care Gastroenterology guideline[36].

In conclusion, compliance with the clinical practice guidelines for GERD by Spanish gastroenterologists is quite good, although a trend to indicate endoscopy in patients older than 50 years without alarm symptoms and treatments with higher PPI doses and longer duration than recommended was observed. Diagnosis of severe esophagitis is extremely infrequent, even in selected patients for endoscopy. Therapeutic response trended to be better when guideline recommendations were followed.

COMMENTS

Background

Gastro-esophageal reflux disease (GERD) is one of the most prevalent gastrointestinal disorders in the general population. GERD diagnosis is made mainly according to the presence of symptoms, especially heartburn and/or regurgitation. An effective management strategy is particularly important because GERD imposes a significant burden of illness. For that purpose several clinical practice guidelines have been developed by different medical societies and expert consensus meetings. However, the impact of these recommendations on the behaviour of physicians has generally been limited.

Research frontiers

It is a prospective, observational and multicentre study evaluating 301 patients with typical symptoms of GERD who should be managed in accordance with guidelines and were attended by gastroenterologists in daily practice. Diagnostic and therapeutic decisions should be made based on specific recommendations of the Spanish clinical practice guideline for GERD which is a widely disseminated and well known instrument among Spanish in digestive disease specialists.

Innovations and breakthroughs

The main findings of this study can be summarized as follows: Upper gastrointestinal endoscopy was requested in 41% of patients, mainly because of the presence of alarm symptoms but also because of age over 50 years without alarm symptoms. Severe esophagitis was infrequently diagnosed even though patients were selected for endoscopy.

Applications

In almost all cases (99%), treatment with Adherence for proton pump inhibitor (PPIs) was prescribed, in the majority of cases (80%) in accordance with doses recommended in the guidelines (lower doses were prescribed in only 5% of cases and higher doses in 15%). Adherence regarding duration of PPI therapy was lower (69%) and most non-compliant behaviours were related to prolonged duration of treatment in patients with mild esophagitis or in those in which endoscopy was not performed.

Terminology

Response to PPI treatment was higher in patients treated with doses of PPIs recommended in the clinical practice guidelines as compared with patients receiving other doses, although the difference was not statistically significant (95% *vs* 85%).

Peer review

Treatment practice guidelines are helpful in securing patients uniform treatment regardless of where they seek help. Such guidelines are of no use, however, if they are not followed. A study of adherence to guidelines is thus of significant importance. The presentation of the study is concise, and was approved by relevant ethics committees.

Abstract

AIM: To evaluate the effect of single nucleotide polymorphisms of interleukin (IL)-28B, rs12979860 on progression and treatment response in chronic hepatitis C.

METHODS: Patients (n = 64; 37 men, 27 women; mean age, 44 ± 12 years) with chronic hepatitis C, genotype 1, received treatment with peg-interferon plus ribavirin. Genotyping of rs12979860 was performed on peripheral blood DNA. Histopathological assessment of necroinflammatory grade and fibrosis stage were scored using the METAVIR system on a liver biopsy sample before treatment. Serum viral load, aminotransferase activity, and insulin level were measured. Insulin resistance index, body mass index, waist/hip ratio, percentage of body fat and fibrosis progression rate were calculated. Applied dose of interferon and ribavirin, platelet and neutrophil count and hemoglobin level were measured.

RESULTS: A sustained virological response (SVR) was significantly associated with IL28B polymorphism (CC *vs* TT allele: odds ratio (OR), 25; CC *vs* CT allele: OR, 5.4), inflammation activity (G < 1 *vs* G > 1: OR, 3.9), fibrosis (F < 1 *vs* F > 1: OR, 5.9), platelet count (> 200 × 10^9/L *vs* < 200 × 10^9/L: OR, 4.7; OR in patients with genotype CT: 12.8), fatty liver (absence *vs* presence of steatosis: OR, 4.8), insulin resistance index (< 2.5 *vs* > 2.5: OR, 3.9), and baseline HCV viral load (< 10^6 IU/mL *vs* > 10^6 IU/mL: OR, 3.0). There was no association with age, sex, aminotransferases activity, body mass index, waist/hip ratio, or percentage body fat. There was borderline significance (P = 0.064) of increased fibrosis in patients with the TT allele, and no differences in the insulin resistance index between groups of patients with CC, CT and TT alleles (P = 0.12). Spearman's rank correlation coefficient between insulin resistance and stage of fibrosis and body mass index was r = 0.618 and r = 0.605, respectively (P < 0.001). Significant differences were found in the insulin resistance index (P = 0.01) between patients with and without steatosis. Patients with the CT allele and absence of a SVR had a higher incidence of requiring threshold dose reduction of interferon (P = 0.07).

CONCLUSION: IL28B variation is the strongest host factor not related to insulin resistance that determines outcome of antiviral therapy. Baseline platelet count predicts the outcome of antiviral therapy in CT allele patients.

INTRODUCTION

Investigations on genetic determinants of chronic hepatitis C (CHC) established that a single nucleotide polymorphism (SNP) in the interleukin (IL)-28B gene promoter region affected the spontaneous and induced clearance of hepatitis C virus (HCV)[1-5]. Among 500 000 genetic variants which were analyzed genome-wide, a few associated with the virologic response were identified, and showed variable frequency and importance across human ethnic groups[3,5-7]. The mechanism by which SNPs influence the outcome of HCV infection and its treatment is not clear. It is suggested that regulation of the promoter region of IL28B in antiviral activity may also affect two other genes belonging to interferon (IFN)-λ family encoded in this region[6,8-12]. According to some authors, IL28B SNPs are merely indicators of more complex mechanisms of CHC pathogenesis[13]. Some factors which determine the efficacy of antiviral therapy influence the course of CHC[14]. The impact of SNPs within the IL28B region on spontaneous and induced HCV clearance suggests the possibility that polymorphism affects the chronic phase of hepatitis. On the basis of previous research, there is no clear evidence that there is a correlation between IL28B SNPs and progression of untreated CHC. In a meta-analysis by Romero-Gomez *et al*[15], an effect of IL28B polymorphism on the progression of fibrosis was disputed. Research evaluating liver cirrhosis and fibrosis progression after liver transplantation in HCV-infected patients indicated a connection with IL28B SNPs[16,17].

However, about 50% of patients with a sustained virological response (SVR) do not carry the favorable IL28B alleles[15]. The factors which increase the chance of a therapeutic response in these patients are not yet known. A detailed analysis of the course of therapy of CHC with pegylated IFNα and ribavirin (RBV) in the presence of a hazardous IL28B allele might better delineate the clinical characteristics of this difficult-to-treat group of patients.

The aim of this study was to determine the impact of IL28B polymorphism on the progression of CHC, in order to identify predictors of effective therapy with IFN and RBV in the group of patients with unfavorable IL28B polymorphism.

Table 1 Characteristics of patients

IL28B polymorphism	*n* (%)	SVR (%)	Gender (M/F)	Age (yr)	BMI (kg/m^2)
CC	13 (20)	77			
CT	34 (53)	38			
TT	17 (27)	6			
All	64	39	27/37	44 ± 12	27 ± 5

The values of BMI and age given as arithmetic mean and standard deviation. CC, CT and TT: Single nucleotide polymorphisms at location *rs12979860* IL28B; SVR: Sustained virological response; BMI: Body mass index; M/F: Male/female.

MATERIALS AND METHODS

Sixty-four patients of European origin (Caucasians) with CHC due to HCV genotype 1 were included in the present study. Patients were treated with standard antiviral therapy with pegylated IFN 2a or 2b and RBV according to standard criteria of inclusion and exclusion. A liver biopsy was performed before treatment, and HCV viral load (COBAS® TaqMan® HCV 2.0) and insulin resistance index (HOMA-IR: homeostasis model of assessment) was determined.

The histopathological assessment of necroinflammatory grade and fibrosis stage were scored using the METAVIR system, and the presence of fatty liver disease was taken into consideration. The course of therapy was monitored on the basis of early virologic response (EVR), end of treatment response (ETR) and SVR.

The presence of the IL28B-related SNP *rs 12979860* variant was determined in whole blood samples. Genomic DNA was isolated from peripheral blood samples using proteinase K ion exchange column extraction kit (A&A Biotechnology, Gdynia, Poland). An amplification product of 190 bp length was obtained using standard polymerase chain reaction with the following primers: 5'- GCC TCT TCC TCC TGC GGG ACA AG and 5'- GCG CGG AGT GCA ATT CAA CCC T. Following digestion with *Bsh*1236I (*Bst*UI) restriction endonuclease, products were separated using agarose gel electrophoresis. The variant C was digested by the enzyme into fragments. All laboratory procedures were performed on blinded samples.

Patient age, sex, measurable anthropometric parameters such as waist, waist/hip ratio, body mass index (BMI) and percentage of body fat from MALTRON® measurements were analyzed in the present study.

Based on estimated duration of infection, the fibrosis progression rate was defined as the ratio between fibrosis stage and HCV duration. The serum aminotransferase levels prior to the start of treatment and after 72 wk was assessed. Patient characteristics are presented in Table 1.

The complete blood count at baseline and its changes during the course of therapy were determined. Thresholds for drug dose reduction were established: white blood cells < 750 cells/μL platelets < 70 000/μL, and

Table 2 Odds ratios of sustained virological response, depending on type of polymorphism of IL28B, inflammation activity, fibrosis, fatty liver, baseline hepatitis C virus viral load, the level of platelets and insulin resistance

Features affecting SVR	*P* value	OR	95% CI
CC *vs* TT	< 0.001	25	3.5-177.5
Platelets CT	0.002	12.8	1.8-42.6

Difference in the risk of a SVR between patients with the CC allele and TT and CT alleles, low and high activity of the inflammatory process (G < 1 *vs* G > 1, according to METAVIR), little and advanced fibrosis (F < 1 *vs* F > 1, according to METAVIR), low and high hepatitis C viral load (< 10^6 IU/mL *vs* > 10^6 IU/mL), and absence or presence of fatty liver, high and low platelet count (> 200 × 10^9/L *vs* < 200 × 10^9/L), low or high insulin resistance index (< 2.5 *vs* > 2.5). Platelets CT: OR of SVR in patients with genotype CT with normal *vs* low platelets. SVR: Sustained virological response; CI: Confidence interval; HCV: Hepatitis C virus; OR: Odds ratio.

hemoglobin < 10 g/L. For each patient the dose of IFN and RBV used in the therapy was established and expressed as a percentage of the recommended dosage. The significance of differences in the clinical parameters as well as anthropometric, biochemical, histological and virological features between patients with and without a SVR was determined based on analysis of variance Kruskal-Wallis rank sum, Mann-Whitney *U* and χ^2 tests. A similar analysis was performed on patients only with the IL28B CT genotype. In patients with CC and TT genotypes, analysis of the diversity of the SVR was not performed because of the disproportionate distribution and small number of patients who did or did not achieve a SVR (Table 1).

Using the Kruskal-Wallis rank sum test, we assessed variations in the investigated clinical features between patients with different IL28B polymorphisms. In the logistic regression model we evaluated the odds ratio (OR) and 95% confidence interval (CI) of SVR, depending on the degree of inflammatory-necrotic activity, fibrosis scores, platelet count, baseline viral load, insulin resistance index (IR index) and IL28B polymorphisms (Table 2). The OR was determined against cases of high inflammatory-necrotic activity, above grade 1 in the METAVIR score, advanced fibrosis according to METAVIR F > 1, presence of steatosis, viral load > 1 × 10^6 IU/mL, alleles TT and CT, baseline platelet count < 200 × 10^9/L and IR index > 2.5.

The study was performed according to ethical guidelines of the 1975 Declaration of Helsinki. All patients were informed about the study, and provided written informed consent.

RESULTS

In the Mann-Whitney *U* test, differences were found in inflammatory-necrotic activity ($P = 0.011$), stage of fibrosis ($P = 0.009$), fibrosis progression rate ($P = 0.015$), EVR and ETR ($P = 0.00001$), baseline viral load ($P = 0.09$), reduction in viral load at 3 mo of therapy ($P = 0.0004$) and the presence of a biochemical response after completion of therapy ($P = 0.03$) between the patients who achieved a SVR and those who did not. In the group of patients who achieved a SVR, a lower incidence of liver steatosis was observed significantly (χ^2 test, $P = 0.062$). In the χ^2 test, there were no significant differences between patients with and without SVR as regards sex, age, comorbidities, and anthropometric factors. Differences in the parameters mentioned above were not observed among the three groups selected on the basis of the IL28B polymorphism. The χ^2 test showed differences in the rate of achievement of EVR ($P = 0.02$), ETR ($P = 0.069$) and SVR ($P = 0.001$) between groups of patients with CC, CT and TT alleles. The Kruskal-Wallis rank sum test showed differences in the size of the reduction of viral load after 3 mo of therapy ($P = 0.019$) between groups of patients with CC, CT and TT alleles. The OR revealed that patients with the CC allele had a 25-fold greater chance of achieving a SVR compared with those with the TT allele ($P < 0.001$) and a 5.4-fold higher chance compared with those with the CT allele ($P = 0.018$) (Table 2). Patients with low liver inflammation had a 3.9 times greater probability of achieving a SVR ($P = 0.026$), and patients with no or little fibrosis had 5.9 times greater probability ($P = 0.008$). HCV viral load < 1 × 10^6 IU/mL increased the chance of achieving a SVR by 3-fold ($P = 0.038$), and an IR index < 2.5 increased the chance by 3.9-fold ($P = 0.029$). The Kruskal-Wallis rank sum test showed no differences in the IR index between groups of patients with CC, CT and TT alleles ($P = 0.12$). Spearman's rank correlation coefficient between IR index and stage of fibrosis and BMI was $r = 0.618$ and $r = 0.605$, respectively ($P < 0.001$). In the Mann-Whitney *U* test, differences were found in the IR index ($P = 0.005$) between patients with and without steatosis. The Kruskal-Wallis rank sum test revealed borderline significance ($P = 0.064$) of increased fibrosis in patients with the TT allele (Figure 1).

The Mann-Whitney *U* test established that patients who did not achieve a SVR had low platelet levels at baseline ($P = 0.001$) compared with subjects with a SVR. A similar trend was also found for neutrophils ($P > 0.05$). Patients without SVR bearing the CT allele, were characterized by lower baseline platelet count ($P = 0.003$) and decreased ($P = 0.02$) drop of platelet count upon treatment. Decreased platelet levels in patients with the CT allele and absence of a SVR were accompanied by a higher incidence of requiring a dose reduction of IFN ($P = 0.07$). No differences in IFN and RBV dosage in patients with the CT allele or other allelic variants were found between groups with or without a SVR.

DISCUSSION

The present study observed an impact of IL28B SNPs

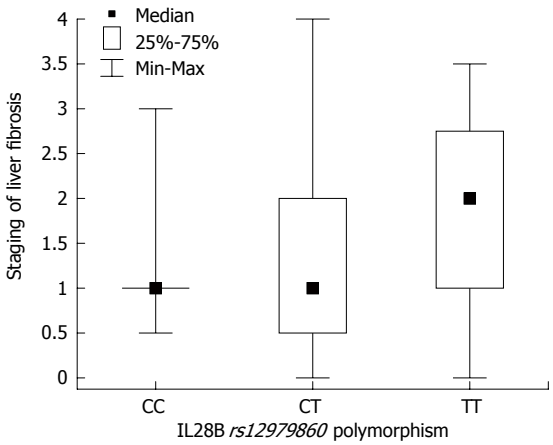

Figure 1 Liver fibrosis stage (by METAVIR) is increased in patients with the TT allele of the *rs12979860* region in the IL28B gene compared with patients with CC and CT alleles using the Kruskal-Wallis test (*P* = 0.06).

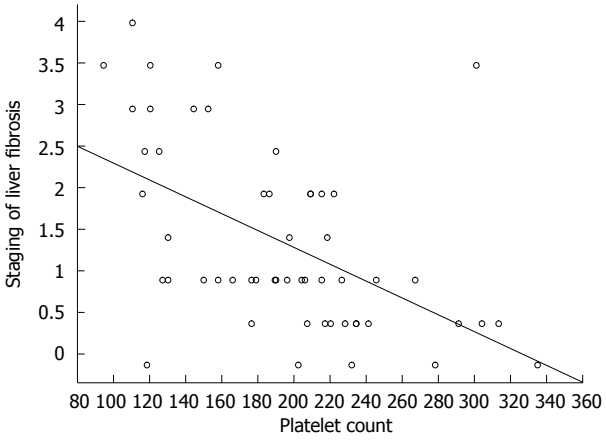

Figure 2 Correlation between liver fibrosis stage (by METAVIR) and the platelet count (10^9/L). Spearman's correlation coefficient r = -0.565, P < 0.001.

on the efficacy of IFN and RBV in CHC, which was consistent with the results from previous research. In patients with TT and CT genotypes, greater severity of liver fibrosis and necroinflammation, presence of liver steatosis, higher HCV viral load, and lower baseline platelets, had a reduced chance of therapeutic success. In the OR of the SVR, the greatest differences concerned the IL28B polymorphism between CC and TT alleles. The difference was more than 4-fold for fibrosis in the comparison of the CC allele with the CT allele. For liver steatosis, low platelet level, necroinflammatory grade, IR index and initial viral load of HCV, the difference was 5-8-fold (Table 2). The results confirm that polymorphism in the IL28B is significantly related to the outcome of antiviral therapy of CHC.

The mechanism by which genetic factors influence the progression of fibrosis in CHC remains unclear[18-21]. In the present study, patients with the TT genotype had a more active state of necroinflammation in the histological analysis, and borderline significance (P = 0.06) of greater severity of fibrosis (Figure 1). This observation is consistent with previous results describing a higher incidence of TT or CT allele in cases of cirrhosis and faster fibrosis progression in HCV-infected liver transplant recipients and liver from donors with the TT genotype[16,17]. Taking into consideration that the correlation between the degree of fibrosis and IL28B was not statistically significant and there was no association with fibrosis progression rate, it was not possible to confirm the impact of the genotype on the progress of CHC. Thus, IL28B polymorphism is probably not the factor which directly affects the outcome of untreated CHC.

The correlation between insulin resistance and stage of fibrosis, presence of the liver steatosis, efficacy of IFN/RBV therapy and higher BMI observed in the present study is consistent with the results from previous observations[22-27]. No statistically significant correlation between insulin resistance and IL28B polymorphism was observed, indicating that there are different mechanisms by which both factors can influence the course and therapy of CHC.

In the present study 60% of patients with SVR had TT (8%) or CT (52%) genotypes, which are not known factors associated with higher IFN responsiveness. These values are similar to those described in previous reports[15]. Analysis of the differences in the course of therapy in patients with the CT allele and a SVR revealed higher baseline platelet and neutrophil levels. These factors were markedly reduced in the group of patients with therapeutic failure. The present results are consistent with existing data, where the platelet level was a predictor of a rapid virological response[28]. In this study, a low baseline platelet count was significantly associated with the need for IFN dose reduction in the group without a SVR. In the group of patients with the CT allele, the platelet count was the only factor differentiating patients with and without a SVR. The chance of a SVR was 8-fold higher in patients with the CT allele and higher platelet count compared with patients with low levels of platelets.

The platelet level is one of the factors used to estimate the risk of the presence of advanced liver fibrosis[29]. In the present study, the platelet level also correlated with the stage of liver fibrosis (Figure 2). More severe fibrosis, and a lower baseline platelet level increased the risk of requiring a reduction in IFN dose and subsequent reduction in the chance of achieving a SVR[13]. Assessment of the platelet level and the IL28B polymorphism can complement the decision-making algorithm for a patient's eligibility for antiviral therapy.

Differentiation of SNPs in the IL28B promoter region is the strongest factor determining the effectiveness of therapy with IFN and RBV. Despite the greater severity of fibrosis in patients with the TT genotype, there was no additional evidence of an IL28B SNP associated with progression of CHC. In patients with the IL28B CT allele, a low baseline platelet count is associated with a requirement to reduce IFN and a decreased chance of obtaining a SVR.

COMMENTS

Background

Ineffective therapy for chronic viral hepatitis type C (CHC) determines the progression of liver disease to cirrhosis and primary hepatocellular carcinoma. Single nucleotide polymorphism (SNP) in the IL28B promoter gene region determines spontaneous and induced clearance of hepatitis C virus.

Research frontiers

Clinical aspects of the impact of IL28B SNPs on the efficacy of antiviral therapy and progression of CHC are not fully recognized. In the present study, potential factors influencing the efficacy of therapy in relation to IL28B polymorphism were investigated.

Innovations and breakthroughs

The results of the study confirm a significant role of SNPs in the IL28B gene among different predictive factors of a sustained virological response (SVR). The impact of IL28B SNPs on the SVR is not related to insulin resistance. In the case of the CT allele, a low baseline platelet count is associated with a reduced chance of a SVR. The phenomenon is connected with the stage of liver fibrosis and need for a reduction of interferon dose during therapy. The results suggest that the progression of CHC is faster in patients with the TT genotype.

Applications

Results of the study can complement the decision-making algorithm for eligibility of patients with CHC for antiviral therapy.

Terminology

Single nucleotide polymorphism is a variation of a single nucleotide usually found in non-coding microsatellite fragments of the genome. It may serve as the fingerprint for predicting susceptibility toward disease. IL28B SNPs include different variants localized in the gene promoter region, among which the most common in clinical practice is C/T SNP of *rs 12979860*.

Peer review

This study examined the association of SNPs of the IL28B, rs12979860 on progression of CHC. They found that SNPs of IL28B had any impact on CHC progression, in spite of apparently more advanced fibrosis among patients carrying TT genotype. In addition, they revealed that, in patients with the CT allele IL28B, low baseline platelets count is linked to the reduction of IFN and decreased chance of reaching the SVR. This study demonstrated a new characteristic of IL-28b in CHC.

Abstract

AIM: To define the clinical characteristics, and to assess the management of colonoscopic complications at a local clinic.

METHODS: A retrospective review of the medical records was performed for the patients with iatrogenic colon perforations after endoscopy at a local clinic between April 2006 and December 2010. Data obtained from a tertiary hospital in the same region were also analyzed. The underlying conditions, clinical presentations, perforation locations, treatment types (operative or conservative) and outcome data for patients at the local clinic and the tertiary hospital were compared.

RESULTS: A total of 10 826 colonoscopies, and 2625 therapeutic procedures were performed at a local clinic and 32 148 colonoscopies, and 7787 therapeutic procedures were performed at the tertiary hospital. The clinic had no perforations during diagnostic colonoscopy and 8 (0.3%) perforations were determined to be related to therapeutic procedures. The perforation rates in each therapeutic procedure were 0.06% (1/1609) in polypectomy, 0.2% (2/885) in endoscopic mucosal resection (EMR), and 3.8% (5/131) in endoscopic submucosal dissection (ESD). Perforation rates for ESD were significantly higher than those for polypectomy or EMR ($P < 0.01$). All of these patients were treated conservatively. On the other hand, three (0.01%) perforation cases were observed among the 24 361 diagnostic procedures performed, and these cases were treated with surgery in a tertiary hospital. Six perforations occurred with therapeutic endoscopy (perforation rate, 0.08%; 1 per 1298 procedures). Perforation rates for specific procedure types were 0.02% (1 per 5500) for polypectomy, 0.17% (1 per 561) for EMR, 2.3% (1 per 43) for ESD in the tertiary hospital. There were no differences in the perforation rates for each therapeutic procedure between the clinic and the tertiary hospital. The incidence of iatrogenic perforation requiring surgical treatment was quite low in both the clinic and the tertiary hospital. No procedure-related mortalities occurred. Performing closure with endoscopic clipping reduced the C-reactive protein (CRP) titers. The mean maximum CRP titer was 2.9 ± 1.6 mg/dL with clipping and 9.7 ± 6.2 mg/dL without clipping, respectively ($P < 0.05$). An operation is indicated in the presence of a large perforation, and in the setting of generalized peritonitis or ongoing sepsis. Although we did not experience such case in the clinic, patients with large perforations should be immediately transferred to a tertiary hospital. Good relationships between local clinics and nearby tertiary hospitals should therefore be maintained.

CONCLUSION: It was therefore found to be possible to perform endoscopic treatment at a local clinic when sufficient back up was available at a nearby tertiary hospital.

INTRODUCTION

Colonoscopy is widely used for the diagnosis, treatment, and follow-up of colorectal diseases[1,2]. The improvement of the equipment and increased needs for screening colonoscopy has increased the number of colonoscopies rapidly not only at hospitals but also in clinics. It is convenient for patients to have lesions treated when they are identified by either a routine-check up or diagnostic endoscopy. Therefore, therapeutic endoscopy is sometimes needed at a local clinic, including on the day surgery to perform polypectomy. The occurrence of complications in such cases negatively affects the quality life of these patients. Bleeding after polypectomy is the most common complication[3]. However, the development of endoscopic clipping prevents the occurrence of bleeding after polypectomy[4]. Therefore, cases that need surgical treatment for bleeding after therapeutic procedures are quite rare. Although perforation occurs less often, it is more problematic than bleeding and should be given the most attention[5,6]. Perforations sometimes require surgical intervention and will decrease the patients' quality of life. Several large, retrospective studies have determined perforation incidences of 0.02%-0.8% and 0.15%-3% for diagnostic and therapeutic colonoscopy, respectively[6-11].

Surgery has been the mainstream treatment for iatrogenic perforation[12-14]. Surgical treatment for iatrogenic perforation should be avoided at local clinics because most such clinics do not have the appropriate equipment for such surgery. As a result, the performance of therapeutic endoscopy has so far not become common at local clinics. However, the use of endoscopic clipping to prevent the leakage of intestinal contents can circumvent the need for surgery[15,16]. Although surgical treatment should be selected when it is needed, the use of endoscopic clipping could potentially extend the therapeutic indications for such treatments at local clinics.

The aim of this study was to determine the incidences, clinical presentations, and management of iatrogenic perforations that occurred after diagnostic and therapeutic colonoscopy at a local clinic. This study compared the data between a local clinic and a tertiary hospital. Finally, the optimal strategies for performing therapeutic endoscopy and steps for dealing with complications at local clinics are also discussed.

MATERIALS AND METHODS

This study retrospectively reviewed the patient database of colonoscopies, and therapeutic procedures at Shirakawa Clinic (Maebashi, Japan) between April 2006 and December 2010. The data from Maebashi Red Cross Hospital (Maebashi, Japan), a tertiary hospital in the same region were also analyzed and compared between January 1996 and December 2010. Endoscopies at Shirakawa Clinic and Maebashi Red Cross Hospital are performed or supervised by staff gastroenterologists or fellows. The Shirakawa Clinic has 19 inpatient beds and appropriate management, such as drip infusion, can be easily carried out. However, the performance of either surgery or intensive care is restricted and patients required such case are therefore referred to the Maebashi Red Cross Hospital which is a tertiary hospital. Patients that required treatment for an iatrogenic colon perforation during the study period were analyzed. The underlying conditions, clinical presentations, perforation locations, treatment types (operative or conservative), and outcome data were analyzed. Possible complications were explained to all patients before the procedures, and all provided their written consent. Outpatients were informed to contact the clinic if they experienced any post-procedural abdominal distension or pain. This study was approved by the institutional ethical committee (No. SC2011/003; date, December 10, 2010).

Endoscopic procedures

The device for diagnostic endoscopy was a single-channel endoscope (CF260AI, Olympus Optical Co, Tokyo, Japan). A single-channel endoscope (GIF230 and/or CF260AI, Olympus) with a hood and a high-frequency generator with an automatically controlled system (Erbotom ICC200 or VIO 300D, ERBE, Tuebingen, Germany) were used for the endoscopic submucosal dissection (ESD) procedure. The patients principally received 24 mg sennoside the night before the examination for bowel preparation, and drank 200 mL polyethylene glycol (PEG) solution (Niflec®, Ajinomoto Pharma Co., Ltd., Tokyo, Japan) every 10 min on the examination day, for a total intake of 2000 mL PEG solution. Polypectomy and endoscopic mucosal resection (EMR) were performed as usual[17,18]. The ESD procedure was performed as described previously[19-21]. Abdominal X-rays were routinely performed after therapeutic procedures to check the perforation. Patients without complications were permitted to take soft food the day after the therapeutic procedures. Hemoclips (HX-600-135 and HX-600-090L, Olympus) were used for the endoscopic closure of any perforation.

Statistical analysis

The data were expressed as the mean ± SD. The data were analyzed using the Fisher's exact probability test,

RESULTS

Patients and characteristics

A total of 10 826 colonoscopies, and 2625 therapeutic procedures were performed at the Shirakawa Clinic between April 2006 and December 2010. Eight (0.07%) perforations were attributed to endoscopy (Table 1). There were no perforation cases for diagnostic procedures. On the other hand, a therapeutic procedure was performed in the 8 perforation cases (perforation rate, 0.3%; 1 per 328 procedures). The perforation rates for specific procedure types were 0.06% (1 per 1609) for polypectomy, 0.2% (1 per 443) for EMR, and 3.8% (1 per 26) for ESD. Perforation rates for ESD were significantly higher than those for polypectomy or EMR ($P < 0.01$). The cases with iatrogenic perforation are shown in Table 2. The study group included 3 females and 5 males aged from 57 years to 80 years of age (mean age 67.4 ± 6.6 years).

A total of 32 148 colonoscopies, and 7787 therapeutic procedures were performed in Maebashi Red Cross Hospital, and 9 (0.03%) perforations were attributed to endoscopy (Table 1). There were 3 (0.01%) perforation cases among the diagnostic procedures. Six perforations occurred with therapeutic endoscopy (perforation rate, 0.08%; 1 per 1298 procedures). Perforation rates for specific procedure types were 0.02% (1 per 5500) for polypectomy, 0.17% (1 per 561) for EMR, 2.3% (1 per 43) for ESD. The patients included 3 females and 6 males from 59 years to 81 years of age (mean age 69.2 ± 8.5 years). The cases with perforation during diagnostic endoscopy were complicated with diverticulitis, radiation colitis and amyloidosis, respectively. These 3 perforations during diagnostic endoscopy were treated by surgery. There were no significant differences in the perforation rates for each therapeutic procedure between the local clinic and the tertiary hospital.

Management and outcomes of perforations in the clinic

Three of 8 cases (37.5%) perforations were detected during the endoscopic procedure due to the visualization of a tear in the serosa. Six (75%) patients were diagnosed to have a perforation within 24 h of colonoscopy. Two patients were diagnosed to have a perforation more than 24 h later. These cases were considered to be delayed perforation caused by electrocautery. Four (50%) of 8 patients had been undergone clipping. Six (75%) patients had free intraperitoneal air and 2 patients showed pneumoretroperitoneum by abdominal radiography or computed tomography (CT). There were no symptoms of peritonitis in 5 patients and 3 patients showed localized peritonitis. All patients were managed conservatively because there no progression to peritonitis symptoms, Conservative treatment included the withholding of oral intake, hydration, intravenous antibiotics and serial abdominal examinations.

The mean maximum C-reactive protein (CRP) titer was 6.3 ± 5.6 mg/dL (range 0.9-17.9 mg/dL) and maximum body temperature was 37.1 ± 0.4 ℃ (range: 36.8-37.9 ℃). The mean fasting period for these patients was 2.3 ± 1.3 d (range: 1-4 d) and the mean hospital stay following perforation was 10.4 ± 1.8 d (range: 7-13 d). The points of references used to discontinue fasting were relief of abdominal pain, improvement of leukocytosis. The mean duration of total intravenous antibiotic treatment was 6.0 ± 1.2 d (range 4-8 d). Flomoxef sodium (FMOX) was administered in all cases. When fasting had been completed, oral ciprofloxacin was prescribed.

The mean maximum CRP titer was 2.9 ± 1.6 mg/dL with clipping and 9.7 ± 6.2 mg/dL without clipping, respectively. The mean maximum CRP titer was significantly lower in the patients with clipping ($P < 0.05$). The duration of fasting with and without clipping were 1.8 ± 1.0 d and 2.8 ± 1.5 d, respectively. The duration of intravenous antibiotics treatment with and without clipping was 5.8 ± 1.7 d and 6.3 ± 0.5 d, respectively. The duration of total the hospital stay with and without clipping were 10.0 ± 2.6 d and 10.8 ± 1.0 d, respectively. There were no significant differences in the total hospital stay, duration of fasting, dose of intravenous antibiotics between those that had or had not undergone clipping because of the small number of patients with perforation. However, the duration of fasting, dose of intravenous antibiotics and total hospital stay tended to be shorter when clipping was successful in comparison to when clipping was not performed.

Representative cases

Perforation discovered during the therapeutic procedure and treated with clipping: The case was 57-year-old male with no major complications. Perforation was observed during an ESD procedure for ascending colon adenocarcinoma (Figure 1A). Carbon dioxide inflation was used during ESD. Endoscopic clipping closed the small tear of the serosa. Abdominal X-ray showed a small amount of extra-bowel gasses. This case was treated conservatively. FMOX was administered for 4 d. The patient fasted for 1 d and food intake was started at day 3. The patient was discharged at day 9.

Perforation discovered more than 24 h after therapeutic procedure and treated without clipping: The case was a 64-year-old male with a past history of myocardial infarction. Abdominal pain was appeared after 2 d an EMR procedure for ascending colon adenoma. Abdominal XP and CT findings revealed free air (Figure 1B). This case was treated conservatively because the symptoms of peritonitis were localized. FMOX was administered for 6 d. The patient fasted for 4 d and food intake was started at day 6. The patient was discharged on day 11.

Perforation discovered just after a therapeutic procedure and treated with suture clippings: The case was a 71-year-old female complicated with hypertension. This case was treated by usual air inflation during the EMR procedure. Abdominal XP and CT findings revealed free air just after the EMR procedure for ascending colon adenoma (Figure 1C). Inflation was changed to CO_2 inflation and endoluminal repair with suture clipping was performed. FMOX was administered for 6 d. The patient fasted for 1 d and food intake was started on day 3. The patient was discharged on day 7.

Trouble shooting for perforation at a local clinic

A management algorithm for colonoscopic bowel perforation at a clinic is shown in Figure 2. A minor colon injury that is recognized during colonoscopy should be treated by changing to CO_2 inflation, endoluminal repair with clips and further conservative treatment could avoid immediate surgical intervention. Delayed endoscopic repair with clipping should be considered only if the condition of the patient is stable and a specific site is highly suspected. This latter recommendation should be useful when the perforation is suspected in the rectosigmoid area, because perforations in this region are easily located on scope reinsertion. An operation is indicated in the presence of a large perforation, and in the setting of generalized peritonitis or ongoing sepsis. Such patients should be immediately transferred to a tertiary hospital. A good relationship between local clinics and nearby tertiary hospitals should therefore be maintained.

DISCUSSION

The perforation risks of diagnostic and therapeutic colonoscopy are 0.02%-0.8% and 0.15%-3%, respectively[6-11]. Large studies of iatrogenic perforation related to colonoscopy are shown in Table 3[6-11,22-24]. New therapeutic approaches including ESD techniques have become more popular and the risk of perforation is increased in comparison to conventional techniques such as polypectomy or EMR. The perforation risk of a therapeutic procedure is usually higher than that of a diagnostic procedure. Fortunately, there were no perforations during diagnostic procedures at the local clinic in the present study.

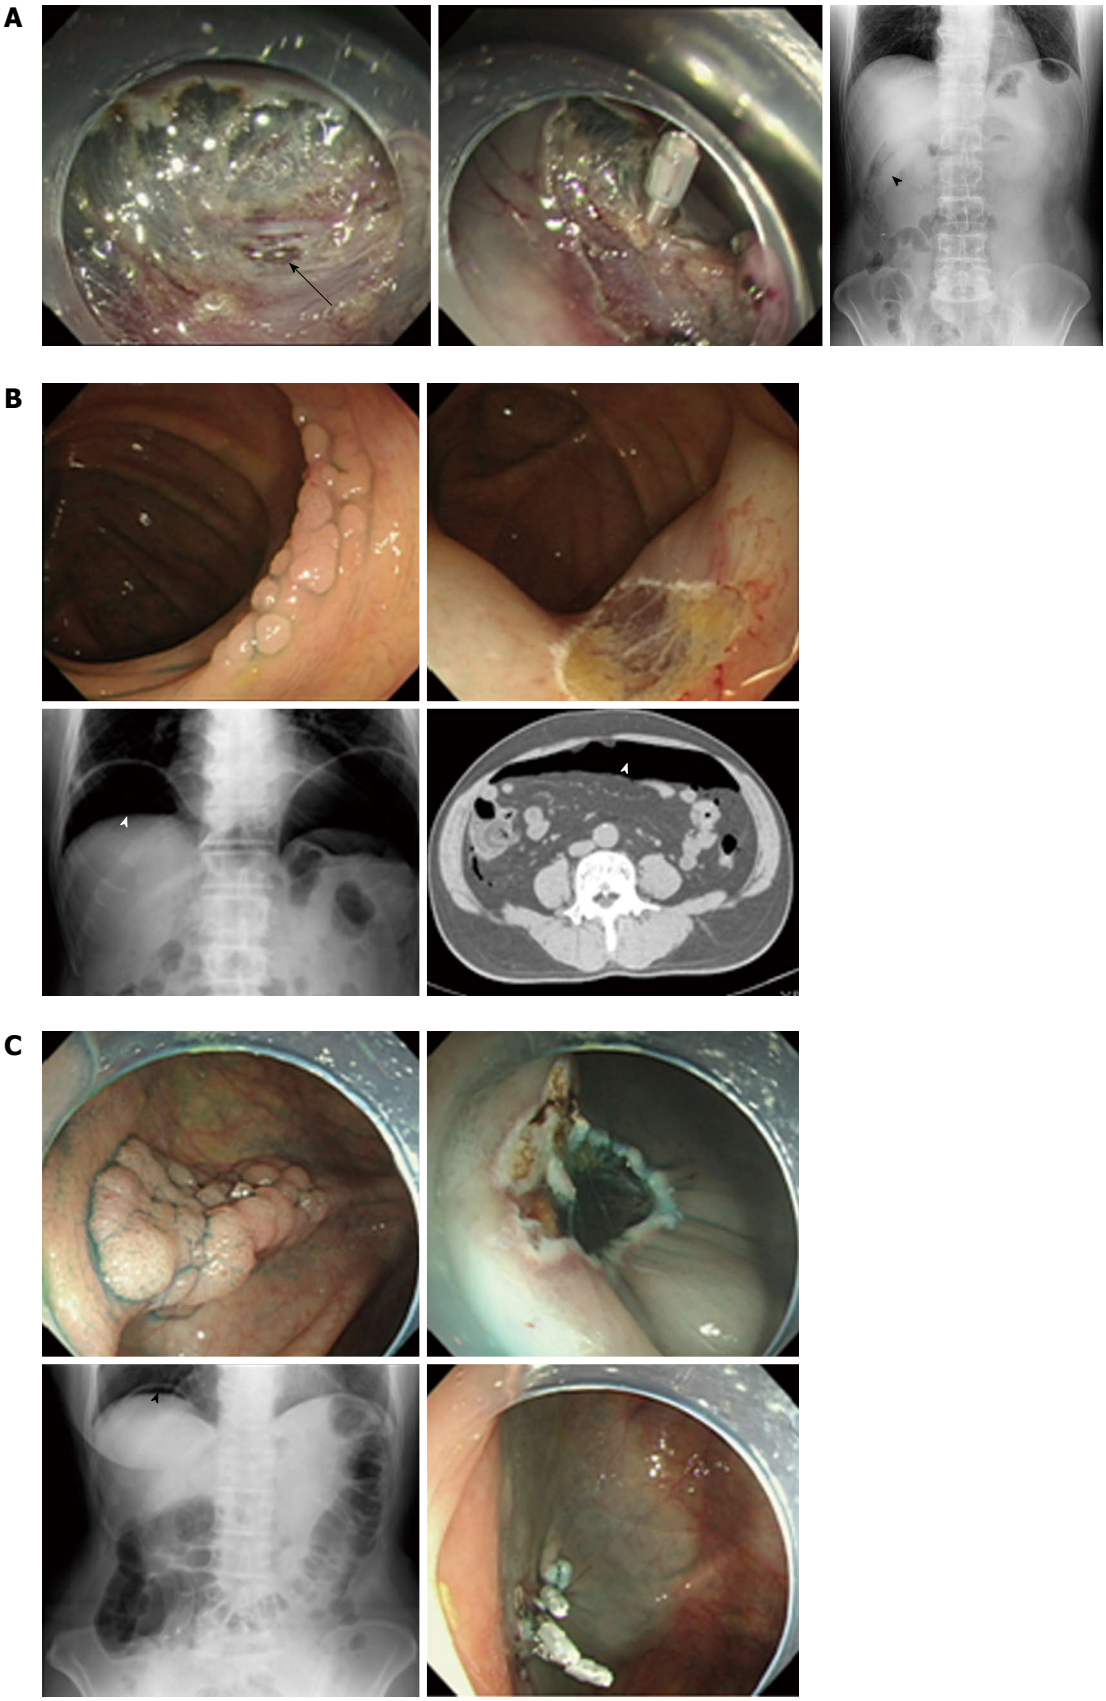

Figure 1 Representative cases of colonoscopic perforations. A: Case 1: Perforation discovered during the therapeutic procedure and treated with clipping; B: Case 2: Perforation discovered more than 24 h later after the therapeutic procedure and treated without clipping; C: Case 3: Perforation discovered just after the therapeutic procedure and treated with suture clipping.

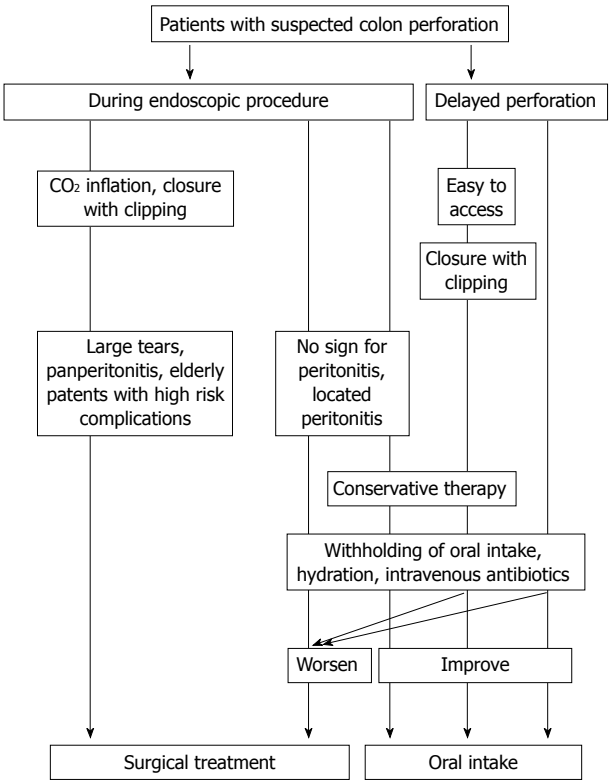

Figure 2 Trouble shooting for perforation at the local clinic.

Recent studies have demonstrated the possibility of endoscopic perforation closure using endoclips[25,26]. Closure by endoscopic clipping significantly reduced the maximum CRP titer in this study. Successful closure with endoscopic clipping in conservatively managed patients can reduce the fasting period, duration of intravenous antibiotic administration, and hospital stay[25,26]. As a result, successful clipping can improve patient quality of life and reduce medical costs. This study found no significant differences in the duration of fasting, intravenous antibiotics treatment, total hospital stay between those that had or had not undergone clipping. It may be due to the small number of patients with perforation.

Perforations associated with diagnostic procedures are usually due to applying pressure to the colonic wall, and they are noticed immediately. However, perforations that occur after therapeutic procedures are often diagnosed late. Ischemia of the colonic wall caused by electrical or thermal injury after electrocoagulation can cause a delayed perforation following therapeutic procedures[10]. Clipping can induce mucosal and submucosal healing and prevent fecal soiling of the peritoneal cavity when the perforation is small and significant colonic pathology does not exist. However, the application of clipping for perforation in delayed perforation still remains controversial. Delayed endoscopic repair with clipping should be considered only if the condition of the patient is stable and a specific site is highly suspected[6]. This recommendation is likely to be useful when the perforation is suspected to be in the rectosigmoid area, because perforations in this region are easily located on scope reinsertion[6].

The limitations of this study include the retrospective nature of the work and the inclusion of descriptions of local experience without the addition of new protocols. However, we believe that investigating a large number of patients at a local clinic will elucidate the role the local clinic plays in therapeutic endoscopies. Furthermore, selection bias between the two institutes of patients or endoscopists may have existed. The incidence of complications depends on the type of lesion or the skill of the endoscopist. Selection bias of patients or endoscopists is a problem to be evaluated in a future study.

Selective patients are likely to improve under conservative management involving hospitalization, intestinal rest, intravenous fluids, and antibiotics to limit peritonitis and allow the perforation to seal. However, conservative management requires careful observation with frequent and repeated abdominal exams. Patients successfully treated non-surgically must be clinically stable, and their abdominal symptoms should improve rapidly with no deterioration due to peritoneal signs[14]. A local clinic does not have any surgical options, so a good relationship and close contact with a tertiary hospital is needed. Patients must be immediately transferred to a tertiary hospital when either abdominal symptoms are observed or peritonitis worsens.

In conclusion, iatrogenic colonic perforation is a serious but uncommon complication of colonoscopy. However, surgery is not mandatory for perforations caused by therapeutic procedures, and endoscopic perforation closure using endoclips should be considered as a helpful adjunct to conservative treatment. It is possible to perform endoscopic treatment at a local clinic when there is appropriate back-up by a nearby tertiary hospital. Of course, close contact between local clinics and a tertiary hospital is essential.

COMMENTS

Background

The number of colonoscopies has increased rapidly, not only in hospitals, but also in clinics. The occurrence of complications negatively affects the quality life of patients. The aim of this study was to determine the incidence, clinical presentation and management of iatrogenic perforations that occurred after diagnostic and therapeutic colonoscopies at a local clinic.

Research frontiers

Data and management strategies regarding iatrogenic perforations at hospitals were reported. However, such reports from clinics were rare. Optimal strategies for performing therapeutic endoscopy and steps for managing complications at local clinics were also discussed.

Innovations and breakthroughs

This study investigated the incidence, management and outcomes of colonoscopic perforation in a local clinic. Performing endoscopic perforation closure using endoclips should be considered as a helpful adjunct to conservative treatment. It is possible to perform endoscopic treatment at a local clinic when appropriate back-up support at a nearby tertiary hospital is available.

Applications

The number of endoscopic treatments performed at local clinics will increase when appropriate back-up support at nearby tertiary hospitals is available.

Terminology

A colonoscopic perforation is a complication of diagnostic or therapeutic colonoscopy. Although perforation occurs infrequently, it is problematic and should be given proper attention. Perforations sometimes require surgical intervention, and will decrease a patient's quality of life.

Peer review

The study is well designed and the paper is well written. Although there is no novelty in the idea and only a description of the local experience is provided, the study is a nice piece of work that includes a large number of patients.

Abstract

AIM: To assess the diagnostic performance of follow-up liver computed tomography (CT) for the detection of high-risk esophageal varices in patients treated with locoregional therapy for hepatocellular carcinoma (HCC).

METHODS: We prospectively enrolled 100 patients with cirrhosis who underwent transcatheter arterial chemoembolization, radiofrequency ablation or both procedures for HCCs. All patients underwent upper endoscopy and subsequently liver CT. Three radiologists independently evaluated the presence of high-risk esophageal varices with transverse images alone and with three orthogonal multiplanar reformation (MPR) images, respectively. With endoscopic grading as the reference standard, diagnostic performance was assessed by using receiver operating characteristic (ROC) curve analysis.

RESULTS: The diagnostic performances (areas under the ROC curve) of three observers with transverse images alone were 0.947 ± 0.031, 0.969 ± 0.024, and 0.916 ± 0.038, respectively. The mean sensitivity, specificity, positive predicative value (PPV), and negative predicative value (NPV) with transverse images alone were 90.1%, 86.39%, 70.9%, and 95.9%, respectively. The diagnostic performances, mean sensitivity, specificity, PPV, and NPV with three orthogonal MPR images (0.965 ± 0.025, 0.959 ± 0.027, 0.938 ± 0.033, 91.4%, 89.5%, 76.3%, and 96.6%, respectively) were not superior to corresponding values with transverse images alone ($P > 0.05$), except for the mean specificity ($P = 0.039$).

CONCLUSION: Our results showed excellent diagnostic performance, sensitivity and NPV to detect high-risk esophageal varices on follow-up liver CT after locoregional therapy for HCC.

INTRODUCTION

More than one-half of patients with cirrhosis eventually develop esophageal varices[1]. Screening upper endoscopy is repeated in 1-3 years in order to evaluate esophageal varices in cirrhotic patients owing to the substantial morbidity and mortality related with variceal bleeding[2]. The presence of high-risk varices seen in up to 30% of patients with esophageal varices on endoscopy is considered as an indication for prophylaxis against variceal bleeding with either endoscopic variceal ligation (EVL) or the administration of β-blockers[1,3].

Of several recent studies that have suggested the usefulness of computed tomography (CT) scans to evaluate esophageal varices[4-8], one study[7] asserted that CT was a better initial screening modality when compared to endoscopy in terms of cost-effectiveness and patient preference. However, for only these reasons, the adoption of CT to replace ultrasound as the surveillance imaging technique in all cirrhotic patients is still subject to debate with the consideration of radiation hazards[9]. As CT is commonly used as a follow-up imaging modality in patients treated with locoregional therapy for hepatocellular carcinoma (HCC)[10], we supposed that replacement of CT for evaluating varices was more persuasive in such patients. The purpose of this study was to evaluate prospectively the diagnostic performance of radiologists for the detection of high-risk esophageal varices on regular follow-up liver multi-detector row computed tomography (MDCT) examinations in patients treated with locoregional therapy for HCC. We also assessed the usefulness of the addition of coronal and sagittal multiplanar reformation (MPR) images.

MATERIALS AND METHODS

Study design and patients

The Institutional Review Board approved the current study and all subjects provided informed consent. In this prospective study, the sample size was determined for overall diagnostic performance based on the area (A_z) under the composite receiver operating characteristic (ROC) curve using pooled data of all observers. We expected that the pooled A_z for the diagnosis of high-risk varices on CT is 0.95, with a width of the 95% confidence interval (CI) of 0.05. When the ratio of the number of patients with high-risk varices ranges from 1:1 to 1:6 and the ratio of standard deviation of pooled A_z with high-risk varices ranges from 1:1 to 3:1, the standard error of estimates of A_z in 100 subjects is $\leqslant$ 0.025. Thus, the 95%CI of A_z is $\leqslant$ 0.05[11].

From June 2009 to December 2010, we enrolled patients with cirrhosis as well as HCCs treated with transcatheter arterial chemoembolization (TACE), radiofrequency (RF) ablation or both procedures who were scheduled to undergo both a regular follow-up liver CT examination and a screening upper endoscopy. We excluded patients who had a history of undergoing EVL for esophageal varices[5]. One-hundred patients who agreed to participate in our prospective study underwent an endoscopy and a subsequent liver MDCT examination within four hours after endoscopy. All patients had undergone one or more regular (all within a 6-mo interval) follow-up liver MDCT examinations following TACE (n = 43), RF ablation (n = 35) or both procedures (n = 22) for HCCs. The patient population consisted of 79 men and 21 women (age range, 35-82 years; median age, 59 years, mean age, 58.4 years). Patients were diagnosed with cirrhosis based on liver histopathology (n = 28), or characteristic clinical features (symptoms and stigmata of cirrhosis and its complications), laboratory results (levels of viral markers, hyperbilirubinemia, hypoalbuminemia and coagulopathy), or imaging findings (liver configuration, splenomegaly, ascites and collateral vessels) (n = 72). Eighteen patients received β-blocker medication. All patients had liver cirrhosis due to hepatitis B infection (n = 76), hepatitis C infection (n = 14), alcohol use (n = 5) or an unknown etiology (n = 5). There were 89 patients with Child-Pugh class A, ten patients with Child-Pugh class B, and one patient with Child-Pugh class C disease.

Upper endoscopy

Patients underwent standard upper endoscopy performed by experienced gastroenterologists (with experience of performing more than 500 endoscopy examinations) in our endoscopy unit. Seven gastroenterologists performed endoscopy of the 100 patients in our study. All endoscopic studies were captured as digital imaging files. On endoscopy, esophageal varices were graded according to criteria proposed by the Japanese Research Society for Portal Hypertension[12]. Grade 2 (varices showing a beaded appearance) or grade 3 (varices running in an oblique course and showing tortuosity with a tumorfactive appearance) was chosen as a cutoff point to define high-risk varices, based on the possibility to develop esophageal bleeding[12]. Two specialized endoscopists (Joon Hyeok Lee and Moon Seok Choi) reviewed all of the stored endoscopic images and the procedure reports for all patients. The endoscopists determined the final grades of the esophageal varices of the study population based on consensus. Disagreement between the two endoscopists was resolved in conference along with a third endoscopist (Geum-Youn Gwak).

Liver computed tomography protocol

Liver CT examinations for follow-up were performed with a 64-slice MDCT scanner (Lightspeed VCT; GE Healthcare, Milwaukee, WI, United States). A total of 120 mL of nonionic contrast material (Ultravist 300, 300 mg/mL iopromide, Schering, Berlin, Germany) was administered intravenously with an automatic injector at a rate of 3-4 mL/s. Images were obtained at 30-40 s, 70 s and 180 s after the initiation of contrast material injection, representing the hepatic arterial, portal venous and equilibrium phases, respectively. In order to determine the appropriate scanning time for hepatic arterial phase imaging, we used an automatic bolus-tracking technique with automated scan-triggering software (SmartPrep; GE Healthcare). Hepatic arterial phase scanning was started automatically 12 s after the trigger threshold (100 HU) was reached at the level of the supraceliac abdominal aorta. Images were obtained from the dome of the diaphragm to the bottom of the liver during a single breath-hold. CT scanning parameters were as follows: 64 detector rows; beam collimation, 0.625 mm × 64 mm; pitch, 0.984; kVp/mA, 120/100-300; gantry rotation time, 0.6 s. Isotropic raw data were acquired with a slice thickness of 1.25 mm and an interval of 1.25 mm with the use of MDCT. Using the raw data, a transverse image was obtained with a slice thickness of 5 mm and an interval of 2.5 mm. During the portal venous phase, coronal and sagittal MPR images were obtained with a 3 mm interval and a slice thickness of 3 mm. No patients received oral contrast material.

Liver computed tomography image analysis

Three abdominal radiologists (Soon Jin Lee, Dongil Choi and Hangi Jo) independently interpreted the liver CT images in order to detect the presence of high-risk (grade 2 or 3) esophageal varices. The radiologists had 13, nine and five years experience, respectively, in the interpretation of abdominal CT images. The radiologists initially evaluated transverse images alone in a random order on a picture archiving and communication system (PACS) monitor. After three weeks, three orthogonal MPR images were assessed in another random order. The radiologists were blinded to the patient physical findings, laboratory values, previous imaging results and endoscopy results.

The CT images were reviewed to detect the presence of high-risk esophageal varices with a 4-point confidence scale for the development of variceal bleeding based on the endoscopic findings that were correlated with variceal bleeding: (1) definitely low-risk or no varices; (2) probably low-risk; (3) probably high-risk; and (4) definitely high-risk. The observers investigated beaded and tortuous varices (distinct enhancing nodular or linear lesions that abutted the surface of the esophageal lumen or protruded into the luminal space) on stack PACS images of CT scans. In addition, the observers measured the shortest diameter of the largest enhancing lesion (varix) during the portal venous phase by the use of an electronic caliper on one-format PACS images. A confidence score of 4 could be assigned if the diameter was definitely greater than 3 mm. A score of 3 was assigned if the diameter was between 2 mm to 3 mm. A score of 2 was assigned if the diameter was between 1 mm to 2 mm. A score of 1 was assigned if the diameter was less than 1 mm[4].

Statistical analysis

The results of liver CT imaging analyzed by three observers were correlated with the endoscopic grading of esophageal varices by the study coordinator (Hyojin Kim). Observer performance for the detection of high-risk esophageal varices was assessed by the use of ROC curve analysis with transverse images alone and with three orthogonal MPR images. A_z under each ROC curve by application of the maximum-likelihood curve-fitting algorithm was used to indicate the diagnostic performance for the detection of high-risk esophageal varices on liver CT images. A_z values were compared by using pseudovalues with the jackknife method developed by Dorfman *et al*[13]. Composite ROC curves for the performance of all observers were obtained by using the pooled data of the three observers.

The sensitivity and specificity for the CT diagnosis of high-risk esophageal varices were calculated. The sensitivity for the detection of varices was determined by use of the number of patients with varices assigned a score of 3 or 4. Sensitivities and specificities for transverse images alone and three orthogonal MPR images were compared with use of the McNemar test. The positive predicative value (PPV) and negative predicative value (NPV) were also calculated and compared with use of the χ^2 test and Fisher's exact test, respectively. A P value of less than 0.05 was considered as significant.

Interobserver agreements for the detection of esophageal varices and high-risk varices were evaluated using κ statistics. The degree of agreement was categorized as follows: κ values of 0.00-0.20 were considered to indicate poor agreement; κ values of 0.21-0.40, fair agreement; κ values of 0.41-0.60, moderate agreement; κ values of 0.61-0.80, good agreement; κ values of 0.81-1.00, excellent agreement[14]. Statistical analyses were performed using commercially available software packages (PASW Statistics, release 17.0.2; SPSS, Chicago, IL, United States; MedCalc, version 7.1; MedCalc Software, Mariakerke, Belgium).

RESULTS

In 50 patients, there were no esophageal varices (grade 0) as determined by endoscopy. Twenty-three patients were classified with grade 1 esophageal varices, 24 patients were classified with grade 2 esophageal varices (Figure 1), and three patients were classified with grade 3 esophageal varices. No patients had a significant endoscopic abnormality other than esophageal varices, such as an ulcer,

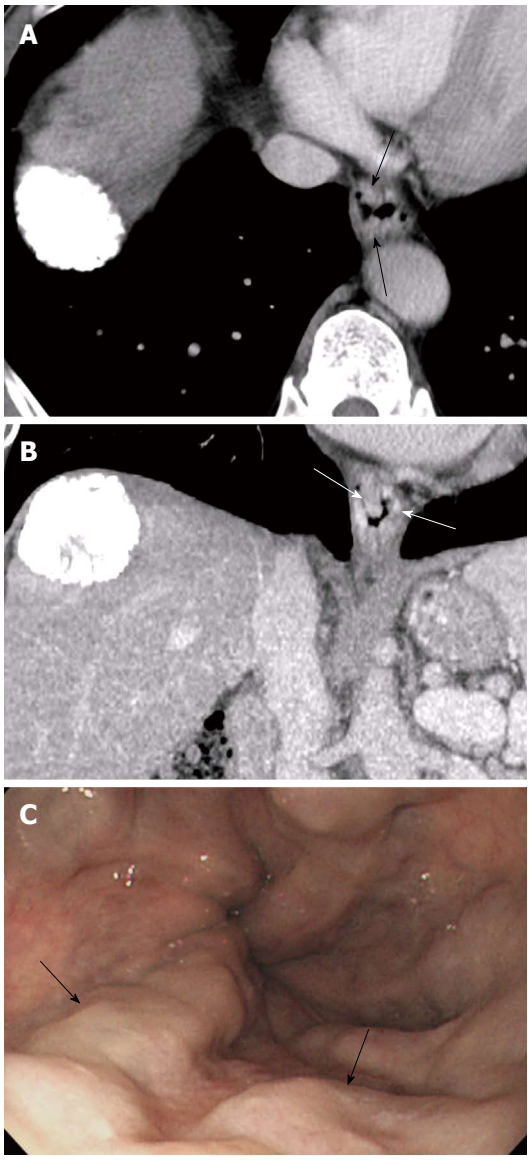

Figure 1 Imaging findings are shown for grade 2 esophageal varices in the distal esophagus in a 61-year-old man with hepatocellular carcinoma and cirrhosis. A: A transversecomputed tomography scan shows distinct enhancing nodular lesions (arrows) protruding into the luminal space. All observers recorded the lesions as high-risk esophageal varices. Periesophageal varices are not found; B: On coronal images, distinct enhancing nodular lesions (arrows) are noted, and all observers considered the lesions as high-risk esophageal varices; C: A conventional endoscopic image confirms the presence of beaded esophageal varices (arrows).

inflammation or mass. The red sign was observed in one (4.3%) of 23 patients with a grade 1 varix, 15 (62.5%) of 24 patients with a grade 2 varix and two (66.7%) of three patients with a grade 3 varix.

The A_z values of the ROC assessment of the three observers for the detection of high-risk esophageal varices with transverse images alone were 0.947 ± 0.031 (95%CI, 0.883-0.982), 0.969 ± 0.024 (95%CI, 0.913-0.993) and 0.916 ± 0.038 (95%CI, 0.843-0.962), respectively. The Az values of the ROC assessment of the three observers with the three orthogonal MPR images were 0.965 ± 0.025 (95%CI, 0.908-0.991), 0.959 ± 0.027 (95%CI, 0.899-0.988) and 0.938 ± 0.033 (95%CI, 0.871-0.976), respectively. The Az values of each observer were similar for transverse images alone and for the three orthogonal MPR images (each $P > 0.05$) (Table 1). In addition, there was no significant difference of mean Az values of pooled data by the three observer for transverse images alone (0.946 ± 0.018; 95%CI, 0.914-0.968) and for the three orthogonal MPR images (0.954 ± 0.017; 95%CI, 0.924-0.975, $P > 0.05$). The A_z values were also similar among the three observers both for transverse images alone and for the three orthogonal MPR images, respectively (each $P > 0.05$) (Table 1).

The mean sensitivity for the detection of high-risk esophageal varices of the three observers with transverse images alone and with the three orthogonal MPR images were 90.1% and 91.4%, respectively ($P > 0.05$). For each observer, the sensitivities of detecting high-risk esophageal varices were also similar for transverse images alone and for the three orthogonal MPR images (each $P > 0.05$) (Table 2). While the specificities of each observer were similar for transverse images alone and for the three orthogonal MPR images (each $P > 0.05$), the mean specificity with the three orthogonal MPR images (89.5%) was better than that with transverse images alone (86.3%) ($P = 0.039$) (Table 2).

There was no significant difference for the mean PPV of three observers for transverse images alone (70.9%) and for the three orthogonal MPR images (76.3%, $P > 0.05$). For each observer, the PPVs were also similar for transverse images alone and for the three orthogonal MPR images (each $P > 0.05$) (Table 3). There was no significant difference of the mean NPV for transverse images alone (95.9%) and for the three orthogonal MPR images (96.6%, $P > 0.05$). For each observer, the NPVs were also similar for transverse images alone and for the three orthogonal MPR images (each $P > 0.05$) (Table 3).

All κ values for agreements among the three observers with transverse images alone showed excellent agreements (range: 0.845-0.933), and κ values for agreements among three observers with three orthogonal MPR images demonstrated good and excellent agreements (range: 0.791-0.910).

DISCUSSION

Although liver CT images always cover the distal esophagus where all varices occur, some radiologists do not comment on either the presence or the degree of esophageal varices in radiological reports. Some endoscopists are unaware that liver CT scans provide excellent images of esophageal varices. Regular follow-up CT examinations are essential to evaluate recurrence and therapeutic effectiveness in patients treated with TACE or ablation therapy for HCC[10,15]. In such patients, we can make an objective decision about the risk of variceal bleeding with the use of regular follow-up CT imaging without the use of an invasive endoscopic evaluation. The presence of periesophageal varices has been correlated with recur-

Specificity%	89.0 (65/73)	90.4 (66/73)	87.7 (64/73)	87.7 (64/73)	82.2 (60/73)	90.4 (66/73)	86.3 (189/219)	89.5 (196/219)
P value	1.000		1.000		0.070		0.039	

For sensitivity, the numbers in parentheses are the number of varices assigned a score of 3 or 4 divided by the total number of varices. *P* values represent the differences of the sensitivity and the specificity for transverse images alone and for the three orthogonal MPR images (McNemar test). MPR: Multiplanar reformation.

Table 3 Positive predictive value and negative predictive value of liver computed tomography for the detection of high-risk esophageal varices by three observers

	Observer 1 Transverse	Observer 1 3 MPR	Observer 2 Transverse	Observer 2 3 MPR	Observer 3 Transverse	Observer 3 3 MPR	All Transverse	All 3 MPR
PPV %	75.8 (25/33)	78.1 (25/32)	73.5 (25/34)	73.5 (25/34)	63.9 (23/36)	77.4 (24/31)	70.9 (73/103)	76.3 (74/97)
P value	0.947		1.000		0.352		0.482	
NPV%	97.0 (65/67)	97.1 (66/68)	97.0 (64/66)	97.0 (64/66)	93.8 (60/64)	95.7 (66/69)	95.9 (189/197)	96.6 (196/203)
P value	1.000		1.000		0.710		0.797	

P values represent the differences of the positive predicative value and the negative predicative value for transverse images alone and for the three orthogonal MPR images (χ^2 test and Fisher's exact test). MPR: Multiplanar reformation; PPV: Positive predicative value; NPV: Negative predicative value.

rence of luminal esophageal varices after treatment[16].

As with the results of previous reports[4-8], the sensitivities for the detection of high-risk esophageal varices for each observer were also high (approximately 90%) in our study (Table 2). Excellent NPVs as well as high sensitivities for the detection of high-risk varices are clinically important, as the goal of endoscopic screening for esophageal varices is to decrease morbidity and mortality resulting from variceal bleeding. As good screening tests should show a low frequency of false negative results, sensitivity and NPV are more important as compared to specificity and PPV in a screening test[17]. Even though both PPV and NPV are influenced by disease prevalence, the prevalence of high-risk esophageal varices in our study was similar to prior studies[4-8].

A recent study[7] mentioned the possibility that sagittal and coronal images with isotropic spacial resolution potentially decrease measurement variability as vessels are displayed within the imaging plane. However, based on the results of our study, additional coronal and sagittal images showed little practical help to evaluate high-risk esophageal varices when compared to assessment of transverse images alone. Moreover, the use of virtual esophagography proposed in another recent study[5] might be impractical because of time-consuming and invasive insertion of the esophagus with a catheter for air insufflation. Insufflation alters both the luminal pressure and the hemodynamics of the varices. Perri *et al*[7] pointed out that the measurement of varices in a non-distended state might provide a more proper assessment for bleeding risk as variceal bleeding occurs while the esophagus is in its normal non-distended state.

Our study has some limitations. The most important limitation is the use of endoscopy as the reference stan-

dard. Prior studies[18,19] have demonstrated a lack of good correlation between endoscopists to evaluate the grades of esophageal varices. In our study, given the semi-open access system of the endoscopy unit, many different endoscopists perform endoscopy procedures. Hence, specialized endoscopists re-evaluated the grades of esophageal varices with review of the stored endoscopic images. Second, we could not evaluate qualitative endoscopic appearances including the presence of red signs such as cherry-red spots and diffuse redness, which is one of the predictors of variceal bleeding. These red signs cannot be depicted on CT images. In a recent report[20], cases with the shortest diameter of the largest varix of more than 4 mm showed positive red signs. In our study, the endoscopic red sign was observed in only one patient with low-risk (grade 1) esophageal varices (4.3%, 1 of 23 cases)[4].

In conclusion, our results have demonstrated excellent diagnostic performance, sensitivity and NPV with low interobserver variability to detect high-risk esophageal varices on regular follow-up liver MDCT examinations in patients treated with locoregional therapy for HCCs. Careful evaluation of high-risk esophageal varices on a liver MDCT examination may be useful to avoid performing low-yield endoscopy in such patients. When compared to the assessment of transverse images alone, additional coronal and sagittal images were of little help to evaluate high-risk esophageal varices. Our results suggest that liver CT can be used as a single noninvasive surveillance tool for both esophageal varices and recurrent HCC after locoregional therapy. However, a definite change of clinical pathways may be needed in a randomized controlled study on the comparison of bleeding frequency and survival in patients treated with locoregional therapy between the use of a regular follow-up liver MDCT examination alone and with the combination of screening endoscopy.

COMMENTS

Background

The presence of high-risk varices seen in up to 30% of patients with esophageal varices on endoscopy is considered as an indication for prophylaxis against variceal bleeding with either endoscopic variceal ligation or the administration of β-blockers. Several recent studies have suggested the usefulness of computed tomography (CT) scans to evaluate esophageal varices, and one study asserted that CT was a better initial screening modality when compared to endoscopy in terms of cost-effectiveness and patient preference.

Research frontiers

As CT is commonly used as a follow-up imaging modality in patients treated with locoregional therapy for hepatocellular carcinoma (HCC), the authors suggested that replacement of CT for evaluating varices was more persuasive in such patients. Careful evaluation of high-risk esophageal varices on a liver multi-detector row computed tomography (MDCT) examination may be useful to avoid performing low-yield endoscopy in such patients.

Innovations and breakthroughs

The results of this study have demonstrated excellent diagnostic performance, sensitivity and negative predicative value with low interobserver variability to detect high-risk esophageal varices on regular follow-up liver MDCT examinations in patients treated with locoregional therapy for HCCs. When compared to the assessment of transverse images alone, additional coronal and sagittal images were of little help to evaluate high-risk esophageal varices.

Applications

The study results suggest that that liver CT can be used as a single noninvasive surveillance tool for both esophageal varices and recurrent HCC after locoregional therapy.

Peer review

This is a good prospective study in which authors evaluate the diagnostic performance of radiologists for the detection of high-risk esophageal varices on regular follow-up liver multi-detector row CT examinations in patients treated with locoregional therapy for HCC.

Abstract

AIM: To determine the effects of pentoxifylline (PTX) on clinical manifestations and evaluate arterial blood gas data in hepatopulmonary syndrome (HPS) in children.

METHODS: In a pilot study of 10 children with chronic liver disease, who had HPS, 20 mg/kg/d PTX was administered for 3 mo. Clinical data and arterial blood gas parameters were evaluated at baseline, the end of the treatment period, and 3 mo after drug discontinuation.

RESULTS: Six patients could tolerate PTX, while four patients experienced complications. Among patients who could tolerate PTX, there was a significant increase in arterial oxygen pressure (PaO_2) (P = 0.02) and oxygen saturation (SaO_2) (P = 0.04) and alveolar-arterial oxygen gradient (P = 0.02) after 3 mo of treatment. Significant decreases in PaO_2 (P = 0.02) and alveolar-arterial oxygen gradient (P = 0.02) were also seen after drug discontinuation.

CONCLUSION: PTX may improve PaO_2, SaO_2 and alveolar-arterial oxygen gradient in the early stage of HPS.

INTRODUCTION

The hepatopulmonary syndrome (HPS) is the triad of liver disease, arterial hypoxemia and widespread pulmonary vascular dilatation[1-3]. Prevalence of this syndrome is 10%-30% among patients with chronic liver disease[4].

The pathogenesis of HPS is unclear. The roles of eicosanoids as vasoconstrictors and the increased number of intravascular macrophage-like cells have been reported previously. Increased pulmonary production of NO in

cirrhosis has been considered as a reason for intrapulmonary venous dilatation. It is claimed that increased pulmonary NO production is due to raised pulmonary vascular endothelial NO synthase (eNOS) and inducible NO synthase expression. Recent studies have shown that increased hepatic production and release of low level of endothelin 1 (ET-1) can act as a trigger for enhancing eNO level. Tumor necrosis factor α (TNFα) and ET-1 have been implicated in the development of experimental HPS. Recent studies have suggested that progression of HPS is due to increased CO production and heme oxygenase 1 expression[5-7]. The presence of HPS increases mortality in cirrhotic patients and may influence the frequency and severity of complications of portal hypertension[8-11]. To the best of our knowledge, there is currently no effective medical therapy for HPS. Several medications such as methylene blue, garlic and aspirin have been reported to have a therapeutic effect[12-15], but curative treatment of this syndrome is still orthotopic liver transplantation[16].

Pentoxifylline (PTX), a nonspecific phosphodiesterase-4 inhibitor, blocks TNFα synthesis[17,18] and seems to prevent HPS. There are limited studies about PTX in adult patients with HPS, with varying results. Until now, no study has been carried out in children. The aim of this study was to evaluate the effect of PTX on clinical manifestations and arterial blood gas data in children with HPS.

MATERIALS AND METHODS

This pilot study was carried out in the Ghaem Medical Center of Mashhad University of Medical Sciences, Iran during a 21-mo period (March 2008-November 2010). The protocol for this study was approved by the Ethics Committee of Mashhad University. Children and their parents were given informed consent forms. A consecutive series of patients with cirrhosis attending our hospital were screened for HPS. HPS was diagnosed according to the European Respiratory Society Task Force criteria: hypoxemia plus positive contrast-enhanced echocardiography[7]. Positive contrast echocardiography was defined by the appearance of air bubbles in the left side of the heart after the first three beats during injection of 10 mL agitated isotonic saline solution in the antecubital vein[19]. Exclusion criteria were active infection, known malignancy, cardiac disease, and kidney disease.

Patient data including demographics, etiology of cirrhosis, clinical manifestations, laboratory results [complete blood count (CBC), diff, blood urea nitrogen, creatinine, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, prothrombin time, partial thromboplastin time, total bilirubin, direct bilirubin, albumin and total protein] were recorded. For each patient, Child score was determined. All patients underwent measurement of arterial oxygen pressure (PaO_2) and oxygen saturation (SaO_2) by blood sampling from the radial artery in a sitting position while breathing ambient air. For each patient, alveolar-arterial oxygen gradient was calculated. Patients were classified in four groups according to severity of hypoxemia: mild HPS with $PaO_2 \geqslant 80$ mmHg, moderate HPS with $60 \leqslant PaO_2 < 80$ mmHg, severe HPS with $50 \leqslant PaO_2 < 60$ mmHg, and very severe HPS with $PaO_2 < 50$ mmHg[7].

PTX at a dose of 20 mg/kg per day orally in three divided doses was administrated for 3 mo. In this period, patients were followed up weekly and whenever patients required, by telephone conference and monthly with outpatient visits. Clinical manifestations and laboratory data were rechecked at the end of the treatment period, 3 mo after drug discontinuation and whenever a child had any deterioration or could not tolerate PTX. Response to PTX was considered as increased $PaO_2 > 10$ mmHg from baseline[20]. Complement a three months period of treatment was considered as primary end point and development of serious side effects, death and liver transplantation was considered as the secondary end point.

After entering data into SPSS version 16.0 software, quantitative data were analyzed by the Wilcoxon signed rank test and qualitative data by the McNemar test. A P value < 0.05 was considered significant.

RESULTS

A total of 65 patients aged < 18 years with cirrhosis were screened for the presence of HPS from March to August 2009. Twelve patients had HPS. Two were excluded. One had kidney disease and one did not allow us to intervene. Ten children were enrolled. Two patients had mild HPS, six moderate HPS, one severe HPS and one very severe HPS. Four patients were girls. Mean age was 9.2 ± 5.0 years old. The most common recognized cause of cirrhosis was Wilson's disease (Table 1). Minimum alveolar-

arterial oxygen gradient at baseline was 18.84 and maximum was 71.98. Clinical and laboratory characteristics of the patients at baseline and end of treatment period are summarized in Table 2.

Six patients completed the treatment period. Petechiae with platelet count 10 000/mm^3 was seen in one patient, 3 wk after the beginning of PTX. He was a 16-year-old boy with Wilson's disease and very severe HPS. His platelet count at the beginning of the study was 159 000/mm^3. Platelet count increased to 100 000/mm^3 2 wk after drug discontinuation. Other laboratory tests did not show any significant change. Although nausea was seen in all patients, only three had severe vomiting that did not respond to symptomatic treatment and caused drug withdrawal. Among them, two had moderate HPS and one had severe HPS. No significant laboratory changes were seen in these patients. Treatment periods were 10 d, 28 d and 45 d. Other adverse effects did not cause drug withdrawal and improved with symptomatic treatment (two patients with fatigue and two with headache).

Among patients who completed the treatment period, average increment in PaO_2 was 26 mmHg and SaO_2 was 4.3%. At least 10 mmHg elevations in PaO_2 level was seen in all patients. Also, PaO_2 significantly decreased 3 mo after the end of treatment. Moreover, there was significant improvement in alveolar-arterial oxygen gradient at the end of the treatment period and a significant increase after drug discontinuation (Table 3). Among these patients, two had mild HPS and four had moderate HPS.

For clinical manifestations, there were no significant change between baseline, the end of treatment, and 3 mo later. There was also no significant change in other laboratory tests. In a 12-mo period of follow-up after drug discontinuation, two patients died. The first was the 16-year-old boy with Wilson's disease. He died from upper gastroesophageal bleeding from esophageal varicose veins, 8 mo after drug withdrawal. The second was a girl of 2 years with cryptogenic cirrhosis who received PTX for 10 d. She was one of the three patients who could not tolerate PTX because of severe vomiting. She died due to hepatic encephalopathy and septicemia.

Table 3 PaO_2, SaO_2 and alveolar-arterial oxygen gradient (A-a G) before, at the end and 3 mo after treatment among patients who could tolerate pentoxifylline (mean ± SD)

[1]Baseline *vs* end of treatment; [2]End of treatment *vs* 3 mo later. PaO_2: Oxygen pressure; SaO_2: Oxygen saturation.

DISCUSSION

In this pilot study, we found significant improvements in PaO_2, SaO_2 and alveolar-arterial oxygen gradient after 3 mo therapy among patients who could tolerate PTX. PaO_2 was also significantly decreased at 3 mo after drug withdrawal, which supports the therapeutic effects of PTX. However, we did not find any significant change in clinical parameters. In this study, 40% of patients could not complete the treatment period. In other studies of patients with liver disease, drug withdrawal rate due to adverse effects ranged from 0% to 40%[17,21,22]. It seems that gastrointestinal intolerance was the most common cause (nausea in 100% and vomiting in 30%). Previously, animal studies have shown that inhibition of TNFα with PTX in cirrhotic rats after common bile duct ligation can improve HPS[23,24].

Tanikella *et al*[25] selected nine adult patients with moderate to severe HPS. There was no significant difference in PaO_2 and alveolar-arterial oxygen gradient before and after PTX administration. High incidences of gastrointestinal adverse effects were the most important reason for intolerance. This resulted in a 44% attrition rate and only one patient (12%) could tolerate PTX for the complete treatment period of 8 wk.

Despite these results, Gupta *et al*[26] have demonstrated that 3 mo treatment with PTX can improve the symptoms and signs in about 90% of patients. There was also a significant increase in median supine, standing and postexercise PaO_2 ($P < 0.01$). Side effects were reported in a few patients (vomiting in three and dyspnea in two), but they did not require drug withdrawal.

In our study, among the four patients who could not

tolerate PTX, two had moderate, one had severe and one had very severe HPS. Also, three patients had Child score C and one had Child score B. The high incidence of intolerance in these patients was comparable with that of the Tanikella *et al*[25] study that was carried out in patients with moderate to severe HPS, and suggests that beginning PTX in the early stages of HPS may increase tolerability and effectiveness.

As far as we are aware, no study has determined the optimal dose of PTX in cirrhotic children. In animal studies, the dose of PTX used was 10-50 mg/kg per day[4,23,24]. PTX was used previously in children for treatment of Kawasaki disease as an antiplatelet drug with the same dose and no side effects were seen[27]. One potential explanation for this difference is significant first pass metabolism of PTX in the liver to an active metabolite, and consequently, serum levels are significantly high in liver dysfunction[28]. This problem does not occur in Kawasaki disease. Furthermore, finding the optimal dosage of PTX in liver dysfunction can be beneficial. In the present study, one patient experienced thrombocytopenia. Although thrombocytopenia is a manifestation of cirrhosis, decreased platelet count after administration of PTX, and increased platelet count after drug withdrawal denote the role of PTX. This implies that CBC is an important laboratory test during PTX administration. We did not observe any change in serum creatinine or liver function before and after therapy with pentoxifylline that may have contributed to changes in pentoxifylline metabolism.

To evaluate effects of PTX in HPS, we suggest double-blind studies, long-term treatment, and contrast echocardiography at the end of the treatment period for later studies. Meanwhile, it is necessary to evaluate optimal dose of PTX in cirrhotic children. In conclusion, it seems that PTX may have beneficial effects on oxygenation in early stages of HPS.

COMMENTS

Background

Hepatopulmonary syndrome (HPS) is a triad of liver disease, arterial hypoxemia and widespread pulmonary vascular dilatation. There is currently no effective medical therapy for HPS in spite of several recommended medications. Recently, pentoxifylline (PTX), a nonspecific phosphodiesterase-4 inhibitor, which blocks tumor necrosis factor α (TNFα) synthesis, has appeared to prevent HPS. The aim of this study was to evaluate the effect of PTX on clinical manifestations and arterial blood gas data in children with HPS.

Research frontiers

This study, possibly for the first time, reported therapeutic effects of PTX in children with HPS. The authors concluded that there were no significant differences in clinical manifestations and other laboratory tests after treatment. PTX may improve arterial oxygen tension, oxygen saturation and alveolar-arterial oxygen gradient in the early stage of HPS. Thus, it seems that PTX may have beneficial effects on oxygenation in early stages of HPS.

Innovations and breakthroughs

PTX, a nonspecific phosphodiesterase-4 inhibitor, blocks TNFα synthesis and seems to prevent HPS. The authors evaluated, perhaps for the first time, the therapeutic efficacy of PTX in children with HPS.

Applications

The authors concluded that PTX may have beneficial effects on oxygenation in early stages of HPS. However, the authors suggest further double blind studies with longer treatment periods and contrast echocardiography at the end of the treatment period until the effect of PTX in HPS are defined clearly. Also, the authors recommend evaluation of the optimal dose of PTX in cirrhotic children.

Peer review

This is a prospective study with a few patients. It is accepted with minor revisions.

Abstract

AIM: To investigate the association of the inducible nitric oxide synthetase (*iNOS*) C150T polymorphism with *Helicobacter pylori* (*H. pylori*) infection and gastric cancer (GC) risk in Iran.

METHODS: In order to determine whether there was a correlation between *iNOS* genotype and GC in Iran, we conducted a case-control study using samples from 329 individuals. For each sample, the C150T *iNOS* polymorphism was genotyped by polymerase chain reaction (PCR) and restriction digestion. Patients were grouped by cancer presence, demographic and behavior characteristics, and *H. pylori* infection status. Statistical tests were conducted to determine whether any behavioral factors or a particular *iNOS* genotype was associated with GC in the study population.

RESULTS: In this population, we found that smoking, hot beverage consumption, a familial history of GC and *H. pylori* infection status were significantly associated with GC development ($P = 0.015$, $P < 0.001$, $P = 0.0034$, and $P < 0.015$, respectively). The distribution of the C150T *iNOS* genotypes among the two study groups was not statistically significant alone, but was impacted by *H. pylori* infection status. When compared to the non-*H. pylori* infected group, cancer patients who had a heterozygous CT genotype and were also infected with *H. pylori* were 2.1 times more at risk of developing GC [odds ratio (OR) = 2.1, $P = 0.03$] while those with a homozygous TT genotype and infected with *H. pylori* were 5.0 times more at risk of developing GC (OR = 5.0, $P = 0.029$). In contrast, this association was not seen in patients in the control group.

CONCLUSION: A CT or TT polymorphism at position 150 in the *iNOS* gene significantly increases the risk of GC and may be a marker for GC susceptibility.

INTRODUCTION

Gastric cancer (GC) is a major cause of morbidity and mortality throughout the world; it is estimated that GC is responsible for over 700 000 deaths per year[1,2], which makes this disease one of the leading causes of cancer-related death worldwide[3]. One of the most prominent risk factors for development of GC is infection with the bacterium *Helicobacter pylori* (*H. pylori*). Indeed, since its discovery in the early 1980s, *H. pylori* has been recognized as the causative agent of two types of cancer, gastric adenocarcinoma and mucosa-associated lymphoid tissue lymphoma[4-8]. The tight association between infection with this pathogen and the development of GC led to the classification of *H. pylori* as a class I carcinogen[9]; it is currently the only bacterium so classified.

Although *H. pylori* infection is relatively common, only a small subset of infected individuals develop GC; some individuals colonized with *H. pylori* carry the organism their entire lives with no overt disease symptoms, while others develop severe disease. Furthermore, recent evidence has begun to suggest that *H. pylori* colonization may be beneficial in some individuals; studies indicate that *H. pylori* protects against the development of esophageal cancer, childhood asthma[10-12] and active tuberculosis[10]. These findings have led researchers to try to define risk factors associated with *H. pylori*-induced disease development. Indeed, years of study have shown that in *H. pylori*-infected individuals, disease development/carcinogenesis is a complex and multifactorial process that involves an intricate interplay between numerous factors; studies indicate that disease etiology is influenced by a combination of bacterial factors, host genetics, and environmental factors such as diet.

Numerous bacterial factors have been identified as being important for *H. pylori*-induced disease development. These include the toxins CagA[13,14] and VacA[15,16], the adhesions BabA[17] and SabA[18], and the outer membrane proteins HomA, HomB, and OipA[19-21]. These and other bacterial factors act in concert to alter host cell signaling pathways, induce epithelial cell proliferation, and disrupt the delicate balance that exists between the bacterium and the host immune system. However, although these bacterial factors play a key role in the development of gastric disease, they represent only one aspect of the story. Indeed, there is a large body of work that suggests environmental factors also affect the risk of GC development. Some of the more prominent environmental risk factors include smoking[22] and high levels of dietary salt intake[23-25].

Besides these exogenous factors, the host immune system also clearly plays a major role in the development of gastric disease. In response to infection with *H. pylori*, the localized gastric environment becomes pro-inflammatory *via* the expression of pro-inflammatory cytokines[26-28]. Because these host factors play an important role in generating and maintaining the pro-inflammatory environment, it is perhaps not surprising that specific mutations in the genes that encode these factors influence gastric disease development. For example, specific interleukin-1 (*IL-1*), *IL-8*, *IL-10*, and tumor necrosis factor-α gene polymorphisms are associated with an increased risk for GC[29,30]. While these cytokines play an important role in the development and maintenance of the pro-inflammatory environment in the gastric mucosa, there are clearly other host factors involved in the disease process.

Nitric oxide (NO) is a molecule that has multiple functions in the gastrointestinal tract. In addition to having anti-microbial properties and playing an active role in vasodilation[31], NO is also a component of the pro-inflammatory immune response that has been linked to carcinogenesis[32]. NO is synthesized from L-arginine by three distinct isoforms of the nitric oxide synthetase (NOS)[31]. Whereas 2 of the 3 isoforms (neuronal NOS and epithelial NOS) are constitutively expressed, the inducible isoform (iNOS) is primarily expressed in response to specific cytokines[31]. Furthermore, expression of iNOS is upregulated during *H. pylori* infection[33]. Several studies have shown a link between increased levels of iNOS and risk of GC development[34,35]. Since one of the end products of NO metabolism is reactive nitrogen species, it is hypothesized that higher levels of iNOS lead to more oxidative DNA damage, thus increasing the risk of cancer development[31]. Interestingly, a single amino acid substitution (Ser 608 Leu) in the iNOS reductase domain has been associated with an increased risk for GC in Asian populations[36,37]. This amino acid change is the result of a single polymorphism (C150T) in exon 16[36,37], which is believed to affect the activity of the iNOS enzyme[36].

Even though the number of GC cases has decreased in many countries in recent years, the incidence of GC in Northern Iran remains high[38]. Several provinces, including Manzadaran, Ardabil, Golestan, Semnan, and the metropolitan area of Tehran, have high rates of GC in both men and women[38]. The age-standardized incidence rate for GC in these areas has been reported as high as 49.1 in men, and 25.4 in women[38]. These incidence rates may be at least partially explained by the fact that a significant proportion of this population is colonized by *H. pylori*. Indeed, the *H. pylori* infection rate for Iranians aged 40 years and over can be as high as nearly 90%[39,40]. A similar prevalence was reported for the Babol city of Iran where the *H. pylori* infection rates are 78% for men and 82% for women[41]. In addition to high rates of *H.*

pylori infection, environmental factors such as consumption of red meat and dairy products, high salt intake, and consuming hot tea have been identified as important risk factors for GC in this region[2].

At present, virtually nothing is known concerning which host genetic factors may influence GC risk in this region. Herein, we describe an epidemiologic study in which we investigate the association of the *iNOS* C150T polymorphism with *H. pylori* infection and GC risk among men and women from the Mazandaran region of Iran. We found that in this population, individuals who are infected with *H. pylori* are at a significantly higher risk for development of GC if they also harbor a CT or TT *iNOS* genotype. To date, this report is the first study that links a host-genetic factor to GC risk in this population. Furthermore, it is the first study to investigate the importance of the *iNOS* polymorphism in a non-Asian population. *En masse*, our data indicated that the *iNOS* C150 allele may be a potential marker for susceptibility to *H. pylori*-mediated GC development in multiple populations.

MATERIALS AND METHODS

Study participants

This case-control study conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Medical Research Ethics Committee at the Mazandaran University of Medical Sciences. Written informed consent was obtained from each individual, and all study participants were given an explanation of the nature of the study prior to enrollment. Patients were enrolled in the study after seeking treatment at Touba Polyclinics or Imam Hospital between April 2008 and March 2011. Patients with GC were diagnosed by gastric endoscopy and cases were defined using the International Classification of Diseases for Oncology and Lauren criteria[42]. During the course of the study, 159 individuals with GC were enrolled. This group had a mean age of 61.32 ± 12.5 years and was composed of 75 female (approximately 47%) and 84 male (approximately 53%) patients. Patients with inflammatory diseases such as rheumatoid arthritis and/or malignancies other than gastric carcinoma were excluded from the study. Members of the control group were matched by age, sex, geographic location, and ethnic background. This group included 170 individuals with a mean age of 58.86 ± 14.2 years. Ninety-eight were male (approximately 58%) and 72 were female (approximately 42%). For this population, healthy controls who were 40 years of age or greater were recruited from the clinics after undergoing an annual medical screening that included a gastric endoscopy. Healthy controls who were less than 40 years of age were recruited after being referred to the clinic for routine laboratory testing. Demographic information, eating habits, and epidemiologic risk factors were provided by study participants during a face-to-face interview. Risk factors that were evaluated included cigarette smoking, drinking hot beverages, and consumption of salted fish and fast food. A person was considered a smoker if they reported smoking at least one cigarette per day for 12 or more months. Consumption of salted fish or fast food was defined as consuming either item one or more times a week for at least 6 mo. Criteria for drinking hot beverages were essentially as described previously[43]. Patients were considered to have a family history of GC if either of their parents currently had or had been diagnosed with GC in the past, or if any of their siblings had a history of the disease.

Inducible nitric oxide synthetase genotyping

In order to investigate *iNOS* gene polymorphisms, venous blood was collected from study participants and used to isolate genomic DNA by the salting-out method[44]. *iNOS* genotyping was performed using an amplicon-restriction fragment length polymorphism (ARFLP) essentially as previously described[37]. Briefly, for each individual a polymerase chain reaction (PCR) was performed using 2 pmol each of the iNOS-F (5'-TGTAAACCAACTTCCGTGGTG-3') and iNOS-R (5'-174 GTCTCTGCGGGTCTGAAG-3') primers, 200 mmol dNTPs, 10 mmol Tris-HCl, pH 8.3, 50 mmol KCl, 1.5 mmol $MgCl_2$, 0.25 U of Hot start Taq DNA polymerase (Fermentas, Italy) and 50 ng of genomic DNA template in a final reaction volume of 25 μL. Each reaction was denatured at 95 ℃ for 5 min followed by 35 cycles of denaturation at 94 ℃ for 60 s, annealing at 58.5 ℃ for 60 s, and extension at 72 ℃ for 40 s. A final extension at 72 ℃ for 5 min was added to ensure complete amplification. Restriction digests were performed by incubating 10 μL of PCR product with 2 U of TSP 509I enzyme (New England Biolabs, Ipswich, MA, United States) in a final volume of 15 μL for 15 h at 65 ℃. Digestion products were separated on a 1.5% SDS-polyacrylamide gel, and visualized after staining with ethidium bromide. Results of the ARFLP analysis allowed us to differentiate between the 3 possible genotypes: (1) digestion of PCR amplicons from homozygous (CC) individuals generated 2 DNA fragments of 113 bp and 175 bp; (2) digestion of amplicons from heterozygous individuals (CT) yielded 3 DNA fragments of 113 bp, 142 bp, and 175 bp; and (3) digestion of amplicons from homozygous (TT) individuals yielded 2 DNA fragments of 113 bp and 142 bp.

H. pylori detection

Infection with *H. pylori* was detected by culturing gastric tissue collected during endoscopy. Identification of clinically isolated *H. pylori* strains was confirmed by Gram stain and urease activity. Additionally, all patients were also tested for infection using an *H. pylori* specific IgG enzyme linked immunosorbent assay (ELISA) (Diagnostic Automation, CA, United States) and by urease breath test (Bahar, Afshan, Iran). Given the difficulties in culturing *H. pylori*, especially from cancerous tissue, individuals were classified as infected with *H. pylori* if they gave a positive result by ELISA.

Table 1 Patient demographics and risk behavior

	Gastric cancer n = 159 (%)	Control n = 170 (%)	P-value
Age (yr)	61.32 ± 12.5	58.86 ± 14.2	0.098
Sex (male/female)	84/75	98/72	0.367
Marital status			
Single	7 (4.4)	3 (1.8)	
Married	149 (93.7)	166 (97.6)	0.002
Divorced	3 (1.9)	1 (0.6)

Positive family history	34 (21.4)	16 (9.4)	0.0034

H. pylori: *Helicobacter pylori*.

Statistical analysis

Fisher's exact test was used to compare the different *iNOS* allele types, and the frequency of each *iNOS* genotype in the patient population(s) was assessed using a χ^2 test. The difference in age between the 2 study groups was evaluated using a two-tailed Student's *t*-test. Deviation from the Hardy-Weinberg equilibrium was evaluated using a χ^2 test. To evaluate the risk factor(s) in the study populations, unconditional logistic regression models were applied to odds ratios (ORs) and 95% confidence intervals (CIs). For all statistical tests, a P value of less than 0.05 was considered significant.

RESULTS

Demographics and epidemiology of the patient population

Complete epidemiologic and demographic information for the study population is given in Table 1. Across the 329 study participants, ages ranged from 28 years to 86 years. Within the control group the mean patient age was 58.9 ± 14.2 years, whereas within the cancer group the mean patient age was 62.1 ± 12.6 years. There was no significant difference between the ages of patients in the two groups (P = 0.098). The control group was comprised of 98 male and 72 female patients while the cancer group was comprised of 84 male and 75 female patients. There was no significant difference between the distribution of male and female study participants in either group (P = 0.367). Patients were categorized by marital status as single, married, or divorced. The cancer group consisted of 7 single, 149 married, and 3 divorced individuals. In contrast, the control group consisted of 3 single, 166 married, and a single divorced patient. The breakdown of marital status between the case and control groups was significant (P = 0.002). The study participants were also broken down into different groups based on occupation. Patients were considered either unemployed, employed, or worked as a housewife; those participants whose employment status did not fall into one of these 3 categories were grouped into a single category, which was named "other". In the GC group, 4 of the study members were unemployed, 24 were employed, 46 were housewives, and the remaining 85 were in the other classification. Within the control group, 1 participant was unemployed, 35 were employed, 74 were housewives, and 60 were included in the other category. The distribution of patient occupation among the case group and the control group was significantly different (P = 0.001).

Risk factors associated with GC

In addition to gathering demographic information about the study participants, we also analyzed behaviors that are known to be associated with increased GC risk. Of the 159 patients who were diagnosed with GC, 33 were smokers whereas only 22 of the healthy controls reported smoking. Since smoking is an established risk factor for development of GC, perhaps it is not surprising that the increased number of smokers in the cancer group was statistically significant (P = 0.015). Another established risk factor for GC is consumption of hot beverages; drinking hot tea is specifically associated with increased risk of esophageal cancer in Iran[43]. Seventy-six participants in the cancer group reported drinking hot beverages on a regular basis. This number was significantly different than the 38 control patients who regularly drank hot beverages (P < 0.0001). Although consuming high amounts of dietary salt has been linked to GC[23-25], we found no significant difference in the number of patients who regularly ate salted fish among the two groups. Similarly, we found no significant difference in the number of patients who consumed pickles among the groups. However, more of the healthy controls reported regularly eating fast food than did the participants who developed GC. In contrast to the other 2 food criteria, this difference was significant (P = 0.037).

Among the most widely recognized factors that are associated with GC risk are *H. pylori* infection and a family history of cancer. Among the control group, only 18 patients had a family history of GC. In contrast, 34 participants in the cancer group reported having a family history of GC (P = 0.003). As it is the most commonly associated risk factor for GC, we next compared the number of *H. pylori*-positive individuals in both of our study groups. In the cancer group, nearly 60% of the study participants tested positive for *H. pylori*. Compared to this relatively high infection rate, the percentage of healthy controls who tested *H. pylori*-positive (45%) was significantly less (P = 0.015).

Frequency and distribution of C150T inducible nitric oxide synthetase polymorphisms

Having established the relative risk factors of our population, we next sought to determine the distribution of the

Table 2 Allele and genotype frequency distribution of C150T polymorphism of the inducible nitric oxide synthetase gene in patients with gastric cancer and controls *n* (%)

iNOS C150T	Gastric cancer *n* = 159	Controls *n* = 170	Odds ratio	95%CI	*P*-value
CC	89 (56)	92 (54.1)	1.00[1]

possible C150T *iNOS* genotypes among the two study groups (Table 2). Patients were genotyped essentially as described[37]; as reported in Japanese populations[36], the distribution of these specific *iNOS* polymorphisms in the control and cancer patient groups fell within the Hardy-Weinberg Equilibrium ($P = 0.07$ and $P = 0.796$, respectively). Among the 159 members of the GC group, 89 were homozygous CC, 59 were heterozygous CT and 11 were homozygous TT. The distribution of allele types within this group was not significantly different when compared to the study control group, which contained 92 homozygous CC, 72 heterozygous CT, and 6 homozygous TT individuals. There was also no difference in the frequency of each individual allele (C or T) found within the two study populations or the frequency of mutant (either CT or TT) genotypes between the GC and control groups.

CT and TT inducible nitric oxide synthetase polymorphisms contribute to GC risk in H. pylori-infected individuals

Since there was no significant difference in the frequency or distribution of *iNOS* C150T alleles in our two patient populations, we next examined any potential epidemiological interaction between *H. pylori* infection and the particular *iNOS* C150T genotype within the 159 GC patients. As shown in Table 3, the number of GC patients who were infected with *H. pylori* ($n = 94$) was slightly higher than the number of patients who were *H. pylori*-negative ($n = 65$). Among the 94 individuals who were infected with *H. pylori*, 46.8% were homozygous CC, 42.6% were heterozygous CT, and the remaining 10.6% were homozygous TT. In contrast, the *H. pylori*-negative group consisted mostly of the homozygous CC genotype (67.7%), followed by the heterozygous CT genotype (29.2%) and the TT genotype (3.1%). When compared to the non-*H. pylori* infected group, GC patients who had a heterozygous CT genotype and were also infected with *H. pylori* were 2.1 times more at risk of developing GC (OR = 2.1, $P = 0.03$, χ^2 test). Similarly, having a homozygous TT genotype and being infected with *H. pylori* also led to an increased risk of developing GC; the risk associated with having the homozygous TT genotype was more than twice the risk associated with having only a single T allele (OR = 5.0). This association was also significant ($P = 0.029$, χ^2 test). Similarly, the presence of either mutant allele (CT or TT) increased the risk of GC nearly 2.5-fold (OR = 2.4, $P = 0.01$, χ^2 test). Taken together, these results indicate that for individuals who are infected with *H. pylori*, carrying either a CT or TT *iNOS* polymorphism at position 150 significantly increases the risk of developing GC. Importantly, unlike those patients within the GC group, there was no significant association between *iNOS* genotype, *H. pylori* infection and risk of developing GC in the control group (Table 3).

DISCUSSION

The study of *H. pylori*-induced disease is complicated by the fact that the etiology of disease appears to result from the intricate interplay between bacterial virulence factors, host genetics and environmental components. Moreover, an increasing body of literature indicates that colonization by *H. pylori* may even be beneficial to some hosts[10-12]. Because of these facts, there is a pressing need to develop new diagnostics that will clearly identify those individuals most at risk for development of the most severe form of *H. pylori*-induced disease-GC. To this end, numerous studies have looked at the role of virulence factors, environmental risk factors and host genetic polymorphisms in disease development. While these studies have shed an enormous amount of light on development of GC, it is becoming increasingly more evident that vari-

ous factors play different roles based on the population being studied[13-21,23-25,27-30]. Thus, there is a need for larger population-based studies to define the role of particular factors in the disease process. Despite the high prevalence of GC and *H. pylori* infection in Northern Iran, there have been relatively few studies that have examined specific risk factors associated with disease development in this population. Of those that have been conducted, one of the studies that investigated the high rate of cancer development in this region concluded that the classic *H. pylori* virulence factors were not a good predictor of disease outcome[45]. Furthermore, the authors went on to suggest that "...the association between strain virulence markers and disease in Iraq but not Iran suggests that other host and environmental factors may be more important in the disease-prone Iranian population"[45]. Given this suggestion and the deficit in our knowledge, we set out to examine the contribution of particular behavioral factors and genetic polymorphism in the *iNOS* gene to GC development in the Iranian population. Using a case-controlled study design we identified a significant association of several factors with an increased risk for GC. Among the behavioral factors that were important, smoking and consumption of hot beverages were both associated with development of GC. Both of these factors have been previously identified as risk factors for cancer in other populations[36,37]. However, our study is the first to link consumption of hot beverages with GC development in this particular region.

In addition to behavioral factors and similar to other previously reported risk factors[46], we found that a familial history of GC was significantly associated with increased risk of GC development in our study population (Table 1). Also similar to at least one other study in this region[2], we found that infection with the gastric pathogen *H. pylori* significantly increased the risk of developing GC. Finally, we found that carrying either a heterozygous (CT) allele or a homozygous (TT) allele at position 150 of exon 16 of the *iNOS* gene combined with *H. pylori* infection resulted in a significant increase in GC development.

In humans, NO is used as an important signaling molecule. However, in the presence of increased and/or sustained levels of this molecule, the beneficial effects of NO can be overcome by deleterious processes such as DNA damage and chronic inflammation. These pathologic events may be catalyzed by increased iNOS activity, which leads to increased NO production and concomitant increases in the amount of downstream free radicals. As the major source of NO in humans, perhaps it is not surprising that even minor amino acid changes in the iNOS enzyme can affect the levels of NO. The (C150T) polymorphism found in exon 16 of the *iNOS* gene was previously suggested to affect activity of this enzyme, leading to increased production of NO[36]. Interestingly, in our or other populations[36,37], the *iNOS* polymorphism alone was not a risk factor for cancer development. This fact suggests that while the C150T polymorphism may affect NO production, it does not do so to such an extent as to induce cancer development in isolation. Instead, a co-carcinogenic factor is required to synergistically interact in such a way as to promote disease progression. Within the population of Northern Iran, this co-carcinogenic factor appears to be *H. pylori* infection (Table 3). A similar result was also found within the Japanese population[36]. Alternatively, the *iNOS* polymorphism was suggested to act as a co-carcinogenic factor with past cigarette smoking and alcohol consumption within the Chinese population[37]. Thus, in multiple populations, iNOS polymorphism synergistically interacts with various factors to affect GC development.

While the molecular mechanism of synergistic interaction between the *iNOS* polymorphism and *H. pylori* infection is not clear, one plausible hypothesis is that since *H. pylori* infection alone is sufficient to increase NO levels in gastric tissue[47,48], the addition of a polymorphism that also increases iNOS enzyme activity could increase the amount of NO in the local tissue to a further degree. In turn, this combined increase in NO could skew the gastric mucosa toward a pro-inflammatory response and increase the likelihood of carcinogenic cellular damage. It is interesting to note that *H. pylori* infection alone creates a chronic pro-inflammatory environment within the gastric mucosa. Furthermore, it has been well documented that the ability of *H. pylori* to establish a persistent infection depends on maintenance of the proper balance between the host immune system and the bacterium (reviewed in[49]). In patients with either the CT or TT *iNOS* polymorphisms, the increased levels of NO may upset this delicate balance, thus perpetuating pathological and carcinogenic events.

H. pylori-mediated cancer development is a complex and multi-faceted process that involves a combination of bacterial, host, and environmental factors. Moreover, infection with *H. pylori* is inversely correlated with development of esophageal cancer[12], and is thought to provide protection against development of autoimmune disorders such as asthma[11]. Thus, the apparent benefit(s) of asymptomatically harboring this organism brings to bear the question of whether it is best to treat all patients for *H. pylori* infection; if not, the question becomes-how do we identify individuals most at risk for developing serious disease? One possible way to differentiate patients who have a high risk for disease development from those who are low-risk is to specifically examine bacterial, host-genetic and environmental factors that have been shown to be associated with cancer development in *H. pylori*-infected individuals. By screening individual patients for these three types of markers, it may be possible to specifically identify and treat those individuals who are at most risk for developing severe disease while reducing the risk of losing the apparent protective effects of *H. pylori* infection in low-risk individuals.

COMMENTS

Background

As gastric cancer (GC) remains a serious source of morbidity and mortality worldwide, the identification of individuals most at risk for disease development is a major concern.

Research frontiers

Recent studies have highlighted the importance of polymorphisms in host genes as a risk factor for GC development. However, as many of these studies have been performed on limited patient populations, it remains unclear whether these polymorphisms are important across diverse ethnic groups and geographic areas. In this study, the authors identified an increase in GC risk in *Helicobacter pylori* (*H. pylori*)-infected Iranian patients who harbored a CT or TT polymorphism at position 150 in the inducible nitric oxide synthetase (*iNOS*) gene.

Innovations and breakthroughs

To the best of our knowledge, this study describes the first known link between a host-genetic factor and GC risk in an Iranian population. In addition, this study is the first to define the importance of the *iNOS* C150T polymorphism in a non-Asian population.

Applications

The results of this study suggest that the C150T *iNOS* polymorphism is a potential marker for susceptibility to *H. pylori*-mediated gastric disease.

Peer review

This is a study aimed at investigating the association of the *iNOS* C150T polymorphism with *H. pylori* infection and GC risk among patients from a region of Iran. The authors present an interesting study from a region that has not been addressed very often in regard to *H. pylori* and its related pathologies.

Abstract

AIM: To investigate the role of bone marrow-derived endothelial progenitor cells (EPCs) in the angiogenesis of hepatocellular carcinoma (HCC).

METHODS: The bone marrow of HCC mice was reconstructed by transplanting green fluorescent protein (GFP) + bone marrow cells. The concentration of circulating EPCs was determined by colony-forming assays and fluorescence-activated cell sorting. Serum and tissue levels of vascular endothelial growth factor (VEGF) and colony-stimulating factor (CSF) were quantified by enzyme-linked immunosorbent assay. The distribution of EPCs in tumor and tumor-free tissues was detected by immunohistochemistry and real-time polymerase chain reaction. The incorporation of EPCs into hepatic vessels was examined by immunofluorescence and immunohistochemistry. The proportion of EPCs in vessels was then calculated.

RESULTS: The HCC model was successful established. The flow cytometry analysis showed the mean percentage of CD133CD34 and CD133VEGFR2 double positive cells in HCC mice was 0.45% ± 0.16% and 0.20% ± 0.09% respectively. These values are much higher than in the sham-operation group (0.11% ± 0.13%, 0.05% ± 0.11%, n = 9) at 14 d after modeling. At 21 d, the mean percentage of circulating CD133CD34 and CD133VEGFR2 cells is 0.23% ± 0.19%, 0.25% ± 0.15% in HCC model *vs* 0.05% ± 0.04%, 0.12% ± 0.11% in control. Compared to the transient increase observed in controls, the higher level of circulating EPCs were induced by HCC. In addition, the level of serum VEGF and CSF increased gradually in HCC, reaching its peak 14 d after modeling, then slowly decreased. Consecutive sections stained for the CD133 and CD34 antigens showed that the CD133+ and CD34+ VEGFR2 cells were mostly recruited to HCC tissue and concentrated in tumor microvessels. Under fluorescence microscopy, the bone-marrow (BM)-derived cells labeled with GFP were concentrated in the same area. The relative levels of *CD133* and *CD34* gene expression were elevated in tumors, around 5.0 and 3.8 times that of the tumor free area. In frozen liver sections from HCC mice, cells co-expressing CD133 and VEGFR2 were identified by immunohistochemical staining using anti-CD133 and VEGFR2 antibodies. In tumor tissue, the double-positive cells were incorporated into vessel walls. In immunofluorescent staining. These CD31 and GFP double positive cells are direct evidence that tumor vascular endothelial cells (VECs) come partly from BM-derived EPCs. The proportion of GFP CD31 double positive VECs (out of all VECs) on day 21 was around 35.3% ± 21.2%. This is much higher than the value recorded on day 7 group (17.1% ± 8.9%). The expression of

intercellular adhesion molecule 1, vascular adhesion molecule 1, and VEGF was higher in tumor areas than in tumor-free tissues.

CONCLUSION: Mobilized EPCs were found to participate in tumor vasculogenesis of HCC. Inhibiting EPC mobilization or recruitment to tumor tissue may be an efficient strategy for treating HCC.

Endothelial precursor cells promote angiogenesis in hepatocellular carcinoma. *World J Gastroenterol* 2012; 18(35): 4925-4933 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i35/4925.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i35.4925

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most vascular solid tumors, and neovascularization plays an important role in HCC development. In HCC, neovascularization status is correlated with disease progression and patient prognosis. Endothelial progenitor cells (EPCs) have been proved to be the main source of adult neovascularization. Until now, there has not been any data regarding the role of EPCs in HCC neovascularization. This study is the first to prove that EPCs incorporate into vessels directly and play an important role in HCC neovascularization.

It has been confirmed that neovascularization is vital to further multiplication, metastasis, and recurrence in malignant tumors. Without exogenous blood vessels, tumors stop growing and enter a state of suspended animation at about 2-3 cubic millimeters. The acquisition of angiogenic capacity is considered a sign of tumor development and of metastasis[1].

Recently, increasing amounts of data have revealed that bone-marrow (BM)-derived EPCs can foster the initiation and maintenance of angiogenic processes by integrating into developing vasculature under hypoxic conditions and into tumors. In 1997, EPCs were first isolated using anti-CD34 monoclonal antibodies. CD34-antigen, however, could not distinguish immature EPCs from mature circulating endothelial cells (CECs) because CD34 is expressed on both. With the discovery of CD133, an antigen restricted to immature EPCs, distinguishing between EPC and CECs has become easier[2]. VEFGR2 is another marker of EPCs. VEFGR2 signaling causes EPCs to differentiate. EPCs resemble embryonic angioblasts, which characteristically migrate, proliferate, and differentiate into mature endothelial cells[3]. In general, EPCs can be identified as cells that simultaneously express the cell surface markers CD133, CD34, and VEGFR2[4,5]. Santarelli *et al*[6] used mouse tumor models to demonstrate that BM-derived EPCs are greatly mobilized into the bloodstream, and home specifically to tumor tissues. In the tumor microenvironment, the recruited EPCs merged with the walls of a growing blood vessel, where they differentiated into endothelial cells and so promoted tumor growth. It has been reported that, during cancer proliferation, the number of circulating BM-derived progenitor cells increases dramatically. Circulating BM-derived EPCs have been used to determine the optimal dose of anti-angiogenic drugs, most successfully in breast cancer[7]. In addition, Taylor proved that high levels of circulating BM-derived progenitor cells are correlated with tumor metastatic status. Recently, the contribution of EPCs to tumor angiogenesis has also been reported in clinical tumor samples from 6 patients who received bone marrow transplants from donors of the opposite sex. The endothelial cells within the tumor vessels were of donor origin, as shown by the mismatched sex chromosomes[8].

At present, the significance of circulating EPCs and the contribution of EPCs to tumor vessels have been confirmed in only a few solid malignancies, such as malignant glioma[6], lung cancer[9], and mammal tumors[10]. However, the extent to which EPCs contribute to the generation of the tumor vessels varies significantly across different studies, from substantial to zero[11,12]. The role of EPCs in neovascularization has been the subject of great debate.

Tumor microvessel density is closely related to tumor growth, invasion, and metastasis and to patient prognosis[13,14]. It has been confirmed that the formation of new capillaries is essential to tumor development, and the status of angiogenesis is an important prognostic indicator in hepatocellular carcinoma[15,16]. There are only three papers in PUBMED, including our previous study[17], that compare the circulating EPC levels of HCC patients to those of healthy controls or those of liver cirrhosis patients[18,19]. We established an orthotropic hepatic cancer model, observed the dynamic changes of circulating EPCs, and determined whether BM-derived EPCs contributed to tumor vessels directly. We also calculated the incorporation rate of the EPCs in vessels. All this information is extremely important to evaluating the role of EPCs in neovascularization in HCC.

MATERIALS AND METHODS

Orthotropic hepatic cancer mouse model

For BM reconstruction, C57BL/6 male mice aged 8-10 wk were lethally irradiated (10 Gy) and transplanted with BM cells collected from green fluorescent protein (GFP)-C57BL/6 transgenic mice[6]. Four weeks later, the HCC

model showed a GFP positive rate of circulating nucleated cells of over 90%, suggesting full BM recovery. The mice were then used to construct an orthotropic hepatic cancer mice model by intra-hepatic injection of 1×10^5-2×10^5 H22 hepatoma cells (given to us by Dr. Ru-Tian Li of the Nanjing University Institute of Oncology, China). Sterile extract H22 hepatoma cells, normal saline to adjust the number of cancer cells to 106/mL for use. Intraperitoneal injection of sodium pentobarbital anesthesia C57BL/6 mice, disinfection shop towel, in the middle upper abdomen about the xiphoid mainly as a 1 cm incision into the abdominal cavity. Gently press out part of the lobe with bilateral costal arch, wet gauze pad in the bottom lobe to protect, and then with 1 mL medical syringe needles inserted along the long axis of lobe about 0.5 cm, the slow injection of H22 hepatoma cells 0.1 mL (cell number 1×10^5-2×10^5). Pull out the needle at the same time, rapidly at the pressure in the eye of a needle, and gently press on it with a cotton for 1 min to stop bleeding. Carefully place the liver back into the abdominal cavity. The control group received same volume of phosphate buffered solution (PBS). All mice were from the national genetically engineered mouse resource bank of China.

Degree of hepatocellular carcinoma mobilization

Flow cytometry (FCM) was used to evaluate the degree of EPC mobilization. Three hundred microliters of peripheral blood was obtained from the retroorbital plexus at 3 d, 7 d, 14 d, and 21 d after the establishment of the orthotropic HCC model. Erythrocytes were split by red blood cell lysis buffer. Mononuclear cells were incubated for 30 min at 4 ℃ with Alexa Fluor488 conjugated anti-CD133, Alexa Fluor647 conjugated anti-CD34, PE-conjugated anti-VEGFR2 (eBioscience, United States). Appropriate fluorochrome-conjugated isotypes were used as controls. In addition, serum concentration of vascular endothelial growth factor (VEGF), platelet-derived growth factor [colony-stimulating factor (CSF)] was tested by enzyme-linked immunosorbent assay kit (ADL, United States) following the collection of serum at the same times.

Identification of BM-derived CD133+CD34+VEGR2+ cells in tissue

Liver tissue was obtained from the GFP labeled BM-HCC model on day 14. After paraformaldehyde perfusion and gradient dehydration, consecutive frozen liver tissue sections 2 μm in thickness were cut in a cryostat, fixed, blocked, and incubated at 4 ℃ overnight with primary antibody rabbit anti-mouse CD133 (1:200), VEGFR2 (1:100, Abcam, United States), rat anti-mouse CD34 (1:250, ebioscience, United States) respectively. Secondary antibody was horseradish peroxidase. Positive reactions were visualized with diaminobenzidine solution followed by counterstaining with hematoxylin. Negative controls were obtained by substituting the primary antibodies with PBS.

Contribution of BM derived EPCs to vessels

Consecutive 2 μm frozen liver tissue sections were cut as stated above. Sections were blocked and then incubated overnight with rat anti-mouse CD31(1:800, eBiosicence, United States). After washing in PBS, slices were incubated with secondary antibodies Alexa Fluor 488-conjugated rabbit anti-rat IgG antibody (1:1000, molecular probes). 4',6'-diamidino-2-phenylindole hydrochloride was used to dry the nucleus. Normal mice given PBS-substituted for antibodies as a negative control. Double-labeled immunofluorescence staining sections were evaluated using fluorescence microscopy.

Proportion of EPCs in vessels

Mouse livers were obtained at 7 d or 21 d after the establishment of the GFP-BM HCC model. Two-microliter frozen anti-CD31 immunofluorescence staining sections were created as stated above. Specimens were analyzed microscopically by two independent observers who counted the number of BM-derived vascular ECs (VECs) co-expressing GFP, CD31, and total VECs in 15 random high-power fields. The quantitative contribution of EPCs to total VECs is expressed as percentages[20].

Expression of intercellular adhesion molecule 1, vascular adhesion molecule 1, and VEGF protein in tissue

Liver tissue was obtained from the GFP-labeled BM-HCC model on day 14. Conventionally processed and embedded sections cut at a thickness of 3 μm were deparaffinized, blocked, and incubated at 4 ℃ overnight with primary antibody: rabbit anti-mouse intercellular adhesion molecule 1 (ICAM1) (1:50, Protein Tech Group, United States), vascular adhesion molecule 1 (VCAM1) (1:200 Santa Cruz Biotech, Santa Cruz, CA, United States), VEGF (1:1000 Abcam, City, State, United States). The secondary antibody was horseradish peroxidase. Positive reactions were visualized with diaminobenzidine solution followed by counterstaining with hematoxylin. Negative controls were obtained by substituting the primary antibodies with PBS.

Levels of CD133 and CD34 genes in tissue

The levels of actin and CD133 mRNAs in the tumor and tumor-free areas were measured by real-time quantitative polymerase chain reaction (PCR). RNA was extracted from the livers with Trizol (Invitrogen, United States). cDNA was generated using Takara Primer ScriptTM 1st stand cDNA synthesis kits (JP). The sequences of primers were designed and synthesized by Takara. Primers for CD133 (5'-AACGTGGTCCAGCCGAATG-3', 5'-TCCCAGGATGGCGCAGATA-3'), CD34 (5'-ACCCACCGAGCCATATGCTTAC-3', 5'-GATACCCTGGGCCAACCTCA-3'), β-actin (5'-CAT CCG TAA AGA CCT CTA TGC CAA C-3', 5'-ATG GAG CCA CCG ATC CAC A-3'). The PCR reactions were performed in the light of instruction of SYBR Premix Ex TaqTM Kit (Takara, Japan) using the Stratagene

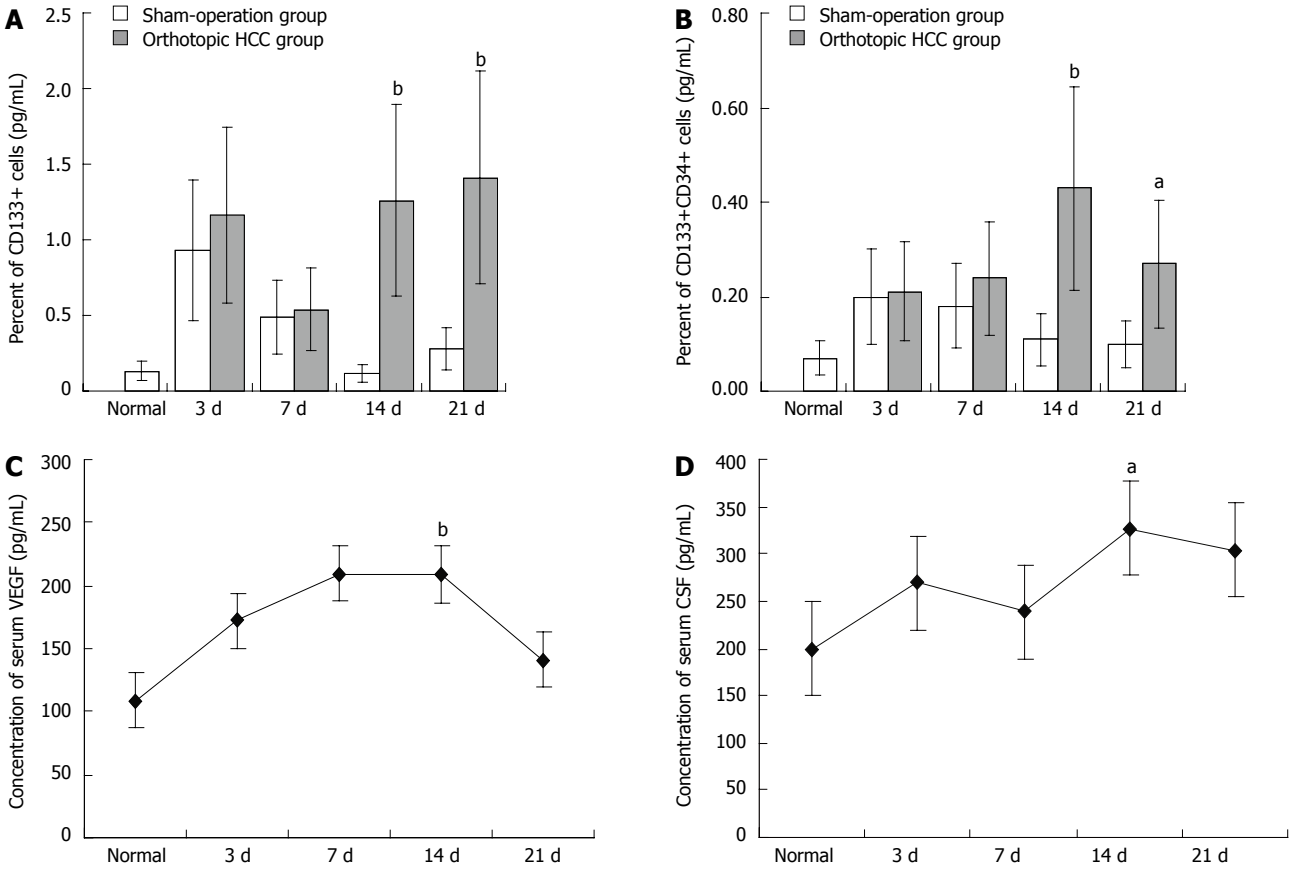

Figure 1 Mobilization of endothelial progenitor cells into circulation. A, B: Flow cytometry analysis of circulating endothelial progenitor cells in hepatocellular carcinoma (HCC) mice (day 14, $n = 7$; day 21, $n = 9$) *vs* sham-operation group (day 14, $n = 9$; day 21, $n = 11$). Normal = normal mice; C, D: Dynamic changes in serum levels of vascular endothelial growth factor and colony-stimulating factor in HCC mice ($n = 8$). $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* normal control ($n = 8$). CSF: Colony-stimulating factor; VEGF: Vascular endothelial growth factor.

Mx3000P QPCR System (Bioscience Corporation). Each sample was measured in duplicate. The relative level of expression was determined by DDCt normalized to endogenous control (β-actin).

Statistical analysis

Statistical comparisons were performed using the *t*-test and analysis of variance when data were normally distributed or with separate variance estimation *t*-test or rank sum test. All statistical procedures were performed using SPSS 15.0. All data are presented as mean ± SD. Values of $P < 0.05$ were considered statistically significant.

RESULTS

Establishment of BM orthotopic hepatocellular carcinoma model

The successful establishment of the HCC model was confirmed by a pathological exam confirming classic clinicopathological characteristics of HCC, intratumor hemorrhage, intrahepatic metastasis, and tumor neovascularization.

Mobilization of EPCs into circulation

The FCM analysis showed the mean percentage of circulating CD133CD34 and CD133VEGFR2 double positive cells in HCC mice to be 0.45% ± 0.16% and 0.20% ± 0.09% ($n = 7$), respectively. These values are much higher than in the sham-operation group (0.11% ± 0.13%, 0.05% ± 0.11%, $n = 9$) at 14 d after modeling. At 21 d, the mean percentage of circulating CD133CD34 and CD133VEGFR2 cells is 0.23% ± 0.19%, 0.25% ± 0.15% in HCC model *vs* 0.05% ± 0.04%, 0.12% ± 0.11% in control. The mobilization of BM cells may have been a response to the operation. Compared to the transient increase observed in controls, the higher level of circulating EPCs were induced by HCC (Figure 1A, B). In addition, the level of serum VEGF and CSF increased gradually in HCC, reaching its peak 14 d after modeling, then slowly decreased (Figure 1C, D).

Recruitment of EPCs to hepatocellular carcinoma tissue

Consecutive sections stained for the CD133 and CD34 antigens showed that the CD133+ and CD34+ VEGFR2 cells were mostly recruited to HCC tissue and concentrated in tumor microvessels (Figure 2A). Under fluorescence microscopy, the BM-derived cells labeled with GFP were concentrated in the same area (Figure 2B). The relative levels of CD133 and CD34 gene expression were elevated in tumors, around 5.0 and 3.8 times that of the tumor free area (Figure 2C, D). As determined by protein and gene expression levels, EPCs in HCC mice were recruited to tumors and tumor microvessels. The results of each three trials were largely consistent with each other.

A: Distribution endothelial progenitor cells (EPCs) in tumor and tumor-free tissue in four consecutive 2 μm sections (arrows: Cells expressing the indicated antigens and recruited to tumors and tumor vessels); B: Bone-marrow cells labeled by green fluorescent protein recruited to tumors and tumor vessels, occupying the same position as antigen positive cells [blue regions: Nuclei stained by DAPI (frozen section, 2 μm, magnification 200)]; C: Relative levels of CD133 mRNA in tumor tissue (n = 7) and tumor-free tissue (n = 6); D: Relative level of CD34 mRNA in tumor tissue (n = 7) and tumor-free tissue (n = 7). TFT: Tumor-free tissues; TT: Tumor tissues; DAPI: 4',6'-diamidino-2-phenylindole hydrochloride; GFP: Green fluorescent protein.

Contribution of BM-derived EPCs to tumor blood vessels

In frozen liver sections from HCC mice, cells co-expressing CD133 and VEGFR2 were identified by immunohistochemical staining using anti-CD133 and VEGFR2 antibodies. In tumor tissue, the double-positive cells were incorporated into vessel walls (Figure 3C). In immunofluorescent staining, an antigen specific to mature endothelial cells CD31[21] was used to identify VECs. The image data show that cells co-expressing CD31 and GFP existed not only in sinusoid endothelial cells (Figure 3A) but also in hepatic veins (Figure 3B). These CD31 and GFP double positive cells are direct evidence that tumor VECs come partly from BM-derived EPCs. The proportion of GFP CD31 double positive VECs (out of all VECs) on day 21 was around 35.3% ± 21.2%. This is much higher than the value recorded on day 7 group (17.1% ± 8.9%) (Figure 3D).

Expression of ICAM1, VCAM1, and VEGF in tumor tissue

For further understanding the mechanism by which BM-derived EPCs home to tumors, we detected the expres-

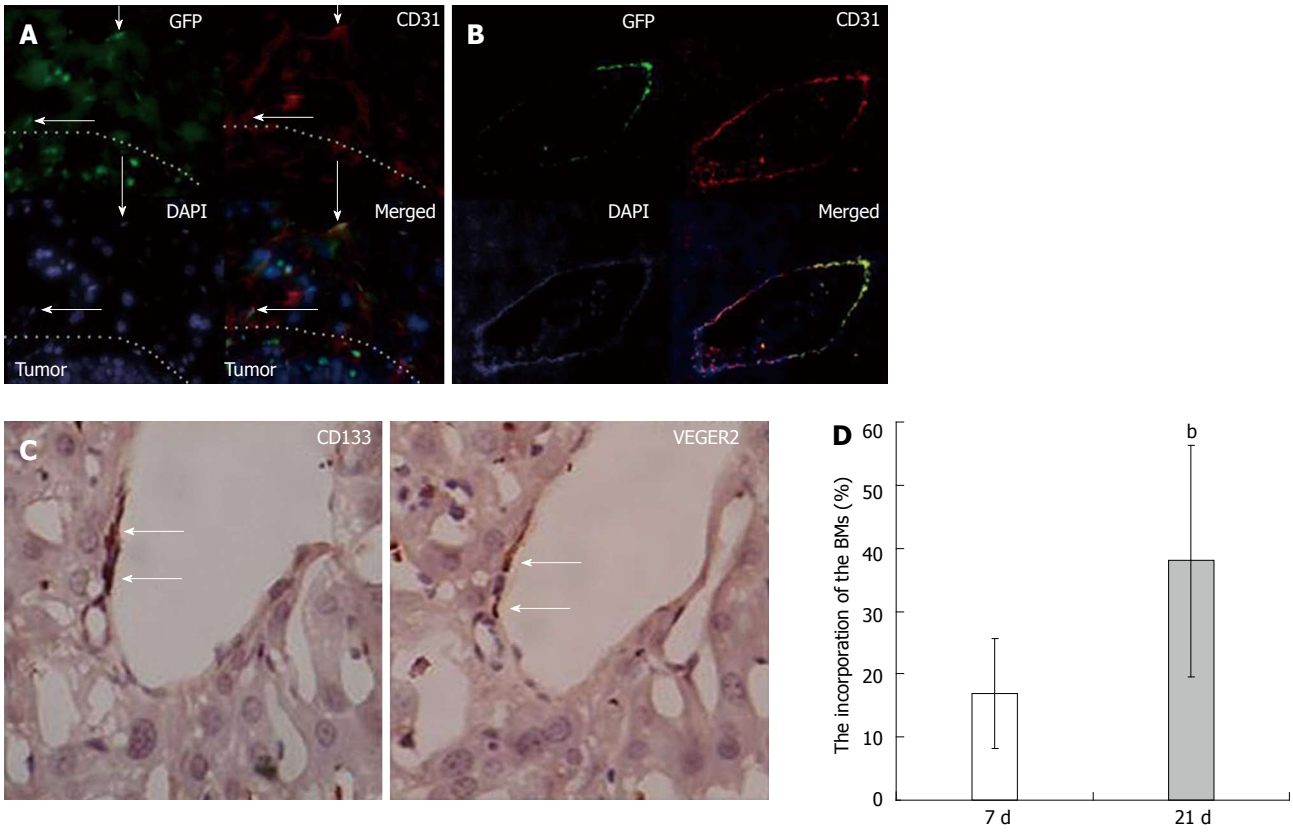

Figure 3 Bone-marrow-derived endothelial progenitor cells were found to contribute to vessel formation in hepatocellular carcinoma tissues. A: Bone marrow derived endothelial progenitor cells (EPCs) incorporated into peritumoral vessels; B: Distribution of CD133 and VEGFR2 antigens in hepatocellular carcinoma (HCC) liver vessels (Arrows: Double-positive cells, CD133+ VEGFR2+ cells incorporating into microvessels in the liver. Magnification, 400); C: Bone-marrow (BM)-derived EPCs incorporated into hepatic veins [Red: Mature vascular endothelial cells (VECs) are marked by CD31; Green: BM derived cells expressing green fluorescent protein (GFP); Blue: Nuclei stained by DAPI; Arrows: VECs co-expressing GFP and CD31, frozen, HCC, 2 μm, magnification 400]; D: The incorporation rate of the EPCs in HCC blood vessels at 7 d *vs* that observed at 21 d. $^{b}P < 0.01$ *vs* that observed at 21 d, $n = 15$. DAPI: 4',6'-diamidino-2-phenylindole hydrochloride.

sion of ICAM1, VCAM1, and VEGF in tumor tissues and tumor-free areas using immunohistochemistry. The results showed that the expression of ICAM1, VCAM1, and VEGF was higher in tumor areas than in tumor-free tissues (Figure 4).

DISCUSSION

Enhanced neovascularization is the most obvious clinicopathological characteristic of HCC, and tumor microvascular density is closely related to HCC progression and patient prognosis[2,22]. Although studies in some tumor models have shown that EPCs are mobilized into peripheral blood and contribute to tumor vascularization, to date, only Hong Kong University, our hepatic cancer institute, and the Medical University of Vienna have successively demonstrated that levels of circulating EPCs increase significantly and are correlated to clinical outcome in patients with HCC. The role of EPCs in HCC neovascularization is not currently clear. Based on our previous clinical findings[17,23], we established an orthotopic HCC model and used GFP as tracer to evaluate the role of EPCs in HCC-related angiogenesis[24,25]. According to PUBMED search, this is the first article to show direct visual evidence proving that EPCs promote angiogenesis by differentiating into vascular endothelia cells in HCC.

Thus far, the clinical significance of circulating EPCs has been confirmed in only a few solid malignancies, such as neurospongioma[25], hepatic cancer[17-19], breast cancer[26,27] and ovarian cancer[28]. Levels of circulating BM-derived stem cells have been used to determine the optimal dose of anti-angiogenic drugs, most successfully in breast cancer patients[7]. In the current investigation, which, unlike our previous clinical study, does not involve any interference from cirrhosis, it is much clearer that the mobilization of EPCs and the up-regulation of the BM-mobilization-related factors VEGF and CSF are the results of the development of HCC (Figure 1). Though wounds and injuries also can mobilize EPCs into the blood[29], the controls in this study showed only transient increases in, VEGF and CSF, and levels of circulating EPCs remained relatively low[30]. In terminal stage of the tumor, the decline in levels of serum cytokines and circulating EPCs may be the result of a disordered environment and systemic failure.

Characterization of EPCs, proof-of-principle strategies design to study the importance of vasculogenesis in tumors are current impediments. CD34-antigen could not distinguish immature EPCs from mature CECs. Recently, scientists discovered an antigen restricted to immature

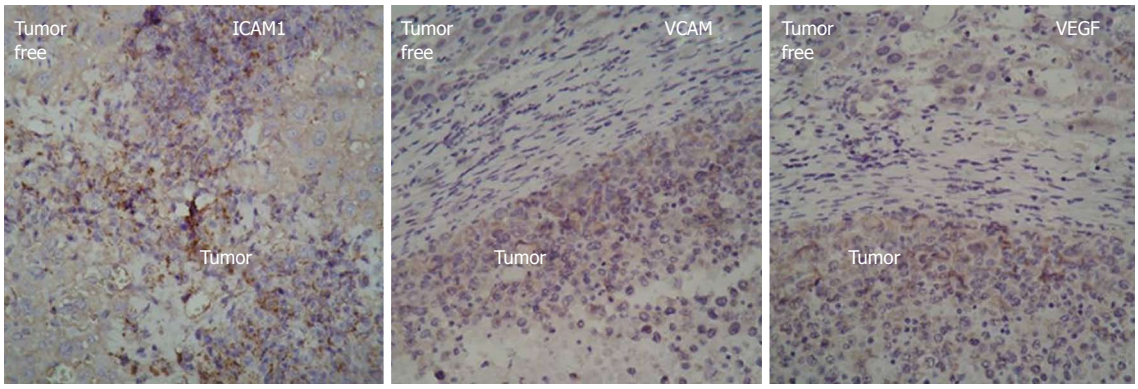

Figure 4 Expression of intercellular adhesion molecule 1, vascular adhesion molecule 1, and vascular endothelial growth factor in tumor tissues and tumor-free tissues as detected by immunohistochemistry (paraffin, liver, 2 μm, magnification, 200).

EPCs named CD133 which can distinguish between EPC and CECs. VEFGR2 is another marker of EPCs. VEFGR2 signaling causes EPCs to differentiate. EPCs resemble embryonic angioblasts, which characteristically migrate, proliferate, and differentiate into mature endothelial cells. Generally, EPCs can be identified as cells that simultaneously express the cell surface markers CD133, CD34, and VEGFR2.

In this study, we used GFP as a tracer because that tumor growth is accompanied by the formation of tumor blood vessels, we hypothesized that EPCs could home to liver tumors specifically. To test this hypothesis. The immunohistochemical image data of HCC tissue serial frozen sections showed many cells expressing EPC-specific antigens CD133, CD34, and VEGFR2, and these were concentrated in tumor tissues and tumor vessels (Figure 2A). Relative to tumor-free tissues, many BM-derived cells labeled by GFP specifically homed to tumor tissues and tumor vessels occupying the same positions as the CD133-, CD34-, and VEGFR2-positive cells (Figure 2B). This indicates that these antigen-positive cells come from bone marrow and co-express the specific antigens CD133, CD34, and VEGFR2. Real-time PCR analysis showed the levels of mRNA for stem cell markers CD133 and CD34 were around 5 and 3 times higher, respectively, than in tumor free tissues (Figure 2C). These results may be due to the fact that CD34 is expressed in both mature and immature cells, while CD133 is limited to immature cells (Figure 3B). EPCs' tropism for malignant tissues can also be observed in other cancer models, in which ICAM-1 is considered the main endothelial surface receptor responsible for recruitment of EPCs[31]. VEGF is believed to be the most important and essential mobilization factor in the induction of matrix metalloproteinase-9 (MMP-9) expression in bone marrow cells (BMCs). MMP-9, in turn, cleaves and activates the VEGF receptor of BMCs, permitting the transfer of BMCs and mobilizing EPCs into circulation[32]. In our HCC model, besides up-regulated VEGF, the levels of VEGF and ICAM1 in tumor tissue also increased significantly. This is consistent with our previously published clinical results[19]. From this, we can reasonably infer that, during tumor growth, HCC tissue releases mobilization factors, such as VEGF, into circulation. As the matrix degrades, BM-derived EPCs migrate into the liver through the bloodstream. Under the chemoattractive influence of locally high VEGF content VEGF and cellular adhesive molecules, the EPCs become come to rest in the hepatic tumor area.

Until now, the contribution of EPCs to blood vessel formation has been proved in only a few types of cancer, including malignant glioma[26] and Ewing's sarcoma[33,34]. We have identified and confirmed the clinical significance of mobilized EPCs in HCC[17]. Here, we directly prove that EPCs contribute to the formation of new HCC vessels not only in hepatic sinusoids (Figure 3A) but also in the veins of the liver (Figure 3C). Moreover, immunohistochemical image data has directly shown that cells co-expressing CD133 and VEGFR2 incorporate into live vessels (Figure 3D). This indicates that BM-derived EPCs stimulate tumor growth by promoting neovascularization. In addition, the incorporation rate of EPCs on day 21 was found to be much higher than on day 7. In this sense, the role of EPCs in neovascularization seem to become more important as HCC growth progresses (Figure 4C). Mature ECs have relatively limited proliferative capacity. In the current body of literature, the proportion of EPCs to VECs has been found to vary widely, from zero to more than 90%[11,12]. Other studies have concluded that EPCs do not contribute to the vascular endothelium and are not needed for tumor growth[35]. The fact that these studies used different tumor models may be the source of these different results.

Ever since 1971, anti-angiogenesis and anti-vascular treatments have emerged as a clinically promising anti-cancer strategy in HCC therapy. However, though anti-angiogenic therapies to HCC have been used clinically for a long time, the actual effect is not as satisfying as would be expected. Damaging tumor vasculature or blood embolization does lead to local metabolic disturbance, acidosis, hypoxia, and eventually to necrosis. This causes the release of soluble factor into the bloodstream by tumors directly and by the responding system indirectly. These soluble factors mobilize more EPCs into the blood and

promote the formation of new blood vessels to compensate for the lost blood supply. In fact, it has been found that tumor necrosis, hypoxia, and ischemia can all cause dramatic increases in serum levels of VEGF and in the number of EPCs in circulation EPCs[36-38]. These cells home to the vasculature of treated tumors and promote tumor neovascularization. In such cases, even if tumor vasculature is damaged and local angiogenesis is inhibited, BM-derived EPCs independently form the blood vessels necessary for tumor regrowth. The existence of compensatory cellular and molecular mechanisms inhibits the efficacy current targeted anti-angiogenic therapies. We suggest inhibiting the recruitment of circulating EPCs in concert with anti-vascular treatment. We have demonstrated previously that the number of circulating EPCs rises dramatically in patients with HCC. Now we further display that, during the course of HCC, large numbers of EPCs are mobilized and recruited to tumor areas, where they promote HCC angiogenesis by integrating directly into the tumor vessels directly. As HCC develops, the proportion of EPCs in vessels seems to rise gradually.

In view of current data, we have reason to believe that the BM is the important source of cells for neovascularization in HCC. We infer that blockage of EPC mobilization or recruitment to tumors may slow down hepatic cancer growth and improve the efficacy of therapies.

COMMENTS

Background

Neovascularization is the key process for tumor development, invasiveness and metastasis. It has been accepted that tumor-neovascularization raised in two ways, one is endothelial sprouting, another is bone marrow derived cells differentiating into mature vascular endothelial cells. Hepatocellular carcinoma (HCC) is one of the most vascular solid tumors, in which neovascularization plays an important role. The status of neovascularization in HCC correlates with the disease progression and patient's prognosis.

Research frontiers

At present, the significance of circulating endothelial progenitor cells (EPCs) and contribution of EPCs to tumor vessels have been confirmed only in a few solid malignancies, such as malignant glioma, lung caner and mammal tumor, however, the extent to which EPCs contribute to the generation of the tumor vessels is highly variable in different studies, from substantial to zero. So the role of EPCs on neovascularization has been argued a lot. Till now, there is no any data to evaluate the role of bone marrow cells (BMCs) in HCC neovascularization yet.

Innovations and breakthroughs

Ever since Professor Folkman put forward the dependence of tumor growth on angiogenesis in 1971, anti-angiogenesis or anti-vascular treatment has emerged as a clinically promising anti-cancer strategy in HCC therapies. However, though anti-angiogenic therapies to HCC such as chemotherapy and embolization have been in clinical application for a long time, the actual effect is not as satisfying as expected yet. It is well known HCC is a highly vascularized solid tumor. The authors have demonstrated that circulation BMCs/bone marrow-derived stem cells rise dramatically in patients with HCC previously in clinical cancer research, now the authors further display during the course of HCC, large number of BMCs was mobilized and recruited to tumor area, then promote HCC angiogenesis by integrating into tumor vessels directly.

Applications

The study results suggest that the BMCs play a prominent role in HCC neovascularization, and inhibiting EPC mobilization or recruitment to tumor tissue may be an efficient strategy for treating HCC.

Terminology

EPCs: Endothelial progenitor cells can differentiate into mature vascular endothelial cells for formation of new vessels (vasculogenesis).

Peer review

This is a good descriptive study to investigate the role of bone marrow-derived EPC in the angiogenesis of HCC. The results are interesting and suggest that mobilized EPCs were found to participate in tumor vasculogenesis of HCC and inhibiting EPC mobilization or recruitment to tumor tissue may be an efficient strategy for treating HCC.

Abstract

AIM: To investigate the correlation of hyperlipemia (HL) and acute cerebral ischemia/reperfusion (I/R) injury on liver damage and its mechanism.

METHODS: Rats were divided into 4 groups: control, HL, I/R and HL+I/R. After the induction of HL *via* a high-fat diet for 18 wk, middle cerebral artery occlusion was followed by 24 h of reperfusion to capture I/R. Serum alanine transaminase (ALT) and aspartate aminotransferase (AST) were analyzed as part of liver function tests and liver damage was further assessed by histological examination. Hepatocyte apoptosis was evaluated by terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) assay. The expression of genes related to apoptosis (caspase-3, bcl-2) was assayed by immunohistochemistry and Western blotting. Serum tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1) and liver mitochondrial superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), malondialdehyde (MDA) and Ca^{2+} levels were measured to determine inflammatory and oxidative/antioxidative status respectively. Microsomal hydroxylase activity of the cytochrome P450 2E1 (CYP2E1)-containing enzyme was measured with aniline as the substrate, and CYP2E1 expression in the liver tissue and microsome was determined by immunohistochemistry and Western blotting respectively.

RESULTS: HL alone induced by high-fat diet for 18 wk resulted in liver damage, indicated by histopathological analysis, and a considerable increase in serum ALT (25.13 ± 16.90 *vs* 9.56 ± 1.99, $P < 0.01$) and AST levels (18.01 ± 10.00 *vs* 11.33 ± 4.17, $P < 0.05$) compared with control. Moreover, HL alone induced hepatocyte apoptosis, which was determined by increased TUNEL-positive cells (4.47 ± 0.45 *vs* 1.5 ± 0.22, $P < 0.01$), higher caspase-3 and lower bcl-2 expression. Interestingly, compared with those in control, HL or I/R groups, massive increases of serum ALT (93.62 ± 24.00 *vs* 9.56 ± 1.99, 25.13 ± 16.90 or 12.93 ± 6.14, $P < 0.01$) and AST (82.32 ± 26.92 *vs* 11.33 ± 4.17, 18.01 ± 10.00 or 14.00 ± 6.19, $P < 0.01$) levels in HL+I/R group were observed suggesting severe liver damage, which was confirmed by liver histology. In addition, HL combined with I/R also caused significantly increased hepatocyte apoptosis, as evidenced by increased TUNEL-positive cells (6.20 ± 0.29 *vs* 1.5 ± 0.22, 4.47 ± 0.45 or 1.97 ± 0.47, $P < 0.01$), elevated expression of caspase-3 and lower expression of bcl-2. Furthermore, when compared to HL or I/R alone, HL plus I/R enhanced serum TNF-α, IL-1, liver mitochondrial MDA and Ca^{2+} levels, suppressed SOD and GSH-Px in liver mitochondria, and markedly up-regulated the activity (11.76 ± 2.36 *vs* 4.77 ± 2.31 or 3.11 ± 1.35, $P < 0.01$) and expression (3.24 ± 0.38 *vs* 1.98 ± 0.88 or 1.72 ± 0.58, $P < 0.01$) of CYP2E1 in liver.

CONCLUSION: The coexistence of HL and acute cerebral I/R induces severe liver damage, suggesting that cerebral ischemic stroke would exaggerate the damage of liver caused by HL. This effect is possibly due to en-

hanced CYP2E1 induction which further promotes oxidative damage, inflammation and hepatocyte apoptosis.

Coexistence of hyperlipidemia and acute cerebral ischemia/reperfusion induces severe liver damage in a rat model. *World J Gastroenterol* 2012; 18(35): 4934-4943 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i35/4934.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i35.4934

INTRODUCTION

The history of hyperlipidemia (HL), an increasing public health problem, is positively associated with acute cerebrovascular diseases (ACD) such as ischemic stroke[1]. Although HL *per se* is not a direct predictor of ACD, the condition with high plasma levels of inflammatory-sensitive proteins associated with HL links to the increased incidence of stroke[2]. Positive correlations between excess lipid levels and the promotion of inflammation have been documented[2]. Moreover, it has been widely accepted that oxidative stress, an early event in the evolution of HL[3], also plays an essential role in the pathophysiology of ischemic stroke[4]. So it can be speculated that HL, as a highly prevalent risk factor for ACD, frequently accompanies ACD.

In addition, HL is also a major risk factor for liver disease[5]. The spectrum of HL-induced liver disease, also known as non-alcoholic fatty liver disease (NAFLD), ranges from "simple" steatosis to non-alcoholic steatohepatitis, which is characterized by oxidative stress, inflammation, and liver damage as well as fat deposition[6]. Of interest is that one of the main complications of the patient with ACD is the risk of secondary liver dysfunction. Ischemic stroke will further trigger the activation of inflammatory cascades leading to systemic inflammatory response[7]. In the systemic inflammatory environment developed by circulating reactive oxygen species (ROS) and pro-inflammatory cytokines after ACD, nonneurological organs, including liver, would be impaired leading to multiple organ dysfunction syndromes (MODS). The incidence of MODS in patients with ACD was reported as 11.5%, the mortality rate was 40.3%[8]. It is noteworthy that one of the major systemic complications of ACD is liver dysfunction, the presence of which is associated with mortality and overall poor outcome[9]. Clinical studies in China have showed, in patients of ACD with MODS, 26.83%[8] or 15.5%[10] had abnormal liver function. Therefore, HL or ACD is respectively known to be the independent risk factor for liver injury. It is thus reasonable to hypothesize that the coexistence of HL and ACD may contribute to more severe liver dysfunction.

As mentioned above, the pathological changes in liver caused by either HL or cerebral ischemia are associated with inflammation and oxidative stress. Inflammatory response and even apoptosis could be triggered by oxidative stress[11], which may be a key mechanism of liver injury induced by HL or cerebral ischemia. The source of oxidative stress is controversial but may result in part from over-expression of the prooxidant enzyme cytochrome P450 2E1 (CYP2E1), that has been reported to occur in human and experimental NAFLD[12]. As a major microsomal source of ROS, CYP2E1 mainly located in the endoplasmic reticulum and played a significant role in the biotransformation of fatty acid oxidation. ROS overproduction induces oxidative damage to liver DNA and contributes to hepatocellular injury[13]. The expression of CYP2E1 in liver can be enhanced in rats treated with high-fat diet[14]. In addition, brain injury or inflammation has influence on some liver cytochrome P450 enzymes[15]. But the effect of HL together with ACD on CYP2E1 is still unclear.

In this study, we hypothesized that HL or cerebral ischemia/reperfusion (I/R) injury may directly induce a series of changes leading to a pro-oxidant and pro-inflammatory state, which may finally result in the onset of liver injury, and the coexistence of HL and cerebral I/R injury may cause much more severe changes and the exacerbation of liver injury. To verify this assumption, a repeatable experimental hyperlipemic rat model with cerebral I/R injury was established to investigate the correlation of HL and/or acute cerebral I/R injury on liver damage, and further examine the effects of HL and/or I/R on hepatocyte apoptosis, CYP2E1, oxidative/antioxidant system and inflammatory process to understand the mechanism of liver damage.

MATERIALS AND METHODS

Animals

Adult male Sprague-Dawley rats, weighing 200-250 g, were obtained from Hubei Laboratory Animals Center for Medical Science and Research (No. 00006231). The animals were allowed to acclimatize for 1 wk while being maintained at a room temperature of 22 ± 2 ℃ on a 12 h light/dark cycle with free access to standard rodent chow food and water (Standard sustain feed, from Hubei Laboratory Animals Center for Medical Science and Research, Wuhan, China). Housing facilities and all experimental protocols were carried out according to the National Institutes of Health Guide for the Care and Use of Laboratory Animals, and approved by the Animals Care and Use Committee of Wuhan University of Science and Technology Medical College which adopts the guideline

Table 1 The examined animal groups

Group	Administration
Control	Rats given normal diet (control) for 18 wk and without I/R
HL	HL rats given high-fat diet for 18 wk and without I/R
I/R	Rats given normal diet (control) for 18 wk and with I/R
HL+I/R	HL rats given high-fat diet for 18 wk and with I/R

HL: Hyperlipidemia; I/R: Ischemia/reperfusion.

for the care and use of laboratory animals published by the US National Institutes of Health (NIH Publication No. 85-23, revised 1996).

Experiment design

The rats were fed either a standard low-fat rat chow diet (control diet) or a high-fat diet (HFD, 1% cholesterol, 10% lard, 20% sugar, 5% egg yolk, 0.2% bile salts and 63.8% standard chow, finally analyzed by the Laboratory Animal Centre of Hubei). After 18 wk of HFD, blood was withdrawn from the tail vein of overnight fasted rats for confirming HL. Serum triglycerides (TG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C) were detected by Beckman Coulter synchron LX20 autoanalyzer (Beckman Coulter Inc., United States). The animals with serum TC level > 3.87 mmol/L were considered HL and included in the study[16]. Subsequently, the control diet group and HL group were respectively divided into two subgroups treated with or without cerebral I/R (Table 1). After HL was confirmed, the rats in I/R or HL+I/R group were subjected to middle cerebral artery occlusion (MCAO)[17] for 2 h and followed by 24 h reperfusion to induce focal cerebral I/R injury. As the sham control, rats in control or HL groups underwent the same surgical procedure as in I/R or HL+I/R group without inserting the nylon thread.

Behavioral score and brain infarct volume were evaluated at 24 h after reperfusion by researchers and another assistant who was not involved in this experiment. The neurological deficits were scored on a 5-point scale based on the report of Longa *et al*[18]. All animals were sacrificed after the evaluation of behavioral scores. The area of cerebral infarction was quantified with TTC (2, 3, 5-triphenyltetrazolium chloride) staining as previous described[13].

Measurement of liver function and serum pro-inflammatory cytokines

Blood samples were obtained from the common carotid artery to detect serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) when rats were sacrificed at 24 h after reperfusion. The levels of serum ALT and AST were measured using corresponding kits (Jiancheng, Nanjing, China) to assess the liver function. Serum TNF-α and IL-1 levels were measured by radioimmunoassay kits (Albert Poole Biotechnology, Beijing, China).

Histological and immunohistochemical examination of liver

Harvested livers were placed into 10% formalin immediately after excision, and immersed for 24 h. Liver specimens were then embedded in paraffin, and sections were cut at 5 μm. Sections were stained for: (1) Hematoxylin and eosin (HE); (2) Apoptosis was detected by the TdT-mediated dUTP-biotin nick end labeling (TUNEL) method using an *in situ* apoptosis detection kit (Boster Biological Engineering, Wuhan, China) as previously described[19]. The number of cells with TUNEL-positive nuclei was counted from 20 randomly selected fields at × 200 magnification per liver sample. Results were expressed as the mean number of TUNEL-positive apoptotic hepatocytes per microscopic field; and (3) Immunohistological analysis of CYP2E1, caspase-3, bcl-2 expression in paraffin wax-embedded liver sections were performed using a standard peroxidase-antiperoxidase technique as described previously[20], using a CYP2E1 rabbit anti-mouse polyclonal antibody (Abcam Inc, United Kingdom) or mouse monoclonal antibodies against caspase-3 and bcl-2 (Santa Cruz, CA, United States) at a 1:150 dilution, with a biotinylated goat anti-rabbit or goat anti-mouse antibody (Santa Cruz, CA, United States) as the secondary antibody. Brown colour in the cytoplasm of the hepatocytes was evaluated as positive staining.

Determination of antioxidant enzymes activities, MDA and Ca^{2+} content in liver mitochondria and microsomal CYP2E1-dependent aniline hydroxylase activity

Liver subcellular fractions were prepared by differential centrifugation according to Khemawoot *et al*[21] with slight modifications. Livers were homogenized (20% w/v) with phosphate buffer (50 mmol/L K_2HPO_4 containing 0.1 mmol/L EDTA, pH 7.4). The homogenate was centrifuged at 200 *g* for 10 min at 4 ℃, and then the supernatant was recentrifuged at 9000 *g* for 20 min. The mitochondrial pellet was collected, resuspended in 0.25 mol/L sucrose solution, and stored at -80 ℃ until detection of superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), malondialdehyde (MDA) and Ca^{2+} levels using the corresponding kits (Jiancheng, Nanjing, China) respectively.

Then the supernatant was recentrifuged at 105 000 × *g* for 60 min. The microsomal pellet was washed, resuspended in 0.25 mol/L sucrose solution, and stored at -80 ℃ until determination of CYP2E1 activity and expression. Microsomal protein concentration was measured according to the method of Lowry *et al*[22]. Microsomal hydroxylase activity of the CYP2E1-containing enzyme was measured with aniline as the substrate according to the procedure described previously[23].

Western blotting of liver caspase-3, bcl-2 and microsomal CYP2E1

Proteins of liver homogenate or microsome were separated by SDS-PAGE and then transferred onto a polyvinylidene difluoride membrane by electroblotting.

Table 2 Blood lipids in different groups after high-fat diet treatment for 18 wk and before middle cerebral artery occlusion (mean ± SD, mmol/L)

Group	*n*	TC	TG	HDL-C	LDL-C
Control	10	1.69 ± 0.14	0.21 ± 0.08	1.14 ± 0.05	0.40 ± 0.10
HL	6	5.11 ± 0.55[b,e]	0.84 ± 0.20[a,f]	0.68 ± 0.15[a,f]	1.72 ± 0.52[a,e]
I/R	10	1.57 ± 0.19	0.19 ± 0.02	1.21 ± 0.16	0.36 ± 0.10
HL+I/R	10	5.33 ± 0.44[b,e]	0.79 ± 0.17[a,f]	0.70 ± 0.19[a,f]	1.64 ± 0.48[a,e]

HL: Hyperlipidemia; I/R: Ischemia/reperfusion; TC: Total cholesterol; TG: Triglyceride; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [e]$P < 0.05$, [f]$P < 0.01$ *vs* I/R group.

Membrane was blocked overnight and then incubated for 2 h with a 1:1000 dilution of a rabbit polyclonal anti-rat CYP2E1 antibody (Abcam Inc, United Kingdom) or a rabbit polyclonal anti-mouse, caspase-3, bcl-2 antibody (Santa Cruz, CA, United States). After incubation with the secondary antibody, proteins were detected with an electrochemiluminescence chemiluminescence detection kit (Amersham Biosciences, Buckinghamshire, United Kingdom), and scanned with a Typhoon 9200 scanner (Amersham Biosciences Europe GmbH, Freiburg, Germany). The amount of protein expression was corrected by the amount of β-actin in the same sample.

Statistical analysis

All data are expressed as mean ± SD. Statistical analysis was performed using Student's *t* test. Probability values less than 0.05 ($P < 0.05$) were considered statistically significant.

RESULTS

Evaluation of animal model

After 18 wk of HFD and prior to ischemia, serum levels of TC, TG and LDL-C in HL or HL+I/R group were significantly higher than those in control or I/R group, whereas HDL-C was lower ($P < 0.05$ or $P < 0.01$) (Table 2). There was no significant difference between the HL group and the HL+I/R group.

At 24 h after reperfusion, rats in the I/R or HL+I/R groups that were successfully operated with MCAO and reperfusion appeared to have a significantly higher neurological deficit score and brain infarct volume than those in the control or HL group ($P < 0.01$) (Table 3). There was no significant difference between the I/R group and the HL+I/R group.

These results strongly suggested that the animal model of HL combined with I/R was established successfully.

Liver damage caused by HL plus I/R

Plasma ALT and AST levels are common biomarkers for liver damage[24]. As compared to the control group, plasma activities of ALT and AST were elevated in the HL group ($P < 0.05$; $P < 0.01$), but not affected significantly by I/R alone; marked changes in serum ALT and AST activities suggesting hepatic damage were shown in the HL+I/R group ($P < 0.01$). The most severe liver damage was found in the HL+I/R group compared to HL or I/R alone ($P < 0.01$) (Table 3).

Table 3 Brain infarct volume and serum alanine aminotransferase and aspartate aminotransferase in different groups after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion (mean ± SD)

Group	*n*	Neurological deficit score	Infarct volume (mm^3)	ALT (U)	AST (U)
Control	10	0	0	9.56 ± 1.99	11.33 ± 4.17
HL	6	0	0	25.13 ± 16.90[b]	18.01 ± 10.00[a]
I/R	7	3.25 ± 0.36[b,d]	33.4 ± 4.16[b,d]	12.93 ± 6.14	14.00 ± 6.19
HL+I/R	6	3.53 ± 0.45[b,d]	34.5 ± 6.23[b,d]	93.62 ± 24.00[b,d,f]	82.32 ± 26.92[b,d,f]

HL: Hyperlipidemia; I/R: Ischemia/reperfusion; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* HL group; [f]$P < 0.01$ *vs* I/R group.

To analyze the extent of liver injury, liver sections were stained with HE (Figure 1A). No apparent damage was found in liver sections from the control or I/R group. Hepatocytes of the HL group showed fatty infiltration changes, light vacuolar change, scattered inflammatory cells and mild hepatocyte necrosis. However, extensive damage was detected in liver sections from HL+I/R rats. The affected livers displayed remarkable fatty accumulation, infiltration of a mixed population of inflammatory cells, hepatocyte ballooning degeneration and focal necrosis. These changes were more prominent when compared to HL or I/R alone.

Hepatocyte apoptosis caused by HL plus I/R

We assessed hepatocyte apoptosis using the TUNEL assay. TUNEL-positive cells appeared occasionally in liver sections of control or I/R groups, diffused widely in the HL group, and were most frequently observed in the HL+I/R group (Figure 1B). The number of TUNEL-positive apoptotic hepatocytes (6.2 ± 0.29 apoptotic cells/× 200 field) in the HL+I/R group was significantly greater than those in the control group (1.5 ± 0.22 apoptotic cells/× 200 field), HL group (4.47 ± 0.45 apoptotic cells/× 200 field), and I/R group (1.97 ± 0.47 apoptotic cells/× 200 field) ($P < 0.01$).

Encouraged by the severe liver damage and hepatocyte apoptosis caused by HL plus I/R, we further investigated whether the CYP2E1, oxidative/antioxidant system and pro-inflammatory cytokines are involved in this pathological condition.

Induction of hepatic CYP2E1 by HL plus I/R

The activities of CYP2E1-dependent aniline hydroxylase activity in the microsome, where CYP2E1 is mainly located in liver, were higher in the HL or the I/R group ($P < 0.01$; $P < 0.05$ *vs* control), and increased consider-

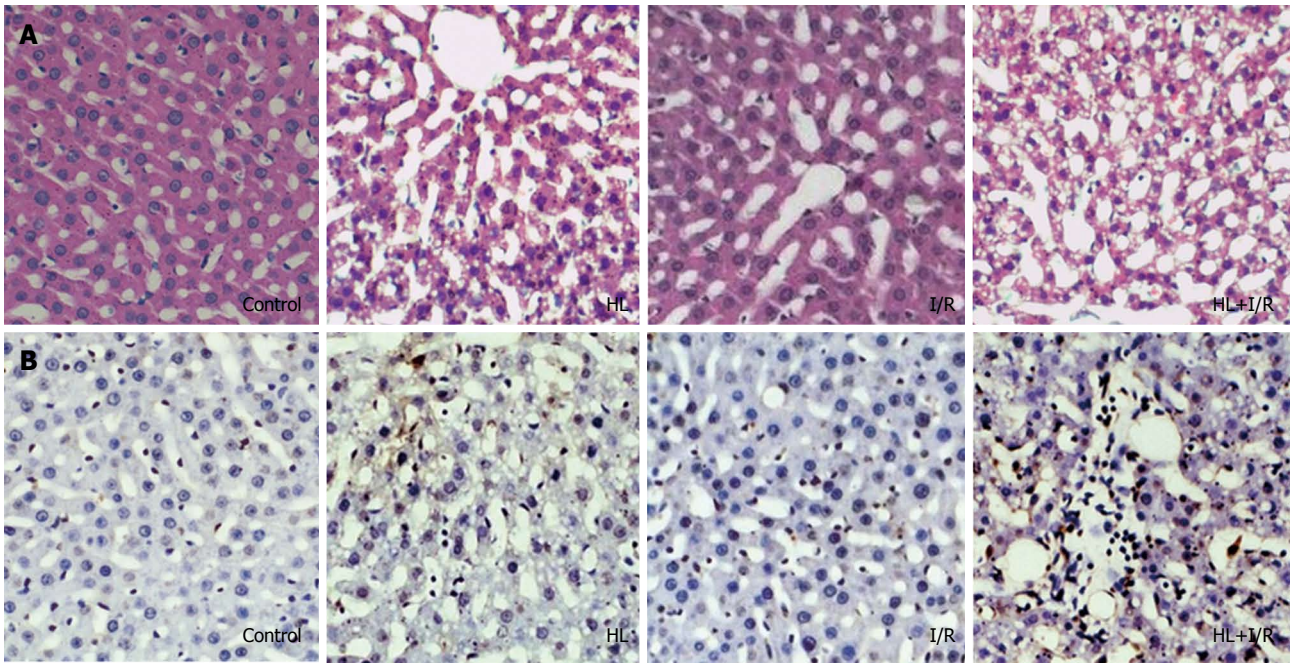

Figure 1 Histology and in situ apoptosis of liver sections from rats after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion. A: HE staining showed liver damage in the hyperlipemia (HL) group and especially in the HL+ ischemia/reperfusion (I/R) group (× 200); B: Transferase dUTP nick-end labeling (TUNEL) staining showed TUNEL-positive apoptotic hepatocytes in the HL+I/R group are significantly greater than those in control, HL or I/R groups (× 200). Slides are representative of 6-10 animals per group.

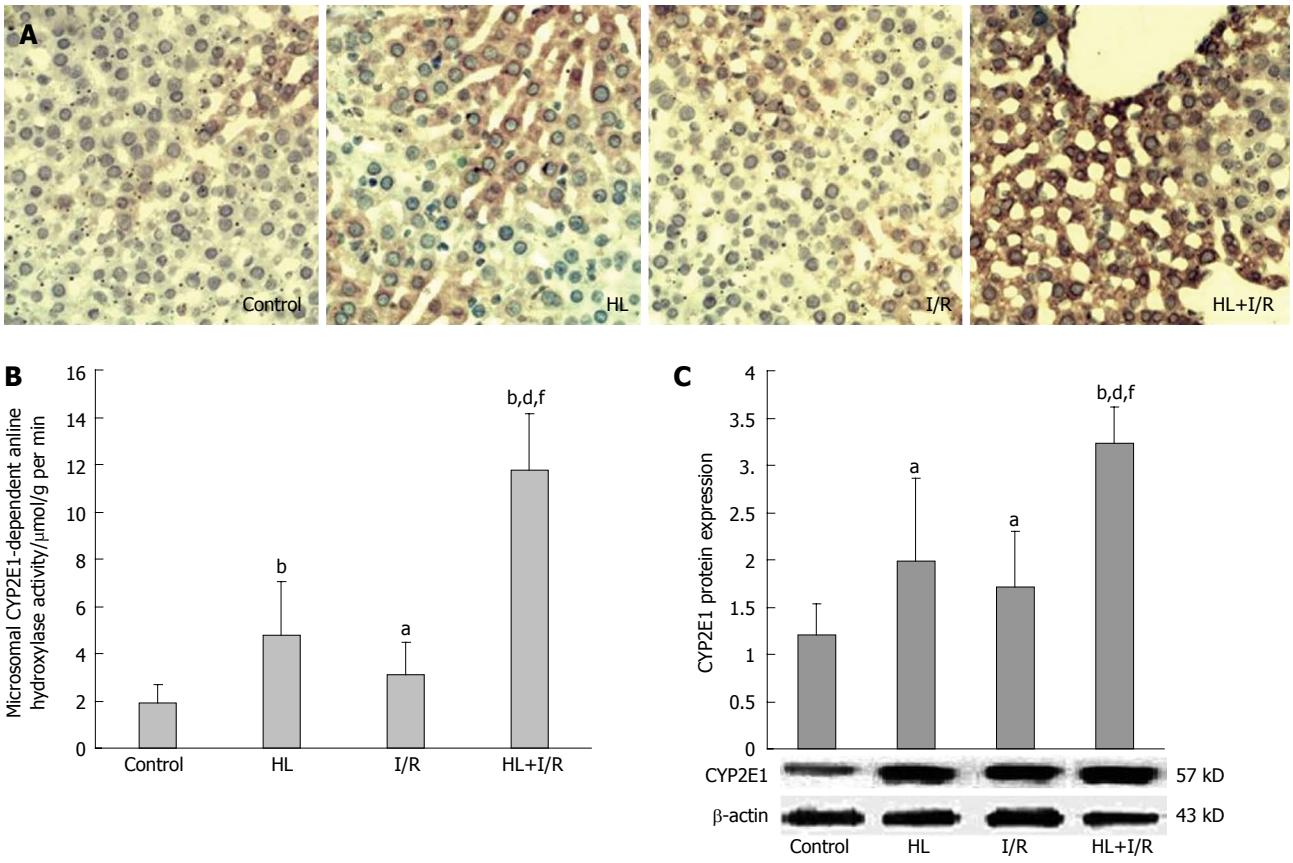

Figure 2 Effect of hyperlipemia plus ischemia/reperfusion on the activity and expression of CYP2E1 in the liver of rats after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion. A: Hepatocytes in the hyperlipemia (HL) + ischemia/reperfusion (I/R) group showed increased cytochrome P450 2E1 (CYP2E1) expression examined by immunohistochemical staining (× 200) than those in other groups. Slides are representative of 6-10 animals per group; B: Microsomal hydroxylase activity of the CYP2E1-containing enzyme measured with aniline as the substrate was much higher in the HL+I/R group; C: HL+I/R enhanced the expression level of CYP2E1 protein in liver microsomes, which was confirmed by Western blotting. Values are the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control group; $^{d}P < 0.01$ *vs* HL group; $^{f}P < 0.01$ *vs* I/R group.

Table 4 Levels of antioxidant enzymes, malondialdehyde and Ca^{2+} in liver mitochondria of different groups after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion (mean ± SD)

Group	*n*	SOD (U/μg protein)	GSH-Px (nmol/g protein per min)	MDA (mmol/g protein)	Ca^{2+} (μmol/g protein)
Control	10	244.93 ± 33.70	2172.26 ± 241.34	7.02 ± 2.58	1.329 ± 0.279
HL	6	100.59 ± 40.72[b]	937.57 ± 228.68[b]	21.84 ± 6.01[b]	2.552 ± 0.317[b]
I/R	7	172.15 ± 57.31[a]	1762.65 ± 409.18	12.58 ± 5.34	2.180 ± 0.431[b]
HL+I/R	6	59.01 ± 21.48[b,c,f]	486.41 ± 230.52[b,d,f]	47.27 ± 7.11[b,c,f]	3.136 ± 0.517[b,c,f]

HL: Hyperlipidemia; I/R: Ischemia/reperfusion; SOD: Superoxide dismutase; GSH-Px: Glutathione peroxidase; MDA: Malondialdehyde. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [c]$P < 0.05$, [d]$P < 0.01$ *vs* HL group; [f]$P < 0.01$ *vs* I/R group.

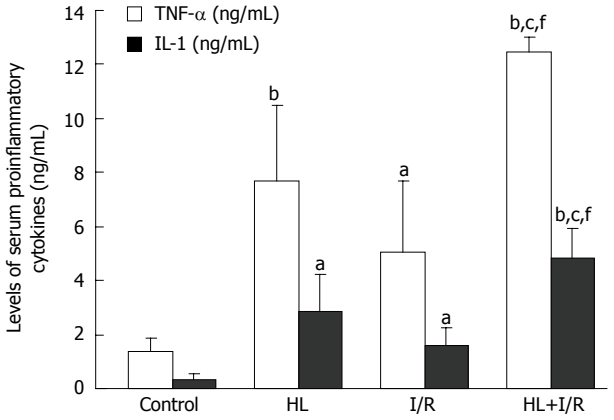

Figure 3 Effect of hyperlipemia + ischemia/reperfusion on the level of serum pro-inflammatory cytokines after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion. Serum pro-inflammatory cytokines in the hyperlipemia (HL) + ischemia/reperfusion (I/R) group were significantly higher compared to those in other groups. A: Tumor necrosis factor (TNF)-α; B: Interleukin (IL)-1. Values are the mean ± SD. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [c]$P < 0.05$ *vs* HL group; [f]$P < 0.01$ *vs* I/R group.

ably especially in the HL+I/R group ($P < 0.01$ *vs* control, HL or I/R groups) (Figure 2B). To understand the basis of aniline hydroxylase activity in rat liver microsome, we carried out immunohistochemistry and Western blotting analysis of CYP2E1. Immunohistochemistrical staining for hepatic CYP2E1 was occasionally detectable in the control group, but increased in the HL or I/R groups. In the HL+I/R group, strong and dense CYP2E1 immunoreactivity was observed, which paralleled the improvement in histological severity of liver damage (Figure 2A). Similar effects were observed in Western blotting. The protein expression of microsomal CYP2E1 was induced by HL ($P < 0.05$ *vs* control) and I/R ($P < 0.05$ *vs* control), and highly enhanced by HL+I/R ($P < 0.01$ *vs* control, HL or I/R group) (Figure 2C).

Effect of HL plus I/R on the levels of antioxidant enzymes, MDA and Ca^{2+} in liver mitochondria

The activities of antioxidant enzymes, including SOD and GSH-Px, fell dramatically in the HL+I/R group ($P < 0.01$ *vs* control, $P < 0.05$ or $P < 0.01$ *vs* HL alone, $P < 0.01$ *vs* I/R alone). SOD activities of the HL, I/R and HL+I/R groups were, respectively, 41.1%, 70.3% and 24.1% of control level; GSH-Px activities were 43.2%, 81.1% and 22.4% of control level, respectively (Table 4).

MDA and Ca^{2+} levels in liver mitochondria were higher in the HL group than the control group ($P < 0.01$). Liver mitochondrial Ca^{2+} levels also increased in the I/R group ($P < 0.01$ *vs* control). In the HL+I/R group, MDA and Ca^{2+} levels were most significantly increased compared with all other groups ($P < 0.01$ *vs* control or I/R group, $P < 0.05$ *vs* HL group) (Table 4).

Effect of HL plus I/R on the level of serum pro-inflammatory cytokines (TNF-α and IL-1)

The levels of serum TNF-α and IL-1 in HL, I/R or HL+I/R groups were significantly higher compared to those in the control group ($P < 0.01$; $P < 0.05$). When compared with HL or I/R alone, the increase of these two pro-inflammatory cytokines in the HL+I/R group also had statistical significance ($P < 0.05$ *vs* HL, $P < 0.01$ *vs* I/R group) (Figure 3).

Effect of HL plus I/R on the expressions of caspase-3 and bcl-2

We further investigated the expression levels of two key apoptosis-related genes- caspase-3 and bcl-2-in liver tissue, which were determined by immunohistochemistry and Western blotting. Immunohistochemistry assay showed protein expression of caspase-3 (Figure 4A) in livers of HL and HL+I/R rats was markedly increased, and the anti-apoptosis gene bcl-2 (Figure 4B) was dramatically decreased. These findings were confirmed by Western blotting, which showed increased expression of caspase-3 (Figure 4C) and decreased expression of bcl-2 (Figure 4D), especially in the HL+I/R group.

DISCUSSION

Dyslipidemia is usually responsible for liver disease including cirrhosis, hepatocellular carcinoma and liver failure[5]. It has also been reported that "high-fat diet" can induce lipid accumulation in rat liver by nutritional intervention[25]. In agreement with previous work[26-28], our study also demonstrated that HL alone induced by HFD for 18 wk resulted in considerable increases in serum ALT and AST levels, marked pathological changes in the liver, increased TUNEL-positive cells, higher caspase-3 and lower bcl-2 expression, suggesting liver damage and hepatocyte apoptosis. Oxidative stress and subsequent

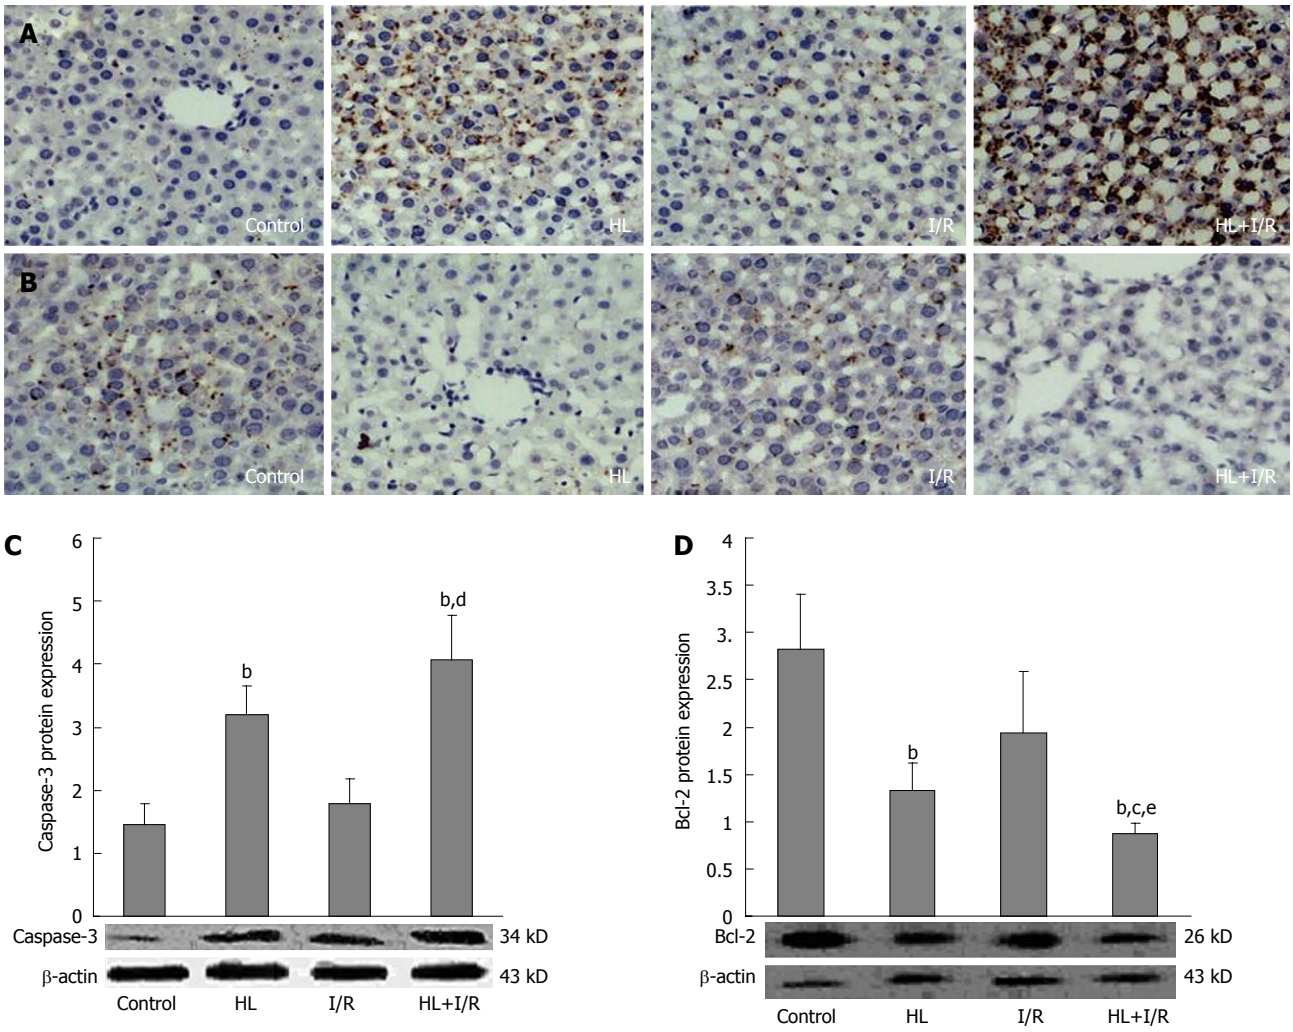

Figure 4 Expressions of bcl-2 and caspase-3 protein in liver after high-fat diet treatment for 18 wk and/or 2 h transient focal cerebral ischemia followed by 24 h reperfusion. Liver sections from different groups were immunohistochemically stained to assay the expression of caspase-3 and bcl-2 (× 200). A: Protein expression of caspase-3 was markedly elevated in the hyperlipemia (HL) + ischemia/reperfusion (I/R) group; B: Protein expression of bcl-2 was dramatically decreased in the HL+I/R group. C, D: Slides are representative of 6-10 animals per group. Liver homogenates were prepared, and then the expression levels of caspase-3 (C) and bcl-2 (D) proteins in liver were confirmed by Western blotting. Values are the mean ± SD. $^{b}P < 0.01$ *vs* control group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* HL group; $^{e}P < 0.05$ *vs* I/R group.

lipid peroxidation, together with the production of pro-inflammatory cytokines have been shown to play important roles in the pathogenesis of nonalcoholic fatty liver disease induced by HFD[29,30], which were also confirmed in our current experiment.

Besides liver damage caused by long-term HFD, our findings are consistent with the literature stating ischemic stroke *per se* is possibly associated with liver dysfunction[31]. Although no significant change in serum ALT and AST levels, histologic examination of liver, the number of TUNEL-positive cells, caspase-3 and bcl-2 expression in liver was found, systemic inflammation and the imbalance in oxidant production and antioxidant defense systems, which are strongly associated with the development of MODS due to I/R, were indeed discovered in the I/R group. Actually, circulating pro-inflammatory cytokines, for example, TNF-α and IL-1, and systemic oxidative stress would influence the nonneurological organs including liver[32].

Taken together, HL *per se* induced systemic inflammation and oxidative stress, and eventually caused hepatocyte apoptosis and liver damage, while I/R *per se* also induced systemic inflammation and oxidative stress but did not cause obvious hepatocyte apoptosis and liver damage.

Most interestingly, we demonstrated that, as expected, the combined action of HL and I/R brought about an abrupt reduction in hepatic function with enhanced hepatocyte apoptosis, which is much worse than the damage caused by I/R or HL alone. The incidence of ischemic stroke increases dramatically with advancing age. Due to aging, many patients with cerebral ischemia also suffer from HL, which is another common geriatric disease. It has also been reported that HL, as a cardiovascular risk factor, would lead to intracranial artery atherosclerosis or blockage, aggravate cerebral infarction, and exacerbate the deleterious effects of I/R on the brain[33]. In our

study, we found the coexistence of HL and cerebral I/R injury would be more dangerous because it induces more severe visceral dysfunction i.e., liver damage than HL alone. This kind of systemic complication may be fatal subsequently.

This liver damage secondary to the coexistence of HL and cerebral I/R injury can be explained readily by the high levels of circulating pro-inflammatory cytokines and oxidative stress, which possibly result from the synergy of systemic inflammatory and oxidative milieu induced by HL *per se* and those induced by I/R *per se*. In support of these concepts, we showed that, compared with I/R or HL alone, enhanced CYP2E1 induction, an increase in serum TNF-α, IL-1, liver mitochondrial MDA, and a decrease in SOD and GSH-Px in liver mitochondria were also measured in the HL+I/R group, which indicated that the coexistence of HL with cerebral I/R injury is associated with increased systemic inflammation and oxidative stress.

A significant change in CYP2E1 should be noted in the liver of HL rats with cerebral I/R injury. CYP2E1, sometimes mediating liver damage through oxidative stress[34,35], is a major adaptive system in the CYP superfamily. CYP2E1 has adjustability, and is inducible under a variety of physiological or pathophysiological conditions. It has been demonstrated that CYP2E1 levels increased in obese rats by feeding with an energy-dense diet[14] and responded quickly to acute stress, such as hypoxia, cold or hunger[36]. In fact, acute cerebral I/R injury also induces an acute stress condition in animals. In the present study, we have corroborated the induction of CYP2E1 by HL *per se* or I/R *per se*, especially I/R combined with HL, as an increase in hepatic CYP2E1 activity and protein expression was found in the HL and I/R groups, and especially in the HL+I/R group. CYP2E1 is known to be a key indicator of lipid peroxidation, and a significant source of ROS[12] contributing to hepatocellular injury. Enhanced CYP2E1 induction oxidizes mitochondrial DNA, proteins and lipids, and triggers hepatic TNF-α formation by activating nuclear factor-κB, which further increases mitochondrial ROS formation. ROS overproduction leads to inflammatory recruitment and apoptosis from oxidative stress[11], and finally exacerbates the disease.

Consistent with the change in MDA, we also revealed that mitochondrial Ca^{2+} content increased in the HL+I/R group. An imbalance of Ca^{2+} homeostasis is thought to be the "common pathway" of hepatocyte damage. Mitochondrial and cellular Ca^{2+} overload facilitates lipid peroxidation, which attenuates the oxidative phosphorylation of the mitochondrion resulting in damage to the mitochondrial structure and function and then the reduction of ATP synthesis. On the other hand, lipid peroxidation will in turn exacerbate the Ca^{2+} overload by acting on the membrane structure[37]. Accordingly, mitochondrial Ca^{2+} overload of hepatocytes is closely relevant to lipid peroxidation, and both are likely to be involved in hepatic injury after HL+I/R.

Moreover, we have evaluated, by immunohistochemistry and Western blotting analysis, two key mediators of apoptosis (caspase-3 and bcl-2), which appear to be adjusted by ROS and cytokines, including TNF-α and IL-1[32,38]. Increased protein expression of key pro-apoptotic factor caspase-3 and markedly down-regulated anti-apoptotic bcl-2 detected in livers of HL rats with cerebral I/R injury in our study which resulted in hepatocyte apoptosis and liver damage.

In summary, based on an experimental HL rat model with cerebral I/R, the present study revealed that the coexistence of HL and acute cerebral I/R induced severe liver damage. These findings suggested cerebral ischemic stroke would exaggerate the damage of liver caused by HL. So it can be reckoned that patients of HL combined with cerebral I/R injury have a higher risk of liver damage compared with patients with HL or cerebral I/R injury alone, the mechanism of which is possibly due to enhanced CYP2E1 induction, which can further increase mitochondrial ROS formation, oxidative damage, inflammation and apoptosis with increased protein expression of key pro-apoptotic factor caspase-3, and markedly down-regulated anti-apoptotic bcl-2. Therefore, special precautions against subsequent liver injury are required after the burst of cerebral ischemic stroke in patients with HL. It seems that the therapeutic approaches to inhibit CYP2E1 activation, rebalance the oxidative/antioxidant system, and suppress inflammation or apoptosis might be efficacious in preventing the liver damage induced by HL plus cerebral I/R injury.

COMMENTS

Background

The history of hyperlipidemia (HL), an increasingly public health problem, is positively associated with acute cerebrovascular diseases (ACD) such as ischemic stroke. Moreover, HL is also a major risk factor for liver disease. One of the main complications of the patient with ACD is the risk of secondary liver dysfunction. It is thus reasonable to hypothesize that the coexistence of HL and ACD may contribute to more severe liver dysfunction.

Research frontiers

The pathological changes in liver caused by either HL or cerebral ischemia are associated with inflammation and oxidative stress. An inflammatory response and even apoptosis could be triggered by oxidative stress, which may be a key mechanism of liver injury induced by HL or cerebral ischemia. The source of oxidative stress is controversial but may result in part from over-expression of the prooxidant enzyme cytochrome P450 2E1 (CYP2E1). CYP2E1 has adjustability, and is inducible under a variety of physiological or pathophysiological conditions. It has been demonstrated that CYP2E1 levels are enhanced in obese rats by feeding with an energy-dense diet and respond quickly to acute stress, such as hypoxia, cold or hunger.

Innovations and breakthroughs

HL or ACD have been known to be independent risk factors for liver injury. In this study, the authors developed a repeatable experimental hyperlipemic rat model with acute cerebral ischemia/reperfusion injury, and investigated the correlation of HL and/or acute cerebral ischemia/reperfusion injury on liver damage, and further examine the effects of HL and/or ischemia/reperfusion on hepatocyte apoptosis, CYP2E1, the oxidative/antioxidant system and inflammatory process to understand the mechanism of liver damage.

Applications

The study results suggest that cerebral ischemic stroke would exaggerate the

damage of liver caused by HL. So it can be reckoned that patients with HL combined with acute cerebral ischemia/reperfusion injury have a higher risk of liver damage compared with patients with HL or cerebral ischemia/reperfusion injury alone, the mechanism of which is possibly due to enhanced CYP2E1 induction, which can further increase mitochondrial reactive oxygen species formation, oxidative damage, inflammation and apoptosis with increased protein expression of key pro-apoptotic factor caspase-3, and markedly down-regulated anti-apoptotic bcl-2. Therefore, special precautions against subsequent liver injury are required after the burst of cerebral ischemic stroke in patients with HL. It seems that therapeutic approaches to inhibit CYP2E1 activation, rebalance the oxidative/antioxidant system, suppress inflammation or apoptosis might be efficacious in prevention and treatment of liver damage induced by HL plus cerebral ischemia/reperfusion injury.

Peer review

The topic is of great clinical importance as the prevalence and incidence of hyperlipidemia and related cerebrovascular diseases as well as non-alcoholic fatty liver disease are increasing in industrialized countries; hence the associated financial problems is a major point to cope with. The rat model based study is well designed and the results are significant.

Abstract

AIM: To assess whether gemcitabine-based combination therapy improves the prognosis of unresectable pancreatic cancer compared with gemcitabine treatment alone.

METHODS: A quantitative up-to-date meta-analysis was undertaken to investigate the efficacy of gemcitabine-based combination treatment compared with gemcitabine monotherapy in locally advanced or metastatic pancreatic cancer. Inclusion was limited to high-quality randomized clinical trials.

RESULTS: Twenty-six studies were included in the present analysis, with a total of 8808 patients recruited. The studies were divided into four subgroups based on the different kinds of cytotoxic agents, including platinum, fluoropyrimidine, camptothecin and targeted agents. Patients treated with gemcitabine monotherapy had significantly lower objective response rate [risk ratio (RR), 0.72; 95% confidence interval (CI): 0.63-0.83; $P < 0.001$], and lower 1-year overall survival (RR, 0.90; 95%CI: 0.82-0.99; $P = 0.04$). Gemcitabine monotherapy caused fewer complications, including fewer grade 3-4 toxicities: including vomiting (RR, 0.75; 95%CI: 0.62-0.89; $P = 0.001$), diarrhea (RR, 0.66; 95%CI: 0.49-0.89; $P = 0.006$), neutropenia (RR, 0.88; 95%CI: 0.72-1.06; $P = 0.18$), anemia (RR, 0.96; 95%CI: 0.82-1.12; $P = 0.60$), and thrombocytopenia (RR, 0.76; 95%CI: 0.60-0.97; $P = 0.03$) compared with gemcitabine combination therapies.

CONCLUSION: Gemcitabine combination therapy provides a modest improvement of survival, but is associated with more toxicity compared with gemcitabine monotherapy.

Sun C, Ansari D, Andersson R, Wu DQ. Does gemcitabine-based combination therapy improve the prognosis of unresectable pancreatic cancer? *World J Gastroenterol* 2012; 18(35): 4944-4958 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i35/4944.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i35.4944

INTRODUCTION

Pancreatic cancer is a highly lethal disease, and represents the fourth cause of cancer-related death in the Western

world. In the United States, the incidence of pancreatic cancer almost equals its mortality, with 43 140 estimated new cases and 36 800 deaths in 2010. Globally, the incidence of new cases is approximately 230 000 each year[1,2]. Despite advances in diagnosis, staging, and surgical management of the disease during the past decade, the 5-year survival rate in the United States, Europe, and Australia is less than 5%[3-5]. Pancreatic cancer is characterized by a rapid disease progression and highly invasive tumor phenotype, with most patients having unresectable disease at diagnosis, and chemotherapy being the only possible treatment option for these patients[6].

Gemcitabine is a pyrimidine antimetabolite and analog of deoxycytidine. It was approved by the Food and Drug Administration as a first-line treatment for patients with locally advanced (stage Ⅱ or stage Ⅲ disease when surgery is not an option) or metastatic (stage Ⅳ) cancer of the pancreas, and has been widely used during the last decade. However, because of high levels of intrinsic and acquired chemoresistance, a large number of patients do not respond to gemcitabine[7]. To improve clinical efficacy, systemically administered gemcitabine is often combined with a second cytotoxic agent, such as platinum analogs, fluoropyrimidine, or a targeted cytotoxic agent. Numerous clinical trials have aimed at proving the superiority of gemcitabine-based combination therapy over single-agent gemcitabine treatment. However, most of the results of clinical trials have important limitations, including lack of statistical power because of small study populations. Thus, there remain several areas of controversy and uncertainty concerning optimal treatment regimens.

In the present study, we undertook a quantitative up-to-date meta-analysis to investigate the efficacy of gemcitabine-based combination treatment in locally advanced or metastatic pancreatic cancer. The aim of this study was to assess whether gemcitabine-based combination therapy improves the prognosis compared with gemcitabine treatment alone and to discuss possible mechanisms.

MATERIALS AND METHODS

Literature search strategy

We carried out a comprehensive search of the literature, including PUBMED (http://www.ncbi.nlm.nih.gov/pubmed), EMBASE (http://www.embase.com/home), American Society of Clinical Oncology abstracts (http://www.asco.org), and the Cochrane Database (http://www.thecochranelibrary.com). The following keywords were used in the search: ("Gemcitabine" or "Gemzar"), and ("pancreatic cancer" or "pancreatic tumor" or "pancreatic carcinoma"), and ("clinical trial"). The deadline for a publication to be eligible for this study was November 5, 2011. In addition to the online search, references from reviews and original articles were also scanned manually to identify further trials that met the eligibility criteria. No language restrictions were applied.

Inclusion and exclusion criteria

Studies included in the analysis had to meet all of the following criteria: (1) prospective, randomized, controlled open or blinded trial; (2) patients with histologically confirmed locally advanced or metastatic pancreatic ductal adenocarcinoma; and (3) assessment of the efficacy of gemcitabine combination therapy *vs* gemcitabine alone. Non-randomized trials and quasi-randomized trials, studies of curatively aimed resection, and studies where patients had multiple cancers, were excluded to avoid clinical heterogeneities between different studies.

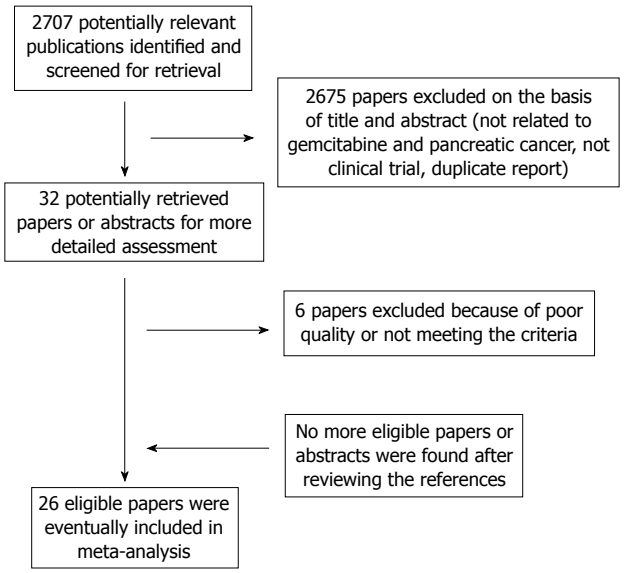

Figure 1 Flow chart of study selection.

Data extraction and quality assessment

Data extraction and quality assessment were performed independently by two reviewers (CS and DA). Any disagreements between the reviewers were discussed with a third reviewer (RA) to achieve a consensus. The data extracted from the eligible studies included: first author, year of publication, patient characteristics, intervention, and clinical outcome (toxicity, response rate, overall survival and progression-free survival). If the same trial appeared on sequential or multiple publications, the data from the most recent or comprehensive one was included.

The methodological quality of included studies was assessed using the "Jadad scale" or "Oxford quality scoring system"[8]. This tool is an evidence-based quality assessment tool. There are three items (randomization, double blinding, withdrawals and dropouts) directly related to bias reduction for assessment. Each item is given a score of 1 point for each "yes" or 0 points for each "no", and 1 additional point for appropriate randomization and double blinding. Every eligible study were assessed and given a score from 0-5.

Data analysis

The outcome measures were objective response rate [objective response rate (ORR) = complete response (CR) + partial response (PR)], as previously defined[9], 1-year overall survival (OS), median progression-free survival (PFS), median OS and toxicity. The analysis of ORR

NR: No record; PFS: Progression-free survival; OS: Overall survival.

(number of partial and complete responses, as defined by Response Evaluation Criteria in Solid Tumors[10]), PFS (time from randomization to progression or death) and OS (time from the date of random assignment until date of death or date last known to be alive) were based on the intent-to-treat population, consisting of all patients randomly assigned onto every study. Toxicity was graded according to the National Cancer Institute Common Toxicity Criteria, and based on the safety population. The median PFS and median OS were assessed using the paired *t*-test. $P < 0.05$ was considered statistically significant.

Meta-analysis was performed using the Review Manager (version 5.1, provided by The Cochrane Collaboration). The strength of the associations between treatment and outcomes were estimated by risk ratio (RR, a ratio

Table 2 Grade 3 or 4 toxicity of selected clinical trials

NR: No record.

of the probability of the event occurring in the exposed group versus a non-exposed group) and 95% confidence interval (CI)[11]. The heterogeneities between different studies or different subgroups were estimated using Cochran's Q test[12,13]. In addition, the I^2 value was used for evaluating the extent of heterogeneity between studies or subgroups[14]. The I^2 index measures the extent of true heterogeneity dividing the difference between the result of the Q test and its degrees of freedom by the Q value itself, and multiplied by 100. I^2 indicated the possibility of the variability among effect sizes caused by true heterogeneity between studies, not by sampling error[14]. If a significant Q test ($P < 0.1$) or $I^2 > 50\%$ indicated that heterogeneity existed between studies, the random effects model was used for meta-analysis, otherwise the fixed effects model was used. Publication bias was assessed by visual inspection of funnel plots.

RESULTS

Literature search and trial flow

The results of the literature search are depicted in Figure

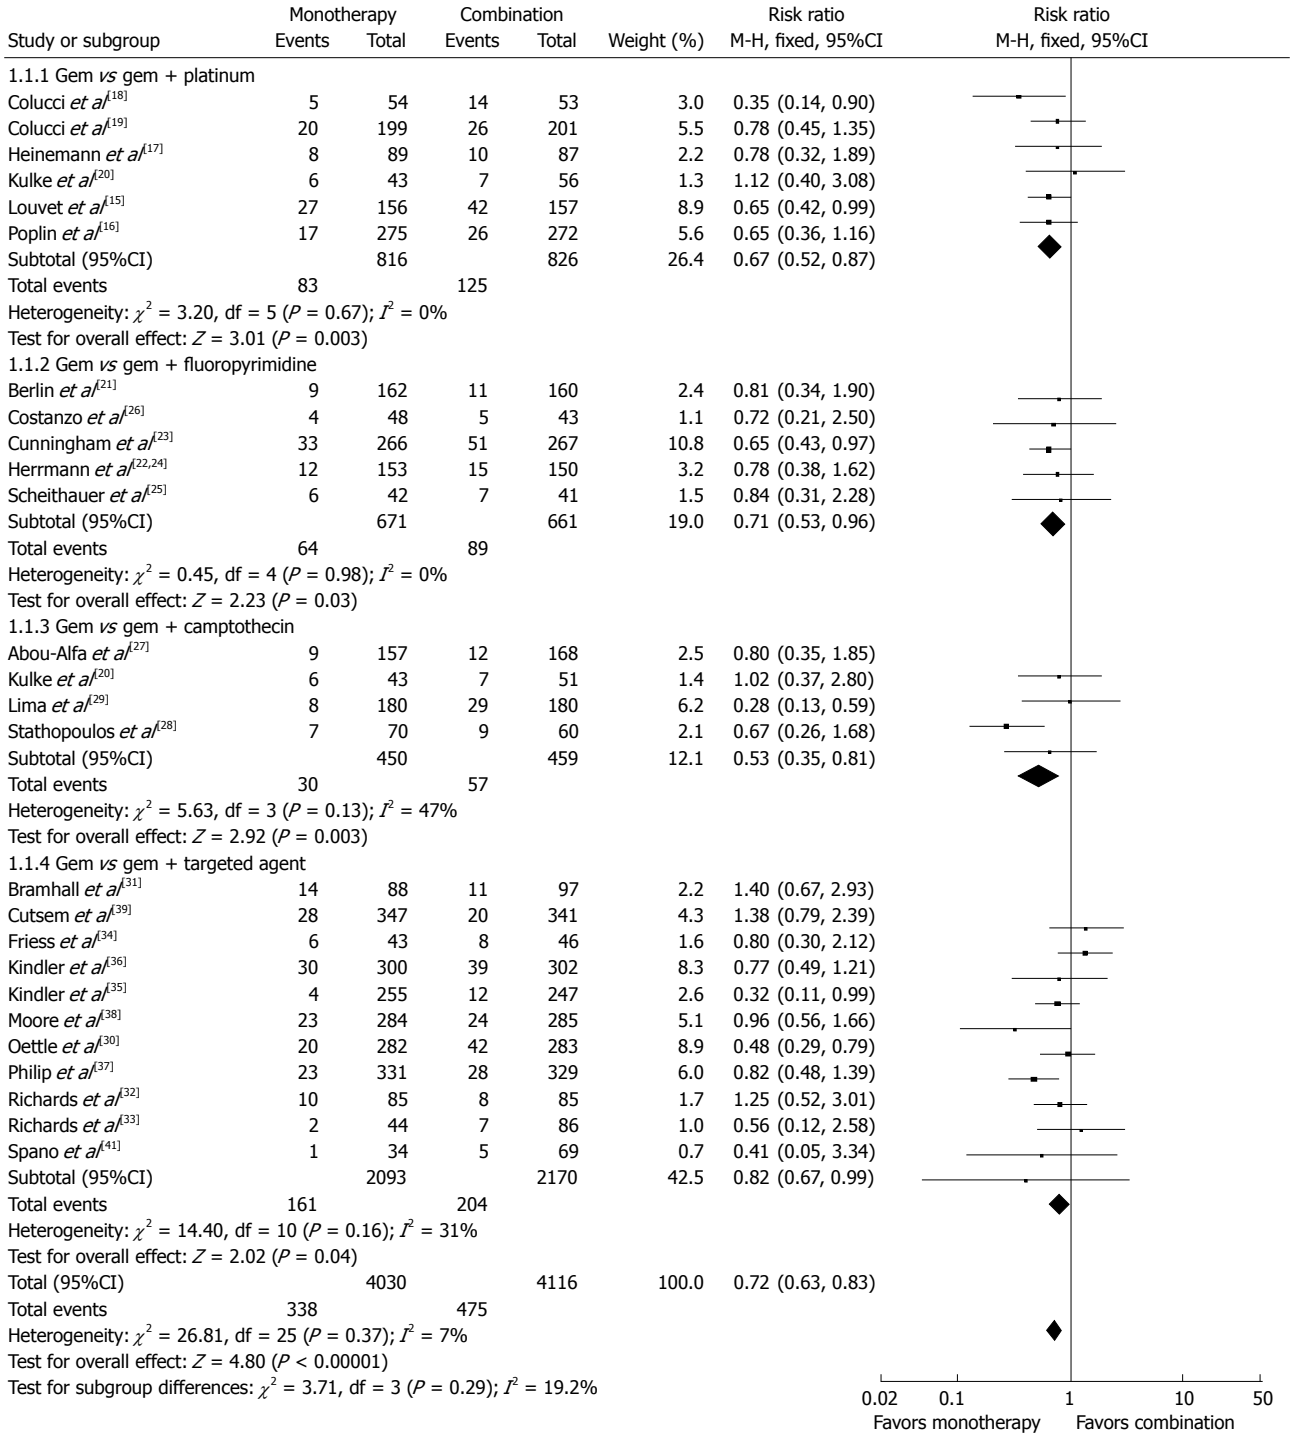

Figure 2 Fixed effect model of risk ratio of objective response rate. CI: Confidence interval.

1. Some 2707 studies were initially retrieved. After reading the title and abstract, 2675 studies were excluded, and 32 studies were left for further review. Six of these were excluded because of poor quality or failure to meet the inclusion criteria.

Characteristics of selected trials

The characteristics of the included studies are shown in Table 1. Twenty-six studies were included in the present analysis, with 8808 recruited patients. The studies were divided into four subgroups based on types of cytotoxic agents used, including platinum[15-20], fluoropyrimidine[21-26], camptothecin[21,27-29] and targeted agents[30-41]. All included studies enrolled patients that were ⩾ 18 years; had a histologically confirmed locally advanced or metastatic pancreatic cancer not amenable to surgical resection; no previous chemotherapy; a life expectancy of at least 12 wk; a Karnofsky performance status ⩾ 50, or World Health Organization performance status of 0-2; and adequate liver, renal, and hematopoietic functions.

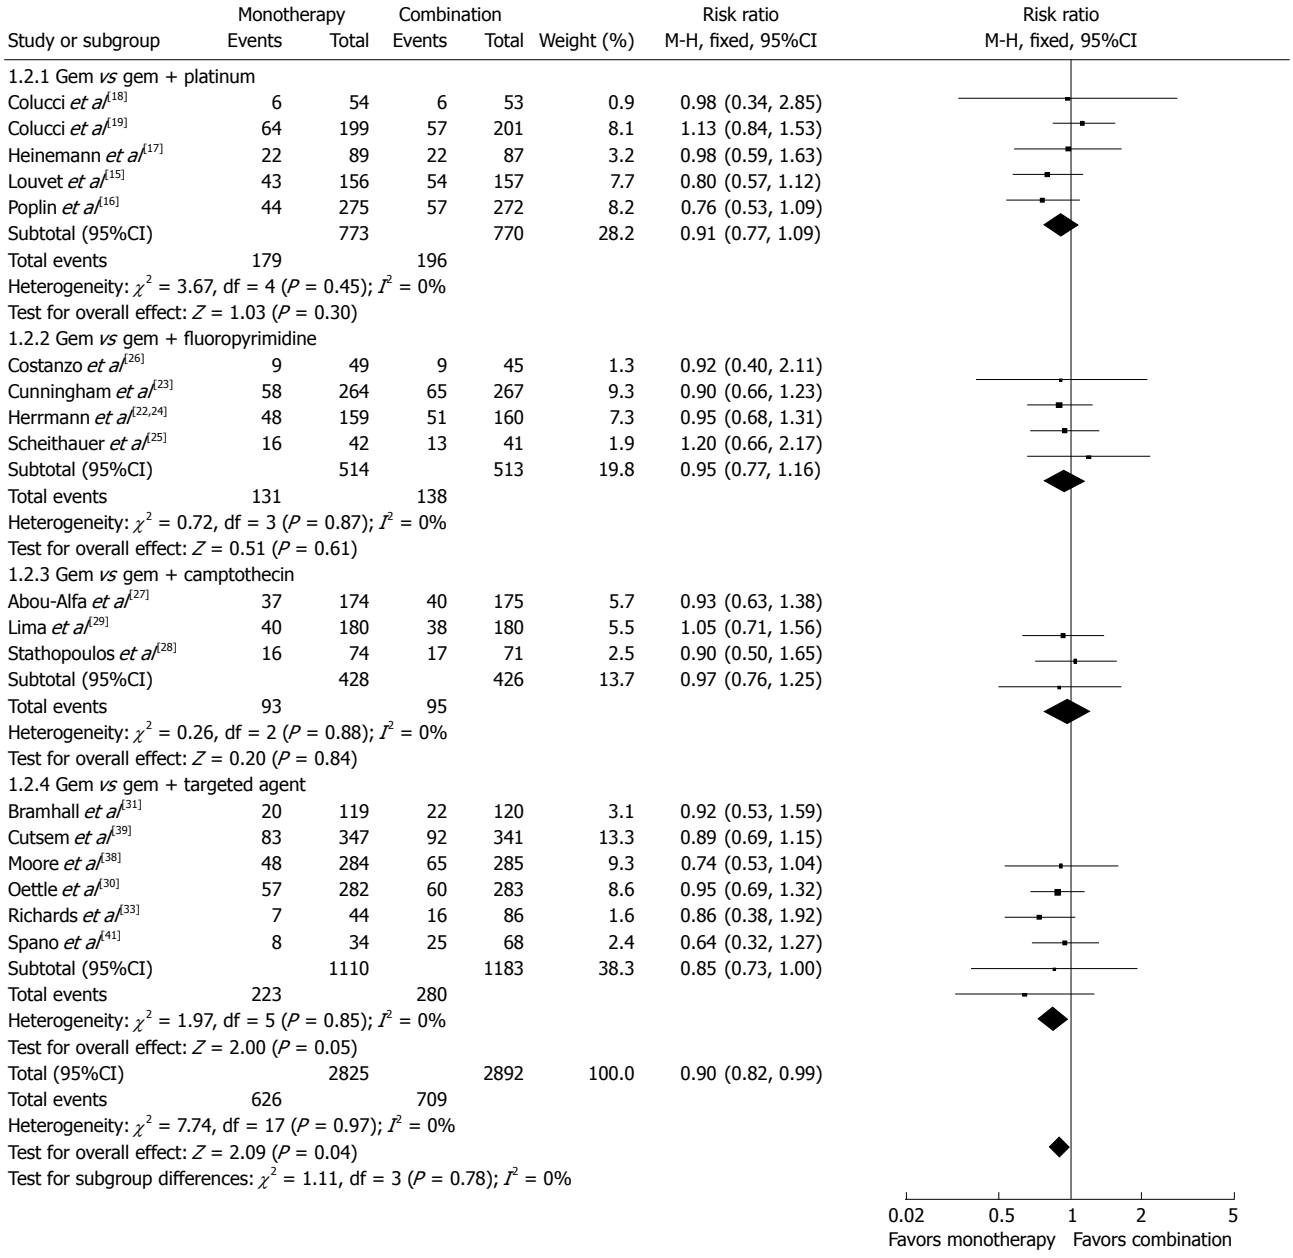

Figure 3 Fixed effect model of risk ratio of 1-year overall survival rate. CI: Confidence interval.

The details of toxicity assessment are shown in Table 2 (only grade 3 and 4 toxic effects are presented), including vomiting, diarrhea, neutropenia, anemia and thrombocytopenia.

The methodological quality of selected studies was high. Most trials had a Jadad score of 3, while three studies had a score of 4. Methods of double blinding were infrequently reported.

Gemcitabine combination therapy improves objective response rate compared with gemcitabine treatment alone

This analysis evaluated 26 trials (8146 patients) comparing gemcitabine monotherapy with the combination of gemcitabine and some other cytotoxic agent. Based on all studies, patients treated with gemcitabine monotherapy had a significantly lower ORR than gemcitabine combination therapy (RR, 0.72; 95%CI: 0.63-0.83; $P < 0.001$). The RRs in the different subgroups were 0.67, 0.71, 0.53 and 0.82, for platinum, fluoropyrimidine, camptothecin and targeted agents, respectively. All RRs in the subgroups were also significant. Data are shown in Figure 2.

Gemcitabine combination therapy improves 1-year overall survival rate compared with gemcitabine alone

5717 patients from 18 trials were included in this meta-analysis comparing gemcitabine monotherapy with combination therapies for 1-year overall survival. The RRs of 1-year overall survival were analyzed both totally and in the different subgroups. Subgroup analysis showed that the RRs of the monotherapy-based 1-year overall survival were lower than for the combination groups (RR:

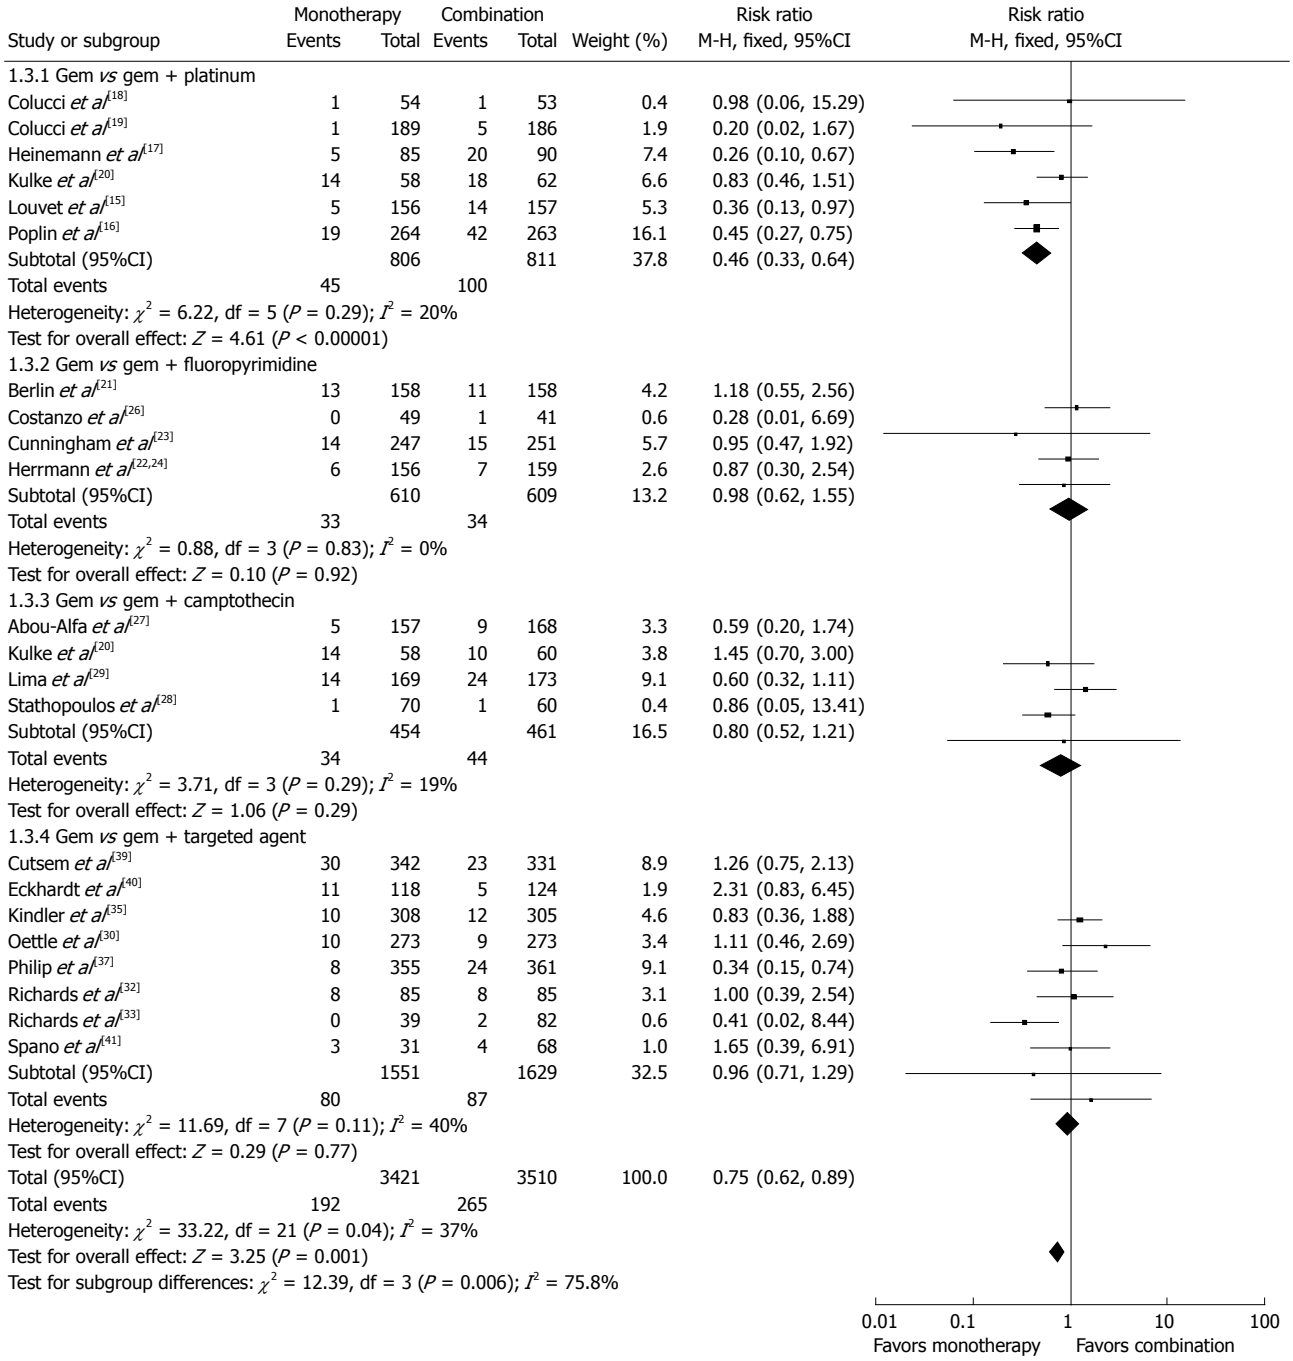

Figure 4 Fixed effect model of risk ratio of grade 3 or 4 vomiting. CI: Confidence interval.

0.91, 0.95, 0.97 and 0.85, for platinum, fluoropyrimidine, camptothecin and targeted agents, respectively), but no significant differences were found. When analyzed in terms of total events, the RR shown in Figure 3 was 0.90 [(95%CI: 0.82-0.99); P = 0.04]. The result showed that the 1-year overall survival rate of gemcitabine monotherapy was almost 90% of that of the combination therapy.

Gemcitabine combination therapy increases the toxicity effect compared with gemcitabine alone

Outcomes of the meta-analysis of the main toxicities are presented in Figures 4-8. All RRs with grade 3-4 toxicities analyzed in this study were lower in the gemcitabine monotherapy group than in the combination group. The incidence of vomiting (RR, 0.75; 95%CI: 0.62-0.89; P = 0.001), diarrhea (RR, 0.66; 95%CI: 0.49-0.89; P = 0.006) and thrombocytopenia (RR, 0.76; 95%CI: 0.60-0.97; P = 0.03) were all significantly different between the treatment groups, while no significant difference was noted regarding neutropenia (RR, 0.88; 95%CI: 0.72-1.06; P = 0.18) and anemia (RR, 0.96; 95%CI: 0.82-1.12; P = 0.60).

In subgroup analysis, the RRs were 0.46-0.98 for vomiting, 0.65-0.70 for diarrhea, 0.70-1.03 for neutropenia, 0.87-1.09 for anemia and 0.65-0.85 for thrombocy-

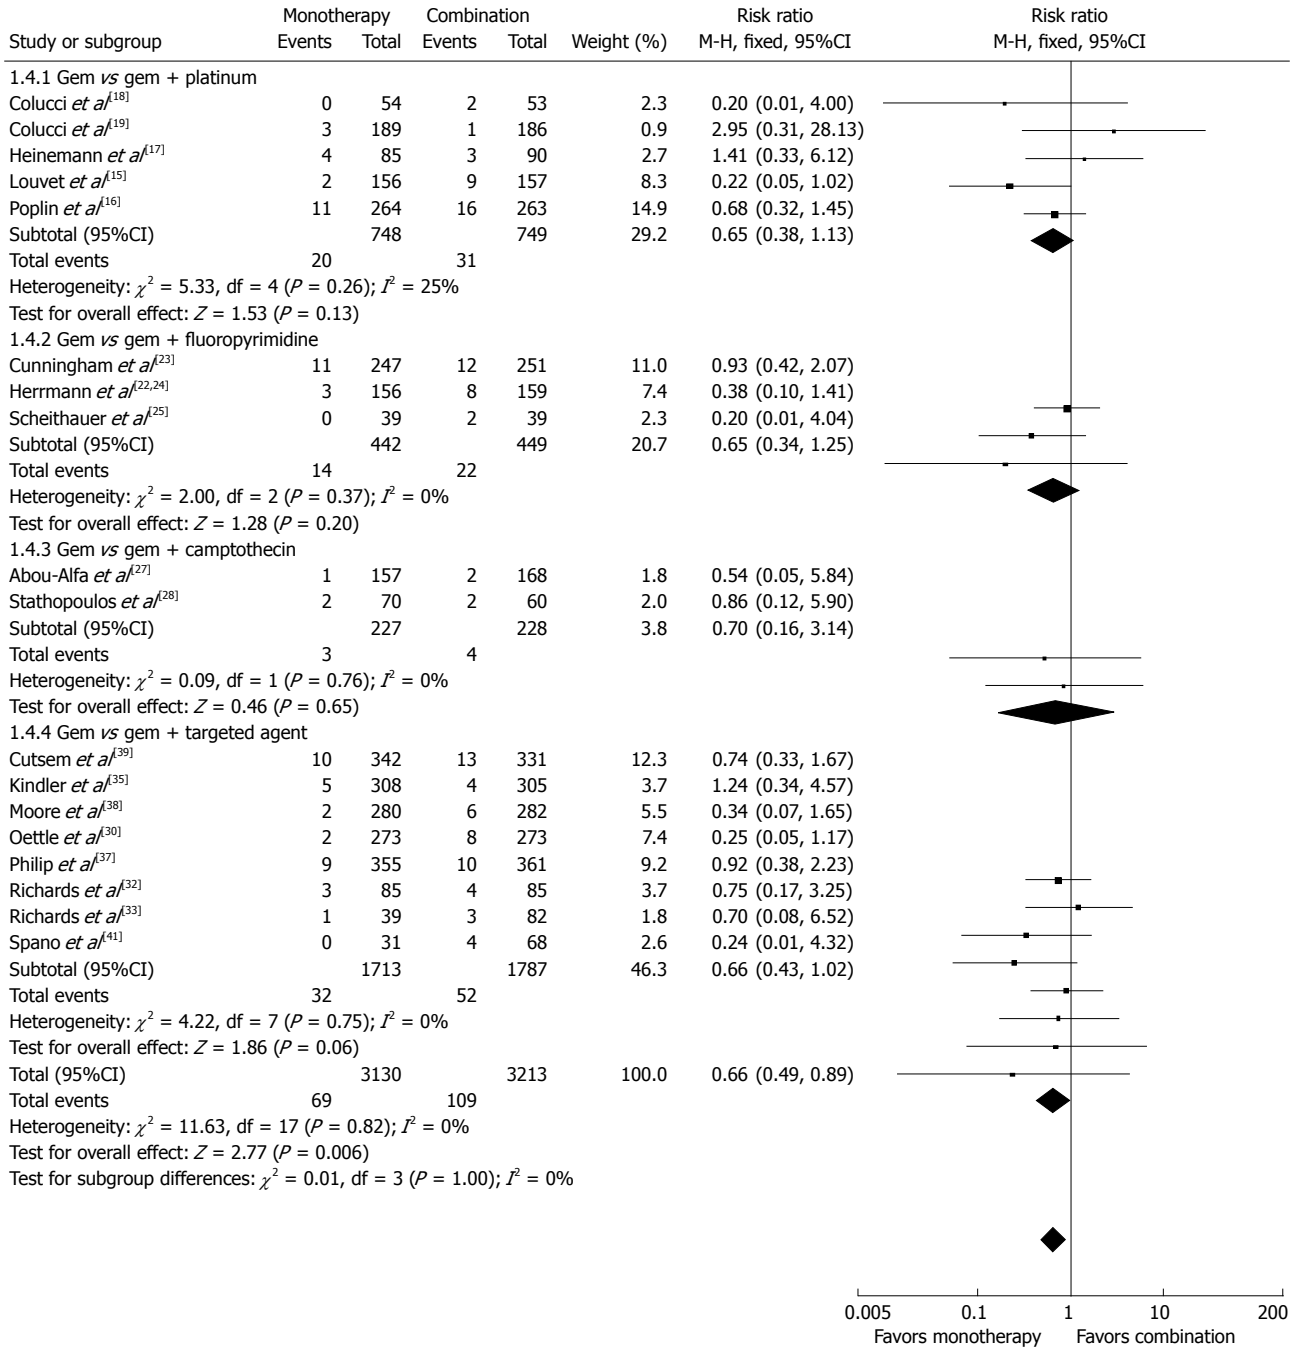

Figure 5 Fixed effect model of risk ratio of grade 3 or 4 diarrhea. CI: Confidence interval.

topenia, respectively. No subgroup differences in overall toxic outcomes, expect for vomiting, were found between the gemcitabine monotherapy group and the combination groups. Gemcitabine monotherapy decreased the incidence rate of vomiting by more than 50% compared with the gemcitabine plus platinum subgroup (RR, 0.46; 95%CI: 0.33-0.64; $P < 0.001$), while no significant differences for other subgroups was seen. In addition, the results showed that gemcitabine plus fluoropyrimidine therapy significantly increased the incidence of neutropenia (RR, 0.70; 95%CI: 0.55-0.88; $P = 0.002$).

The median PFS and median OS between gemcitabine monotherapy and combination therapies

The data of median PFS and OS in every study were extracted and assessed by a paired *t*-test. The results showed that only gemcitabine plus fluoropyrimidine significantly increased the median PFS (3.480 *vs* 4.520; $P = 0.045$) and median OS (6.950 *vs* 7.840; $P = 0.038$). Data are shown in Figure 9.

Publication bias

The funnel plots are shown in Figure 10. There was no

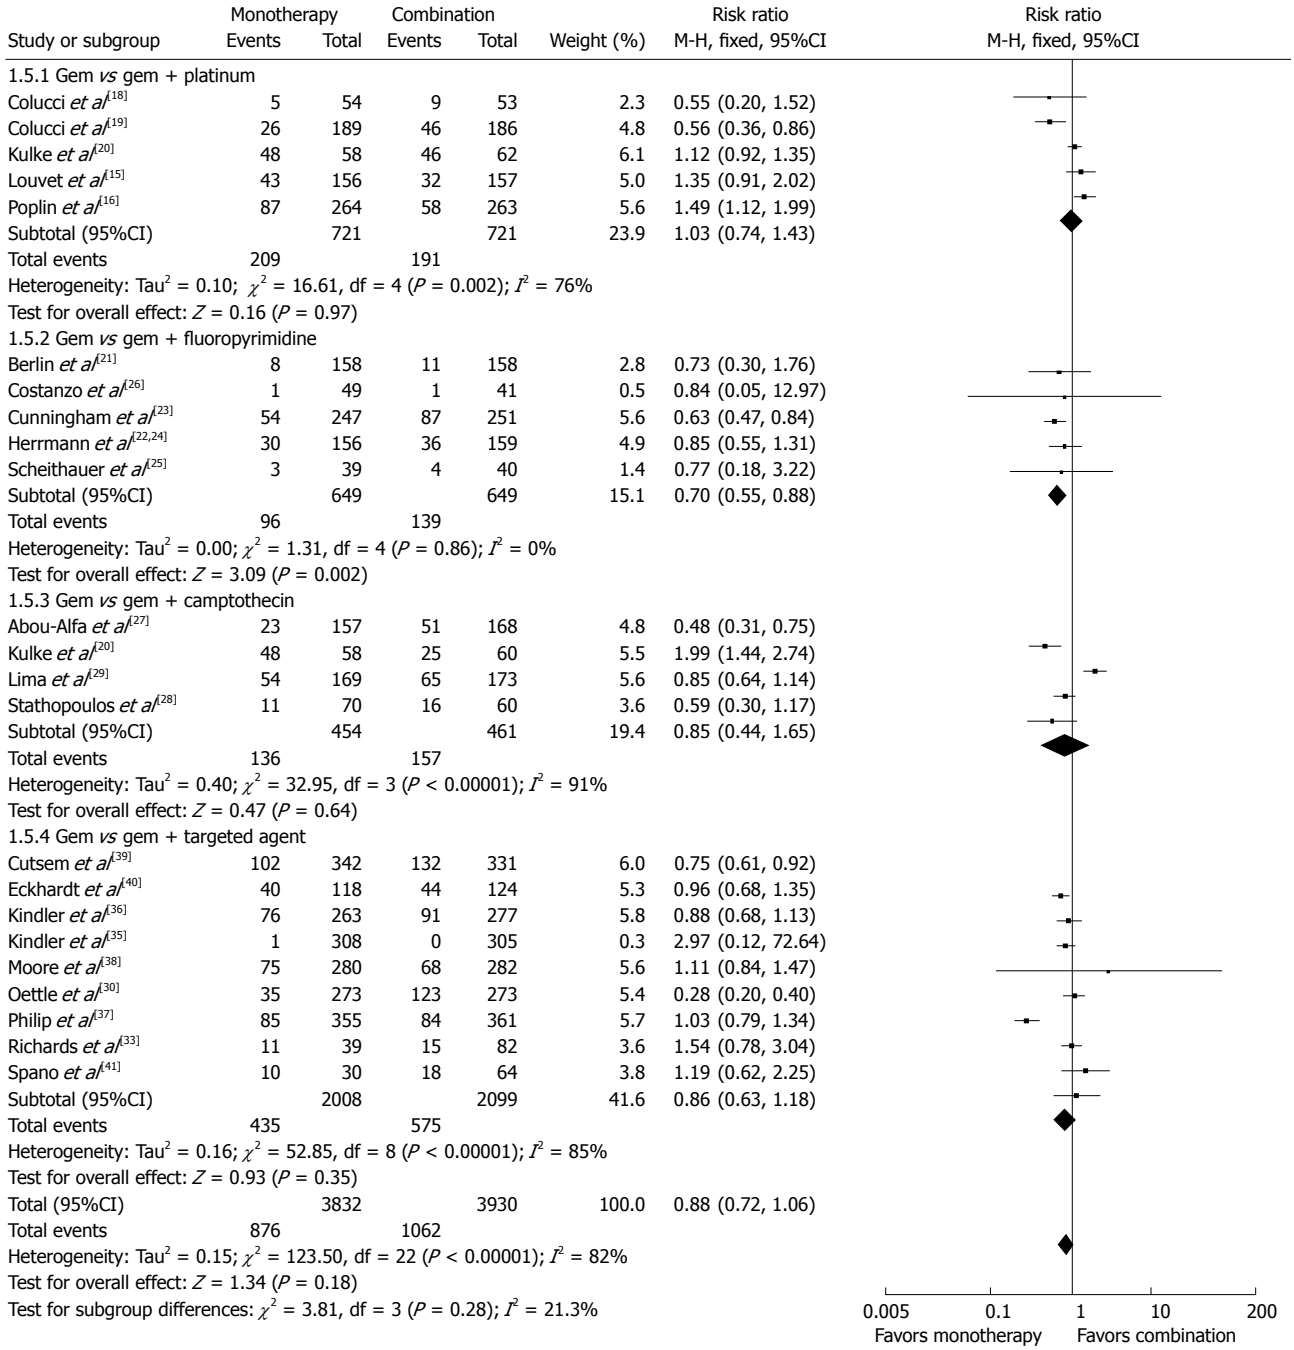

Figure 6 Random effect model of risk ratio of grade 3 or 4 neutropenia. CI: Confidence interval.

obvious publication bias found in the analysis.

DISCUSSION

Pancreatic cancer is a devastating disease with a dismal prognosis. Most of patients present with locally advanced or metastatic disease and are thus not candidates for surgical resection, thereby having to rely on palliative chemotherapy as the only treatment option. In this situation, the goals of chemotherapy should be to control tumor progression, decrease toxicity, and improve the survival rate. At present, gemcitabine monotherapy remains the standard treatment for patients with locally advanced or metastatic pancreatic cancer, but its efficacy is unsatisfactory. During the last decade, several randomized controlled clinical trials have evaluated gemcitabine in combination with various agents in an attempt to improve the prognosis of pancreatic cancer. The aim of this meta-analysis was to compare the therapeutic efficacy of gemcitabine-based combination treatments with gemcitabine alone in patients with locally advanced or metastatic pancreatic cancer. The results of this study showed that various combination therapies overall did not provide any major benefit compared with gemcitabine monotherapy.

Moreover, gemcitabine monotherapy had an almost 30% lower ORR than combination therapy regimens, but

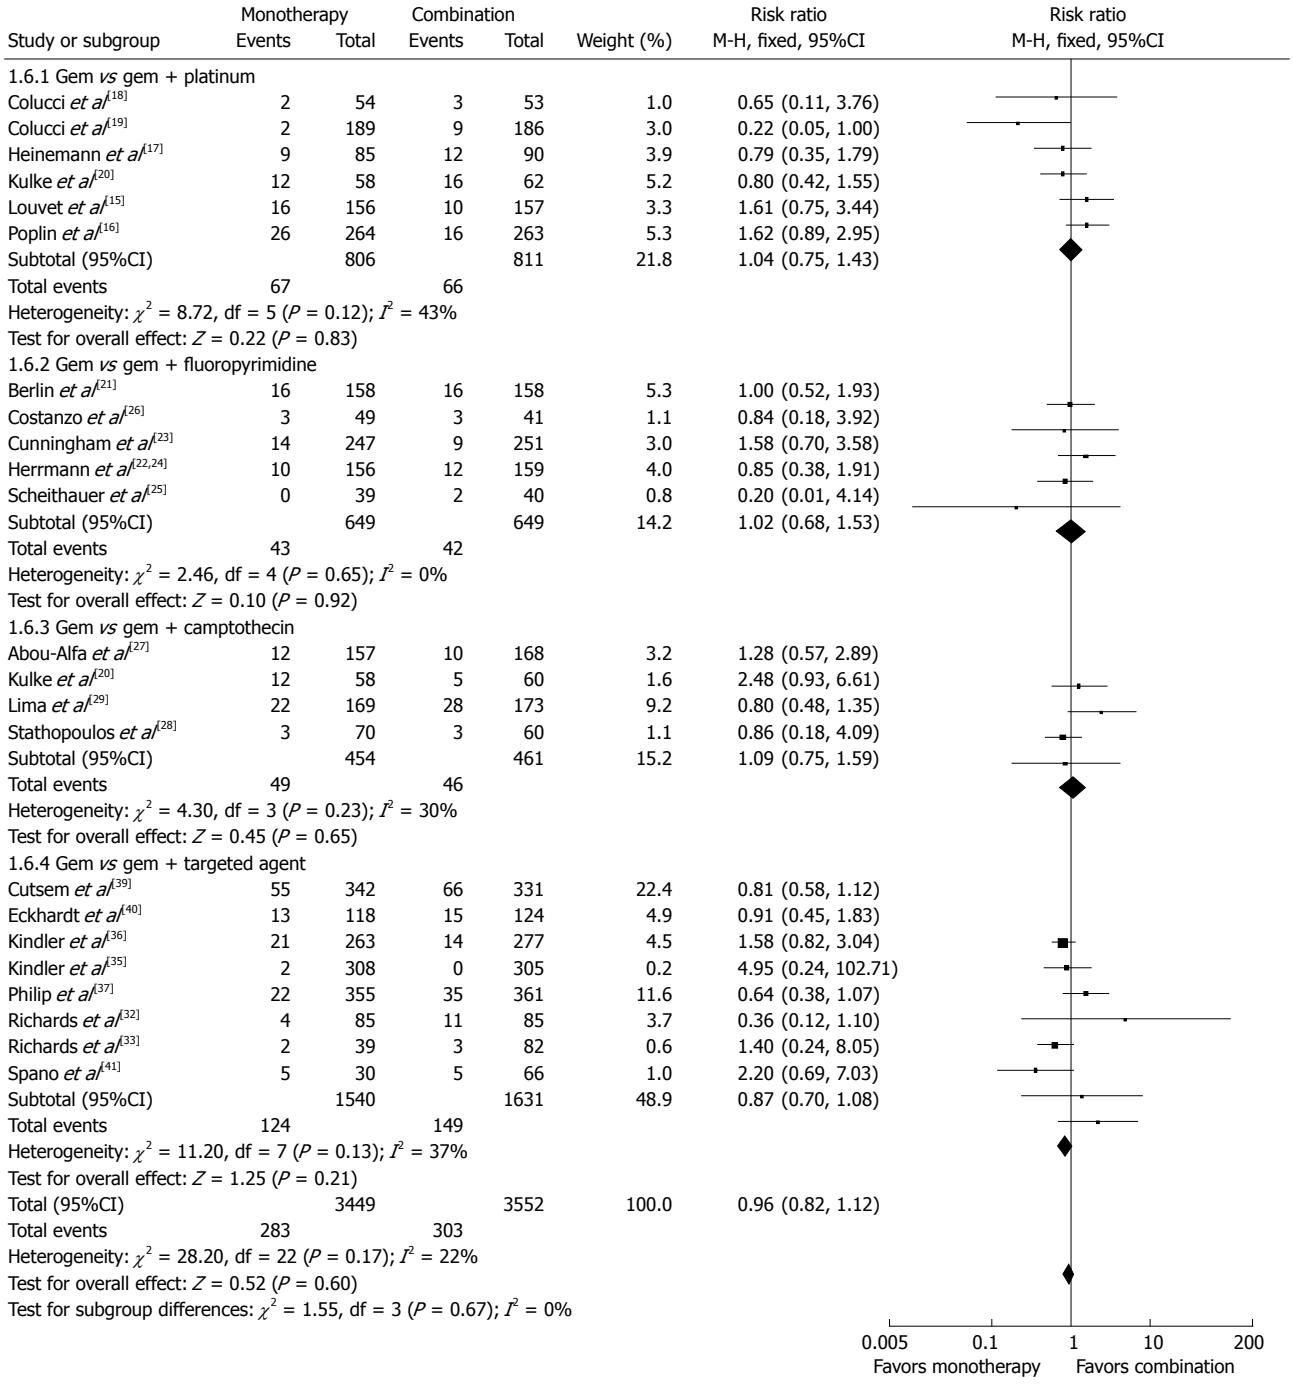

Figure 7 Fixed effect model of risk ratio of grade 3 or 4 anemia. CI: Confidence interval.

only had a 10% lower 1-year OS than combination therapy. According to the present data, 1-year OS in advanced or metastatic pancreatic cancer was low (less than 20%) after gemcitabine monotherapy; therefore, the combination therapy options studied did not improve outcome in a substantial way, the prognosis still being poor[21,31,42]. In addition, there were no significant improvements found in this analysis in median PFS and median OS after combination therapy compared with monotherapy, except for gemcitabine plus fluoropyrimidine treatment. Our results are similar to previously published analyses[23,43,44]. We also assessed the five most common toxicities related to chemotherapeutic treatment of locally advanced or metastatic pancreatic cancer, including hematological and gastrointestinal side effects. Grade 3-4 toxicities tended to be higher following combination therapy compared with monotherapy, and three of the five investigated toxicities reached significant differences. The RRs of vomiting, diarrhea, and thrombocytopenia in the monotherapy group were about 70% of that noted in the combination therapy group. Furthermore, subgroup analysis showed that the RR of vomiting after treatment with gemcitabine plus platinum was twice that of monotherapy. The results presented here showed that combination therapy induced

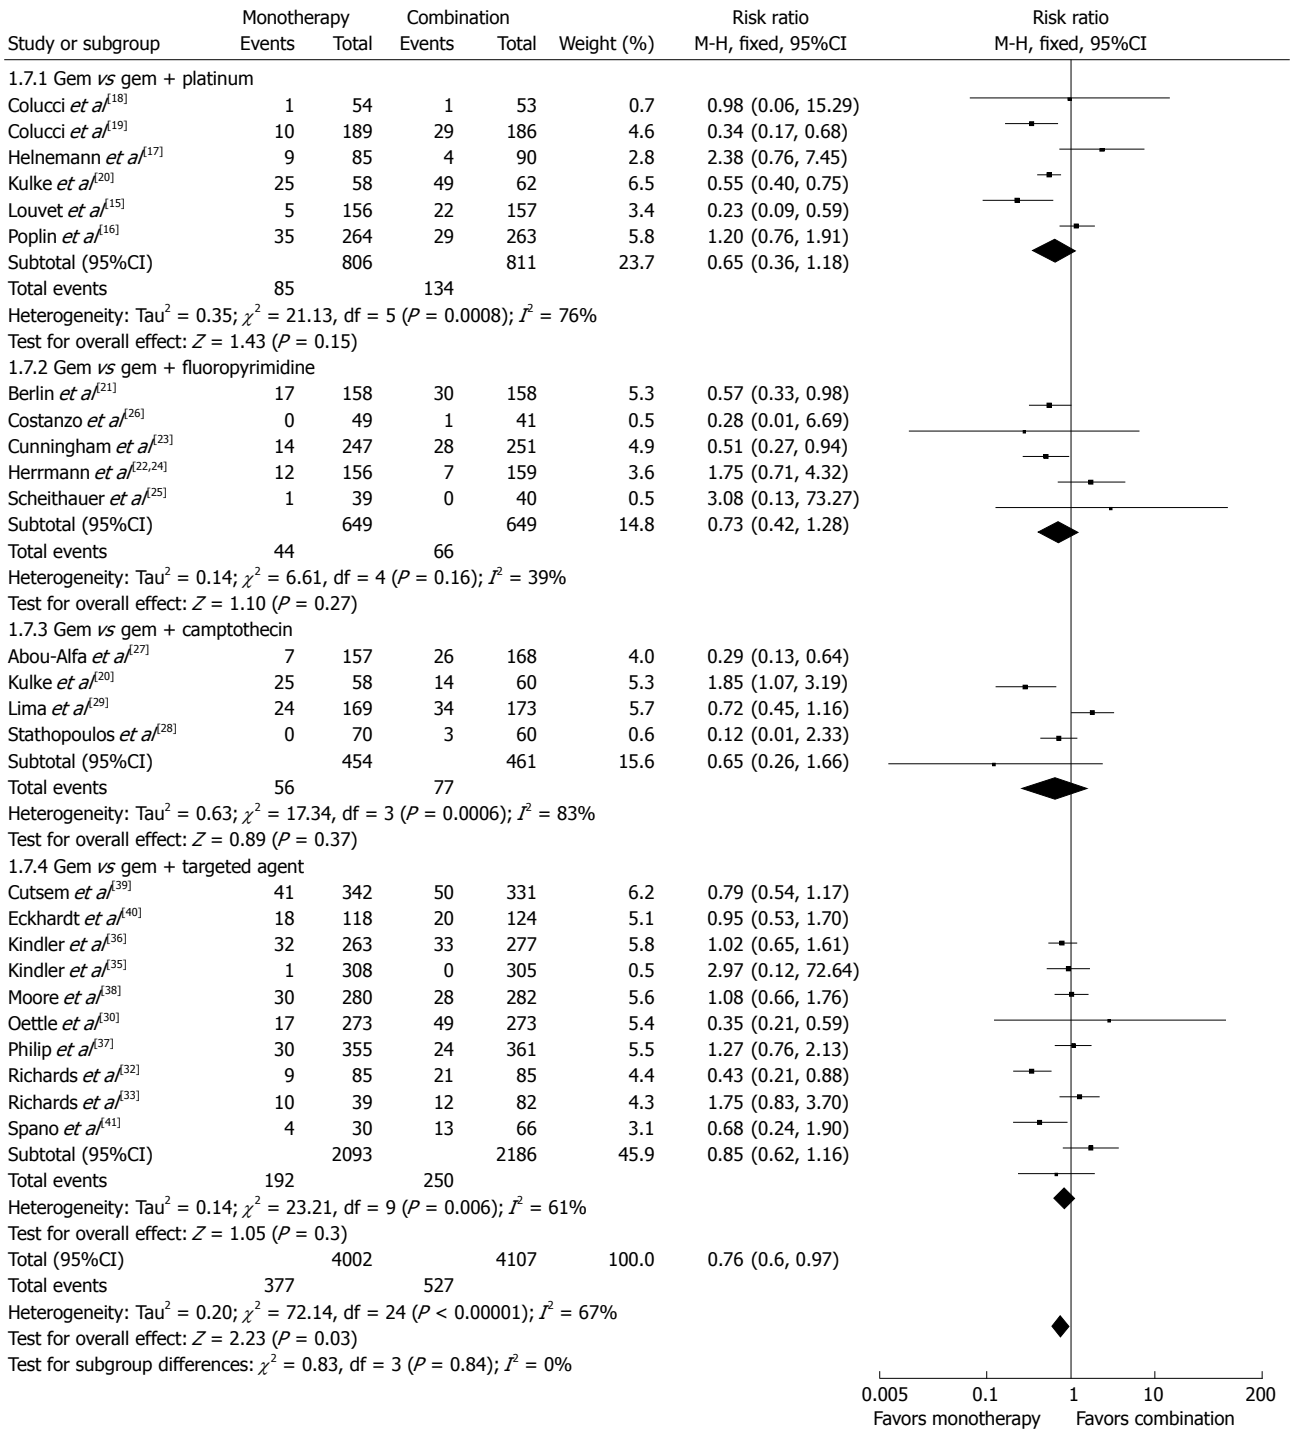

Figure 8 Random effect model of risk ratio of grade 3 or 4 thrombocytopenia. CI: Confidence interval.

more toxicity than gemcitabine alone. Similar results were found in a previous study[45]. This finding might explain why combination therapy received higher ORR, but without affecting the overall prognosis, as toxicities counterbalanced the positive effects.

In the present analysis, we included several kinds of combination therapies with gemcitabine, which could provide different anti-tumor effects and different uptake and toxicity profiles, including platinum based agents, topoisomerase inhibitors, taxanes, bevacizumab, cetuximab and other biologically targeted agents. However, no significant differences were found between the subgroups, except for side-effects (vomiting). In addition, the analysis of heterogeneity was not significant in most subgroups. This is interesting, and indicates that effectiveness of the different combinations regarding outcomes could not clearly be shown. There are two possible reasons that could explain these results. One is related to gemcitabine-uptake receptors. The other one could be the inherent drug-resistant character of pancreatic carcinoma cells and

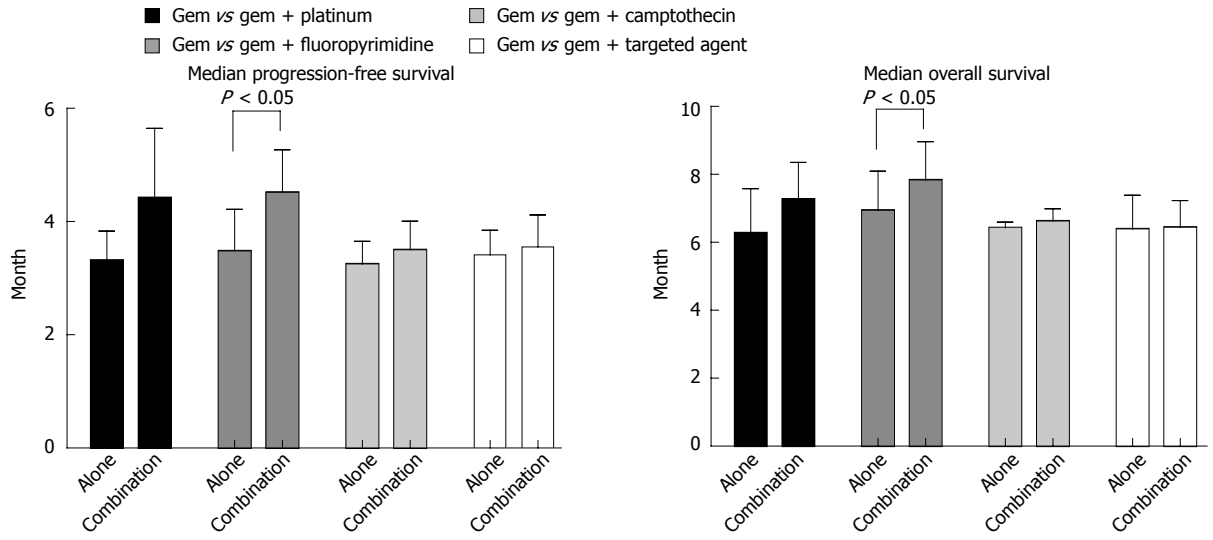

Figure 9 Median progression-free survival and overall survival between gem-monotherapy and combination therapy.

the effect of the surrounding stroma.

Human equilibrative nucleoside transporter-1 (hENT-1) is the main membrane channel responsible for intracellular bioavailability of gemcitabine. Preclinical and clinical data have revealed that only a minority of patients have high hENT1 expression and reduced levels of hENT-1 expression correlate with increased resistance to gemcitabine[7]. To increase gemcitabine efficiency and

avoid overtreatment, determination of the hENT1 status at the time of diagnosis and modifying gemcitabine to allow it to bypass the receptor may represent a future mode of overcoming gemcitabine resistance[7]. Multidrug resistance proteins, including ABC transporters, have also been implied in drug resistance in pancreatic cancer and limit the efficacy of gemcitabine[46]. The pancreatic stellate cell has a key role in stroma formation and secretes factors that promote pancreatic tumor growth and resistance to radiation and gemcitabine chemotherapy[47]. The hypoxic stroma could be a physical barrier preventing chemotherapeutic drugs from reaching the pancreatic cancer cells per se, and depletion of the stroma could enhance cancer drug delivery[48]. Recently, cancer stem cells and epithelial to mesenchymal transition (EMT)-type cells have been implicated in metastasis formation and drug resistance[49]. Selective targeting of cancer stem cells and EMT-type cells might represent a future strategy to enhance chemosensitivity. The plasma circulating time of gemcitabine is short and its rapid metabolism thus limits tumor uptake. Using novel formulas such as PEGylated gemcitabine may result in a prolonged circulation time, and possibly inducing cytotoxicity at lower concentrations than those required with treatment with the native drug[50]. Pancreatic cancer, including its concurrent stroma, is complex; therefore, treatment with a single anti-tumor agent may not be effective enough. Determining the underlying mechanisms of drug resistance in pancreatic cancer will provide ways of overcoming chemoresistance and provide a foundation for novel therapies.

During the last decade, several meta-analyses have focused on the efficacy of combination therapy in locally advanced or metastatic pancreatic cancer[43,44,51-54]. Most of these studies have reported positive trends or have concluded that combination treatments may improve outcome, but only a limited number of the studies have reported toxicity data, or have only focused on one anti-tumor agent. In the present study, we collected and analyzed the outcomes in different chemotherapeutic subgroups, as well as toxicity, to make the result more comprehensive and convincing. However, several limitations in this analysis should still be considered. Firstly, some endpoints were not evaluated in all of the included randomised controlled trials. Secondly, heterogeneity of certain endpoints in some subgroups might limit the comparability between studies and affect the validity, despite the use of randomized models.

In conclusion, we compared the outcomes of different combination therapies with gemcitabine monotherapy, including ORR, OS, PFS and major toxicity. The results showed that gemcitabine combination therapy leads to a modest improvement in survival, though with more toxicity reported compared with gemcitabine monotherapy.

COMMENTS

Background

Pancreatic cancer is a devastating disease with a dismal prognosis. The majority of patients (80%-90%) have unresectable disease at diagnosis and have to rely on palliative chemotherapy alone. In this situation, the goals of chemotherapy should be to control tumor progression and improve the survival rate with minimal toxicity.

Research frontiers

Gemcitabine has long been the first-line chemotherapeutic agent in pancreatic cancer. However, because of high levels of intrinsic and acquired chemoresistance, a large number of patients do not respond to the drug. In an attempt to improve clinical efficacy, systemically administered gemcitabine has been combined with a second cytotoxic agent, such as platinum analogs, fluoropyrimidine, or a targeted cytotoxic agent. However, the added value of these additive agents is unknown.

Innovations and breakthroughs

The present meta-analysis included 26 high-quality randomized trials comparing gemcitabine monotherapy with gemcitabine combination therapy. The primary outcome variables evaluated were objective response rate, overall survival, progression-free survival and major toxicity. The results showed that gemcitabine combination therapy was associated with only a modest improvement in survival, though with more toxicity reported, compared with gemcitabine monotherapy.

Applications

The results of this study imply that current treatments for unresectable pancreatic cancer are not sufficiently effective. Further research concerning the mechanisms involved in drug resistance in pancreatic cancer could discover ways of overcoming chemoresistance and lead to novel types of therapy.

Peer review

This is a meta-analysis concerning combination chemotherapy with Gemcitabine unresectable pancreatic cancer. The manuscript is well written and represents elaborative work.

Abstract

Cameron lesions represent linear gastric erosions and ulcers on the crests of mucosal folds in the distal neck of a hiatal hernia (HH). Such lesions may be found in upto 50% of endoscopies performed for another indication. Though typically asymptomatic, these may rarely present as acute, severe upper gastrointestinal bleed (GIB). The aim is to report a case of a non-anemic 87-year-old female with history of HH and atrial fibrillation who presented with hematemesis and melena resulting in hypovolemic shock. Repeat esophagogastroduodenoscopy was required to identify multiple Cameron ulcers as the source. Endoscopy in a patient with HH should involve meticulous visualization of hernia neck and surrounding mucosa. Cameron ulcers should be considered in all patients with severe, acute GIB and especially in those with known HH with or without chronic anemia.

INTRODUCTION

The incidence of hiatal hernia (HH) rises with age[1]. Given the rising demographics and the growing number of endoscopies, this condition now constitutes an increasingly common endoscopic finding. One study reported the incidence to be upwards of 50% during upper endoscopies performed for another indication[2]. Though typically asymptomatic, several complications can occur including gastroesophageal reflux disease[3], iron deficiency anemia[4], acute or chronic bleeding[5], and ulcer or erosion formation[2]. Usually an incidental endoscopic finding, Cameron lesions represent linear gastric erosions and ulcers on the crests of mucosal folds in the distal neck of a HH. Both erosions and ulcers are thought to be distinct forms of the same disease process. Lesions are found in 5.2% of patients with HH identified on upper endoscopy[6] and in over 60%, multiple lesions may be found[1].

CASE REPORT

An 87-year-old female presented to the Emergency Department (ED) with several episodes of bright red hematemesis and black, tarry stools over six hours. She complained of severe lightheadedness and crampy, lower abdominal pain. On examination, she was found to be hypotensive with systolic blood pressures in the 60s, and despite aggressive resuscitation with intravenous fluids

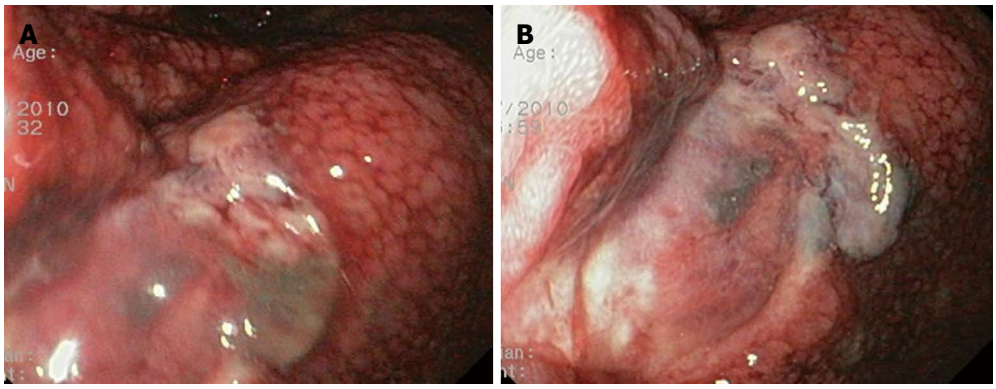

Figure 1 Ulcer with vessel in hernia sac. A: Retroflexed view of cameron ulcer; B: Second ulcer.

and blood products, she required vasopressors.

Two days earlier, she had been discharged following a brief hospital stay for atrial fibrillation and a large HH. She had been conservatively treated with proton pump inhibitor, Sucralfate, and Ondansetron as needed with fair results.

At this presentation, hemoglobin (Hgb) was 12.7 g/dL (baseline of 14.8 g/dL). Nasogastric lavage returned 500 cc of bright red blood. Intravenous proton pump inhibitor was started, patient was intubated and an emergent EGD revealed a large clot in the gastric fundus along with diffuse, friable mucosa in the mid-distal esophagus. No other bleeding site was identified. Despite multiple units of packed red blood cells and fresh frozen plasma, the patient's hemoglobin continued to decline. A repeat EGD demonstrated multiple circumferential non-bleeding Cameron ulcers at 37 cm with large placental clots in the fundus (Figure 1). Small clots were also seen at the gastroesophageal junction. In total, the patient received 14 units of packed red blood cells, multiple units of fresh frozen plasma, protamine sulfate and Vitamin K. Her Hgb stabilized on hospital day 10. During the course, she developed aspiration pneumonia, which was successfully treated with antibiotics. No further bleeding occurred and the patient recovered.

DISCUSSION

The pathogenesis of Cameron lesions is poorly understood. Some attribute lesion formation to mechanical trauma to the esophagus caused by respiration-related diaphragmatic contractions[6]. Other etiological factors may include acid reflux, ischemia, *Helicobacter pylori* infection, gastric stasis or vascular stasis[7]. It is likely that the etiology is multifactorial, and includes genotype, phenotype and patient risk factors including underlying co-morbidities and medication use. The prevalence is also likely dependent on the size of the HH with a 10%-20% risk for Cameron ulcers in hernias 5 cm in size or greater[8]. However, the absence of HH should not rule out Cameron lesions either. One study used push enteroscopy to evaluate ninety-five patients with obscure GIB previously investigated with standard endoscopy. Of the thirty-nine patients with an identifiable source, Cameron lesions were the second most commonly missed lesion (21%)[9]. Presumably, the lack of a large HH may have reduced the suspicion for Cameron lesions. Among the most concerning clinical manifestations of Cameron lesions are acute and chronic GIB. Chronic blood loss resulting in anemia has been well described. A large prospective, national, population-based study found that patients with HH had a significantly higher association of iron-deficiency anemia as compared to those with esophagitis[4]. Additionally, in a case-controlled study, Cameron showed that of 259 patients with radiographic evidence of HH, 18 were anemic compared to 1 in the control group ($P < 0.001$)[10]. Patients with Cameron lesions typically respond well to medical treatment consisting of iron supplementation with or without acid-suppression therapy. It is worth noting that our patient's MCV was 97 on admission without any supplementation.

More alarming are lesions that present as severe, acute GIB. Studies have reported rates of 29%-58%, raising the possibility of life-threatening hemorrhage[2,10]. To our knowledge, there are very few reports of life-threatening upper GIB secondary to a Cameron ulcer. One case report describes the successful treatment of a visible vessel within a Cameron ulcer with band ligation[11]. However, in these cases, surgical intervention is recommended, as endoscopic hemostasis can be technically difficult. Potential risks of endoscopy in acute, upper GIB include deep ulcers and perforation as the gastrointestinal wall around the gastroesophageal junction lacks fibrous tissue. Thus, surgery should be considered in those with either severe sliding hernias with Cameron lesions and in patients with lesion-related complications refractory to medical treatment[12]. Long-term recurrence rates are extremely low following surgery[13].

Complicating our case was the need to anticoagulate the patient for atrial fibrillation prior to endoscopy. More studies are needed to evaluate whether radiographic evidence of large HH should prompt an endoscopy prior to anticoagulation. In conclusion, endoscopy in a patient with radiographic evidence of large HH should involve meticulous antegrade and retrograde visualization with views of hernia neck and surrounding mucosa. Cameron

ulcers are a potential source of severe, acute GIB in patients with known HH with or without chronic anemia.

Abstract

Metastases of esophageal carcinoma to the skeletal muscle are rare, but the incidence may be increasing because of better diagnosis resulting from widespread use of positron emission tomography/computed tomography (PET/CT). A cohort of 205 patients with esophageal carcinoma treated at our center who had PET/CT between 2006 and 2010 was retrospectively evaluated for the presence of skeletal muscle metastases. Four patients had skeletal muscle metastases of esophageal carcinoma, including two patients with squamous cell carcinoma. In another patient with squamous cell carcinoma of the esophagus and synchronous skeletal muscle metastases, muscle metastases were subsequently shown to be related to second primary pancreatic adenocarcinoma. In all cases, skeletal muscle metastases were the first manifestation of systemic disease. In three patients palliation was obtained with the combination of external beam radiation therapy, systemic chemotherapy or surgical resection. Skeletal muscle metastases are a rare complication of esophageal carcinoma.

INTRODUCTION

The prognosis of esophageal carcinoma is, in general, poor, with the mortality rate reaching 90% of the incidence rate[1]. Both uncontrolled growth of the primary tumor or locoregional recurrence and distant metastases may be the ultimate cause of death in individual patient.

Esophageal carcinoma commonly spreads to the liver, lung, adrenals, bone, pleura, peritoneum or pericardium. Less frequent sites of metastases include thyroid, pancreas, spleen, ovary, kidney, heart, skin, gallbladder or small and large bowel[2,3]. Metastatic involvement of skeletal muscle is rare.

Until recently, asymptomatic skeletal muscle metastases (SMM) were detected only fortuitously. The widespread use of positron emission tomography/computed tomography (PET/CT) resulted in the detection of asymptomatic metastases in different organs, including skeletal muscle. A number of case reports or case series on SMM in patients with different primary tumors, including esophageal carcinoma, have been published[4-8], but the natural history of SMM in patients with esophageal carcinoma remains largely unknown. We report here five cases of patients with esophageal carcinoma and SMM observed in our center.

CASE REPORT

Records of 205 patients with esophageal carcinoma treated at our center who had PET/CT between 2006 and 2010 were searched to identify patients who had SMM diagnosed.

SMM were diagnosed in 5 patients (2%), all males. In one of these patients, SMM were subsequently shown to be related to a second primary tumor (Table 1). The details of these cases are outlined below.

Case 1

A 64-year-old male was diagnosed with adenocarcinoma of the distal esophagus in February 2004. The staging examination that included laparoscopy did not reveal distant metastases. The patient was treated with neoadjuvant chemoradiation. Transhiatal esophagectomy was performed on June 1, 2004. Histological examination of the resection specimen revealed pathologic complete response. The course of the follow-up was uneventful until October 2006 when the patient observed a resistance in the left thigh. Whole body [^{18}F] fluorodeoxyglucose (FDG) PET/CT performed in December 2006 revealed high focal uptake in the left quadriceps femoris muscle and in the left inguinal and iliac lymph nodes (Figure 1), with no evidence of a second primary tumor. An excisional biopsy established the diagnosis of SMM of adenocarcinoma.

The metastatic involvement of skeletal muscle and lymph nodes was treated with external beam radiation (50 Gy) that was administered in February and March 2007 along with 2 cycles of systemic chemotherapy (cisplatin and 5-fluorouracil). Four cycles of systemic chemotherapy using the same schedule have been administered subsequently until September 2007. A control FDG PET/CT in October 2007 demonstrated persistent uptake of radioactivity in the thigh metastasis that decreased in size. Additional metastatic lesions were discovered in medial condylus of the left femur and the retroperitoneal lymph nodes. The patient was feeling well and was subsequently only followed. In May 2008 an edema of the left lower extremity manifested. Control FDG PET/CT in June 2008 demonstrated uptake in retroperitoneal, mediastinal and left supraclavicular lymph nodes, lungs and left tibia as well as persistent accumulation in the left thigh. Between July and October 2008, the patient was treated with 5 cycles of combination of cisplatin and 5-fluorouracil. After the completion of chemotherapy, only symptomatic therapy was administered. The patient died on May 18, 2009, 31 mo after the diagnosis of skeletal muscle metastasis. An autopsy was not performed.

Case 2

76-year-old male was diagnosed in June 2006 with squamous cell carcinoma of the middle esophagus. Staging FDG PET/CT did not reveal distant metastases or evidence of a second primary tumor. The patient was treated with neoadjuvant chemoradiation that consisted of external beam radiation (50 Gy in 25 fractions of 2 Gy with systemic cisplatin and 5-fluorouracil). The control FDG PET/CT in November 2006 revealed complete disappearance of FDG uptake in the primary, but a pathologic accumulation in the right gluteus minimus muscle (21 mm × 14 mm in size) was noted. Because of complete response, patient age and uncertainty about the systemic disease, esophagectomy was not performed, and the patient was further only followed. On control FDG PET/CT, no uptake in the primary tumor was observed, but the size of the lesion in gluteus minimus muscle increased to 66 mm × 44 mm × 34 mm and involved bone. In addition, similar lesion was noted in the left psoas muscle. A biopsy performed in April 2007 confirmed metastasis of squamous cell carcinoma. Between May and July 2007 external beam radiation was administered to both lesions (70 Gy in 35 fractions of 2 Gy) concomitantly with 2 cycles of systemic cisplatin and 5-fluorouracil. Control FDG PET/CT in September 2007 demonstrated metastatic spread to the lungs, pleura, adrenals and retroperitoneal lymph nodes. Only symptomatic therapy was administered after the diagnosis of progressive metastatic disease, and the patient died on March 4, 2008, 16 mo after detection of SMM. An autopsy was not performed.

Case 3

A 57-year-old male was diagnosed in September 2006 with squamous cell carcinoma of the middle third of the esophagus. Staging FDG PET/CT performed in October 2006 revealed an accumulation of radioactivity not only in the primary tumor, but also in the skeleton of the pelvis and in the right subscapularis muscle. No evidence of a second primary tumor was found. The biopsy of the lesions was considered technically difficult, and the diagnosis of metastatic esophageal carcinoma was made based on multiplicity and appearance of lesions. Between October and December 2006 the patient was treated with 3 cycles of systemic chemotherapy (cisplatin and 5-fluorouracil). Chemotherapy had to be interrupted in January 2007 because of pneumonia. A control FDG PET/CT

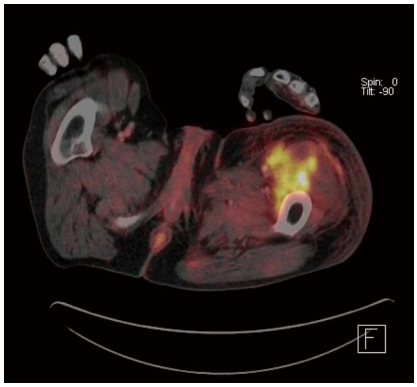

Figure 1 [^{18}F] fluorodeoxyglucose positron emission tomography/computed tomography showing a metastasis in the left quadriceps femoris muscle.

in February 2007 revealed mild progression. Palliative external beam radiation therapy (45 Gy in 18 fractions of 2.5 Gy) of all three sites of disease was then performed, but the condition of the patient deteriorated, with the progression of dysphagia. The patient died on March 24, 2007, 5 mo after the diagnosis of SMM. An autopsy was not performed.

Case 4

42-year-old male presented with adenocarcinoma of distal esophagus and cardia in April 2010. Staging FDG PET/CT demonstrated high FDG uptake in the primary tumor and a 2 cm mass in the iliacus muscle, with no evidence of a second primary tumor. As staging laparoscopy performed in May 2010 did not reveal spread in the abdominal cavity, the patient was referred for concomitant chemoradiation (50 Gy in 25 fractions of 2 Gy) and 2 cycles of systemic chemotherapy (cisplatin and 5-fluorouracil). Control PET/CT in October 2010 demonstrated only moderate progression in the primary, but marked progression of SMM (4 cm). The patient underwent subsequently (in October 2010) esophagectomy and resection of the muscle mass. Histologic examination of the muscle metastasis demonstrated poorly differentiated adenocarcinoma similar to the esophageal primary. The patient was then followed. In April 2011, the patient presented again with dysphagic complaints. Stenosis of the anastomosis was detected, and biopsy confirmed recurrence of adenocarcinoma. During the surgery to perform a jejunostomy, peritoneal carcinomatosis was detected and a large abdominal metastasis was resected. After a brief course of investigational therapy in a clinical trial the disease progressed and the patient was treated symptomatically. The patient died on August 27, 2011, 16 mo after diagnosis of SMM. An autopsy was not performed.

Case 5

60-year-old male was diagnosed in January 2010 with squamous cell carcinoma of the distal esophagus. Staging FDG PET/CT performed in February 2010 demonstrated high uptake in the tumor of distal esophagus, in lymph nodes adjacent to lesser curvature of the stomach, in the liver, left adrenal, bone and multiple metastases in skeletal muscle, including gluteus maximus muscle. Because of the extent of metastatic disease, only symptomatic therapy was indicated and histological verification of metastases was not sought. An esophageal stent was introduced to palliate the stenosis. The procedure resulted in the relief of the symptoms of short duration, but in March 2010 the condition of the patient deteriorated, he was admitted for back pain and died on March 21, 2010. Autopsy demonstrated, besides squamous cell carcinoma of the distal esophagus, a second primary pancreatic adenocarcinoma. Autopsy also revealed metastases in mediastinal and abdominal lymph nodes, peritoneum, pleura, lung, liver, kidneys, adrenal, thyroid, left submandibular gland, skeletal muscle, subcutis and bone. The histology of all metastases was adenocarcinoma pointing to pancreatic primary.

DISCUSSION

The 2% incidence of SMM in the present series may be affected by selection bias, as the primary diagnosis in one of the patients was performed before 2006. The information on esophageal carcinoma SMM is limited to individual case reports (Table 2), or to series of patients with SMM[5]. However, in most series of patients with SMM, no cases of patients with esophageal primary have been described[4,6-8]. SMM were also not reported in most autopsy series of esophageal carcinoma patients[2,3,9,10]. Cases of SMM have also been described in patients with gastric cancer[6]. To the best of our knowledge, only one case of squamous cell carcinoma of the esophagus metastatic to the skeletal muscle has been reported so far, with few details described[5]. Two of the patients reported here therefore represent the second description SMM of squamous cell carcinoma of the esophagus. The case of the patient with clinically undetected pancreatic adenocarcinoma demonstrates that histological verification may be needed not only to verify the neoplastic nature of the muscle lesion, but also to determine the primary as the frequency of second primary tumors is increasing. This case also indicates that a possible occult second primary tumor represents limitation in retrospective series of rare distant metastases. Histological verification confirming esophageal primary origin was possible in 3 out of 4 remaining cases. In all four cases SMMs were the first manifestation of metastatic disease. In patients with metachronous metastases, SMM involvement preceded the manifestation of metastatic spread to other organs by several months and survival times were relatively favorable in the context of metastatic esophageal carcinoma.

SMM detected with imaging studies were reported in 1%-2% of all patients with metastatic disease, with metastatic involvement limited to skeletal muscle reported in less than 10% of patients[11]. Similarly to the present series, most patients with SMM have metastasis only in one muscle[11]. Given the mass of skeletal muscle in the body, one would expect the metastases to this tissue to be more frequent. Experimental data suggest that muscle contractions result in mechanical destruction of tumor cells arrested in the microvasculature[12]. It has also been hypothesized that high lactate concentrations in the skeletal muscle microenvironment may decrease the responsiveness of muscle vessels to hypoxia, creating an environment unfavorable to angiogenesis[13].

PET/CT is currently being extensively utilized for pre-therapeutic staging of esophageal carcinoma because it was demonstrated that distant metastases missed by other imaging studies may be detected[14,15]. Individual cases of esophageal carcinoma SMM have been noted in cohorts of patients staged by PET/CT[16]. The increased incidence of esophageal carcinoma SMM may not only be the result of better diagnosis with PET/CT, but also of improved prognosis resulting from better control of the primary with the use of combined modality treatment. In fact, in one of the patients in the present series, the patient who had pathologic complete response after primary treatment two years earlier, the diagnosis could be made based on clinical presentation. It is therefore possible that with advances in the therapy of esophageal

carcinoma we will witness a further continuous increase of the incidence of SMM.

Little is known about the outcome of metastases affecting specific sites and optimal management of these patients, with the only source of information being anecdotal reports like the present series. In contrast to metastases affecting other organs, e.g., bone, no organ-specific drugs like bisphosphonates are available for SMM. Moreover, the potential utilization of new radiotherapy techniques in SMM is, for obvious reasons, limited. Prolonged survival has been observed in individual patients managed by combination of external beam radiation, surgery or chemotherapy[4,17]. Based on the experience in the present series and other cases reported in the literature, only general recommendations for the management of patients with SMM, including SMM of esophageal carcinoma, can be outlined. Important consideration is symptom control, and the therapeutic strategy has to be tailored according the muscle affected. Similarly to metastases of other location, the best control may be obtained with surgery which is, however, meaningful only in patients with isolated SMM. In addition, surgery may be necessary to establish the diagnosis of SMM. External beam radiation should be reserved for patients with inoperable or recurrent SMM, including patients with metastases in other sites, and best results may be obtained when combining radiation with platinum-based chemotherapy. No standard fractionation regimen or technique has been established in this rare indication. Outside of setting of chemoradiation regimens, the role of systemic chemotherapy in the management of SMM seems to be limited, but systemic chemotherapy may be an only option in patients with widespread metastases and good general condition. For patients in poor general condition, only symptomatic therapy (mostly corticosteroids and pain medication) is indicated.

In conclusion, while SMM represent a rare event in patients with esophageal carcinoma, the incidence may be increasing because of better diagnosis or improved control of the primary. SMM may represent the first manifestation of metastatic disease. An active therapeutic approach using surgery, external beam radiation and chemotherapy may result in survival that is substantially longer compared to other cases of metastatic esophageal carcinoma.

Abstract

A primary benign schwannoma of the liver is extremely rare and is difficult to preoperatively discriminate from a malignant tumor. We compared the imaging and pathological findings, and examined the possibility of preoperatively diagnosing a benign liver schwannoma. A 72-year-old woman was admitted to our hospital because of a 4.6-cm mass in the liver. A malignant tumor was suspected, and a right hepatectomy was performed. After this, the diagnosis of a primary benign schwannoma of the liver was made through pathological examination. Contrast-enhanced ultrasonography (CEUS) with Sonazoid showed minute blood flows into the septum and solid areas of the tumor in the vascular phase; most likely due to increased arterial flow associated with infiltration of chronic inflammatory cells. In the postvascular phase, CEUS showed contrast defect of cystic areas and delayed enhancement of solid areas; most likely due to aggregation of siderophores. Because discriminating between a benign and malignant schwannoma of the liver is difficult, surgery is generally recommended. However, the two key findings from CEUS may be useful in discriminating ancient schwannoma by recognizing the hemorrhage involved in the secondary degeneration and aggregation of siderophores.

INTRODUCTION

A schwannoma is a benign nerve sheath tumor that

originates from the Schwann cells of the nerve sheath. Schwannomas can occur in patients at any age, but are most commonly detected in patients between 20 years and 50 years of age. Although a schwannoma can develop in any part of the body, the most common sites include the head, neck, and flexor surfaces of the extremities[1]. Schwannomas develop infrequently in the gastrointestinal tract, the retroperitoneal cavity, and any other part of the body[2]. Thus, a primary benign schwannoma of the liver is extremely rare. Preoperative discrimination between a benign and malignant schwannoma is difficult; therefore, operation is typically recommended for a diagnosis. In the current study, we used a combination of computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET), but discrimination was still difficult. The use of preoperative imaging findings to detect liver schwannoma or the use of contrast-enhanced ultrasonography (CEUS) to detect and characterize focal liver lesions has not been previously undertaken. In this paper, we report a case of benign schwannoma, which we diagnosed using a novel method that combined CEUS with CT, MRI and PET imaging. In addition, we compared the imaging and pathological findings.

CASE REPORT

A 72-year-old woman was admitted to our hospital because a 4.6-cm mass was detected in her liver by ultrasonography (US) at a private clinic. Upon physical examination, the abdomen was soft and flat without tenderness. The liver, spleen, and superficial lymph nodes were not palpable. Blood analysis showed almost normal liver function. Carcinoembryonic antigen (CEA) and α-fetoprotein (AFP) were both negative. Hepatitis B surface antigen and hepatitis B e antibody were positive, but hepatitis C virus marker was negative. The patient's serum antibodies were negative for specific echinococcal antigens.

CT, MRI, PET and CEUS were used for the qualitative diagnosis of the liver mass. Multiphasic contrast-enhanced CT in the arterial dominant, portal venous and late venous phases was performed using a 64-slice CT scanner. A CT scan of the abdomen showed an approximately 5-cm, well-defined round tumor in segment 8 of the right hepatic lobe. The mass was hypodense and contained a minute partial calcification (Figure 1A). The mass showed heterogeneous enhancement in the arterial dominant phase (Figure 1B) and delayed enhancement until the portal venous (Figure 1C) and late venous (Figure 1D) phases. There was no evidence of fatty infiltration or cirrhosis in the background liver.

MRI revealed a hypointense mass with T1-weighted imaging (Figure 2A) and a mixed hypo- and hyperintense mass with T2-weighted imaging (Figure 2B) and diffusion-weighted imaging (DWI) (Figure 2C). The diffusion images were obtained with a b value of 1000 s/mm^2. Because the mass was hyperintense on the apparent diffusion coefficient maps, it was also hyperintense on DWI under the influence of the T2 shine-through. Gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid (Gd-EOB-DTPA) was injected at 0.025 mmol/kg body weight. Gd-EOB-DTPA-enhanced MRI showed heterogeneous enhancement in the arterial phase and delayed enhancement until the late venous phase (similar to dynamic CT imaging), but a defect in the hepatobiliary phase (Figure 2D).

An F-18 fluorodeoxyglucose PET (FDG-PET) system was used (Discovery VCT; GE Healthcare, Tokyo, Japan) with the following conditions: PET, 2-3 min/1 bed, 3.75-mm slice; CT, 120 kV, 100 mA with auto mA; tube rotation time, 0.6 s/rotation; detector collimation, 64 mm × 1.25 mm; beam pitch, 0.984; section thickness, 5.0 mm; and reconstruction pitch, 3.27 mm. FDG-PET revealed abnormal uptake in the lesion, with a maximum standardized uptake value of 3.9. There was no additional lesion in the liver, no evidence of extrahepatic disease, and no lymphadenopathy.

US showed a 4.6-cm mass that contained multiple hypoechoic cysts with mixed internal septations and solid areas (Figure 3A). CEUS with Sonazoid showed minute blood flows into the septum and solid areas of the tumor in the vascular phase (Figure 3B), and contrast defects of cystic areas and delayed enhancement of solid areas in the postvascular phase (Figure 3C).

A malignant tumor, such as a biliary cystadenocarcinoma or cholangiocellular carcinoma (CCC), was suspected. Because there was danger of seeding, we did not perform a biopsy. An operation was performed to remove the mass. At surgery, it was discovered that the tumor originated from the anterior segment of Glisson's sheath, but was tightly attached to the posterior segment of the sheath. Intraoperative cholangiography revealed a stricture in the posterior segment of the bile duct, and there was no extension of the distal bile duct. The bile duct did not have a tumor projection until strangulation. Because the tumor involved the bile duct, dissection was not possible; therefore, the patient underwent right hepatectomy.

The gross findings were a well-circumscribed, whitish/brownish, localized mass, 4.5 cm in size, which was surrounded by a fibrous capsule. The division surface of the tumor showed large and small multilocular cysts. Microscopic examination revealed that the tumor was adjacent to the peripheral nerve of the portal area, and the Antoni A hypercellular area and Antoni B hypocellular area were present in a complex (Figure 4A). In the Antoni A region, an array of irregular groups of spindle cells was seen, but nuclear palisading with Verocay bodies was not observed. In the Antoni B region, there was edematous stroma, vasodilatation, aggregation of siderophores, and slight permeation of chronic inflammatory cells of the histiocyte and the lymphocyte types (Figure 4B). Immunohistochemical staining showed a strong positive S-100 protein reaction. Vimentin, nonspecific enolase, bcl-2, and MIC2 (also known as CD99) staining

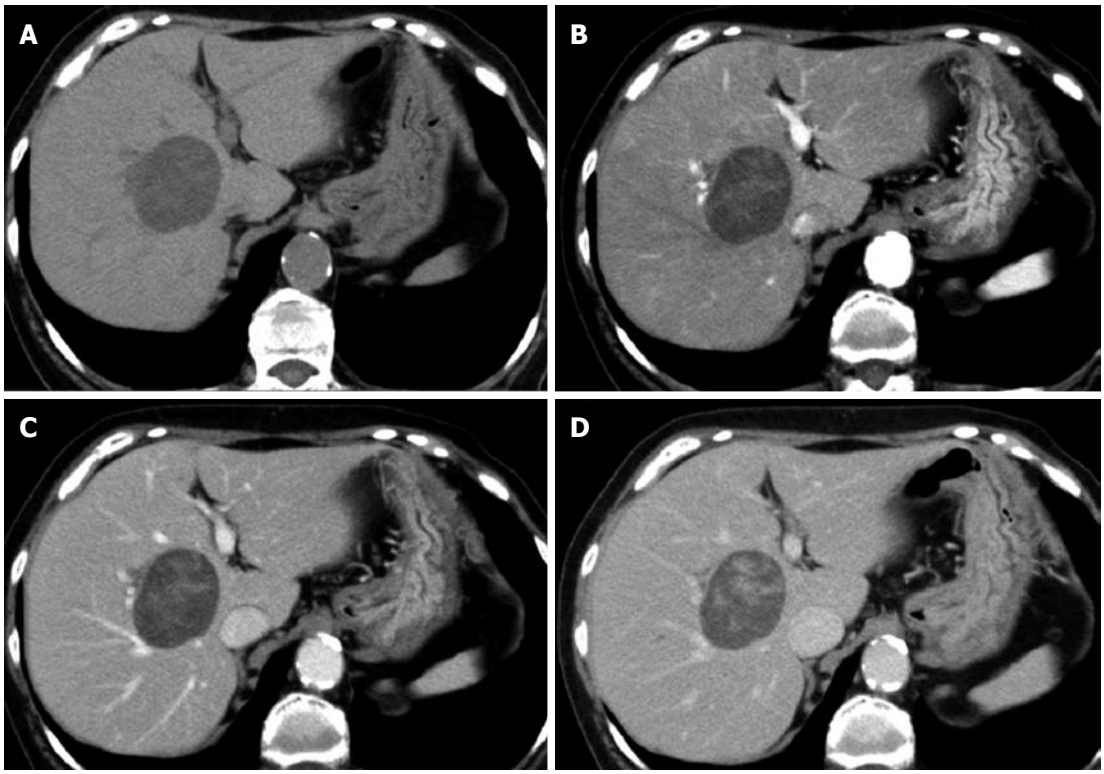

Figure 1 Abdominal computed tomography. A: Plain; B: Arterial dominant phase; C: Portal venous phase; D: Late venous phase. Abdominal computed tomography (CT) showed an approximately 5-cm well-defined round tumor in segment 8 of the right hepatic lobe. CT showed heterogeneous enhancement in the arterial dominant phase; and delayed the enhancement until the portal venous and late venous phases.

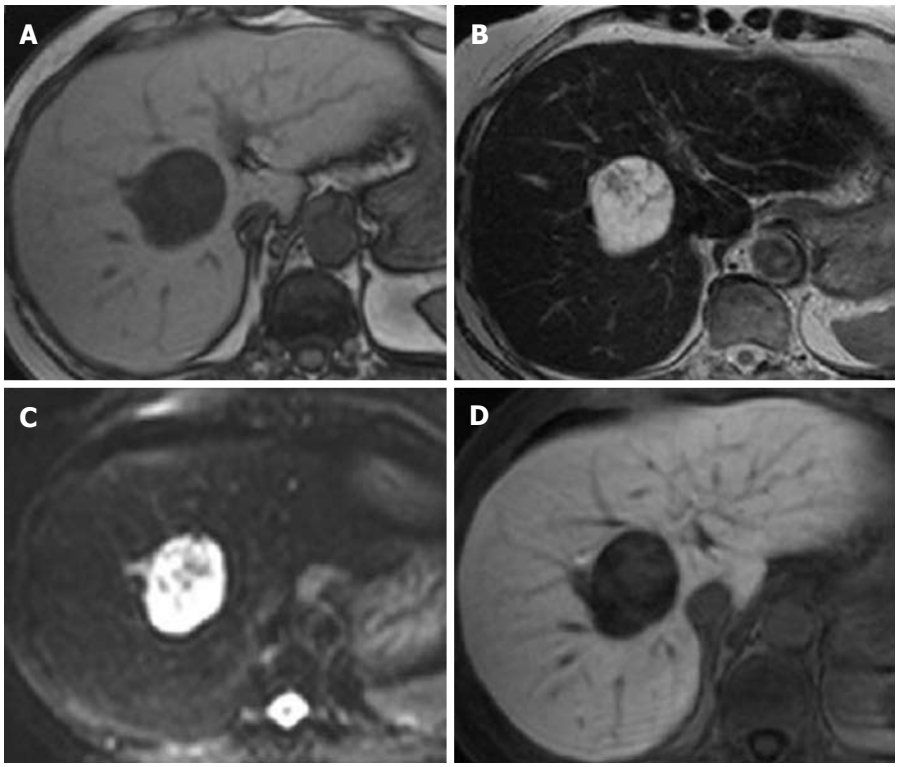

Figure 2 Magnetic resonance imaging. A: T1-weighted imaging; B: T2-weighted imaging; C: Diffusion-weighted imaging (DWI); D: Hepatobiliary phase. Magnetic resonance imaging (MRI) revealed a hypointense mass on T1-weighted imaging, and a mixed hypo- and hyperintense mass on T2-weighted imaging and on DWI. Gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid-enhanced MRI showed a defect in the hepatobiliary phase.

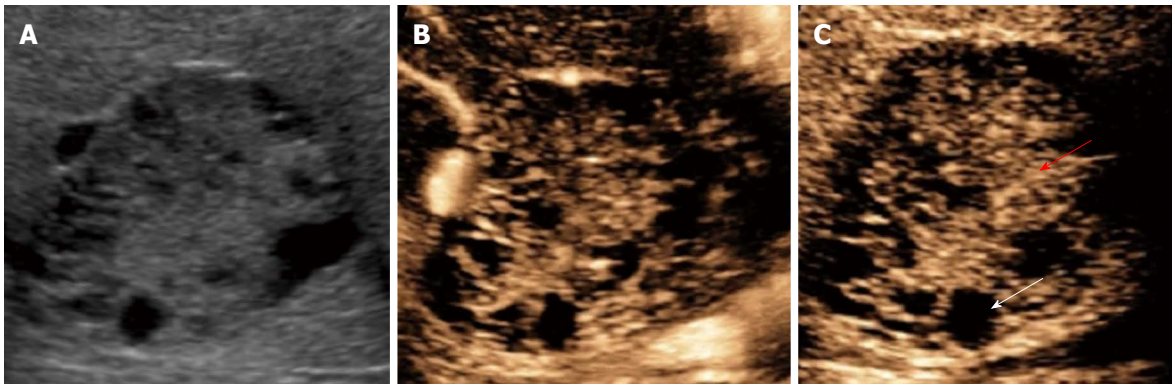

Figure 3 Contrast-enhanced ultrasonography with Sonazoid. A: B-mode ultrasound; B: Vascular phase; C: Postvascular phase. Ultrasonography showed a 4.6-cm mass that contained multiple hypoechoic cysts with mixed internal septations and solid areas. Contrast-enhanced ultrasonography with Sonazoid showed minute blood flow into the septum and solid areas of the tumor in the vascular phase, and contrast defect of cystic areas (white arrow) and delayed enhancement of solid areas (red arrow) in the postvascular phase.

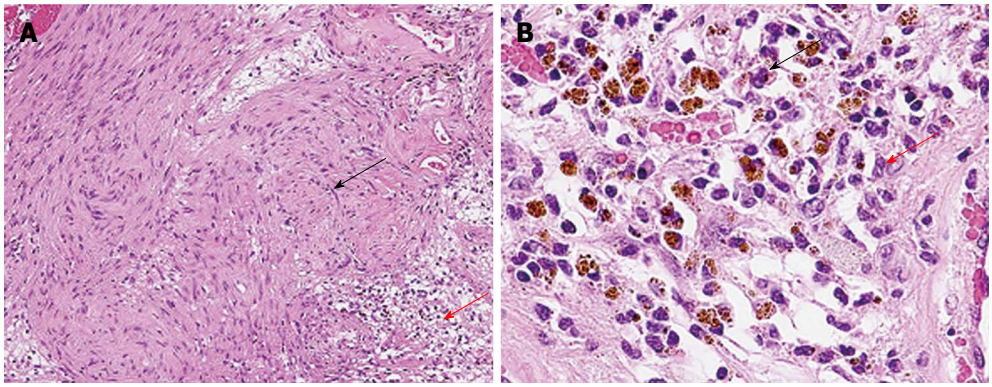

Figure 4 Microscopic examination. A: B-mode ultrasound. Microscopic examination revealed that Antoni A hypercellular area (black arrow) and Antoni B hypocellular area (red arrow) existed together in a complex; B: Vascular phase. In the Antoni B region, there were edematous stroma, vasodilatation, aggregation of siderophores (black arrow), and slight permeation of chronic inflammatory cells of the histiocyte and lymphocyte types (red arrow).

was also positive. The MIB-1 index was 2%. However, desmin, α-smooth muscle actin, CD34, c-kit, HMB-45, neurofilament, glial fibrillary acidic protein, and cytokeratin (AE1/AE3) staining was all negative.

On the basis of these findings, we diagnosed the patient as having a primary benign schwannoma of the liver. The patient was healthy and free from recurrence at a follow-up CT scan, which was performed 12 mo after surgery.

DISCUSSION

Histologically, schwannomas are encapsulated tumors that arise within nerve sheaths and consist of a highly ordered cellular component (Antoni A area) and a loose myxoid component (Antoni B area). In the subcellular component, spindle cells are present. Larger schwannomas have a tendency to undergo secondary degeneration, such as pseudocystic regression, hemorrhage, and calcification[3]. A primary benign schwannoma of the liver is an isolated benign tumor surrounded by a fibrous capsule. Immunohistochemical staining is diffusely and strongly positive for S-100 protein in a schwannoma, which is consistent with the markers for a nerve sheath tumor[3]. There are no specific characteristics with regard to the radiological appearance[1].

We reviewed the country of origin, size, age, sex, associated diseases, diagnosis, and prognosis of primary benign or malignant schwannomas; the findings are shown in Table 1[3-18]. Primary benign or malignant schwannomas were found in 14 women and 4 men. The age of onset was from 35 years to 74 years, and the mean age of onset was 57.5 years. While 13 cases were Asian in origin, there were no race differences. Although many hepatic schwannomas were Asian in origin, there has been no report of a causal relationship with hepatitis-associated viruses, and thus the reason for this correlation is unknown.

Generally, a CT scan depicts a schwannoma as a well-defined hypodense area, and enhanced CT shows peripheral enhancement, with an irregular pattern on the inside[10]. A delayed peripheral subject enhancement until the late venous phase in the CT scan reflects a fibrous capsule and an internal fibrillary element. With the aid of MRI, schwannomas have been described as masses with hypointensity on T1-weighted images and as masses with inhomogeneous hyperintensity or, in some cases, masses with internal heterogeneous mixed hypo- and hyperin-

Table 2 Comparison between preoperative imaging and pathological findings

Preoperative imaging technique		Characteristics	Pathology
Dynamic CT		Delayed peripheral subject enhancement	A fibrous capsule An internal fibrillary element
T2-weighted MRI		Internal heterogeneous mixed hypo- and hyperintensity	Secondary degeneration such as pseudocystic regression and hemorrhage
FDG-PET		Abnormal uptake	High cellular density (Antoni A area)
Ultrasonography	B mode	Mixed internal septations and solid areas	Division surface showed big and small multilocular cysts
	Vascular phase	Minute blood flows into septum and solid areas	Increased arterial vessel flows associated with infiltration of chronic inflammatory cells
	Postvascular phase	Delayed enhancement of solid areas	Aggregation of siderophores

CT: Computed tomography; MRI: Magnetic resonance imaging; FDG-PET: F-18 fluorodeoxyglucose-positron emission tomography.

tensity on T2-weighted images[8]. These findings reflect secondary degeneration, such as pseudocystic regression and hemorrhage. Abnormal uptake in FDG-PET reflects the high cellular density of schwannomas[19] (Table 2).

In this study, CT and MRI showed a tumor containing multiple cysts. Therefore, echinococcosis, hepatobiliary cystadenoma/adenocarcinoma or cystic liver metastasis of epithelial tumor, angiomyolipoma, leiomyoma, solitary fibrous tumor, schwannoma, or neurofibroma of the mesenchyma were possible differential diagnoses. However, it is very difficult to diagnose a schwannoma preoperatively based on its radiological appearance. Furthermore, abnormal uptake in FDG-PET did not aid the diagnosis.

Therefore, we used CEUS with Sonazoid for the preoperative diagnosis. Mixed internal septations and solid areas in B mode were reflected faithfully in the gross findings of a division surface with large and small multilocular cysts. CEUS showed minute blood flows into the septum and solid areas of the tumor in the vascular phase. The start of an inflow into a node can be confirmed within 18 s after the administration of Sonazoid. We accordingly determined that the minute blood flows were derived from the hepatic artery. Increased arterial flows were observed with the infiltration of chronic inflammatory cells of the histiocyte and lymphocyte types.

CEUS showed a contrast defect in the cystic areas and a delayed enhancement of the solid areas in the postvascular phase, which may reflect aggregation of siderophores. For example, in the case of echinococcosis, hepatobiliary cystadenoma/adenocarcinoma, cystic metastases, or CCC, CEUS shows contrast defects of the entire tumor in the postvascular phase (Table 2). Therefore, the two findings in CEUS (minute arterial flows into the tumor along the nodal septum in the vascular phase and contrast defects of the cystic areas and delayed enhancement of solid areas in the postvascular phase) are potentially useful for diagnosing an ancient schwannoma by recognizing the hemorrhage involved in the secondary degeneration and aggregation of siderophores.

The discrimination of a benign or a malignant schwannoma is difficult with preoperative imaging. However, some findings may indicate the presence of rare neoplasms such as a malignant schwannoma. The radiological features of hepatic malignant schwannoma include a well-demarcated, hypodense mass on CT, non-enhancement

on enhanced CT, and hypovascularity on angiography; in particular, hypovascularity may be an important finding for diagnosis, because most malignant hepatic tumors are hypervascular. Another important finding is the high level of alkaline phosphatase in serum with normal serum levels of hepatic transaminase and tumor markers, including CEA and AFP[13]. Nonetheless, because discrimination between a benign and malignant schwannoma is difficult, surgery is typically recommended.

In cases of malignant schwannoma, there are no reported chemotherapies and the prognosis is poor. Because the schwannoma may be tightly attached to Glisson's sheath (as in this case), surgical removal of the tumor could be very difficult, and hepatectomy that includes Glisson's sheath could be required.

In conclusion, here, we report a case of benign schwannoma, which we diagnosed using a novel method that combined CEUS with CT, MRI and PET. Because it is difficult to discriminate between a benign or malignant schwannoma of the liver, surgery is generally recommended for such tumors. Our findings with CEUS revealed minute arterial flow into the tumor along the nodal septum in the vascular phase, and delayed enhancement of solid areas in the postvascular phase. These two key observations may be useful in diagnosing an ancient schwannoma by recognizing the hemorrhage involved in the secondary degeneration and aggregation of siderophores.

Events Calendar 2012

January 13-15, 2012
Asian Pacific *Helicobacter pylori* Meeting 2012
Kuala Lumpur, Malaysia

January 19-21, 2012
American Society of Clinical Oncology 2012 Gastrointestinal Cancers Symposium
San Francisco, CA 3000, United States

January 19-21, 2012
2012 Gastrointestinal Cancers Symposium
San Francisco, CA 94103, United States

January 20-21, 2012
American Gastroenterological Association Clinical Congress of Gastroenterology and Hepatology
Miami Beach, FL 33141, United States

February 3, 2012
The Future of Obesity Treatment
London, United Kingdom

February 16-17, 2012
4th United Kingdom Swallowing Research Group Conference
London, United Kingdom

February 23, 2012
Management of Barretts Oesophagus: Everything you need to know
Cambridge, United Kingdom

February 24-27, 2012
Canadian Digestive Diseases Week 2012
Montreal, Canada

March 1-3, 2012
International Conference on Nutrition and Growth 2012
Paris, France

March 7-10, 2012
Society of American Gastrointestinal and Endoscopic Surgeons Annual Meeting
San Diego, CA 92121, United States

March 12-14, 2012
World Congress on Gastroenterology and Urology
Omaha, NE 68197, United States

March 17-20, 2012
Mayo Clinic Gastroenterology and Hepatology
Orlando, FL 32808, United States

March 26-27, 2012
26th Annual New Treatments in Chronic Liver Disease
San Diego, CA 92121, United States

March 30-April 2, 2012
Mayo Clinic Gastroenterology and Hepatology
San Antonio, TX 78249, United States

March 31-April 1, 2012
27th Annual New Treatments in Chronic Liver Disease
San Diego, CA 92121, United States

April 8-10, 2012
9th International Symposium on Functional GI Disorders
Milwaukee, WI 53202, United States

April 13-15, 2012
Asian Oncology Summit 2012
Singapore, Singapore

April 15-17, 2012
European Multidisciplinary Colorectal Cancer Congress 2012
Prague, Czech

April 18-20, 2012
The International Liver Congress 2012
Barcelona, Spain

April 19-21, 2012
Internal Medicine 2012
New Orleans, LA 70166, United States

April 20-22, 2012
Diffuse Small Bowel and Liver Diseases
Melbourne, Australia

April 22-24, 2012
EUROSON 2012 EFSUMB Annual Meeting
Madrid, Spain

April 28, 2012
Issues in Pediatric Oncology
Kiev, Ukraine

May 3-5, 2012
9th Congress of The Jordanian Society of Gastroenterology
Amman, Jordan

May 7-10, 2012
Digestive Diseases Week
Chicago, IL 60601, United States

May 17-21, 2012
2012 ASCRS Annual Meeting-American Society of Colon and Rectal Surgeons
Hollywood, FL 1300, United States

May 18-19, 2012
Pancreas Club Meeting
San Diego, CA 92101, United States

May 18-23, 2012
SGNA: Society of Gastroenterology Nurses and Associates Annual Course
Phoenix, AZ 85001, United States

May 19-22, 2012
2012-Digestive Disease Week
San Diego, CA 92121, United States

June 2-6, 2012
American Society of Colon and Rectal Surgeons Annual Meeting
San Antonio, TX 78249, United States

June 18-21, 2012
Pancreatic Cancer: Progress and Challenges
Lake Tahoe, NV 89101, United States

July 25-26, 2012
PancreasFest 2012
Pittsburgh, PA 15260, United States

September 1-4, 2012
OESO 11th World Conference
Como, Italy

September 6-8, 2012
2012 Joint International Neurogastroenterology and Motility Meeting
Bologna, Italy

September 7-9, 2012
The Viral Hepatitis Congress
Frankfurt, Germany

September 8-9, 2012
New Advances in Inflammatory Bowel Disease
La Jolla, CA 92093, United States

September 8-9, 2012
Florida Gastroenterologic Society 2012 Annual Meeting
Boca Raton, FL 33498, United States

September 15-16, 2012
Current Problems of Gastroenterology and Abdominal Surgery
Kiev, Ukraine

September 20-22, 2012
1st World Congress on Controversies in the Management of Viral Hepatitis
Prague, Czech

October 19-24, 2012
American College of Gastroenterology 77th Annual Scientific Meeting and Postgraduate Course
Las Vegas, NV 89085, United States

November 3-4, 2012
Modern Technologies in Diagnosis and Treatment of Gastroenterological Patients
Dnepropetrovsk, Ukraine

November 4-8, 2012
The Liver Meeting
San Francisco, CA 94101, United States

November 9-13, 2012
American Association for the Study of Liver Diseases
Boston, MA 02298, United States

December 1-4, 2012

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/esps/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Pancreatic ductal adenocarcinoma accounts for more than 90% of all pancreatic cancers and its incidence has increased significantly worldwide. Patients with pancreatic ductal adenocarcinoma have a poor outcome and more than 95% of the people affected die from the disease within 12 mo after diagnosis. Surgery is the first-line treatment in the case of resectable neoplasm, but only 20% of patients are candidates for this approach. One of the reasons there are few candidates for surgery is that, during the early phases of the disease, the symptoms are poor or non-specific. Early diagnosis is of crucial importance to improve patient outcome; therefore, we are looking for a good screening test. The screening test must identify the disease in an early stage in order to be effective; having said this, a need exists to introduce the concept of "early" ductal adenocarcinoma. It has been reported that at least five additional years after the occurrence of the initiating mutation are required for the acquisition of metastatic ability of pancreatic adenocarcinoma and patients die an average of two years thereafter. We have reviewed the most recent literature in order to evaluate the present and future perspectives of screening programs of this deadly disease.

INTRODUCTION

Pancreatic ductal adenocarcinoma accounts for more than 90% of all pancreatic cancers. Over the last thirty years, its incidence in Europe and the United States has increased significantly; it ranks tenth among the most common solid tumours and it is the fourth leading cause of cancer death[1]. In addition, patients with pancreatic ductal adenocarcinoma have a poor outcome; more than 95% of the people affected die from the disease within 12 mo after diagnosis[2]. There is also a lack of really effective therapy; surgery is the first-line treatment in case of resectable neoplasm, but only 20% of patients are candidates for this approach[3].

One of the reasons there are few candidates for surgery is that, during the early phases of the disease when there is greater possibility of radical surgical treatment, the symptoms are poor or non-specific. On the other hand, when the symptoms become clear, the prognosis is poor. Specifically, the majority of patients have some

disturbances only shortly before diagnosis or problems 6 mo or less before diagnosis (pain or jaundice), and only a small portion have problems more than 6 mo before diagnosis. Among the latter, some patients have anorexia and/or early satiety and/or asthenia (7-20 mo before pain or jaundice), others have a distaste for coffee and/or smoking and/or wine (7-20 mo before) and still others have diabetes (7-24 mo before) or acute pancreatitis (8-26 mo before)[4]. Thus, the United States Preventive Services Task Force has a grade D recommendation against routine screening for pancreatic cancer for asymptomatic adults using abdominal palpation, ultrasonography or serologic markers for various clinical motives: (1) there is a poor prognosis for those diagnosed with pancreatic cancer; (2) it is thought that the evidence for diet-based prevention of pancreatic cancer is limited and conflicting; and (3) only some experts recommend lifestyle changes which may help to prevent pancreatic cancer, such as stopping the use of tobacco products, moderating alcohol intake and eating a balanced diet with sufficient fruit and vegetables[5].

On the other hand, we encourage the search to continue; the do-nothing attitude must be abandoned. Early diagnosis would be of crucial importance in improving the course of the disease; therefore, we are looking for a good screening test. The screening test must identify the disease in an early stage in order to be effective; having said this, a need exists to introduce the concept of "early" ductal adenocarcinoma. Yachida *et al*[6] report the data generated by sequencing the genomes of seven pancreatic cancer metastases to evaluate the clonal relationships among primary and metastatic cancers. The authors found that clonal populations which give rise to distant metastases are represented within the primary carcinoma, but these clones are genetically evolved from the original parental, non-metastatic clone. A quantitative analysis of the timing of the genetic evolution of pancreatic cancer indicates that there is at least a decade between the occurrence of the initiating mutation and the birth of the parental, non-metastatic founder cell. Thus, at least five additional years are required for the acquisition of metastatic ability and patients die on an average of two years thereafter. This conclusion indicates that the concept of early diagnosis of ductal adenocarcinoma should be moved back several years as compared to current practice, and this renders the screening increasingly more complicated.

PAST KNOWLEDGE

Traditionally, serum markers have been used for the early diagnosis and screening of ductal pancreatic adenocarcinoma, similar to what happens in other cancers. The most widely used serum markers for pancreatic cancer are the carcinoembryonic antigen and carbohydrate antigen 19-9 (CA 19-9); although their use has been extensively evaluated in clinical practice, several studies have shown that both have a low specificity as well as a low sensitivity[7]. We found that no significant differences in serum CA 19-9 levels were observed between patients with jaundice and those without as well as between those who underwent pancreatic resection and those who were medically treated because of advanced disease[7]. In addition, we found that in the 50 patients with histological/cytological examination, the sensitivity of this marker was 57.4%, the specificity was 0%, the positive predictive value was 90.0% and the negative predictive value was 0%[7]. Finally, elevated serum CA 19-9 values were present in similar proportions in patients with (61.9%) and without jaundice (64.7%, $P = 1.000$) as well as in 58.1% of resected patients and in 68.3% of those medically treated because of advanced disease ($P = 0.459$)[7]. These data further support the conclusions of the two American Society of Clinical Oncology recommendations for the use of tumor markers in pancreatic cancer, suggesting that CA 19-9 determination is not recommended for use as a screening test for pancreatic cancer and the use of CA 19-9 testing alone is not recommended for use in determining operability or the results of surgery in pancreatic cancer[8]. The reason for which biochemical screening fails to detect pancreatic cancer is that the production of CA 19-9 becomes readily detectable only in the advanced stages of pancreatic ductal adenocarcinoma after the onset of clinical symptoms, and it would not provide opportunities for early detection and cure (for example, in detecting precancerous lesions such as pancreatic intraepithelial neoplasia or intraductal pancreatic mucinous neoplasia at the initial stages)[9]. In conclusion, it is now time to abandon the routine use of CA 19-9 determination when pancreatic cancer is suspected.

PRESENT KNOWLEDGE

Currently, screening strategy is based on the identification of genetic alterations and populations at risk in order to identify algorithms for prevention and treatment[10].

There are many syndromes associated with pancreatic cancer, such as familial pancreatitis (associated with mutations in the *PRSS1* and *SPINK1* genes)[11], Peutz-Jeghers syndrome and familial atypical multiple mole melanoma syndrome[12]. In these cases, the suggested screening techniques are endoscopic ultrasound (EUS) or abdominal magnetic resonance imaging (MRI)[13]. Another risk factor is the presence of chronic pancreatitis; in fact, approximately 5% of patients with chronic pancreatitis will develop pancreatic cancer over a 20-year period. In these cases, until the development of more sophisticated imaging procedures able to detect the presence of cancer in an altered gland affected by chronic involvement, a screening test is not recommended[14].

Similarly to other cancers, such as colon cancer, pancreatic adenocarcinoma may be present in the same family[12]. It should be pointed out that subjects from families with a history of pancreatic cancer have an inherited predisposition of developing the disease, and subjects having familial pancreatic cancer may have at least two first-

Table 1 Major molecular markers in pancreatic ductal adenocarcinoma and their roles in screening

Marker	Implication of mutation	Diagnosis
EGF/EGFR	Constitutive activation of mitogen-activated protein kinase pathway	Screening for the patients more likely to respond to EGFR inhibitors
TGF-A	Promotes metastasis	
	Brings about epithelial mesenchymal transition	
VEGF/VEGFR	Tumor cell invasion and migration promoting tumor progression	Good diagnostic tool especially in combination with Cx43
	Lymphangiogenesis and lymphatic metastasis	
FGF	Cell proliferation, migration, and invasion	Serum FGF-BP1 can be used as a marker for high-risk premalignant lesions
MMPs	Digestion of extracellular components	MMP-2 in pancreatic juice
	Cell dissociation and subsequent invasion	Serum MMP-9
		Plasma MMP-7 levels help to distinguish between PC and CP
miRNAs	Invasive capacity	Plasma miRNA profiling for blood-based biomarkers
	Metastasis and maintenance of cancer	

EGF: Endothelial growth factor; EGFR: Endothelial growth factor together with its receptors; TGF-A: Tumor growth factor-A; VEGF: Vascular endothelial growth factor; VEGFR: Vascular endothelial growth factor and its receptor; FGF: Fibroblast growth factor; MMPs: Metalloproteinases; PC: Pancreatic carcinoma; CP: Chronic pancreatitis.

degree relatives with this disease, probably demonstrating autosomal dominant transmission[15]. A computer-based risk assessment tool has recently been developed and it has been shown to provide an accurate risk assessment for relatives with familial pancreatic cancer[16]. In addition, several studies have been carried out in patients with familial pancreatic cancer[17-23]; screening relatives from families in which pancreatic cancer is familial has a significant diagnostic yield, particularly in relatives > 65 years of age, confirming prior studies showing that magnetic resonance cholangiopancreatography as an initial screening modality is safe and effective[23].

One of the few currently known pre-neoplastic lesions is that of an intraductal papillary mucinous neoplasm (IPMN). If this lesion is located in the main duct (IPMN types 1 and 3), the treatment is surgical resection; on the other hand, if the lesion is located in the branch duct (IPMN type 2), the treatment depends on the size; if the diameter is less than 1 cm, therapeutic monitoring with MRI or CT scan once a year is sufficient. Monitoring is indicated every 6-12 mo if the diameter is between 1 and 2 cm; lesions between 2 and 3 cm should be monitored every 3-6 mo while, if the lesion is greater than 3 cm, or it is smaller but with the presence of high risk stigmata or symptoms, surgery is indicated[24]. Nevertheless, the diagnosis of IPMNs is usually incidental and therefore, a screening strategy in the general population is not possible; in fact, clinical symptoms are often vague or absent, and there is rarely an increase of serum amylase and lipase[25].

FUTURE PERSPECTIVES

The future of screening for pancreatic ductal adenocarcinoma is represented by the OMICs (genomic, proteomic, metabolomic). In particular, with regard to genomic, there are two studies which correlate the genetic alterations of pancreatic cells and the genetic alterations in the genome of the cells of the immune system. Baine *et al*[26] have studied the peripheral blood mononuclear cells from pancreatic cancer patients and matched healthy controls, analyzing them by means of whole genome cDNA microarray. They found that 383 genes were significantly different between pancreatic cancer patients and healthy controls, and 65 had at least a 1.5 fold change in expression. Pathway analysis revealed that many of these genes fell into the pathways responsible for hematopoietic differentiation, cytokine signaling, and natural killer cell and CD8+ T-cell cytotoxic response. Unsupervised hierarchical clustering analysis identified an eight-gene predictor set, consisting of *SSBP2*, *Ube2b-rs1*, *CA5B*, *F5*, *TBC1D8*, *ANXA3*, *ARG1* and *ADAMTS20* capable of distinguishing pancreatic cancer patients from healthy controls with an accuracy of 79% (sensitivity 83% and specificity 75%). In the future, these data may help in diagnosing pancreatic cancer earlier. In the same way, De Monte *et al*[27] have identified the complex interaction involving cells, such as stromal and immune cells, and tumor cells in the tumor microenvironment. The result of this is an alteration of the T-cells which, instead of producing cytokines effective in fighting cancer, produce cytokines capable of promoting further progression of the disease; this lymphocyte derangement has been called "deviant lymphocytes" by the authors. The authors also identified the molecules involved in this mechanism which will allow the development of therapies to curb this activity. Antibodies are already available for some of these molecules and they are capable of blocking their activity. Most important, in a series of patients undergoing surgery, the authors also showed the existence of a correlation between the quantity of "deviant cells" present in the tumor and patient survival showing the possibility of stratifying pancreatic cancer patients into two categories having a better or a worse prognosis.

The other aspect of the future of screening for pancreatic ductal adenocarcinoma is the proteomic; in particular, it is interesting to evaluate studies with large populations whether (or not) cancer cells secrete proteins whose levels rise early in serum or in pancreatic juice.

Presently, as shown in the Table 1, the major molecular markers in pancreatic ductal adenocarcinoma evaluated in clinical practice are the following: endothelial growth

factor together with its receptors (EGFR) involved in the activation of the mitogen-activated protein kinase pathway and used as a screening test for patients who are that more likely to respond to EGFR inhibitors: (1) tumor growth factor-A, which promotes metastasis and brings about epithelial mesenchymal transition; (2) vascular endothelial growth factor and its receptor, which indicate tumor cell invasion and migration promoting tumor progression, lymphangiogenesis and lymphatic metastasis and seem to be a good diagnostic tool, especially in combination with Cx43; (3) fibroblast growth factor, which is involved in cell proliferation, migration and invasion, and can be used as a marker for high-risk premalignant lesions; (4) metalloproteinases, which are markers of the digestion of extracellular components, cell dissociation and subsequent invasion found in the pancreatic juice, in serum or in plasma and help to distinguish between pancreatic adenocarcinoma and chronic pancreatitis; and (5) miRNAs which represent a marker of invasive capacity, metastasis and maintenance of cancer, and may be an aid for developing blood-based biomarkers[28]. However, the clinical studies are largely disappointing regarding the routine use of these markers[29-31].

Finally, it should be remembered that the last OMIC is metabolomic. Neoplastic cells have an accelerated metabolism; this results in an increase of the concentration of some biochemical components in serum, and these changes may be used as markers of pancreatic cancer. Bathe *et al*[32] have studied the variations of these biochemical components in patients with pancreatic cancer. In the pancreatic cancer group, as compared to benign cases, the serum concentrations of glutamate and glucose were the most elevated on multivariate analysis. In benign cases, creatine and glutamine were most abundant. To examine the usefulness of this test, a comparison was made to age- and gender-matched controls with benign lesions which mimicked cancer, also checking for the presence of jaundice and diabetes; the results were encouraging because the metabolic profile in patients with pancreatic cancer was distinguishable from patients with benign pancreatic lesions.

In conclusion, the primary prevention of pancreatic cancer is based on the assessment and elimination of major risk factors: smoking, high fat diet, diet rich in meat and low in vegetables and folate, occupational exposure, and obesity[33,34]. Presently, secondary prevention is limited to patients at risk for familial cancer and a screening plan should be established based on the implementation of an annual MRI or EUS.

Abstract

Hepatorenal syndrome (HRS) is defined as a functional renal failure in patients with liver disease with portal hypertension and it constitutes the climax of systemic circulatory changes associated with portal hypertension. This term refers to a precisely specified syndrome featuring in particular morphologically intact kidneys, where regulatory mechanisms have minimised glomerular filtration and maximised tubular resorption and urine concentration, which ultimately results in uraemia. The syndrome occurs almost exclusively in patients with ascites. Type 1 HRS develops as a consequence of a severe reduction of effective circulating volume due to both an extreme splanchnic arterial vasodilatation and a reduction of cardiac output. Type 2 HRS is characterised by a stable or slowly progressive renal failure so that its main clinical consequence is not acute renal failure, but refractory ascites, and its impact on prognosis is less negative. Liver transplantation is the most appropriate therapeutic method, nevertheless, only a few patients can receive it. The most suitable "bridge treatments" or treatment for patients ineligible for a liver transplant include terlipressin plus albumin. Terlipressin is at an initial dose of 0.5-1 mg every 4 h by intravenous bolus to 3 mg every 4 h in cases when there is no response. Renal function recovery can be achieved in less than 50% of patients and a considerable decrease in renal function may reoccur even in patients who have been responding to therapy over the short term. Transjugular intrahepatic portosystemic shunt plays only a marginal role in the treatment of HRS.

PATHOPHYSIOLOGY

The organic intactness of kidneys, a condition for the diagnosis of this syndrome, has been demonstrated repeatedly in terms of morphology as well as by normal function of kidneys from an individual with hepatorenal syndrome (HRS) transplanted to a person without any liver disease[1]. The main pathophysiological mechanisms include increased renal arterial resistance, especially affecting the cortex of kidneys, which results in renal hypoperfusion[2,3], and arterial hypotension. The small volume of the ultrafiltrate is reabsorbed almost completely in the proximal tubule whereas almost a zero quantity of sodium flows to the Henle's loop. As a result, enhanced aldosterone activity is of little application in this phase and standard diuretics have no effect either. Due to the adiuretin-vasopressin activity, final urine is produced through an essentially zero hyperosmolar natriuresis, and its quantity ranges between oliguric and anuric values. Under such conditions, the local prostaglandin regulation system, which is of little clinical significance other-

wise, comes to play a crucial role in the maintenance of residual renal perfusion, and its elimination (e.g., by non-steroidal antirheumatics) can have distinct consequences.

The principal mechanisms leading to renal vasoconstriction consist of alterations in systemic circulation, accompanying portal hypertension[4], which are represented by decreased peripheral vascular resistance with subsequent vasodilatation (a consequence of the hyperactivity of vasodilating agents), central hypervolemia, hyperkinetic circulation, and the activation of compensatory mechanisms, i.e., the sympathetic nervous system (SNS), renin-angiotensin-aldosterone system (RAAS) and adiuretin-vasopressin. What is more, adenosine, for example, which has a vasodilating effect in most tissues, produces vasoconstriction in kidneys[5]. The direct impact of the SNS and RAAS also stimulates the reabsorption of sodium in the proximal tubule[6].

It is important to point out that renal vasoconstriction itself is not sufficient for the development of hepatorenal syndrome. Arterial hypotension is the key factor which, even if it does not reach shock values, causes simultaneous renal vasoconstriction and renal hypoperfusion with decreased glomerular filtration[7]. Thus, cardiac output is the relevant factor. Cardiac output may be low, normal or high, but is relatively insufficient[8,9] to prevent a severe reduction of effective circulating volume due to the splanchnic arterial vasodilatation in patients with HRS. The reasons why cardiac output is relatively insufficient in end-stage liver disease is still unknown, but in recent years several specific cardiac abnormalities, such as reduced systolic and diastolic responses to stress stimuli, electrophysiological repolarisation changes or enlargement of cardiac ventricles, have been recognised as so-called "cirrhotic cardiomyopathy"[10].

In addition to this, other factors such as the release of endotoxins and a further release of biologically active substances such as inflammatory cytokines, nitric oxide, carbon monoxide and others as a result of a bacterial infection may further impair cardiac function in patients with end-stage liver disease.

The once considered theory of a direct reflex link between the liver (or the portal system) and renal circulation has been abandoned lately, although several experiments in the past managed to prove renal vasoconstriction (accompanied by renal function alterations in terms of sodium and water retention) as a result of portal (or intrasinusoidal) pressure elevation[11,12].

Because the above-mentioned circulatory alterations can virtually be observed from very early stages in diseases with portal hypertension, HRS has to be viewed as their climax, and the refractory ascites stage constitutes a significant turning point in such development. Nevertheless, there is surprisingly little connection to the progression of hepatic lesions; in other words, it cannot be assumed automatically that a patient with HRS has reached their terminal liver failure stage. In fact, a patient with a Child-Pugh Score of 8 or less has the same risk of HRS development as a patient in C class. In this respect, determination of sympathetic activity (plasma noradrenaline) or RAAS[13], or renal arterial resistance ("resistive index" in ultrasonography) has a considerably better prognostic value[14]. In principle, a high risk of hepatorenal failure must be expected in patients with liver disease and ascites, with an indication of dilution hyponatremia, with tachycardia and mean arterial pressure below 80 torr.

Consistent with the adopted diagnostic criteria, it would be suitable to differentiate between diagnoses of "hepatorenal syndrome" and "hepatorenal failure". In both cases, the clinical parameters of renal function are identical; however, the fundamental difference lies in the circumstances of their occurrence and prognosis. Hepatorenal syndrome means a precisely specified state of kidney function failure where all of its eliminable causes and precipitant factors have been excluded. "Hepatorenal failure" is a more general term which can be applied to any kidney function failure in liver disease with portal hypertension which adds a significant disposition to it. This implies that the presence of liver disease with liver function alterations and with portal hypertension is of crucial importance as well as the absence of an organic renal defect (proteinuria < 0.5 g/d, erythrocyturia < 50/field of view in high-resolution, normal ultrasound findings in kidneys and the excurrent duct system).

CLINICAL PRESENTATION

HRS occurs almost exclusively in patients with ascites. The occurrence probability in patients having an ascites for more than 5 years reaches 40%. Besides the above-mentioned laboratory prognostic factors, ascitic patients with a small liver, oesophageal varicose veins and an unbalanced diet have a higher risk of HRS incidence. Dilution hyponatremia, tachycardia and arterial hypotension with a mean arterial pressure of approximately 80 torr or less must be perceived as warning signs.

The prevalence of HRS in patients affected by liver cirrhosis with ascites is in effect equal to 18% after 1 year, rising to 39% at 5 years. In almost half of the cases of HRS, one or more precipitating factors can be identified, among which we can include bacterial infections (57%), gastrointestinal haemorrhage (36%) and therapeutic paracentesis (7%)[13].

According to the progression, or more precisely according to clinical seriousness, HRS can be classified in 2 types[15]: Type 1 - rapidly progressive, where the serum creatinine doubles in 2 wk and values of approximately 350 μmol/L (2.5 mg/dL) are usually achieved. This type accompanies clinically more serious conditions and it is typically unstable. Its main clinical feature is acute renal failure. Type 2 - slowly progressive, this state was described later and, despite the otherwise typical signs of hepatorenal failure, it is quite stable. Serum creatinine rises slowly or not at all and it usually does not exceed 180 μmol/L (1.3 mg/dL). The clinical record is dominated by refractory ascites and relatively stable liver function[16].

The difference in prognosis between the two types

of HRS is essential as the median survival of type 1 is about 2 wk while that of type 2 is generally around 4-6 mo[17]. Type 1 HRS is often induced by the occurrence of a precipitating stimulus. The important factor seems to be infections (e.g., urinary tract infections and infections of the biliary or intestinal tract)[18] but the most important thing is the development of a spontaneous bacterial peritonitis[19]. Almost one third of patients with spontaneous bacterial peritonitis develop a non-transient form of renal failure which in most cases fits the diagnostic criteria of type 1 HRS. The independent predictive factors for the development of renal failure as a consequence of bacterial infections are the severity of infection, the model for end-stage liver disease score at the diagnosis of infection and the lack of resolution of infection by means of antibiotics[20,21].

Up to the end of the last century, the prognosis for cirrhotic patients developing HRS was very poor. Thereafter, some new effective treatments of HRS which improve survival have been introduced with encouraging results.

DIAGNOSIS

There is no specific test to determine an unequivocal diagnosis of HRS. The prime finding consists of reduced glomerular filtration (creatinine clearance) < 40 mL/min or serum creatinine increase > 135 μmol/L under the exclusion of other causes of renal failure. The most relevant indications of the functional character of such failure include: natriuresis < 10 mmol/L, urine osmolality higher than plasma osmolality, natremia < 130 mmol/L and diuresis < 500 mL/d.

The criteria for diagnosing HRS have recently been re-examined by the International Ascites Club[22] (Table 1).

The main changes in the new diagnostic criteria of HRS as compared to those previously used[23] are the removal of minor diagnostic criteria and the removal of ongoing bacterial infection as an exclusion criterion for the diagnosis of HRS. Other important changes are that plasma volume expansion should no longer be performed with saline but with albumin, and creatinine clearance is no longer considered as a tool for diagnosis. The presence of shock, even of septic shock, as well as previous treatment with nonsteroidal anti-inflammatory drugs, other nephrotoxic drugs (i.e., aminoglycosides) and vasodilators (i.e., nitrates, prazosin and renin-angiotensin system inhibitors) are still considered exclusion criteria for the diagnosis of HRS, along with the presence of proteinuria, hematuria or ultrasound alterations of the kidneys.

In clinical practice, it is absolutely essential to examine urinalysis and sodium concentration in urine in order to differentiate organic renal insufficiency.

Certain diagnostic difficulties regarding differentiation may be the result of acute tubular necrosis which has been observed by approximately 5% of patients dying of renal failure. It is potentially reversible and is characterised by higher Na concentration in urine, isoosmolar urine, and the ratio of urine and plasma creatinine below 20:1. This disease often develops after the administration of a contrast medium to cirrhotic patients in computed tomography examination. Therefore, a very precise indication for use of computed tomography is required by such patients, or a substitution by magnetic resonance.

Table 1 New diagnostic criteria of hepatorenal syndrome

New diagnostic criteria of hepatorenal syndrome
Cirrhosis with ascites
Serum creatinine > 133 μmol/L (1.5 mg/dL)
No sustained improvement of serum creatinine (decrease to a level of 133 μmol/L or less) after at least 2 d of diuretic withdrawal and volume expansion with albumin; the recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/d
Absence of shock
No current or recent treatment with nephrotoxic drugs
Absence of parenchymal disease as indicated by proteinuria > 500 mg/d microhematuria (> 50 red blood cells per high-power field) and/or abnormal renal ultrasonography

Even the presence of hepatitis B and C virus can damage kidneys as it leads to membranous glomerulonephritis or vasculitis as well as chronic autoimmune liver disease. In such patients, renal failure may also be induced by cyclosporine treatment.

Finally, it is again worth pointing out that the risk of an organic renal defect tends to be higher in patients with advanced liver disease due to the impact of reduced blood perfusion of kidneys as well as alterations of immune and metabolic functions, and this needs to be taken into account.

TREATMENT

Although HRS is a terminal manifestation of portal hypertension in parenchymatous liver disease, it no longer ranks among the fundamentally insolvable issues. In specific cases, however, availability matters and the rational and ethical grounds for this rather costly treatment have to be considered.

Influence on causative factors

If there are indications of renal failure, first of all, the causative factors have to be eliminated and treated, such as: elimination of nephrotoxic medications; elimination or treatment of a suspect bacterial infection including spontaneous bacterial peritonitis with focus on gram-negative flora; elimination of bleeding in gastrointestinal tract and, if need be, adequate compensation for losses; elimination of nonsteroidal antirheumatics; elimination of diuretics (they enhance central hypervolemia and the sympathetic and RAAS activity); supplementation of intravascular volume, preferably through hypoalbuminemia correction (albumin is the most reliable volume expander with the longest lasting impact). Another effect, even if just transitory, may be brought about by the

partial evacuation of tension ascites accompanied by a consistent compensation for albumin. Efforts concerning hyponatremia substitution must be avoided (risk of cerebral oedema) - fluid restriction is more suitable.

Liver transplantation

Naturally, liver transplantation is the only rational solution in cases of advanced liver disease. However, the presence of a kidney function failure considerably aggravates the prognosis of such patients[24,25].

During the last century, only a few patients with HRS underwent liver transplantation, because most patients died before surgery as a consequence of the rapid evolution of type 1 HRS.

Novel treatment approaches, especially terlipressin plus albumin therapy, provide a "treatment bridge" towards liver transplantation. Treatment with terlipressin 4-6 mg/d for up to eight mo has been described, completed by successful liver transplantation[26,27]. The number of transplanted patients is still very low, however. In a prospective study, none of 15 type 1 HRS patients referred to a tertiary care transplant centre was transplanted: 12 patients had contraindications against transplantation and the remaining three patients died while awaiting transplantation[28].

Hypovolemia correction

With regards to the fact that the HRS laboratory finding is similar to prerenal uraemia, attempts have been made since the very beginning to influence this syndrome by means of hypovolemia correction. A physiological solution or Dextran has been administered, which is unfortunately inappropriate in this case. Nevertheless, human albumin has proven the most suitable. Nowadays, it is used for expansion of circulatory blood volume and has been shown to successfully reduce the incidence of HRS type 1. When used for treatment of HRS, it has shown better results when used in combination therapy as it amplifies the effect of other pharmacologic therapies in the treatment of HRS. Often, the quantity to be administered is high - up to 50 g/d. Anyway, hypovolemia correction is required before, as well as during, the subsequent treatment with medicaments[29] and albumin is now the basis of the therapy in combination with vasoconstrictors.

Vasoconstrictors

The first group of medicaments used for this indication in an effort to reduce intrarenal vascular resistance were prostaglandins. In spite of the fact they used to be recommended, they have not shown any provable improvement in renal function[30].

On the other hand, the application of systemic vasoconstrictors has been justified with respect to known pathogenetic factors. In HRS, marked reduction of effective circulating volume was found, which is related to a splanchnic arterial vasodilation and inadequate cardiac output, which implies an extreme overactivation of the endogenous systemic vasoconstrictor systems, i.e., the RAAS, SNS and nonosmotic release of vasopressin. This means that the final aim of the therapeutic approach is to reduce severe renal arterial vasoconstriction[51]. In the early years of treatment, dopamine was tested in a small to medium dose. Dopamine has been shown to reduce renal vascular resistance and increase renal blood flow. It was therefore thought to be potentially useful in the treatment of HRS and was tested in a small to medium dose. But its clinical effect has not been confirmed unequivocally[11], alone or even in combination with ornipressin[32].

Nonetheless, the application of synthetic analogues of vasopressin-terlipressin (N-triglycyl-8-lysine-vasopressin synthesised in the laboratories of the Czechoslovak Academy of Sciences in Prague, Czech Republic in 1964), or ornipressin represented a considerable step forward. Analogues act on the abundant V1 receptors in the splanchnic vasculature, causing greater vasoconstrictive effects in the mesenteric circulation than in renal or other vascular systems.

In retrospective studies, as well as in small prospective pilot studies, it has been demonstrated that prolonged use of an ornipressin[33,34], terlipressin[35-48] or α-agonist vasoconstrictor (midodrine plus octreotide, noradrenaline alone)[49-56] in association with human albumin is capable of recovering renal function in 40%-60% of patients with type 1 HRS. The use of ornipressin was, however, abandoned because of its high rate of ischemic side effects.

Currently, terlipressin is the preferred product. Treatment with terlipressin and albumin has become a major breakthrough in the field of cirrhosis[57]. It has been used in a broad range of HRS treatment applications and there are many studies demonstrating its efficiency. In 2006, The Cochrane Library published a review with the conclusion that terlipressin treatment was promising but its results had to be confirmed[58].

Nowadays, however, it has become the clearly preferred treatment in general recommendations and is the most widely used agent in the treatment of type 1 HRS. The terlipressin treatment protocol comprises an initial dose of 0.5-1 mg terlipressin applied by intravenous injection every 4-6 h or continuous intravenous infusion starting at an initial dose of 2 mg/d. Unless the creatinine level has dropped by 25% on the third day, the dose is raised to 2 mg every 4 h or 12 mg/d by continuous intravenous infusion, respectively. Intravenous albumin is administered in case of failure to maintain the central venous pressure at 10-15 cm H_2O (initially 1 g of albumin/kg for two days up to a maximum of 100 g/d followed by 20-40 g/d)[59].

The treatment continues until laboratory values have improved, otherwise no longer than 2 wk. Complete reversal (i.e., decrease of serum creatinine with a final value < 133 μmol/L) or partial reversal (defined with a decrease of serum creatinine > 50% with a final value ⩾ 133 μmol/L) of type 1 HRS has been observed in almost 59% of patients[60].

Usually, diuretics are not administered during therapy

with terlipressin and albumin; however, some surveys have used furosemide and albumin. Type 2 HRS is more frequent in clinical practice than type 1 and liver transplantation can cure this syndrome as well as other complications relating to hepatic insufficiency. Treatment efficiency has reached 80% in this indication. Nevertheless, recurrence is very common after discontinuation of treatment[61].

Recurrence of HRS after treatment withdrawal (i.e., a sharp increase in serum creatinine within a few days) occurs in approximately 20% of patients. Treatment with terlipressin should be repeated in these patients and this measure is frequently effective. This can result in long-term treatment (up to 8 mo) in some cases. The dose of terlipressin can be up to 4-6 mg/d and albumin up to 100 g/d[26,27,59].

An important question is prediction of response to this treatment. The most consistent predictor of response to terlipressin and of survival is the baseline serum creatinine, bilirubin and an increase in mean arterial pressure of $\geqslant$ 5 mm Hg at day 3 of treatment. Patients most likely to benefit from terlipressin have earlier onset renal failure [i.e., serum creatinine < 445 μmol/L (5.0 mg/dL)]. The cutoff level of serum bilirubin that best predicted response to treatment was 170 μmol/L (10 mg/dL). Improvement in the hyperdynamic circulation (measured by sustained rise in mean arterial pressure) is also important for reversal of HRS[62,63].

Other treatment alternatives, with a similar effect on circulatory parameters, may include alpha-adrenergic agonists. Their advantage compared to terlipressin is their lower price, but they seem to be less effective than terlipressin now. Several small studies have shown promise for norepinephrine in the treatment of HRS, however just one study showed a better (but not statistically significant) response to terlipressin.

Midodrine is an alpha-agonist and appears more convenient than norepinephrine. It offers the advantage of oral administration; however it was used in combination with octreotide (and albumin). It has been shown to moderately improve the systemic and renal hemodynamics.

Transjugular intrahepatic portosystemic shunt

Transjugular intrahepatic portosystemic shunt (TIPS) interferes with the hepatorenal reflex and brings about reduced sympathetic and RAAS activity through intensified hyperdynamic circulation. TIPS results in a positive effect on renal function, including HRS, demonstrated by a rapid increase in urinary sodium excretion, urinary volume, and improvement in plasma creatinine concentration. Its positive impact on renal function in liver cirrhosis with ascites has already been proven in several studies[64-67]. The first prospective survey with a well-documented type 1 HRS was published as early as 1998[68] and the effectiveness of TIPS has been reconfirmed since. TIPS can be applied to patients with a certain liver function reserve, either as a bridge treatment extending the waiting period for a liver transplant, or as a long-term, definitive therapy in case of satisfactory and stabilised liver function. As a rule however, the curative effect only comes after several days or weeks following intervention[69].

According to surveys published to date, it has been effective in ascites treatment in principle, and moreover, it can contribute to improvement of renal function[70,71].

Abstract

Cholestasis results in a buildup of bile acids in serum and in hepatocytes. Early studies into the mechanisms of cholestatic liver injury strongly implicated bile acid-induced apoptosis as the major cause of hepatocellular injury. Recent work has focused both on the role of bile acids in cell signaling as well as the role of sterile inflammation in the pathophysiology. Advances in modern analytical methodology have allowed for more accurate measuring of bile acid concentrations in serum, liver, and bile to very low levels of detection. Interestingly, toxic bile acid levels are seemingly far lower than previously hypothesized. The initial hypothesis has been based largely upon the exposure of μmol/L concentrations of toxic bile acids and bile salts to primary hepatocytes in cell culture, the possibility that *in vivo* bile acid concentrations may be far lower than the observed *in vitro* toxicity has far reaching implications in the mechanism of injury. This review will focus on both how different bile acids and different bile acid concentrations can affect hepatocytes during cholestasis, and additionally provide insight into how these data support recent hypotheses that cholestatic liver injury may not occur through direct bile acid-induced apoptosis, but may involve largely inflammatory cell-mediated liver cell necrosis.

CHOLESTATIC LIVER INJURY - CLINICAL RELEVANCE

A reduction in bile flow (cholestasis) can result from gall stones, impingement from a local tumor, intrahepatic cholestasis of pregnancy, genetic deficiency in bile export proteins or in autoimmune disorders amongst other etiologies[1,2]. Cholestasis results in a dramatic increase in liver and serum bile acid levels that eventually lead to acute liver toxicity, proliferation of bile ducts, and fibrosis progressing to cirrhosis[3]. Neonatal disorders such as progressive familial intrahepatic cholestasis and biliary atresia are particularly difficult to treat effectively[4]. While surgical means can prevent disease progression in the case of gall stones or biliary atresia, there are a limited number of treatment options pharmacologically for diseases such as primary sclerosing cholangitis or primary biliary cirrhosis[5]. Ursodiol, a pharmaceutical form of ursodeoxycholic acid, is the current mainline defense against cholestasis, although its efficacy is limited in

some circumstances[5,6].

While many of the etiologies of disease initiation are well described, the molecular mechanisms behind the early liver injury associated with cholestasis are extensively studied, but not well understood. A major hypothesis was based on the assumption that the buildup of bile acids in hepatocytes and blood results in hepatocellular apoptosis dependent upon bile acid concentrations[6,7]. While these studies on the direct toxicity of bile acids have been supported by many *in vitro* studies from multiple groups, recent methodology measuring the concentrations of individual bile acids after the onset of cholestasis *in vivo* has cast some doubt that bile acid levels may actually reach the levels necessary for cell toxicity[8-10]. A growing volume of work has instead focused on how sterile inflammation and innate immunity may result in the initial injury[11-15]. This review will discuss current and developing paradigms in the pathophysiology of early cholestatic liver injury, and provide insight into how recent advances in methodology may affect these theories.

DIRECT BILE ACID TOXICITY AS A MODEL FOR CHOLESTATIC LIVER INJURY

High concentrations of bile acids given to cultured hepatocytes *in vitro*[16] and bile acid-induced cholestasis[17], or bile duct ligation *in vivo*[18], have long been established as models of toxicity to hepatocytes. After the discovery that ursodeoxycholic acid could be used pharmacologically as a choleretic agent with protective effects against cholestasis[19], a renewed interest in the subject emerged. While previous papers had focused on the detergent properties of amphipathic bile acids[20,21] recent research resulted in a series of papers illustrating a detailed mechanism of how toxic bile acids or the respective bile salt, could induce apoptosis in primary human and rat hepatocytes[22-27]. Much of this work has spearheaded the current revival of direct bile acid toxicity as a model of cholestasis, or liver injury, *in vitro* and *in vivo*.

Apoptosis and intracellular signaling mechanisms in bile acid-induced toxicity

The most commonly studied bile acid for its toxicity to hepatocytes is glycochenodeoxycholic acid (GCDCA), or its bile salt glycochenodeoxycholate, due to it being a major constituent of human serum and bile after cholestasis[28] and its relatively higher level of toxicity when compared to other bile acids[29]. Galle *et al*[22] first established GCDCA as toxic to primary human hepatocytes and in the same paper also established ursodeoxycholate (UDCA) as protective against the GCDCA-induced injury. Due to the limited availability of primary human hepatocytes, much of the subsequent research into mechanism of injury occurred in rodent, especially rat hepatocytes. GCDCA-induced hepatocellular death was first established as apoptotic using electron microscopy[23]. Incubation of primary rat hepatocytes with 50 μmol/L GCDCA induced DNA fragmentation, chromatin margination and condensation, cellular shrinkage and blebbing of the membrane with intact organelles enclosed, all of these classical hallmark characteristics of apoptosis[23]. While it has been extensively shown that DNA fragmentation is common to both necrosis and apoptosis[30-33], the morphological changes present after GCDCA exposure provided strong evidence of bile acid-induced apoptosis of primary hepatocytes. In addition, caspase activation is a feature of GCDCA-induced apoptosis[27,34-36] and caspase inhibitors were shown to protect[27,34,36].

Investigation into intracellular mechanisms of bile acid toxicity showed cellular apoptosis was associated with mitochondrial instability and mitochondrial membrane permeability transition pore (MPTP) formation that was preventable by either UDCA, ketohexoses such as fructose, or cyclosporine A and trifluoroperazine[36-39]. As mitochondria are essential for ATP production and GCDCA depleted ATP levels[29], the idea that UDCA, or other protective interventions, were sustaining ATP levels was tested; however, protection was not due to reduced ATP depletion, but by blockage of the MPTP[37]. This suggested that UDCA may prevent injury during cholestasis not only by enhancing bile flow, but by preventing initiation of the MPTP[37], a facet which has been confirmed in other models[40-42]. Mitochondrial reactive oxygen species (ROS) production and MPTP initiation was later also shown in human hepatocytes exposed to toxic bile acids such as GCDCA indicating the mitochondrial dysfunctions occur in more than just rodent species[43]. Adult rats fed a diet supplemented with deoxycholic acid (DCA) for 10 d also showed significant mitochondrial swelling, peroxynitrite formation and ROS production[44]. These data suggest that exposure of cultured hepatocytes to high levels of hydrophobic bile acids causes formation of ROS, reactive nitrogen species, and initiation of the MPTP, which is directly involved in the injury. In immortalized cell lines transfected with the basolateral transporter NTCP, bile acids like GCDCA could directly stimulate both Fas-dependent apoptosis *via* activation of Fas receptor[26] and Fas-independent apoptosis *via* previously established mitochondrial damaging mechanisms[41,42]. These experiments indicate that uptake of bile acids can cause both intrinsic and extrinsic apoptosis, and that cell death could be ameliorated by protecting against MPTP formation. These observations were critical in establishing the role of intracellular signaling and mitochondrial stress in the pathophysiology of bile acid-induced toxicity, as previous hypotheses revolved largely around the idea of inherent bile acid toxicity.

Although GCDCA and its bile salt have been extensively studied, other toxic bile acids have also effects on intracellular signaling mechanisms. Taurolithocholic acid (TLCA), taurochenodeoxycholic acid, and DCA increase intracellular ROS species in hepatocytes[45,46] and toxicity from these bile acids is responsive to antioxidants such as N-acetylcysteine and α-tocopherol[45]. DCA has also been shown to induce apoptosis and mitochondrial

instability in adult rats and primary hepatocytes at high concentrations[44,47,48]. Interestingly the taurine conjugate of UDCA, TUDCA, is protective against bile acid-induced apoptosis through activation of mitogen-activated protein kinase survival pathway signaling including p38 and extracellular signal-regulated kinase[55]. While GCDCA may be one of the most toxic and perhaps the most interesting bile acid scientifically and mechanistically, the total bile acid milieu probably contributes to the overall effect more than a single bile acid, with anti-apoptotic bile acids such as TUDCA and UDCA counteracting some of the effects of pro-apoptotic bile acids such as GCDCA.

Bile acids are also known to target intracellular nuclear receptors, especially the liver X receptor (LXR) family such as farnesoid X receptor (FXR), pregnane X receptor (PXR), constitutive androstane receptor (CAR) and more[49]. The first LXRs identified as bile acid receptors were FXR[50,51], LXR[52], and later PXR[53]. FXR has been established as a key regulator in bile acid synthesis and transport[54]. Agonism of FXR with the synthetic drug GW4064 is hepatoprotective against both intra- and extrahepatic cholestasis[55] and agonism of PXR is protective against certain bile acid-induced cholestatic syndromes[56]. Nevertheless, the FXR knockout mouse were also protected against bile duct ligation-induced injury[57,58], which was found to be *via* increases in phase I detoxifying reactions and renal excretion of bile acids[59]. This suggests that both agonism and antagonism may be beneficial, depending on the type of cholestasis and the individual response to alterations in master regulators such as FXR. There is evidence for reduced bile acid load by either a reduction in synthesis in the case of agonism or enhanced excretion in antagonism of FXR. In cases of agonism a reduced bile acid load also correlated with a reduction in the hepatic inflammatory response in both steatotic and non-steatotic models[55,60] and loss of FXR has also protected against inflammatory injury in other organs[61]. These data indicate that increasing bile acid levels may have a strong signaling effect through FXR, PXR and more in hepatocytes that results in decreased bile acid synthesis, increased bile acid excretion and recruitment of inflammatory cells to the area. Early growth response factor-1 (Egr-1) has been clearly established as a master regulator in the sterile inflammatory response that hepatocytes express after exposure to high levels of bile acids[62]. Future research investigating interplay between FXR and Egr-1 in this signaling axis may be fruitful.

Bile acid concentrations: The in vivo to in vitro shift and back again

While it seems undeniable that bile acids have the capacity to elicit multiple different signaling cascades ranging from mitochondrial dysfunction and cell death to bile acid synthesis and glucose homeostasis[49,63], there remains some debate over the models used to dissect these actions and their physiological relevancy. In particular, there appears to be a discrepancy between the concentration of bile acids used *in vitro* to cause toxicity, and the levels of bile acids occurring during cholestasis both in rodents and in man[8,9].

Table 1 Human plasma bile acid concentrations in healthy volunteers and patients with extrahepatic cholestasis

BA	Healthy volunteers (nmol/L)	Cholestatic patients (nmol/L)
CDCA	257 ± 56	84 ± 60
TCDCA	120 ± 22	16 578 ± 4370
GCDCA	776 ± 112	28 535 ± 5734
CA	182 ± 83	173 ± 137
TCA	180 ± 47	54 487 ± 13 419
GCA	233 ± 56	56 222 ± 15 714

Data adapted from Trottier *et al*[9].

Table 1 illustrates the increases in serum bile acids found in sex and age matched patients after multiple forms of cholestasis in man[9]. Full details on the patients are provided by Trottier *et al*[9] and Lai *et al*[64]. In brief, bile acid concentrations were measured in human serum from healthy volunteers and from patients with extrahepatic cholestasis[9]. Seventeen patients (8 men and 9 women) were recruited to the study. Clinical diagnoses of the patients included 8 common bile duct stones, 5 pancreatic tumors, 1 bile duct tumor, 1 benign common bile duct stenosis and 1 chronic pancreatitis. Age and sex matched (20 male, 20 female) non-cholestatic volunteers were used as controls[9], selected from the Genetics of Lipid Lowering Drugs and Diet Network study[64].

Previous work suggests serum bile acid levels are highly similar to total liver levels when comparing bile acid concentrations *in vivo*[8]. The bile acids that show the greatest increase in concentration in the serum are not toxic bile acids, but largely non-toxic bile acids such as TCA and GCA in man[9] or TCA, α- and β-muricholic acid (MCA) and TMCA in mice[8]. Levels of the primary toxic bile acid in humans, GCDCA, rise substantially, to almost 30 μmol/L under severe cholestatic conditions as measured by serum levels in man[9]. However, studies with primary human hepatocytes have shown little to no increase in toxicity until levels greater than 100 μmol/L for 24 h with significant toxicity beginning around 500 μmol/L[22,65]. The only paper to demonstrate toxicity at a level close to 30 μmol/L reported that GCDCA showed morphological characteristics in primary human hepatocytes that resembled

Table 2 Murine plasma bile acid concentrations after bile duct ligation

BA	Sham control (μmol/L)	BDL 6 h (μmol/L)

Data adapted from Zhang *et al*[8].

apoptosis and a 60% increase in DNA fragmentation at 50 μmol/L[66]. However, a significant increase in serum aspartate aminotransferase activities over control levels was only observed at 100 μmol/L GCDCA[66]. These data suggest that direct bile acid toxicity may not be the main mechanism of cholestatic liver injury in humans and seem to be supported by findings in mouse models of obstructive cholestasis[8,15]. Table 2 shows plasma bile acid concentrations in sham-operated controls or after 6 h of bile duct ligation (BDL)[8]. This is a time point corresponding with either maximal or near maximal increases in bile acid concentrations. Data are expressed as mean ± SE of $n = 6$ per group. For toxic bile acids such as GCDCA or LCA, the levels required to initiate toxicity in murine hepatocyte cultures are up to 3000-fold higher than the corresponding bile acid levels *in vivo*[8]. In the case of GCDCA, the most commonly used bile acid for *in vitro* toxicity, *in vivo* levels never exceed about 24 nmol/L throughout the first 3 d of injury[8]. This compares to 50 μmol/L GCDCA that is required to cause toxicity in cultured rodent hepatocytes *in vitro*[23,26]. In addition, during cholestasis *in vivo*, hepatocytes are exposed to a mixture of bile acids, some of which have actually an anti-apoptotic effect by causing the upregulation of inhibitor of apoptosis proteins, which may serve to counterbalance the apoptotic effect of specific bile acids[67,68].

While it is known that cultured hepatocytes lose expression of bile acid transporters such as NTCP and the OATPs over time in culture, cells freshly taken from the liver express nearly the same amount of transporter as whole liver tissue[69], and nearly the same level at 3 h after plating[70], when many of these experiments begin[23,71,72]. Even given a 30% decrease in mRNA levels of transporters such as NTCP 3 h after plating, cells maintain over 50% of their NTCP function up to 24 h after plating as measured by kinetic parameters[70]. Thus, it stands to reason that these hepatocytes are concentrating bile acids *in vitro* at levels within a 2 fold difference of the *in vivo* physiology, yet it takes multiple orders of magnitude, up to a 3000 fold difference in the case of GCDCA, to account for the difference between bile acid levels used on rodent hepatocytes *in vitro* and levels observed in murine samples *in vivo*. Still, even given that serum or liver levels may underestimate the true concentrations of bile acids hepatocytes are exposed to after BDL when bile leaks back into the parenchyma[73,74], the principle bile acid composition in bile is similar to serum, i.e. the non-toxic bile acids predominate, thus it is unlikely that cells are exposed to micromolar concentrations of the *toxic* bile acids *in vivo*[75].

INFLAMMATORY LIVER INJURY AFTER BDL - A NOVEL HYPOTHESIS

If bile acids are not directly responsible for cholestatic liver injury *in vivo,* then what is the mechanism of injury, and what role do bile acids play in the pathophysiology and progression of the injury? Accumulation of neutrophils, largely around sites of cell injury, within 24 h after bile duct ligation has been reported numerous times[11,12,76,77]. In addition, an increase in macrophage accumulation is observed approximately one week post ligation[77,78]. Figure 1 shows typical histology and neutrophil extravasation after bile duct ligation in mice. H&E staining shows multiple areas of hepatic focal necrosis throughout the liver. Neutrophils are present around the site of injury as early as six hours post BDL, and peak around 48-72 h after BDL, which is also the peak of liver injury[8,11,77].

Neutrophil accumulation has been directly associated with the injury, as deficiency of adhesion molecules such as ICAM-1 or CD18 reduced the number of neutrophils that extravasate into liver parenchyma, and drastically reduced liver injury[11,12]. A neutrophil is a particularly toxic leukocyte due to its capacity to produce superoxide *via* nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and the potent oxidant hypochlorous acid *via* myeloperoxidase[79]. Neutrophil accumulation after bile duct ligation has been associated with an increase in myeloperoxidase activity[80] and intracellular chlorotyrosine adduct formation in hepatocytes[11,12,81]. This indicates that neutrophil-derived hypochlorous acid can cause an intracellular oxidant stress in hepatocytes, which is responsible for cell injury[82,83]. Inhibition of NADPH oxidase reduces neutrophil-mediated oxidant stress and protects against neutrophil cytotoxicity[84,85]. In addition, hepatic NADPH oxidases located in hepatic stellate cells (Nox1) and Kupffer cells (Nox2) contribute to BDL-induced fibrosis[86,87] but their contribution to the initial liver injury (bile infarcts) has not been determined.

Together these data strongly implicate neutrophils

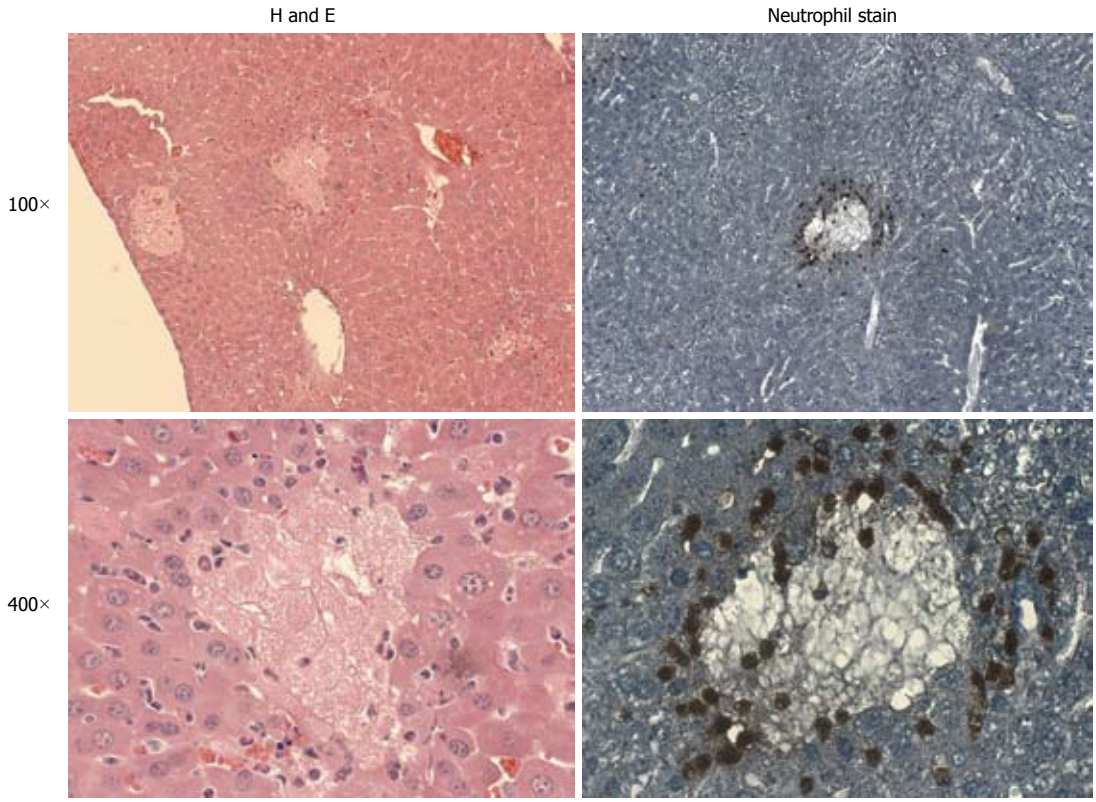

Figure 1 Sample liver sections from C57Bl/6 mice illustrating neutrophil accumulation after bile duct ligation. C57BL/6 mice were subjected to bile duct ligation and sacrificed 24 h later. Hematoxylin and eosin (H and E) stained sections showing focal necrosis at 100× and 400× magnification. Sections stained with an anti-neutrophil antibody. Neutrophils are present largely around areas of focal necrosis in this model.

in the pathogenesis of early cholestatic liver injury. In support of this hypothesis is recent data that exposure of cultured hepatocytes to both toxic and non-toxic bile acids at levels that recapitulate the *in vivo* concentrations result in dramatic increases in chemotactic factors such as MIP-2 and mKC, and adhesion molecules such as ICAM-1, all factors that can be involved in hepatic neutrophil recruitment[15]. The inflammatory mediator induction is dependent on the activation of the transcription factor Egr-1 in bile duct-ligated mice and in bile acid-exposed hepatocytes[15,62]. Egr-1 expression is also increased in human patients with cholestatic liver disease and the hepatic Egr-1 levels correlate with interleukin-8 and ICAM-1 induction[15]. Therefore, we initially hypothesized that after BDL, bile leaks back into the parenchyma after rupture of bile ducts and hepatocytes are locally exposed to high concentrations of pro-inflammatory bile acids such as TCA, β-MC and TMC that initiate an inflammatory response[8,13,15]. Additionally these hepatocytes are exposed to low concentrations of cytotoxic bile acids such as DCA, TLCA, and GCDCA that may initiate a low level of mitochondrial dysfunction that stresses the hepatocytes, but is insufficient to directly kill the cells[8,29,37,38,41-43]. This bile acid-induced stress triggers the expression of ICAM-1, MIP-2, and mKC in hepatocytes[8,15]. The subsequent release of these CXC chemokines can activate neutrophils in circulation[88] and provide a chemotactic gradient for the extravasation of neutrophils, which then attack the stressed hepatocytes and cause cell death through reactive oxygen formation[11,12,81,82]. Given a dramatic enough increase in toxic bile acid concentrations by feeding e.g. a lithocholic acid-containing diet[89], it is possible to directly cause cell death *via* bile acid toxicity but independent of neutrophils (Woolbright and Jaeschke unpublished observation). However the *in vivo* bile acid concentrations in models such as BDL are insufficient to meet this threshold, and thus the neutrophil-mediated cell death is dominant.

APOPTOTIC AND NECROTIC CELL DEATH AFTER BDL

A central but controversial issue in the debate on the mechanisms of cell death in cholestatic liver disease is whether the injury occurs through apoptosis or necrosis[90]. This is a key point as the therapeutic options to prevent injury will progress in two very different directions depending on the answer. Necrosis is characterized by cellular swelling, membrane blebbing, DNA fragmentation and release of cellular components, whereas apoptosis is characterized by cellular shrinking, caspase activation, DNA fragmentation, chromatin condensation with initially no release of cellular contents[32]. These processes lead to dramatically different outcomes after cell death in regards to progression of disease with ne-

crosis leading to increased inflammation and further aggravation by inflammatory cells[81,90,91].

Although there is no question that high concentrations of certain hydrophobic bile acids can cause apoptotic cell death in cultured rodent hepatocytes[22-27, 34-42,67,68] as discussed earlier, the pathophysiological relevance of these observations for *in vivo* models, e.g., BDL, is questioned due to the fact that the pro-apoptotic bile acids do not achieve sufficiently high levels *in vivo* to directly cause cell death[8,9]. Thus, the evaluation of the mechanism of cell injury has to be based on the *in vivo* evidence. Early studies concluded that BDL-induced liver injury was caused by apoptosis mainly due to the positive terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) assay[92-94] which is clearly not specific for apoptotic cell death[30-32]. In addition, immunofluorescence was used to detect cells with active caspases 3/7[95] but this was not confirmed by others[96]. Additional arguments for apoptosis were the reduced BDL-induced liver injury in Fas receptor-deficient *lpr* mice[94] and after anti-sense treatment to reduce Bid expression[97]. However, *lpr* mice are protected due to the reduced inflammatory response[98] and genetically Bid-deficient mice did not show reduced liver injury[96]. In contrast, numerous studies did not find any morphological evidence of apoptosis[11,12,68,98-101] and no evidence of caspase activation (enzyme activity and/or active fragments) or immunohistochemical staining for cytokeratin 18 cleavage products or active caspase-3/7[96,98,99]. In addition, potent caspase inhibitors, which effectively eliminated caspase activation and cell death in Fas- or TNF-mediated apoptosis models[98,102], did not protect against BDL-induced liver injury[98]. The one study reporting reduced injury after a caspase inhibitor in the absence of relevant caspase activation[95] may be due to off-target effects on other proteases[103]. Likewise, the anti-sense knock-down of Bid gene expression may have caused compensatory protective gene activation, which may have attenuated BDL-induced liver injury[95]. Clearly, Bid-deficient mice were not protected against BDL-induced liver injury[96]. The cathepsin B knockout mouse also showed protection against apoptotic injury[92], although apoptosis was assessed entirely based on the TUNEL assay. While the reduction in injury was attributed to lack of cathepsin B, and thus a lack of apoptotic processing proteins, the paper also showed a significant reduction in the neutrophilic inflammatory response[92]. Thus, the reduced injury in cathepsin B-deficient mice may have been due to reduced inflammation rather than apoptotic cell death. Taken together, the preponderance of experimental evidence supports the conclusion that liver injury after BDL involves mainly necrotic cell death.

In conclusion, when using morphological criteria of apoptosis and caspase activation in combination with positive controls of apoptotic cell death *in vivo*, the overwhelming experimental evidence supports the conclusion that there is no relevant apoptotic cell death but almost exclusively necrosis after BDL. The main paradigm shift comes from the recognition that the well-known hepatotoxic bile acids never reach concentrations in the liver after BDL that would directly cause cell death. In contrast, the most common bile acids that reach close to mmol/L levels trigger inflammatory mediator formation, which initiates an inflammatory response and cell death caused by neutrophils through oxidant stress. Initial data from human patients with cholestatic liver disease appear to confirm several aspects of the mouse model. Thus, the focus of future research should be on evaluating the cell stress mechanisms in hepatocytes considering pathophysiologically relevant bile acid mixtures and on further characterizing the initiation of the inflammatory response after BDL. Understanding these early injury mechanisms may not only reveal therapeutic approaches to reduce liver injury but also the subsequent fibrosis.

Abstract

The second part of the Consensus Statement of the Italian Association of Hospital Gastroenterologists and Italian Society of Colo-Rectal Surgery reports on the treatment of chronic constipation and obstructed defecation. There is no evidence that increasing fluid intake and physical activity can relieve the symptoms of chronic constipation. Patients with normal-transit constipation should increase their fibre intake through their diet or with commercial fibre. Osmotic laxatives may be effective in patients who do not respond to fibre supplements. Stimulant laxatives should be reserved for patients who do not respond to osmotic laxatives. Controlled trials have shown that serotoninergic enterokinetic agents, such as prucalopride, and prosecretory agents, such as lubiprostone, are effective in the treatment of patients with chronic constipation. Surgery is sometimes necessary. Total colectomy with ileorectostomy may be considered in patients with slow-transit constipation and inertia coli who are resistant to medical therapy and who do not have defecatory disorders, generalised motility disorders or psychological disorders. Randomised controlled trials have established the efficacy of rehabilitative treatment in dys-synergic defecation. Many surgical procedures may be used to treat obstructed defecation in patients with acquired anatomical defects, but none is considered to be the gold standard. Surgery should be reserved for selected patients with an impaired quality of life. Obstructed defecation is often associated with pelvic organ prolapse. Surgery with the placement of prostheses is replacing fascial surgery in the treatment of pelvic organ prolapse, but the efficacy and safety of such procedures have not yet been established.

MEDICAL AND REHABILITATIVE TREATMENT

Behavioural modification is considered to be the first-line treatment in patients with symptomatic chronic constipation. If the behavioural modification proves unsuccessful, various pharmacological approaches are available.

Behavioural modification

Recommendations for lifestyle changes in patients with chronic constipation are based on the widespread belief that constipation is associated with low physical activity, reluctance to defecate whenever the need is felt, and poor fluid intake.

Can behavioural changes help the patient with chronic constipation?

Physical exercise: Epidemiological studies report that constipation is more frequent in subjects with a sedentary lifestyle[1]. Physical activity can increase colonic transit time[2] and reduce other symptoms of constipation in elderly subjects[3]. Trials evaluating the effect of exercise in constipated patients are lacking. Increased physical activity is often recommended for patients with chronic constipation, but there is no evidence that constipation can be improved by increased physical activity.

Defecation habits: Patients with chronic constipation are often instructed to defecate when the need is felt and to try to defecate at the same time every day, ideally upon awakening and after meals, when the colonic motor activity is highest. This recommendation is based on the observation that many people with normal colonic activity routinely defecate at the same time each day[4]. Trials evaluating this recommendation in constipated patients are also lacking.

Increased fluid intake: It is generally believed that increased fluid intake improves constipation. In one trial, healthy volunteers were given increasing amounts of liquids, up to 2 L/d. The volume of urine increased, but the stool frequency did not[5]. This finding is not surprising because the absorption capacity of the small intestine is 7-10 L/d. Trials evaluating the effect of increased liquid intake in constipated patients are lacking, and there is no evidence that constipation can be improved by increasing oral fluid intake, unless the patient is dehydrated[6]. Suggestions for behavioural changes are not usually helpful. These recommendations are supported by Level V evidence, Grade C recommendation.

PHARMACOLOGICAL THERAPY

Various drugs are available to treat chronic constipation (Table 1). Laxatives generally can resolve the symptoms of constipation, but few rigorous studies on their effectiveness have been conducted[7]. Placebo-controlled trials conducted over a sufficient period of time are needed to demonstrate the actual efficacy of an agent. Many trials have been of short duration (4 wk), which limits the validity of their conclusions because cognitive studies have shown that half of all patients become dissatisfied with their therapy over time[8]. Furthermore, the results of different studies are not always comparable; the definition of constipation may not be sufficiently specific, and the therapeutic end-point may simply be stool frequency, without taking other symptoms into account.

The resolution of constipation-related symptoms is an important therapeutic target because constipation is a complex condition, with hard stool, straining, incomplete evacuation, bloating, and abdominal discomfort. Infrequent bowel movements are not always present, and infrequent bowel movements are certainly not the most unpleasant[8] symptom of constipation. Additionally, investigators have only recently begun to address the important problem of quality of life in patients with constipation, which has been shown to worsen as constipation-related symptoms increase[9-11].

Defining constipation remains difficult[12]. Patients and physicians often have different feelings and opinions on the matter; patients use the word "constipation" to mean the annoying symptoms related to defecation, but physicians use this term to describe infrequent bowel movements[13,14]. Constipation has two different but overlapping pathophysiological characteristics: delayed transit and evacuation disorders. The Roma Ⅲ criteria[15,16] were developed by an international panel of experts and have been applied in several clinical trials of laxatives. These criteria have also been adopted in this consensus statement and are useful in clinical practice and for clinical research.

Bulking laxatives

Bulking laxatives consist of fibre. These agents must be ingested with sufficient amounts of water to increase the weight of the faeces. Their action begins within 12 to 72 h, but their effectiveness should be assessed after a period of some weeks. There are two types of fibre: in-

Table 1 Classes of drugs used to treat chronic constipation

Type of medication	Drugs
Laxatives	
Bulking (insoluble and soluble fibres)	Bran, methylcellulose, psyllium
Osmotic	Lactulose, sorbitol, magnesium hydroxide, magnesium salts, polyethylene glycol
Stimulant	Anthraquinone derivatives: senna, aloe, cascara
	Diphenylmethane derivatives: bisacodyl, sodium picosulfate
Softening	Liquid paraffin (vaseline oil), docusate, glycerine
Serotoninergic enterokinetic agents	Tegaserod, prucalopride, renzapride
Prosecretory agents	Lubiprostone, linaclotide
Gastrointestinal μ-opioid antagonists	Methylnaltrexone, alvimopan
Probiotics	Bifidobacterium, lactobacillus
Colchicine	

soluble and soluble. Insoluble fibre consists of bran containing cellulose, hemicellulose and lignin. Galattomannan, pectin, gum and mucilage are types of soluble fibre that can be found in fruits and in some vegetables. Most types of soluble fibre are completely fermented in the colon, except psyllium, which is only partially fermented. Fermentation increases the production of short-chain fats and gas; therefore, one side effect of bulking laxatives is bloating.

What evidence is there for the effectiveness of added fibre intake?

Current guidelines recommend the use of fibre in both dietary and supplement form for the first-line treatment of chronic constipation[17], but a recent review showed that there is little evidence to support this approach[18].

Trials of insoluble fibre

There have been only two well-conducted placebo-controlled trials of insoluble fibre[18]; the first used bran and the second used rye bread. The first trial was a crossover study that enrolled 24 patients. In this study, the effectiveness of bran was documented only if the placebo was given before the bran[19]. The second trial studied 29 patients and compared a diet rich in rye bread to a diet containing low-fibre bread. The bowel movement frequency and difficulty in defecation significantly improved with a diet rich in rye bread[20].

In a randomised trial, 117 constipated patients were treated with bran plus water: one group was told to drink water as desired, whereas the other group was instructed to consume 2 L of water per day. The ingestion of bran plus 2 L of water increased the stool frequency ($P < 0.001$) and reduced the use of rescue laxatives[21]. Fibre supplementation may lead to the increased use of enemas and suppositories[22]. The data regarding insoluble fibre are conflicting[18]. Treating constipation with bran is supported by Level Ⅲ evidence, Grade C recommendation.

Trial of soluble fibre

Placebo-controlled trials of psyllium: Psyllium fibre is partially soluble and is the most studied type of fibre. Three placebo-controlled trials on the efficacy of psyllium have been published[23-25]. Two found that psyllium was superior to a placebo in increasing the frequency of defecation ($P < 0.05$) and improving the consistency of the stool ($P < 0.05$)[23,24]. Ashraf *et al*[23] conducted a well-designed study, but it only lasted 8 wk and only enrolled 22 patients. The third study reported no significant difference between psyllium and a placebo[25].

Studies comparing psyllium with other laxatives: One trial reported no difference in the stool frequency between a regimen of senna plus psyllium and psyllium alone[26]. A study comparing psyllium and laxatives (lactulose, bisacodyl, docusate, senna and magnesium salts) found that psyllium was more effective in increasing the stool frequency and improving the stool's consistency[27]. The use of psyllium is supported by Level Ⅱ evidence, Grade B recommendation.

Osmotic laxatives

Osmotic laxatives attract water into the colon by osmosis. Sugar-based laxatives and polyethylene glycol (PEG) are effective after 24 to 48 h. Magnesium hydroxide and magnesium salts are effective after 6-8 h.

How effective are osmotic laxatives?

Placebo-controlled trials of lactulose: Three trials have shown the effectiveness of lactulose[28-30] in increasing the stool frequency ($P < 0.05$). These trials may be biased, however, because of the number of patients enrolled and their age; furthermore, the sex distribution and treatment duration were not specified. The side effects of lactulose include bloating, nausea and abdominal cramps.

Trials of lactulose *vs* other laxatives: Several trials have compared lactulose with other laxatives. Lactulose was shown to be less effective than PEG[31,32]. Psyllium plus senna was shown to be more effective than lactulose, but this combination can cause incontinence[33-35]. No difference was found between lactulose and psyllium[36] or lactulose and sorbitol[37], but nausea was reported more frequently in patients treated with lactulose ($P < 0.05$)[37]. The recommendation regarding sorbitol could not be graded because of insufficient data; the trial only enrolled men, and the randomisation procedure was not described[37]. The use of lactulose is supported by Level Ⅱ evidence, Grade B recommendation.

Magnesium hydroxide and magnesium salts: There is only one study in the literature that compares magnesium hydroxide to bulking laxatives[38]. Published in 1987 and focusing on elderly patients, this study has various drawbacks. However, in patients receiving magnesium hydroxide, the stool frequency was higher ($P < 0.001$), and the use of rescue laxatives was lower ($P < 0.01$).

The possible risk of hypermagnesemia with these agents must be mentioned[38]. Hypermagnesemia was not reported in this study but can occur in patients suffering from renal disease[39].

No clinical trials using magnesium salts (Epsom salts, English salt) have been published in the last 40 years. The use of magnesium hydroxide is supported by Level V evidence, Grade C recommendation.

Placebo-controlled trial of PEG: PEG is an organic polymer that is not degraded by the intestinal flora. The effectiveness of PEG has been documented in numerous trials[40-44]. PEG increased the stool frequency ($P < 0.01$) while improving the stool consistency[40,41,43] and reducing other symptoms of constipation[41,43]. Iso-osmotic or hypo-osmotic solutions of PEG consistently improved the frequency of bowel movements compared with the frequency before treatment ($P < 0.001$)[45]. PEG was well tolerated, and side effects (abdominal cramps, flatulence, nausea) were rare.

Trials of PEG *vs* other laxatives: PEG is more effective than lactulose[31,32] in increasing the stool frequency and improving the stool's consistency. In patients treated with PEG, there are also lower rates of rescue medication use and flatulence. One trial showed that PEG was more effective than Tegaserod[46]. PEG is a pillar in the treatment of chronic idiopathic constipation because of its high efficacy. There is evidence that PEG provides significant benefits compared with placebos and other laxatives. Furthermore, retrospective studies show that PEG remains effective for up two years of treatment[46,47]. The use of PEG is supported by Level I evidence, Grade A recommendation.

Stimulant laxatives

Stimulant laxatives are not absorbed and have a prokinetic effect in the colon; they stimulate the production of secretions and reduce the absorption of water and electrolytes. Stimulant laxatives begin to take effect 6 to 12 h after administration. Bisacodyl and sodium picosulfate (SPS) are prodrugs[48].

How effective are the stimulant laxatives?

Placebo-controlled trial of stimulant laxatives: Although stimulant laxatives have been used for many years to treat patients with constipation and are often used as rescue medications in clinical trials of other laxatives, only recently have placebo-controlled trials of stimulant laxatives been conducted. SPS[49] and oral bisacodyl[50] increase the stool frequency ($P < 0.0001$) while improving the stool consistency and decreasing the symptoms of constipation and the use of rescue medications ($P < 0.01$). These drugs are well tolerated and appear to generally improve the patient's quality of life.

Comparison of stimulant laxatives and other laxatives

Senna plus a bulk laxative[33,34] is more effective than lactulose ($P < 0.05$) but less effective than psyllium alone[26]. The faeces are softer with lactulose than with stimulant laxatives ($P < 0.001$)[51].

Adverse effects of stimulant laxatives include abdominal cramps and diarrhoea. Experimental studies have shown that stimulant laxatives do not damage the colonic epithelium[52]. Hepatotoxicity has been reported with some products; anthraquinone derivatives can cause melanosis of the colon.

Some physicians fear that the prolonged use of stimulant laxatives can induce dependency. The classical concept of dependency to a drug is characterised by specific features such as lack of control over intake, compulsive use and craving for the drug. The addiction to drugs usually occurs via the activation of dopaminergic systems after passage through the blood-brain barrier. Stimulant laxatives are not absorbed and do not pass the blood-brain barrier, so there is no pharmacologic basis for dependency. Moreover, the existence of "rebound constipation" after the laxatives are stopped has not been definitively established[6]. However, many constipated patients require a constant intake of laxatives to achieve normal (or what they believe to be "normal") bowel movements. Additionally, the abuse of laxatives has been reported in some patients; these cases of laxative misuse are often the result of psychological/psychiatric problems[53]. The use of SPS and bisacodyl is supported by Level I evidence, Grade B recommendation. It is not possible to provide graded recommendations for the other stimulant laxatives because placebo-controlled trials are lacking.

Softening laxatives

Softening laxatives make the stool softer by forming an emulsion of the faeces with lipids and water. Olive oil and sweet almond oil can function as softeners if their intake exceeds the absorptive capacity of the small intestine.

What evidence is there for the effectiveness of softening laxatives?

Docusate: Docusate is an anionic detergent that mixes aqueous and fatty components, thereby softening the stool; it may be administered orally or rectally through enemas or micro-enemas. When administered per rectum, docusate acts within 30 min.

Placebo-controlled trial of docusate: Two trials testing orally administered docusate yielded conflicting results. In the first trial, there was no difference in the stool frequency[54], but in the other study, a significant difference in stool frequency was observed ($P < 0.01$)[55].

Comparison of docusate with other laxatives: Psyllium was more effective than docusate for stool softening ($P < 0.04$)[56]. Therapy with docusate is supported by Level V evidence, Grade C recommendation.

Liquid paraffin (vaseline oil): Liquid paraffin is taken

orally and begins to take effect 6-12 h after administration. It acts by reducing the absorption of water and electrolytes. Its chronic use can damage the mucosal epithelium and lead to malabsorption of fat-soluble vitamins; aspiration can cause lipoid pneumonia. We did not find any randomised clinical trials in the literature on this product.

Glycerine: Glycerine, used as a suppository and mixed into enemas, is classified as a softening laxative, but its mechanism of action is unclear. It is assumed that, applied locally, glycerine produces tissue dehydration and irritation that in turn stimulate contractions of the rectum and defecation.

Serotoninergic enterokinetic agents

Serotonin (5-HT) is a critical component in the regulation of gut motility, visceral sensitivity, and intestinal secretion. Serotonin acts mainly on the 5-HT3 and 5-HT4 receptors expressed by enteric nervous system interneurones. Stimulation of the 5-HT4 receptor is responsible for excitatory effects such as the peristaltic reflex.

The 5-HT4 receptor agonists belong to several different classes of drugs. Cisapride is a substituted benzamide that acts as a partial 5-HT4 receptor agonist. Renzapride is a benzamide hydrochloride that is a full agonist of the 5-HT4 receptor, an antagonist of the 5-HT3 receptor, and a weak partial antagonist of the 5-HT2b receptor. Tegaserod is an aminoguanidineindole that is a 5-HT4/5-HT1 receptor partial agonist and a 5-HT2 receptor antagonist. It also has been shown to inhibit dopamine and noradrenaline transporters. Prucalopride is a dihydrobenzofurancarboxamide that is a selective 5-HT4 receptor agonist.

What evidence is there for the effectiveness of these drugs?

Placebo-controlled trials of serotoninergic enterokinetic agents: A recent systematic review of available controlled trials[57] showed that cisapride was more effective than a placebo in improving the gastrointestinal transit time. However, there was no evidence that cisapride use resulted in a global improvement of constipation-related symptoms compared to the placebo. It was concluded that cisapride use had no clear benefit and that the use of this drug could not be justified because of its cardiotoxic side effects. Indeed, in 2000, cisapride was withdrawn from the market because it had been associated with rare dose-dependent cardiac events, including lengthening of the QT interval, syncope, and ventricular arrhythmia in patients with predisposing conditions. These effects may be caused by the interaction of cisapride with the cardiac hER potassium channel. Although cisapride was withdrawn from the market, it can still be purchased online.

In a placebo-controlled trial, renzapride[58] was only marginally superior to a placebo in reducing the symptoms of constipation and did not improve the quality of life. This drug can cause ischemic colitis.

Large studies of tegaserod[59-61] and prucalopride[62-65] have been conducted that enrolled over 2500 and 2000 patients, respectively. Both drugs improved the stool frequency ($P < 0.001$), improved stool consistency, decreased the need for rescue medications, and reduced the symptoms of constipation. Tegaserod was previously approved in the United States but was not approved in Europe, except in Switzerland. It was withdrawn from the market in March 2007 because of an increased risk of cardiovascular adverse events (including myocardial infarction, unstable angina, and stroke) and is now only available for emergency use. The cardiovascular side effects may be related to vasoconstriction mediated by 5-HT1B receptors in the vascular wall[66].

Drugs with a higher selectivity for 5-HT4 receptors (e.g., prucalopride) may be able to minimise the incidence of cardiac side effects. In a small trial of patients with chronic noncancer pain suffering from opioid-induced constipation, prucalopride was found to be effective and safe[67]. The European Medicines Agency (EMA) approved the use of prucalopride in July 2009. The use of prucalopride is supported by Level I evidence, Grade A recommendation.

Prosecretory agents

Prosecretory agents stimulate the secretion of fluid into the intestinal lumen by activating intestinal chloride channels (lubiprostone) or the guanylate-cyclase receptors of enterocytes (linaclotide).

What evidence is there for the effectiveness of the prosecretory agents?

Placebo-controlled trials using lubiprostone: Two trials[68,69] showed that lubiprostone significantly increased the stool frequency, improved the stool consistency and reduced straining. Nausea was reported as a side effect. The Food and Drug Administration approved the use of lubiprostone for the treatment of adult patients with chronic idiopathic constipation in 2006. The EMA has not yet approved its use in Europe. The use of lubiprostone is supported by Level I evidence, Grade B recommendation.

Linaclotide: This drug has been reported to be effective in irritable bowel syndrome (IBS)[70]. In patients with chronic constipation[71,72], linaclotide significantly increased the stool frequency, improved the stool consistency and reduced straining. The health-related quality of life improved. Diarrhoea can be a side effect. The drug is currently being tested in a phase Ⅱ study.

Gastrointestinal μ-opioid receptor antagonists

Constipation is a side effect of opioid treatment that results from interference with the gastrointestinal μ-opioid receptors. Methylnaltrexone and alvimopan can increase the intestinal motility in patients taking opioid medications ($P < 0.001$) without neutralising the analgesic effect

of opioids[73-75].

One trial showed these drugs to be ineffective in patients with constipation-predominant IBS[76]. It therefore appears that gastrointestinal μ-opioid receptor antagonists are only effective against opioid-induced constipation. Level I evidence, Grade A recommendation regarding the ineffectiveness of this drug in patients with functional constipation.

Probiotics

Probiotics are orally administered living microorganisms that can reach and colonise the bowel. They are mainly prescribed to reduce the bloating and abdominal pain that accompany IBS.

How effective are probiotics in the treatment of chronic constipation?

Milk fermented with *Bifidobacterium lactis* reduced the symptoms of IBS but not constipation in 41 female IBS patients[77]. In women with "self-reported" constipation, probiotics reduced the severity of constipation (P = 0.003)[78]. *Bifidobacterium animalis* increased the stool frequency ($P < 0.01$) and improved the stool consistency in both healthy and constipated women[79]. A study involving 28 subjects reported that *Lactobacillus rhamnosus* + *Propiobacterium freudenreichii* improved the stool frequency but did not decrease the consumption of laxatives[80].

Placebo-controlled trials of probiotics in chronic idiopathic constipation are lacking. Probiotics can be considered for use in conjunction with other drugs in the treatment of chronic constipation. The use of probiotics to treat chronic constipation is supported by Level V evidence, Grade C recommendation.

Colchicine

Colchicine is effective in the treatment of a variety of inflammatory syndromes. In two controlled trials that enrolled a total of 72 patients, colchicine increased the stool frequency and reduced the consumption of laxatives[81,82]. The use of colchicine is supported by Level Ⅲ evidence, Grade C recommendation.

Procedures to empty the rectum and sigmoid colon

There is no controlled randomised trial in the literature addressing the chronic use of suppositories or enemas, which are commonly used for relief from occasional constipation and to empty the rectum in bedridden patients or those with impacted faeces.

Suppositories act by making the stool softer and by generating a foreign body stimulus that leads to the defecation reflex. The precise mechanism of action of transanal irrigation is unknown. Its efficacy may be related to a wash-out effect, and large volumes of liquid generate mass movements[83]. Irrigation volumes of less than 100 mL do not produce distension of the rectum. Without evacuation, the liquid and its solutes are absorbed from the rectum.

Hyperphosphatemia has been reported as a serious adverse event following the misuse of sodium phosphate enemas. A trial recently showed that transient mild hyperphosphatemia following the use of sodium phosphate enemas correlates with retention time but not with dose[84].

Transanal irrigation of the colon, with or without a rectal balloon catheter (Peristeen®), is a useful approach in patients with neurogenic bowel dysfunction secondary to spinal injury[85].

What is the evidence confirming the effectiveness of transanal irrigation in chronic constipation?

Based on the rate of colonic emptying, transanal irrigation appears to be more effective in patients with spinal cord damage than in those with chronic constipation[85].

Retrospective studies report the benefits of transanal irrigation for constipated patients. In one study of 16 patients, symptoms were reduced in 19% of patients suffering from constipation or obstructed defecation[86]. In another study of 37 patients, with a mean observation period of 4.5 years and a maximum observation period of 13 years, transanal irrigation was beneficial in 45% of patients with defecation disturbances[87]. Cazemier *et al*[88] consulted the database of enterostomal therapists for 12 patients for constipation and reported that after a mean observation period of 8.5 years, 42% of patients routinely used transanal irrigation, and 60% were satisfied with this method.

In patients with obstructed defecation, Gosselink *et al*[87] and Gardiner *et al*[89] reported, with colonic irrigation, an effectiveness of 65% and 57%, respectively. Recently, Christensen *et al*[90] presented the results of a long-term study on Peristeen® and reported positive effects in 31% of patients with slow transit constipation, in 43% of patients with obstructed defecation, and in no patients with indeterminate constipation. Retrograde irrigation for the treatment of chronic constipation is supported by Level V evidence, Grade C recommendation. Table 2 summarises the levels of evidence and the recommendation grade for various drugs.

At what point and on what grounds should we judge a treatment to be ineffective?

Generally accepted criteria to define the response to medical therapy have not yet been developed. To date, every clinical trial has defined its own endpoints in terms of the response to therapy.

A medical treatment should be considered unsatisfactory when a patient with good compliance does not report an appreciable improvement in the symptoms and quality of life after at least 4 wk of treatment at the full dose. To assess the therapeutic response, patients should be encouraged to keep a daily diary of their symptoms[91].

REHABILITATIVE TREATMENT

Dys-synergic defecation can be effectively treated by rehabilitative treatment (RT). Protocols vary among dif-

[1]Food and Drug Administration prescribing restrictions; [2]Not approved in Europe; [3]Phase II study. Adapted from: American College of Gastroenterology Chronic Constipation Task Force[184]; and Rao[249].

ferent centres, but all RT programs aim to improve defecation-related behaviour and restore a normal pattern of defecation with both instruments and educational devices.

Electrostimulation, kinesitherapy, biofeedback and volumetric rehabilitation can be used in various combinations to correct the dys-synergic behaviour of abdominal, rectal, and anal sphincter muscles and to improve rectal sensory perception.

RT requires a highly trained therapist and is time-consuming both for the therapist and the patient. Patients must therefore be strongly motivated.

When should RT be prescribed for obstructed defecation?

Functional obstructed defecation is the main indication for RT. Biofeedback is the treatment of choice for patients affected by pelvic floor dys-synergia. Three randomised controlled trials[92-94] have shown a success rate of approximately 70%[76] and a long-term success rate of approximately 50%[94]. Level I evidence, Grade A recommendation.

RT is also an effective therapy for organic diseases such as descending perineum syndrome, rectocele, recto-anal intussusception, rectal mucosal prolapse, rectal solitary ulcer syndrome not related to rectal prolapse, and second-degree sigmoidocele[95,96]. Level IV evidence, Grade C recommendation.

What is the recommended RT for obstructed defecation?

There are no universally accepted recommendations for RT, and there are no specific criteria to evaluate the efficacy of this intervention. The methods used such as biofeedback, kinesitherapy, electrostimulation and volumetric rehabilitation can differ greatly, resulting in a considerable variation in rehabilitation programmes among centres[97]. For this reason, the results of different studies may not be comparable[98-100].

Biofeedback is a technique based on the use of instruments to provide an information loop whose aim is to achieve operant conditioning[101]. Information on a physiological function (such as muscle contraction/relaxation) is translated into a visual or audio signal. When the execution of a muscle movement is correct, a signal is activated. Thus, erroneous functioning can be immediately corrected and the subject is conditioned to perform the correct contraction or relaxation movement. Some authors have studied the use of biofeedback combined with kinesitherapy for the pelvic and perineal muscles. The aim of the therapy in this setting is to teach the patient the correct sequence of contraction and relaxation of the striated muscles that is required for defecation[102-105]. It must be noted that these rehabilitative techniques have not been codified, they vary widely from one country to another, and they are supported by only one randomised trial[98]. Level II evidence, Grade B recommendation.

RT may be useful for improving rectal sensation when anorectal manovolumetry demonstrates rectal hyposensitivity in patients with obstructed defecation[106]. Such RT may be performed through biofeedback ("sensory retraining")[107] or volumetric rehabilitation using an inflated balloon or water enemas of decreasing volume and a probe to monitor muscle movement[108]. Neither biofeedback nor volumetric rehabilitation is supported by randomised controlled trials. Level IV evidence, Grade C recommendation.

Is RT the first therapeutic option?

Biofeedback, either alone or in combination with other rehabilitative techniques[102,103], is generally attempted only after pharmacological therapy has failed[95]. After drugs, however, rehabilitation is the treatment of choice in patients affected by obstructed defecation because there are no side effects. Even if RT fails, it will not have a deleterious effect on the patient's condition, and its results will not affect future decisions regarding therapy, including surgery[106,108,109].

Is RT more effective than drug therapy?

One randomised trial showed that biofeedback was su-

perior to laxatives in improving defecation in patients affected by pelvic floor dys-synergia[97]. It should be noted that the laxative dosage was not high in the control group, but the finding remains that rehabilitation reduced the need for laxatives. Level I evidence, Grade B recommendation.

What factors may influence the efficacy of RT?

There is no general agreement as to what factors may predict or influence the outcome of RT[93,105,110]. In one study, no correlation was found between specific conditions (rectocele, ano-rectal intussusception, descending perineum and sigmoidocele) and the efficacy of biofeedback in patients with dys-synergic defecation[111]. Level Ⅳ evidence, Grade B recommendation. In a more recent study, harder stools, shorter duration of laxative use, higher rectal pressure while straining and prolonged balloon expulsion independently predicted a positive outcome for RT[112]. Level Ⅲ evidence, Grade C recommendation.

Nevertheless, significant anatomic damage, severe psychiatric or neurological disease, poor patient compliance, and poor patient–physiotherapist interactions could pose major obstacles to the success of RT[97,113]. Level Ⅲ evidence, Grade C recommendation.

Does surgery make RT superfluous?

No, the experience suggests that RT, even if it does not achieve satisfactory function, can improve pelvic floor muscle tone and coordination and can contribute significantly to a positive outcome in ano-rectal surgery[114]. Level V evidence, Grade C recommendation.

How should patients who do not respond to RT be managed?

It is not clear how non-responsive patients should be managed because a validated, universally accepted set of criteria regarding the response to RT has not yet been developed. If the clinical grounds for prescribing RT were appropriate (presence of dys-synergic defecation and/or inadequate propulsive forces) and no negative predictive factors are present, the failure of a patient to respond to RT should raise the suspicion of significant organic damage (e.g., a rectocele or rectal intussusception) and lead to the evaluation of surgical options[115]. In fact, in patients with a rectocele and/or ano-rectal intussusception, one of the prerequisites for surgery to correct obstructed defecation is the failure to respond to RT[115]. Level Ⅱ evidence, Grade C recommendation.

In one report on a small number of patients, sacral neuromodulation was found to be effective[116]. Level Ⅳ evidence, Grade C recommendation.

Should RT be prescribed before or after ano-rectal surgery?

Although it is difficult to discriminate between patients who will derive some benefit from RT and those who instead will require surgery, the generally accepted procedure is to begin with RT[117] and, if this proves ineffective, to then consider surgery[115]. Level Ⅱ evidence, Grade B recommendation.

There are no clear guidelines to help the clinician decide between the approaches of "rehabilitation-surgery" and "rehabilitation-surgery-rehabilitation". RT should certainly be prescribed if the outcome of ano-rectal surgery is unsatisfactory[117]. In cases involving large rectoceles, anal fissures or severe anatomical anorectal changes, where it is unlikely that RT will have any direct effect, rehabilitative therapy should be prescribed after surgery[118]. Level V evidence, Grade C recommendation.

Concerning the efficacy of RT following surgery, only a handful of reports on patients who underwent RT for obstructed defecation after ano-rectal surgery have been published, each involving a different protocol. RT has been successful in treating persistent symptoms of obstructed defecation after stapled trans-anal rectal resection (STARR)[119,120], hemorrhoidectomy, and surgery for mucosal rectal prolapse[121]. Level V evidence, Grade C recommendation.

What are the medium- and long-term effects of RT?

Lasting improvement has been observed in patients with dys-synergic defecation (confirmed clinically and by manometry) up to 2 years after RT[92,122-124]. Level I evidence, Grade B recommendation.

SURGICAL TREATMENT FOR SLOW-TRANSIT CONSTIPATION

Colectomy

What are the conditions and selection criteria for colectomy?: There are no randomised trials focusing on the selection of constipated patients for surgery. The most commonly described selection criteria for segmental, subtotal or total colectomy are (Level V evidence, Grade C recommendation): (1) ≤ 2 weekly defecations[125-131]; (2) duration of symptoms (mean 5-17 years)[130,132]; (3) the presence of symptoms such as abdominal bloating or pain, nausea, and vomiting that have a significant impact on the patient's quality of life[110,113,130,132,117]; (4) failure of behavioural, dietetic, pharmacological and RTs to improve the symptoms[109-114,133]; (5) radiological evidence of slow-transit constipation[130,131,133-138]; (6) exclusion of organic or functional pelvic floor disorders (obstructed defecation, Hirschsprung's disease) based on defecography and ano-rectal manometry[131,136-138]; (7) exclusion of upper gastrointestinal tract dysmotility based on functional (manometric, scintigraphic) examinations, if dyspeptic symptoms are present[137,139-141]; and (8) normal results of psychological evaluation (patients with psychological disorders tend to show poor results after surgery for constipation)[136,142-145].

Total or subtotal colectomy with ileorectal anastomosis

What are the levels of evidence and grades of recommendation for this procedure?: No randomised or controlled studies have been published on this proce-

dure. Level V evidence, Grade C recommendation.

What is the success or satisfaction rate following surgery?: Definitive conclusions regarding the effectiveness of surgery cannot be drawn. The methods used to assess the outcome of surgery and patient satisfaction vary greatly. Among 39 published studies, 6 did not define the criteria used, in 17 the assessment was based solely on patient feedback, and in 8 the conclusions were based on the results of post-operative functional tests. Only in 8 studies was the success of surgery determined from functional results and the patient's evaluation. The data collection methods also differ between the studies; they were not defined in 15 of the 39 studies reviewed, whereas a questionnaire was used in 15 studies; only in 9 studies was a post-operative interview conducted. The overall rate of success or satisfaction documented in 39 studies involving 1423 patients was 86% (39%-100%)[125,129,130,133,136,146-149].

What are the post-operative morbidity and mortality rates?: The overall post-operative morbidity in 25 series was 20% (2%-71%)[125,129,130,134,149], and the mortality documented in 26 studies was 2.6% (0%-15%)[125,130,134,146].

Post-operative complications

What is the incidence of small bowel obstruction, diarrhoea, faecal incontinence and abdominal pain, and what is the re-operation rate?: The complication rates were (mean and range): (1) small bowel obstruction, evaluated in 26 series with 913 patients: 18% (2%-71%)[125,129,130,134,146]; (2) chronic diarrhoea, in 19 series with 843 patients: 14% (0%-46%)[130,136,146,148]; (3) faecal incontinence, in 21 series with 913 patients: 15% (0%-52%)[125,129,130,136,146,148]; (4) abdominal pain, in 19 series with 839 patients: 35% (0%-90%)[125,129,130,136,143,146,148]; and (5) re-operation rate, evaluated in 5 studies with 965 patients: 14% (0%-50%)[125,130,134,149].

What are the functional results after surgery, in terms of daily bowel movement rates and recurrent constipation?: In 26 studies[125,129,130,133,146,148] involving 1047 patients and with a mean follow-up period of 44.8 (12-180) mo, the rate of bowel movements reported by the patients was 2.8 times per day, whereas recurrent constipation was reported by 9% (0%-33%) of 683 patients in 17 series[129,130,136].

How often is a permanent stoma the only solution for a patient?: The incidence of permanent stoma placement as a therapy of last resort was 5% (0%-28%) in 27 studies involving 930 patients[125,130,150].

What prognostic factors have been identified?: Preservation of the ileocaecal valve and caecum during isoperistaltic anastomosis resulted in a higher rate of persistent or recurrent constipation[145,146,150,151]. One controlled study[146] reported better results in 45 patients who underwent ileosigmoid anastomosis compared with 34 patients who underwent isoperistaltic caecorectal anastomosis (93% *vs* 73%). Level Ⅲ evidence, Grade C recommendation. (1) Negative prognostic factors described in the literature include the onset of constipation in adulthood or after pelvic or intestinal surgery[151-153]; (2) Positive prognostic factors include childhood onset and "lifelong" duration of symptoms[154,155].

Is autonomic neuropathy an indication for surgery?: A higher rate of post-operative complications (especially small bowel obstruction) and the persistence of pre-operative symptoms (abdominal pain and bloating) have been reported in patients with autonomic neuropathy[141]. Therefore, some authors consider autonomic neuropathy to be a contraindication to surgery[138]. Level V evidence, Grade C recommendation.

Can laparoscopy yield better results than surgery?: Four studies without controls and one evaluating a "hand-assisted" technique have been published, but these were primarily feasibility studies[129,134,136,156,157].

Segmental colectomy

Can segmental colectomy lead to better functioning?: It appears that if the decision to undertake segmental colectomy is based on radiologically demonstrated segmental colonic slow transit, good results can be achieved in 82%-96% of patients[136,158,159]. Without this evaluation, the failure rate is 100%[151,160]. Level V evidence, Grade C recommendation.

Subtotal colectomy with antiperistaltic caecoproctostomy (Sarli's procedure)

Can this procedure lead to better results than conventional total or subtotal colectomy?: In the literature, 3 series[126,157,161] have reported on a total of 43 patients in whom a subtotal colectomy with caecal preservation and antiperistaltic cecorectal anastomosis was performed. These were non-randomised but controlled studies, with subjects undergoing ileorectal anastomosis. Level Ⅲ evidence, Grade C recommendation. Patients reported less faecal incontinence (documented by the Wexner score), less use of anti-diarrhoeal drugs, fewer defecations per day, more consistent faeces and a better quality of life after surgery. After 4.5 years (range 2-7) of follow-up, the mean daily number of bowel movements was 2.5, and the success rate of the surgical procedure was 88% (65% in patients with ileorectal anastomosis).

Does this procedure have a lower incidence of complications?: The cumulative post-operative complication rate was 9% (in 22 patients); 2 (1%) patients experienced small bowel obstruction, but none complained of diarrhoea[126,157,161].

Malone antegrade continence enema

What patients are candidates for this procedure?: Although good results have been reported recently in

adults, Malone antegrade continence enema (MACE) is most successful in paediatric patients[162,163] or in patients with neurological diseases such as myelomeningocele, cerebral or spinal cord injuries, or Hirschsprung's disease[163-169]. The greatest improvement in the quality of life was observed in patients with concomitant faecal incontinence[168]. Level V evidence, Grade C recommendation.

What is the level of evidence and recommendation grade for this procedure?: The level of evidence and recommendation grade cannot be determined because there are no randomised or controlled studies on MACE in the literature[162-172].

What is the success or satisfaction rate with the Malone procedure?: The methods of assessing the overall success or satisfaction rate vary widely among studies. Among 7 studies, the criteria were not clearly defined in one, success/satisfaction was based on the patient's judgement in another, and in 5 the outcome was evaluated based on functional results and the patient's judgement. The data collection methods also varied; they were based on a questionnaire and interview in 4 studies, whereas an interview was conducted in only 3 studies. With a mean follow-up period of 44 (range 12-78) mo, the overall success or satisfaction rate, documented in 7 studies on 67 patients, was 74% (50%-100%)[164-166,169-172], but within 3 years, the MACE procedure was replaced by other therapies in 50%-75% of cases[165,171].

What complications have been observed?: The main complication of this procedure is stenosis of the stoma (8%-50%)[163,165,166,169-171].

Sacral nerve stimulation

What is the level of evidence and the recommendation grade for this procedure in patients with constipation?: One double-blinded, placebo-controlled crossover study in 2 patients[173] and 7 non-randomised studies[116,174-179] have been published, but 3 of these studies[173-175] probably used the same patients. One of these trials was presented only in the form of an abstract at Digestive Diseases Week in 2007[177] and for this reason was not taken into consideration in the calculation of the mean success rate. In this report by Kamm *et al*[177], the success rate of a temporary implant was 66% (n = 67), and all patients with a permanent implant continued to show good results after 12 mo of follow-up.

In a recent prospective study at five European sites, sacral nerve stimulation (SNS) was effective among patients with idiopathic slow and normal transit constipation resistant to conservative treatment. The primary end points were increased defecation frequency, decreased straining and decreased sensation of incomplete evacuation ($P < 0.001$)[179] (Level Ⅲ evidence, Grade C recommendation).

What is the mean success rate of percutaneous nerve evaluation followed, if indicated, by the insertion of a permanent pacemaker?: The overall success rate of percutaneous nerve evaluation, as documented in 4 studies involving 86 patients, was 60% (25%-75%)[174,176,177,179]. In 2 studies[116,175] involving a total of 12 patients who received permanent pacemakers, the reported success rates were 100% and 75% after a median follow-up of 11 and 8 mo, respectively. Finally, the multicentre prospective study coordinated by Kamm *et al*[179] reported that after a median of 28 mo (range 1-55), the frequency of defecations increased from a baseline of 2.3 evacuations per week to 6.6 evacuations per week.

SURGERY FOR OBSTRUCTED DEFECATION

The management of patients affected by obstructed defecation can be challenging because of the frequent association of anatomical and functional anomalies, which makes it difficult to distinguish between the causes and consequences of excessive strain[180,181]. The complexity of the syndrome and the range of available treatments make the outcome of the therapy unpredictable[182]. Surgery is usually considered for patients with reparable anatomical defects, concomitant pathologies, or symptoms that severely impact their quality of life[183].

Indications for surgery in constipation arising from obstructed defecation

Surgical treatment is indicated in cases of reparable anatomical defects, severe symptoms, symptoms leading to a poorer quality of life, or concomitant pathologies[183,184]. Level V evidence, Grade C recommendation.

What criteria are there for evaluating treatment efficacy (severity score, defecography, quality of life)?

The obstructed defecation syndrome (ODS) score is a tool designed to evaluate patients suffering from *pure* outlet obstruction without slow transit or mixed forms of constipation. The ODS provides an index of the disease severity and can be used to monitor the efficacy of therapy[182]. Level Ⅲ evidence, Grade C recommendation. Other tools, such as the Constipation Scoring System[185] and the KESS Score[186], are not specific for ODS but can be employed to study other forms of constipation; some items in these scores are not influenced by the therapy[185].

There are two approaches - abdominal (rectopexy) and trans-anal (STARR or Delorme transrectal excision) - to surgically correct internal intussusception: Which is recommended on the basis of the clinical evidence?

The results of rectopexy are uncertain. Some studies report the persistence or worsening of constipation and difficulty in emptying the rectum in approximately 50% of cases, although the prolapse is corrected in almost all patients[187]. Other studies report that resection and rec-

topexy improve the symptoms relating to intussusception and coexisting anatomical and functional pathologies of the pelvic floor, such as enterocele, solitary ulcer of the rectum, incontinence and descending perineum syndrome[188]. Level V evidence, Grade C recommendation.

Colonic resection and rectopexy can reduce intussusception in 100% of cases, restore anal muscle tone (P = 0.002), reduce the descending perineum ($P < 0.001$) and accelerate colonic transit ($P < 0.001$) with stable results over time (based on a 5-year follow-up)[188]. Level V evidence, Grade C recommendation.

Sutureless rectal mobilisation, suture rectopexy, and mesh rectopexy: Which is better?

In a multicenter randomised study of 252 patients, an actuarial analysis demonstrated a significant difference in 5-year recurrence rates between no-rectopexy and rectopexy groups (8.6% *vs* 1.5%) (log-rank, $P = 0.003$)[189]. Level V evidence, Grade C recommendation.

A ventral instead of posterior mobilisation and fixation of the mesh have recently been advocated and popularised. Excellent results have been claimed, but no randomised comparative trials have been conducted thus far[190-193]. Level V evidence, Grade C recommendation.

Laparoscopy or laparotomy for rectopexy?

Although there are no studies comparing the two different approaches, there is a tendency in the literature to perform this operation laparoscopically because of the potential of this approach to shorten hospital stays, decrease the incidence of abdominal wound complications and improve cosmesis.

A trial assessed the quality of life in ODS patients comparing STARR with biofeedback and reported that the STARR was better ($P < 0.0001$)[115]. Level II evidence, Grade C recommendation.

Which approaches to repair a rectocele (trans-anal, trans-vaginal, perineal, etc.) can be recommended on the basis of evidence based medicine?

The indications for surgery and the choice of procedure are still being debated, and a clear correlation between the correction of the anatomical problem and the improvement of symptoms has not yet been demonstrated[194]. Surgery should only be considered when conservative therapy has failed. Options include trans-vaginal posterior colporraphy and trans-rectal or trans-perineal repair[183]. In terms of an improvement in symptoms, Arnold *et al*[195] did not find any difference between the trans-anal and the trans-vaginal approaches. Level V evidence, Grade C recommendation. Even when the surgical repair has been correctly performed, 30%-72% of patients still experience difficulties in defecating[196]. Level V evidence, Grade C recommendation. Post-surgical complications include faecal incontinence and sexual dysfunction[197,198].

Is there a technique that can be considered the gold standard for the treatment of ODS?

Numerous surgical procedures using different approaches (abdominal, vaginal, trans-anal or perineal) are available for the treatment of ODS, but none has been identified as the gold standard[115]. Level II evidence, Grade B recommendation.

Can obstructed defecation resulting from rectocele/intussusception also be associated with slow-transit constipation?

Slow colonic transit is often observed in patients with a symptomatic rectocele[198,199]. The obstructed defecation in these patients does not appear to exclusively result from the rectocele (Level V evidence). Although improved rectal emptying may be observed after surgical correction, this effect is not likely to affect colonic function. It has been demonstrated that patients with poor functioning after repair of the rectocele still have a prolonged colonic transit time[200]. Furthermore, patients with a slow transit time before the operation show little improvement after surgery[198] (Level V evidence).

Can STARR be effective in the treatment of patients with ODS who fail to respond to medical and RT?

The efficacy and safety of STARR has been demonstrated in ODS patients in whom 5-10 sessions of biofeedback therapy (BF) failed[115]. Level II evidence, Grade B recommendation. This study showed a reduction of the ODS score in 81.5% of patients after STARR (one-year follow-up) compared with a reduction of 13% after BF (difference between the two groups: 48.1%, $P < 0.0001$, 95% CI: 30.1%-66.2%). This study had several drawbacks, however, including the small number of participants enrolled, a 50% dropout rate in the BF group, and the fact that a surgical approach was compared with a non-surgical one.

Can STARR improve the quality of life in patients with rectal intussusception or a rectocele?

The STARR procedure can significantly improve the quality of life in patients suffering from ODS arising from rectal intussusception or a rectocele compared with biofeedback ($P < 0.0001$)[115]. However, other options, such as pelvic floor rehabilitation or the internal Delorme procedure[201], could be considered instead to prevent any potential risk associated with the stapling procedure. Level II evidence, Grade B recommendation.

In cases of ODS arising from rectal intussusception or rectocele, can stapled trans-anal prolapsectomy with perineal levatorplasty alleviate the symptoms?

Boccasanta *et al*[202] compared the stapled trans-anal prolapsectomy with perineal levatorplasty (STAPL) and STARR procedures in a randomised trial. All of the symptoms relating to obstructed defecation improved following both procedures. After a 20-mo follow-up, the

results were still good in 76% of the STAPL patients and in 88% of the STARR patients. The authors nonetheless concluded that STARR is preferable because of the lower post-operative pain ($P < 0.001$), reduced rectal sensitivity ($P < 0.017$), absence of dyspareunia ($P < 0.018$), and a more marked reduction in the rectocele. Level I evidence, Grade B recommendation.

What procedure should be performed in cases of complete rectal prolapse?

Abdominal rectopexy with sigmoidectomy and plain rectopexy with mesh are safe and effective procedures for the treatment of complete rectal prolapse[202]. Level Ⅱ evidence, Grade B recommendation. Only one prospective randomised trial has compared abdominal rectopexy and sigmoidectomy (group Ⅰ) with rectopexy and a polyglycolic acid mesh (group Ⅱ). After correction of the prolapse, 8/11 patients in group I suffering from incontinence and 10/12 in group Ⅱ who had incontinence improved. Six months after surgery, the constipation had disappeared in 3 and 7 patients from groups I and Ⅱ, respectively, but 5 other patients from group Ⅱ required a colectomy within one year after the operation because of severe constipation[203].

Is abdominal rectopexy with sigmoidectomy associated with higher rates of morbidity than simple rectopexy in patients with complete rectal prolapse? Should this procedure be performed in cases of slow transit constipation or only in patients with dolicocolon?

Sigmoid resection with rectopexy is effective in reducing post-operative constipation arising from outlet obstruction without increasing the rate of morbidity[201]. Level Ⅱ evidence, Grade B recommendation. Rectopexy with sigmoid resection can improve the colonic transit ($P < 0.001$)[196], even in the presence of dolicocolon (Level V evidence, Grade C recommendation).

Is SNS effective for the treatment of patients with ODS constipation?

SNS may be effective in the treatment of chronic constipation when other approaches have failed[204]. In a recent prospective study at five European sites, SNS was effective in patients with idiopathic slow and normal transit constipation who failed conservative treatment. In this study, the primary end points were increased defecation frequency, decreased straining and decreased sensation of incomplete evacuation ($P < 0.001$)[179] (Level Ⅲ evidence, Grade C recommendation).

When surgery is indicated for solitary rectal ulcer syndrome, what procedure should be adopted?

Solitary rectal ulcer may be associated with paradoxical contraction of the puborectal muscle, recto-anal intussusception, rectal prolapse and descending perineum syndrome. Treatment of this condition must be conservative. Surgery can be considered for patients with full-thickness rectal prolapse or intractable haemorrhage, but the degree of continence and constipation and the risks of surgery must be carefully assessed in each individual patient, and the patient's preferences regarding treatment should be taken into account. The procedure selected must be safe and balance the risk of morbidity with an acceptable recurrence rate[183,205,206]. Level V evidence, Grade C recommendation. The surgical options include repair of the rectal prolapse with or without resection of the lesion, although the long-term results of this procedure were found to be uncertain. Anterior resection and proctocolectomy have shown satisfactory long-term results[207].

When is surgery indicated for sigmoidocele?

Surgery is indicated for symptomatic patients with third-degree sigmoidocele (below the ischiococcygeal line) or patients who require other pelvic surgery with an abdominal or vaginal approach (hysterectomy, rectal prolapse, rectocele repair). The surgery consists of sigmoid resection and rectopexy with obliteration of the Douglas pouch. Jorge *et al*[208] documented an improvement of the symptoms in 100% of patients undergoing this procedure, compared with 33% of patients who were treated conservatively, after a mean follow-up of 33 mo. Level V evidence, Grade C recommendation.

What is the best surgical treatment for megarectum with or without megacolon?

There has been considerable debate regarding the surgical treatment for megarectum. In megarectum with megacolon, colectomy and ileo-rectal anastomosis is the procedure with the best functional results and the lowest morbidity[209]. In patients who do not experience satisfactory results, total proctocolectomy and ileo-pouch-anal anastomosis is the treatment of choice to avoid permanent ileostomy[210,211] (Level V evidence). In idiopathic megarectum, proctectomy and colo-anal anastomosis with or without colonic reservoir has shown good results; defecation and faecal continence were satisfactory in 72% of patients[212,213] (Level V evidence). The Duhamel procedure is less successful for the treatment of idiopathic megarectum than for Hirschsprung's disease[214]. In idiopathic megarectum, this procedure is associated with the persistence of symptoms and often with the need for a repeat operation[215]. It has been reported that rectoplasty with vertical reduction of the rectum and sigmoid resection results in a significant improvement in the frequency of defecation, a reduced consumption of laxatives or enemas, and satisfaction with surgery in 83% of the patients[216] (Level V evidence, Grade C recommendation).

SURGERY FOR OBSTRUCTED DEFECATION WITH ASSOCIATED PELVIC DISEASES

How often is obstructed defecation associated with pelvic organ prolapse?

A posterior colpocele in pelvic organ prolapse (POP)

may be linked to anatomical conditions such as a rectocele, enterocele or sigmoidocele[217]. Of POP patients, 24%-52% complain of difficulties in defecation[218]. Straining is more common in women with prolapse (61% *vs* 4%; $P < 0.001$)[219].

Is there a correlation between POP and chronic constipation?

The literature is sparse on this point. In a study of 302 patients with urinary incontinence and/or POP, Jelovsek *et al*[220] concluded that chronic constipation plays no significant role in the etiology of the prolapse (Level Ⅳ evidence). Soligo *et al*[221] found that the prevalence of constipation was 33% (95% with obstructed defecation) in 786 women suffering from uro-gynecologic dysfunctions. A significant correlation was noted between constipation and posterior genital prolapse (Level Ⅳ evidence). Similar data have been reported by other authors[222-224].

How does the physiopathologic correlation between POP and obstructed defecation contribute to posterior colpocele and rectocele?

At present we do not know whether constipation is a symptom caused by anatomic functional defects of the pelvic floor[221], or whether it is the cause of static and dynamic changes in the pelvis. Pudendal neuropathy arising from stretching of the pudendal nerve while straining in patients with chronic constipation[225] (Level Ⅲ evidence) may explain the prolapse of the posterior wall and the overall weakening of the pelvic floor[226,227] (Level Ⅳ evidence). According to DeLancey[226], the tonic contraction of the levator ani, the perineal membrane and the endopelvic fascia provide the main support for the posterior vaginal wall. Under physiologic conditions, the levator ani has a double vector. The muscle exerts forward force (closing the vaginal walls) and then extends downward to the perineal body, supported by the perineal membrane, which anteriorly is anchored to the ischiopubic branches. This compensating balance eliminates any traction on the endopelvic fascia (corresponding to the middle third of the vagina or DeLancey level Ⅱ). Pudendal neuropathy reduces the strength of the levator ani, and the downward vector will tend to be toward the posterior vaginal wall rather than the perineal body. A weak endopelvic fascia leads to posterior vaginal wall prolapsed, which may explain both the high and low rectoceles involving the middle vagina and the perineal body, respectively.

What are the most recent anatomical and functional developments in pelvic reconstructive surgery?

Increasingly, prostheses are replacing fascial surgery in the treatment of POP. The synthetic prosthesis is set in a tension-free position and connected to structures such as the obturator membrane, the arcus tendineous of the pelvic fascia, the sacrospinous ligaments or the perineal body. The use of a synthetic mesh has resulted in a marked decrease in recurrence (from 29% in fascial reconstructions to 9% with synthetic mesh), and a significant increase in erosion from 0.7% with the re-absorbable mesh to 10.2% with the synthetic mesh[228] has been observed. Level Ⅱ evidence, Grade B recommendation. However, the efficacy and safety of the prostheses used for the posterior vaginal wall have not yet been established[228] (Level Ⅱ evidence).

Surgical treatment for rectocele has been evaluated in 4 randomised studies (Cochrane Review, 2007[229-233]. The transvaginal approach was associated with the lowest number of recurrences, the use of biologic prostheses did not reduce the recurrence rate, and there was no significant difference between trans-anal and transvaginal procedures in terms of effects on defecation. Level I evidence, Grade A recommendation.

Does obstructed defecation improve after the correction of a posterior colpocele with mesh?

Few studies have considered the effect of surgery for posterior colpocele on posterior compartment dysfunction. The improvement reported in 24%-28%[234,235] of cases in two studies was not based on an adequate scoring system (Level V evidence). The presumption that a dysfunction such as constipation can be treated simply by correcting an anatomic defect is probably incorrect. Approximately 30% of patients with obstructed defecation also complain of slow-transit constipation[236] (Level V evidence). We do not yet understand the pathophysiology of these conditions, particularly with respect to the role of the CNS and ENS. The severity of the obstructed defecation is also not correlated with the results of the pelvic organ prolapse quantification[237-239] or to the anatomic-functional data provided by defecography[222] (Level V evidence, Grade C recommendation).

What is the recommended surgical procedure for post-hysterectomy voltocele?

Voltocele affects 18.2% of women with genital prolapse after hysterectomy. In 72% of these patients, there is also an anterior (cystocele) or posterior colpocele (rectocele or enterocele)[240,241]. The incidence of enteroceles after hysterectomy is between 0.1% and 16%[242]. Voltocele is caused by damage to the supporting uterosacral and cardinal ligaments. Enterocele, a herniation of the Douglas pouch between the vagina and the rectum, is caused by damage to the perineal membrane, which supports the posterior vaginal wall and connects the ischiopubic branches to the perineal body (Level V evidence)[243,244]. The levator ani muscle is also important because it is connected to the middle of the vagina by the endopelvic fascia. Three procedures designed to prevent enterocele and posterior colpocele after hysterectomy, i.e., the Moschcowitz method, the McCall method, and simple closure of the Douglas pouch, were compared in a prospective randomised study with 3 years of follow-up, and the best results were obtained with the McCall operation[245] (Level Ⅱ evidence, Grade B recommendation).

Many techniques have been proposed to correct a

voltocele associated with an enterocele. The abdominal approach with mesh sacrocolpopexy and Douglas obliteration repairs the anatomic defect in 90% of cases[246-248]. In a Cochrane review of 22 controlled randomised studies, abdominal sacrocolpopexy appeared to be superior to the transvaginal approach (vault sacrospinous fixation), with fewer recurrences and less dyspareunia[229], but it is a longer and more painful procedure that involves a longer hospital stay and higher costs[241]. Level I evidence, Grade A recommendation. No data are available on the effects of these procedures on constipation.

APPENDIX

This paper is the second part of the consensus statement of the AIGO/SICCR regarding the diagnosis and treatment of chronic constipation and obstructed defecation. This section will focus on the treatment of this condition.

The first part of the paper was published in the *World Journal of Gastroenterology* 2012 April 14 (ISSN 1007-9327) and describes the materials and methods used to generate these recommendations. Similar to that paper, this article presents the results in a "question-and-answer" format.

Abstract

Portal vein thrombosis (PVT) is one of the most common complications occurring during the natural course of liver cirrhosis. Even though PVT is often asymptomatic, the worsening of liver function, an unexpected episode of gastrointestinal bleeding or ascitic decompensation may be landmarks of PVT development. Beyond these clinical manifestations, it is debated whether PVT really has an impact on liver cirrhosis natural history or rather represents only one of its consequences. Probably PVT development should not only be considered as a matter of impaired blood flow or pro-coagulation tendency. On one hand, PVT seems a consequence of the worsening in portal vein outflow due to the increased hepatic resistance in cirrhotic livers. On the other hand, vascular microthrombosis secondary to necroinflammation may cause liver ischemia and infarction, with loss of hepatic tissue (parenchymal extinction) which is replaced by fibrotic tissue. Therefore, PVT might also be considered as the overt manifestation of the liver fibrosing process evolution and anticoagulant therapy may thus have microscopic indirect effects also on the progression of liver disease. At present, a connection between PVT development and the progression of liver fibrosis/cirrhosis has not yet been demonstrated. Nevertheless, it is not clear if PVT development may worsen cirrhotic patients' outcome by itself. Some authors tried to assess liver transplant benefit in PVT cirrhotic patients but data are contrasting. In this review, we will try to answer these questions, providing a critical analysis of data reported in literature.

INTRODUCTION

Portal vein thrombosis (PVT) is a well-known complication occurring during the course of liver cirrhosis, frequently in the advanced stages. It has been demonstrated that the alteration of blood flow within the portal vein plays an important role in PVT development, together with inherited or acquired pro-thrombotic disorders.

Over the past few years, PVT diagnosis has been constantly increasing due to the amelioration of diagnostic imaging, with partial PVT being now more easily recognizable (Figure 1).

When PVT occurs in a cirrhotic patient, it is always considered a harmful event, because the increase of portal pressure and impaired liver vascularization may lead to gastrointestinal bleeding, worsening of liver function, and ascitic decompensation.

PVT is a matter of concern, especially regarding its treatment. Since PVT occurrence often represents a precipitating event during the course of cirrhotic disease, at the moment of the diagnosis every clinician will try to resolve the obstruction. However, it is unclear whether it could be beneficial or not to treat asymptomatic patients, and which treatment could have the best risk/benefit ratio in cirrhotics. Although anticoagulants seem to be the most used treatment in the last few years, there is at present no consensus regarding the dose and duration of treatment[1].

Some cardinal questions regarding PVT still remain unanswered: as PVT occurs often in the advanced stages of liver disease, what is the connection between PVT development and the progression of liver fibrosis/cirrhosis? Does PVT really have an impact on liver cirrhosis natural history or is PVT only one of its consequences?

In this review we will try to answer to these questions, on the basis of the evidence reported in literature. We intend to point out the question if there really is a connection between PVT development, which often occurs in the advanced stages of liver disease, and histological progression of fibrosis.

PREVALENCE AND CAUSES

Among all cases of PVT, cirrhosis is the underlying cause in 22%-28%[2,3]. Studies based on ultrasonography have reported a prevalence of 10%-25%, excluding neoplastic thrombosis[4-7]. The prevalence of PVT increases with the severity of cirrhosis, being approximately 1% in patients with compensated cirrhosis[8] and rising to 8%-25% in candidates for liver transplantation (LT)[5]; evidence for hepatic vein thrombosis was found in 70% of livers explanted at a stage of advanced cirrhosis[9]. This large variability is due to the fact that PVT is often asymptomatic, therefore its frequency may be underestimated. Indeed, in the majority of patients with cirrhosis, PVT is diagnosed as an incidental finding, often during routine ultrasound evaluation. However, when an episode of decompensation such as the development of ascites or gastrointestinal bleeding occurs, the presence of PVT should always be suspected and investigated[10,11]. At the time of evaluation for LT[12], at LT[13] or at surgical porto-systemic shunting[14], the model for end-stage liver disease (MELD) and Child-Pugh scores seems to be higher in patients with PVT than in those without.

At the origin of PVT development, there is always one or more of the following reasons, which are included in the "Virchow triad": an impaired portal blood outflow (liver architectural changes of liver cirrhosis increase the resistances to flow), a tendency to hypercoagulability, or vascular damage, together with the development of hepatocellular carcinoma[15-17]. In cirrhotic patients, some of these factors may have a greater impact on PVT development (Table 1). Zocco *et al*[18] showed that portal flow velocity is the most important predictive factor for PVT development, especially when portal flow velocity is lower than 15 cm/s at Doppler ultrasound evaluation. It has been reported that when cirrhotic patients develop a hepatocellular carcinoma, PVT incidence rises to 10%-40%[19]. However, although the evidence of a pro-thrombotic condition is not frequent in cirrhotic patients, it should not be a priori excluded.

In a recent study including 136 consecutive cirrhotic outpatients (24.2% diagnosed with PVT), a significant

Figure 1 Portal vein thrombosis. Table 1 Risk factors most frequently involved in portal vein thrombosis. Development in cirrhotic patients, according to the Virchow triad, with the addition of vascular invasion

Circulatory stasis	Procoagulant status	Vascular injury	Vascular invasion
Cirrhosis	Inherited:	Trauma	Hepatocellular carcinoma
	Factor V Leiden mutation	Surgery (e.g., splenectomy colectomy, gastrectomy cholecystectomy	Cholangiocarcinoma
	Factor Ⅱ (prothrombin) mutation	Liver transplantation	
	Protein C deficiency	Invasive procedures (TIPS placement, fine needle aspiration, radiofrequency)	
	Protein S deficiency antithrombin deficiency	Chemical irritation (alcoholization)	
	Acquired:	Infections	
	Myeloproliferative disorder antiphospholipid syndrome	Focal inflammatory lesions (e.g., diverticulitis, appendicitis, pancreatitis, duodenal ulcer, cholecystitis, tuberculous)	
	Hyperhomocysteinemia		
	Malignancy (any abdominal organ)		
	Pregnancy/puerperium		
	Oral contraceptives		
	Sepsis		

TIPS: Transjugular intrahepatic portosystemic shunt.

increase of factor Ⅷ and D-dimer was observed in those with advanced liver cirrhosis. High levels of factor Ⅷ have already been reported in cirrhotic patients and it is now well known that they represent an intrinsic feature of the disease (plasmatic levels of factor Ⅷ beyond the 66th percentile - 129 IU/dL - are reported to have a 6-fold greater risk of PVT development[20]), while the increase in D-dimer is rather considered to be a non-specific finding[21]. However, the only conclusion the author could provide was that low values of D-dimer had high sensitivity and specificity in excluding PVT[22]. Among the other inherited pro-thrombotic disorders, prothrombin gene *G20210A* mutation seems to be the most frequent in cirrhotics with PVT[23-27], while the role of anticardiolipin antibodies is still a matter of concern, due to a high susceptibility to infections and to the presence of liver damage[28-33]. Recently, it has also been reported the presence of the *JAK2 V617F* gene mutation in about 17%-35% of PVT patients without a known underlying disease[34-36]; however, even if it could be a marker of a myeloproliferative disorder before it becomes clinically evident, the prevalence among cirrhotic PVT patients is actually unknown.

PVT DEVELOPMENT AND THE PROGRESSION OF LIVER FIBROSIS/CIRRHOSIS

Is there a link between the progression of liver disease throughout the development of liver cirrhosis and portal vein thrombosis? The answer may be "yes". Different factors appear to be involved in chronic liver injury; among them, the coagulation system appears to be particularly involved. Animal models of cirrhosis confirmed that mice carrying the factor V Leiden mutation exhibit more severe fibrosis than wild-type littermates[37,38]. In other clinical studies, factor V Leiden mutation was reported to be associated with a 3.28-fold increased risk of rapid fibrosis progression in patients with hepatitis C[39]. A similar tendency has been demonstrated in patients with protein C deficiency, increased factor Ⅷ expression and hyperhomocysteinemia[40]. The main link between hypercoagulability and fibrosis progression is still being investigated, but it is more likely due to a reaction to liver tissue ischemic damage. It has been postulated that micro-infarcts resulting from thrombosis of the hepatic and portal vein branches may cause ischemia and cell death, with consequent parenchymal collapse manifesting with areas of parenchymal extinction[41,42]. These areas are then replaced by fibrous tissue producing cirrhosis[37]. Liver injury is able to activate the perisinusoidal hepatic stellate cells, which can transdifferentiate into myofibroblasts, showing pro-inflammatory and pro-fibrogenic activity[38,43]. A similar mechanism of intrahepatic thrombosis of portal vein branches has been recognized at the origin of nodular regenerative hyperplasia development, which could be confused with liver cirrhosis[44].

Indeed, the t-PA-plasmin system is involved in activation of transforming growth factor-beta (TGF-β), a pro-fibrogenic cytokine, which is essential in the pathogenesis of liver cirrhosis. Wanless *et al*[41,42] demonstrated that microthrombi are frequently present within hepatic vessels of patients with liver cirrhosis and other studies showed a correlation between inherited thrombophilic conditions and severity and progression of liver disease. Moreover, hepatitis C virus infected haemophilic patients seem to have a slower disease progression, supporting the hypothesis that a hypercoagulant state may heavily worsen the natural history of liver disease[45].

Even if the exact mechanism is still unknown, a primary role of parenchymal extinction and of stellate cells activation in triggering this process has been postulated. Indeed, vascular microthrombosis secondary to necroinflammation, may cause liver ischemia and infarction, with loss of hepatic tissue (parenchymal extinction) which is replaced by fibrotic tissue. Cirrhosis will therefore result from the confluence of these microfibrotic areas. Alter-

natively, thrombin may induce fibrogenesis by itself, both activating specific receptors on stellate cells, or indirectly, stimulating release of platelet-derived growth factors by platelets and promoting post-translational activation of TGF-β[37,39,40,46]. The first of these is a direct mechanism; G-protein coupled protease activated receptor (PAR)-1, PAR-3 and PAR-4 are associated to thrombin signaling[47-50]. Thrombin exerts a chemotactic effect on monocytes and a mitogenic stimulus for smooth muscle cells, fibroblasts and hepatic stellate cells[51], which express members of the PAR family *via* PAR-1[52-54]. Therefore both an increased generation of thrombin, due to the activation of the coagulation system, and the lack of an adequate inhibition of thrombin generation, as in patients carrying the factor V Leiden mutation or PC deficiency, may contribute to liver fibrogenesis. Elevated levels of factor Ⅷ may also activate PAR-1 signaling[55].

The role of FXa/PAR-2 signaling in hepatic fibrosis is less well characterized, however, there is now evidence for its role in several fibrotic diseases through fibroblast activation including α-smooth muscle actin production, monocyte chemoattractant protein-1 and interleukin-6 secretion, and TGF-β expression[51]. Moreover, FXa signaling *via* PAR-1 remains the most important although this may vary in different tissues[56].

In conclusion, stellate cells activation and parenchymal extinction play a pivotal role in determining liver fibrosis evolution, with a recognized trigger in the coagulation system[33]. In this perspective, PVT development should not only be considered as a matter of impaired blood flow or pro-coagulation tendency, but also as the overt manifestation of the liver fibrosing process.

HOW MUCH DOES PVT IMPACT ON THE NATURAL HISTORY OF LIVER CIRRHOSIS?

Impact on complications

In the past years, cirrhotic patients developing PVT where considered at high risk of mortality for gastrointestinal bleeding, especially in case of complete occlusion. The risk of variceal bleeding is nearly 80-120 times higher in cirrhotics with PVT than in those without liver disease (19%-40%)[17,19,57]. Therefore an episode of unexpected variceal hemorrhage can be linked with a high probability to acute PVT development, as well as refractory ascites in a patient previously responsive to the diuretic treatment[58]. In addition, when the thrombus extends to the superior mesenteric vein, the risk of intestinal infarction is high[59].

PVT has been found to be an independent predictor for failure to control active variceal bleeding and prevent variceal re-bleeding, irrespective of the use of endoscopic hemostasis or surgical shunting as treatment modalities[60,61]. There are some doubts about a supposed favoring role of the endoscopic therapy of esophageal varices in PVT development; probably, varices represent by themselves a marker of portal hypertension, which might be a risk factor for PVT independently of the procedure[59].

Recent data highlight that the prevention of PVT development is a useful tool to avoid the occurrence of decompensation in cirrhotic patients. Zecchini *et al*[62] randomized 51 cirrhotics with advanced liver disease (Child B7-C10) to receive enoxaparin 4000 IU/d (26 patients) or placebo (25 patients) for 12 mo; PVT occurred in 5 patients in the placebo group (2 complete, 3 partial) and in none in the treatment group. Treated patients experienced fewer episodes of decompensation.

Impact on survival

The natural history of cirrhosis in patients with PVT is largely unknown. In the past, patients with PVT were considered to be at increased risk of mortality related to bleeding complications, but the improvement in gastrointestinal bleeding management has changed this perspective[23].

Ferreira *et al*[63] reported data about prognosis of non-tumoral PVT in 40 consecutive cirrhotic patents (median follow-up 6.5 mo). Fifty-eight percent of patients survived at the end of follow-up and PVT was associated with increased risk of mortality at 3 years (but not at 1 year) compared to controls, and this effect was evident only in patients with Child Pugh score lower than 10 (Child Pugh A and B patients).

Englesbe *et al*[64] recently performed a retrospective study to evaluate the survival of cirrhotic PVT patients including a small sample of 148 cirrhotic patients presenting with occlusive PVT followed-up at the University of Michigan during a large period (1995-2007). In this study, which has the limitation of retrospective studies, only patients undergoing pre-transplant screening were included, and there was no certain data regarding the presence of pro-thrombotic disorders, administration of anticoagulants and thrombosis grading. The authors reported 54.7% of deaths in patients with PVT versus 37.2% in patients without PVT. Interestingly, from the time of the initial evaluation, PVT patients had a risk of mortality similar to that of patients with a MELD score of 26, even if their MELD score at the time of LT evaluation was of 12. This risk increased over the time, reaching that of patients who presented for listing with a MELD score of 31. PVT was also showed to influence short-term survival after LT too. Differently from other previous studies, this by Englesbe *et al*[64] took into account MELD score.

On this basis, Englesbe *et al*[64] postulated that, if patients with PVT have significantly worse waiting list survival and an increased mortality, they should consequently have an augmented access to LT. However, the most used allocation system, based on the classification of waiting list patients according to the MELD score, may not represent the real priority of PVT patients as well, since they could maintain a good liver function for long times. Moreover, the assignation of MELD extra points, such as in case of hepatocellular carcinoma, has not yet been introduced in PVT patients. Therefore, Englesbe *et al*[64]

tried to assess the real LT benefit for patients with PVT analyzing data on adult liver transplant candidates waitlisted between September 2001 and December 2007 from the Scientific Registry of Transplant Recipients. Candidates with PVT had similar survival rates on the waiting list compared to those without PVT, but they had a significantly inferior post-LT survival. Therefore, even if a low MELD score may reflect better clinical conditions for liver candidates, with obvious benefits in terms of peri- and post-LT outcomes, especially in presence of PVT that seems by itself to complicate the LT procedure, it seems disadvantageous to allow an early access to LT for cirrhotic patients with PVT. Specifically, the threshold for transplant benefit among patients without PVT was MELD score > 11 compared to MELD score > 13 for patients with PVT. The authors concluded that clinicians should carefully consider the risks of LT in clinically stable patients with PVT. Another recent interesting but small study confirmed this evidence[65]. In this study PVT was related to a decreased post-LT survival only in patients with a low MELD score, while no difference in outcome between PVT and non-PVT patients were found for MELD scores > 15. Notably, there was no difference in PVT extension between the groups with high and low MELD scores. Indeed, the impact of PVT on patients' survival seems to be dependent by its extension; Doenecke *et al*[65] reported 90% 1 year post-LT survival for PVT grade 1/2 patients, compared to 57% for PVT grade 3/4. Except for a slightly higher transfusion requirement for PVT patients, intraoperative parameters as well as the duration of in-hospital stay and the incidence of post-operative liver dysfunction or failure did not differ significantly between high and low MELD PVT groups. In the study by Englesbe *et al*[12] the presence of occlusive PVT at the time of LT was associated with an increased 30 d risk of mortality. Therefore, the increased risk of post-LT mortality in PVT patients seems not only a matter of MELD score[65].

Taking together all these considerations, the outcome of PVT patients undergoing LT still seems to be controversial, almost similar to that of non-PVT patients or rather worse. Even if some authors conclude that no increased risk of mortality was observed for PVT patients while on waiting list and that there was no transplant benefit with an early LT, these considerations should be more cautious. Certainly, PVT grading could be a useful tool to identify those patients with a higher risk of mortality or complications. The observation that PVT patients are not at increased risk of mortality may be a too hazardous generalization of a more complex problem, and the prioritization of these patients should be evaluated on a single case basis.

CONCLUSION

Interesting perspectives may be opened by the connection between hypercoagulation, intrahepatic microthrombosis and progression of liver fibrosis. In particular, stellate cell activation and parenchymal extinction seem to play together a pivotal role in determining liver fibrosis evolution, with a recognized trigger in the coagulation system[33]. From this point of view, PVT development should not only be considered as a matter of impaired blood flow or pro-coagulation tendency, but also as the overt manifestation of liver fibrosing process evolution. Moreover, fibrogenesis itself could be controlled by targeting thrombin generation or its downstream signaling. It has been shown that administration of PAR-1 antagonist, thrombin inhibitor SSR182289, dipyridamole, rivaroxaban (a FXa inhibitor), vitamin K or low molecular weight heparin was able to reduce hepatic fibrosis in animal models[41,52,66-69]. Unfortunately, to date, data about the use of anticoagulants as anti-fibrotic therapy are scarce in humans but they are subject of many ongoing clinical trials.

As regards the second question of this review we can conclude that PVT represents an important event in the natural history of liver cirrhosis. We agree with Tripodi *et al*[55] that liver cirrhosis, slowing-down the physiologic flow of blood in the portal venous system, might favor PVT development but also that PVT development might have an impact on liver function by decreasing portal perfusion. This looping interaction confirms the strict connection between PVT and liver disease. First, PVT could not be merely considered as a problem to solve but, rather, as the alarm-bell that liver disease is evolving. In this perspective PVT prevention could be very important in order to control disease evolution and reduce episodes of decompensation as demonstrated by a recent study by Zecchini *et al*[62].

Second, the impact of PVT development on liver disease progression opens a new debate on the assignation of MELD extra points, such as in the case of hepatocellular carcinoma, in PVT patients on a waiting list for liver transplantation. This point of view is supported by the evidence that PVT cirrhotic patients have a high mortality risk compared to non-PVT ones from the time of evaluation for LT, which could be comparable to that of a MELD score as high as 26-31[64]. On the other hand, it seems that transplant benefit and the post-LT survival of PVT patients might not be advantageous in those with a low risk of liver disease-related mortality (low MELD scores)[12]. In our opinion, this problem should be seen from another perspective; the severity of liver disease may have a heavy impact on patients' survival despite the presence of PVT, which, in turn, should not represent a good reason to prioritize all patients on waiting list, especially those with a low MELD score. However, the presence of major complications, such as chronic hepatic encephalopathy, refractory ascites, recurrent variceal bleeding, with either major or minor bleeding episodes with scarce response to the endoscopic or medical therapy, could represent reasons for the prioritization on waiting list for patients with PVT. Probably, PVT extension should also be considered since it has been reported to impact on post-LT survival[65]. Even

if we are far away from the solution of this debate, we would like to remark that in those countries (e.g., Italy, United States) where the access to LT is determined by the risk of mortality on the waiting list, it is essential to determine how PVT could increase the risk of mortality of cirrhotics awaiting for LT. In this age characterized by organ shortage, liver graft loss should be avoided, thus maximizing the benefit of LT.

Abstract

AIM: To evaluate the agreement between transrectal ultrasound (TRUS) and magnetic resonance imaging (MRI) in classification of ⩾ T3 rectal tumors.

METHODS: From January 2010 to January 2012, 86 consecutive patients with ⩾ T3 tumors were included in this study. The mean age of the patients was 66.4 years (range: 26-91 years). The tumors were all ⩾ T3 on TRUS. The sub-classification was defined by the penetration of the rectal wall: a: 0 to 1 mm; b: 1-5 mm; c: 6-15; d: > 15 mm. Early tumors as ab (⩽ 5 mm) and advanced tumors as cd (> 5 mm). All patients underwent TRUS using a 6.5 MHz transrectal transducer. The MRI was performed with a 1.5 T Philips unit. The TRUS findings were blinded to the radiologist performing the interpretation of the MRI images and measuring the depth of extramural tumor spread.

RESULTS: TRUS found 51 patients to have an early ⩾ T3 tumors and 35 to have an advanced tumor, whereas MRI categorized 48 as early ⩾ T3 tumors and 38 as advanced tumors. No patients with tumors classified as advanced by TRUS were found to be early on MRI. The kappa value in classifying early versus advanced T3 rectal tumors was 0.93 (95% CI: 0.85-1.00). We found a kappa value of 0.74 (95% CI: 0.63-0.86) for the total sub-classification between the two methods. The mean maximal tumor outgrowth measured by TRUS, 5.5 mm ± 5.63 mm and on MRI, 6.3 mm ± 6.18 mm, P = 0.004. In 19 of the 86 patients the following CT scan or surgery revealed distant metastases; of the 51 patients in the ultrasound ab group three (5.9%) had metastases, whereas 16 (45.7%) of 35 in the cd group harbored distant metastases, P = 0.00002. The odds ratio of having distant metastases in the ultrasound cd group compared to the ab group was 13.5 (95% CI: 3.5-51.6), P = 0.00002. The mean maximal ultrasound measured outgrowth was 4.3 mm (95% CI: 3.2-5.5 mm) in patients without distant metastases, while the mean maximal outgrowth was 9.5 mm (95% CI: 6.2-12.8 mm) in the patients with metastases, P = 0.00004. Using the MRI classification three (6.3%) of 48 in the MRI ab group had distant metastases, while 16 (42.1%) of the 38 in the MRI cd group, P = 0.00004. The MRI odds ratio was 10.9 (95% CI: 2.9-41.4), P = 0.00008. The mean maximal MRI measured outgrowth was 4.9 mm (95% CI: 3.7-6.1 mm) in patients without distant metastases, while the mean maximal outgrowth was 11.5 mm (95% CI: 7.8-15.2 mm) in the patients with metastases, P = 0.000006.

CONCLUSION: There is good agreement between TRUS and MRI in the pretreatment sub-classification of ⩾ T3 tumors. Distant metastases are more frequent in the advanced group.

INTRODUCTION

Depth of tumor spread beyond the rectal wall has been validated as an important prognostic indicator[1-3]. Tumors with 5 mm or less of extramural spread regardless of node status have an 85% cancer-specific survival rate compared with poorer-prognosis tumors with more than 5 mm spread, which have only a 54% 5-year cancer-specific survival rate[4]. The MERCURY study[5] showed that tumor spread can be estimated accurately with magnetic resonance imaging (MRI) in comparison with pathologic results. Studies have shown that there was good to very good agreement on measuring the maximal extramural tumor spread using MRI compared to histopathology[6,7]. The clinical guidelines for neoadjuvant therapy vary among countries.

The tumor extending 5 mm or more into perirectal fat is considered a high-risk disease[8]. Patients with a tumor infiltration depth more than 5 mm are at some institutions offered preoperative long-course chemoirradiation therapy. However, MRI cannot be used in all patients due to contraindications, pacemaker, claustrophobia, *etc*.

Transrectal ultrasound (TRUS) has been shown to be accurate in staging early rectal tumors[9-12] including accurate evaluation of penetration of the rectal wall[13-17]. The ability of TRUS to discriminate between early and advanced tumors has not been well documented. The aim of the present study was to compare the intermodality agreement of TRUS with MRI in measuring the depth of extramural tumor spread in rectal tumors, and to determine the incidence of distant metastases with regard to tumor invasion measured by TRUS.

MATERIALS AND METHODS

The study was approved by the local ethics committee and by the National Data Protection Agency (jr. nr. 2011-41-6988), according to national law.

From January 2010 to January 2012, 153 consecutive patients with suspected rectal carcinomas were referred to the Department of Radiology for local staging. The patients were retrieved in the Radiology Information System (Kodak Carestream RIS 2008, Eastman Kodak Company, NY, United States). Fourteen patients having neither TRUS nor MRI were excluded as well as 11 patients with other cancers. The reasons for exclusion are listed in Table 1. A total of 86 patients with sonographical ⩾ uT3 tumors were included in this study, five of these were uT4. The mean age of the patients was 66.4 years (range: 26-91 years). Forty-five of the 86 patients were treated with radio-chemotherapy. The diagnosis of rectal carcinoma was confirmed in all patients by histopathological examination of the biopsy material. The sub-classification of ⩾ T3 was defined as: a with a penetration of the rectal wall from 0 to 1 mm, b: 1-5 mm, c: 6-15 mm, d: > 15 mm. Early ⩾ T3 tumors as ab (⩽ 5 mm penetration) and advanced tumors as cd (> 5 mm penetration).

All patients underwent TRUS using a 6.5 MHz forward looking transrectal transducer (EC9-4) connected to a Siemens S 2000 ultrasound machine (Issaquah, Washington, United States). The transducer was used to facilitate visualization of stenotic tumors. Patients received a cleansing enema prior to their examination and all procedures were carried out with the patient in the left lateral position. All observers who performing and interpreting the TRUS were specialists in radiology with more than 10 years' experience in TRUS and all had participated in a special training course. The level above the anal verge and location of the tumor were not blinded to the observers. The extent of wall invasion was assessed according to uT criteria as described by Hildebrandt *et al*[18]. In all ⩾ T3 patients in the study population the maximal depth of extramural tumor spread was prospectively measured in mm and the ultrasound images were stored in the radiological electronic picture archive computer system (PACS).

The MRI scan was carried out using an up-graded 60 cm bore Achiva 1.5 Tesla MRI unit with a 5-element wrap-around surface coil over the pelvis (Philips, Eindhoven, The Netherlands). After localizer scans, fast T2-weighted (w) spin-echo sequences were obtained. The scan included high-resolution 3 mm axial slices at a 90-degree angle to the tumor. The axial scans were prepared by the MR radiographer with assistance from the radiologists to ensure perpendicular images. No contrast enhancement was used. Each patient underwent the TRUS and MRI examinations on the same day. The MRI images were interpreted and reported by two experienced radiologist after the TRUS examination in the daily clinical setting. The depth of extramural tumor spread was measured blindly to the TRUS findings in this study, with special focus on the axial MRI images. All images were evaluated using an Impax PACS workstation (Agfa, Mortsel, Belgium) with two Coronis monitors (1600 1200 pixels; Megapixels Diagnostic Display System; Barco, Kortijk, Belgium). Presence or absence of any distant metastasis at subsequent CT and surgery was recorded.

Table 1 Transrectal ultrasound and magnetic resonance imaging were requested in 153 patients with rectal tumors detected by endoscopy

Patients with suspected rectal cancer admitted to local staging using TRUS and MRI	*n*
Excluded:	
No MRI: pacemaker: 3; claustrophobia: 1	4
No TRUS: poor cleansing: 4; pain: 2; refused: 2	8
Other cancers excluded: anal cancer: 7; carcinoid: 2; GIST: 1; prostate cancer: 1	11
Adenocarcinomas excluded: duplex tumour: 1; stent: 1; sigmoid tumour: 5	7
< uT3: uT1: 9; uT2: 18	27
uT3 with insufficient documentation of outgrowth measurement	4
uT4 with insufficient documentation of outgrowth measurement	6
Total study group	86

Of these, 67 were patients excluded from the study. TRUS: Transrectal ultrasound; MRI: Magnetic resonance imaging; GIST: Gastrointestinal stromal tumor.

Table 2 Extramural invasion measured by transrectal ultrasound and magnetic resonance imaging

	MRI-a	MRI-b	MRI-c	MRI-d
TRUS-a	10	6		
TRUS-b	1	31	3	
TRUS-c			25	3
TRUS-d			2	5

TRUS: Transrectal ultrasound; MRI: Magnetic resonance imaging. The sub-classification of ⩾ T3 was defined as: a: 0 to 1 mm; b: 1-5 mm; c: 6-15 mm; d: > 15 mm.

Statistical analysis

Statistical analysis were performed using Number Cruncher Statistical Systems (NCSS, Kaysville, Utah, United States). Intermodality agreements were assessed with Cohen's kappa statistics. Kappa values were interpreted the following way: absence of agreement 0, slight agreement 0.20, fair agreement 0.21-0.40, moderate agreement 0.41-0.60, substantial agreement 0.61-0.80, and almost perfect agreement 0.81-1.0 as proposed by Landis *et al*[19]. Confidence limits were set at 95 percent. Descriptive statistics were used. Means between TRUS and MRI were analyzed using Paired *t* test. Comparison of proportions was performed by χ^2 test or, when appropriate, Fisher's exact test. *P* values less than 0.05 were considered significant.

RESULTS

TRUS found 51 patients to have an early ⩾ T3 tumor and 35 to have an advanced tumor, whereas MRI categorized 48 as early ⩾ T3 tumors and 38 as advanced tumors (Table 2). Three patients had tumors characterized as early by TRUS (uT3b), but advanced by MRI; however the extent of outgrowth was only 6 mm when measured by MRI. No patients with tumors classified as advanced by TRUS were found to be early on MRI. The unweighted and linear weighted kappa values in classifying early versus advanced ⩾ T3 rectal tumors were both 0.93 (95% CI: 0.85-1.00).

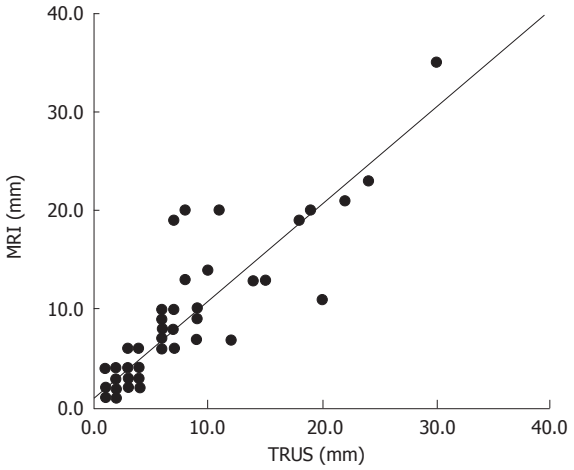

Figure 1 Plot graph showing agreement on depth of extramural tumor spread in mm. The x-axis represents the distance measured by transrectal ultrasound (TRUS) and the magnetic resonance imaging (MRI) results are shown on the y-axis. Correlation coefficient = 0.90.

The results of the subgroup classification are shown in Table 2. TRUS sub-classified 16 patients as uT3a, while MRI categorized six of these as ⩾ T3b. The actual outgrowth measure by MRI was 2 mm in five and 4 mm in one of these patients. One MRI a sub-stage was b sub-stage using TRUS, the difference was 1 mm in this patient.

Three MRI d-group patients were only c-group on TRUS. Two patients had a difference of 12 mm and one with 9 mm (Figure 1 and Table 2). Two were in the d-group on TRUS but on MRI the same patients were in the c-group; the difference in outgrowth was 9 and 2 mm, respectively. We found a kappa value of 0.74 (95% CI: 0.63-0.86) for the total sub-classification between the two methods (Figures 2 and 3).

Figure 1 shows plots of the data from TRUS versus MRI, with respect to maximum extramural tumor spread. Multiple values occurring at a specific point were more common where the tumor outgrowth was limited.

The overall mean maximal tumor outgrowth measured on TRUS, 5.5 mm ± 5.63 mm and on MRI, 6.3 mm ± 6.18 mm, $P = 0.004$. The highest value in the same patient was 30 mm on TRUS and 35 mm measured by MRI.

In 19 of the 86 patients the following CT scan or surgery revealed distant metastases; of the 51 patients in the ultrasound ab group three (5.9%) had metastases, whereas 16 (45.7%) of 35 in the cd group harbored distant metastases, $P = 0.00002$. The odds ratio was 13.5 (95% CI: 3.5-51.6), $P = 0.00002$. The mean maximal ultrasound measured outgrowth was 4.3 mm (95% CI: 3.2-5.5 mm) in patients without distant metastases, while the mean maximal outgrowth was 9.5 mm (95% CI: 6.2-12.8 mm) in the patients with metastases, $P = 0.00004$. Using the MRI classification three (6.3%) of 48 in the

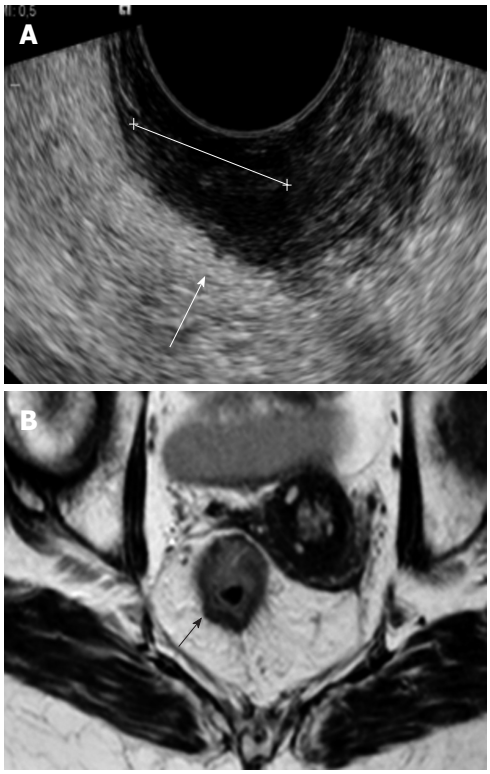

Figure 2 Early T3 rectal tumor on both transrectal ultrasound (A) and axial magnetic resonance imaging image (B). The maximal outgrowth (arrow) was 2 mm using both methods.

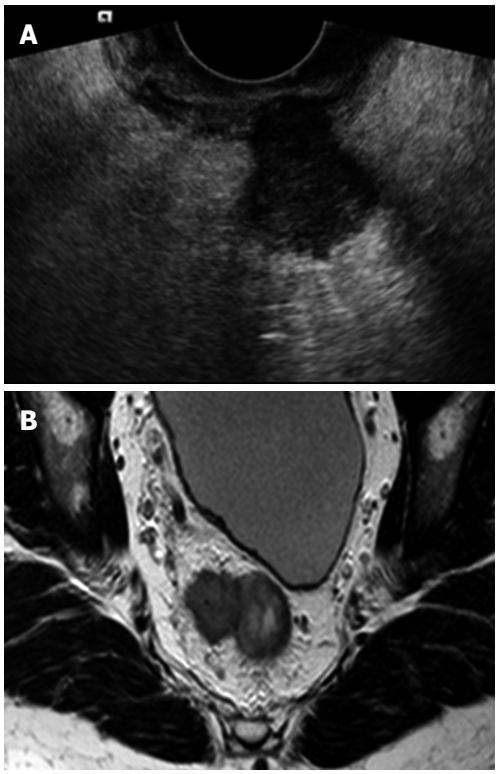

Figure 3 Transrectal ultrasound (A) and axial magnetic resonance imaging images (B) of a patient showing an advanced T3 rectal tumor. The maximal outgrowth on the right side measures 20 mm equally on transrectal ultrasound and axial magnetic resonance imaging.

MRI ab group had distant metastases, while 16 (42.1%) of the 38 in the MRI cd group, $P = 0.00004$. The MRI odds ratio was 10.9 (95% CI: 2.9-41.4), $P = 0.00008$. The mean maximal MRI measured outgrowth was 4.9 mm (95% CI: 3.7-6.1 mm) in patients without distant metastases, while the mean maximal outgrowth was 11.5 mm (95% CI: 7.8-15.2 mm) in the patients with metastases, $P = 0.000006$.

DISCUSSION

This first study on the correlation between TRUS and MRI in discrimination of early *vs* advanced rectal cancer might have clinical implications concerning patients with contraindications to MRI. The results indicate that these patients can be evaluated using TRUS to determine whether the patient has an early or advanced rectal cancer. Patients with claustrophobia, implanted cardiac prostheses, metallic cardiovascular electronic devices, intravascular stents and filters, cochlear implants, bullets, etc. are either not suitable for MRI or there is a serious risk involved in having an MRI performed[20]. Patient movements during the MRI scan are also associated with reduced image quality[21].

Patients with tumors confined to the rectal wall or early T3 tumors can be treated with surgery alone unless suspicious lymph nodes are detected, whereas tumors with advanced mesorectal involvement may benefit from preoperative treatment[22-24]. According to our results three patients were classified as T3b using TRUS, but as T3c using MRI. These three patients would not have been treated with radiochemotherapy using this setting if MRI was contraindicated. However, the invasion in the mesorectal fat was only 6 mm in all three MRI advanced patients.

The discrepancies in the sub-group staging using TRUS and MRI were only minor distances, except for a difference up to a 12 mm outgrowth in a patient with an advanced tumor on both modalities. In the patient with the most extensive outgrowth the measurement varied from 30 to 35 mm and was categorized equally as d-group with the two methods. The resolution of a 6.5 MHz transrectal tranducer is high and approximately the same or higher as the resolution for thin slice axial T2 weighted MRI, ranging about 0.3-0.4 mm. Thus, variances in resolution cannot explain this difference between large tumors. The reason could be measurements at different positions. TRUS can have difficulties in imaging the total volume of large tumors and perhaps this result in underestimation. The presence of a large tumor is significantly related to a poorer performance of TRUS[25]. This can in part explain why TRUS more often underestimated the tumors in the subclassification compared to MRI, than the vice versa (Table 2).

The anal sphincter was involved in three patients, seminal vesicles in a male patient and vagina in a female patient. A recent Japanese pathological study found a 5-year survival of 72.4% *vs* 30.0% in patients with early *vs* advanced T3/T4 tumors[26]. The depth of tumor

invasion beyond the rectal wall is considered to be an important prognostic factor for patients with T3 and T4 rectal carcinoma. The patients classified as advanced had an odds ratio of 13.5 of having distant metastases in the advanced group, although both uT1 and uT2 tumors were excluded. A new MRI study reported that patients with more than 5 mm tumor outgrowth have a higher risk of harboring distant metastases with an odds ratio of six and these patients may undergo more intensive preoperative staging including FDG-PET/CT and liver MRI and be considered for chemotherapy[27]. Another study found a higher incidence of lung metastases with higher T stage[28].

The main strength of the blinded study is that we compared state of the art TRUS with MRI using experienced readers. The ultrasound measurements were performed in a prospective clinical setting but analysed retrospectively. We did not have any lack of thin-slice or high-resolution T2-weighted MRI images perpendicular to the tumor resulting in satisfactory image quality. We did not find any different correlation between TRUS and MRI regarding the TRUS observers. An inter-observer variation study of infiltration depth of ≥ T3 tumors using TRUS will require a 3-dimensional stored image block of the ultrasound data which could be blindly re-evaluated. It was not possible in our clinical setting; an inter-observer study on plane two-dimensional images would introduce an operator bias.

Only a few previous studies have focused on the aspect of tumor outgrowth using ultrasound. Harewood *et al*[29] used TRUS in 14 patients with minimally invasive T3 and 28 patients with advanced T3 disease. They used 2 mm invasion as a cut-off. Digital images were obtained during each TRUS procedure, at least 10 images per patient, illustrating the deepest extent of tumor involvement. These images were reviewed by two observers and a kappa value of 0.62 was reported. The mean depth of invasion beyond the rectal wall was 3.9 mm *vs* 5.5 mm in the present study. The mean outgrowth was 9.5 mm in the metastatic group.

A recent study by Jürgensen *et al*[30] found 16 patients with minimal invasive uT3 tumors and 24 with advanced uT3 cancers. The depth of infiltration beyond the muscularis propria was determined retrospectively by evaluation of paper prints and reports. Six patients could not be classified retrospectively. This discrimination between minimally invasive and advanced cancers correlated well to the pathological stage. In our study we also found a good intermodality agreement between TRUS and MRI, if the cut off between early and advanced ≥ T3 tumors was less than 5 mm.

The patient population of the present study was uniform, containing all patients with advanced rectal cancer, for determining intermodality agreement. In the study period there was no screening programme running for colorectal cancer, favouring a relatively high proportion of advanced tumors. The staging of the stenotic tumors has been accomplished by the use of a forward looking transrectal transducers[31,32] as in the present study. Side-viewing transducers including rotating transducers do not have this possibility of adequate visualising stenotic tumors[33].

The retrospective setting allowed us to evaluate a large number of MRI scans within a relatively short time period, but may invite learning bias of the MRI findings. Another limitation is the use of MRI as reference and not the histopathology of the surgical specimens. The latter was not possible since the majority of the patients underwent preoperative radiochemotherapy. This may explain that our mean invasion depth beyond the rectal wall was more pronounced than in the study by Harewood *et al*[29].

Another drawback of this retrospective study is the exclusion of a few patients with missing values of the precise extent of the tumor outgrowth. Four of the excluded uT3 patients were from the first part of the study period and during vacations, but there was agreement on the T-stage between TRUS and MRI. Finally, TRUS cannot detect the mesorectal fascia as with MRI[34,35], and consequently, MRI is used as a first choice staging modality.

In conclusion, there was very good intermodality agreement between TRUS and MRI in the pretreatment in classification of tumors as early and advanced ≥ T3. Patients with more than 5 mm outgrowth measured by ultrasound have an increased risk of harboring distant metastases. TRUS can be used to predict advanced rectal cancers and thus be helpful if chemoradiation is considered in patients with contraindications to MRI.

COMMENTS

Background

Magnetic resonance imaging (MRI) is widely used in preoperative staging of rectal cancer. Patients with claustrophobia cannot benefit from this method. The depth of tumor outgrowth is an important prognostic factor.

Research frontiers

MRI has recently shown to be accurate in measuring tumor outgrowth and the MRI measured maximal depth of outgrowth seems to be related to presence of distant metastases.

Innovations and breakthroughs

Previously it has been shown that MRI measured extratumoral outgrowth is related to distant metastases. In the present study the authors have demonstrated an almost perfect agreement between MRI and transrectal ultrasound (TRUS) in categorizing early and advanced tumors.

Applications

TRUS can be used to discriminate between early *vs* advanced rectal cancer, and thus be helpful if chemoradiation is considered in patients with contraindications to MRI.

Peer review

Transrectal ultrasound and MRI measurement of depth of extramural tumor spread in rectal tumors Rafaelsen. In this study the authors investigated the depth of tumor spread beyond the rectal wall using MRI and ultrasound (US) techniques in patients with suspected rectal carcinomas. They correlated the data between MRI and US and to metastasis of the cancer. Extension of the tumor beyond the rectal wall was subclassified in units of millimeters. Early tumors were considered to have ≤ 5 mm penetration while advanced tumors were defined as those with > 5 mm penetration. Three patients had tumors characterized as early by US but advanced by MRI, where in the three cases the outgrowth measured by MRI was 6 mm. No patients with tumors classified as advanced by US were classified as early type using MRI. Overall this is an interesting and well done study.

Abstract

AIM: To evaluate gastric motility using electrical bio-impedance (EBI) and gastric changes as a result of stress induced by psychological tests.

METHODS: A group of 57 healthy women, aged 40-60 years, was recruited, and a clinical history and physical examination were performed. The women were free from severe anxiety, chronic or acute stress, severe depression, mental diseases and conditions that affect gastric activity. The women were evaluated under fasting conditions, and using a four-electrode configuration, the gastric signals were obtained through a BIOPAC MP-150 system. The volunteers were evaluated using the following paradigm: basal state, recording during the Stroop Test, intermediate resting period, recording during the Raven Test, and a final resting period. We analyzed the relative areas of the frequency spectrum: A1 (1-2 cpm), A2 (2-4 cpm), A3 (4-8 cpm), and A4 (8-12 cpm), as well as the median of area A2 + A3. The data were analyzed by an autoregressive method using a Butterworth filter with MatLab and Origin. Analysis of variance (ANOVA) and Friedman ANOVA (for nonparametric variables) were performed; in addition, pairs of groups were compared using the *T* dependent and Wilcoxon *T* tests.

RESULTS: The results of the main values of area A2 were not significantly different comparing the five steps of the experimental paradigm. Nevertheless, there was a tendency of this A2 region to decrease during the stress tests, with recuperation at the final resting step. When an extended gastric region was considered (1-4 cpm), significant differences with the psychological stress tests were present ($F = 3.85$, $P = 0.005$). The A3 region also showed significant changes when the stress psychological tests were administered ($F = 7.25$, $P < 0.001$). These differences were influenced by the changes in the adjacent gastric region of A2. The parameter that we proposed in previous studies for the evaluation of gastric motility by electrical bio-impedance (EBI) was the median of the area under the region from 2 to 8 cpm (A2 + A3). The mean values of these frequencies (median of the A2 + A3 area) with the stress test showed significant changes ($F = 5.5$, $P < 0.001$). The results of the Wilcoxon *T* test for the A4 area parameter, which is influenced by the breathing response, changed significantly during the Raven stress test ($P < 0.05$).

CONCLUSION: We confirm that the gastric response to acute psychological stress can be evaluated by short-term EBI.

INTRODUCTION

The relationship between emotions and gastric motility has been documented since the beginning of the last century by Cabanis and Beaumont and thereafter by Pavlov and Canon, who were the pioneers in determining the gastric response after an emotional stimulus in animal models[1-3]. In 1934, Hall described the autonomic response of rats exposed to unfamiliar events[1,4]. The effects of stress on the gastrointestinal (GI) tract have been reported since the first studies on the general adaptation syndrome by Selye[5] in 1936, who confirmed the physical, physiological and psychological responses of a living organism due to stress. In healthy humans, anger, fear, labyrinthine stimulation, painful stimuli, preoperative anxiety and intense exercise are some of the causes of slow gastric emptying[1,6,7]. The inhibition of gastric emptying and stimulation of colonic motor function are the most commonly encountered patterns induced by various stressors[1].

In the study of psychological stress as a risk factor for human health, there are few scientific reports in relation to the GI system, and most of the studies in humans have focused on the cardiovascular system because there is a clinical association of psychological and physical stress with a high risk for stroke and cardiovascular events, as well as with increased morbidity and mortality of the population. However, the evaluation of gastric function, particularly gastric motility and emptying, during psychological stress has not been given sufficient scientific attention despite the high prevalence of gastric problems due to psychological stress, such as gastritis, abdominal pain and gastroenteritis[8]. The alterations in the GI motility pattern by various stressors have been documented, although scarcely, with the development of quantitative techniques to monitor GI motility and transit in experimental animals and humans[9,10]. The gold standard technique accepted for gastric activity evaluation is scintigraphy, although this technique measures gastric emptying as the main consequence of gastric motility[11]; however, this technique is invasive. For the direct assessment of gastric motility, there are other invasive methods, such as manometry, which uses a probe placed at a specific point in the GI tract to record directly the frequency and amplitude of the GI movements[12].

Electrogastrography (EGG) is considered an invasive procedure when placing the electrodes in the GI cavity to record the myoelectrical activity of a specific inner surface of the tract[13,14]. However, EGG is a noninvasive technique in which the electrodes are placed on the skin. Another similar technique is the use of electrical bio-impedance (EBI), which also uses cutaneous electrodes in the gastric region[15-17]. In these last two techniques, the main challenge is the interpretation of the signal due to the overlapping information from different regions in the gastric system, particularly with respect to lung region movements in the case of EBI; in both cases, different motility frequencies are involved[16,18]. In general terms, gastric clinical research requires a strong link between the accuracy and reliability of the method and the comfort of the patient[14]. Thus, from this point of view, noninvasive EGG and EBI assessments have advantages over other techniques[19]. Therefore, the use of short-term EBI can be a good tool to evaluate the gastric response to psychological stress.

Furthermore, the possibility of permanent monitoring at a low cost is the preamble for a feedback program to be used in stress treatment and control. Gastric signals are not frequently used for this purpose, although this physiological function is definitively affected by stress. Gastric waves occur at a rate of 3 cpm on average and up to 12 cpm in the intestinal region, therefore, a long recording period is likely needed to assess gastric motility accurately, which contrasts with the need for short, acute stress tests and hence the need for short-term gastric motility recordings. Our hypothesis is that by observing the relative changes of the entire GI activity in the window of frequencies from 1 to 8 cpm, gastric motility can be used to monitor the responses to acute stress that results from the application of psychological tests that last < 10 min, such as the Stroop[20,21] and Raven tests[22].

MATERIALS AND METHODS

Subjects

A group of 57 healthy women, aged 40-60 years (mean ± SD: 48.19 ± 5.98 years), was recruited after the protocol was approved by the Division of Health Sciences Campus Leon at the University of Guanajuato, Mexico. Written informed consent was obtained from all participants, and the study was conducted according to the guidelines outlined in the Declaration of Helsinki (World Health Organization, 1996)[23].

Clinical evaluation

Before starting the experiment, clinical assessments were

conducted for all participants. These assessments included the following: (1) general information, including name, age, sex, and occupation; (2) clinical history, with a clinical evaluation of GI-related diseases; (3) physiological data, anthropometric measurements, and body mass index; (4) lifestyle information, including exercise, sleep habits, and substance abuse (tobacco, alcohol, medication); and (5) additional information obtained by a physical examination. For the purpose of this study, this information was used to assure the internal validity of the study (homogeneity of the study group and the absence of health problems related to the GI tract). To participate in the study, the women had to have met the following criteria: 40-60 years of age, no prior GI disease, and no prior disease that may affect the GI system (diabetes, Parkinson's disease, amyloidosis, myotonic dystrophy, polymyositis, human immunodeficiency virus infection or cytomegalovirus infection). The women were required not to have been taking any treatment that could interfere with gastric activity, have any other endocrine disorder, or have had significant weight loss within 3 mo prior to the study. In addition to these physical criteria, the women had to be free from psychological problems, such as severe anxiety, chronic or acute stress, severe depression and mental disease, because these conditions could potentially affect gastric activity though endocrine and central nervous system modulation[1].

Gastric EBI recordings

Prior to the evaluation, each woman was asked to arrive under fasting conditions (more than 8 h). In addition, the women refrained from smoking, alcohol consumption, strenuous exercise and caffeine for 24 h before the evaluation. The women were evaluated while in the semi-Fowler supine position to enable them to observe a screen on the wall with the projection of the psychological test (Stroop and Raven tests). For this experiment, we used the four-electrode configuration. This configuration consisted of two electrodes placed on the abdomen and two on the back. One pair (one electrode placed on the back and the other placed on the anterior part) was used for the current injection, and the other pair was used for voltage recording. The first electrode was placed near the rib cage using the midline of the abdomen as a reference. The second electrode was placed approximately 5 cm from the first, 45 degrees down and left of the umbilicus. The back electrodes were placed at 2.5 cm off the spine at the level of both electrodes on the abdomen. The electrode configuration used in this study was similar to that used in previous studies, which has shown good results[24]. The gastric signals were obtained through a BIOPAC MP-150 system and the corresponding EBI module[24]. The rough data mainly show oscillations due to breathing and a slower oscillation due to gastric movements (Figure 1).

Paradigm of the stress test

The gastric function for all volunteers was evaluated before, during and after being subjected to two psychological tests that have been shown to produce psychological stress: the Stroop and Raven tests[20-22]. The Stroop Test consisted of a 3-min session during which words in color were projected upon a screen at the rate of one word per second. The participant was asked to say the color of the word. During the first 40 s, words that name several objects were projected on a screen, followed by 1 min of words that name colors. The written color sometimes corresponded to the color of the word and sometimes did not[20]. Finally, words that named several objects but not colors were shown[21]. The Raven Test is a psychological test to determine the intelligence quotient (IQ), which consists of solving sequences and completing figures or truncated shapes. This test was performed without a time limit because the purpose was not the evaluation of IQ but simply to induce a state of psychological stress in the participant[22].

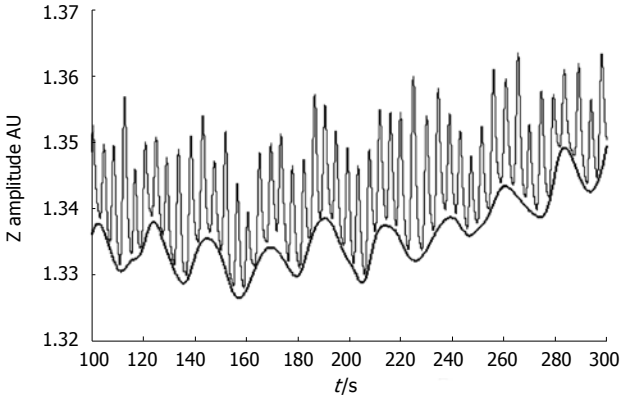

Figure 1 Raw data of the gastric bio-impedance signal showing mainly the breathing oscillations (fast oscillations) and the gastric contribution (2-4/min), which are shown by the dashed curve. AU: Arbitrary units.

The following paradigm was used in this study: (1) 10 min of basal gastric motility (BGM) recording by EBI (before the test); (2) EBI recording during the Stroop Test, lasting 3 min; (3) an intermediate resting period (IRP) of 3 min; (4) EBI recording during the Raven Test, lasting approximately 4 min; and (5) the final resting period (FRP), lasting 3 min.

Data analysis

In general, the parameter used to evaluate gastric motility is the position of the main peak in the region from 2 to 4 cpm of the frequency spectrum of gastric activity. In this study, we proposed alternative parameters when EBI was used[16] to examine the gastric motility changes due to psychological stress. We proposed the analysis of the relative area under the frequency domain curve in different regions of the spectrum as a relative measure of the gastric global activity in each frequency region. The frequency range was divided into four regions: the first (A1) included frequencies from 1 to 2 cpm and defined the low frequencies; the second (A2) included the frequencies from 2 to 4 cpm and defined the main frequency range of the gastric region activity according to

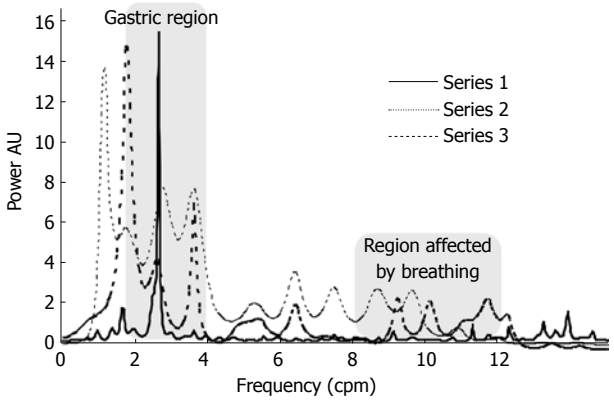

Figure 2 Typical frequency spectrum of the electrical bio-impedance gastric signal. The three curves show the typical changes during the tests (Stroop Test in this example): series 1: solid line, before the test; series 2: dotted line, during the test; series 3: dashed line after the test. AU: Arbitrary units.

the literature[1,7,9] (although some authors define a more restricted region for gastric motility as 2.5 to 3.75 cpm); the third (A3) included the frequencies from 4 to 8 cpm and contained the frequencies for the regions where bowel movements were important, which was mainly from the ileum (7-8 cpm)[1] or when tachygastria was present; and the fourth (A4) included the frequencies from 8 to 12 cpm and accounted for duodenum motility, breath frequency and tachygastria. The latter region, due to the strong contribution of the respiratory system, was not considered useful for gastric activity analysis because stress causes the breath frequency to change to higher values, diminishing the contribution of this area. A typical frequency spectrum and gastric changes occurring during the stress tests is shown in Figure 2.

We recorded the areas relative to the total area A_T from 1 to 12 cpm. In addition, the median of the area from 2 to 8 cpm (frequency for which the area under the spectrum was divided into two equal regions) was considered for analysis. This median changed when the relative areas of 2-4 cpm and/or 4-8 cpm changed, providing a good indication of the importance of the gastric motility compared with the adjacent frequency region. The advantage of these parameters was that small changes in the frequency spectrum, due to small variations in the data or data analysis, did not significantly affect these global parameters.

Statistical analysis

The data were analyzed by an autoregressive method using a Butterworth filter in the frequency range from 1 to 12/min (or cpm), i.e., 0.017-0.2 Hz. Particular attention was given to the region from 2 to 4/min (0.033-0.066 Hz) and from 4 to 8/min (0.066-0.132 Hz). In addition to this range, we analyzed the adjacent region, from 1 to 2 cpm, presented as the integrated region from 1 to 4 cpm, which is viewed as an extended gastric region. These analyses were performed using MatLab 6.5 and Origin 6.0 according to previous studies[16,24].

The comparison analysis within and between the experimental paradigm steps (BGM, Stroop Test, IRP, Raven Test, FRP) was performed using analysis of variance (ANOVA) and *post-hoc* analysis for variables with a normal distribution (A2, A1 + A2, A3, and the median under A2 + A3) and using the Friedman ANOVA for variables with a non-normal distribution (A4). Considering that the same women were evaluated before and after the psychological stress tests, we compared the dependent variables in the different experimental paradigm steps (BGM, Stroop Test, IRP, Raven Test, FRP) using the T dependent test on the normally distributed data (A1, A2, and A3 regions and the median of the area under the A2 + A3 region), and the T of the Wilcoxon test when non-normal distribution was found (A4 region). The statistical analyses were performed using STATISTICA 7 (Stat-Soft, Inc. Tulsa, OK, United States). We considered a P value $\leqslant 0.05$ to be significant.

RESULTS

The results of the gastric activity A2 area, indicated by the main range from 2 to 4 cpm, are presented in Figure 3A. We observed that none of the mean values of this A2 region changed significantly by ANOVA ($F = 1.46$, $P = 0.22$), even when we compare pairs of steps from the experimental paradigm (BGM, Stroop Test, IRP, Raven Test, FRP). However, a tendency towards a decrease in this A2 region during the stress tests was observed with a remarkable recovery during the FRP.

The results of the ANOVA for A1 + A2, A3 and the median under A2 + A3 had significant differences among the steps of the experimental paradigm ($F = 3.85$, $P = 0.005$, $F = 7.25$, $P < 0.001$, and $F = 5.5$, $P < 0.001$, respectively). Pairs for the group data analysis are presented in Figure 3B, which shows the results for the region from 1 to 4 cpm (referred to as the extended gastric region). We observed significant changes from the BGM step to the Stroop Test ($P = 0.02$), from the BGM step to the IRP ($P = 0.003$), and from the BGM step to the Raven Test ($P < 0.001$). In addition, we found significant changes from the IRP and Raven Test to the FRP, with $P = 0.01$ and $P = 0.007$, respectively. Similar results to the A1 + A2 region were observed in the A3 region (4-8 cpm), which showed significant changes when the stress psychological tests were administrated from BGM to Stroop Test, IRP, and Raven Test ($P < 0.001$, $P = 0.002$, and $P < 0.001$, respectively) (Figure 3C). There were also significant changes from the IRP to the Raven Test ($P = 0.043$) and from the Raven Test to the FRP ($P = 0.001$) (Figure 3C). These differences were influenced by changes in the adjacent gastric region, A2 (2-4 cpm), and the higher frequency region, A4 (8-12 cpm), but not as much by the decreased ileum activity. As we described in the methodology, one of the parameters that we have proposed in previous studies[16,24] as a useful parameter for EBI gastric studies is the median of the area under the region from 2 to 8 cpm (A2 + A3); namely, the frequency that divides this area into two equal parts. The mean values of these

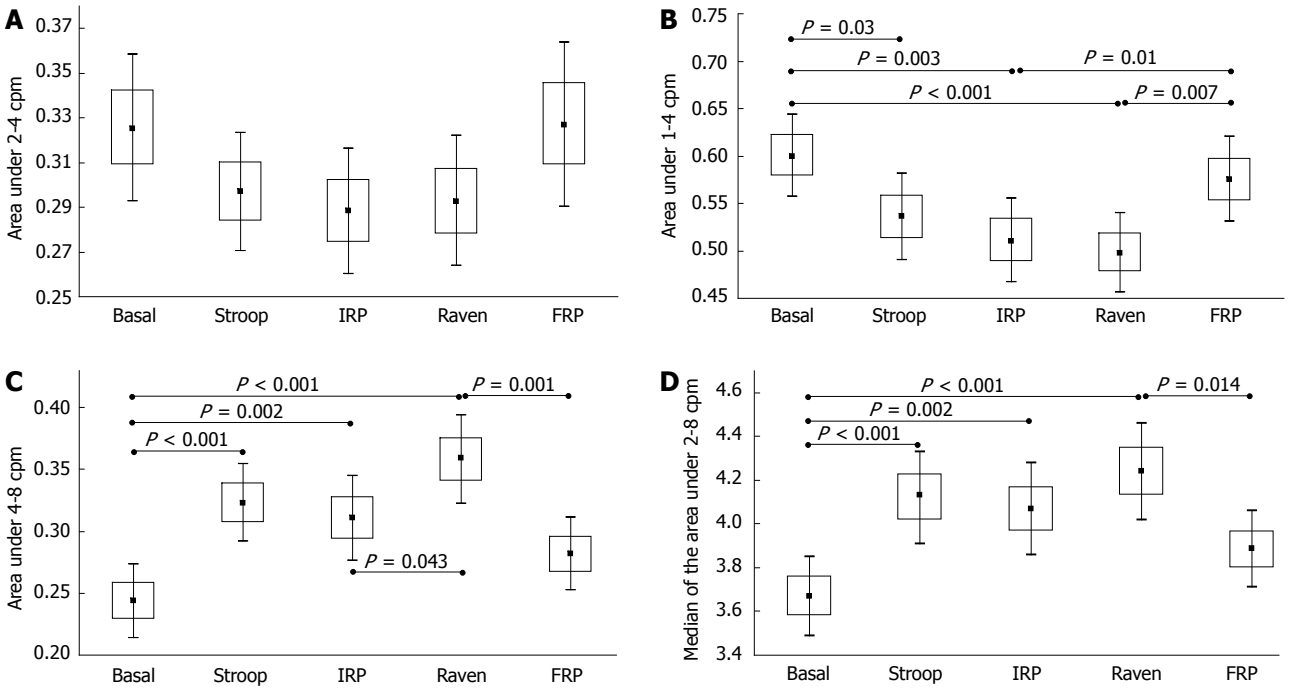

Figure 3 Changes in the relative area under the frequency spectrum of the gastric electrical bio-impedance signal (mean ± SE). A: From 2 to 4 cpm; B: From 1 to 4 cpm; C: From 4 to 8 cpm; D: Median of the area from 2 to 8 cpm. Basal: Basal gastric motility recording; Stroop: Recording during the Stroop Test; IRP: Intermediate resting period; Raven: Recording during the Raven test; FRP: Final resting period.

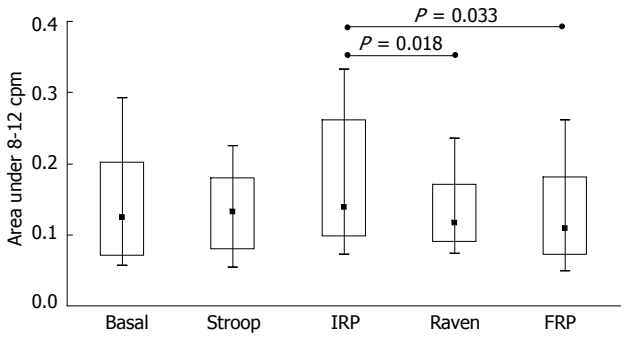

Figure 4 Changes in the relative area under the frequency spectrum of the gastric electrical bio-impedance signal from 8 to 12 cpm (median and interquartile range). Basal: Basal gastric motility recording; Stroop: Recording during the Stroop Test; IRP: Intermediate resting period; Raven: Recording during the Raven Test; FRP: Final resting period.

parameters (median of the A2 + A3 area) are presented in Figure 3D, which also shows the statistical changes when the stress psychological tests were administered, with significant variations from the BGM step to the Stroop Test, IRP and Raven Test ($P < 0.001$, $P = 0.002$, and $P < 0.001$, respectively). We also observed significant changes from the Raven Test to the FRP ($P = 0.014$).

The results of the A4 (8-12 cpm) Friedman ANOVA did not show a significant difference ($\chi^2 = 8.44$, $P = 0.077$). The comparisons among the groups of variables are presented in Figure 4, which gives the results of the Wilcoxon T test for the A4 area. This region, which was influenced by the breathing response, changed significantly during the Raven Test, with significant changes from the IRP step to the Raven Test and from the IRP to the FRP ($P = 0.018$ and $P = 0.033$, respectively).

DISCUSSION

We used the short-term EBI technique to evaluate the physiological changes in gastric activity due to psychological stress caused by the Stroop[20,21] and Raven[22] Tests in healthy women. Several studies have shown that gastric motility alterations are good clinical indicators of diseases[18,25-28]. Using EGG and EBI as noninvasive techniques for assessing gastric motility, we can ensure that the accuracy and reliability of the test and the comfort of the patient are the prevailing conditions under which each patient is assessed[29-32].

As described above, the most widely used parameter for the assessment of gastric motility is the highest peak of activity in the region from 2 to 4 cpm of the frequency spectrum. This parameter could not be trusted in our case because the EBI recorded information from other parts of the GI tract and other systems (breathing)[33-35] strongly interfered with the desired signal. In addition, the short-term EBI recording prevented us from relying on a parameter as being punctual in the low frequency region (2-4 cpm). The area under a specific frequency region is expected to give the relative level of activity in that frequency region without needing the details of the spectrum. An alternative to the EBI gastric motility measurement of two or more areas is the recording of the median of the entire area. In this study, the changes found in gastric motility, as measured by the relative areas, were considered to have statistical significance when P was $\leqslant 0.05$, and in other cases, we included the graph

only to present the tendencies that were physiologically compatible with what we expected as a response to gastric stress[24].

Taking the basal gastric measurement as a reference, we observed that the Stroop Test induced changes in the A1 + A2, A3 and the median of the A2 + A3 parameters (Figure 3B-D), in agreement with the inhibition of gastric activity during psychological stress. We hypothesized that the decrease in the activity in the gastric region produced the increase in the A3 region (Figure 3C). The region from 8 to 12 cpm did not show significant changes during the Stroop Test.

In the intermediate resting period, we observed a slight recovery in the A3 and A4 regions and in the median of the A2 + A3 region; the A1 + A2 region showed a continuing effect of the Stroop Test. None of these changes were statistically significant. During the Raven Test, the A3 region changed significantly by a strengthened effect of the stress caused by the Stroop Test. This effect was also observed in the A4 region. The final resting period change was highly significant in the regions A1 + A2 and A3 and in the median of A2 + A3.

Some general observations should be addressed at this point. All of the parameters consider relative areas under the whole region from 1 to 12 cpm or the median frequency of a relative area; thus, a change in any of these parameters is not only due to the local change, but is also influenced by the changes in the other parameters. The apparent stability of the relative area of A4, which represents approximately 15% of the total area and which includes the breathing frequency, is the result of the breath going beyond the higher frequency limit (12 cpm) and the real decrease in the GI activity (A1 + A2). We believe that the continuing effects of stress after completing the Stroop Test were due in part to the knowledge of the participants that they would receive a second test, which predisposed them towards having a continuous stress response (Figures 3B-D and 4). The immediate recovery of the participants at the end of the Stoop and Raven Tests, as shown by the evaluated parameters reaching the basal values, was likely affected by the knowledge of the participants that the test was complete (Figure 3B-D).

Changes due to stress vary between participants. Typically, the stress starts at the beginning of the psychological test, with a variable reaction time, duration and intensity[24]. Gastric motility changes, with an acceptable physiological explanation, give a clear indication that short-term gastric EBI recording could be useful in routine studies of the response to psychological stress. Further research should address alternative signal analysis approaches, validation, movement discrimination, limitations, variability factors, the normal range of significant parameters, and assessment protocols.

Psychological stressors may have different patterns, accompanied by increases in the sympathetic nervous system activity and total blood vessel peripheral resistance[36]. Therefore, more cardiovascular activity is involved in a specific task that requires active action (as in the Stroop Test) than in those that are considered passive, maintaining a close similarity to the response to a real situation. After using the Stroop Test as a stressor, there was an increase in anxiety, heart rate, respiration, electrodermal activity, muscle tension and the levels of catecholamines, among other psychophysiological variables. The Stroop Test includes complex neuropsychological processes related to the ability to classify information, act selectively, and block non-requested information linked to frontal lobe functions. It is based on the observation that naming colors occurs noticeably slower than reading words. This test assesses some cognitive functions, such as attention, mental flexibility, and the inhibition of automatic responses, related to executive functions associated with the frontal lobes. The other test that has been certified widely in the literature for its usefulness is the Raven Test; however, it is limited by the verbal and cultural influences, level of schooling, economic level, and age. Taken together, the results presented here indicate that short-term gastric EBI has great potential to become a user-friendly methodology to assess gastric motility, particularly with respect to the evaluation of the acute stress response.

In conclusion, the results from this study, which was performed in healthy women, clearly demonstrated that using different parameters, such as the relative areas under the frequency spectrum and the analysis of the median of those areas, in short-term recordings of gastric EBI may be useful for the evaluation of the sympathetic nervous system response to acute psychological stress. The relatively simple signal analysis required for the gastric EBI could make this technique a good candidate for a basic clinical evaluation and even an ambulatory method to assess gastric motility. One of the main advantages of this technique is that it can be implemented using small and inexpensive devices once the frequency and amplitude of the stimulation are known.

COMMENTS

Background

The relationship between emotions and gastric motility has been documented since the last century. Likewise, psychological stress produces alterations in gastrointestinal tract response in humans. There are several methods for measuring gastric response to stress, but many of these methods are invasive. In this study, authors proposed a novel technique, which was inexpensive and easy to manage, to measure the gastric response to psychological stress by electrical bio-impedance (EBI).

Research frontiers

In healthy humans, anger, fear, painful stimuli, preoperative anxiety and intense exercise are some of the causes of slow gastric emptying. The principal noninvasive techniques to evaluate the gastric motility response during psychological stress are electrogastrography (EGG) and the EBI. In these two techniques, the main challenge is the interpretation of the signal due to the overlapping information from different regions in the gastric system, particularly with respect to lung region movements in the case of EBI; in both cases, different motility

frequencies are involved.

Innovations and breakthroughs

The authors confirm that the gastric response to acute psychological stress can be evaluated by short-term EBI.

Applications

The short-term technical EBI is useful for measuring the gastric response to psychological stress. Besides, it may be useful for frequent monitoring of health status of patients with gastric disorders; being an easy-to-use method of clinical monitoring and diagnosis.

Terminology

EGG is a technique to record the myoelectrical activity of a specific inner surface of the gastrointestinal tract. EGG is a noninvasive technique, in which the electrodes are placed on the skin. EBI records the motility of the stomach using cutaneous electrodes placed in the gastric region. Stroop and Raven Tests are valid and reliable tests to produce psychological stress.

Peer review

This study clearly demonstrated that short-term EBI may be useful for evaluating the gastric activity response to acute psychological stress.

Abstract

AIM: To elucidate the role of neuropilin-1 (Nrp-1) and semaphorin 3A (Sema3A) in sinusoidal remodeling during liver regeneration in rats.

METHODS: Male Wistar/ST rats at 7 wk of age, weighing about 200 g, were used for all animal experiments. *In vivo*, at 24, 48, 72, 96, 144 and 192 h after two-thirds partial hepatectomy (PHx), the remnant livers were removed. Liver tissues were immunohistochemically stained for Nrp-1, Sema3A and SE-1, a liver sinusoidal endothelial cell (SEC) marker. Total RNA of the liver tissue was extracted and reversely transcribed into cDNA. The mRNA expression of Sema3A was analyzed by quantitative real-time polymerase chain reaction and normalized to that of ribosomal protein S18. *In vitro*, SECs were isolated from rat liver and cultured in endothelial growth medium containing 20 ng/mL vascular endothelial cell growth factor. Migration of SECs in primary culture was assessed by cell transwell assay with or without recombinant Sema3A. Apoptotic cells were determined by a terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling method.

RESULTS: *In vitro*, immunohistochemistry study revealed that Sema3A and Nrp-1 were constitutively expressed in hepatocytes and SECs, respectively, in normal rat liver tissues. Nrp-1 expression in SECs was quantified by the percentage of immunostained area with anti-Nrp-1 antibody in relation to the area stained with SE-1. Between 24 h and 96 h following resection of liver, Nrp-1 expression in SECs was transiently increased. Compared with the baseline (5.2% ± 0.1%), Nrp-1 expression in SECs significantly increased at 24 h (17.3% ± 0.7%, $P < 0.05$), 48 h (39.1% ± 0.6%, $P < 0.01$), 72 h (46.9% ± 4.5%, $P < 0.01$) and 96 h (29.9% ± 3.8%, $P < 0.01$) after PHx, then returned to the basal level at termination of liver regeneration. Interestingly, the expression of Sema3A was inversely associated with that of Nrp-1 in liver after PHx. Sema3A mRNA expression was significantly reduced by about 75% over the period 24-144 h after PHx ($P < 0.05$), and returned to basal levels at 192 h after PHx. *In vitro*, SECs isolated from rats after PHx (PHx-SECs) were observed to migrate to the lower chamber of the cell transwell system after incubation for 24 h, but not cells from normal rats (CONT-SECs), indicating that mobility of PHx-SECs increases as compared with that of CONT-SECs. Moreover, recombinant Sema3A significantly attenuated migration in PHx-SECs in primary culture (vehicle-treated

100% ± 7.9% *vs* Sema3A-treated 42.6% ± 5.4%, $P < 0.01$), but not in CONT-SECs. Compared with CONT-SECs, the apoptotic rate of PHx-SECs decreased by 78.3% ($P < 0.05$). There was no difference in apoptosis between CONT-SECs that were treated with vehicle and Sema3A. However, in PHx-SECs, apoptosis was induced by the presence of 5 nmol Sema3A for 24 h (vehicle-treated 21.7% ± 7.6% *vs* Sema3A-treated 104.3% ± 8.9%, $P < 0.05$). In addition, immunohistochemistry confirmed the increased expression of Nrp-1 in PHx-SECs, while it was noted to a lesser extent in CONT-SECs.

CONCLUSION: The interplay of Nrp-1 and Sema3A shown in our results may lead to a better understanding of interaction between sinusoidal remodeling and SECs during liver regeneration.

INTRODUCTION

In liver, adult hepatocytes are long-lived and normally do not undergo cell division, but they maintain the ability to proliferate in response to toxic injury or partial resection of liver[1,2]. The process of liver regeneration (LR) is complex and involves a finely orchestrated balance of cell proliferation to reconstruct the normal liver architecture. Although hepatocyte proliferation is a major feature of the regenerating liver, it involves the interactions of other hepatic cell types (non-parenchymal cells), including Kupffer cells, stellate cells, sinusoidal endothelial cells (SECs) and biliary epithelial cells[3-5].

In the rat liver after two-thirds hepatectomy, the rate of DNA synthesis in hepatocytes begins to increase after about 12 h and peaks around 24 h. However, the induction of DNA synthesis occurs later in the non-parenchymal cells (at approximately 48 h for Kupffer and biliary epithelial cells, and at approximately 96 h for SECs), and subsequently, LR terminates at approximately 192 h[6,7]. In the late stage of this process, angiogenesis and/or vasculogenesis is essential to supply blood flow to newly replicating avascular islands of hepatocytes, in which SECs migrate and proliferate, leading to the formation of new functional sinusoids[8,9].

Indeed, many of the growth factors have been reported to be upregulated in a regenerating liver. Vascular endothelial growth factor (VEGF) is a major proangiogenic factor and is thought to improve sinusoid reconstruction during the LR process[10,11]. Hepatocyte growth factor (HGF) levels are dramatically increased after partial hepatectomy, but HGF is also a potent proangiogenic factor *in vivo* and stimulates endothelial cell protease production, motility, proliferation and differentiation *in vitro*.

Recently, the importance of neuropilins (Nrps) as proangiogenic factors has been highlighted[12]. Nrps are transmembrane glycoproteins with large extracellular domains that interact with both class 3 semaphorins and VEGF, and they are involved in the regulation of many physiological pathways including angiogenesis[13,14]. The semaphorins were initially described as axon guidance factors that affect the development of the central nervous system[15]. However, semaphorin receptors were subsequently found to be expressed by multiple types of cells including endothelial cells and cancer cells. These observations were followed by studies that indicate that the semaphorins can modulate the behavior of cancer cells and endothelial cells[16,17].

In this study, we report the inverse expression of Nrp-1 and semaphorin 3A (Sema3A) in liver tissues during liver regeneration in rats. We further show that Sema3A significantly attenuated migration and induced apoptosis in SECs isolated from rats after partial hepatectomy, but not in cells from normal rats.

MATERIALS AND METHODS

Animals and treatment

Male Wistar/ST rats, 7 wk of age, weighing about 200 g (Sankyo lab, Tokyo, Japan), were used for all animal experiments. Two-thirds partial hepatectomy (PHx) was performed under sevoflurane inhalant anesthesia according to the method of Higgins *et al*[18]. The left lateral and median lobes of the liver were excised. At 24, 48, 72, 96, 144 and 192 h after PHx, the rats were anesthetized and the remnant livers were removed. Control livers were obtained from sevoflurane-anesthetized non-manipulated animals.

Liver tissues were obtained from the right lateral lobe, embedded in Tissue Tek OCT Compound (Electron Microscopy Sciences, Hatfield, PA), frozen and stored at -80 ℃ until use. All procedures involving animals were approved by the Animal Care and Use Committee of Juntendo University, which conforms to the National Institutes of Health Guideline.

Immunofluorescent staining

Double staining of Nrp-1 and SE-1 was performed as follows: tissue fixed with 4% paraformaldehyde for 10 min at

room temperature, incubated with goat polyclonal anti-Nrp-1 antibody (R and D Systems, Minneapolis, MN) (diluted 1:50) and mouse monoclonal SE-1 (Immuno-Biological Laboratories, Gunma, Japan) (diluted 1:20) at 4 ℃ overnight prior to incubation with Alexa-488 rabbit anti-goat (diluted 1:300) and Alexa-594 donkey anti-mouse antibody (diluted 1:300) (Invitrogen, Carlsbad, CA) for 1 h, then mounted in Vectashield mounting medium with 4,6-diamidino-2-phenylindole dihydrochloride (Vector Laboratories, Burlingame, CA). The immunostained samples were observed and analyzed with a BIOREVO BZ-9000 microscope system (KEYENCE, Osaka, Japan).

For Sema3A staining, frozen sections of liver tissues were fixed with -20 ℃ acetone for 5 min, incubated with rabbit polyclonal anti-Sema3A antibody (diluted 1:200) (Abcam, Cambridge, United Kingdom) at 4 ℃ overnight prior to incubation with Alexa-488 goat anti-rabbit antibody (diluted 1:300) for 1 h.

Quantitative real-time polymerase chain reaction

Total RNA of the liver tissue was extracted using TRIzol reagent (Invitrogen, Carlsbad, CA), and reversely transcribed into cDNA using the RT reagent kit (TaKaRa Bio Inc., Shiga, Japan). Quantitative real-time polymerase chain reaction (PCR) was performed using ABI PRISM 7900HT Sequence Detector System (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions. The following primers were used: Sema3A (accession number: NM_017310.1) CTG CTC CGA CTT GCA GCA TC (sense) and CGC CTC TGA AAT TGC CAA TAT ACC (antisense); ribosomal protein S18 (RPS18) (accession number: NM_213557.1) AAG TTT CAG CAC ATC CTG CGA GTA (sense) and TTG GTG AGG TCA ATG TCT GCT TTC (antisense). The Sema3A mRNA expression was normalized to that of RPS18.

Preparation of SECs in primary culture

SECs were isolated from rat liver based on a modification of the method of Braet *et al*[19], as we previously reported[20]. Briefly, liver was perfused with 0.05% collagenase A and 0.001% DNase. SECs were then purified by isopycnic sedimentation in a two-step Percoll gradient (25% and 50%). SECs were cultured in EBM-2 medium containing 20 ng/mL VEGF. These cells displayed a number of fenestrae in sieve plates, the characteristic of SECs *in vivo*. In separate experiments, SECs were isolated from rats 4 d after PHx (PHx-SECs).

Cell transwell migration assay

SEC transwell migration assay was performed using 24-well culture inserts (BD Biosciences, San Jose, CA). Polyethylene terephthalate membranes with a pore size of 8 μm were coated with fibronectin. SECs were loaded to the upper chamber. Recombinant Sema3A (R and D Systems, Minneapolis, MN) or vehicle was added to the lower chamber. After incubation for 24 h, non-migrated cells on the upper surface of the filter were removed with a cotton swab and the cells which traversed and spread on the lower surface of the membrane were fixed with 2.5% glutaraldehyde and stained with hematoxylin. The average number of the cells per field was counted ×10 objective magnification from five microscopic fields. Migration index represents the number of migratory cells/number of migratory cells in vehicle-treated control.

Apoptosis assay

After incubation with 5 nmol recombinant Sema3A for 24 h, SECs were fixed with 4% paraformaldehyde for 10 min at room temperature. Apoptotic cells were determined by a terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling (TUNEL) method with a fluorescent apoptosis detection system kit (Promega, Madison, WI).

Statistical analysis

Results are expressed as the mean ± SE. Statistical analysis were performed using GraphPad Prism v5.00 for Windows (GraphPad Software, San Diego, CA). Statistical significance was determined by one-way analysis of variance.

RESULTS

Nrp-1 expression in SECs increases in regenerating liver after PHx

To investigate Nrp-1 expression in SECs during LR, liver tissues after PHx were analyzed by immunofluorescent staining with anti-Nrp-1 antibody and SE-1, a monoclonal antibody that specifically reacts with rat liver SECs[21,22]. As shown in Figure 1A, SECs stained with SE-1 were positive for Nrp-1 in control liver, and Nrp-1 expression in SECs was enhanced in regenerating liver at 72 h after PHx.

Nrp-1 expression in SECs was quantified by the percentage of immunostained area with anti-Nrp-1 antibody in relation to the area stained with SE-1. Nrp-1 expression in SECs significantly increased at 24 h ($P < 0.05$), peaked at 72 h ($P < 0.01$), and recovered to the basal level at 144 h after PHx (Figure 1B).

Sema3A expression decreases in regenerating liver after PHx

To test the expression of Sema3A during LR, liver tissues were examined by immunofluorescence with anti-Sema3A antibody in control rats and rats at 72 h after PHx. Sema3A was strongly stained in hepatocytes, which display round and big nuclei, in control liver. However, Sema3A expression was attenuated at 72 h after PHx (Figure 2A). Furthermore, real-time PCR analysis confirmed the decline of Sema3A expression during the process of LR. As shown in Figure 2B, Sema3A mRNA expression was significantly reduced by about 75% over the period 24-144 h after PHx ($P < 0.05$), and returned

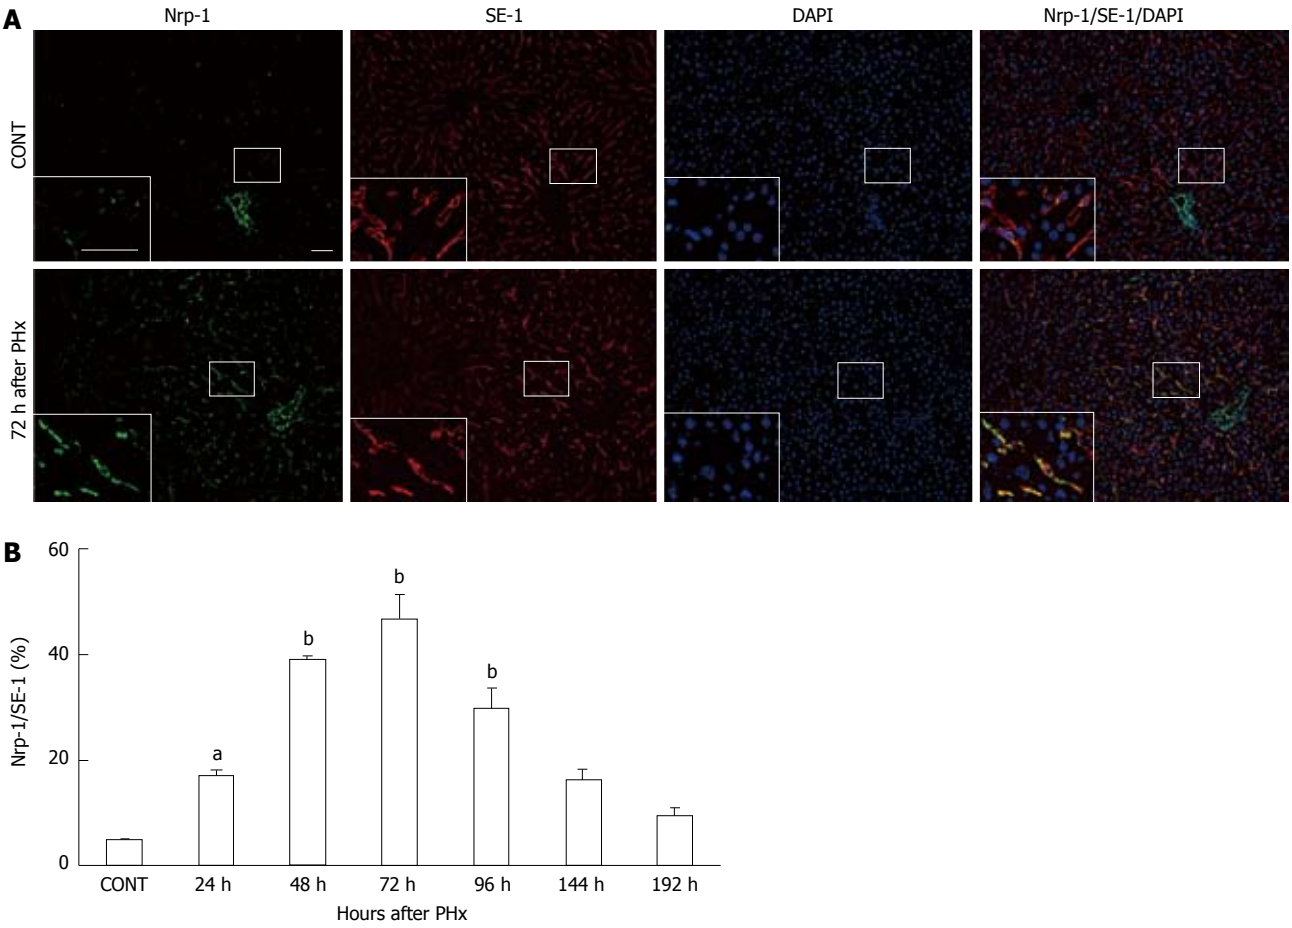

Figure 1 Neuropilin-1 expression in sinusoidal endothelial cells in regenerating liver. Green: Nrp-1; Red: SE-1; Blue: Nuclei stained with 4,6-diamidino-2-phenylindole dihydrochloride (DAPI). Scale bar, 20 μm.

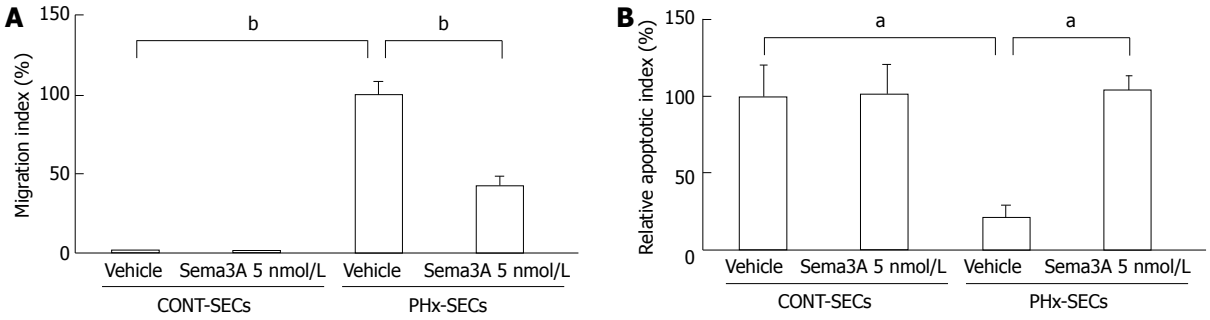

Figure 4 Role of semaphorin 3A in sinusoidal endothelial cell migration and apoptosis. A: Effect of semaphorin 3A (Sema3A) on migration of sinusoidal endothelial cells (SECs) isolated from normal rats (CONT-SECs) and rats after partial hepatectomy (PHx-SECs). SEC migration was assessed by cell transwell assay in the presence or absence of 5 nmol Sema3A for 24 h. Migration index represents the number of migratory cells/number of migratory cells in vehicle-treated PHx-SECs; B: Effect of Sema3A on apoptosis of CONT-SECs and PHx-SECs. Following incubation of SECs with 5 nmol Sema3A or vehicle for 24 h, apoptotic cells were determined by a terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling method. Results are expressed as the mean ± SE. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* vehicle-treated PHx-SECs ($n = 4$).

to baseline at 192 h after PHx.

Nrp-1 expression increases in PHx-SECs as compared with CONT-SECs in primary culture

To confirm that Nrp-1 is expressed in SECs, immunofluorescent analysis was performed in SECs isolated from rat liver. Both CONT-SECs and PHx-SECs at 24 h in culture were stained positive for Nrp-1 and SE-1, and Nrp-1 expression was increased in PHx-SECs as compared with CONT-SECs (Figure 3A and B). The up-regulated Nrp-1 expression in PHx-SECs was consistent with *in vivo* data shown in Figure 1. Although fluorescence is observed in the perinuclear region as well as the plasma membrane, this may suggest that Nrp-1 presents intracellular trafficking between plasma membrane and intracellular compartments, such as endoplasmic reticulum, Golgi, endosomes and lysosomes.

Sema3A attenuates migration and elicits apoptosis of PHx-SECs

To investigate the effect of Sema3A on SEC mobility, migration of cells was quantified by cell transwell assay in SECs isolated from rats after PHx (PHx-SECs) and normal rats (CONT-SECs). As a result, PHx-SECs were observed to migrate to the lower chamber after incubation for 24 h, but not CONT-SECs, indicating that mobility of PHx-SECs increases as compared with that of CONT-SECs. Moreover, 5 nmol Sema3A significantly attenuated migration of PHx-SECs by 57% ($P < 0.01$, Figure 4A), while it did not affect proliferation of PHx-SECs (data

not shown).

Based on previous reports showing that Sema3A induces apoptosis[23-25], we explored the effect of Sema3A on apoptotic rate in PHx-SECs and CONT-SECs with TUNEL assay. Compared with CONT-SECs, apoptotic rate in PHx-SECs decreased by 78% ($P < 0.05$, Figure 4B). There was no difference in apoptosis between CONT-SECs that were treated with vehicle and Sema3A. However, in PHx-SECs, apoptosis was induced by the presence of 5 nmol Sema3A for 24 h ($P < 0.05$, Figure 4B).

DISCUSSION

The adult hepatocyte is normally a quiescent, highly differentiated cell, but almost immediately it can begin the process of replication in response to conditions that induce cell loss by physical, infectious, or toxic injury. The events involved in the regenerative response are precise, carefully orchestrated, and highly regulated. Indeed, the hepatocyte is a key player in the process of LR, but other cell types, including non-parenchymal cells, also play important roles in reformation of the normal liver architecture.

Among non-parenchymal cells, SECs line the intrahepatic circulatory vessels, named sinusoids, and provide a large surface area for nutrient absorption. Thus, in regenerating liver, SECs play a central role in reconstruction of sinusoids through which blood flow is supplied into the hepatocytes[8,9,26]. Previous reports using electron microscopy have shown that SECs proliferate and migrate into initially formed avascular clusters of proliferating hepatocytes, leading to the formation of new functional sinusoids[9].

In the process of sinusoidal remodeling, various proangiogenic factors are produced in response to upregulation of hypoxia-inducible factor, which is generated within the avascular clusters of hepatocytes. Among these, vascular endothelial growth factor (VEGF) has been shown to be a key regulator of hepatic neovascularization, and is involved in three tyrosine kinase receptors (VEGFR1, R2, and R3), and two non-tyrosine kinase receptors (Nrp-1 and Nrp-2) in inducing signal transduction[27].

Neuropilins were first identified as receptors for class 3 semaphorins, a family of soluble molecules with neuronal guidance functions[28,29]. During development, Nrp-1 is preferentially expressed in arteries, and Nrp-2 is expressed in veins and lymphatics[30]. There is a degree of specificity in semaphorin/neuropilin binding and activity, with semaphorin 3A (Sema3A) binding to Nrp-1, Sema3F binding to Nrp-2 and Sema3B binding to both receptors on endothelial cells[13]. Recently it has been suggested that these semaphorins may interact with the vasculature in an inhibitory manner. Indeed, *in vitro* studies suggest that class 3 semaphorins compete with VEGF for Nrp-1/Nrp-2 binding, thereby inhibiting mitogenic effects of VEGF in endothelial cells, and leading to apoptosis and inhibition of migration in breast cancer cell lines[31,32].

In this study, to investigate interplay of Nrp-1 and Sema3A in sinusoidal remodeling during LR, we examined the expression of Nrp-1 in liver tissues after PHx in rats, and found that Nrp-1 is constitutively expressed in SECs in normal liver, but its expression is increased following resection of liver, returning to the basal level at termination of liver regeneration. This is consistent with well-documented findings that, following hepatocyte proliferation, DNA synthesis of SECs begins in the late stage of LR[2,7]. Increased expression of Nrp-1 was further confirmed by *in vitro* study with SECs isolated from rats after PHx, while it was noted to a lesser extent in cells from normal liver.

Interestingly, the inverse expression of Sema3A and Nrp-1 was observed in liver during the process of LR. Immunohistochemistry also indicated the expression of Sema3A in hepatocytes, suggesting the possibility that Sema3A may interact with Nrp-1 that is expressed in SECs. Indeed, our *in vitro* results show that Sema3A significantly attenuated migration and induced apoptosis in SECs isolated from rats after PHx, but not in cells from normal rats.

Recently, many studies have illustrated the crucial role of Nrp-1 in cell proliferation in development and cancer. The absence of a functional Nrp-1 receptor results in embryonic lethality as a result of impaired heart and blood vessel development, indicating that this receptor plays a central regulatory role during developmental angiogenesis[33]. Furthermore, in endothelial-specific Nrp-1 knockouts, certain arterial markers are missing from arterioles and arteries[34,35]. Alternatively, a selective Sema3A inhibitor has been shown to enhance regenerative responses and functional recovery of the injured spinal cord[36].

Although further studies are required to reveal the underlying mechanism, our results showing inverse expression of Nrp-1 and Sema3A in liver after PHx may provide a better understanding of sinusoidal remodeling in LR.

ACKNOWLEDGMENTS

We thank Dr. Mitsutoshi Tominaga for providing anti-Sema3A antibody and for useful suggestions.

COMMENTS

Background

The process of liver regeneration (LR) is complex and involves a finely orchestrated balance of cell proliferation to reconstruct the normal liver architecture. Although hepatocyte proliferation is a major feature of the regenerating liver, it involves the interactions of other hepatic cell types (non-parenchymal cells), including Kupffer cells, stellate cells, sinusoidal endothelial cells and biliary epithelial cells.

Research frontiers

Many of the growth factors have been reported to be upregulated in a regenerating liver. Vascular endothelial growth factor (VEGF) is a major proangiogenic

factor and is thought to improve sinusoid reconstruction during the LR process.

Innovations and breakthroughs

Recently, the importance of neuropilins (Nrps) as proangiogenic factors has been highlighted. Nrps are transmembrane glycoproteins with large extracellular domains that interact with both class 3 semaphorins and VEGF, and are involved in the regulation of many physiological pathways including angiogenesis. Semaphorin receptors were subsequently found to be expressed by multiple types of cells including endothelial cells.

Applications

The findings of this study may offer new insights into the role of Nrp-1 and semaphorin 3A (Sema3A) as a target for novel therapeutic strategies in impaired liver regeneration.

Terminology

Nrp-1 was originally characterized as a Sema3A receptor regulating axon guidance, and it was later demonstrated that Nrp-1 is also important for vascular morphogenesis. Nrp-1 acts as receptor for VEGF, whereby it serves to promote VEGF-induced angiogenesis. Because Sema3A inhibits angiogenesis through Nrp-1, it has been suggested that it acts by merely competing with VEGF and thus inhibiting its proangiogenic effects.

Peer review

The authors present interesting results on the interaction of neuropilin and semaphorin in control of angiogenesis during liver regeneration. Overall, the results presented support the conclusions.

Abstract

AIM: To determine the effect of tumor necrosis factor alpha (TNF-α) on intestinal permeability (IP) in mice with fulminant hepatic failure (FHF), and the expression of tight junction proteins.

METHODS: We selected D-lactate as an index of IP, induced FHF using D-galactosamine/lipopolysaccharide and D-galactosamine/TNF-α, assessed the results using an enzymatic-spectrophotometric method, transmission electron microscopy, immunohistochemistry, Western blotting and real-time quantitative polymerase chain reaction. The effect of the administration of anti-TNF-α immunoglobulin G (IgG) antibody, before the administration of D-galactosamine/lipopolysaccharide, on TNF-α was also assessed.

RESULTS: IP was significantly increased in the mouse model of FHF 6 h after injection (13.57 ± 1.70 mg/L, 13.02 ± 1.97 mg/L *vs* 3.76 ± 0.67 mg/L, $P = 0.001$). Electron microscopic analysis revealed tight junction (TJ) disruptions, epithelial cell swelling, and atrophy of intestinal villi. Expression of occludin and claudin-1 mRNA was significantly decreased in both FHF models (occludin: 0.57 ± 0.159 fold *vs* baseline, $P = 0.000$; claudin-1: 0.3067 ± 0.1291 fold *vs* baseline, $P = 0.003$), as were the distribution density of proteins in the intestinal mucosa and the levels of occludin and claudin-1 protein (occludin: 0.61 ± 0.0473 fold *vs* baseline, $P = 0.000$; claudin-1: 0.6633 ± 0.0328 fold *vs* baseline, $P = 0.000$). Prophylactic treatment with anti-TNF-α IgG antibody prevented changes in IP (4.50 ± 0.97 mg/L *vs* 3.76 ± 0.67 mg/L, $P = 0.791$), intestinal tissue ultrastructure, and the mRNA levels of occludin and claudin-1 expression (occludin: 0.8865 ± 0.0274 fold *vs* baseline, $P = 0.505$; claudin-1: 0.85 ± 0.1437 fold *vs* baseline, $P = 0.1$), and in the protein levels (occludin: 0.9467 ± 0.0285 fold *vs* baseline, $P > 0.05$; claudin-1: 0.9533 ± 0.0186 fold *vs* baseline, $P = 0.148$).

CONCLUSION: Increased in IP stemmed from the downregulation of the TJ proteins occludin and claudin-1, and destruction of the TJ in the colon, which were induced by TNF-α in FHF mice.

Li GZ, Wang ZH, Cui W, Fu JL, Wang YR, Liu P. Tumor necrosis factor alpha increases intestinal permeability in mice with fulminant hepatic failure. *World J Gastroenterol* 2012; 18(36): 5042-5050 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i36/5042.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i36.5042

INTRODUCTION

Fulminant hepatic failure (FHF) is a devastating disease with high mortality. The intestinal mucosal barrier plays an important role in the body's protection against luminal pathogens and antigenic molecules. Increased intestinal permeability (IP) and disruption of the intestinal mucosal barrier have been observed in many hepatic diseases[1-4] that cause intestinal endotoxemia (IETM), also called gut-derived endotoxin. High levels and incidence of IETM have been reported in many hepatic diseases[5,6]. The IETM results in excessive inflammatory responses, with serious hepatic necrosis, further severe hepatitis, and even accelerated liver failure.

There are two potential pathways for passive permeation across the intestinal epithelia: the transcellular pathway (through the cells) and the paracellular pathway (between cells). The tight junction (TJ) is a semipermeable barrier that allows certain solutes (depending upon their size and charge) to pass through the paracellular pathway between the cells from one fluid component to the other, and even regulates the permeability of the paracellular spaces. It is thought that TJ may be functionally altered in model disease states, even when the intestinal epithelium remains confluent[7]. Structurally, TJs are composed of cytoplasmic proteins, including the zonula occludens (ZO) proteins, ZO-1, ZO-2, and ZO-3[8,9], as well as two distinct transmembrane proteins, occludin and claudins[10,11], especially claudin-1, the most widely distributed protein in the intestinal epithelium. Occludin and claudins are the major transmembrane proteins that interact with intracellular plaque proteins such as ZO-1, ZO-2, and ZO-3, which in turn interact with the actin cytoskeleton to anchor occludin and other transmembrane proteins at the apical end of the lateral membrane[1]. It has been shown that TJ proteins and IP could be modulated by many factors, including shock[12], hyperthermia[13], alcoholic or nonalcoholic liver disease[2,3], and referred to the cytokines, tumor necrosis factor alpha (TNF-α), and interleukin (IL)-1, and nitric oxide (NO)[14-17]. There are few studies on IP and its mechanism of modulation in FHF.

TNF-α is a key pro-inflammatory cytokine with a broad-spectrum of effects, and is primarily secreted by monocytes and macrophages. It can induce a hepatocyte necrosis *in vivo* or *in vitro*, and is elevated in FHF[18,19]. TNF-α can increase IP *in vitro*[14,17]; thus its role in the possible alteration of IP in FHF should be considered. D-lactate is produced by indigenous bacteria in the gastrointestinal tract[20]. Mammals do not have the enzyme systems to rapidly metabolize D-lactate. Evaluation of D-lactate levels indicates readily the change of IP[21]. We have tested TNF-α concentrations and intestinal ZO-1 expression in the FHF model in mice[22]. In this study, we utilized the same model and controls to investigate the changes in the permeability of the intestinal mucosa and attempted to elucidate the underlying molecular mechanisms by examining TJ ultrastructure and by measuring the expression of the TJ proteins, occludin, and claudin-1.

MATERIALS AND METHODS

Animals and treatment

Male, six-to eight-week-old BALB/c mice (China Medical University) were obtained from the China Medical University (Shenyang, China). They were housed and cared for in rooms maintained at a constant temperature and humidity. Food and water were allowed ad libitum. The mice were fasted overnight for the experiment. All animal experimental procedures were approved by the Ethics Committee of China Medical University before the commencement of the study. All mice were randomly divided into eight groups (n = 7 per group). One group of mice was given intraperitoneal injections of D-galactosamine (GalN; 800 mg/kg body weight; Sigma, Saint Louis, United States) and lipopolysaccharide (LPS; 10 μg/kg body weight; Sigma) to induce acute liver failure (ALF). A second ALF-induction group was also given intraperitoneal injections of GalN (800 mg/kg body weight) and TNF-α (10 μg/kg body weight; Sigma). First group was given anti-TNF-α immunoglobulin G (IgG) (100 μg per mouse; US Biological, United States) antibody treatment prior to ALF induction. The anti-TNF-α IgG antibody was injected *via* the vena caudalis 30 min before GalN/LPS administration. There were four control groups, which were injected intraperitoneally with GalN, LPS, TNF-α, or normal saline (NS). In summary, the eight groups were: (1) GalN/LPS; (2) GalN/TNF-α; (3) GalN control; (4) LPS control; (5) TNF-α control; (6) NS control; and (7) anti-TNF-α antibody and GalN/LPS (named anti-TNF-α IgG antibody pretreated group). Mice in first group were euthanized 2, 6, 9, 12 and 24 h after treatment. Other aforementioned groups were euthanized 6 h after administration of GalN/LPS.

D-lactate determination

The plasma from systemic blood samples was obtained and subjected to a deproteination and neutralization process by acid/base precipitation using perchloric acid and potassium hydroxide. The protein-free plasma was then assayed for D-lactate concentration by enzymatic-spectrophotometric method[23].

Detection and observation of colonic mucosal ultrastructure

Ultrathin (70 nm) colon sections were examined using a transmission electron microscope (Hitachi H-600, Japan).

Immunohistochemistry of occludin, claudin-1

Frozen colon tissue sections (5 μm thick) were fixed on glass slides by incubating them in acetone for 10 min at 4 ℃. The slides were incubated with 3% H_2O_2 for 20 min at room temperature and indirectly immunolabeled using an ABC kit (Takara, Japan) according to the manufacturer's instructions. Slides were then blocked in goat serum for 30 min at 37 ℃ and incubated with a rabbit anti-mouse polyclonal occludin, claudin-1 antibody (dilution, 1:50; Santa Cruz Biotechnology, United States) at

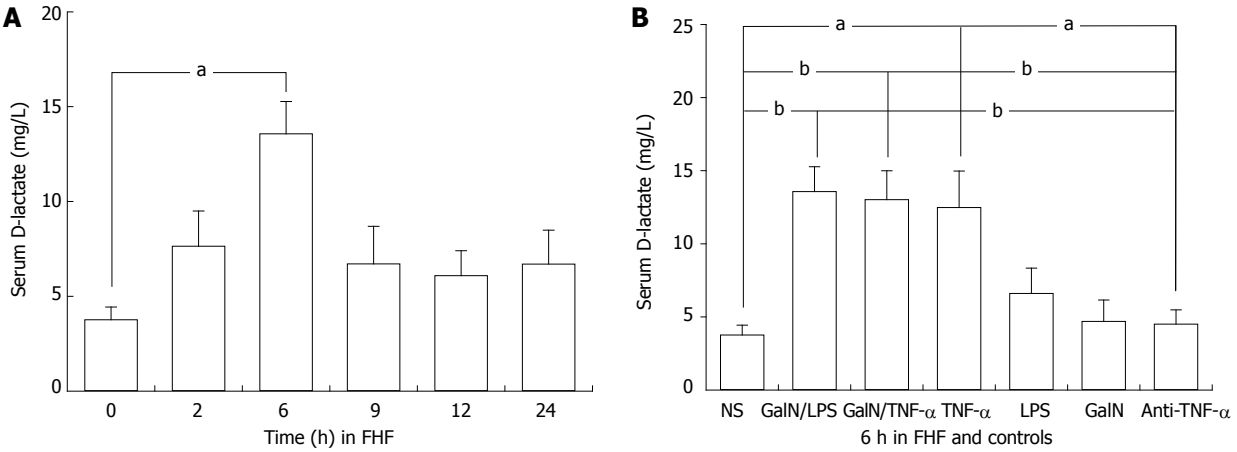

Figure 1 Systemic blood D(-)-lactate levels in the mouse model of fulminant hepatic failure and controls. Systemic blood D (-)-lactate levels 2, 6, 9, 12 and 24 h after injection in D-galactosamine (GalN)/lipopolysaccharide (LPS)-treated mice, and 6 h after injection in the saline, GalN, LPS, tumor necrosis factor alpha (TNF-α), anti-TNF-α immunoglobulin G antibody-pretreated groups. *n* = 5 rats for each time point. NS: Normal saline; FHF: Fulminant hepatic failure. The level of significance was set at $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* baseline (NS group). Data are reported as the mean ± SD.

4 ℃ overnight. For the negative controls, the primary antibody was replaced with phosphate buffered saline (PBS). This incubation was followed by incubation with biotinylated goat anti-rabbit IgG (Histostain-Plus kit, ZYMED) diluted 1:300 in PBS for 2 h at room temperature. Sections were rinsed in PBS and then in distilled water. The slides were stained with 3,3'-diaminobenzidine and counterstained with hematoxylin.

Western blotting analysis of occludin, claudin-1

Intestinal tissue samples were homogenized in lysis buffer [20 mmol Tris-HCl (pH 7.5), 1% Triton X 100, 0.2 mol NaCl, 2 mmol ethylene diamine tetraacetic acid, 2 mmol ethylene glycol tetraacetic acid, 1 mol dithiothreitol and 2 mol aprotinin]. Proteins (50 μg) were electrophoresed using sodium dodecyl sulfate polyacrylamide gel electrophoresis (8%) and transferred to a nitrocellulose membrane. Membranes were blocked with non-fat dried milk in tris buffered saline containing 0.05% Tween-20 (TTBS) for 1 h at room temperature and incubated with a rabbit anti-mouse polyclonal occludin, claudin-1 antibody (diluted 1:400; Santa Cruz Bio-technology) at 4 ℃ overnight. After three washes in TTBS, the membranes were reacted with a 1:2000 dilution of alkaline phosphatase-labeled goat anti-rabbit IgG (Santa Cruz Biotechnology) for 2 h at room temperature. The immunoreaction was visualized using α-dianisidine and β-naphthyl acid phosphate (Sigma, United States).

RNA isolation and real-time quantitative polymerase chain reaction

Total RNA was isolated from intestinal tissues using TRIzol Reagent (Invitrogen, United States). RNA was purified using DNase I and depurified using PI-PCI-EHCO. SYBR-green-based real-time polymerase chain reaction (PCR) [TaKaRa SYBR reverse transcription-PCR kit, Japan] was used to measure relative gene expression in each sample. PCR was performed using *Taq* DNA polymerase (Qiagen, Valencia, United States) and oligonucleotide primers for mouse were occludin (forward 5'-GCTTATCTTGGGAGCCTGGACA-3', reverse 5'-GTCATTGCTTGGTGCATAATGATTG-3'), claudin-1 (forward 5'-AGACCTGGATTTGCATCTTGGTG-3', reverse 5'-TGCAACATAGGCAGGACAAGAGTTA-3') and glyceraldehyde 3-phosphate dehydrogenase (GAPDH: forward 5'-TGTGTCCGTCGTGGATCTGA-3', reverse 5'-TTGCTGTTGAAGTCGCAGGAG -3'). PCR conditions were as follows: one cycle at 95 ℃ for 30 min followed by 45 cycles of PCR amplification, each consisting of 95 ℃ for 5 s and 57 ℃ for 20 s. The concentration of mRNA was calculated according to the standard curve and then normalized to that of GAPDH.

Statistical analysis

SPSS version 13.0 Software was used to perform the statistical analyses. All datas were analyzed using analysis of variance followed by a least-squares difference test. A $P < 0.05$ was used to indicate statistical significance.

RESULTS

D-lactate

Compared to the normal control, plasma D-lactate levels increased after 2 h and reached significant levels 6 h after injection in GalN/LPS-treated mice (13.57 ± 1.70 mg/L *vs* 3.76 ± 0.67 mg/L, $P < 0.01$) (Figure 1A). The levels also increased significantly 6 h after injection in GalN/TNF-α- and TNF-α-treated mice (13.02 ± 1.97 mg/L, 12.48 ± 2.49 mg/L *vs* 3.76 ± 0.67 mg/L, $P < 0.01$), but did not show an increase in LPS-, GalN- and prophylactically anti-TNF-α IgG- treated groups (6.60 ± 1.73 mg/L, 4.69 ± 1.46 mg/L, 4.50 ± 0.97 mg/L *vs* 3.76 ± 0.67 mg/L, $P > 0.05$) (Figure 1B).

Ultrastructural characteristics of the colonic mucosa

We observed obvious ultrastructural changes in the intes-

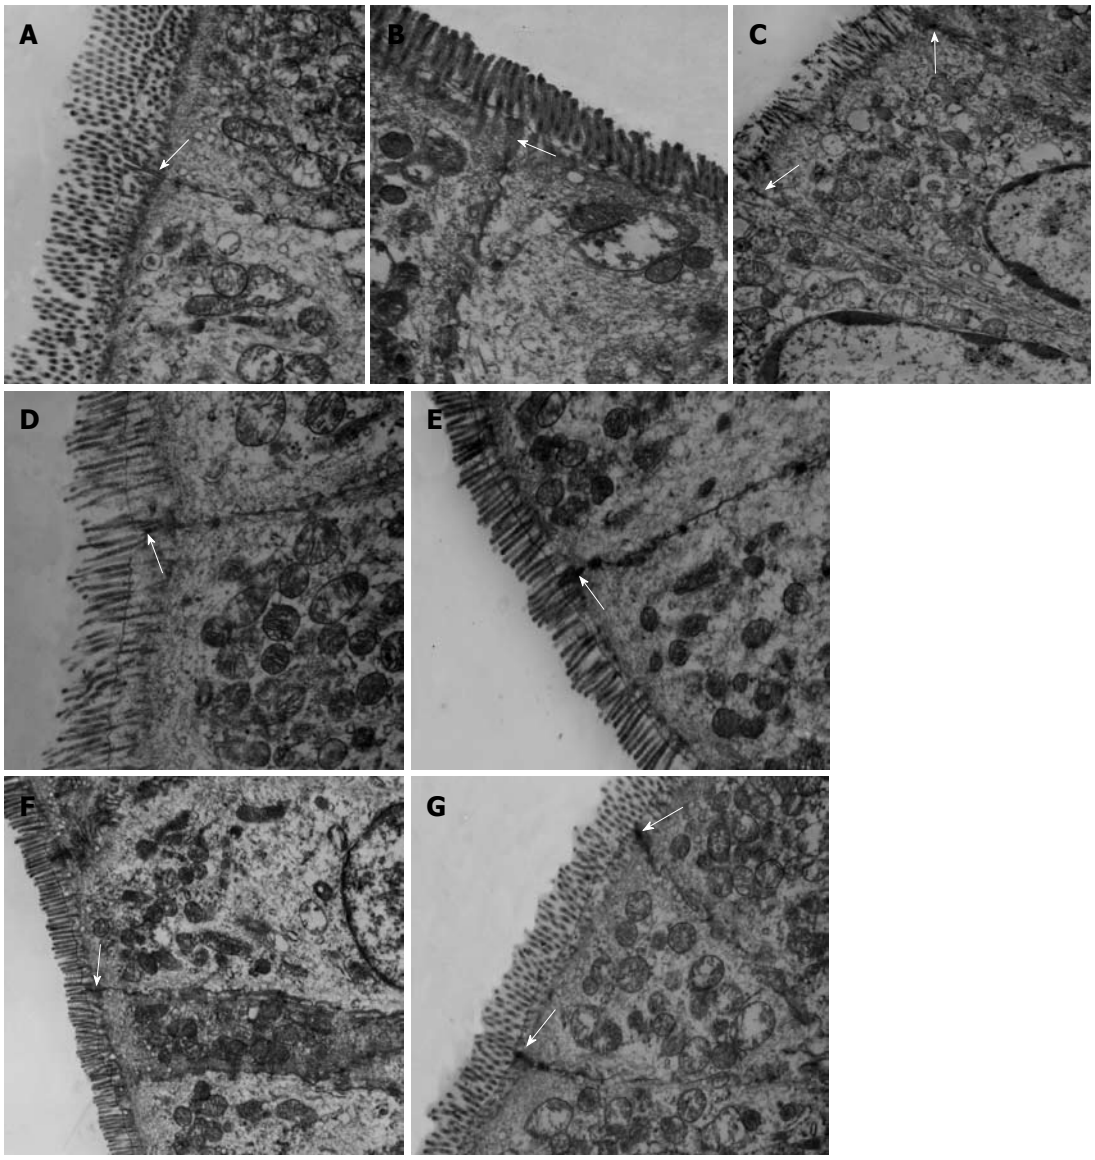

Figure 2 Transmission electron microscopy of mouse intestine (8000×). Transmission electron microscopy of mice intestine from the D-galactosamine (GalN)/lipopolysaccharide (LPS) and GalN/tumor necrosis factor alpha (TNF-α) groups (A and B), the control groups (C, D, E and F), and the group that received antibody prior to fulminant hepatic failure induction (G) (8000×). A: At 6 h after injection in the GalN/LPS group. The mitochondria of the endothelial cells were loose. Tight junctions (TJs) (arrow) were disrupted. Organelles were swollen and had reduced electron density; some microvilli were loose. A TJ (arrow) was disrupted; B: At 6 h after injection in the GalN/TNF-α group, mitochondria, organelles and microvilli were similar to A. A TJ (arrow) was disrupted; C: The GalN control group; D: The LPS control group. Epithelial cells were slightly shrunken and TJs (arrow) were intact; E: TNF-α-treated group. TJ (arrow) was intact; F: The normal saline control group. Epithelial cells and TJ (arrow) were intact; G: Anti-TNF-α antibody and the GalN/LPS group. Epithelial cells were slightly shrunken and TJs (arrows) between endothelial cells were intact.

tinal mucosa 6 h after GalN/LPS administration. Some epithelial cell microvilli were disordered and distorted, and they were sparsely distributed. The epithelial cells were swollen or shrunken. Mitochondrial swelling was observed; cristae breakdown and disrupted tight junctions were also noted. The changes in the intestinal mucosa of mice treated with GalN/TNF-α were less severe than those of mice treated with GalN/LPS. There was no disruption of TJs in the control groups, including GalN, LPS and TNF-α groups; only less swelling of epithelial cells and distorted microvilli were observed. Pathological changes in the group prophylactically treated with antibody were less severe than those in the ALF groups, and even similar to the NS control group (Figure 2).

Expression of occludin and claudin-1 proteins in the colon

Immunohistochemical analysis revealed a high density of occludin and claudin-1 expression in the lateral membrane of the intestinal epithelium in the anti-TNF-α IgG antibody-pretreated group and the saline group. The traces of occludin and claudin-1 proteins weakened in the intestinal tissue 2 h after GalN/LPS treatment, and were most pale 9 h after the injections (Figure 3A and B). The traces slightly weakened even in the TNF-α control group.

The protein level of the NS group was set to 1 as the baseline. Western blotting analysis showed that occludin and claudin-1 expressions decreased significantly in the GalN/LPS-treated mice, particularly 6 h and 9 h after

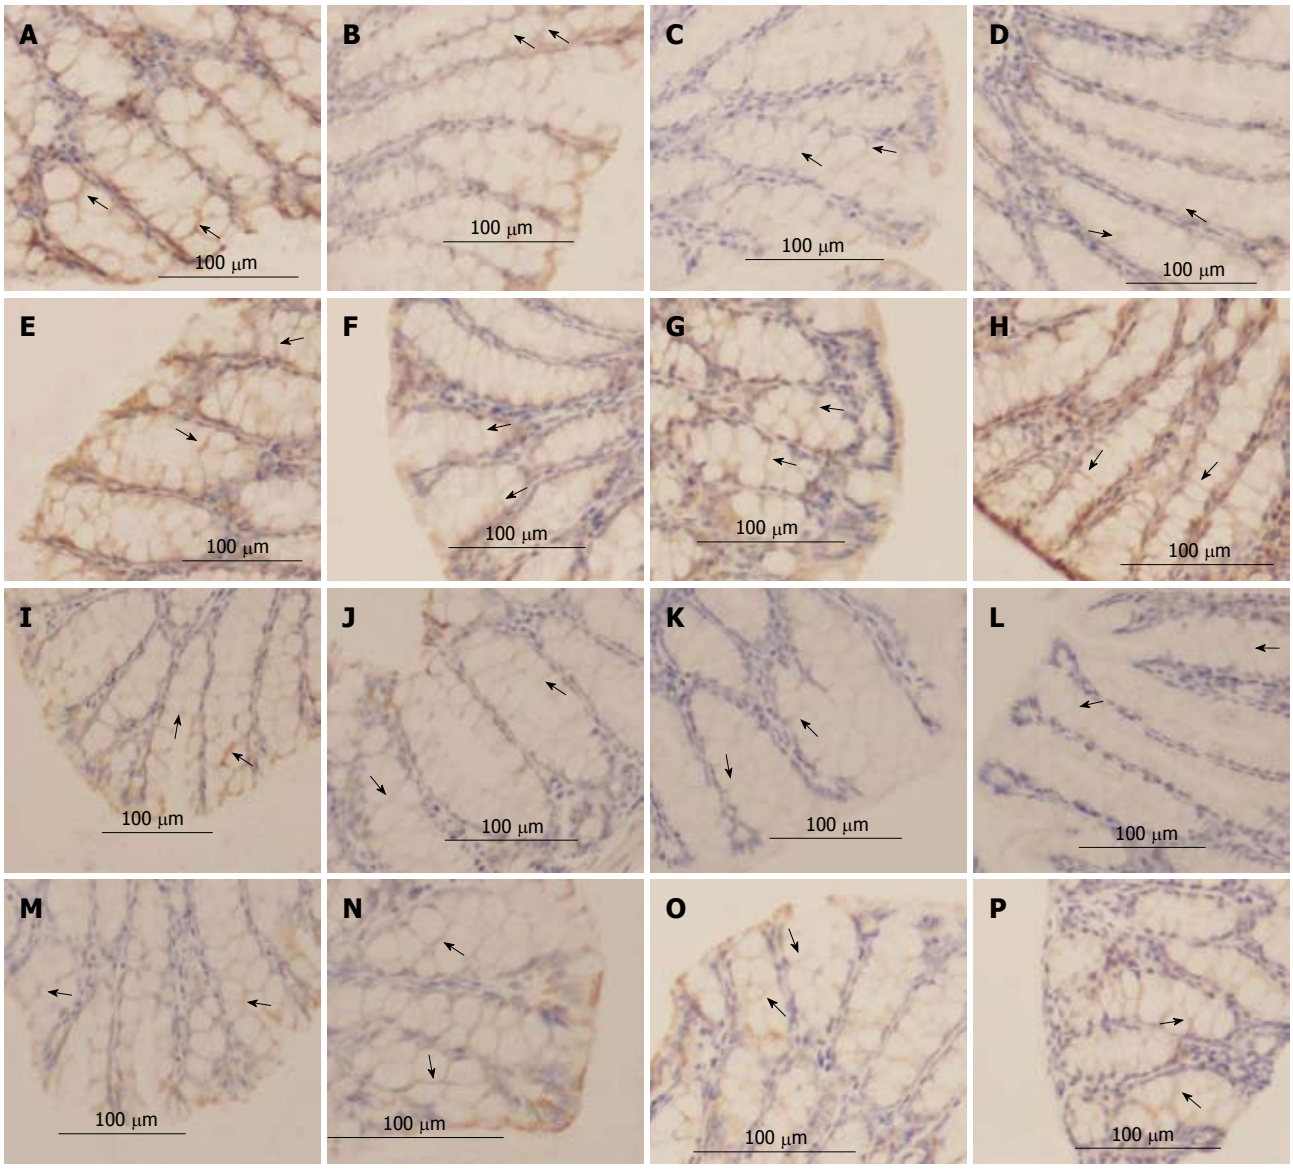

Figure 3 The tight junction proteins, occludin and claudin-1 determined by immunohistochemistry (400×). A: Occludin staining in the saline group; B-D: Occludin staining 2 h, 6 h, and 9 h after injection in the D-galactosamine (GalN)/lipopolysaccharide (LPS)-treated mice; E-H: Occludin staining 6 h after injection in the anti-tumor necrosis factor alpha (TNF-α) immunoglobulin G (IgG) antibody pretreated group within the TNF-α-treated group; the LPS-treated group and the D-GalN-treated group, respectively; I: Claudin-1 staining in the saline group; J-L: Claudin-1 staining 2, 6, and 9 h after injection in the GalN/LPS-treated mice; M-P: Claudin-1 staining 6 h after injection in the anti-TNF-α IgG antibody pretreated group, the TNF-α-treated group, the LPS-treated group and the D-GalN-treated group, respectively. The mucosal tissue sections were double-labeled for proteins (brown color). Labeled sections were analyzed immunohisto-chemically. Decreased protein staining in the epithelial cells were observed at 2-9 h after injection in the GalN/LPS-treated mice and the TNF-α-treated group, and was absent in the other controls and the antibody pretreated group.

the GalN/LPS injections (occludin: 0.6733 ± 0.0433, 0.61 ± 0.0473 fold *vs* baseline, $P < 0.01$; claudin-1: 0.8600 ± 0.0208, 0.6633 ± 0.0328 fold *vs* baseline, $P < 0.01$) (Figure 4A and C). Expressions of these proteins were decreased significantly in the GalN/TNF-α and TNF-α groups 6 h after injection (occludin: 0.6133 ± 0.0145 fold *vs* baseline, $P < 0.01$, 0.8933 ± 0.01 fold *vs* baseline, $P < 0.05$; claudin-1: 0.6267 ± 0.0145 fold *vs* baseline, $P < 0.01$, 0.92 ± 0.0173 fold *vs* baseline, $P < 0.05$), which were less in the later group (Figure 4B and D). The protein expression in the antibody-treated group was close to the normal range (occludin: 0.9467 ± 0.0285 fold *vs* baseline, $P > 0.05$; claudin-1: 0.9533 ± 0.0186 fold *vs* baseline, $P > 0.05$) (Figure 4B and D).

Expression of occludin and claudin-1 mRNA in the colon

The mRNA level of the NS group was set to 1 as baseline. We obtained a reasonable amplification curve and a standard curve of occludin, claudin-1 and GAPDH RNAs, respectively. The correlation coefficients of all standard curves were 0.999. Real-time PCR quantitative analysis showed that there were marked decreases in occludin and claudin-1 expression in ALF mice 6 h and 9 h after GalN/LPS treatment (occludin: 0.57 ± 0.159 fold *vs* baseline, 0.345 ± 0.0247 fold *vs* baseline, $P < 0.01$; claudin-1: 0.3067 ± 0.1291 fold *vs* baseline, 0.2233

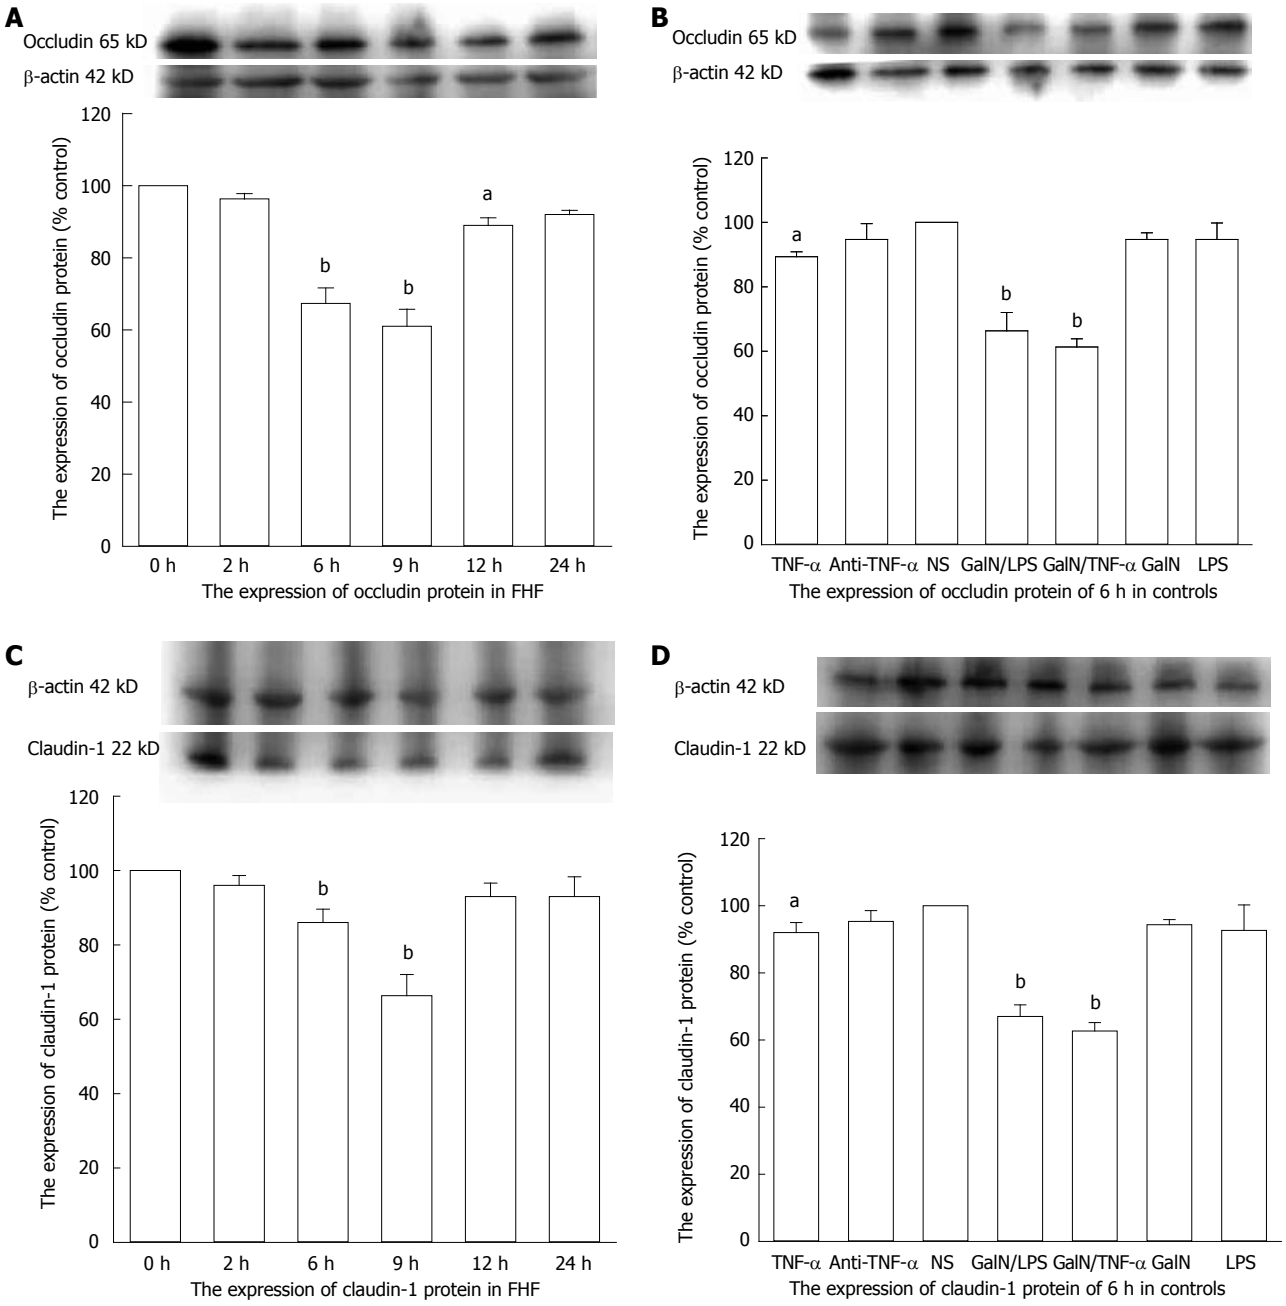

Figure 4 Mucosal colonic tissues from fulminant hepatic failure and control mice were analyzed for the protein expression of occludin and claudin-1 by Western blotting analysis. A: Occludin expression decreased significantly 6, 9 and 12 h after D-galactosamine (GalN)/lipopolysaccharide (LPS) injection; B: Occludin expression decreased significantly 6 h after injection in the GalN/ tumor necrosis factor alpha (TNF-α)- and TNF-α-treated mice; C: Claudin-1 expression decreased significantly 6 h and 9 h after GalN/LPS injection; D: Claudin-1 expression decreased significantly 6 h after injection in the GalN/TNF-α- and TNF-α-treated mice. NS: Normal saline; FHF: Fulminant hepatic failure. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* baseline. Data are reported as the mean ± SD.

± 0.1155 fold *vs* baseline, $P < 0.01$) (Figure 5A and C), as well as 6 h after GalN/TNF-α treatment and TNF-α treatment (occludin: 0.2562 ± 0.0945 fold *vs* baseline, $P < 0.01$; 0.6421 ± 0.164 fold *vs* baseline, $P < 0.05$; claudin-1: 0.1366 ± 0.0661 fold *vs* baseline, $P < 0.01$; 0.5356 ± 0.1874 fold *vs* baseline, $P < 0.05$) (Figure 5B and D). The mRNA expression in the antibody-treated group was close to the normal range (occludin: 0.8865 ± 0.0274 fold *vs* baseline, $P > 0.05$; claudin-1: 0.85 ± 0.1437 fold *vs* baseline, $P > 0.05$) (Figure 5B and D).

DISCUSSION

The intestinal mucosa is the physical and metabolic barrier that separates cytotoxic components from gut lumen. Disruption of the gastrointestinal barrier function and the diffusion of luminal toxins and pathogens into the systemic circulation are central to the pathogenesis of a number of diseases. Increased IP has been reported in many hepatic diseases[2-4,6]. IETM shows an inclination correlation with the D-lactate levels in liver cirrhosis

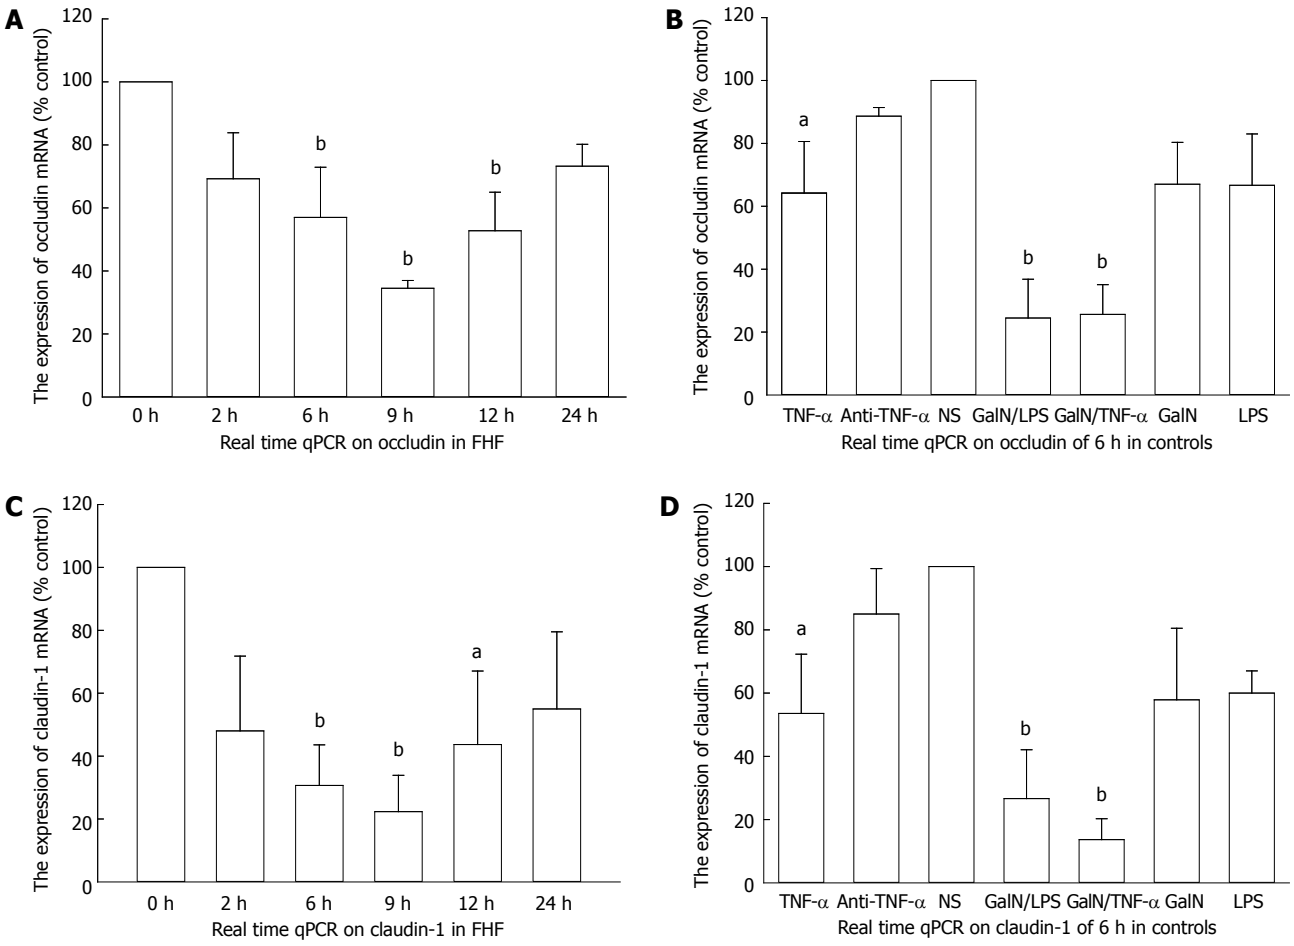

Figure 5 Real-time quantitative reverse transcription-polymerase chain reaction for occludin and claudin-1 mRNA in the fulminant hepatic failure groups and the control groups. A: Occludin significantly decreased 6 h, 9 h and 12 h after D-galactosamine (GalN)/lipopolysaccharide (LPS) injections in GalN/LPS-treated mice; B: Occludin markedly decreased 6 h after injection in the GalN/tumor necrosis factor alpha (TNF-α) or TNF-α treated mice; C: Claudin-1 significantly decreased 6 h, 9 h and 12 h after GalN/LPS injections in the GalN/LPS treated mice; D: Claudin-1 markedly decreased 6 h after injection in the GalN/TNF-α- or TNF-α-treated mice. NS: Normal saline; FHF: Fulminant hepatic failure; qPCR: Quantitative polymerase chain reaction. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* baseline. Data are reported as the mean ± SD.

and severe injuries[24,25], and appears to be related to IP. The incidence of IETM reaches 80%-100% in severe hepatitis, and plays an important role in the secondary liver injury observed in FHF[9]. How is IETM generated in FHF? When derived from overproduced bacteria in the lumen of the colon and terminal ileum[26,27], endotoxin (LPS) is translocated through the intestinal mucosa and into blood, causing IETM. Binding to LPS-binding protein, high density lipoprotein and low density lipoprotein[28,29], IETM is transported into the portal vein and achieves a higher level in the portal circulation than in peripheral veins[30]. When beyond the detoxification capability of debilitated monocytes and Kupffer cells, IETM damages hepatocytes and accelerates liver failure, even causing systemic injury[9,31]. To detect IP, we utilized D-lactate as an index. IP reached a peak 6 h post-injection of GalN/LPS. In GalN/LPS-treated mice, TNF-α levels reached its first peak 2 h post-injection[22]. When TNF-α was blocked with anti-TNF-α IgG antibody, there was a significant decrease in the IP of the mice. Considering that TNF-α causes an increase in the epithelial barrier permeability *in vivo* and *in vitro*, it is concluded that TNF-α is a crucial factor in the increased IP in FHF mice.

Borgstrom *et al*[32] have showed that at least 85% of the passive flow across the mammalian small intestine takes the paracellular route. Since the cotransporters of the apical membrane are saturated at a low nutrient concentration (below 25 mmol for glucose), but after a meal, nutrient concentrations in the proximal intestine often exceed 200 mmol, it follows that the paracellular pathway may be the major route of nutrient uptake. Drewe *et al*[33] has indicated that LPS is taken up by the intestinal mucosa predominantly by a transcellular pathway through enterocytes. Under ischemic conditions, the permeability of LPS is increased mainly by an enhanced paracellular translocation across the gut wall, whereas little apoptosis was observed in the intestinal epithelium. In several studies TNF-α induced an increase in the TJ permeability of Caco-2 cells, and did not induce apoptosis in the cells[14,34], indicating that apoptosis was not responsible for the increase in epithelial TJ permeability. In our previous study, terminal dUTP nick end labeling-positive enterocytes were not seen in the intestine of

GalN/LPS and GalN/TNF-α-treated mice until 12 h after injection[35]. The increased IP observed 6 h after GalN/LPS and GalN/TNF-α treatment was not related significantly to the transcellular pathway. Because TJ regulates the paracellular route in the leakage of macromolecules, we examined TJ with TEM and tested the protein and mRNA levels of TJ proteins. Disrupted TJ structures, down-regulated occludin and claudin-1 protein and RNA levels, and a lower density of proteins distributed in the intestinal mucosa were observed in GalN/LPS- and GalN/TNF-α-treated mice 6 h after injection. These were not observed in normal controls and in the group treated prophylactically with anti-TNF-α IgG antibody. Similar results were obtained with another TJ protein, ZO-1, in our previous study[22]. These observations indicate that TNF-α plays a central role in the regulation of TJ proteins, resulting in the disruption of TJ structure. Considering that TNF-α disrupts TJ structure and increases transepithelial permeability *in vitro* and *in vivo*, we conclude that the altered IP is induced by TNF-α *via* the destruction of TJ. The destruction of TJ by TNF-α was the result of down-regulation of TJ proteins. In the TNF-α-treated group, because of the lower extent of down-regulation of the TJ proteins, ZO-1[22], occludin and claudin-1 in the TNF-α-treated group, TJs were not visibly disrupted.

When IP was increased in GalN/LPS-treated mice 6 h after injection, the TJ structure was disrupted. In our previous study, ZO-1 showed an insignificant down-regulated expression[22], whereas occludin and claudin-1 were significantly down-regulated in GalN/LPS-treated mice 6 h after injection. This indicated a crucial role of occludin and claudin-1 in the composition of TJ. *In vitro*, TNF-α had a dose-dependent increasing effect on the permeability of the epithelium[15], and IETM had a severe effect on IP[36]. TNF-α could stimulate the expression of IL-1 and NO, which could disrupt TJ structure and increase epithelium permeability[14,18,37,38], and even synergize with interferon-α to induce intestinal epithelial barrier dysfunction[38]. *In vitro* on Caco-2 cell monolayers, TNF-α decreased the expression of phosphorylated occludin in detergent-insoluble fractions, but did not affect the expression of non-phosphorylated occludin protein. It also caused a decrease in Caco-2 transepithelial resistance and an increase in transepithelial permeability to a paracellular marker, Lucifer yellow[15]. It seemed that the combined decreased effect on IP was maximized 6 h after injection of GalN/LPS in the mouse model of FHF. Few studies on the mechanism of TNF-α-mediated decrease in the induction of TJ proteins were found. This effect might be related to nuclear factor kappa B (NF-κB). NF-κB activation and nuclear translocation of NF-κB p65 has been observed when TNF-α induces an increase in the TJ permeability of Coca-2 cell monolayers[34]. In our previous experiments on Caco-2 cell monolayers, TNF-α induced an increase of TJ permeability to Lucifer yellow, which could be partially inhibited by preincubation with 2 μg/mL anti-TNF receptor I monoclonal antibody and anti-TNF receptor Ⅱ monoclonal antibody (data not shown). This observation suggests that TNF receptor I and TNF receptor Ⅱ mediate the TNF-α induced increase in tight junction permeability. Further studies are necessary to clarify the underlying signal transduction system of the TNF-α-induced decrease in the induction of TJ proteins and the increase in TJ permeability *in vitro* and *in vivo*.

In conclusion, we found that the increase in IP stems from the downregulation of TJ proteins, especially occludin and claudin-1, and the subsequent destruction of the TJ structure that were induced by TNF-α in the mouse model of FHF.

COMMENTS

Background

Fulminant hepatic failure (FHF) is a devastating disease with many complications. Intestinal endotoxemia can lead to the pathogenesis of hepatic failure. It was therefore essential to detect the intestinal permeability (IP) in hepatic failure as the source of intestinal endotoxemia.

Research frontiers

It has been shown that altered IP occurs in many hepatic diseases. It seems that these alterations are induced by a variety of cytokines. Moreover, specified dates and underlying mechanisms deserved to illustrate about pathogenesis of IP alteration.

Innovations and breakthroughs

This is the first study to report an increased IP in FHF. Their observations support the hypothesis that tumor necrosis factor alpha down-regulates intestinal tight junction proteins and constructed to the progress of IP alteration.

Applications

The study provides insights into the mechanisms of increased IP in FHF, which probably contributes to the progress of the disease.

Peer review

This study has shown the increased IP in FHF and illustrated a probable mechanism. It therefore contributes to the understanding of intestinal complications in FHF.

Abstract

AIM: To examine the predictive factors of capsule endoscopy (CE) completion rate (CECR) including the effect of inpatient and outpatient status.

METHODS: We identified 355 consecutive patients who completed CE at Rush University Medical Center between March 2003 and October 2005. Subjects for CE had either nothing by mouth or clear liquids for the afternoon and evening of the day before the procedure. CE exams were reviewed by two physicians who were unaware of the study hypotheses. After retrospective analysis, 21 cases were excluded due to capsule malfunction, prior gastric surgery, endoscopic capsule placement or insufficient data. Of the remaining 334 exams [264 out-patient (OP), 70 in-patient (IP)], CE indications, findings, location of the patients [IP *vs* OP and intensive care unit (ICU) *vs* general medical floor (GMF)] and gastrointestinal transit times were analyzed. Statistical analysis was completed using SPSS version 17 (Chicago, IL). Chi-square, *t* test or fisher exact-tests were used as appropriate. Multivariate logistic regression analysis was used to identify variables associated with incomplete CE exams.

RESULTS: The mean age for the entire study population was 54.7 years. Sixty-one percent of the study population was female, and gender was not different between IPs *vs* OPs (P = 0.07). The overall incomplete CECR was 14% in our study. Overt obscure gastrointestinal bleeding (OGB) was a significantly more common indication for the IP CE (P = 0.0001), while abdominal pain and assessment of IBD were more frequent indications for the OP CE exams (P = 0.002 and P = 0.01, respectively). Occult OGB was the most common indication and arteriovenous malformations were the most common finding both in the IPs and OPs. The capsule did not enter the small bowel (SB) in 6/70 IPs and 8/264 OPs (P = 0.04). The capsule never reached the cecum in 31.4% (22/70) of IP *vs* 9.5% (25/264) of OP examinations (P < 0.001). The mean gastric transit time (GTT) was delayed in IPs compared to OPs, 98.5 ± 139.5 min *vs* 60.4 ± 92.6 min (P = 0.008). Minimal SB transit time was significantly prolonged in the IP compared to the OP setting [IP = 275.1 ±

111.6 min *vs* OP = 244.0 ± 104.3 min (P = 0.037)]. CECR was also significantly higher in the subgroup of patients with OGB who had OP *vs* IP exams (95% *vs* 80% respectively, P = 0.001). The proportion of patients with incomplete exams was higher in the ICU (n = 7/13, 54%) as compared to the GMF (n = 15/57, 26%) (P = 0.05). There was only a single permanent SB retention case which was secondary to a previously unknown SB stricture, and the remaining incomplete SB exams were due to slow transit. Medications which affect gastrointestinal system motility were tested both individually and also in aggregate in univariate analysis in hospitalized patients (ICU and GMF) and were not predictive of incomplete capsule passage (P > 0.05). Patient location (IP *vs* OP) and GTT were independent predictors of incomplete CE exams (P < 0.001 and P = 0.008, respectively).

CONCLUSION: Incomplete CE is a multifactorial problem. Patient location and related factors such as severity of illness and sedentary status may contribute to incomplete exams.

INTRODUCTION

In recent years, capsule endoscopy (CE) has emerged as a sophisticated and widely used tool to evaluate small bowel pathology. It has applications in Crohn's disease, celiac disease, Peutz-Jeghers syndrome, familial adenomatous polyposis, and hereditary polyposis syndromes[1-4]. CE is also particularly useful for the investigation of obscure gastrointestinal bleeding (OGB)[5,6], especially if upper and lower endoscopies fail to reveal the underlying pathology and a small bowel source is suspected. Locating the source and treating OGB has long been a challenge for physicians. Identification of the bleeding site is the key step not only to diagnose but also to provide effective treatment. During a brisk overt hemorrhage, the rapidity at which the bleeding site is found is critical. CE is therefore utilized often in patients hospitalized for bleeding and anemia. The hospital setting, however, may not be ideal in obtaining optimal results with CE. In-patients tend to be sedentary and are more prone to delayed transit or ileus, which may prolong gastric and small bowel transit times. Therefore, we hypothesized that in-patient (IP) CE is more often incomplete as compared to out-patient (OP) CE. The two previously published European studies indirectly examining this question have compared IP *vs* OP CE completion rates (CECR)[7,8], but both studies have limitations: both used a prokinetic agent and/or bowel preparation to increase CECR and neither of these interventions is part of the standard CE protocol at United States institutions. Furthermore, the patient numbers were small and the studies did not examine the effects of inpatient location (i.e., an intensive care unit (ICU) *vs* a general medical floor (GMF) setting). In this study, we aimed at overcoming these limitations by analyzing all consecutive IPs and OPs, studying a larger IP group, doing a subgroup analysis to compare the ICU and GMF settings, without the use of prokinetic and bowel preparation agents.

MATERIALS AND METHODS

This study was conducted in compliance with ethical guidelines and was approved by Rush University Institutional Review Board. All CE examinations done at Rush University Medical Center between March, 2003 and October, 2005 were identified retrospectively. A total of 355 CE exams, which were performed using a Given PillCam™ small bowel (SB) capsule, were reviewed using the Given Rapid® Access software. Patients with capsule malfunction (n = 6), prior gastric surgery (n = 3), endoscopic capsule placement (n = 3) and studies lacking sufficient data for analysis were excluded (n = 9; 8 OP, 1 IP). In the remaining 334 exams (264 OP, 70 IP), patient characteristics such as age, gender, gastric retention of the capsule, completeness of the examination (whether or not the capsule reached the cecum), gastric and small bowel transit times, indications and findings were recorded.

Subjects for capsule endoscopy had either nothing by mouth (except their medications) or clear liquids (excluding any red colored foods) for the afternoon and evening of the day before the procedure. The CE exam was delayed if subjects used iron supplementation within the past 5 d prior to the procedure.

CE exams were reviewed by two physicians. For the majority of cases, gastroenterologists who read the CE exams did not have any information regarding patient location. The hypotheses of the study were conceived after the exams were read and gastroenterologists were unaware of the study hypotheses.

Overt gastrointestinal bleed (GIB) was defined as having melena and/or hematochezia with a hemoglobin < 10 g/dL. Occult obscure GIB was defined as subjects

Table 1 Baseline characteristics of study population, capsule endoscopy indications and findings *n* (%)

Patient characteristics	IP (*n* = 70)	OP (*n* = 264)	*P* value

IP: In-patient; OP: Out-patient; GIB: Gastrointestinal bleed; IBD: Inflammatory bowel disease; AVM: Arteriovenous malformation; SB: Small bowel. [1]*t* test; the rest, Chi-square or fisher exact test as appropriate.

who had a positive fecal occult blood test or complaints of intermittent black bowel movements, and who had both colonoscopy and upper endoscopy without any source of bleeding identified. Accurate SB transit time (SBTT) were obviously not available in those subjects in whom the capsule stopped recording before reaching the colon. In this circumstance the minimum SBTT, which reflects the minimum time the capsule spent in the small bowel, was calculated using the formula, 480 min - the gastric transit time (GTT) (min) = minimum SBTT. Four hundred and eighty minutes was used as this has the generally accepted battery life of the Given PillCam™ SB capsule at the time of the CE exams.

Statistical analysis was completed using SPSS version 17 (Chicago, IL). Chi-square, *t* test or fisher exact-test was used as appropriate. Multivariate logistic regression analysis was used to identify variables associated with incomplete CE exams. A multivariate logistic regression model was constructed using forward stepwise method with capsule reaching the cecum or not as the dependent variable using the univariate variables that were significantly predictive of incomplete capsule passage. In addition, differences in bowel transit time between the groups were compared by a survival model (Kaplan-Meier) and (Log-Rank test).

RESULTS

Study population

The baseline characteristics of the IPs *vs* OPs that underwent CE are shown in Table 1. The mean age for the entire study population was 54.7 (17-92) years. The mean age for the IPs was greater than the OPs (60.9 ± 18.4 *vs* 53 ± 17.7, $P = 0.001$). Sixty-one percents of the study population was female, and gender was not different between IPs *vs* OPs ($P = 0.07$). The indications for CE were occult OGB, overt OGB, abdominal pain, and assessment for inflammatory bowel disease (IBD), SB masses, celiac disease and other pathologies. Several patients had more than one indication for the CE examination. Occult OGB was the most common indication for both the IPs and OPs. While evaluation of overt OGB was significantly more common for the IP CE ($P = 0.0001$), abdominal pain and assessment of IBD were more frequently the indications for the OP CE exams ($P = 0.002$ and $P = 0.01$, respectively). Arteriovenous malformations (AVM) were the most common finding both in the IPs and OPs. Active bleeding was seen more often in the IPs ($P = 0.001$); while SB ulcerations and erosions were more frequently observed in the OP CE exams ($P = 0.011$).

Completion rates of CE

The overall incomplete CECR was 14% in our study. A higher number of patients in the OP group had complete CE with visualization of the entire SB, compared to the IP group (90.5% *vs* 68.6%, $P < 0.001$). The capsule remained within the stomach for the duration of the study in 8.6% (6/70) of the IPs and 3% (8/264) of the OPs ($P = 0.04$). When these cases of gastric capsule retention were excluded, 25% (16/64) of the IPs and 6.6% (17/256) of the OPs had exams that were not complete, as the capsule did not reach the cecum ($P = 0.001$). Therefore, both gastric capsule retention with reduced entry into the SB as well as delayed transit in the SB played a role in the incomplete CE exams in the IPs. Obstructing lesions in the SB were uncommon. There was only a single permanent small bowel retention case in the dataset, who was an OP with a previously unrecognized stricture. The remainder of the incomplete SB exams appeared to be due purely to slow transit. To exclude a diagnosis related bias in the analysis, we also looked at the OGB subset of our data. CECR was also significantly higher in OGB patients who had OP *vs* IP exams (95% *vs* 80% respectively, $P = 0.001$). Therefore, the result obtained can not be solely explained by differences in the OP *vs* IP diagnoses.

Transit times in the stomach and small bowel

A Kaplan-Meier plot of total bowel transit time for the IPs *vs* the OPs is shown in Figure 1. As time passes more studies get completed in the OP group compared to the IP group. The median total capsule transit time to the cecum was longer in IP *vs* OP (368 min *vs* 279 min) ($P < 0.0001$, log-rank for median total capsule transit time).

In 10 patients (3 IPs and 7 OPs), GTT were not recorded into the CE report. In the remaining 324 patients, the mean GTT was prolonged in the IP setting. GTT was 98.5 ± 139.5 min in IP *vs* 60.4 ± 92.6 min in OP setting ($P = 0.008$). After removing those patients with gastric capsule retention and lack of GTT measurements from the dataset, minimum SBTT were signifi-

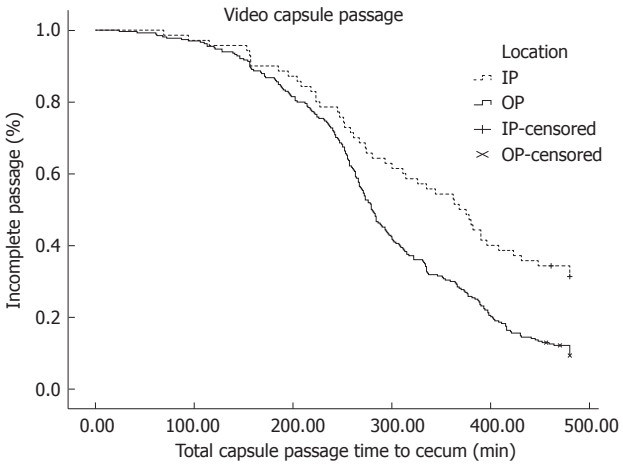

Figure 1 Kaplan-Meier plot of total capsule passage time to cecum. Incomplete passage percentage and total capsule passage time to cecum were different between inpatients (IP) and outpatients (OP). Data is shown for the IP group (dotted line) *vs* the OP group (solid line). X-axis represents bowel passage time and Y-axis represents the percentage of patients in whom the capsule has not reached the cecum.

cantly prolonged in the IP setting (275.1 ± 111.6 min) *vs* the OP setting (244.0 ± 104.3 min) ($P = 0.037$).

Effect of inpatient location

Among the 70 IPs studied, 13 were in the ICU and 57 were on a GMF. There was no statistical difference in mean age and gender in the ICU *vs* GMF groups, although the ICU patients were relatively older (68.8 ± 13.6 years *vs* 59.1 ± 19.0 years, $P = 0.084$).

The proportion of patients with incomplete exams was higher in the ICU ($n = 7/13$, 54%) as compared to the GMF ($n = 15/57$, 26%) ($P = 0.05$). Gastric capsule retention also was more common among ICU patients compared to the GMF [2/13 (15.3%) *vs* 4/57 (7%), $P = 0.331$]. When subjects with gastric retention were excluded, the proportion of subjects with incomplete small bowel exams were numerically higher 5/11 (45%) in the ICU setting *vs* 11/53 (32%) in the GMF setting, but the difference was not statistically significant ($P = 0.085$). The GTTs were not significantly different between the ICU and GMF patients (154.4 ± 181.4 min *vs* 85.0 ± 125.8 min, $P = 0.108$) although a trend toward longer GTT in ICU patients was noted. Minimum SBTT were also not significantly different between the ICU (272.1 ± 131.4 min) and GMF patients (275.8 ± 108.4 min) ($P = 0.922$).

Risk factors for an incomplete exam

We looked at the effects of potential risk factors for an incomplete exam in univariate analyses in all subjects (Table 2). Among pre-procedure risk factors, location (IP *vs* OP setting) and having an indication for gastrointestinal (GI) bleed (either occult or overt) were predictive of incomplete capsule passage. Among post-procedure risk factors, the following findings were predictive of having an incomplete exam: having an AVM, blood, visible vessel, lymphoid hyperplasia, gastric vascular ectesia, findings suggesting Crohn's disease (CD), excess food particles in the GI tract, phlebectasia, having large gastric folds, white appearing villi, GTT, and SBTT. We could not evaluate the effect of medication use in the entire dataset due to lack of accurate medication data in outpatients.

Table 2 Identification of potential risk factors for an incomplete exam by univariate analysis in all patients

Pre-procedure factors	*P* value	Post-procedure factors	*P* value
Location	0.0001	AVM	0.001
Occult GIB	0.042	Blood	0.016

Table 3 Effect of medication use and comorbidities on capsule endoscopy completion rate in hospitalized patients

Risk factors	*P* values
Diabetes	0.416
Neuropathy	0.382
Hypotension	0.947
Immobility	0.381
Medications in aggregate	0.271
Narcotics	0.311
Anticholinergics	0.815
Beta-blockers	0.711
Calcium channel blockers	0.931
Inotropes	0.197
Motility enhancers	0.337

Medications which affect GI system motility were tested both individually and also in aggregate in univariate analysis in hospitalized patients (Table 3). These medications included narcotics, anticholinergics, beta-blockers, calcium channel blockers, inotropic agents, and motility enhancers. None of the medications individually or in aggregate were predictive of "capsule passage" or

Table 4 Independent predictors of incomplete capsule endoscopy in multivariate analysis

Factors	Beta value	SE	Wald × 2	*P* value	Odds ratio	95% CI
Intercept	-3.369	0.349	93.344	0.000		
Location	1.457	0.415	12.328	0.000	4.294	1.904-9.686
GTT	0.012	0.003	18.177	0.000	1.012	1.006-1.017

GTT: Gastric transit time.

"incomplete capsule exam" ($P > 0.05$, Table 3). Other factors such as diabetes, neuropathy, hypotension, and immobility were not predictive of "capsule passage" or "incomplete capsule exam" either ($P > 0.05$, Table 3).

In the multivariate logistic regression model that utilized all patients, except those who did not have gastric transit times recorded, patient location (IP *vs* OP) and GTT were independent predictors of incomplete CE exams ($P < 0.001$ and $P = 0.008$, respectively). Further details of the model are given in Table 4.

DISCUSSION

Our study represents a first look at the CECR in IPs in the United States, and demonstrates that both GTT and SBTT are significantly prolonged in IP CE exams compared to OP exams. In a multivariate regression model, we show that patient location (IP *vs* OP) and GTT are independent predictors of incomplete CE, suggesting factors other than GTT must be contributing to the lower CECR in inpatients. Here we demonstrate that increased SBTT is another important contributor for low CECR in addition to GTT. We further show that the CECR is lowest in the ICU setting.

CECR in patients with OGB has been investigated previously. In these studies, CECR are variable and lower than what we note in our study. In a prospective European study of only mild to moderate obscure overt GI bleeders, incomplete IP CEs were 21.6%, but in 75% of the incomplete exams there was some localization of the bleed site[9]. However, this study excluded all severe bleeders and inpatients with other indications. In another study of 48 inpatient obscure overt GI bleeders from Europe, incomplete CE rates were 27%[10]. In a recent Canadian study of 535 patients, overt GI bleed was found to be a major risk factor for incomplete CE ($P = 0.002$, OR = 2.7) and the overall incomplete CE rate was 29.5%[11]. However, in this study, only 31 subjects were inpatients. Therefore, hospitalization status did not reach statistical significance despite a large trend ($P = 0.054$). In studies that analyzed CECR in patients with GIB, CECR in relation to patient location was not examined and direct comparisons to outpatients were not complete. Using subgroup analysis of our patients with GIB, we found a lower IP CECR compared to these prior studies (95% in OP *vs* 80% in IP). More interestingly, regardless of the GIB diagnosis, incomplete CE rate was also significantly lower in the OP setting compared to the IP setting ($P = 0.001$).

The relationship between CECR and hospitalization was addressed more directly in two other previous European studies. When all indications were taken into account, incomplete CE rate was higher in hospitalized patients, 34%-35%[7,8]. Our results in the United States confirm these findings in a larger dataset. GTT was elevated in the IP setting in both studies, similar to our findings. In the former studies, there were additional interventions to improve CE quality: per protocol, some patients received bowel preparation[8], while others received both bowel preparation and prokinetic agents[7]. Bowel preparation and the use of prokinetic agents are not routine in the United States. None of these prior studies specifically investigated the effect of IP location in CECR, and in one of these studies, patients underwent a 23 h hospitalization solely to perform the CE, which is not done in the United States. In addition lower IP CECR shown in these studies were attributed to decreased gastric motility; whereas we now show that the minimum SBTTs are also significantly prolonged in patients who had IP CE, suggesting that factors such as generalized dysmotility of gastrointestinal tract may be at play.

The overall CECR has been reported to be 81.1% and 83.5% in two recent meta-analyses[12,13]. The first meta-analysis compared CECR in patients who were prepped with purgatives *vs* clear liquid diet prior to the CE and showed that there was no significant difference in CECR, although the purgative use resulted in better small bowel visualization quality and increased diagnostic yield[13]. The second study reported an overall CECR of 83.5% in patients with OGIB, CD, and neoplastic lesions[12]. The overall CECR in our study at 86% reflects a slightly higher value than reported in these two meta-analyses. Nevertheless, even if we were to assume that the CECR in our OP group was as low as 81%-83% (similar to the two meta-analyses), this would still be markedly numerically higher than our observed CECR of 68% in the IPs, and should not alter our conclusions. Our CECR may perhaps be reflective of the careful case selection at a tertiary urban medical center, in order to avoid retention. Alternative explanations could include a larger number of OPs compared to IPs in our study. Notably, the percentage of OPs and IPs were not delineated in the meta-analyses. While the latter studies included in the meta-analyses all come from the English literature, they could be conducted in various countries, where CE may not be routinely done as an outpatient. Additionally even within the United States, the capture area of each medical center may be different and may require some subjects to be IPs especially if the patient catchment area is wide and mostly rural. Our findings of lower CECR rates in the ICU setting might suggest that the severity of the acute illness may also play important roles in CECR. However, possible confounding factors such as medication use and certain comorbidities such as diabetes, neuropathy, and hypotension were not predic-

tive of incomplete CE in hospitalized patients. This suggests that multiple factors may have a combined effect in the outcomes observed in hospitalized patients. While our hospitalized patients were older than our outpatients and while our ICU patients were older than our GMF patients, age was not an independent factor that explained CECR differences, which have previously been demonstrated[10,14].

Our study has several strengths including a larger IP sample size and a sub-group analysis on patient location and GIB. In our study, no confounding prokinetic agents or bowel preparations were used, and the hospitalization status was exclusively based on the severity of patients' clinical condition reflective of the current practice patterns in the United States. The major limitation of our study is its retrospective design; therefore, further prospective studies in inpatients are necessary to confirm our observations. Additionally, we took consecutive patients who had CE, and did not do a matched case-control design. This resulted in more subjects in our OP group compared to IP group - due to increasing use of CE in the OP setting. Therefore, it is possible that having less number of IPs may have resulted in potential unidentified confounders. As such, larger studies on IPs are needed to confirm our findings. Another potential limitation of our study is that, the readers of CE examinations were not blinded to the patient's clinical data. However, the readers were blinded to the hypotheses, making an outcome bias less likely to impact the study results. The lack of data regarding medication use, diabetes, and neuropathy in the outpatient group, lack of a generalized quality measure of the views obtained during CE exams, and the single center design are other limitations of our study.

Several interventions have been undertaken to improve CECR. The results of the studies which investigated the effect of bowel preparation on CECR were not consistent with each other[15-22], but improved image quality has been reported. Previous studies also investigated the role of endoscopic placement of capsule and/or real-time viewing and showed that these approaches can improve CECR[23-26]. Use of 12 h CEs could also be used to improve CECR[27]. Future studies are needed to examine the effects of such interventions to improve CECR among inpatients.

In conclusion, inpatients have a lower than usual CECR, which is more pronounced if admitted to the ICU. While gastric retention is a reason in some patients for the lower CECR, there seems to be generalized dysmotility in inpatients with incomplete CE exams. Other factors embodied in the IP setting such as sedentary status and acuity of the illness could be partially contributing. A large prospective study is needed to further delineate the most important factors that contribute to incomplete exams in the inpatient setting and determine the impact of incomplete CE on patient outcomes.

COMMENTS

Background

Capsule endoscopy (CE) is being used widely to evaluate small bowel pathologies. It has applications in Crohn's disease, celiac disease, Peutz-Jeghers syndrome, familial adenomatous polyposis, hereditary polyposis syndromes, and particularly in the investigation of obscure gastrointestinal bleeding. However, the hospital setting may not be ideal in obtaining optimal results with CE as hospitalized patients tend to be more sedentary and have prolonged gastric and small bowel transit times.

Research frontiers

Two previously published studies indirectly examined the effect of patient location on CE completion rates (CECR), but both studies had limitations. Earlier studies also investigated the effect of bowel preparation, endoscopic placement of capsule and/or real-time viewing, and the use of 12 h CEs on CECR.

Innovations and breakthroughs

This is the first study to investigate the effect of patient location on CECR in United States. The authors demonstrated that both gastric transit time (GTT) and small bowel transit time (SBTT) are significantly prolonged in in-patient (IP) CE exams compared to out-patient (OP) exams. The authors also showed that patient location (IP *vs* OP) and GTT are independent predictors of incomplete CE. The authors further show that the CECR is lowest in the intensive care unit setting. While gastric retention is a reason in some patients for the lower CECR, there seems to be generalized dysmotility in IPs with incomplete CE exams. Other factors such as sedentary status and acuity of the illness could be partially contributing to lower CECR in hospitalized patients.

Applications

In addition to patient location other factors such as severity of illness and sedentary status may contribute to incomplete exams in hospitalized patients. CECR can be improved by doing CE studies as outpatient, placing the capsule endoscopically, using real-time viewing or 12 h CEs, and limiting the use of medications which decrease gastrointestinal transit time.

Terminology

CE is a procedure in which a small camera (capsule) swallowed to investigate the small bowel pathologies; CECR shows the percentage of CE exams that are completed; GTT is the time capsule spends in the stomach during the study; SBTT is the time capsule spends in the small bowel during the study.

Peer review

In this study, the authors investigated the effect of IP and OP status on SBTT and CECR. This is an interesting and well written paper.

Abstract

AIM: To investigate genetic differences between Crohn's disease (CD) patients with a sustained remission *vs* relapsers after discontinuing infliximab while in corticosteroid-free remission.

METHODS: Forty-eight CD patients received infliximab and were in full corticosteroid-free clinical remission but then discontinued infliximab for reasons other than a loss of response, were identified by review of an electronic database and charts. Infliximab-associated remission was defined as corticosteroid-free plus normalization of clinical disease activity [CD activity index (CDAI) < 150] during follow-up visits based on physician global assessments. A CD relapse (loss of infliximab-induced remission) was clinically defined as a physician visit for symptoms of disease activity (CDAI > 220) and a therapeutic intervention with CD medication(s), or a hospitalization with complications related to active CD. Genetic analyses were performed on samples from 14 patients (n = 6 who had a sustained long term remission after stopping infliximab, n = 8 who rapidly relapsed after stopping infliximab). Nucleotide-binding oligomerization domain 2 (NOD2)/caspase activation recruitment domain 15 (CARD15) polymorphisms (R702W, G908R and L1007fs) and the inflammatory bowel disease 5 (IBD5) polymorphisms (IGR2060a1 and IGR3081a1) were analyzed in each group.

RESULTS: Five single nucleotide polymorphisms of IBD5 and NOD2/CARD15 genes were successfully analyzed for all 14 subjects. There was no significant increase in frequency of the NOD2/CARD15 polymorphisms (R702W, G908R and L1007fs) and the IBD5 polymorphisms (IGR2060a1 and IGR3081a1) in either group of patients; those whose disease relapsed rapidly or those who remained in sustained long term remission following the discontinuation of infliximab. Nearly a third of patients in full clinical remission who stopped infliximab for reasons other than loss of response remained in sustained clinical remission, while two-thirds relapsed rapidly. There was a marked difference in the duration of clinical remission following discontinuance of infliximab between the two groups. The patients who lost remission did so after 1.0 years ± 0.6 years, while those still in remission were at the time of this study, 8.1 years ± 2.6 years post-discontinuation of infliximab, P < 0.001. The 8 patients who had lost remission after discontinuing infliximab had a

mean number of 5 infusions (range 3-7), with a mean treatment time of 7.2 mo (range 1.5 mo-15 mo). The mean duration of time from the last infusion of infliximab to the time of loss of remission was 382 d (range 20 d-701 d). The 6 patients who remained in remission after discontinuing infliximab had a mean number of 6 infusions (range 3-12), with a mean treatment duration of 12 mo (range 3.6 mo-32 mo) (P = 0.45 relative to those who lost remission).

CONCLUSION: There are no IBD5 or NOD2/CARD15 mutations that predict which patients might have sustained remission and which will relapse rapidly after stopping infliximab.

INTRODUCTION

Crohn's disease (CD), a type of inflammatory bowel disease (IBD), is a complex chronic condition characterized by relapsing transmural inflammation throughout the gastrointestinal tract. The etiology of CD remains unclear and as with most complex-trait diseases, the development of IBD involves a combination of genetic and environmental risk factors. Epidemiological data and family studies do suggest a genetic basis for CD[1,2]. For instance, the single greatest risk factor for developing IBD is having an affected family member, as demonstrated by twin studies in which a monozygotic twin of a CD proband has approximately a 1 in 3 lifetime risk of developing IBD[3]. Genome-wide association studies have found approximately 100 genetic loci to be significantly associated with IBD[4].

In terms of CD itself, a potent proinflammatory cytokine, tumor necrosis factor alpha (TNF-α), is a well-known mediator of inflammation[5]. Clinical trials have shown anti-TNF-α agents such as infliximab to be highly efficacious in terms of induction and maintenance responses (ACCENT 1 and 2)[6,7]. However, anti-TNF-α agents are costly, and the long-term safety risks such as development of autoantibodies, drug-induced lupus, infection, and neoplasia can be concerning in the long term[5,8-10]. Furthermore, the appropriate duration of anti-TNF-α therapy for CD patients who are in remission is as yet undefined; specifically, the factors which affect the duration of sustained clinical benefit after discontinuation of infliximab remain poorly understood.

As part of a project to achieve such an understanding, a longitudinal cohort study at our institution of over 7 years duration, identified CD patients who were in full corticosteroid-free clinical remission and then discontinued infliximab for reasons unrelated to loss of response[11]. This study demonstrated that one third of these CD patients remained in a sustained clinical remission for up to 7 years after the infliximab was discontinued, and that concomitant drug therapy, number of infliximab doses, age, gender, and CD location were not predictive of this sustained clinical benefit. This finding lends support to the hypothesis that a patient-unique genotype of CD may play a role in determining the duration of long-term remission after the discontinuation of anti-TNF-α agent therapy.

Research on CD genotypes associated with anti-TNF-α therapy has generally studied infliximab responders and compared the results to infliximab non-responders. Caspase activation recruitment domain 15 (*CARD15*) was the first gene to be associated with CD[12,13]. The nucleotide-binding oligomerization domain 2 (*NOD2*)/*CARD15* product is an intracellular protein involved in recognizing bacterial lipopolysaccharides in the nuclear factor kappa B-TNF-α pathway[14]. This *NOD2*/*CARD15* gene is known to be associated with susceptibility to CD[12,15]. Previous studies have identified certain TNF-α polymorphisms as predictive of a lack of response to infliximab[16], while other studies focusing on *NOD2*/*CARD15* mutations (R702W, G908R, 1007fs)[17,18] have not confirmed a relationship between such mutations and the response to anti-TNF-α agents. Urcelay *et al*[19] studied 40 Spanish CD patients who received infliximab, 25 responders and 15 non-responders, and identified a homozygous mutant in the IBD5 region on chromosome 5q31 that was significantly associated with a lack of response to infliximab[19]. However, no studies have reported correlations of CD genotypes for patients who relapse rapidly versus patients who do not relapse after discontinuing anti-TNF-α therapy.

This study thus examined a cohort of CD patients who had discontinued infliximab for reasons other than non-response while in full corticosteroid-free remission, to determine if genotypic differences might contribute to the varying lengths of post-infliximab remission times observed.

MATERIALS AND METHODS

Selection of infliximab-treated patients in remission who then discontinued infliximab

This study was reviewed and approved by the ethics

board at the University of Alberta prior to study initiation and subjects were provided informed consent before study participation. Forty-eight Caucasian CD patients who received infliximab between July 2001 and July 2007, and who were in full corticosteroid-free clinical remission but then discontinued infliximab for reasons other than a loss of response, were identified by review of an electronic database and chart reviews. Reasons for infliximab discontinuance included physician choice, loss of insurance coverage, fear of side-effects, adverse events, and pregnancy. These patients were referred from the IBD practices of thirteen gastroenterologists associated with the University of Alberta. Long-term follow-up data for each patient was available through to July 6, 2011.

Patients with CD were eligible for study inclusion based on the following criteria: (1) clinical response to infliximab (5 mg/kg) induction dosing administered at weeks 0, 2 and 6; (2) advancement to scheduled maintenance infliximab therapy every 8 wk; (3) maintenance of a stable corticosteroid-free clinical benefit for at least 6 mo; (4) discontinuation of infliximab therapy for reasons other than loss of response; and (5) sufficient follow-up that allowed assessment of ongoing wellness and/or disease relapse. A subject was excluded from the study if he/she was under the age of 18 years. Eligible patients were contacted via telephone by a research associate with a request for participation in the current study.

Standardized infliximab administration

Each patient included in the study had received her or his infliximab in accordance with the Canadian Association of Gastroenterology's anti-TNF-α treatment guidelines for CD patients[20]. The "step-up" approach specified by these guidelines requires that both corticosteroids and immunosuppressive (azathioprine or methotrexate) treatments have failed the patient due to a lack of response or intolerance before infliximab therapy is begun.

Definition of infliximab-induced remission

Infliximab-associated induction and maintenance remission were defined as corticosteroid-free plus normalization of clinical disease activity [CD activity index (CDAI) < 150] during follow-up based on physician global assessments at each successive visit. The dates of each initial and final infliximab infusion were determined using an infliximab infusion database.

Definition of loss of remission after discontinuing infliximab

A CD relapse, and thus loss of infliximab-induced remission (CDAI > 220), for those patients who had discontinued infliximab was defined as a physician or hospital visit for documented symptoms of disease activity and a therapeutic intervention with CD medication(s), or a hospitalization with complications related to active CD. The date of a CD relapse after discontinuation of infliximab therapy was identified through review of patient medical records. Mucosal healing, laboratory investigations such as CRP and radiological evaluation were analyzed for each patient but not reported in this paper.

Genotyping

Informed consent for participation in the study and genotyping was obtained from those participants who met the inclusion criteria and who were willing to join the study. Urban patients attended an appointment at the University of Alberta outpatient gastroenterology clinic, where an 8 mL blood sample was obtained via arm venipuncture. For patients residing in rural areas, the blood sample was obtained by the patient's local laboratory and was couriered to the University of Alberta hospital for genetic processing.

The laboratory scientists who analyzed the disease loci from these samples were blinded to the study groups as they performed the following steps. Genomic DNA was purified from peripheral blood leukocytes. All sam-ples were amplified from an individual FTA card. Five single nucleotide polymorphisms (SNPs) (R702W, G908R, L1007fs, IGR2060a1, IGR3081a1) were detected. R702W and G908R were analyzed using the SNaPshot method (Single base pair extension). L1007fs, IGR2060a1, and IGR3081a1 were analyzed using the Sanger sequencing method. All samples were run on a capillary instrument. Previously sequenced samples were used as controls. The polymerase chain reaction primers are listed in Table 1.

Statistical analysis

Statistical analysis was performed using SPSS 16.0 software (Statistical Package for the Social Sciences Inc., Chicago, IL). Association between genotype mutation and CD remission status was estimated using the odds ratio with a 95% CI. Fisher's exact test was utilized to calculate *P* values. A *P* value of 0.05 was considered to indicate statistical significance.

RESULTS

Patient recruitment

A total of 48 CD patients whose disease was in an infliximab-induced corticosteroid-free clinical remission, and who had then discontinued infliximab for reasons other than non-response (see Methods above) were identified from an electronic database and chart reviews. Six patients were excluded from the study for the following reasons: 2 patients were excluded due to non-Caucasian ancestry and its possible confounding effects on genetics and 4 patients were not interested in participating. Of the 42 patients who met the inclusion criteria, 3 had changed their telephone number and were unable to be contacted, 5 had moved out of province, 10 rural patients agreed to participate but did not have blood samples drawn, 3 patients missed venipuncture appointments, and 7 could not be reached by telephone despite two messages being left. The remaining fourteen CD patients were stratified into a group of those still in full clinical remission (n = 6) and a group of those who had

Table 2 Characteristics for Crohn's disease patients still in remission and those who lost remission after discontinuing infliximab

Characteristic	Remaining in remission following discontinuing infliximab (n = 6)	Lost remission following discontinuing infliximab (n = 8)
Male:female (n)	4:2	4:4
Age of Crohn's disease onset (yr), mean (range)	30 (14-47)	26 (15-38)
Current age (yr), mean (range)	53 (41-60)	41 (25-57)
Duration of disease prior to first infliximab infusion (yr), mean ± SD	15 ± 8.0	10.1 ± 11.3
Age at first infliximab infusion (yr), mean ± SD	45 ± 7.6	36 ± 11.1
Number of infusions, mean ± SD	5.7 ± 3.5	4.7 ± 1.7
Duration of infliximab treatment (mo), mean (range)	12 (3.6-36.2)	7.2 (1.5-15)
Duration of remission after infliximab stopped (yr), mean ± SD	8.1 ± 2.6[1]	1.0 ± 0.6[2]
Disease distribution, n (%)		
Ileum	2 (33)	2 (25)
Ileo-colonic	3 (50)	4 (50)
Colon	1 (17)	2 (25)
Current medications in patients who lost remission, n		
Adalimumab		4
Infliximab		2
Azathioprine alone		1
No Biological or immunosuppressive therapy[3]		1

[1]All patients still remain in remission at the time of this study; [2]Follow-up time from last dose of infliximab to either date of flare or last day of study (July 6, 2011), $P < 0.001$; [3]This patient developed both basal cell and renal cell carcinoma.

lost remission (n = 8).

Characteristics of patients still in remission and those who lost remission after discontinuing infliximab

There were no statistical significant differences in terms of the mean age, gender, disease duration, disease location, duration of disease prior to first infliximab infusion, age at first infliximab infusion, mean number of infliximab infusions, or mean duration of infliximab treatment between the CD patients who were still in remission after discontinuing infliximab (n = 6) and those who had lost remission after discontinuing their infliximab (n = 8) (Table 2).

The 8 patients who had lost remission after discontinuing infliximab had a mean number of 5 infusions (range 3-7), with a mean treatment time of 7.2 mo (range 1.5-15 mo). The mean duration of time from the last infusion of infliximab to the time of loss of remission was 382 d (range 20-701 d). The 6 patients who remained in remission after discontinuing infliximab had a mean number of 6 infusions (range 3-12), with a mean treatment duration of 12 mo (range 3.6-32 mo) (P = 0.45 relative to those who lost remission). Of the 8 patients who lost remission, 4 patients are currently on adalimumab, 2 patients are again on infliximab, 1 patient remains on azathioprine alone, and 1 patient is currently on no biological or immunomodulating agents due to a malignancy.

In contrast, there was a marked difference in the duration of clinical remission following discontinuance of infliximab between the two groups. The patients who lost remission did so after just 1.0 years ± 0.6 years, whereas those who were still in remission were at the time of this study, 8.1 years ± 2.6 years post-discontinuation of infliximab, $P < 0.001$ (Table 2). This marked difference confirms a group of patients that remained in remission for an extended interval of time after infliximab was discontinued while another group rapidly relapsed. We proceeded to genetically type these two groups.

Patient genotypes

Five SNPs of IBD5 and NOD2/CARD15 genes were successfully analyzed for all 14 subjects. There were no significant differences in SNPs between the group of patients who remained in remission for an extended interval of time after infliximab was discontinued, and the group of those who relapsed rapidly after infliximab was discontinued (Table 3).

DISCUSSION

Anti-TNF-α agents are well known to be effective for both induction and maintenance of remission in CD. However, no phenotypic features, environmental fac-

tors, or clinical markers have been definitively shown to predict the duration of sustained clinical benefit after discontinuation of infliximab.

The lack of response to infliximab in patients with CD appears to be a stable occurrence over time, thus suggesting that infliximab response/non-response is related to a genetic predisposition[5]. Though over 100 genetic loci have been associated with IBD thus far, only two genes, *IBD5* and *CARD15*, have reliably been linked to CD susceptibility, and few genes have been proven to influence response to infliximab[12,19,21]. Although less than 20 percent of patients are homozygous for *CARD15* and the relative risk of developing CD for these individuals ranges from 10 to 40 percent, genetic markers remain important to understanding the complex pathogenesis of this disorder[22]. In comparison to biochemical markers such as C-reactive protein, genetic elements theoretically offer ideal markers for predicting disease outcomes, as genes are not affected by disease activity and are stable over time. As we more fully understand genetic variants and the roles they play in the development of CD, it is very plausible that certain genetic polymorphisms may be predictors of response to or relapse from anti-TNF-α agents such as infliximab.

Utilizing a well-defined cohort of patients with CD who were in an infliximab-induced corticosteroid-free clinical remission and then discontinued infliximab for reasons other than non-response[11], we studied two genetic variants of the IBD5 locus on chromosome 5q31 (IGR 2060a1 and IGR3081a1) along with three *NOD2/CARD15* polymorphisms (Arg702Trp, Gly908Arg, Leu1007fs insC), in those patients who had relapsed rapidly and compared them to those patients who remained in a long-term sustained remission.

Our study results show no significant increase in frequency of the *NOD2/CARD15* and IBD5 polymorphisms, for either the CD patients whose disease relapsed rapidly or for the CD patients who remained in a long-term sustained remission following the discontinuation of infliximab.

Urcelay *et al*[19] reported that the homozygous mutants in the 5q31 locus were related to a significant lack of response to infliximab and the frequency of these mutants was significantly higher in the non-responder group. Our study did not identify such findings, likely due to the fact that we were examining those infliximab-treated patients who had initially all responded to infliximab but after discontinuing infliximab fell into two groups: those that had a long-term sustained remission and those that rapidly relapsed.

Other studies have also shown no association between *NOD2/CARD15* genotype and response to infliximab[17,18]. In a large study of two CD patient cohorts with 534 participants (ACCENTI), Mascheretti *et al*[18] found no association between SNPs 8, 12 and 13 of the *CARD15* gene and infliximab response. SNP 8 includes the variant R702W and SNP12 includes G908R, which were also analyzed in our study. Genes encoding for TNF-α and TNF-α receptors have also been an area of some study, given the primary role of TNF-α in the inflammation of CD. A large cohort study by Louis *et al*[23] in 2002 did not show a CD response to infliximab amongst patients with the -308 polymorphism, a TNF-α promoter region mutation thought to influence TNF-α transcription. In another study focusing on the receptors TNFR1 and TNFR2, where TNF-α binds and exerts its effects, no clear effect of the polymorphisms on infliximab response was observed[24]. Again, the results from these previous investigations may not be comparable to those of the current study, in that we examined those infliximab-treated patients who initially responded to infliximab but who after discontinuing infliximab, fell into two groups: those that had a long-sustained response and those whose disease rapidly relapsed.

Of our 8 patients who experienced a flare of their disease after the discontinuation of infliximab, 4 are on adalimumab, 2 are on infliximab, 1 is only on azathioprine, and the remaining patient is on no therapy due

to active malignancy. Interestingly, of the 48 initially identified CD patients in the longitudinal cohort who were in an infliximab-induced clinical remission and then discontinued infliximab, approximately 16 patients (34%) remained in clinical remission a median of 477 d (95% CI; range of 290 to 1339 d; data from Waugh *et al*[11] as of July 2009. However, as time progressed, of these 16 patients who had remained in remission, 6 additional patients have now flared and are on alternative therapy as of July 2011 and only 10/48 (21%) remained in remission. This implies that even those patients who are in a long term sustained remission after discontinuing infliximab may ultimately relapse.

As we have seen with infliximab primary response, no genetic markers have been predictive of CD response to adalimumab. In a recent study assessing such a response to adalimumab, the same three NOD2 polymorphisms (Arg702Trp, Gly908Arg, Leu1007fs insC), in addition to TLR4 and CD14 mutations, were analyzed for 24 Spanish CD patients who had lost response to, or were unable to tolerate infliximab[25]. No association with any of these polymorphisms for the adalimumab response was noted.

There is a complex and not yet well-understood relationship between gene expression and disease behavior; indeed many genes remain to be identified in the case of CD. Of the genes identified so far, no variants have adequate sensitivity and specificity to be used in clinical decision making with biologic agent response[26]. Perhaps attention should be turned to pharmacogenetic studies, as despite being given optimal doses and duration of medications, 20 to 30 percent of IBD patients find their disease refractory to any given medication[26]. Currently, the only genetic test available in guiding clinical treatment decisions is that used for assessing risk of hematopoeitic toxicity from metabolism of thiopurine analogues by the enzyme thiopurine methyl transferase, which is under genetic control[27]. Polymorphisms of proteins targeted by drugs or enzymes involved in drug metabolism may be potential areas of useful study. However, limitations related to heterogeneity in IBD, such as disease severity, behaviour, and environmental factors affecting drug response, also make this a challenging area.

In the case of other autoimmune conditions such as rheumatoid arthritis, advancements have been made in predicting response to infliximab, specifically using whole-genome gene expression analysis with microarrays[27]. Julià *et al*[28] have presented an 8-gene model obtained from whole blood RNA samples with an 85.7% prediction accuracy of treatment response. However, like CD, no studies in rheumatoid arthritis have examined the genotypes responsible for relapse or remission after anti-TNF-α therapy has been stopped.

In conclusion, this study found that, in a cohort of infliximab-treated CD patients who had a sustained corticosteroid-free clinical remission and then discontinued infliximab, there are two groups; those who relapsed early usually within a year, and those who have a sustained clinical remission of up to a decade. Furthermore, this study was the first to attempt to identify genetic polymorphisms in these two subgroups, though the findings suggest no specific correlations for the polymorphisms tested.

COMMENTS

Background

The etiology of Crohn's disease (CD) remains unclear and as with most complex-trait diseases, it involves a combination of genetic and environmental risk factors. Although over 100 genetic loci have been associated with inflammatory bowel disease (IBD) thus far, only two genes, *IBD5* and caspase activation recruitment domain 15 (*CARD15*), have reliably been linked to CD susceptibility. In terms of CD itself, a potent proinflammatory cytokine, tumor necrosis factor alpha (TNF-α), is a well-known mediator of inflammation. Furthermore, the appropriate duration of anti-TNF-α therapy for CD patients who are in remission is as yet undefined; specifically, the factors which affect the duration of sustained clinical benefit after discontinuation of infliximab remain poorly understood. This lends support to the possibility that a patient-unique genotype of CD may play a role in determining the duration of long-term remission after the discontinuation of anti-TNF-α agent therapy. Previous studies have analyzed genetic differences in infliximab responders and compared the results to infliximab non-responders, but the patient population does not include patients who have all initially responded to infliximab such as in this study.

Research frontiers

In the area of identifying genetic factors responsible for infliximab responses, the research hotspot has mainly focused on nucleotide-binding oligomerization domain 2 (*NOD2*)/*CARD15* genotypes and few studies have analyzed TNF-α receptor and promoter region polymorphisms. No genetic markers have been definitively predictive of CD response to infliximab.

Innovations and breakthroughs

A breakthrough in the area has been that over 100 genetic loci have been associated with IBD and thus far, two genes, *IBD5* and *CARD15*, have reliably been linked to CD susceptibility. However, few genes have been proven to influence response to infliximab. Utilizing a well-defined unique CD patient population who were in an infliximab-induced corticosteroid-free clinical remission and then discontinued infliximab for reasons other than non-response, the authors studied two genetic variants of the IBD5 locus on chromosome 5q31 (IGR 2060a1 and IGR3081a1) along with three *NOD2*/*CARD15* polymorphisms (Arg702Trp, Gly908Arg, Leu1007fs insC), in those patients who had relapsed rapidly and compared them to those patients who remained in a long-term sustained remission. These patients experienced either a sustained remission up to a decade or have relapsed rapidly often within a year. The study results show no significant increase in frequency of the *NOD2*/*CARD15* and *IBD5* polymorphisms for either group of CD patients. This study was the first to attempt to identify genetic differences in these two unique subgroups.

Applications

There is a complex and not yet well-understood relationship between gene expression and disease behavior. Anti-TNF-α agents such as infliximab are costly, and the long-term safety risks can be concerning in the long term. Furthermore, the appropriate duration of anti-TNF-α therapy for CD patients who are in remission is as yet undefined; specifically, no genes have been definitively identified to predict which CD patients who discontinued their infliximab while in full corticosteroid-free clinical remission might either have a sustained remission or will relapse rapidly after stopping infliximab.

Terminology

CARD15 was the first gene to be associated with CD; The *NOD2*/*CARD15* product is an intracellular protein involved in recognizing bacterial lipopolysaccharides in the nuclear factor kappa B-TNF-α pathway. This *NOD2*/*CARD15* gene is known to be associated with susceptibility to CD. IBD5 is a 250 kb haplotype in the 5q31 gene cluster associated with increased risk of CD.

Peer review

This is an interesting study comparing genetic differences between Crohn's disease patients who after discontinuing their infliximab while in full corticosteroid-free clinical remission, experienced a sustained remission versus those patients whose disease relapsed rapidly.

Abstract

AIM: To assess clinical and endoscopic response to propionyl-L-carnitine hydrochloride (PLC) in colonic inflammatory bowel disease.

METHODS: Patients suffering from mild to moderate ulcerative colitis (UC) or Crohn's disease (CD) colitis, with disease activity index (DAI) between 3 and 10 and under stable therapy with oral aminosalicylates, mercaptopurine or azathioprine, for at least 8 wk prior to baseline assessments, were considered suitable for enrollment. Fourteen patients were enrolled to assume PLC 2 g/d (two active tablets twice daily) orally. Clinical-endoscopic and histological activity were assessed by DAI and histological index (HI), respectively, following a colonoscopy performed immediately before and after 4 wk treatment. Clinical response was defined as a lowering of at least 3 points in DAI and clinical remission as a DAI score $\leqslant$ 2. Histological response was defined as an improvement of HI of at least 1 point. We used median values for the analysis. Differences pre- and post-treatment were analyzed by Wilcoxon signed rank test.

RESULTS: All patients enrolled completed the study. One patient, despite medical advice, took deflazacort 5 d before follow-up colonoscopy examination. No side effects were reported by patients during the trial. After treatment, 71% (SE 12%) of patients achieved clinical response, while 64% (SE 13%) obtained remission. Separating UC from CD patients, we observed a clinical response in 60% (SE 16%) and 100%, respectively. Furthermore 60% (SE 16%) of UC patients and 75% (SE 25%) of CD patients were in clinical remission after therapy. The median DAI was 7 [interquartile range (IQR): 4-8] before treatment and decreased to 2 (IQR: 1-3) ($P < 0.01$) after treatment. Only patients with UC showed a significant reduction of DAI, from a median 6.5 (IQR: 4-9) before treatment to 2 (IQR: 1-3) after treatment ($P < 0.01$). Conversely, in CD patients, although displaying a clear reduction of DAI from 7 (IQR: 5.5-7.5) before therapy to 1.5 (IQR: 0.5-2.5) after therapy, differences observed were not significant ($P = 0.06$). Seventy-nine percent (SE 11%) of patients showed improvement of HI of at least 1 point, while only one CD and two UC patients showed HI stability; none showed HI worsening. Median HI

decreased from 1 (IQR: 1-2), to 0.5 (IQR: 0-1) at the endoscopic control in the whole population ($P < 0.01$), while it changed from 1 (IQR: 1-2) to 0.5 (IQR: 0-1) in UC patients ($P < 0.01$) and from 1.5 (IQR: 1-2) to 0.5 (IQR: 0-1) in CD patients (P = not significant). The two sample tests of proportions showed no significant differences in clinical and histological response or in clinical remission between UC and CD patients. No side effects were reported during treatment or at 4 wk follow-up visit.

CONCLUSION: PLC improves endoscopic and histological activity of mild to moderate UC. Further studies are required to evaluate PLC efficacy in colonic CD patients.

Propionyl-L-carnitine hydrochloride for treatment of mild to moderate colonic inflammatory bowel diseases. *World J Gastroenterol* 2012; 18(36): 5065-5071 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i36/5065.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i36.5065

INTRODUCTION

Inflammatory bowel diseases (IBDs) are idiopathic, immune-mediated and multifactorial diseases, including Crohn's disease (CD) and ulcerative colitis (UC)[1]. IBD pathogenesis has not been definitely clarified and UC and CD are considered complex diseases of unknown etiology, in which genetic and environmental factors force an abnormal intestinal mucosa immune reaction towards food and bacterial antigens[2-4]. Regardless of the main and unknown cause, several mechanisms sustain chronic inflammation and the vicious circle in IBD. Among those factors, energy deficiency[5-7] and peroxidative damage[8,9] of colonocytes play a pivotal role in IBD pathogenesis.

Propionyl-L-carnitine hydrochloride (PLC) is the (*R*)-3-(1oxo-propoxy)-4-(N,N,N-trimethyl amonium chloride) butanoic acid. It is a natural derivative of L-carnitine, produced in the body by the carnitine-acetyltransferase-mediated reaction between propionyl-CoA and L-carnitine. Physiologically, L-carnitine has an important role in energy regulation, taking part in fatty acid β-oxidation and glucose metabolism, and it has been used as a therapeutic option in conditions characterized by decreased ATP levels, such as heart failure and ischemia[10]. Moreover, PLC acts as an antioxidant molecule, reducing the lipid peroxidation in coronary endothelial cells[11-15]. Furthermore, PLC is a carrier of propionate moiety, which enters the Kreb's cycle, once transformed in succinate, contributing to energetic sources of the cell[16]. Finally, PLC has been used for the therapy of cutaneous trophic ulcers[17].

Based on these results, a similar effect of PLC in colonic IBD has been supposed; a condition characterized by peroxidative damage, energy impairment, ulcers and abnormal epithelial function of colonocytes. Beyond intriguing pathogenic considerations, the effect of PLC on IBD and in particular on UC patients, has been recently addressed by a positive phase II trial[18] on mild to moderate UC patients.

Carnitine transport deficiency could also play a role in CD pathogenesis, as suggested by genetic studies, showing mutations in genes coding for carnitine transporters, *OCTN1* (*SLC22A4*) and *OCTN2* (*SLC22A5*), in CD patients[19]. Furthermore, in a murine model with loss-of-function mutation in the *OCTN2* gene, the defect in carnitine transporter function in intestinal epithelial cells leads to atrophy of the small intestine and colon, and subsequent onset of inflammation[20].

Based on these considerations, in this proof-of-concept pilot study, we investigated the efficacy of PLC not only in UC, but also in colonic CD patients.

MATERIALS AND METHODS

This was a prospective, single center, open label, proof-of-concept pilot study on 14 patients, to investigate the efficacy of PLC (ST 261) colon release tablets at the dosage of 2 g/d in patients affected by mild to moderate colonic IBD, with stable oral treatment.

The protocol was approved by the Ethics Committee of "A. Gemelli" Hospital, Rome, Italy. The trial was conducted according to the Helsinki Declaration and the Good Clinical Practice Guidelines adopted by the European Medicines Agency in 1996. Every patient signed a written informed consent.

Study endpoints

Primary endpoint of the study was to evaluate the percentage of patients displaying clinical/endoscopic response following 4 wk of stable therapy, defined as a lowering of the disease activity index (DAI score, Table 1) of at least 3 points upon the baseline. Percentage of patients reaching clinical remission, defined by a DAI score $\leqslant 2$ with no individual subscore > 1, was also evaluated. As secondary endpoint, histological response to the treatment was assessed, defined as an improvement of the histological index (HI) of at least 1 point at the end of the study compared to baseline.

Inclusion and exclusion criteria

Patients suitable for the enrollment met all the following

Table 1 Disease activity index evaluation according to Mayo score

	Stool frequency	Mucosal appearance	Rectal bleeding	Physician's overall assessment of disease severity
0	Normal number of stools for the patient	Normal	None	Normal
1	1-2 stools/d more than normal	Mild friability	Streaks of blood	Mild
2	3-4 stools/d more than normal	Moderate friability	Obvious blood	Moderate
3	5 or more stools/d more than normal	Exudation, spontaneous bleeding	Mostly blood	Severe

Score subtotal on the left column.

inclusion criteria: age between 16 and 80 years; if female, not pregnant or nursing; for women of childbearing potential, willingness to avoid a pregnancy during the treatment period and for at least 1 mo from the last dose of drug; availability of pancolonoscopy and histology both confirming the diagnosis of active inflammatory bowel disease; DAI between 3 and 10 (mild to moderate disease); under stable therapy with oral aminosalicylates (mesalazine, balsalazide, olsalazine or sulfasalazine for ⩾ 8 wk prior to baseline assessments), mercaptopurine or azathioprine for ⩾ 8 wk prior to baseline assessments.

The exclusion criteria were: first diagnosis of IBD; known CD of the small intestine or of other sites rather than the colon; current or previous (in the past 30 d before the screening) use of systemic corticosteroids; use of antibiotics in the past 7 d before the screening; use of NSAIDs in the past 7 d preceding screening; positive stool culture (when performed, according to investigator's judgment, to assess possible parasitological infection); significantly impaired liver, renal, pulmonary or cardiovascular function; history of total colon resection; active or chronic infection.

Study design

During a screening phase of 2 wk, each patient was clinically evaluated and underwent colonoscopy with biopsy sampling for histology, to assess HI and DAI score. Clinical/endoscopic evaluation was performed using DAI, a validated index[18] for UC patients, whose criteria are reported on Table 1. In this trial, we also used DAI to assess Crohn's colitis. In agreement with its use in other clinical trials, a DAI score of 3-10 was considered evidence of a mild (3-6) to moderate (7-10) disease[18].

After the enrollment, patients were administered with two PLC colon release 500 mg tablets twice daily (1 h before breakfast and 1 h before dinner) for a total daily dose of 2 g, for 4 wk. After 4 wk of treatment, at a control visit, each patient underwent colonoscopy with biopsy sampling for histology and clinical evaluation with assessment of HI and DAI score. After 4 wk since the last visit, a follow-up visit was performed to assess safety of the treatment.

To assess safety and tolerability, vital signs, physical examinations, electrocardiograms and laboratory tests were registered at each visit (at the enrollment and after 4 and 8 wk).

Histological score

All histological scores were calculated by a single expert pathologist, following histological criteria described in Mikhailova *et al*[18] and modified from Truelove *et al*[21]. Briefly, inflammation was classified as grade 0: if indistinguishable from normal intestinal mucosa or, where structural features of UC were present, there were no polymorphs in the crypt epithelium; grade 1: if there was an increased number of leukocytes in the lamina propria and initial infiltration of crypt epithelium, but no abscesses or epithelial erosions were present; grade 2: if crypt abscesses (mandatory) and erosive foci, but no ulcerative lesions, were detected; and grade 3: if ulcerative lesions were clearly evident. The same score was also used to classify colonic CD. Lowering of HI by at least 1 point was considered as histological response.

Statistical analysis

Statistical analysis was performed by using IC STATA Release 12.0 for MAC. Data were reported as absolute numbers, percentage, median and interquartile ranges (IQRs), as specified. Mann-Whitney test was used to compare UC and CD patients. Differences were analyzed by Wilcoxon signed rank test, while the proportion of binary variables (clinical or histological response/clinical remission) between UC and CD patients was evaluated by a two-sample test of proportions. $P < 0.05$ was considered statistically significant. We used median values for the analysis, because of the small number of patients enrolled, and we preferred nonparametric tests.

RESULTS

Fourteen patients were enrolled. The mean age, female/male ratio and demographics are indicated in Table 2. With regard to therapy, six patients were treated with mesalamine 2.4 g/d; three with azathioprine at 2 mg/kg; and one with 7.5 mg/d deflazacort, starting 5 d before follow-up colonoscopy, despite medical advice to the contrary; the remaining four patients did not receive any treatment. CD patients were overall younger than UC patients and they were all male, but they were comparable to UC patients in term of DAI and HI at the time of enrollment. However, no significant differences were detected between UC and CD patients in term of demographic data.

Efficacy of PLC on clinical/endoscopic disease activity

After treatment, 71% (SE 12%) and 64% (SE 13%) of patients achieved a clinical response, or obtained remission, respectively. Separating UC patients from CD patients, we observed a clinical response after therapy

Table 2 Features of patients enrolled into the study

Patients features	All	UC	CD
No. of patients	14	10	4
Sex (F/M)	5/9	5/5	0/4
Age (yr), mean ± SD	49.4 ± 17.7	54.9 ± 17.5	34.7 ± 7.6
Disease duration at enrollment (yr), mean ± SD	4.8 ± 3.1	4.9 ± 3.1	4.5 ± 3.7
Diagnosis			
Pancolitis	8	-	-

No other therapy	4	3	1

AZA: Azathioprine; F: Female; M: Male; UC: Ulcerative colitis; CD: Crohn's disease; DAI: Disease activity index; HI: Histological index.

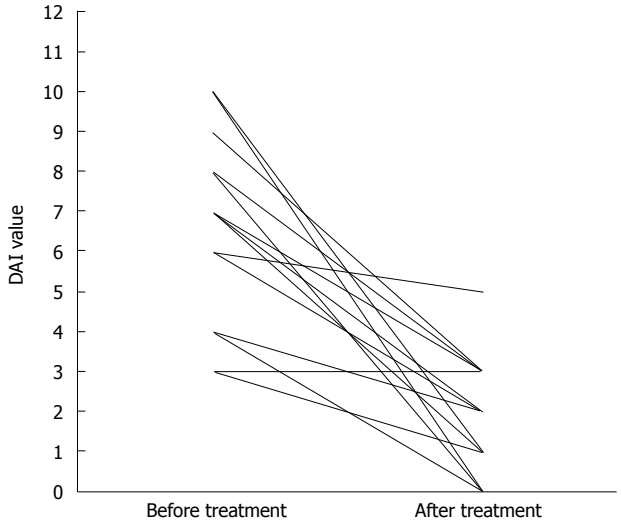

Figure 1 Disease activity index before and after treatment in all patients. In the left part of the graph, there are disease activity index (DAI) values for every patient affected by ulcerative colitis or Crohn's disease at enrollment. In the right part of the graph, there are DAI values for every patient after treatment.

in 60% (SE 16%) of UC patients and in 100% of CD patients; furthermore 60% (SE 16%) of UC patients and 75% (SE 25%) of CD patients were in clinical remission after therapy. The median DAI was 7 (IQR: 4-8) before treatment and decreased to 2 (IQR: 1-3) ($P < 0.01$) after treatment (Table 2 for mean values and Figure 1 for details). Stratifying by disease, only patients with UC showed a significant reduction of DAI, from a median

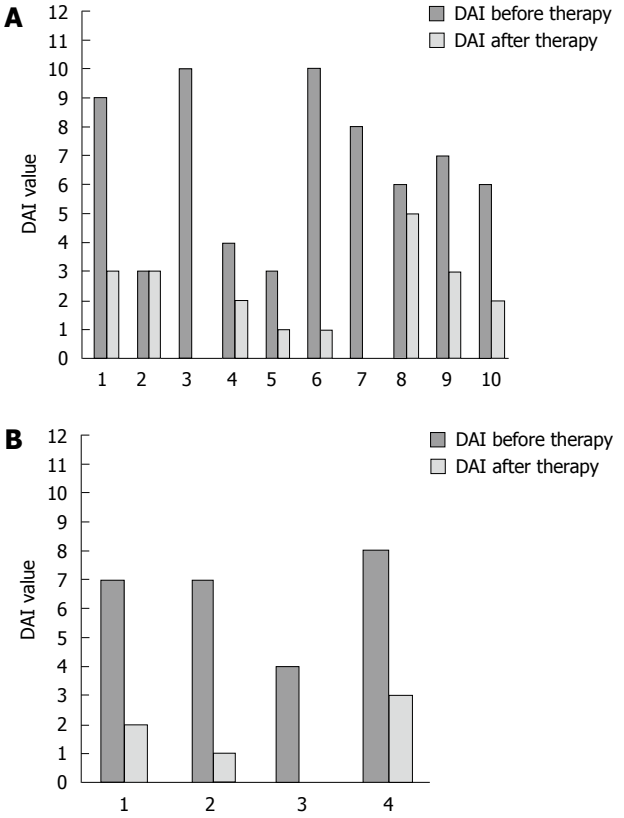

Figure 2 Disease activity index in patients affected by ulcerative colitis and Crohn's disease. A: The dark grey columns show disease activity index (DAI) values before treatment, while the light grey columns show DAI values after treatment in patients with ulcerative colitis; B: The dark grey columns show DAI values before treatment, while the light grey columns show DAI values after treatment in patients with Crohn's disease.

value of 6.5 (IQR: 4-9) before treatment to a median value of 2 (IQR: 1-3) ($P < 0.01$) after treatment (Figure 2A). Conversely, in CD patients, although displaying a clear reduction of DAI from 7 (IQR: 5.57-5) before therapy to 1.5 (IQR: 0.5-2.5) after therapy, differences observed were not significant ($P = 0.06$) (Figure 2B).

Efficacy of PLC on ameliorating HI

Overall, 79% (SE 11%) of patients showed an improvement in HI of at least 1 point, while only one CD and two UC patients showed HI stability; none showed HI worsening (Figure 3). Median HI decreased from 1 (IQR: 1-2), to 0.5 (IQR: 0-1) at the endoscopic control in the whole population ($P < 0.01$), while it changed from 1 (IQR: 1-2) to 0.5 (IQR: 0-1) in UC patients ($P < 0.01$) (Figure 4A) and from 1.5 (IQR: 1-2) to 0.5 (IQR: 0-1) in CD patients (P = not significant) (Figure 4B). The two-sample tests of proportions showed no significant differences in clinical/histological responses or clinical remissions between UC and CD patients.

Safety

No side effects were reported during treatment or at 4 wk follow-up visit.

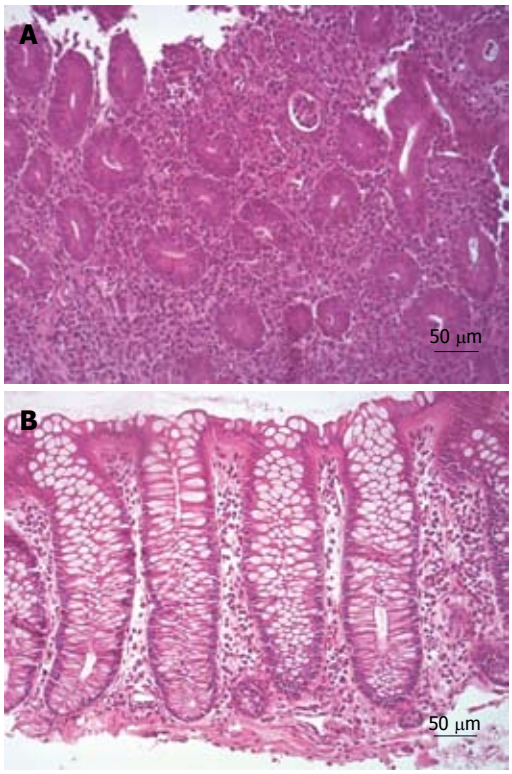

Figure 3 Histological samples before and after therapy. A: Biopsy specimen showing crypt abscess and perycriptitis (histological grade 2); B: Biopsy specimen morphologically indistinguishable from normal intestinal mucosa (histological grade 0).

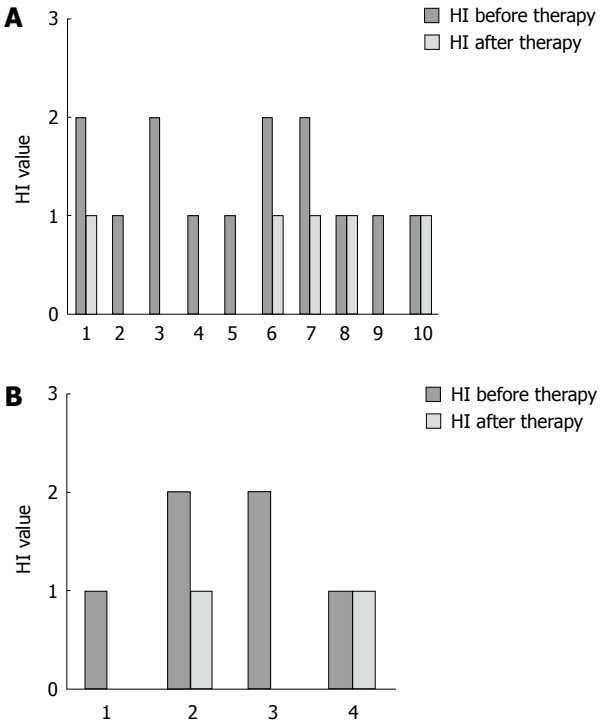

Figure 4 Histological index in patients affected by ulcerative colitis and Crohn's disease. A: The dark grey columns show histological index (HI) values before treatment, while the light grey columns show HI values after treatment in patients with ulcerative colitis; B: The dark grey columns show HI values before treatment, while the light grey columns show HI values after treatment in patients with Crohn's disease.

DISCUSSION

We enrolled 14 patients who were under stable oral therapy, without a complete control of symptoms and with evidence of endoscopic/histological disease. Therapeutic options sustained by strong clinical data for these patients are nowadays particularly limited.

Each patient underwent colonoscopy with biopsy sampling for histology and clinical evaluation with calculation of DAI score before starting treatment and repeated the same evaluation after 4 wk of therapy with PLC (ST 261) colon release tablets at a dose of 2 g/d. Following active treatment, the majority of them displayed a clear clinical improvement (70% of patients achieved clinical response) and 79% of patients presented with histological improvement. Our study confirmed the good clinical efficacy of PLC, in contrast to other studies using only SCFA or butyrate enemas in patients with more severe forms of UC[22-25]. Our results confirmed preclinical data showing the efficacy of PLC in reducing the damaged colon area in acute and chronic models of murine colitis. In humans, PLC given intrarectally shows good results in improving clinical and histological activity in patients suffering from UC[26]. Oral formulation of PLC is more agreeable for patients, and probably improves patient compliance with therapy.

Our single center study confirms the results from a multicentre phase Ⅱ, double-blind, parallel-group trial by Mikhailova *et al*[18] in patients suffering from UC. That trial showed a clinical/endoscopic response rate of 75% in patients exposed to PLC 1 g/d and a response rate of 69% in patients exposed to PLC 2 g/d, with remission rates of 55%, 49% and 35% respectively for PLC 1 g, 2 g and placebo groups. Histological responses rates were 40%, 33% and 35%, respectively. Histological assessment, however, was not significantly different among the groups. We showed a similar clinical/endoscopic remission rate and, moreover, a higher histological response rate after therapy. Furthermore, we also investigated the efficacy of PLC in CD patients, who showed a significant clinical/endoscopic response.

Nevertheless, our study had several limitations. This was an open label study, without a placebo group. Furthermore, one patient, considered in the final analysis, took 7.5 mg/d deflazacort for 5 d, despite medical advice, just before the follow-up endoscopy evaluation. This particular patient had UC, but was still considered for the final analysis because we did not consider this duration and dose of deflazacort to affect clinical and histological outcome significantly, for the purpose of our study. Furthermore, our patients, as happens frequently in clinical practice, were receiving concomitant therapy with mesalamine and/or azathioprine. The limited number of patients did not permit a stratification based on use of concomitant medication. However, we can exclude that the clinical response and remission in these patients were dependent on other therapy, which

remained unchanged for at least 2 mo before enrollment and throughout the study. Patients enrolled in this study were a mixed population of UC and colonic CD patients. One can argue that these different diseases would lead to nonhomogenous results among subgroups and potentially different responses, but the number of patients enrolled was too small to allow subgroup analysis. Therefore, with our data, we cannot make conclusions about different responses to treatment in UC and colonic CD.

However, based on the supposed mechanisms of action of this drug, we expected a response in both UC and CD. In fact colonocytes from UC and colonic CD patients, showing defect in carnitine functions, would probably both benefit from PLC therapy.

Compared with the study of Sandborn *et al*[27], the present trial suggests a possible role of this drug in colonic CD patients, even if our results in these patients did not reach statistical significance; probably because of the small number of patients. Nevertheless, the clinical response in CD patients was good and, despite the limitation of the absence of a placebo arm, it can be argued that it was higher than expected from the response to a placebo arm, as based on the literature. For this reason, this proof-of-concept pilot study lays the foundations for future studies on the use of PLC in colonic CD patients.

In conclusion, PLC (ST 261) colon release tablets at a dose of 2 g/d were effective in inducing clinical and endoscopic/histological improvement in mild to moderate colonic IBD. Other studies are required to define the real efficacy and the correct therapeutic dosage of this promising drug for both colonic forms of IBD, and specially to evaluate its efficacy in CD patients.

ACKNOWLEDGMENTS

In memory of Dr. Claudio Cavazza, for his love for research and for having believed in this project.

COMMENTS

Background

There are few options in inflammatory bowel disease (IBD) therapy, mainly because pathogenetic mechanisms of these diseases are still unclear. Several components could play a role in IBD pathogenesis, including peroxidative damage, energy impairment and abnormal epithelial function on colonocytes. Propionyl-L-carnitine hydrochloride (PLC) modulation of these impaired functions could be useful in IBD therapy.

Research frontiers

PLC has demonstrated efficacy in reducing clinical and endoscopic disease activity in patients suffering from ulcerative colitis (UC), but only a few studies have investigated its use. Based on its mechanism of action, this drug could be effective also in patients affected by Crohn's disease (CD), but no clinical trials have assessed the efficacy of this drug in CD.

Innovations and breakthroughs

This is one of the first studies to investigate the use of PLC in patients suffering from UC and CD. The data suggest that this drug demonstrates efficacy and safety in both conditions.

Applications

With regard to UC, these data are in accordance with previous findings emerging from a multicenter, double-blind, placebo-controlled clinical trial. Furthermore, they suggest a possible use of this drug also in CD colitis and, even if few patients have been treated, this proof-of-concept study lays the foundations for future wider clinical trials.

Terminology

PLC has an important role in energy regulation, taking part in fatty acid β-oxidation and glucose metabolism. Moreover, PLC acts as an antioxidant molecule and it is a carrier of propionate moiety, which enters the Kreb's cycle, once transformed in succinate, contributing to energy sources in the cell. Finally, PLC has shown efficacy in treatment of cutaneous trophic ulcers.

Peer review

This is an interesting and important study that provides clinical evidence of the benefit of this novel therapy in patients with colitis. The topic is hot and of great clinical importance and these promising data would support further clinical assessment of this agent.

Abstract

AIM: To assess the prognostic value of preoperative 18 fluorodeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT) in patients with resectable colorectal cancer.

METHODS: One hundred sixty-three patients with resectable colorectal cancer who underwent FDG-PET/CT before surgery were included. Patient data including pathologic stage at presentation, histology, treatment, disease-free survival and the maximum standardized uptake value (SUVmax) of the primary tumor on FDG-PET/CT were retrospectively analyzed. Median follow up duration was 756 (range, 419-1355). The primary end point was disease-free survival.

RESULTS: Twenty-five of 163 patients (15.3%) had recurrences. The median SUVmax values of the recurrence and no-recurrence groups were 8.9 (range, 5-24) and 8.2 (range, 0-23, P = 0.998). Receiver operating characteristic (ROC) curve analysis showed no significant association between SUVmax and recurrence (area under the curve = 0.5, P = 0.998, 95% CI: 0.389-0.611). Because a statistically significant value was not found, SUVmax was dichotomized at its median of 8.6. The disease-free survival curve was analyzed using the median SUVmax (8.6) as the cut off. Univariate and multivariate analysis did not provide evidence that disease-free survival rates for the subgroups defined by the median SUVmax were significantly different (P = 0.52, P = 0.25).

CONCLUSION: Our study suggests that the high FDG uptake of primary mass in resectable colorectal cancer doesn't have a significant relationship with tumor recurrence and disease-free survival.

INTRODUCTION

Colorectal cancer is the third most common malignancy and the second most frequent cause of cancer-related deaths in the United States, with approximately 51 370 cancer-related deaths in 2010[1]. Despite improvement in diagnosis and treatment modalities, mortality from colon cancer has decreased slightly over the past 30 years. Therefore, methods for identifying patients at high risk of recurrence could influence posttreatment surveillance with the ultimate goal of improving survival.

Fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) is a functional imaging method for measurement of tumor glucose use. FDG-PET combined with computed tomography (FDG-PET/CT) was recently introduced and is expected to provide more precise anatomical data along with metabolic information. FDG-PET/CT imaging may be useful for diagnosis of patients with malignant disease, assessment of the extension of disease, detection of tumor recurrence and for monitoring responses to therapy[2-5].

In addition, some researchers have suggested that metabolic activity on FDG-PET may be a predictive marker for some types of malignancies[6-9]. Recent studies have demonstrated that there is a correlation between the maximum standardized uptake value (SUVmax) and survival in patients with gastrointestinal cancers such as esophageal and stomach cancer[10-12]. However, the prognostic value of FDG-PET/CT for colorectal cancer is less well studied. Several studies have found that metabolic activity on FDG-PET/CT is correlated with tumor biology and survival in colon cancer[13-15]. However, these studies were limited by experimental studies, small numbers of patients, and one report focused on stage Ⅳ colorectal cancer[14]. Therefore, in this study, we evaluated FDG-PET/CT imaging of patients with resectable colorectal cancer and determined whether metabolic activity is correlated with recurrence and disease-free survival.

MATERIALS AND METHODS

Patients

We retrospectively reviewed the tumor registry at our institution and identified all patients who were diagnosed with colorectal cancer and underwent curative resection between January 2006 and June 2008. Patients were required to have undergone the FDG-PET/CT study before surgery and to have received no treatment before the FDG-PET/CT. Primary colorectal cancer was confirmed by endoscopic biopsy. Patients who received neoadjuvant treatment or had a previous history of another malignancy were excluded. Patients with colorectal perforation or less than 1 year of follow-up were also excluded. Patients who did not receive adjuvant therapy despite lymph node-positive cancer were excluded from the analysis.

All patients underwent full imaging of the colon by colonoscopy unless an obstructing lesion was encountered. In this instance, colonoscopy was performed after recovery from surgical treatment. All surgeries were performed by two experienced colorectal surgeons.

Data were collected on demographic details, tumor node metastasis (TNM) and Duke staging at presentation, recurrence, histology, survival, disease-free survival, and SUVmax of the primary tumor. Tumor stage was classified according to the sixth edition of the TNM classification of the Union for International Cancer Control[16].

A total of 163 patients (65 women and 98 men) were eligible for this study. The median age of the patients was 60 years (range, 30 to 81 years).

Patient anonymity was preserved and the Institutional Review Board of Seoul St. Mary's Hospital approved the study. The study protocol was in complete compliance with the Declaration of Helsinki, as revised in Edinburgh in 2000.

Positron emission tomography imaging

All patients were fasted for at least 6 h before FDG injection; their blood glucose levels were determined from capillary blood samples collected before intravenous FDG injection. In our institution, the cut-off blood glucose level that contraindicates FDG injection is 8 mmol/L.

PET images were acquired 1 h after injection of 370-570 MBq of 18F-FDG. The patients were scanned generally from the base of the skull to the upper thighs with their arms raised above their heads.

FDG/PET-CT images were reviewed using fusion software (Syngo, Siemens; Knoxville, TN). An experienced nuclear medicine physician reviewed the PET/CT images. PET, CT and fused whole-body images displayed in axial, coronal, and sagittal planes were available for review. The PET data were also displayed as a rotating maximum-intensity projection. Abnormal FDG uptake, SUVmax of the primary tumor and distant metastases were evaluated.

Treatment and follow-up

All patients who were included in this study underwent curative resection based on a standardized technique and principle, which were not changed during the period of this study. Curative resection was defined as achieving complete microscopic/macroscopic clearance with no evidence of metastatic spread (except resectable liver or lung metastasis) at the time of surgical resection. The surgical margins were reported by experienced pathologists and all the margins were clear.

After curative resection of the tumor, adjuvant chemotherapy or chemoradiotherapy were indicated for all patients with lymph node-positive colorectal cancer. Patients were scheduled for follow-up visits every 3-6 mo for the first 2 years, every 6-12 mo for up to 4 years, and

annually thereafter. Follow-up evaluations included physical examinations at each visit, analysis of carcinoembryonic antigen (CEA) levels, abdominal and pelvic CT scans, and chest X-rays. A colonoscopy was performed 1 year after resection and then as indicated clinically. Abnormal physical findings or laboratory results mandated further screening with ultrasonography, CT, magnetic resonance imaging, or FDG-PET/CT, as indicated according to the clinician's decision.

Sample size calculation

In the previous study, the 2-year survival rates for an SUVmax of less than 10 and an SUVmax of 10 or more were 90% and 65%, respectively[14]. Based on the findings of our previous report, we hypothesized that the high SUVmax group would have a higher recurrence rate (the assumed odds ratio was 3 or more). The assumed odds ratio was decided based on the previous study for other malignancies, such as lung cancer and stomach cancer. We calculated that 163 patients would be required to detect these differences with an alpha level of 0.05 and a power of 0.80.

Statistical analysis

The predictive value of SUVmax for tumor recurrence was determined by analysis of the area under the receiver operating characteristic (ROC) curve. Because a statistically significant value was not found, SUVmax was dichotomized at its median of 8.6. The significance of the predictive value was analyzed by log-rank testing in univariate analysis and by Cox proportional hazards regression testing in multivariate analysis.

For statistical analysis, group means were compared using the Mann-Whitney or χ^2 tests, and disease-free survival was evaluated using a Kaplan-Meier survival analysis. For all tests, a P value of < 0.05 was considered statistically significant. All statistical analysis were performed using the Statistical Package for Social Sciences (SPSS), version 16 (SPSS, Chicago, IL).

RESULTS

Patient characteristics

The characteristics of the 163 patients enrolled in this study are shown in Table 1. The pathologic tumor stages were stage I in 23 patients, stage Ⅱ in 67 patients, stage Ⅲ in 64 patients, and stage Ⅳ in nine patients. Nine patients with stage Ⅳ tumors had metastases confined to the liver. Metastatic nodules on the liver numbered 1 or 2. The median size of the metastatic nodules was 1.2 cm (range, 0.5-2.5 cm). During the follow-up, recurrence was observed in 25 of 163 patients (15.3%). Three patients died with a median follow-up of 25.2 mo.

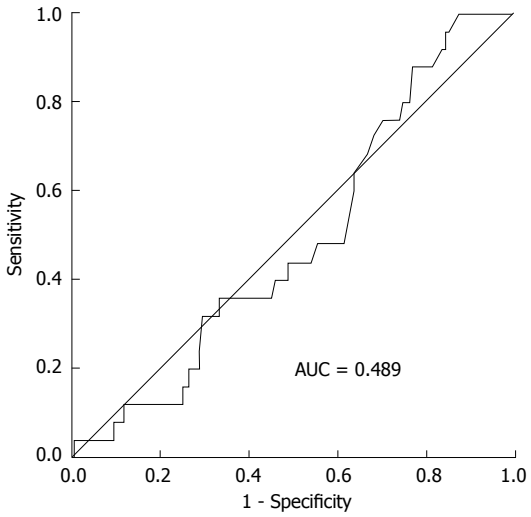

Figure 1 Receiver operating characteristic curve for prediction of recurrence from the maximum standardized uptake value. AUC: Area under curve.

SUVmax and recurrence

The median of SUVmax of the primary tumor was 8.6. ROC curve analysis showed no significant association between the SUVmax and recurrence (area under the curve = 0.5, P = 0.998, 95% CI: 0.389-0.611; Figure 1). As survival in patients with colorectal cancer is stage related, ROC curve analysis was conducted according to tumor stage. Patients with stage I tumors were excluded because they had no recurrence. Three ROC curves (stage Ⅱ and Ⅲ). None showed a statistically significant result. ROC curves according to stage showed that SUVmax was not a valid marker for predicting recurrence. Because a statistically significant value was not found, SUVmax was dichotomized at its median of 8.6. The disease-free survival curve was analyzed using the median SUVmax (8.6) as the cut off (Figure 2).

In a comparison between two groups differing in median SUVmax, tumor size (P = 0.02) and T stage (P = 0.018) showed significant differences. However, tumor recurrence, N stage, M stage, and histologic grade showed no significant differences (Table 2).

A disease-free survival curve calculated according to the Kaplan-Meier method for SUVmax of the primary tumor is shown in Figure 3 and Table 3. The difference in disease-free survival of patients categorized by median SUVmax was not statistically significant (P = 0.53).

After multivariate survival analysis, N stage and elevated CEA were independent prognostic predictors for disease-free survival (Table 4).

DISCUSSION

FDG-PET/CT has been proposed for use in the diagnosis and staging of several malignancies[4]. Furthermore, recent studies have demonstrated that there is a correlation between SUVmax and survival in patients with gastrointestinal cancers such as esophageal and stomach cancer[10-12].

This study focused on the role of FDG-PET/CT in providing prognostic information on patients with resectable colorectal cancer. We analyzed whether the SUVmax in the primary mass was associated with recurrence and disease-free survival. Our study demonstrates that the SUVmax of the primary mass in patients with resectable colorectal cancer provides no prognostic information.

FDG-PET/CT is a molecular imaging tool that monitors tissue glucose metabolism[17]. The biologic correla-

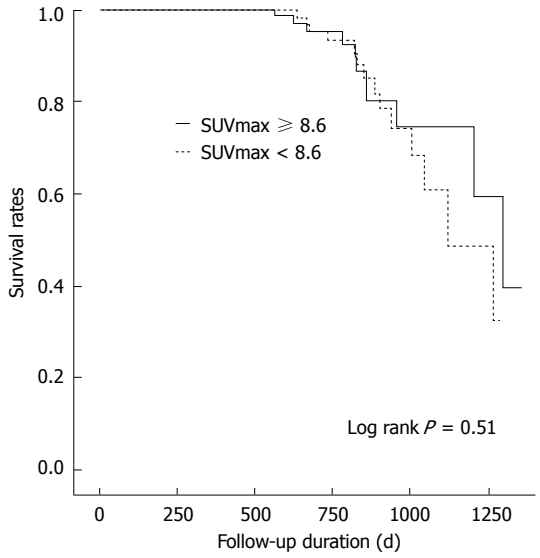

Figure 3 Disease-free survival according to the maximum standardized uptake value. SUVmax: Maximum standardized uptake value.

tions of FDG accumulation are less well studied for colorectal cancer than for other cancers. That cellular glucose metabolism may be correlated with tumor growth and aggressiveness has been suggested in some studies[17-21]. Previous *in vitro* and clinical studies indicated an association between elevated FDG uptake and colon tumor glucose metabolism, such as the activity of GLUT1, Ki-67, and p53[13,22-25]. A study by Gu *et al*[22] indicated that tumor size and depth of invasion were associated with higher SUVs in both primary colon tumors and hepatic metastatic foci. However, the study was limited by a small sample size (20 patients) and survival analysis was not performed. The other report demonstrated that a high SUVmax is correlated with poor prognosis and predicts mortality for patients with colorectal cancer after liver metastasectomy[14]. However, in this study, the highest SUVmax value was selected regardless of whether the lesion was primary or metastatic. In addition, the authors did not state whether complete resection was achieved and multivariate analysis of prognostic factors was not performed. Past studies that showed a correlation between survival and SUV were focused on stage Ⅳ colorectal cancer. In this study, we included only resectable colorectal cancers, in which clinicians are most interested. The main prognostic factors for disease-free survival were tumor stage, especially nodal stage, and elevated CEA. The SUVmax of the primary tumor was not a significant prognostic factor.

There are several limitations to this study. First, this study was a retrospective review with variation between treatment protocols. However, to reduce the heterogeneity of the study population, we excluded patients who did not receive adjuvant therapy, despite a positive lymph node status. Most adjuvant regimens consisted of FOLFOX (infusion of 5-fluorouracil, leucovorin, and oxaliplatin). Second, the duration of follow-up was relatively short. However, a recent analysis showed that most relapses occur within 2 years of surgery. This study suggested that disease-free survival after 2 and 3 years of follow-up is an appropriate end point for clinical trials in the adjuvant setting[26]. Third, immunohistochemical information on glucose metabolism in colorectal cancer was unavailable. Therefore, a biological explanation for the correlation between FDG accumulation and the behavior of the tumor was not suggested.

In conclusion, our study suggests that high FDG uptake of the primary mass in resectable colorectal cancer is not associated significantly with tumor recurrence or disease-free survival.

COMMENTS

Background

Despite improvement in diagnosis and treatment modalities, mortality from colon cancer has decreased slightly over the past 30 years. Therefore, methods for identifying patients at high risk of recurrence could influence posttreatment surveillance with the ultimate goal of improving survival. Fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) is a functional imaging method for measurement of tumor glucose use. Some researchers have suggested that metabolic activity on FDG-PET may be a predictive marker for some types of malignancies. However, the prognostic value of FDG-PET/CT for colorectal cancer is less well studied.

Research frontiers

FDG-PET/CT is a molecular imaging tool that monitors tissue glucose metabolism. That cellular glucose metabolism may be correlated with tumor growth and aggressiveness has been suggested in some studies. The biologic correlations of FDG accumulation are less well studied for colorectal cancer than for other cancers. Therefore, in this study, authors evaluated FDG-PET/CT imaging of patients with resectable colorectal cancer and determined whether metabolic activity is correlated with recurrence and disease-free survival.

Innovations and breakthroughs

Several studies have found that metabolic activity on FDG-PET/CT is correlated with tumor biology and survival in colon cancer. However, these studies were limited by experimental studies, small numbers of patients, and one report focused on stage Ⅳ colorectal cancer. This study focused on the role of FDG-PET/CT in providing prognostic information on patients with resectable colorectal cancer. Authors included only resectable colorectal cancers, in which clinicians are most interested. Univariate and multivariate analysis did not provide evidence that disease-free survival rates for the subgroups defined by the median SUVmax were significantly different.

Applications

High FDG uptake of primary mass in resectable colorectal cancer doesn't have a significant relationship with tumor recurrence and disease-free survival.

Peer review

This manuscript evaluate the prognostic value of preoperative FDG-PET/CT in patients with resectable colorectal cancer. This study suggests that the high FDG uptake of primary mass in resectable colorectal cancer doesn't have a significant relationship with tumor recurrence and disease-free survival. The results demonstrate evidence can be considerate by clinicians.

Abstract

AIM: To identify the risk factors in predicting the outcome of acute-on-chronic hepatitis B liver failure patients.

METHODS: We retrospectively divided 113 patients with acute-on-chronic liver failure-hepatitis B virus (ACLF-HBV) and without concurrent hepatitis C or D virus infection and hepatocellular carcinoma into two groups according to their outcomes after anti-HBV therapy. Their demographic, clinical, and biochemical data on the day of diagnosis and after the first week of treatment were analyzed using the Mann-Whitney *U* test, Fisher's exact test, and a multiple logistic regression analysis.

RESULTS: The study included 113 patients (87 men and 26 women) with a mean age of 49.84 years. Fifty-two patients survived, and 61 patients died. Liver failure (85.2%), sepsis (34.4%), and multiple organ failure (39.3%) were the main causes of death. Multivariate analyses showed that Acute Physiology and Chronic Health Evaluation (APACHE) Ⅱ scores ⩾ 12 [odds ratio (OR) = 7.160, 95% CI: 2.834-18.092, $P < 0.001$] and positive blood culture (OR = 13.520, 95% CI: 2.740-66.721, $P = 0.001$) on the day of diagnosis and model for end-stage liver disease (MELD) scores ⩾ 28 (OR = 8.182, 95% CI: 1.884-35.527, $P = 0.005$) after the first week of treatment were independent predictors of mortality.

CONCLUSION: APACHE Ⅱ scores on the day of diagnosis and MELD scores after the first week of anti-HBV therapy are feasible predictors of outcome in ACLF-HBV patients.

Fan HL, Yang PS, Chen HW, Chen TW, Chan DC, Chu CH, Yu JC, Kuo SM, Hsieh CB. Predictors of the outcomes of acute-on-chronic hepatitis B liver failure. *World J Gastroenterol* 2012; 18(36): 5078-5083 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i36/5078.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i36.5078

INTRODUCTION

Hepatitis B virus (HBV) infection is a major global health problem, with higher prevalence in Asia than in the West. In Taiwan, its prevalence is estimated at more than 8%[1]. Approximately 15%-40% of the patients with HBV infection eventually develop cirrhosis, hepatocellular carcinoma, or liver failure[2]. Acute-on-chronic liver failure (ACLF) is characterized by an acute deterioration in liver function due to a precipitating event such as infection, sepsis, alcohol, or variceal bleeding, in a patient with previously chronic liver disease. The reactivation of HBV infection plays an important role in the progression of ACLF in the Asian region[3]. Therefore, the first goal of treatment is to inhibit HBV replication.

Lamivudine, an L-nucleoside analog, has good therapeutic efficacy for suppressing HBV replication[4,5]. Consciousness and coagulopathy recover within only one week of lamivudine therapy, and the response rate to treatment is 86.66%[6]. Lamivudine therapy prevents the progression from acute exacerbation of hepatitis B to liver failure[6]. However, one report has indicated that lamivudine has no overall survival benefit in the management of severe flare-ups of chronic hepatitis B (CHB) with jaundice[7]. Therefore, patients unresponsive to anti-HBV therapy require alternative and effective treatments.

Liver transplantation (LT) is widely performed in patients with fulminant hepatitis B[8,9]. Advances in the transplantation techniques have resulted in good outcomes after living donor liver transplantation (LDLT) or dual-graft LDLT in patients with ACLF-HBV[9,10]. It is important for the transplant surgeon to know the optimal timing and the criteria for LT in patients with ACLF-HBV.

Because both anti-HBV therapy and LT are suitable treatments for ACLF-HBV, hepatologists and transplant surgeons require a practical model to predict the outcomes of ACLF-HBV. The model for end-stage liver disease (MELD) is one such prognostic model[11,12]; however, MELD scores alone do not predict the prognosis accurately[13], and their suitability as prognostic indicators is controversial. Acute Physiology and Chronic Health Evaluation Ⅱ (APACHE Ⅱ) scores are widely used in intensive care units to assess the severity of disease. Although this scoring system has been investigated with respect to its utility in predicting outcomes in critically ill patients with cirrhosis, the suitability of APACHE Ⅱ scores as prognostic indicators for ALCF is also controversial[14-16]. In addition, APACHE Ⅱ scores have rarely been evaluated for predicting the outcomes of acute hepatic failure[17-19].

Previous studies have focused on various risk factors of mortality on the day of diagnosis, reflecting the severity of disease only at the time of diagnosis. ACLF-HBV has a rapidly progressing clinical course. Therefore, prompt evaluation of the efficacy of anti-HBV or supportive treatment would have a great impact on the outcomes of this disease. Accordingly, we aimed to assess the applicability of MELD and APACHE Ⅱ scores as predictors of the outcomes of ACLF-HBV and develop predictive models of mortality from ACLF-HBV based on the clinical and biochemical data recorded on the day of diagnosis and after the first week of anti-HBV and supportive treatment.

MATERIALS AND METHODS

Patients and study design

Between January 2001 and June 2010, 113 patients were diagnosed with ACLF-HBV at these two institutions in Taiwan. ACLF-HBV was defined as the recent development of jaundice (serum total bilirubin level ≥ 10 mg/dL), with an international normalized ratio (INR) > 1.5, and complicated with ascites and/or encephalopathy in a patient previously diagnosed or underdiagnosed with CHB[18]. The definition of underdiagnosed CHB was that HBV tests were performed for the first time and positive in patients with cirrhosis. The exclusion criteria were concurrent hepatitis C or D virus infection, a history of alcoholic drinking, malignant jaundice, hemolytic jaundice, prolonged prothrombin time induced by blood system disease, Wilson disease, autoimmune hepatitis, and anti-HBV therapy for liver failure diagnosed at another hospital.

All the enrolled patients received 100 mg lamivudine (tablets) once daily. Their medical records were retrospectively reviewed, and they were followed up for at least 3 mo. The outcome of each patient was recorded, and the causes of death were documented.

Observed parameters

The results of blood tests performed on the day of diagnosis and after the first week of anti-HBV therapy were recorded. The blood tests performed included white blood count (WBC), hemoglobin level, platelet count, prothrombin time (PT), INR, creatinine level, aspartate, alanine transaminase (ALT) level, total bilirubin (TBil) level, direct bilirubin (DBil) level, total cholesterol level, triglyceride level, albumin level, ammonia level, serum sodium level, serum potassium level, serum chloride level, total serum calcium level, and serum magnesium level.

MELD scores were calculated according to the following formula: MELD score = [3.78 × $\log_e$(bilirubin level in mg/dL)] + [11.2 × $\log_e$(INR)] + [9.6 × $\log_e$(creatinine level in mg/dL)] + [6.4 × (etiology: 0 if cholestatic or alcoholic, 1 otherwise)][20]. APACHE Ⅱ scores were calculated from 12 physiological and laboratory values: temperature, mean arterial pressure, heart rate, respiratory rate, oxygenation (PaO_2 or A-aDo_2), arterial pH, serum sodium level, serum potassium level, serum creatinine level, hematocrit, WBC count, and Glasgow coma score. Each value was marked from 0 to 4, where 0 = normal and 4 = most abnormal. The sum of these values was adjusted according to the patient's age and chronic health problems[21].

Table 1 Patient characteristics and blood tests on the day of diagnosis

	Survival	Dead	*P* value
Case number	52	61	
Age (yr)[1]	43.00 (17.00)	55.00 (19.00)	< 0.001

APACHE-Ⅱ score[1]	12.00 (5.00)	14.00 (3.00)	< 0.001

P values were derived from [1]the Mann-Whitney *U* test, [2]the χ^2 test, and [3]Fisher's exact test. The median (interquartile range) is presented for continuous variables and the number (percentage) is presented for categorical variables. MELD: Model for end-stage liver disease; APACHE-Ⅱ: Acute Physiology and Chronic Health Evaluation Ⅱ; INR: International normalized ratio; ALT: Alanine transaminase; WBC: White blood cell.

Statistical analysis

Unless otherwise stated, continuous variables are presented as the median (interquartile range), and categorical variables are expressed as the number (percentage) of events. To detect differences between the groups, the Mann-Whitney *U* test was used for continuous variables, and the χ^2 test was used for categorical variables. If 20% of the cells had expected numbers < 5, Fisher's exact test was used instead of the χ^2 test. The cut-off value of continuous variables with a *P* value < 0.05 in the Mann-Whitney *U* test was determined by finding the point on the receiver operating characteristic curve closest to (0,1)[22]. Statistically significant variables with a *P* value < 0.05 in the univariate analysis were put into a backward multivariate analysis. New models to predict the outcomes were established based on the results of the backward multivariate analysis. All the statistical calculations were performed using SPSS version 15.0 (IBM-SPSS, Inc., Chicago, IL). Significance was defined as $P < 0.05$.

Table 2 Univariate and multivariate analysis of clinical and biochemical data on the day of diagnosis

	Univariate analysis		Multivariate analysis	
	OR (95% CI)	*P* value	OR (95% CI)	*P* value
Age ⩾ 45	6.912 (3.009-15.879)	< 0.001	NI	
Serum potassium ⩾ 4.0	1.994 (0.928-4.284)	0.077	NI	
APACHE-Ⅱ score ⩾ 12	7.167 (3.072-16.724)	< 0.001	7.160 (2.834-18.092)	< 0.001
Blood culture: Positive	14.103 (3.125-63.639)	0.001	13.520 (2.740-66.721)	0.001
Past diabetes history: Positive	6.837 (1.884-24.814)	0.003	NI	

Age and history of diabetes mellitus were not included for multivariate analyses because these parameters had been calculated for the APACHE-Ⅱ score. OR: Odds ratio; APACHE-Ⅱ: Acute Physiology and Chronic Health Evaluation Ⅱ; NI: Not included in model.

RESULTS

Patient characteristics

The study included 113 patients (87 men and 26 women) with a mean age of 49.84 years. The patient characteristics are summarized in Table 1. Overall, 52 (46%) patients survived the anti-HBV therapy, and 61 (54%) patients died during therapy. The patients who died were older (55 years *vs* 43 years, $P < 0.001$), more often had a history of diabetes mellitus (29.5% *vs* 5.8%, $P = 0.004$), and tended to have positive blood cultures (36.1% *vs* 3.8%, $P < 0.001$). The groups showed no significant differences in terms of gender, body mass index, history of hypertension or coronary artery disease. Liver failure (85.2%), sepsis (34.4%), and multiple organ failure (39.3%) were the main causes of death.

Observed parameters on the day of diagnosis

The results of the blood test on the day of diagnosis are shown in Table 1. The patients who died had significantly higher values of serum potassium ($P = 0.008$) than the survivors. The groups showed no significant differences in the other observed parameters. Furthermore, the patients who died had significantly higher APACHE Ⅱ scores than the survivors (14 *vs* 12, $P \leqslant 0.001$), but no significant difference in MELD scores was detected.

A univariate analysis showed that the frequency of age ⩾ 45 years ($P < 0.001$), history of diabetes mellitus ($P = 0.003$), positive blood culture ($P = 0.001$), and APACHE Ⅱ score ⩾ 12 ($P < 0.001$) differed significantly between the groups (Table 2). However, potassium levels ⩾ 4.0 mmol/L were not a significant risk factor for dying based on the results from the univariate analysis. The trend ($P = 0.077$) was included in the multivariate analysis.

The multivariate analysis included all the significant parameters in the univariate analysis except for age, history of diabetes mellitus and serum potassium level,

Table 3 Laboratory tests after the first week of anti-hepatitis B virus therapy

	Survivors (n = 52)	Dead (n = 61)	P value
White blood cell count ($\times10^3$/cumm)	6.50 (3.40)	9.35 (6.95)	< 0.001
Hemoglobin (g/dL)	10.25 (1.95)	0.20 (3.70)	0.780
Platelet ($\times10^3$/cumm)	92.50 (74.50)	79.50 (91.25)	0.356
Prothrombin time (s)	17.20 (4.85)	21.65 (9.35)	< 0.001
INR	1.96 (1.00)	2.87 (2.38)	< 0.001
Creatinine (mg/dL)	0.70 (0.50)	1.10 (1.35)	< 0.001
ALT (U/L)	95.50 (331.25)	115.50 (299.00)	0.238
Total bilirubin (mg/dL)	12.75 (9.60)	20.30 (15.20)	0.003
Direct bilirubin (mg/dL)	7.45 (7.85)	10.30 (8.60)	0.093
Albumin (g/dL)	3.00 (0.70)	2.80 (0.85)	0.098
Ammonia (μg/dL)	118.00 (96.00)	159.50 (223.00)	0.005
Serum sodium (mmol/L)	134.00 (8.00)	138.00 (8.00)	0.003
Serum potassium (mmol/L)	4.10 (0.90)	3.80 (1.00)	0.649
Serum chloride (mmol/L)	104.00 (14.00)	105.00 (18.00)	0.338
Serum calcium (mg/dL)	8.40 (1.25)	8.45 (1.43)	0.922
Serum magnesium (mg/dL)	1.80 (1.45)	2.30 (0.93)	0.216
MELD score	25.00 (7.00)	32.00 (12.00)	< 0.001
APACHE-Ⅱ score	13.00 (10.00)	17.50 (9.00)	0.014

The median (interquartile range) is presented for continuous variables. P values were derived using the Mann-Whitney U test. MELD: Model for end-stage liver disease; APACHE-Ⅱ: Acute Physiology and Chronic Health Evaluation Ⅱ; INR: International normalized ratio; ALT: Alanine transaminase.

because these parameters were calculated as part of the APACHE Ⅱ scores. Multivariate analysis showed that an APACHE Ⅱ score ≥ 12 [odds ratio (OR) = 7.160, 95% CI: 2.834-18.092, P < 0.001] and positive blood culture (OR = 13.520, 95% CI: 2.740-66.721, P = 0.001) were independent predictive factors of mortality in patients with ACLF-HBV (Table 2).

Observed parameters after the first week of anti-HBV therapy

Table 3 shows the results of blood tests performed after the first week of anti-HBV therapy. WBC count, PT, INR, creatinine level, TBil level, ammonia level, serum sodium level, MELD score, and APACHE Ⅱ score showed significant differences, and their cut-off values were determined by using the Shock index. In the univariate analysis, WBC count ≥ 8500/mm^3 (P = 0.001), PT ≥ 19 s (P < 0.002), INR ≥ 2.5 (P = 0.002), creatinine level ≥ 0.9 mg/dL (P < 0.001), TBil level ≥ 15.5 mg/dL (P = 0.001), ammonia level ≥ 166 μg/dL (P = 0.008), serum sodium level ≥ 136 mmol/L (P = 0.006), MELD score ≥ 28 (P < 0.001), and APACHE Ⅱ score ≥ 14 (P = 0.0018) differed significantly between the survivors and the patients who died (Table 4).

The multivariate analysis included all the significant parameters in the univariate analysis except for WBC count and serum sodium level because these parameters were calculated as part of the APACHE Ⅱ scores. INR, TBil level, and creatinine level were calculated as part of the MELD scores. Multivariate analysis showed that MELD scores ≥ 28 (OR = 8.182, 95% CI: 1.884-35.527, P = 0.005) were independent predictive factors of mortality in patients with ACLF-HBV (Table 4).

Table 4 Univariate and multivariate analysis of clinical and biochemical data after the first week of anti-hepatitis B virus therapy

	Univariate analysis		Multivariate analysis	
	OR (95% CI)	P value	OR (95% CI)	P value
White blood cell count ≥ 8.50	5.940 (2.129-16.571)	0.001[a]	NI	
Prothrombin time ≥ 19	4.018 (1.656-9.747)	0.002[a]	1.264 (0.254-6.296)	0.775
INR ≥ 2.5	3.960 (1.635-9.590)	0.002[a]	NI	
Creatinine ≥ 0.9	4.819 (2.090-11.112)	<0.001[a]	NI	
Total bilirubin ≥ 15.5	4.271 (1.878-9.714)	0.001[a]	NI

Serum sodium ≥ 136	3.479 (1.432-8.448)	0.006[a]	NI	
MELD score ≥ 28	13.000 (4.604-36.711)	<0.001[a]	8.182 (1.884-35.527)	0.005
APACHE-Ⅱ score ≥ 14	2.941 (1.201-7.203)	0.018[a]	1.597 (0.375-6.809)	0.527

The parameters of white blood cell count, serum sodium, INR, total bilirubin and creatinine were not included for multivariate analyses because these parameters had been calculated for the APACHE-Ⅱ score or MELD score. OR: Odds ratio; MELD: Model for end-stage liver disease; APACHE-Ⅱ: Acute Physiology and Chronic Health Evaluation Ⅱ; INR: International normalized ratio; NI: Not included in model. [a]P < 0.05.

DISCUSSION

ACLF-HBV has a poor prognosis and is associated with high mortality. Sun *et al*[13] reported that the 3-mo overall mortality of patients with ACLF-HBV without lamivudine treatment was 57.84%. Despite lamivudine treatment, the prognosis is unsatisfactory with a mortality rate of approximately 50.7%-75.7%[23]. We found that the 3-mo overall mortality was 54.0%, which is consistent with previous reports. These results indicate that mortality from ACLF-HBV depends on multiple factors other than HBV replication. One relevant factor may be physiological changes in these patients. In addition to liver failure (85.2%), sepsis and multiple organ failure were also important causes of death in the present study, responsible for 34.4% and 39.3% of patient deaths, respectively. Both HBV-induced primary injury and cytokine-induced secondary injury confirm that physiological change is equally important to HBV replication in the pathogenesis of ACLF-HBV. Physiological changes other than HBV replication in a patient with ACLF-HBV are highly associated with patient outcomes. HBV load and a decline in HBV DNA load are proven risk factors[23]. Other risk factors of mortality from ACLF-HBV should be investigated.

Determining which method to use for describing the severity of physiological changes or cytokine-induced secondary injury in patients with ACLF-HBV was an issue of concern in this study. APACHE Ⅱ scores are widely used in intensive care units to evaluate the severity and prognosis of a disease[21]. The predictive accuracy of APACHE Ⅱ scores for mortality in patients with acetaminophen-induced acute liver failure has been reported in terms of the area under the receiver operating characteristic (ROC) curve, sensitivity, and specific-

ity (0.77, 67% and 76%, respectively)[24]. We found that APACHE Ⅱ scoring on the day of diagnosis does not exhibit good predictive accuracy. Through multiple logistic regression analysis, an APACHE Ⅱ score ⩾ 12 and positive blood culture on the day of diagnosis were identified as independent predictive factors of mortality. These two factors accurately predicted the outcome of ACLF-HBV patients better than the APACHE-Ⅱ score alone or prior associated studies (predictive accuracy was 76.6%; area under the ROC curve was 0.804). We ignored age and history of diabetes mellitus in the multivariate analysis because they were calculated in the APACHE Ⅱ scores, but we supposed that these parameters play an important role in determining APACHE Ⅱ scores. The identification of positive blood culture as a predictor of mortality suggests that physicians should treat infection in patients with ACLF-HBV aggressively.

MELD scores are widely used to assess the severity of chronic liver disease and indications for LT[24]. Sun *et al*[13] found that MELD scoring alone had lower predictive accuracy than their predictive model. Our results are consistent with those of Sun *et al*[13] and suggest that MELD scoring on the day of diagnosis does not accurately predict mortality from ACLF-HBV. We supposed that MELD scores, which include INR, TBil level, and creatinine level, are not acute-stage indicators. However, the fact that MELD scores ⩾ 28 after 1 wk are strongly associated with mortality implies that after the acute complications of ACLF are treated and HBV is suppressed, liver function again becomes important as a prognostic factor as it is in cirrhosis without ACLF. The change in MELD score may reflect the efficacy of anti-HBV therapy in patients with ACLF-HBV. Our findings also highlight the importance of repeated evaluations after 1 wk of anti-HBV therapy, given the fact that ACLF-HBV progresses rapidly and that disease severity and the patient's condition cannot be evaluated completely on the day of diagnosis. Furthermore, our results suggest that cytokine-induced physiological changes recover after one week of anti-HBV treatment; therefore, progressive liver injury determines the outcome of ACLF-HBV.

The English literature includes few reports on the prognostic factors of ACLF-HBV. Before the lamivudine era, the prognostic model for ACLF-HBV consisted of the presence of hepatorenal syndrome, the presence of liver cirrhosis, the presence of hepatitis B e antigen, low albumin level, and low prothrombin activity[13]. With the development of anti-HBV therapy, the HBV factor has been investigated further. Dai *et al*[25] found that albumin level, INR, and HBV DNA level are good predictors of mortality in patients with CHB-related decompensation treated with lamivudine. Furthermore, Yu *et al*[26] reported that MELD scores of 30 to 40, low HBV load, and rapid declines in HBV DNA load are good predictors of mortality in patients with ACLF-HBV treated with plasma exchange and lamivudine. Similarly, Sun *et al*[23] showed that MELD scores of 20 to 30, low HBV load, and rapid declines in HBV DNA load are good predictors in patients with ACLF-HBV treated with lamivudine. Therefore, HBV replication is the key factor for predicting mortality. We did not analyze HBV factors because of the lack of complete data.

The present study has some limitations. Because of its retrospective nature, some laboratory data, such as lactate acid level and HBV load, could not be collected and analyzed. These data are considered good predictors of the outcomes of ACLF-HBV[23]. In addition, the results need to be interpreted cautiously, given the differences in the definition of ACLF-HBV between this and previous studies. For example, the plasma TBil level ranged from ⩾ 5 mg/dL to ⩾ 10 mg/dL, which define the jaundice of liver failure in acute-on-chronic liver failure in previous studies; we adopted a plasma TBil level ⩾ 10 mg/dL, which seems to be the most common criterion[13,23,25]. However, the Asian Pacific Association for the Study of Liver held a meeting in 2008, where liver failure in acute-on-chronic liver failure was defined as jaundice (serum bilirubin ⩾ 5 mg/dL) and coagulopathy (INR ⩾ 1.5). In the future, researchers must follow the above definition to help clinicians improve the identification and management of these patients[3].

In conclusion, our logistic regression models have good predictive accuracy. APACHE Ⅱ score ⩾ 12 and positive blood culture on the day of diagnosis reflect severe liver failure. Anti-HBV medication, aggressive supportive treatment, and the control of infection are important for patients with ACLF-HBV. The need for appropriate donors among relatives, the evaluation of liver structures, and the ethical issues inherent in LT should be considered. Patients should be re-evaluated after the first week of anti-HBV treatment. MELD scores ⩾ 28 indicate that the patient is in poor condition. These patients should undergo LT as soon as possible. This study emphasized the selection of an APACHE Ⅱ score and a MELD score as predictors because these two scores are used clinically in many institutions and utilized easily by clinicians. Future research efforts should verify the outcome of liver transplantation for these ACLF-HBV patients with the risk factors described above.

COMMENTS

Background

Acute-on-chronic hepatitis B liver failure has a poor prognosis with high mortality. Despite lamivudine treatment, the prognosis in still unsatisfactory. Acute-on-chronic hepatitis B liver failure has a rapidly progressing clinical course. Prompt evaluation of the efficacy of anti-hepatitis B virus (HBV) treatment would have a great impact on patient outcomes.

Research frontiers

To assess the applicability of Acute Physiology and Chronic Health Evaluation (APACHE)-Ⅱ and model for end-stage liver disease (MELD) scores to predict the outcome of acute-on-chronic hepatitis B liver failure.

Innovations and breakthroughs

The suitability of MELD scores as prognostic indicators for these patients is controversial. APACHE-Ⅱ scores have rarely been evaluated among these patients. Importantly, these two scores are easily available in clinical practice.

Applications

APACHE Ⅱ scores on the day of diagnosis and MELD scores after the first

week of anti-HBV therapy are feasible predictors in determining the outcome of acute-on-chronic hepatitis B liver failure even after treatment with anti-hepatitis B virus therapy.

Terminology

Acute-on-chronic liver failure is characterized by an acute deterioration in liver function as a result of a precipitating event such as infection, sepsis, alcohol toxicity, or variceal bleeding, in a patient with previously chronic liver disease.

Peer review

In this article, the authors have compared various parameters to predict the outcomes of acute-on-chronic hepatitis B liver failure. The immediate message of the conclusion is that we apparently have two concrete, bedside early prognostic indicators. The authors have included the limitations of the presented study.

Abstract

AIM: To determine whether alteration of the mitochondria DNA (mtDNA) copy number and its oxidative damage index (mtDNA$^{\Delta CT}$) can be detected by analysis of peripheral blood cells in hepatitis C virus (HCV)-infected patients.

METHODS: This study enrolled two groups of patients aged 40-60 years: a control group and an HCV-infected group in Department of Gastroenterology and Hepatology in Changhua Christian Hospital. Patients with co-infection with hepatitis B virus or human immunodeficiency virus, autoimmune disease, malignant neoplasia, pregnancy, thyroid disease, or alcohol consumption > 40 g/d were excluded. HCV-infected patients who met the following criteria were included: (1) positive HCV antibodies for > 6 mo; (2) alanine aminotransferase (ALT) levels more than twice the upper limit of normal on at least two occasions during the past 6 mo; and (3) histological fibrosis stage higher than F1. The mtDNA copy number and oxidative damage index of HCV mtDNA (mtDNA$^{\Delta CT}$) were measured in peripheral blood leukocytes. The association between mtDNA copy number and mtDNA$^{\Delta CT}$ was further analyzed using clinical data.

RESULTS: Forty-seven normal controls (male/female: 26/21, mean age 50.51 ± 6.15 years) and 132 HCV-infected patients (male/female: 76/61, mean age 51.65 ± 5.50 years) were included in the study. The genotypes of HCV-infected patients include type 1a (n = 3), type 1b (n = 83), type 2a (n = 32), and type 2b (n = 14). Liver fibrosis stages were distributed as follows: F1/F2/F3/F4 = 1/61/45/25 and activity scores were A0/A1/A2/A3 = 7/45/55/25. There were no age or gender differences between the two groups. HCV-infected patients had higher hepatitis activity (aspartate transaminase levels 108.77 ± 60.73 *vs* 23.19 ± 5.47, $P < 0.01$; ALT levels 168.69 ± 93.12 *vs* 23.15 ± 9.45, $P < 0.01$) and lower platelet count (170.40 ± 58.00 *vs* 251.24 ± 63.42, $P < 0.01$) than controls. The mtDNA copy number was lower in HCV-infected patients than in controls (173.49 *vs* 247.93, $P < 0.05$). The mtDNA$^{\Delta CT}$ was higher in HCV-infected patients than in controls (2.92 *vs* 0.64, $P < 0.05$). To clarify the clinical significance of these results in HCV-infected patients, their association with different clinical parameters among HCV-infected patients was analyzed. A negative association was found between mtDNA copy number and elevated aspartate transaminase levels (r = -0.17, $P < 0.05$). Changes in mtDNA copy number were not associated with HCV RNA levels, HCV genotypes, liver fibrosis severity, or inflammatory activity in the liver biopsy specimen. However, a correlation was observed between mtDNA$^{\Delta CT}$ and platelet count (r = -0.22, $P < 0.01$), HCV RNA level (r = 0.36, $P < 0.01$), and hepatitis activity (r = 0.20, P = 0.02). However, no difference in the change in mtDNA$^{\Delta CT}$ was observed between different fibrosis stages or HCV

genotypes.

CONCLUSION: Oxidative stress and mtDNA damage are detectable in patient's peripheral leukocytes. Increased leukocyte mtDNA$^{\Delta CT}$ correlates with higher HCV viremia, increased hepatitis activity, and lower platelet count.

INTRODUCTION

Mitochondria play an important role in energy metabolism of cells[1,2]. Human mitochondrial DNA (mtDNA) is prone to oxidative injury because mitochondria generate reactive oxygen species during adenosine triphosphate (ATP) synthesis[3]. Unlike genomic DNA, mitochondria are unique in that they possess multiple copies of mtDNA. Alteration or depletion of mtDNA copy number in tissues or serum has been linked to various diseases[4-7] associated with different oxidative stress conditions.

Hepatitis C virus (HCV) is an important cause of chronic viral hepatitis. Without treatment, patients progress to cirrhosis and eventually develop hepatocellular carcinoma. Several mechanisms have been postulated for HCV-induced liver injury, including immunological hepatocellular damage, cytotoxicity of different viral products, and increased oxidative stress[8]. In previous studies, HCV infection (especially by HCV genotype 1) has also been found to be associated with decreased hepatocyte mtDNA[9]. Some studies suggested hepatocyte mtDNA depletion in HCV/human immunodeficiency virus (HIV) co-infected patients[7,10-12]. However, these studies were limited to a small number of cases and did not include a group of normal controls. Alterations of mtDNA and oxidative stress in HCV-infected patients have been mainly studied in tissues; however, recent observations suggested that use of peripheral blood cells may also be informative[4,5]. Cardin *et al*[13] observed increased oxidative DNA damage in peripheral lymphocytes of HCV-infected patients, and Levent *et al*[8] observed increased oxidative stress in erythrocytes of chronic HCV-infected patients. Thus, we hypothesized that alteration of mtDNA copy number and oxidative damage of mtDNA may be detected by analyzing peripheral blood leukocytes of chronic HCV-infected patients.

MATERIALS AND METHODS

Subjects

The control group comprised 47 healthy persons aged 40-60 years who had been included in our previous study of mtDNA copy number in human leukocytes[5]. The 132 HCV-infected patients included in this study were aged 40-60 years, had undergone liver biopsy, and had received interferon (IFN)-based therapy at the Department of Gastroenterology and Hepatology of Changhua Christian Hospital between October 2003 and July 2009. Exclusion criteria were coinfection with hepatitis B virus or HIV, autoimmune disease, malignant neoplasia, pregnancy, thyroid disease, alcohol consumption > 40 g/d, intravenous drug abuse, and any contraindication for pegylated IFN-α or ribavirin therapy. The study was approved by the Institutional Review Board of Changhua Christian Hospital and conducted in accordance with institutional guidelines.

Criteria for chronic hepatitis C that required combined IFN-based therapy were as follows: (1) patients demonstrating positive HCV antibodies for > 6 mo; (2) patients with alanine aminotransferase (ALT) levels more than twice the upper limit of normal on at least two occasions during the 6 mo prior to enrolment into the study; and (3) patients with a histological fibrosis stage of more than F1 (F0: no fibrosis; F1: portal fibrosis without septa; F2: portal fibrosis with rare septa; F3: numerous septa without cirrhosis; and F4: liver cirrhosis) in the METAVIR scoring system[14].

Assessment of medical history and laboratory tests

Any history of hypertension, diabetes, and hyperlipidemia was recorded. Hypertension was defined as systolic blood pressure > 140 mmHg or use of antihypertensive drugs; diabetes mellitus as hemoglobin A1c > 6.5% or use of oral antidiabetic agents/insulin injection; and hyperlipidemia as total cholesterol level of > 200 mg/dL, low-density lipoprotein cholesterol level of > 130 mg/dL, or triglyceride level of > 200 mg/dL.

Biochemical and hematological tests were performed prior to IFN therapy using commercially available assays. HCV genotype was assigned at baseline by sequencing using a Beckman CEQ 8000 Sequencer (Beckman Coulter, Fullerton, CA, United States). Serum HCV RNA was measured using a quantitative assay (COBAS AMPLICOR Hepatitis C Virus Test, version 2.0; Roche, Branchburg, NJ, United States) with a detection limit of 50 IU/mL. The degree of liver fibrosis (F0: no fibrosis; F1: portal fibrosis without septa; F2: portal fibrosis with

rare septa; F3: numerous septa without cirrhosis; and F4: liver cirrhosis) and the intensity of liver necroinflammation (A0: no activity, A1: mild activity, A2: moderate activity, and A3: severe activity) were graded according to the METAVIR scoring system[14] by a single expert pathologist.

Determination of total copy number and oxidative damage in leukocyte mtDNA

Leukocytes were separated from the blood sample taken prior to IFN therapy, and DNA was isolated as described previously[5]. Fluorescence-based quantitative polymerase chain reaction (FQ-PCR) was performed using the LightCycler FastStart DNA Master Kit (Roche Molecular Biochemicals, Penzberg, Germany) to measure total copy number in leukocyte mtDNA[15]. In brief, the threshold cycle number of mitochondrial ND1 and β-globin genes was determined in leukocytes of HCV-infected patients. mtDNA copy number was calculated according to a previously described method[5]. The total amount of mtDNA in leukocytes was expressed as copy number/cell. In addition, the mtDNA oxidative damage index (mtDNA$^{\Delta CT}$) was evaluated as described previously[15]. In brief, human 8-oxoguanine DNA glycosylase (hOGG1) was used to remove 8-hydroxydeoxyguanosine (8-OHdG) from the damaged DNA template in which lesion sites were formed. Amplification in FQ-PCR was then blocked, and the cycle threshold (Ct) value increased. Thus, ΔCt value was determined by calculating the difference between values before and after treatment with hOGG1. A higher mtDNA$^{\Delta CT}$ value indicated the presence of more 8-OHdG in mtDNA, and thus greater oxidative damage.

Statistical analysis

Continuous variables in the groups were compared using the Student's t test or Mann-Whitney U test as appropriate. Categorical variables were evaluated using the χ^2 test.

Table 2 Correlation between mitochondrial DNA and clinical findings in hepatitis C virus-infected patients

Characteristics	Correlation statistics

HCV: Hepatitis C virus; ALT: Alanine aminotransferase; AST: Aspartate transaminase; Hb: Hemoglobin; WBC: White blood cell.

Relationships between two continuous variables were evaluated by Pearson correlation. Differences between the two groups were considered significant when the P value was < 0.05. Statistical analyses were performed using MedCalc software version 11.5 (MedCalc Software bvba, Broekstraat 52, 9030 Mariakerke, Belgium).

RESULTS

Controls and HCV-infected patients

Clinical features of the controls and HCV-infected patients are shown in Table 1. Genotypes of HCV-infected patients include type 1a (n = 3), type 1b (n = 83), type 2a (n = 32), and type 2b (n = 14). The distribution of liver fibrosis stages was as follows: F1/F2/F3/F4 (n = 1/61/45/25) and activity score A0/A1/A2/A3 (n = 7/45/55/25). A negative association (r = -0.2277, P < 0.01) was found between mtDNA content and the extent of mtDNA oxidative stress (measured as mtDNA$^{\Delta CT}$) (Figure 1). There were no age or gender differences between the patient and control groups. A lower platelet count and higher hepatitis activity were found in HCV-infected patients (P < 0.01). In addition, the peripheral blood lymphocyte mtDNA copy number in HCV-infected patients was lower (173.5 *vs* 247.93, P < 0.01) and mtDNA$^{\Delta CT}$ was higher (2.92 *vs* 0.67, P < 0.01) than those in the control group.

Alterations in mtDNA copy number in HCV-infected patients

To clarify further the clinical significance of alterations in mtDNA copy number in HCV-infected patients, their association with different clinical parameters was analyzed (Table 2). A negative association was found with elevated aspartate transaminase (AST) levels (r = -0.17, P < 0.05). However, alterations in mtDNA copy number were not associated with the HCV viremia level, HCV genotypes, severity of liver fibrosis, or inflammatory activity in the liver biopsy specimen.

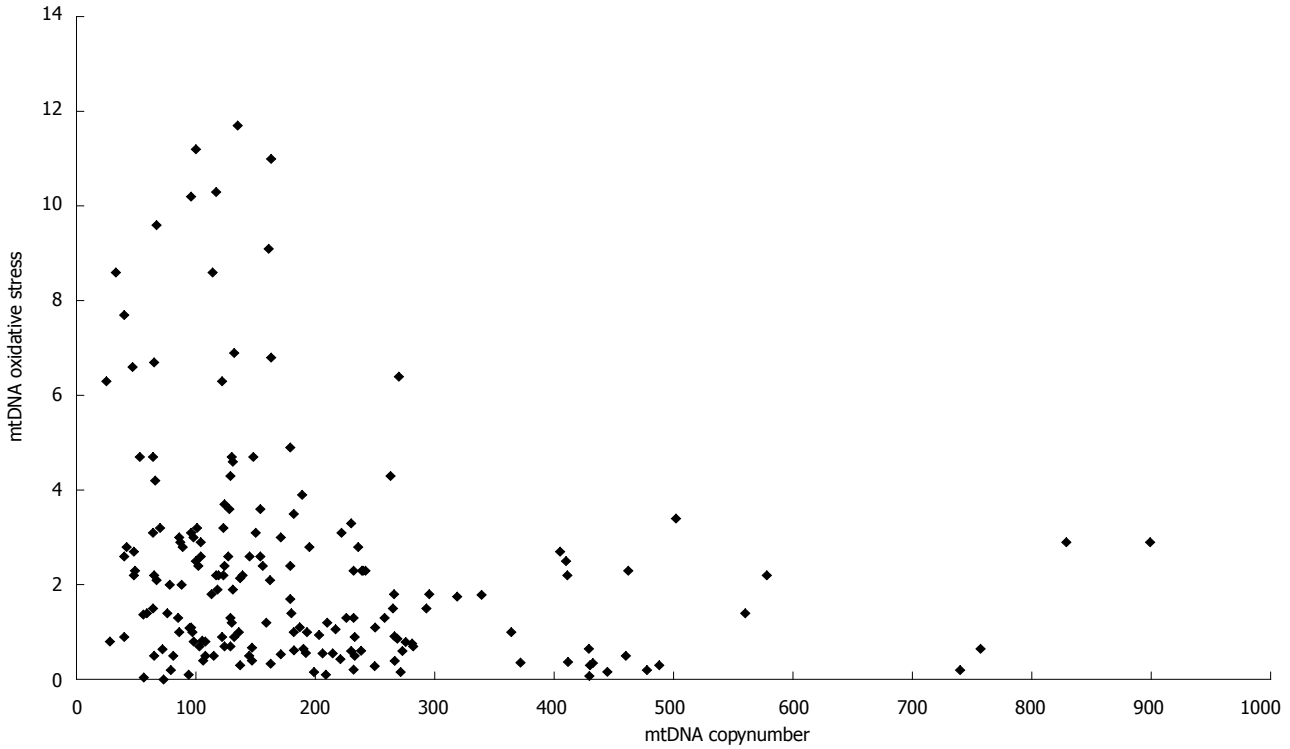

Figure 1 Scatter diagram. A negative correlation is seen between mitochondria DNA (mtDNA) copy number and its oxidative damage index (n = 179, r = -0.24; P < 0.01).

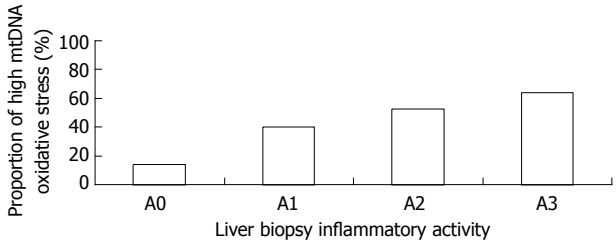

Figure 2 Increased hepatic inflammatory activity is correlated with increased peripheral blood mitochondrial oxidative stress, and mitochondria DNA oxidative damage increased with increased hepatic inflammatory activity (Cochran-Armitage test for trend, P < 0.01). mtDNA: Mitochondria DNA.

Alterations in 8-OHdG content (ΔCt) in HCV-infected patients

To evaluate the clinical significance of alterations in 8-OHdG content in mitochondrial DNA (measured as $mtDNA^{\Delta Ct}$) in HCV-infected patients, their association with different clinical parameters was analyzed (Table 3). Higher $mtDNA^{\Delta Ct}$ suggested higher mitochondrial oxidative stress. A negative association with $mtDNA^{\Delta Ct}$ was observed for decreased platelet count (r = -0.22, P < 0.01). Increased $mtDNA^{\Delta Ct}$ was associated with increased inflammatory activity in liver tissue (r = 0.20, P = 0.02) and the HCV RNA level (r = 0.36, P < 0.01). The trend of mtDNA oxidative damage (low damage: $mtDNA^{\Delta Ct}$ ≤ median $mtDNA^{\Delta Ct}$) increased with increased hepatic inflammatory activity (Cochran-Armitage test for trend, P < 0.01) (Figure 2).

DISCUSSION

This was the first study to detect and compare differences in mtDNA copy number and $mtDNA^{\Delta CT}$ between a normal population and HCV-infected patients.

Oxidative stress and mitochondrial injury have been postulated as mechanisms in the pathogenesis of HCV-related liver injury and subsequent development of cirrhosis or hepatocellular carcinoma. Previous studies have suggested that protein products of hepatitis C, for example, core, NS5A, and NS3 proteins, may directly in-

duce oxidative injury in hepatocytes[2,16]. These proteins cause Ca^{2+} uptake into the mitochondria, oxidation of mitochondrial glutathione, and subsequent production of free radicals by the mitochondrial electron transport complex, and induce apoptosis of HCV-infected hepatocytes[2,17]. Consequently, the extent of mitochondrial injury and the severity of oxidative injury exerted in the liver tissue are correlated with the severity of HCV infection[9]. Barbaro *et al*[9] first studied liver biopsy specimens from 75 HCV-infected patients and 22 normal subjects. Hepatic mtDNA levels were decreased in HCV-infected patients, especially in those with HCV genotype 1, with increased free radical production. These findings were also observed in subsequent studies[18,19]. However, direct measurement of such changes in the liver tissue is difficult and invasive, whereas measurements in peripheral blood are more attractive because they are easier and less invasive. HCV is also lymphocytotropic[20], which accounts for the many immunological manifestations in HCV-related disease. Peripheral blood leukocytes can therefore be used as surrogates for hepatocytes.

Cardin *et al*[13] measured 8-OHdG levels as a marker of DNA oxidative damage in circulating leukocytes from 110 HCV-infected patients and 20 normal subjects and found increased levels in the former, showing that increased oxidative DNA can also be detected in peripheral blood leukocytes. In our previous studies[5,21,22], we found that measurement of the peripheral blood mtDNA copy number was a useful marker of oxidative stress and was associated with differences in disease status. The present study suggests that measurement of the peripheral blood leukocyte mtDNA copy number and oxidative stress can be used as a noninvasive marker of mitochondrial damage in HCV-infected patients. Whether or not this information can be utilized as a biomarker to evaluate the activity or severity of HCV-related liver disease remains unclear.

Blood ALT levels and severity of liver inflammation have been found to correlate with 8-OHdG levels in liver tissue, reflecting oxidative DNA damage in hepatocytes[18,19,23]. However, Chuma *et al*[23] found that 8-OHdG levels in serum tended to correlate with those in liver tissue. In the present study, all HCV-infected patients underwent liver biopsy for pretreatment evaluation, thereby facilitating comparison of mtDNA copy number and oxidative stress in different HCV-infected patient groups in terms of the degree of inflammation or fibrosis. The mtDNA copy number was negatively associated with AST levels, but was not correlated with the severity of liver fibrosis or inflammation. In contrast, $mtDNA^{\Delta CT}$ was correlated with inflammatory activity and HCV viremia levels. This finding suggested that $mtDNA^{\Delta CT}$ in peripheral blood leukocytes can be used as a biomarker to evaluate the severity of hepatocyte injury.

This study had several limitations. First, HCV-infected patients eligible for IFN-based treatment were cases with ALT levels two-fold higher than the normal limit or with a biopsy-proven liver fibrosis score more than F1 determined on the basis of national treatment guidelines that were in effect before 2009. Therefore, use of mtDNA copy number and changes in oxidative markers may not be extrapolated to HCV-infected patients with less severe disease (i.e., ALT levels less than two-fold higher than the normal limit or a fibrosis score lower than F1). A recent report[20] suggested that mtDNA damage can be observed even in occult HCV-infected patients. Further studies are still required to evaluate and compare the clinical significance of mtDNA damage between occult and overt HCV-infected patients. Second, subjects in this study were not followed for subsequent measurement of alterations in mtDNA or liver biopsy following IFN-based therapy. Therefore, changes in mtDNA damage over time among different HCV-infected patient groups remain to be investigated. Mutation or depletion of mtDNA has been implicated in development of several cancers[24-26] through changes in the microenvironment of nuclear DNA that lead to progression of cancer[26]. Several reports have suggested that such oxidative DNA damage in the liver tissue can be a risk factor for the subsequent development of hepatocellular carcinoma[4,23,27]. This also supports the finding that antiinflammatory therapy[28,29], in addition to IFN, can decrease the risk of hepatocellular carcinoma. Further studies are still required to evaluate changes in peripheral leukocyte mtDNA damage over time and the risk of the subsequent development of hepatocellular carcinoma.

In conclusion, oxidative stress and mtDNA damage is detectable in peripheral leukocytes of HCV-infected patients. The degree of peripheral leukocyte mtDNA damage correlated with increased hepatic inflammation. However, further studies are required to explore the long-term clinical significance of these findings in HCV patients.

COMMENTS

Background

The alteration of mitochondria DNA (mtDNA) copy number and its oxidative damage index ($mtDNA^{\Delta CT}$) is associated a different disease status. It is not clear whether such changes can be detected by analysis of peripheral blood cells in hepatitis C virus (HCV)-infected patients.

Research frontiers

Previous studies utilize the liver tissue to evaluate the mitochondria injury in chronic hepatitis C infected patients. In this study, the authors studied the change of mitochondrial injury of peripheral blood cells among HCV-infected patients and normal controls. The authors also use a simplified method to determine the extent of mitochondrial oxidative injury (measured as $mtDNA^{\Delta CT}$) among these two groups of patients. In addition, the authors further study the association of mitochondrial damage with different clinical parameters among HCV-infected patients.

Innovations and breakthroughs

This study aimed to detect and compare differences in mtDNA copy number and $mtDNA^{\Delta CT}$ between a normal population and HCV-infected patients. Oxidative stress and mitochondrial injury have been postulated as mechanisms in the pathogenesis of HCV-related liver injury and subsequent development of cirrhosis or hepatocellular carcinoma. Direct measurement of such changes in the liver tissue is difficult and invasive. In this study, the authors found suggestions

that measurement of the peripheral blood leukocyte mtDNA copy number and oxidative stress can be used as a noninvasive marker of mitochondrial damage in HCV-infected patients.

Applications

The study results suggest that measurement of peripheral blood leukocytes for changes in mitochondrial damage provides an alternative approach to assessing hepatitis C related liver injury.

Peer review

The authors examined the mtDNA copy number and oxidative damage index of mtDNA in the peripheral blood leukocytes of HCV-infected patients in comparison with normal controls. This is an interesting study utilizing unique techniques to determine the copy number of mtDNA and its oxidative damage index. The results are interesting and suggest that oxidative stress and mtDNA damage are detectable in peripheral leukocytes of HCV-infected patients. These findings may lead people to an alternative approach to treatment of HCV infection.

Abstract

AIM: To investigate the symptom presentation and quality of life in obese Chinese patients with gastroesophageal reflux disease (GERD).

METHODS: Data from patients diagnosed with GERD according to the Montreal definition, were collected between January 2009 to March 2010. The enrolled patients were assigned to the normal [body mass index (BMI) < 25 kg/m^2], overweight (25-30 kg/m^2), and obese (BMI > 30 kg/m^2) groups. General demographic data, endoscopic findings, and quality of life of the three groups of patients were analyzed and compared.

RESULTS: Among the 173 enrolled patients, 102, 56 and 15 patients were classified in the normal, overweight, and obese, respectively. There was significantly more erosive esophagitis (73.3% *vs* 64.3% *vs* 39.2%, P = 0.002), hiatal hernia (60% *vs* 33.9% *vs* 16.7%, P = 0.001), and males (73.3% *vs* 73.2% *vs* 32.4%, P = 0.001) in the obese cases. The severity and frequency of heartburn, not acid regurgitation, was positively correlated with BMI, with a significant association in men, but not in women. Obese patients were prone to have low quality of life scores, with obese women having the lowest scores for mental health.

CONCLUSION: In patients with GERD, obese men had the most severe endoscopic and clinical presentation. Obese women had the poorest mental health.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a chronic disease that tends to relapse and develop complications. According to previous studies, the risk factors in patients with GERD include age[1,2], obesity[3,4], hiatal hernia[5,6], and an unfavorable lifestyle, such as alcohol drinking and cigarette smoking. Obesity, defined by a body mass

index (BMI) over 30 kg/m^2, constitutes a public health problem in most industrialized countries, and impairs health-related quality of life[7]. At present, there are few studies on the assessment of quality of life on obese patients with GERD. There might exist a difference in the presentation of symptoms and quality of life between obese and normal weight patients. The aim of the study was to investigate symptom presentation and quality of life in GERD patients with normal or high BMI among a Chinese population in Taiwan.

MATERIALS AND METHODS

Data from consecutive adult patients, older than 18 years, in our hospital, diagnosed with GERD according to the Montreal definition, were collected from January 2009 to March 2010. The Montreal definition of GERD is a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications[8]. Exclusion criteria were as follows: (1) GERD combined with other structural gastrointestinal disorders, such as peptic ulcer disease, esophageal or gastric malignancy; (2) prior gastric and esophageal surgery; (3) use of chronic antacid medication, such as proton pump inhibitors or H2-receptor antagonists, for more than 2 mo prior to enrollment; and (4) pregnancy. This study was conducted with the approval of the Clinical Research Ethics Committee of Taichung Veterans General Hospital.

General data of enrolled patients, including age, gender, BMI, and symptom duration, were recorded. All patients underwent an open-access transoral upper gastrointestinal endoscopy, and details of esophagocardiac mucosal break or hiatal hernia in each case were collected.

The patients were stratified into three groups according to BMI: a normal weight group (BMI < 25 kg/m^2), an overweight group (BMI 25-30 kg/m^2), and an obese group (BMI > 30 kg/m^2). All patients were asked to complete the modified Chinese GERD questionnaire (GERDQ) and the short-form 36 (SF-36) questionnaire (Chinese version).

The modified Chinese GERDQ included with the severity and frequency of symptoms of regurgitation and heartburn, graded on a 3-point Likert scale. Mild, moderate and advanced severity were defined, respectively, as symptoms that can easily be ignored, symptoms that can be easily tolerated, and symptoms sufficient to cause interference with normal activities. Low, middle, and high frequency were classified, respectively, as at least once per month, at least once weekly, and at least once daily[9].

The SF-36 questionnaire measures generic quality of life, which allows comparisons between different disease states. It measures health status in eight domains: physical functioning, role limitations-physical, bodily pain, general health, vitality, social functioning, role limitations-emotional, and mental health. Two summary scores are also calculated from subject responses: the physical health (PH) score and the mental health (MH) score. Scores on the SF-36 range from 0 to 100 on each dimension and on the summary scales, with higher scores indicating better quality of life[10,11].

Data are expressed as mean and standard deviation for each of the measured parameters. Gender and endoscopic findings, including hiatal hernia and erosive esophagitis, are expressed as a percentage of the total patient number. A P value < 0.05 was considered statistically significant. Statistical comparisons were made using Pearson's χ^2 test to compare the effects of gender and endoscopic findings; analysis of variance was used to analyze age, symptom duration, and of questionnaire scores.

RESULTS

A total of 173 consecutive patients were enrolled between January 2009 and March 2010, with 102 (58.9%), 56 (32.4%), and 15 patients (8.7%) assigned to the normal weight, overweight, and obese groups, respectively. As shown in Table 1, there were significantly more women in the normal weight group (67.6%), but significantly more men in the overweight (73.2%) and obese (73.3%) groups. A longer mean duration of GERD symptoms was noted in patients with increased BMI (normal weight group 2.17 mo, overweight group 2.64 mo, obese group 3.15 mo, P = 0.406), although the differences were not significant. The mean age of the cases in these three groups were similar.

The endoscopic findings among the three groups are also summarized in Table 1. The more obese patients had a significantly greater rate of erosive esophagitis (73.3% in the obese group, 64.4% in the overweight group, 39.2% in the normal weight group, P = 0.002), and hiatal hernia (60% in the obese group, 33.9% in the overweight group, 16.7% in the normal weight group, P = 0.001). Furthermore, there was a trend for the rate of esophagocardiac ulcer to be increased in obese patients (13.3% in the obese group, 8.9% in the overweight group, 6.9% in the normal weight group, P = 0.666).

The severity and frequency of heartburn and acid regurgitation, measured by the modified Chinese GERDQ, among the three groups are presented in Table 2. There was significantly greater severity and higher frequency of heartburn in obese patients than in those with normal BMI. In contrast, the severity and frequency of acid regurgitation wer similar among these groups.

The total scores, PH scores and MH scores, measured by the SF-36 questionnaire, are shown in Figure 1. The patients in the obese group tended to have lower scores (mean total score 63.64, PH score 63.44, MH score 58.32), than those in the overweight group (mean total score 65.69, PH score 66.90, MH score 60.20) and in the normal group (mean total score 71.47, PH score 69.02, MH score 66.87), but there was no significant difference among these groups (P = 0.351).

Comparing the endoscopic findings by gender, as

[1]Pearson's χ^2 test; [2]Analysis of variance. ECJ: Esophagocardiac junction; EE: Erosive esophagitis; NERD: Non-erosive reflux disease.

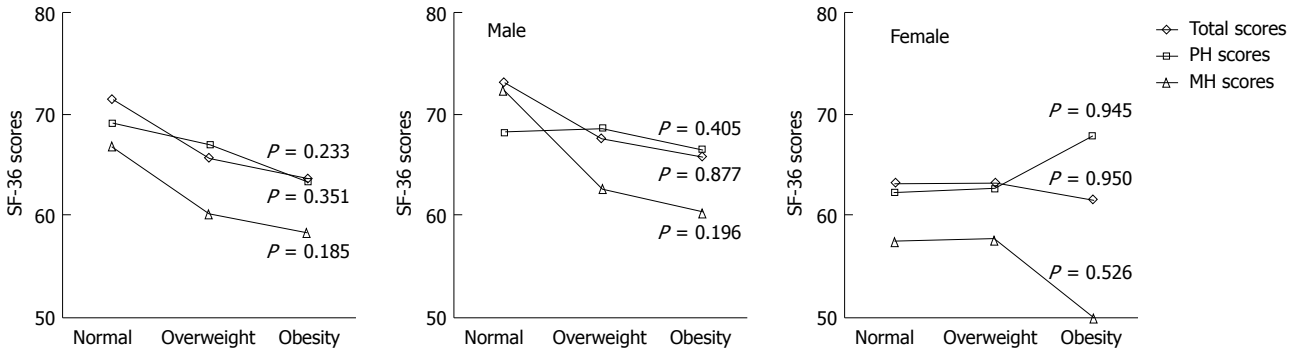

Figure 1 Characteristics of short-form 36 questionnaire scores in obese patients with gastroesophageal reflux disease. SF-36: Short-form 36; PH: Physical health; MH: Mental health.

shown in Table 2, men were more prone to have erosive esophagitis in the overweight (75.6%) and obese (63.6%) groups. In contrast, women had similar rates of erosive eosphagitis, in the normal weight group (39.1%) or the overweight group (33.3%), though all four obese women had erosive esophagitis. The occurrence of hiatal hernia had a significantly positive correlation with obesity in women (P = 0.014), but not in men (P = 0.126).

The severity and frequency of heartburn and acid regurgitation among the three groups of men and women are shown separately in Figure 2. In general, the male cases had more serious symptoms, and there was significantly greater severity and frequency of heartburn in obese males (P = 0.001). In contrast, there were no differences in severity and frequency of heartburn and acid regurgitation among female patients in all groups

The scores of the SF-36 questionnaire in male and female patients are also summarized in Figure 1. The men in the obese group had the lowest scores (mean total score 65.97, PH score 66.33, MH score 60.33), followed

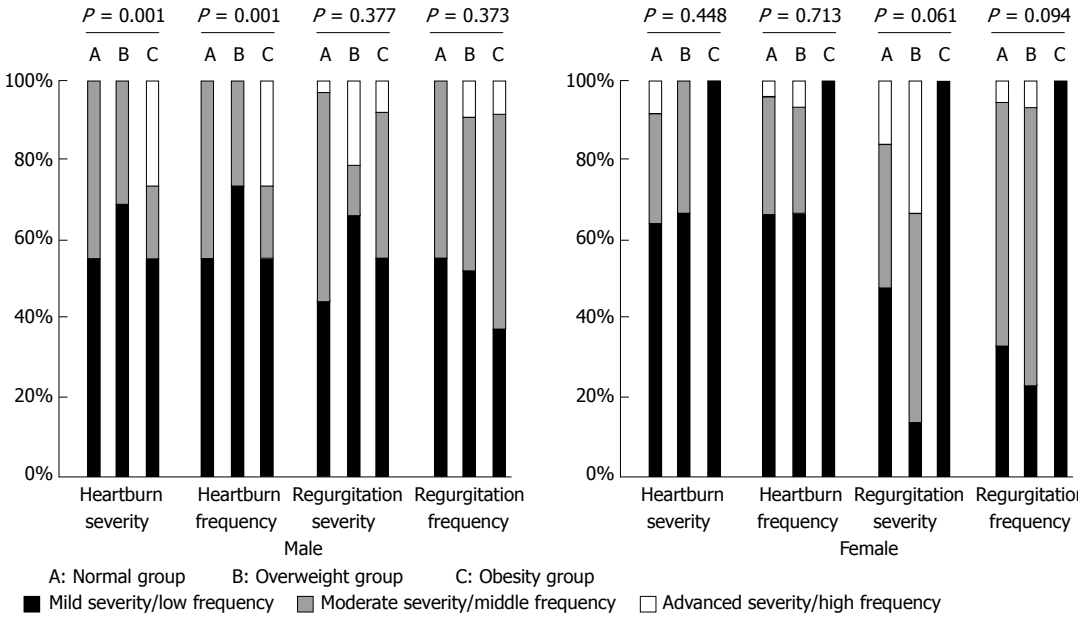

Figure 2 Rates of clinical presentation of symptoms in obese patients with gastroesophageal reflux disease.

by those in the overweight group (mean total score 67.59, PH score 68.61, MH score 62.63) and those in the normal weight group (mean total score 73.27, PH score 68.09, MH score 72.82). In contrast, there were no differences in women's scores among the obese group (mean total score 61.67, PH score 68.02, MH score 49.32), the overweight group (mean total score 63.40, PH score 62.91, MH score 67.81) and the normal weight group (mean total score 63.06, PH score 62.52, MH score 57.59).

DISCUSSION

GERD is a chronic disease which has an impact on the everyday lives of affected individuals, and obesity is found to be a significant risk factor in the development of severe forms of GERD. Changes in gastroesophageal anatomy and physiology caused by obesity may explain the association. Thus, obese patients may experience extrinsic gastric compression by surrounding adipose tissue, and has been associated with significantly increased intra-abdominal pressure[12], impaired gastric emptying[13], decreased lower esophageal sphincter pressure, and increased frequency of transient sphincter relaxation[14,15], leading to increased esophageal acid exposure time[5] .

Obesity is also considered an independent risk factor for the presence of a hiatal hernia[6], which has a role in initiating and promoting GERD. In patients with a hiatal hernia, esophagitis or abnormal low distal esophageal pH were more common than in those without a hiatal hernia[5]. However, after controlling for the presence of hiatal hernia, obesity still remained an independent risk factor for severe esophagitis[3].

In our study, obese patients with GERD had a significantly higher rate of erosive esophagitis and hiatal hernia, but the mean age and GERD symptom duration of these cases were not different. Furthermore, obese men had a more significant association with erosive esophagitis than obese women, but the association of hiatal hernia and obesity was significant only in female patients. Thus, both obesity and hiatal hernia were contributing factors to GERD, but there existed a complicated pathogenesis.

A German study reported that neither the frequency nor the duration of symptoms, including heartburn and acid regurgitation, differed significantly between obese patients and normal body mass cases[16]. Another study reported a positive association between frequency of reflux symptoms and BMI[17]. In addition, an increase in reflux symptoms has been shown to occur in individuals who gain weight, contributing to the epidemiological evidence for a possible dose-response relationship between BMI and increasing GERD symptoms[4].

There were many previous studies discussing the impact of different genders on GERD. One famous study examined a large population-based cohort and found that obese women had an increased risk for GERD symptoms compared with obese men, and the risk was highest in premenopausal women and postmenopausal women receiving estrogen therapy[18]. Other population-based case-control endoscopic studies found a strong and dose-dependent association between BMI and reflux esophagitis, particularly in women rather than men, and hypothesized that this might be caused by increased estrogen activity in overweight and obese females[19,20].

However, several other studies found that the increased risk of acid-related esophageal disease among overweight and obese persons was neither confounded nor modified by gender. For example, a large cross-sectional study found that increased BMI was associated with reflux symptoms, but the relationship differed for different ethnic groups, with a much greater association in whites, but no relationship in the Asian population

in either men or women[21]. A recent systematic review either found no association between gender and GERD symptoms[22]. Thus, the estrogen hypothesis does not explain the gender- or race-related differences in GERD.

Our study documented that both the severity and frequency of heartburn had a positive correlation with BMI, but the symptom of acid regurgitation did not. The relationship was present in male patients, but not in females. A Spanish study in severely obese patients found higher rates of heartburn (46.4%) than acid regurgitation (22.5%), and the frequency of symptoms was higher in men than in women[23], which was similar to our results. The possible explanation of the gender predilection of GERD symptoms in males is that abdominal obesity is characteristic of male pattern obesity, and abdominal obesity is known to be a key factor in both the symptoms and perhaps even the complications of GERD.

The results of our study also found reduced overall quality of life scores, measured by the SF-36 questionnaire, in obese patients with GERD, and the association was observed in male patients, but not in females. Increasing overweight has been associated with a deterioration in quality of life, and the risk of suffering from any longstanding illness is associated with an increased BMI[6]. Obese women perceived markedly more psychosocial problems due to their obesity than men[24]. In our patients, obese women had the lowest MH scores (60.33) among all groups in our study.

There were some limitations in our study. Firstly, the lifestyle characteristics in our study were only limited to the patients' current status, and the past history of each case, such as cigarette smoking and alcohol consumption, was not recorded. Secondly, comorbidity in these patients that tend to influence the severity of GERD, such as chronic heart failure or chronic obstructive pulmonary disease, were not considered, and this might have led to inaccurate outcomes. Thirdly, we only collected the BMI of each patient, but abdominal girth, an indicator of abdominal obesity, might be more correlated with GERD. In addition, a long-term record of BMI would also be necessary to ensure adequate analysis of the relationship of obesity with GERD. Lastly, our study's design was hospital-based and included only a small number of cases. Further research in representative samples of the general population are needed to confirm these results.

In conclusion, in the present study, obese GERD patients were more likely to have higher rates of erosive esophagitis and hiatal hernia, more severe and frequent heartburn symptoms, and a poorer quality of life. Obesity in men was associated with the most severe endoscopic and clinical presentations, but obesity in women had the greatest influence on mental health.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a chronic disease that tends to relapse and develop complications. Obesity constitutes a public health problem in most industrialized countries, and impairs health-related quality of life. At present, there are few studies on the assessment of quality of life performed on obese patients with GERD.

Research frontiers

Body mass index is one risk factor for GERD. The aim of the study was to investigate symptom presentation and quality of life in male and female obese patients with GERD among a Chinese population.

Innovations and breakthroughs

Obese GERD patients had higher rates of erosive esophagitis and hiatal hernia, more severe and frequent heartburn, and poorer quality of life. Obese men had the most severe endoscopic and clinical presentation, while obese women had the poorest mental health.

Applications

The presentations and impact of GERD were apparent in obese patients, but different between men and women. Obese women had the worst quality of life.

Peer review

This is a good descriptive study in which authors investigate the symptom presentation and quality of life in the obese patients with GERD among a Chinese population. The results are interesting and suggest that the obese men owned the most severe endoscopic and clinical presentation, but obese women had the worst mental health.

Abstract

AIM: To compare ghrelin levels in plasma and gastric mucosa before and after *Helicobacter pylori* (*H. pylori*) treatment in children with *H. pylori*-associated functional dyspepsia.

METHODS: Children with *H. pylori*-associated functional dyspepsia were enrolled in this study. *H. pylori* infection was confirmed by positive bacterial culture results. All of the children received triple *H. pylori* eradication therapy (a 2 wk course of omeprazole, amoxicillin, and clarithromycin). The children were divided into two groups based on the success of the *H. pylori* treatment: group 1 (eradicated) - patients who had a negative 13C-urea breath test 2 mo after the end of therapy; and group 2 (non-eradicated) - patients who had a positive 13C-urea breath test. Plasma ghrelin, gastric ghrelin mRNA, and the body mass index were evaluated in both groups before and after the *H. pylori* treatment. The plasma ghrelin levels were measured by a radioimmunoassay. The expression of gastric ghrelin mRNA was determined by real-time reverse transcription polymerase chain reaction.

RESULTS: A total of 50 children with *H. pylori*-associated functional dyspepsia were treated with triple *H. pylori* eradication therapy. The mean age of the children was 5.52 ± 0.83 years, and there were 28 males and 22 females. Among the 50 *H. pylori*-positive children, 30 successfully achieved eradication, and 20 did not. The mean plasma ghrelin levels of group 1 were 22.17 ± 1.73 ng/L and 26.59 ± 2.05 ng/L before and after the treatment, respectively, which was a significant increase (P = 0.001). However, the mean plasma ghrelin level of group 2 before and after the *H. pylori* treatment was 21.34 ± 2.40 ng/L and 22.24 ± 2.10 ng/L (P = 0.785). The plasma ghrelin levels increased substantially after treatment in group 1 but showed only minor changes in group 2. Similarly, the gastric ghrelin mRNA expression in group 1 before treatment was 2.84 ± 0.08. After treatment, the level was 3.11 ± 0.65, which was significantly different (P = 0.023). The gastric ghrelin mRNA expression in group 2 did not change significantly during the treatment (2.82 ± 0.44 *vs* 2.79 ± 0.31, P = 0.875). The plasma ghrelin and gastric ghrelin mRNA levels in group 1 increased substantially after the treatment but did not do so in group 2. In addition, the body mass index the two groups did not differ significantly 2 mo before and after the *H. pylori* treatment.

CONCLUSION: *H. pylori* eradication increases the plasma and tissue ghrelin levels in children with *H. pylori*-associated functional dyspepsia.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is an emerging global health problem. It is regarded as a major cause of chronic gastritis, duodenitis and peptic ulcers. *H. pylori* is generally acquired early in life[1,2]. The prevalence of *H. pylori* infection is higher in children from developing countries than in those from developed countries. *H. pylori* is the major pathogen of the gastrointestinal tract and may also be responsible for dyspeptic symptoms and reduced appetite that can lead to malnutrition and impaired growth[3,4].

The gastrointestinal hormone ghrelin is a recently discovered gut-brain peptide that regulates food intake in humans and has strong growth hormone-releasing activity[5,6]. Ghrelin is composed of 28 amino acids and has been confirmed to both stimulate the hypothalamic appetite center through neuropeptide YNPY/AGRP and to directly regulate gastrointestinal function and appetite[7,8]. In addition, ghrelin enhances gastrointestinal tract motility and accelerates gastric emptying, which explains its appetite-promoting effects[9,10]. Ghrelin is mainly synthesized and secreted by gastric endocrine cells. Thus, chronic persistent damage to the gastric mucosa, which occurs in *H. pylori* infection, may affect ghrelin production and lead to changes in food intake and body weight.

In adults, there are contradictory reports on the relationship between *H. pylori* infection and ghrelin. Some studies have demonstrated that *H. pylori* infection decreased ghrelin secretion[11,12], whereas other studies have reported that *H. pylori* infection has no effect on plasma ghrelin levels[13,14]. There have been only a few small studies evaluating the relationship between ghrelin and *H. pylori* infection in children. A direct relationship between *H. pylori* infection and gastric ghrelin production in children remains to be demonstrated.

Thus, we studied children with *H. pylori*-associated functional dyspepsia (FD) and evaluated their plasma and gastric ghrelin production before and after treating their *H. pylori* infection. FD is a syndrome characterized by chronic and recurrent gastroduodenal symptoms in the absence of any organic or metabolic disease. *H. pylori* infection has been suggested to play a role in the development of FD. FD in patients with *H. pylori* infection is defined as a different disease entity. We recruited FD subjects to minimize any confounding factors that might have affected the study.

MATERIALS AND METHODS

Subjects

This study examined children with FD and *H. pylori* infection that had been confirmed by positive bacterial culture results. The FD diagnosis was based on the Rome Ⅲ criteria[15]. Patients with histopathological examination showed normal mucosa. The children were divided into two groups, depending on the *H. pylori* treatment results: the *H. pylori* eradication group (group 1) and the *H. pylori* failed eradication group (group 2). The patients who had the following symptoms or diseases were excluded from the study: serious infections, heart, lung, kidney or other major organ disorders, use of drugs that may affect the *H. pylori* test results (antibiotics, H2 blockers, proton pump inhibitors and bismuth preparations) and use of corticosteroids. The patients who showed severe gastritis, ulcers or erosion by endoscopy were also excluded.

Endoscopy and biopsy samples

All of the participants underwent an initial upper gastrointestinal endoscopy. Six biopsy specimens were taken from the intact mucosa in the gastric antrum. Two of these specimens were used for bacterial cultures. Another two specimens were used for histological assessment. The remaining specimens were immediately snap frozen and stored in liquid nitrogen for ghrelin mRNA detection.

Radioimmunoassay for serum ghrelin levels

On the day of the endoscopy, blood samples were taken between 8:00 am and 10:00 am after an overnight fast, transferred into tubes containing EDTA and centrifuged. The plasma was then separated and stored at -80 ℃ until needed. The blood samples were taken before and after the *H. pylori* treatment. The plasma ghrelin concentrations were measured by radioimmunoassay.

Real-time reverse transcription polymerase chain reaction of ghrelin

Quantitative reverse transcription polymerase chain reaction was used to detect ghrelin mRNA. cDNA was generated using M-MLV reverse transcriptase (Sangon Biological Engineering Technology And Service Co., Shanghai, China), 1 μg of total RNA as a template and random hexamer priming. The resulting cDNA was amplified using an Exicycler. The real-time PCR analysis was conducted using SYBR® Premix Ex Taq™ and specific primers. The forward ghrelin primer was TGGAGGTCAAGCAGAAGGG, and the reverse primer was GCAGAAGCAAGCGAAAAGC. The mRNA levels were normalized using β-actin.

Bacterial culture and identification

Selective Columbia blood agar (containing 5 mg/L TMP, 10 mg/L vancomycin, 2500 U/L polymyxin and 2 mg/L amphotericin B) was used for the culture. The *H. pylori* identification was based on colony morphology, the catalase and urease tests, and Gram staining to determine the morphological and staining properties.

Table 1 The characteristics of the study population at baseline

	Group 1	Group 2
Number of children (male/female)	17/12	11/10
Age (yr)	6.15 ± 0.74	5.49 ± 0.23
BMI (kg/m^2)	14.7 ± 1.5	15.9 ± 1.7

Group 1: *Helicobacter pylori* (*H. pylori*) eradication group; Group 2: *H. pylori* failed eradication group. BMI: Body mass index.

H. pylori eradication

The *H. pylori*-infected children were treated with omeprazole (20 mg/d), amoxicillin (50 mg/kg per day), and clarithromycin (15 mg/kg per day) for two weeks. The children were not given any other medication after the triple therapy. The *H. pylori* infection status was evaluated using the 13C-urea breath test 2 mo after the end of the therapy.

Follow-up

The patients were followed up 2 mo after the end of therapy. Endoscopy and biopsy sampling were conducted, and plasma was collected again. We monitored serum ghrelin and gastric ghrelin mRNA and assessed the changes in their body mass indexs (BMIs).

Statistical analysis

All of the data were expressed as mean ± SE. The Student's *t* test was used to compare mean. $P < 0.05$ was considered to be significantly different.

RESULTS

From January 2009 to April 2011, we studied 50 children with *H. pylori*-associated FD. The characteristics of the children, including their mean age, gender and BMI, are shown in Table 1. The *H. pylori* therapy was effective in 30 children and failed in 20 children.

In group 1, the plasma ghrelin levels before and after the treatment were significantly different (22.17 ± 1.73 ng/L and 26.59 ± 2.05 ng/L, respectively, $P = 0.001$). However, the plasma ghrelin levels in group 2 before and after the treatment were similar (21.34 ± 2.40 ng/L and 22.24 ± 2.10 ng/L, respectively, $P = 0.785$). The plasma ghrelin levels in group 1 increased substantially after the therapy, but those in group 2 showed only minor changes.

We also compared gastric ghrelin mRNA expression in the two groups before and after the *H. pylori* treatment. Similar to the changes in the plasma ghrelin levels, the gastric ghrelin mRNA expression in group 1 was 2.84 ± 0.08 and 3.11 ± 0.65 ($P = 0.023$) before and after the treatment, respectively, which was significantly different. These values were not significantly different in group 2 (2.82 ± 0.44 and 2.79 ± 0.31, $P = 0.875$).

The plasma ghrelin levels and gastric ghrelin mRNA increased significantly in group 1 but showed inconsistent changes in group 2 (Figures 1 and 2). The plasma ghrelin levels paralleled the gastric ghrelin mRNA expression levels in the *H. pylori* eradication group. These results suggest that attenuating ghrelin production in the gastric mucosa accounts for the decrease in the plasma ghrelin concentrations.

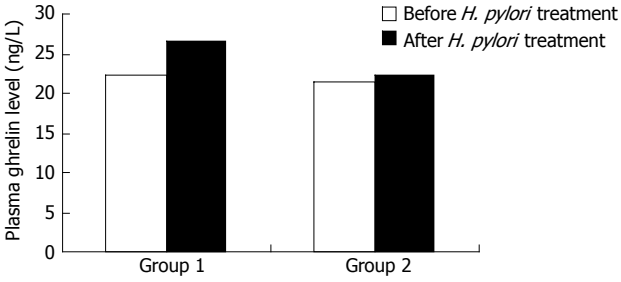

Figure 1 Plasma ghrelin levels before and after the *Helicobacter pylori* treatment in group 1 ($P = 0.001$) and group 2 ($P = 0.785$). Group 1: *Helicobacter pylori* (*H. pylori*) eradication group; Group 2: *H. pylori* failed eradication group.

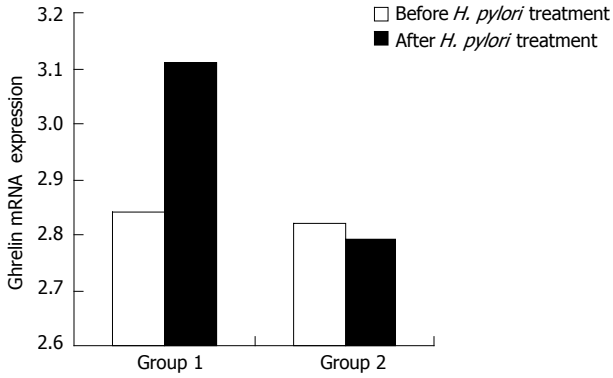

Figure 2 Ghrelin mRNA expression in the gastric mucosa before and after the *Helicobacter pylori* treatment in group 1 ($P = 0.023$) and group 2 ($P = 0.875$). Group 1: *Helicobacter pylori* (*H. pylori*) eradication group; Group 2: *H. pylori* failed eradication group.

The mean BMI in the *H. pylori* eradication group before and after the treatment was 14.7 ± 1.5 kg/m^2 and 15.6 ± 1.2 kg/m^2 ($P = 0.765$), respectively. The mean BMI in the *H. pylori* failed eradication group before and after the treatment was 15.9 ± 1.7 kg/m^2 and 15.5 ± 1.6 kg/m^2 ($P = 0.825$), respectively. Our study found that BMI did not change significantly before and after the *H. pylori* treatment in either group.

DISCUSSION

Our study found that the plasma ghrelin and gastric ghrelin mRNA levels increased significantly in those patients for whom the *H. pylori* treatment was successful and were not significantly different in those patients for whom the *H. pylori* treatment failed. These findings are consistent with those of other studies in which subjects underwent *H. pylori* treatment and had increased plasma ghrelin[16,17] and gastric ghrelin mRNA levels[18].

Inflammation of the gastric mucosa is the one of the important mechanisms of *H. pylori*-induced changes in ghrelin production. However, severe inflammation of the mucosal layers by other factors, such as ulcers and

atrophic gastritis, can also influence ghrelin production. Cummings *et al*[19] found that plasma ghrelin levels were low in a young woman with an evolving autoimmune gastric process. Thus, the change in ghrelin production caused by *H. pylori* infection might be confused with the severe inflammation caused by diseases such as ulcers and atrophic gastritis. Therefore, we recruited FD subjects without severe histopathological changes to minimize the confounding factors and found that ghrelin production increased after *H. pylori* eradication independent of inflammation. Furthermore, diseases such as ulcers, atrophic gastritis and cancer are seen much less frequently in children than in adults, and the host genetic and environmental factors (such as diet, alcohol, and smoking) that play an important role in ghrelin production are more uniform in children. Studies of children can clarify the relationship between *H. pylori* and ghrelin more directly than can studies of adults.

The reports on the influence of *H. pylori* eradication on ghrelin concentrations in children are contradictory. Pacifico *et al*[20] have reported that successful *H. pylori* treatment in children was associated with increased BMI and lean and fat mass but not with increased ghrelin levels, which were actually decreased. These results may suggest that changes in ghrelin levels after the *H. pylori* infection has been cured are epiphenomenal. By contrast, Konturek *et al*[21] found that eliminating *H. pylori* from the stomach using triple eradication therapy resulted in enhanced circulating plasma ghrelin in *H. pylori*-positive shepherds and their children. The discrepancies in the response to *H. pylori* treatment may be related to the strain of *H. pylori*. Patients with the type I strain, which expresses the cytotoxin-associated gene product and vacuolating cytotoxin A virulence factors, have lower circulating ghrelin levels than those with the less virulent type II strain, which does not express these virulence factors[22]. The features of *H. pylori* strains are known to differ between developed and developing countries, and *H. pylori* infection is also known to be associated with socio-economic conditions. The patients in the study by Konturek *et al*[21] were shepherds who may have the same *H. pylori* strain as our patients, and our results are similar to those reported by Konturek *et al*[21].

Ghrelin-producing cells have been found mainly in the oxyntic mucosa of the stomach. Decades of acquired *H. pylori* infection can lead to chronic gastritis and atrophy. Thus, some authors have demonstrated that ghrelin production was influenced by reductions in the number of oxyntic cells caused by atrophy. Cindoruk *et al*[14] have shown that eradicating *H. pylori* has no affect on the plasma ghrelin concentration in patients without atrophy. Osawa *et al*[11] have also suggested that impaired gastric ghrelin production in association with the atrophic gastritis caused by *H. pylori* infection accounted for the decreased plasma ghrelin concentration. There was no evidence of gastric atrophy or intestinal metaplasia in our study. The functional impairment of ghrelin-producing cells due to inflammation, perhaps mediated by cytokines, may account for reduced ghrelin production[23,24]. Recent studies have shown that H. pylori infection causes the release of many pro-inflammatory cytokines, such as interleukin (IL)-1, IL-6 and IL-8, and influences decreases in ghrelin production[25]. Abiko *et al*[26] further confirmed the relationships among H. pylori infection, ghrelin secretion and cytokines. A comparison of the ghrelin level, appetite and body weight of *H. pylori*-infected *IL-1* gene knockout and wild-type mice showed no obvious changes in the knockout mice but significant reductions in the ghrelin level, appetite and body weight of the infected wild-type mice. These results indicated that *H. pylori* infection can affect ghrelin secretion *via* IL-1. Therefore, further investigations are required to understand the relationships among ghrelin, *H. pylori* infection and inflammatory cytokines in children.

Compared with previous studies of children, our study not only demonstrated that plasma ghrelin concentrations were influenced by *H. pylori* eradication but also focused on the gastric mucosa to better understand the effects of *H. pylori* infection on ghrelin expression changes. Increases in gastric ghrelin production may account for the higher concentrations of plasma ghrelin seen after *H. pylori* eradication.

A previous study has reported that BMI increased significantly 12 mo after *H. pylori* eradication[27]. Our study was designed to evaluate ghrelin changes at 2 mo after *H. pylori* treatment and was therefore too short to detect changes in BMI.

The changes in ghrelin production can be related to successfully eradicating the *H. pylori* infection. Ghrelin has also been suggested as a potential marker for *H. pylori* treatment success and may be an indicator of children who should be treated for *H. pylori* infection.

In conclusion, we demonstrated that plasma and gastric tissue ghrelin levels in children are increased after *H. pylori* eradication. *H. pylori* may influence ghrelin production. We also hypothesize that ghrelin may play an important role in the mechanism of *H. pylori*-associated FD in children. Future studies are needed to investigate this hypothesis.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) infection in children is higher in developing country. It not only is the major pathogen of the gastrointestinal tract but also may be responsible for dyspeptic symptoms and reduces appetite that might lead to malnutrition to impair growth. Ghrelin is primarily secreted from the stomach and has been implicated in the coordination of eating behavior and weight regulation. Thus, there exists the possibility that chronic persistent damage of the gastric mucosa, such as *H. pylori* infection, might affect ghrelin production and lead to changes in food intake and body weight. The direct relationship between *H. pylori* infection and gastric ghrelin production is needed to be demonstrated.

Research frontiers

Many studies assessing the relationship between *H. pylori* and Ghrelin in adults have been published but a comparable study in children is lacking. The important area in the study is selected children with *H. pylori*-associated dyspepsia as subjects and evaluates plasma and gastric ghrelin production before and after treating *H. pylori*.

Innovations and breakthroughs

Compared with previous studies in children, the authors' study not only demonstrates that plasma ghrelin concentrations are influenced after *H. pylori* eradication but also focused on the gastric musca to better understand the effects of *H. pylori* infection on the alteration of ghrelin expression. Increases in gastric ghrelin production may account for higher concentration of plasma ghrelin after *H. pylori* eradication. The authors' study also suggested that level of ghrelin can be considered as one of the maker of *H. pylori* successfully or not and can be one of the indication for children *H. pylori* infection therapy. Furthermore, this report provide novel insights for understanding the physiological function of ghrelin and its relation to associated disease.

Applications

The study results suggest that gherlin levels in plasma and gastric tissue in children are increased after *H. pylori* eradication and ghrelin may play an important role in the mechanism of *H. pylori*-associated dyspepsia in children.

Terminology

Ghrelin: Ghrelin is a gastrointestinal hormone and possesses strong growth hormone-releasing activity and is recently discovered gut-brain peptide that regulates food intake of human; Functional dyspepsia: Functional dyspepsia is a syndrome characterized by chronic and recurrent gastroduodenal symptoms in absence of any organic or metabolic disease.

Peer review

This is a novel study in which authors evaluate plasma and gastric ghrelin production before and after treating *H. pylori* in children with *H. pylori*-associated dyspepsia. The results suggest that ghrelin may play an important role in the mechanism of *H. pylori*-associated dyspepsia in children.

Abstract

AIM: To evaluate the predictive value of neutrophil infiltration as a marker of *Helicobacter pylori* (*H. pylori*) infection.

METHODS: A total of 315 patients with dyspepsia symptoms who underwent upper gastrointestinal endoscopy were enrolled in this study. Biopsies were evaluated using the updated Sydney system. The medication history of all patients in the preceding 4 wk was recorded. The diagnosis of *H. pylori* infection was based on ^{13}C-urea breath test at least 4 wk after withdrawal of antisecretory drugs, antibiotics and related drugs. For the patients with subtotal gastrectomy, the diagnosis of *H. pylori* infection was based on anti-*H. pylori* immunoglobulin G (IgG) antibody. Serum anti-*H. pylori* IgG antibody was measured by enzyme-linked immunosorbent assays (Biohit, Finland).

RESULTS: The sensitivity, specificity, positive predictive value and negative predictive value of neutrophil infiltration in the diagnosis of *H. pylori* infection were 92.3%, 83.5%, 77.4% and 94.7%, respectively. Neutrophil infiltration of gastric mucosa in the histological analysis was strongly associated with *H. pylori* infection (77.4% *vs* 5.3% in the neutrophil infiltration negative group, P = 0.000). Moderate neutrophil infiltration was more frequent in *H. pylori* infection when compared to mild infiltration (81.8% and 75%, respectively), but did not reach statistical significance. For those patients with negative rapid urease test, *H. pylori* was detected in 73.2% of patients with positive neutrophil infiltration on histology. In patients with subtotal gastrectomy, the diagnostic accuracy of neutrophil infiltration in *H. pylori* infection was 50%.

CONCLUSION: Neutrophil infiltration is closely associated with *H. pylori* and may be recognized as a sign of this infection.

INTRODUCTION

Detection of *Helicobacter pylori* (*H. pylori*) infection is the first and the most important step in the treatment of *H. pylori*-associated diseases. Urease-based tests, including the rapid urease test (RUT) and $^{13}C/^{14}C$ urea breath test (UBT), are common in the clinical practice of gastrointestinal (GI) diseases. Because of the high prevalence of *H. pylori* infection and high incidence of gastric cancer in China, endoscopy is recommended as the first-line management option for uninvestigated dyspepsia patients[1]. Endoscopy examination can not only diagnose pathological changes in the stomach, but the RUT based on gastric biopsy can detect *H. pylo*ri infection and has the advantages of speed and accuracy. The urea breath test as a non-invasive choice is universally accepted as the "gold standard" for the diagnosis of *H. pylori* infection. However, as urease-based tests, the RUT and UBT have some limitations. Many medications including acid suppressors [e.g., proton pump inhibitors (PPI), H_2-receptor antagonists (H_2RA)], antibiotics and bismuth influence these tests and cause false negative results[2-7]. The detection of *H. pylori* in histology requires experienced pathologists and special staining. It becomes very difficult in cases with a low number of organisms and in cocci-shaped organisms[5,7,8].

In patients with subtotal gastrectomy due to gastric cancer, the examination and treatment of *H. pylo*ri are the key points in preventing the recurrence of gastric cancer. The detection of *H. pylo*ri in patients after gastrectomy is difficult due to low accuracy of the UBT in this situation[9,10].

Some studies have reported that *H. pylori* infection is suggested by the presence of active inflammation[11,12]. Neutrophil infiltration is a hallmark of active inflammation. It is unknown whether neutrophil infiltration may be a marker of *H. pylori* infection. In this survey, we enrolled: (1) randomly-selected patients; (2) patients with neutrophil infiltration but negative-RUT; and (3) patients with subtotal gastrectomy and neutrophil infiltration on routine endoscopy and biopsy histology to explore the predictive value of neutrophil infiltration in the diagnosis of *H. pylori* infection.

MATERIALS AND METHODS

Patients

Patients presenting with upper gastrointestinal symptoms and endoscopically proven functional dyspepsia and scarred ulcer were enrolled into the study from June 2010 to September 2011 in Renji Hospital, Shanghai. Patients with active peptic ulcer and gastric cancer were excluded. A total of three biopsy specimens from the antrum or gastric remnant were taken during each endoscopy. One biopsy was used for the RUT to detect *H. pylori* and the other two biopsies were analyzed histologically. Informed consent was obtained from all patients in the study. Medication in the preceding 4 wk and previous *H. pylori* treatment before endoscopy examination were recorded.

Study design

Study 1: Patients without previous gastric surgery or antibiotic therapy, bismuth, PPI or H_2RA in the preceding 4 wk were included in this study.

Study 2: Only patients with neutrophil infiltration on histological analysis, but negative RUT were candidates for entry into this study. Patients with previous gastric surgery were excluded.

Study 3: Ten subtotal gastrectomy patients with neutrophil infiltration on histological analysis were recruited into this study. Patients who had received previous *H. pylori* eradication therapy or antibiotic therapy, bismuth, PPI or H_2RA in the preceding 4 wk were excluded.

Histology

All specimens for histological analysis were fixed in 10% formalin. An experienced pathologist analyzed the histological features of each sample using hematoxylin and eosin staining and made the diagnosis according to the updated Sydney classification[13]. The histological parameters included histological activity (neutrophil infiltration), chronic inflammation, glandular atrophy and intestinal metaplasia. Active inflammation meant the presence of neutrophil polymorphs in a background of chronic inflammation. Each category (mild, moderate, and severe) resulted in a score on a scale of 0-3 (none, 0; mild, 1; moderate, 2; severe, 3). The pathologist blinded to any clinical information counted the two specimens and calculated the average.

Assessment of H. pylori infection

^{13}C-UBT: ^{13}C-UBTs were performed after endoscopy examination or 4 wk after withdrawal of antisecretory drugs, antibiotics and related drugs. *H. pylori* infection was considered positive when values were $^{13}CO2 \geqslant 4.0‰$ delta over baseline.

Serological antibody test: Blood samples (5 mL venous blood) were taken from each patient prior to endoscopy. These samples were stored before analysis and then centrifuged at -20 ℃. Serum anti-*H. pylori* immunoglobulin G (IgG) antibody was measured by enzyme-linked immunosorbent assays (Biohit, Finland) according to the manufacturer's instructions. The IgG cut-off value which determined samples as Hp-positive was 2.5-80 ng/L.

RESULTS

Characteristics of patients included

A total of 315 patients were recruited in this study, including 261 with functional dyspepsia, 44 with scarred peptic ulcer and 10 with gastric remnant after distal gastrectomy (Table 1). Of the 10 patients with distal gastrectomy, 4 had a history of complicated peptic ulcer

Table 1 Baseline demographic characteristics of subjects

disease and 6 had a history of gastric cancer.

Accuracy of neutrophil infiltration in the diagnosis of H. pylori infection

Study 1: The diagnosis of *H. pylori* infection was based on ^{13}C-UBT. Sixty-two cases were positive for neutrophil infiltration, including 40 with mild and 22 with moderate infiltration. Of these 62 patients, 14 had a negative ^{13}C-UBT and 48 had a positive ^{13}C-UBT. Of the 40 patients with mild neutrophil infiltration, 10 had a negative ^{13}C-UBT and 30 had a positive ^{13}C-UBT. Of the 22 patients with moderate neutrophil infiltration, 4 had a negative ^{13}C-UBT and 18 had a positive ^{13}C-UBT. Seventy-five cases were negative for neutrophil infiltration. Of these patients, 71 had a negative ^{13}C-UBT and 4 had a positive ^{13}C-UBT (Table 2). The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) of neutrophil infiltration in the diagnosis of *H. pylori* infection were 92.3%, 83.5%, 77.4% and 94.7%, respectively. Neutrophil infiltration was strongly associated with *H. pylori* infection (77.4% *vs* 5.3% in the neutrophil infiltration negative group, $P = 0.000$). Moderate neutrophil infiltration was more frequent in *H. pylori* infection when compared to mild infiltration (81.8% and 75%, respectively), however, this difference failed to reach statistical significance.

Study 2: In 168 patients with negative RUT and positive neutrophil infiltration on histological analysis, the diagnosis of *H. pylori* infection was based on positive ^{13}C-UBT. ^{13}C-UBT is the gold standard, and *H. pylori* was detected in 73.2% (123/168) of patients with negative RUT and positive neutrophil infiltration on histology. 27.6% (34/123) of patients had a history of medication use (antibiotic therapy, bismuth, PPI or H_2RA) in the preceding 4 wk. Of 122 patients with mild neutrophil infiltration, 87 had a positive ^{13}C-UBT and the diagnostic accuracy was 71.3%. Of 46 patients with moderate neutrophil infiltration, 36 had a positive ^{13}C-UBT and the diagnostic accuracy was 78.2%.

Study 3: For the patients with subtotal gastrectomy and positive neutrophil infiltration on histological analysis, the diagnosis of *H. pylori* infection was based on positive anti-*H. pylori* IgG antibody. Serum anti-*H. pylori* antibody is the gold standard, and *H. pylori* was detected in 50% (5/10) of patients including 8 with mild neutrophil infiltration and 2 with moderate neutrophil infiltration. The diagnostic accuracy was 50% (Table 3).

DISCUSSION

The accurate diagnosis of *H. pylori* infection is an important step in the treatment of *H. pylori*-associated diseases. However, the outcome of the most commonly used urease-based *H. pylori* tests (RUT and UBT) may be veiled by some drugs and gastrectomy resulting in false negative results. PPIs have a marked influence on gastric pH or *H. pylori* density, inducing bacteria to migrate to atypical sites, thus leading to false negative UBT results as well as false negative RUT results[3,14]. Antibiotics active against *H. pylori* can cause a temporary decrease in the bacterial load and hinder the detection of *H. pylori* infection[5]. Discontinuation of antisecretory drugs and antibiotics four weeks before detection of *H. pylori* is currently recommended[2]. However, it is impractical for some patients suffering from severe symptoms such as acid reflux and upper GI hemorrhage to discontinue drug treatment. Gastrectomy and reconstruction make the UBT unreliable[15]. *H. pylori* is also difficult to detect in cases of extensive intestinal metaplasia[16]. However, detection of *H. pylori* infection is very important for patients with early gastric cancer, peptic ulcer and chronic atrophic gastritis.

H. pylori is found within the mucous gel layer covering the gastric mucosa. It is characterized by infiltration of inflammatory cells into the gastric mucosa which are dependent on the production of proinflammatory cytokines, especially the potent neutrophil chemotactic and activating peptide interleukin (IL)-8[17]. IL-8 is produced by gastric epithelial cells and binds to the extracellular matrix producing a chemotactic gradient that directs neutrophil migration to the epithelial surface. The density of intraepithelial neutrophils is closely related to the extent of mucosal damage and to the intensity of *H. pylori* infection[18-21]. Some researchers have investigated the association between the activity of inflammation and

H. pylori infection and have shown that colonization of the human stomach by *H. pylori* can induce an inflammatory response that is characterized by dense mucosal infiltration by neutrophils[18,22,23]. According to the updated Sydney system, gastric specimens containing neutrophils indicate *H. pylori*-positive patients if a sufficient number of biopsies from both the antrum and corpus are taken[13]. A study by Warren *et al*[24] showed that neutrophils gradually disappeared after starting *H. pylori* treatment. Neutrophils were rapidly detected again if the treatment failed. Without treatment, the changes are life-long. However, there are no studies on the predictive value of neutrophil infiltration as a marker of *H. pylori* infection.

Serology testing is the preferred method for patients with bleeding ulcers and PPI consumption[8]. Fischbach *et al*[25] found that serum IgG, determined by ELISA, was correlated with the histological degree and the activity of gastritis. The antibody absorbance index was correlated with severe activity of gastritis in the antrum, but not with the severity of body gastritis[26]. Vorobjova *et al*[27] reported that seropositivity for CagA antibody was a sign of gastritis activity. In our study, we used anti-*H. pylori* IgG antibody as a standard to diagnose *H. pylori* infection in patients with subtotal gastrectomy. We found that the diagnostic accuracy was 50% for neutrophil infiltration as a marker of *H. pylori* infection in this situation.

Our study showed that the sensitivity, specificity, PPV and NPV of neutrophil infiltration in the diagnosis of *H. pylori* infection were 92.3%, 83.5%, 77.4% and 94.7%, respectively. Neutrophil infiltration was strongly associated with *H. pylori* infection. There was no significant difference between moderate and mild neutrophil infiltration in the diagnosis of *H. pylori* infection. For those with a negative RUT, *H. pylori* was detected in 73.2% of patients with positive neutrophil infiltration on histology.

In patients with subtotal gastrectomy due to a history of complicated peptic ulcer disease and gastric cancer, eradication of *H. pylori* infection can prevent ulcer relapse and metachronous gastric cancer in these patients. However, the UBT is not accurate in this situation and some patients are unable to discontinue medication. In our study, we used anti-*H. pylori* IgG antibody as a standard to diagnose *H. pylori* infection. We found that the diagnostic accuracy was 50% for neutrophil infiltration.

Detection of *H. pylori* infection is key step in the treatment of certain diseases. Medication and gastrectomy can result in false negative urease-based tests for *H. pylori*. Neutrophils are a sensitive indicator of the presence of *H. pylori*. In clinical practice, neutrophil infiltration in the gastric mucosa may provide the clinician with a clue for the diagnosis of *H. pylori* infection.

COMMENTS

Background

The accurate diagnosis of *Helicobacter pylori* (*H. pylori*) infection is the key role in the treatment of *H. pylori*-associated diseases. Urease-based tests, including the rapid urease test and the $^{13}C/^{14}C$ urea breath test, are common in the diagnosis of *H. pylori* infection. However, medications and surgery can cause false negative results in urease-based tests. Gastric mucosa with active inflammation on histology is highly suggestive of *H. pylori* infection and neutrophil infiltration is a hallmark of active inflammation.

Research frontiers

The predictive value of neutrophil infiltration as a marker of *H. pylori* infection was studied, which may provide clinicians with a clue for the diagnosis of *H. pylori* infection in clinical practice.

Innovations and breakthroughs

This study showed that neutrophil infiltration of gastric mucosa on histological analysis was strongly associated with *H. pylori* infection and suggested that neutrophil infiltration may be a sign of this infection.

Applications

The association between neutrophil infiltration and *H. pylori* infection, shown in the present study, may provide clinicians with a clue for the diagnosis of *H. pylori* infection and help them identify false negative results in urease-based tests.

Peer review

In this manuscript, the authors verified neutrophil infiltration of gastric mucosa in histology analysis was strongly associated with *H. pylori* infection and highlighted neutrophil infiltration can be considered as a sign of the infection, which may help the clinicians diagnose the infection of *H. pylori* more accurately.

Abstract

AIM: To evaluate quality of life (QOL) following Ivor Lewis, left transthoracic, and combined thoracoscopic/laparoscopic esophagectomy in patients with esophageal cancer.

METHODS: Ninety patients with esophageal cancer were assigned to Ivor Lewis (n = 30), combined thoracoscopic/laparoscopic (n = 30), and left transthoracic (n = 30) esophagectomy groups. The QOL-core 30 questionnaire and the supplemental QOL-esophageal module 18 questionnaire for patients with esophageal cancer, both developed by the European Organization for Research and Treatment of Cancer, were used to evaluate patients' QOL from 1 wk before to 24 wk after surgery.

RESULTS: A total of 324 questionnaires were collected from 90 patients; 36 postoperative questionnaires were not completed because patients could not be contacted for follow-up visits. QOL declined markedly in all patients at 1 wk postoperatively: preoperative and 1-wk postoperative global QOL scores in the Ivor Lewis, combined thoracoscopic/laparoscopic, and left transthoracic groups were 80.8 ± 9.3 *vs* 32.0 ± 16.1 (P < 0.001), 81.1 ± 9.0 *vs* 53.3 ± 11.5 (P < 0.001), and 83.6 ± 11.2 *vs* 46.4 ± 11.3 (P < 0.001), respectively. Thereafter, QOL recovered gradually in all patients. Patients who underwent Ivor Lewis esophagectomy showed the most pronounced decline in QOL; global scores were lower in this group than in the combined thoracoscopic/laparoscopic (P < 0.001) and left transthoracic (P < 0.001) groups at 1 wk postoperatively and was not restored to the preoperative level at 24 wk postoperatively. QOL declined least in patients undergoing combined thoracoscopic/laparoscopic esophagectomy, and most indices had recovered to preoperative levels at 24 wk postoperatively. In the Ivor Lewis and combined thoracoscopic/laparoscopic groups, pain and physical function scores were 78.9 ± 18.5 *vs* 57.8 ± 19.9 (P < 0.001) and 59.3 ± 16.1 *vs* 70.2 ± 19.2 (P = 0.02), respectively, at 1 wk postoperatively and 26.1 ± 28.6 *vs* 9.5 ± 15.6 (P = 0.007) and 88.4 ± 10.5 *vs* 95.8 ± 7.3 (P = 0.003), respectively, at 24 wk postoperatively. Scores in the left transthoracic esophagectomy group fell between those of the other two groups.

CONCLUSION: Compared with Ivor Lewis and left transthoracic esophagectomies, combined thoracoscopic/laparoscopic esophagectomy enables higher postoperative QOL, making it a preferable surgical approach for esophageal cancer.

INTRODUCTION

China has the highest incidence (13/0.1 million) of esophageal cancer worldwide. Surgery is often the main treatment modality for patients with resectable esophageal cancer because it is potentially curative in up to 40% of cases[1-3]. However, conventional radical surgeries incur a large amount of trauma and result in poor postoperative quality of life (QOL)[4-7]. Recently developed minimally invasive surgical treatments for esophageal cancer, such as laparoscopic surgery, may improve patients' postoperative QOL. We compared postoperative QOL in patients with esophageal cancer who underwent combined thoracoscopic/laparoscopic esophagectomy, conventional Ivor Lewis esophagectomy, or single-incision esophagectomy through the left thorax in our hospital in 2010.

MATERIALS AND METHODS

Participants were selected from a group of 90 patients (62 male, 28 female; aged 46-81 years) treated by the same surgical team under the direction of Jinshi Liu to avoid bias. Inclusion criteria were: patients with resectable esophageal cancer who underwent surgical resection in our hospital between January and December 2010. The postoperative pathological diagnosis was squamous cell carcinoma in all patients. Patients with diabetes mellitus, hypertension, or psychiatric disorders were excluded from the study sample. No participant had received radiotherapy or chemotherapy before surgery, and no tumor showed significant invasion or distant metastasis.

This clinical trial was registered on the Chinese Clinical Trial Registry website (No. ChiCTR-TRC-12001861). The study was approved by the Ethics Committee of our hospital.

The patients were prospectively assigned to one of three surgical treatment groups of 30 patients each based on their order of presentation: Ivor Lewis esophagectomy, combined thoracoscopic/laparoscopic esophagectomy, or left transthoracic esophagectomy (Table 1). We performed bilateral cervical lymphadenectomy in patients with middle thoracic cancer in the Ivor Lewis and combined thoracoscopic/laparoscopic esophagectomy groups because of the survival benefits associated with this procedure[8]. Cervical lymphadenectomy could not be performed in patients undergoing left transthoracic esophagectomy. During the execution of the study, two surgeries had to be converted to open operations because the huge tumor compressed the left principal bronchus, and another case was converted because of extensive pleural adhesion. To avoid bias, we excluded these three patients from the study sample and recruited additional participants to maintain a sample size of 30 patients per group.

Surgery

Combined thoracoscopic/laparoscopic esophagectomy: General anesthesia was administered to each patient with a double lumen tube. The patient was then placed in the left recumbent position, and a thoracoscope camera port was placed at the midaxillary line of the 7th intercostal space. The camera was inserted, and the location of the work port was adjusted under its guidance. In general, the posterior 7th intercostal axillary line and 5th intercostal infrascapular line were selected as main work ports, and the anterior 4th intercostal axillary line as a secondary work port. The intrathoracic esophagus was mobilized while taking care not to damage the bilateral recurrent laryngeal nerve and trachea, and the intrathoracic lymph node was dissected. The patient was then placed in a supine position and the stomach was mobilized under camera guidance. The main work port was generally located 1 cm below the costal arch at the midclavicular line on the right abdominal wall, and the secondary work port was located 40% along a line extending from the navel to the main work port. On the left side, the port was located 1 cm below the left costal arch at the anterior axillary line. After mobilization of the stomach and dissection of the celiac lymph node, a approximately 5-cm-long incision was made in the abdominal wall, the cardia and proximal stomach were lifted manually, and a linear cutter was used to construct a gastric tube. The gastric tube was then returned to the abdomen. Finally, anastomosis was performed at the left cervix with a stapler. If indicated, a bilateral cervical lymphadenectomy was performed.

Left transthoracic esophagectomy: Anesthesia was the same as for combined thoracoscopic/laparoscopic esophagectomy. The patient was placed in the right lateral position and the chest was entered at the 6th or 7th intercostal space according to the disease focus. The diaphragm was opened, the stomach was isolated, and a gastric tube was made. The intrathoracic esophagus was mobilized and local lymph nodes were cleared. Anastomosis was performed above or below the costal arch with a stapler.

Ivor Lewis esophagectomy: Anesthesia was the same as for combined thoracoscopic/laparoscopic esophagectomy. The patient was placed in a supine position and the abdomen was opened. The stomach was mobilized, a gastric tube was made, the celiac lymph node was dissected, and the abdomen was closed. The patient was then placed in a left recumbent position and the chest was entered through the 5th intercostal space. The intrathoracic esophagus was mobilized and local lymph nodes were dissected. Finally, anastomosis was performed at the cupula pleurae or left neck, according to the disease focus. The superior margin of the cancer was located endoscopically. Patients underwent neck anastomosis if the distance between the incisor and the superior margin of cancer was less than 25 cm, and otherwise underwent intrathoracic anastomosis. A bilateral cervical lymphadenectomy was performed in cases of left cervix anastomosis.

The posterior mediastinal route was used in all patients. All patients received thoracic epidural analgesia for 3 d postoperatively.

Evaluation of quality of life

QOL was evaluated in all patients using the quality of life-core 30 questionnaire (QLQ-C30; ver. 3.0, in Chinese) and the supplemental quality of life-esophageal module 18 questionnaire (QLQ-ES18, in Chinese) for patients with esophageal cancer, both of which were developed by the European Organization for Research and Treatment of cancer (EORTC)[9,10]. For this evaluation, each patient was visited in person during hospitalization 1 wk before and 1 wk after surgery, and contacted by telephone at 12 and 24 wk postoperatively. Patients completed the self-administered questionnaires, with the assistance of their physicians and/or relatives in cases of reading or writing difficulty. These assistants explained questions to the patients and recorded responses. Because the patients fasted during the first postoperative week, food intake was not evaluated.

The QLQ-C30 (including the Chinese version) has been used in QOL studies of patients with all kinds of cancer, and has shown good reliability and validity[11,12]. This questionnaire includes a total of 30 items in five functional scales (physical, role, emotional, cognitive, and social), three general symptom scales (fatigue, nausea and vomiting, and pain), one global QOL scale, and six single-item measures of general symptoms or problems (dyspnea, insomnia, appetite loss, constipation, diarrhea, and financial difficulties). Responses to each item are structured on a four-point scale: "not at all" (scored as 1), "a little" (scored as 2), "quite a bit" (scored as 3), and "very much" (scored as 4). The global QOL scale ranges from "very poor" (scored as 1) to "excellent" (scored as 7). Higher functional and comprehensive QOL index scores indicate better functions and QOL, whereas higher symptomatic index scores indicate worse symptoms and lower QOL[13].

The QLQ-ES18 is a QLQ-C30 supplement that is applied specifically to patients with esophageal cancer. This questionnaire contains a total of 18 items assessing symptoms such as dysphagia, reflux, and coughing when swallowing. Responses to each item are structured on the same four-point scale used in the core questionnaire[10]. Blazeby *et al*[10] demonstrated that the QLQ-ES18 had good psychometric and clinical validity, and recommended its use in combination with the core questionnaire, the QLQ-C30, to assess QOL in patients with esophageal cancer. Numerous studies have shown that the combined use of the QLQ-C30 and QLQ-ES18 (including Chinese versions) reflects QOL objectively in patients with esophageal cancer[14-17].

Statistical analysis

Each questionnaire item score was converted linearly to a scale of 1-100 according to the EORTC scoring manual[10,12,18], and means and standard deviations were then calculated. Data were processed using the SPSS software (ver. 13.0; SPSS Inc., Chicago, IL, United States) and QOL indices were compared among groups using the independent-samples *t* test. General patient information was compared among groups using the χ^2 test. $P < 0.05$ was considered statistically significant.

RESULTS

The three groups showed no significant difference in age, sex, average tumor length, or clinical stage.

The mean operation time for left transthoracic esophagectomy (143 ± 23 min) was shorter than those for combined thoracoscopic/laparoscopic esophagectomy (306 ± 67 min; $P < 0.01$) and Ivor Lewis esophagectomy (287 ± 49 min; $P < 0.01$). The amount of blood loss did not differ among the three groups. One case of anastomotic leakage, one incision infection, and one chylothorax occurred postoperatively in the Ivor Lewis group. In the combined thoracoscopic/laparoscopic esophagectomy group, three cases of anastomotic leakage occurred postoperatively. No complication was found in the left transthoracic esophagectomy group (Table 1). The incidence of postoperative complications did not differ among groups, and all patients recovered completely after surgery. All patients were alive at 24 wk after surgery. No cancer recurrence or metastasis was found in any patient during the 24-wk follow-up period.

In total, 324 questionnaires were collected from 90 patients; 36 postoperative questionnaires were not completed because the patients could not be contacted for follow-up visits. No significant difference in QOL indices was found among the three groups at 1 wk before surgery. Compared with preoperative scores, the QOL of all patients had declined significantly at 1 wk after surgery (Figures 1 and 2). Preoperative and 1-wk postoperative global QOL scores in the Ivor Lewis, combined thoracoscopic/laparoscopic, and left transthoracic

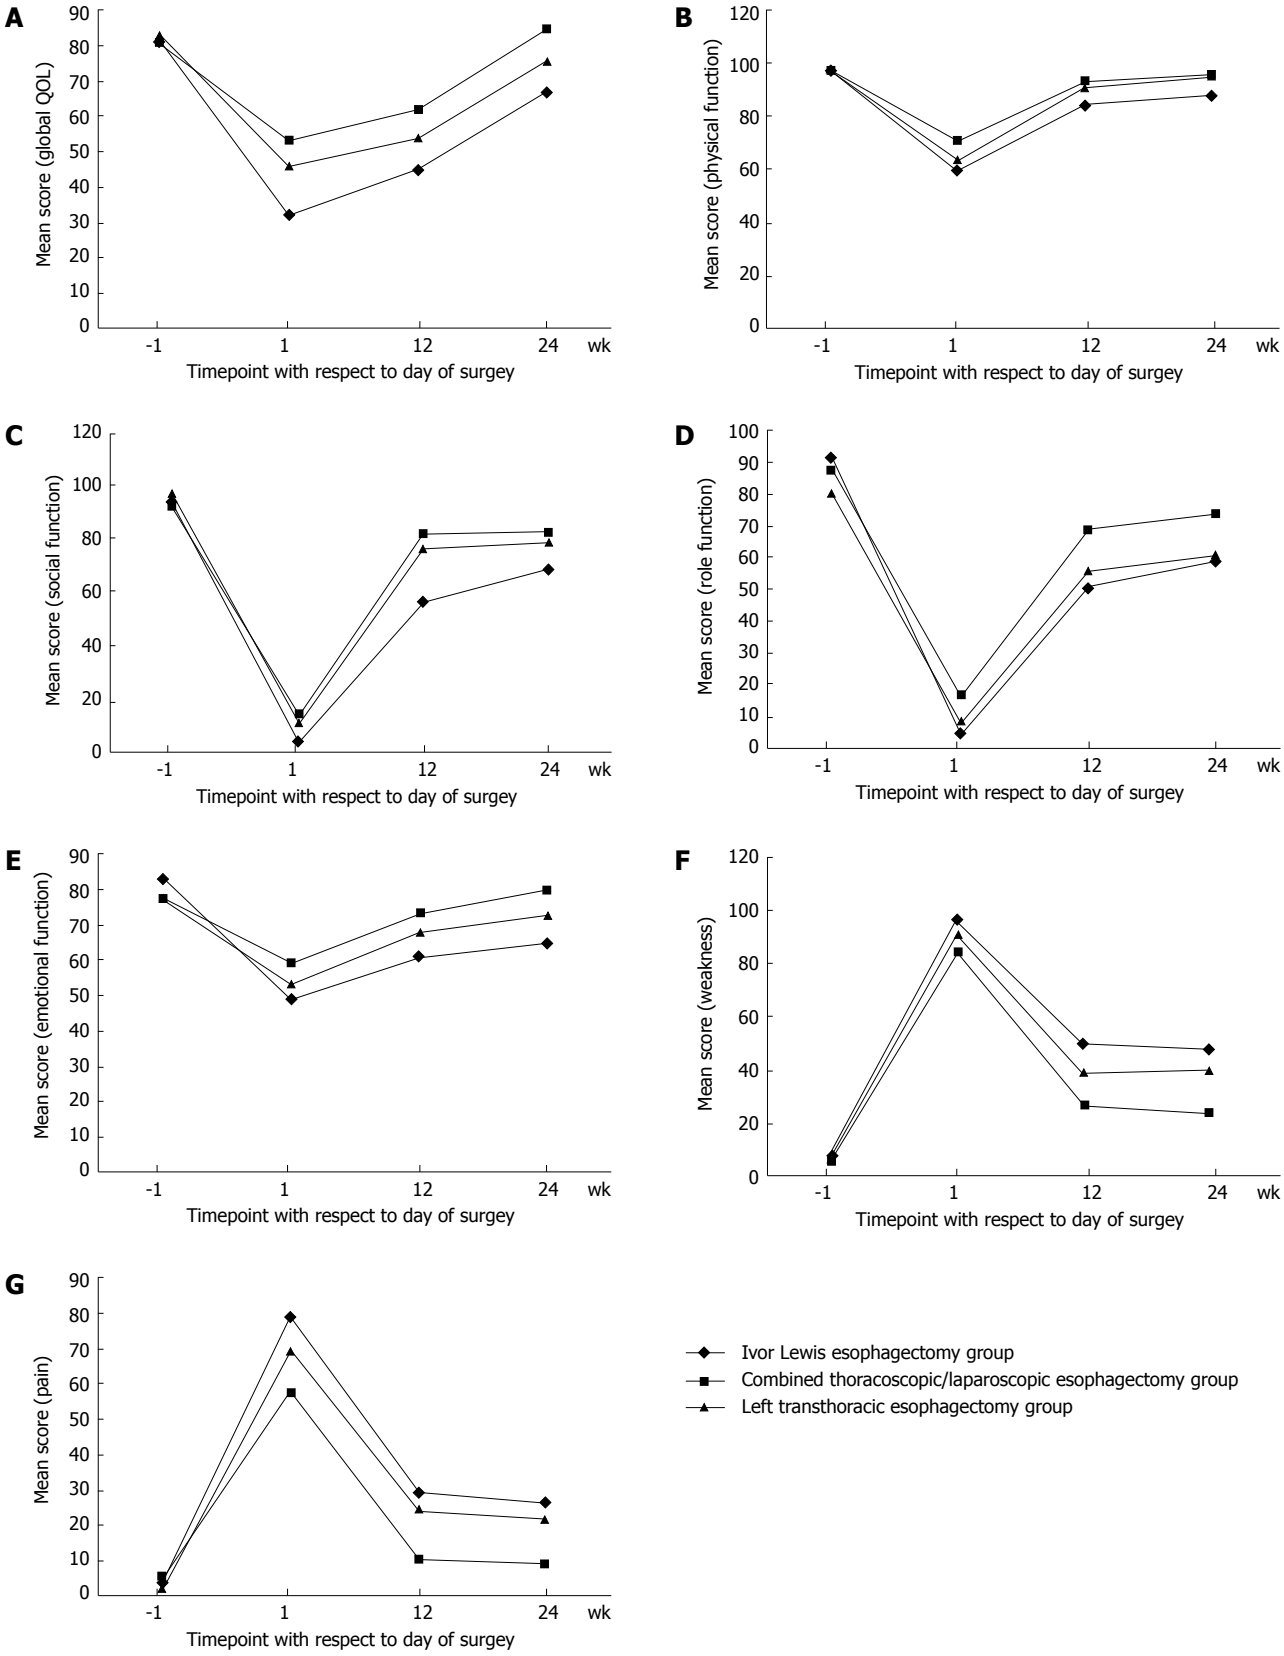

Figure 1 Quality of life, as determined by quality of life-core 30 questionnaire scores at 1 wk before and 1, 12 and 24 wk after surgery, in patients with esophageal cancer undergoing one of three esophagectomy procedures. A: Global scores; B: Physical function; C: Social function; D: Role function; E: Emotional function; F: Weakness; G: Pain. QOL: Quality of life.

groups were 80.8 ± 9.3 *vs* 32.0 ± 16.1, 81.1 ± 9.0 *vs* 53.3 ± 11.5, and 83.6 ± 11.2 *vs* 46.4 ± 11.3, respectively (all $P < 0.001$; Figure 1A). Most functional index scores decreased, with physical, emotional, social, and role scores

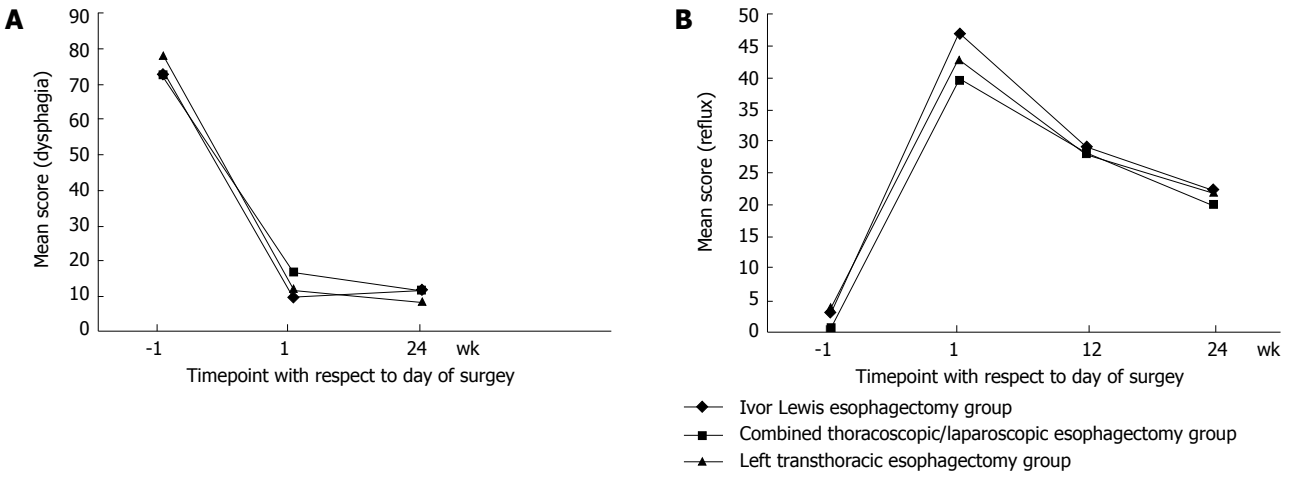

Figure 2 Severity of symptoms associated with esophageal cancer, as determined by quality of life-esophageal module 18 questionnaire scores at 1 wk before and 1, 12 and 24 wk after surgery, in patients with esophageal cancer undergoing one of three esophagectomy procedures. A: Dysphagia; B: Reflux.

showing the greatest declines (Figure 1B-E). The majority of symptomatic index scores, such as pain and weakness, increased (Figure 1F and G). QOL declined most in the Ivor Lewis group, which showed significantly lower physical and emotional function and significantly higher pain index scores compared with the combined thoracoscopic/laparoscopic esophagectomy group (all $P < 0.05$; Figure 1B, E and G). The degree of QOL decline in the left transthoracic esophagectomy group fell between those of the other two groups (Figures 1 and 2).

After surgery, QOL improved gradually in all three groups. All QOL indices were partially restored at 12 wk after surgery. Most functional indices approached preoperative levels in the combined thoracoscopic/laparoscopic esophagectomy group, but QOL status was not restored to preoperative levels in the left transthoracic esophagectomy and Ivor Lewis groups; the Ivor Lewis group showed the worst QOL status. Global QOL scores were higher in the combined thoracoscopic/laparoscopic group than in the other two groups at 1, 12 and 24 wk postoperatively (all $P < 0.05$; Figure 1A). Global QOL scores were higher in the left transthoracic group than in the Ivor Lewis group at 1 and 12 wk postoperatively (both $P < 0.05$), but showed no significant difference at 24 wk after surgery ($P = 0.053$). At 24 wk postoperatively, the incidence rates of pain in the combined thoracoscopic/laparoscopic esophagectomy, Ivor Lewis, and left transthoracic esophagectomy groups were 33.3%, 66.7% and 50%, respectively. All symptoms of dysphagia were alleviated in all groups (Figure 2).

Postoperative reflux occurred frequently after esophagectomy, and reflux scores showed no significant difference among groups during the 24-wk follow-up period. At 24 wk postoperatively, 66.7% of patients in the combined thoracoscopic/laparoscopic esophagectomy group complained of varying degrees of reflux, and rates were similar in the other two groups (Figure 2B).

DISCUSSION

The World Health Organization defined QOL as "an individual's perceptions of their position in life, in the context of the culture and value systems in which they live, and in relation to their goals, exceptions, standards and concerns"[19]. In the treatment of patients with esophageal cancer, more attention is usually given to the operation and postoperative survival rate than to QOL, even during long-term follow-up. However, patients often have many complaints about uncomfortable symptoms during this period; symptoms affecting postoperative QOL thus require further investigation and appropriate treatment. Today, within the context of the bio-psychosocial medical model, postoperative QOL should be included in the evaluation of treatment effectiveness. Unfortunately, not enough has been done in this respect. Thus, for patients with malignant neoplasms such as esophageal cancer, the improvement of QOL is especially important in the absence of a breakthrough in long-term survival rate improvement.

The surgical treatment of esophageal cancer has been a focus of modern medicine for more than 100 years. Given the deep location of the esophagus and the proximity of the intrathoracic esophagus to the heart, lungs, and other vital organs, esophagus substitutes are needed to restore the alimentary tract after the excision of the primary focus, and some doctors have advocated the "three-field esophagectomy" approach[20], such procedures are complex, difficult, and lengthy. Conventional open esophagectomy through the left thorax, a left thoracoabdominal incision or Ivor Lewis esophagectomy through the right thorax require the excision of the ribs and the use of a rib spreader, tearing part of the latissimus dorsi muscle or even severing the serratus anterior muscle. Thus, such surgery can result in major lesions that may not recover well after surgery and affect postoperative QOL. In this study, patients undergoing

left transthoracic or Ivor Lewis esophagectomy showed significant postoperative declines in QOL, and several index scores (i.e., physical, social, and emotional function indices; pain scores) had not recovered well at 24 wk postoperatively. However, patients undergoing left transthoracic esophagectomy showed better postoperative QOL than patients in the Ivor Lewis group, especially with respect to physical function index scores. This result was likely because left transthoracic esophagectomy produces fewer lesions than the Ivor Lewis procedure, the patient's position does not need to be changed during the operation, operation times are shorter, and the clearance is of smaller scope; left transthoracic esophagectomy thus inflicts less bodily harm, which benefits the restoration of postoperative QOL.

In the past 10 years, the updating of the theory of cancer therapy and improvements in technology and equipment, especially the introduction of new endoscopic imaging systems, have provided advantages for esophagectomy and lymphadenectomy such as the ability to perform these procedures under endoscopic guidance. With the accumulation of abundant experience in minimally invasive surgery for esophageal cancer, surgeons' skills, and thereby the clinical effects of these procedures, have improved[21-25]. Wang *et al*[26] compared short-term QOL in patients with esophageal cancer after subtotal esophagectomy *via* video-assisted thoracoscopic surgery or open surgery. They mobilized the stomach with dissection of the celiac lymph node by laparoscopy or laparotomy. However, QOL has not been compared previously in patients with esophageal cancer undergoing combined thoracoscopic/laparoscopic, Ivor Lewis, or left thorax esophagectomy.

Since 2010, when our hospital began to perform combined thoracoscopic/laparoscopic esophagectomy, we have performed this procedure in 50 patients with satisfying results. In this study, we found a smaller decline in postoperative QOL and a more rapid recovery in patients undergoing this procedure than in patients undergoing open esophagectomy, as indicated by symptomatic index and postoperative pain and weakness scores. Chronic pain complaints after thoracic surgery are clinically termed post-thoracotomy pain syndrome (PTPS). As an important QOL index, PTPS is a very common symptom that severely affects patients' satisfaction with life. PTPS represents a significant clinical problem in 25%-60% of patients, and intercostal nerve injury seems to be the most important pathogenic factor[27]. Because of the smaller thoracic wall cut, patients in our cohort experienced less pain after combined thoracoscopic/laparoscopic esophagectomy compared with open surgery. Because combined thoracoscopic/laparoscopic esophagectomy does not require the severing of the latissimus dorsi and serratus anterior muscles, most physical function index scores were restored to preoperative levels at 24 wk after surgery. The recovery of role, emotional, and social functions were also better in these patients than in the other two groups. Many patients scored lower in social and role functions due to postoperative surgical scars; thus, the smaller scars that remain after combined thoracoscopic/laparoscopic esophagectomy may help to restore patients' self-confidence, explaining why patients in this group scored higher than other groups on these two function indices.

A high incidence of postoperative reflux was observed in all of our patients during the 24-wk follow-up period; this might attributed to the elimination of the gastroesophageal sphincter mechanism preventing reflux, the persistence of gastric acid secretion, and the deterioration of esophageal clearance mechanisms[28,29]. In addition, gastric content may readily flow backward into the esophagus in the thoracic cavity due to negative pressure[30]. Although several anastomotic techniques have been used to construct a new antireflux barrier after esophagogastric junction resection[31-34], postoperative reflux after esophagectomy is a problem that warrants further attention and study.

Endoscopic esophagectomy has incomparable advantages given its minimally invasive nature in comparison with conventional surgery, but it also has some shortcomings. The procedure is less intuitive than an open operation, and thus has higher technical requirements for the operator. In cases of a huge tumor, obvious leftward displacement of the thoracic esophagus, or extensive pleural adhesion, endoscopic esophagectomy is very difficult to perform. As reported above, three cases in our series had to be converted to open operations for these reasons. However, with the continuous development of endoscopic equipment and improvement of surgical techniques, higher success rates of endoscopic esophagectomy are expected.

The currently leading viewpoint guiding the treatment of esophageal cancer is that the prognosis of this systemic disease depends mainly on biological activities and pathologic stage, whereas surgical treatment provides only local therapy. Thus, current surgical techniques of all types, including access through the left or right thorax and the use of one to three incisions, have little impact on patients' long-term survival[35,36]. Thus, if indications are precisely defined, appropriate cases are selected, and endoscopically guided operation skills are perfect, minimally invasive surgery should achieve long-term survival rates similar to those of open surgery[37,38]. Lazzarino *et al*[39] compared patients' survival status after minimally invasive or open esophagectomies performed in England between 1996 and 2007, and found better 1-year survival rates in patients undergoing minimally invasive procedures. On the basis of those findings, we performed minimally invasive surgery whenever possible for patients with esophageal cancer to improve their postoperative QOL. If camera-guided surgery is not available, an appropriate open surgical technique should be chosen according to the disease focus. For patients with distal esophageal cancer lacking evident mediastinal lymph node metastasis, we found that single-incision left transthoracic esophagectomy was much easier and pro-

duced fewer lesions. When the focal location is high or subcarinal lymph nodes or bilateral recurrent laryngeal nerves need to be cleared, the more thorough Ivor Lewis technique should be chosen.

This study had some limitations. The assignment of patients to the three groups was not strictly randomized, but was based on patients' order of presentation. Furthermore, endoscopic esophagectomy was a new operation carried out in our hospital during the study period, and surgical proficiency increased gradually. These factors may have introduced biases in the analysis. The 24-wk follow-up period was also relatively short and the sample size was small, preventing the comparison of long-term curative effects for these different esophageal cancer treatments. To evaluate long-term effects and survival rates, larger samples and further observation are needed.

COMMENTS

Background

Conventional radical operations for esophageal cancer incur a large amount of trauma and result in poor postoperative quality of life (QOL). The improvement of postoperative QOL in patients with esophageal cancer is particularly important in the absence of a breakthrough in long-term survival rate improvement.

Research frontiers

Recently developed minimally invasive surgical treatments for esophageal cancer, such as laparoscopic surgery, may improve postoperative QOL in patients with esophageal cancer.

Innovations and breakthroughs

In the past 10 years, the updating of the theory of cancer therapy and improvements in technology and equipment, especially the introduction of new endoscopic imaging systems, have provided advantages for esophagectomy and lymphadenectomy such as the ability to perform these procedures under endoscopic guidance. The authors compared postoperative QOL in patients after endoscopically guided esophagectomy or one of two other conventional open surgeries.

Applications

Compared with Ivor Lewis and left transthoracic esophagectomies, the study results suggested that combined thoracoscopic/laparoscopic esophagectomy resulted in higher postoperative QOL, making it a preferable surgical approach for esophageal cancer.

Terminology

QOL was defined by the World Health Organization as "an individual's perceptions of their position in life, in the context of the culture and value systems in which they live, and in relation to their goals, exceptions, standards and concerns."

Peer review

This is a good clinical study in which the authors compare patients' QOL following endoscopic esophagectomy or one of two other conventional open surgeries. The results are instructional and suggest that, in terms of postoperative QOL, combined thoracoscopic/laparoscopic esophagectomy is a preferable surgical approach for esophageal cancer.

Abstract

AIM: To investigate health-related quality of life (HRQoL) and psychological outcomes in 256 adults who had undergone liver transplantation (LT).

METHODS: A stratified random sampling method was used in this follow-up multicenter study to select a representative sample of recipients undergoing either living donor liver transplantation (LDLT) or deceased donor liver transplantation (DDLT). HRQoL was measured by using the Chinese version of Medical Outcome Study Short Form-36 (SF-36), and psychological outcomes by using the beck anxiety inventory (BAI) and the self-rating depression scale (SDS). Clinical and demographic data were collected from the records of the Chinese Liver Transplant Registry and *via* questionnaires.

RESULTS: A total of 256 patients were sampled, including 66 (25.8%) receiving LDLT and 190 (74.2%) undergoing DDLT; 15 (5.9%) recipients had anxiety and four (1.6%) developed severe depression after the operation. Compared with LDLT recipients, DDLT patients had higher scores in general health (60.33 ± 16.97 *vs* 66.86 ± 18.42, $P = 0.012$), role-physical (63.64 ± 42.55 *vs* 74.47 ± 36.46, $P = 0.048$), role-emotional (61.11 ± 44.37 *vs* 78.95 ± 34.31, $P = 0.001$), social functioning (78.60 ± 22.76 *vs* 88.16 ± 21.85, $P = 0.003$), vitality (70.30 ± 15.76 *vs* 75.95 ± 16.40, $P = 0.016$), mental health (65.88 ± 12.94 *vs* 71.85 ± 15.45, $P = 0.005$), physical component summary scale (PCS, 60.07 ± 7.36 *vs* 62.58 ± 6.88, $P = 0.013$) and mental component summary scale (MCS, 52.65 ± 7.66 *vs* 55.95 ± 10.14, $P = 0.016$). Recipients > 45 years old at the time of transplant scored higher in vitality (77.33 ± 15.64 *vs* 72.52 ± 16.66, $P = 0.020$), mental health (73.64 ± 15.06 *vs* 68.00 ± 14.65, $P = 0.003$) and MCS (56.61 ± 10.00 *vs* 54.05 ± 9.30, $P = 0.037$) than those aged ⩽ 45 years. MCS was poorer in recipients with than in those without complications (52.92 ± 12.21 *vs* 56.06 ± 8.16, $P = 0.017$). Regarding MCS (55.10 ± 9.66 *vs* 50.0 ± 10.0, $P < 0.05$) and PCS (61.93 ± 7.08 *vs* 50.0 ± 10.0, $P < 0.05$), recipients scored better than the Sichuan general and had improved overall QoL compared to patients with chronic diseases. MCS and PCS significantly correlated with scores of the BAI ($P < 0.001$) and the SDS ($P < 0.001$).

CONCLUSION: Age > 45 years at time of transplant, DDLT, full-time working, no complications, anxiety and depression were possible factors influencing postoperative HRQoL in liver recipients.

INTRODUCTION

Liver transplantation (LT) has been an established therapy for various end-stage liver diseases for more than three decades. Aside from the role of ensuring the survival of individuals with liver disease, LT also offers patients the health they enjoyed prior to the disease, achieving a good balance between the functional efficacy of the graft and the patient's mental and physical integrity. Satisfactory overall long-term outcomes have been reported by many transplant centers around the world[1-3]. Saab *et al*[4] have reported that most patients were able to resume occupation early after liver transplantation. In addition, a Portuguese study showed that the majority of recipients could enjoy improved post-LT mental health[5]. However, Kousoulas *et al*[6] have published their results that patients who survived > 15 years after orthotopic LT demonstrated poor quality of life (QoL). It has also been suggested by de Kroon *et al*[7] that some patients exhibit physiological or psychological difficulties irrespective of favorable overall HRQoL.

Discordant conclusions with regard to post-LT overall QoL drawn from transplant centers have resulted in studies to identify potential influencing factors of health-related QoL (HRQoL). More than 10 years survival[8] and male sex[9] have been found to contribute to better post-LT QoL among recipients. Additionally, many studies have reported equivalent recipient results with living donor LT (LDLT) *vs* deceased donor LT (DDLT) in adult recipients. This was mainly indicated by similar short-term patient survival rates in both groups[10]. However, few studies have focused on the relationship of QoL, severity of depression, and incidence of anxiety. Thus, more careful analysis is warranted to ensure that a meaningful comparison is being made. The present study sought to evaluate carefully the HRQoL and psychological outcomes of adult recipients who underwent DDLT or LDLT between 2001 and December 2010 in Sichuan Province, China. We also aimed to establish the potential factors influencing QoL in our recipients after transplantation. In addition, comparisons of Short Form-36 (SF-36) scores were made between our sample and those of the Sichuan general population, patients with chronic illness, and 126 healthy controls.

MATERIALS AND METHODS

Follow-up model

To keep track of our recipients after transplantation and help them enjoy good physical and psychosocial recovery, our center developed its own follow-up model. At discharge, patients and their family members were lectured about what to pay attention to in daily life. It was also suggested that patients visit their doctors monthly in the first 6 mo, every 2 mo in the second 6 mo, and quarterly beyond 12 mo. In addition, patients were welcome to contact our transplant panel or their regular physicians by mail, telephone or fax if they had any transplant-related difficulties or it was inconvenient to come back. Regular contact was made to maintain follow-up in recipients. As soon as abnormalities were identified, patients underwent further examination or intervention or even readmission if necessary. Besides, an annual reunion was held to update our patients with information pertinent to medication and daily care, as well as to facilitate professional consultation. Simultaneously, sharing of feelings about surgery and postoperative life, experience of daily care, and maintaining good QoL were encouraged at the annual reunion. Therefore, no patient was lost to follow-up.

Study population and design

The study was designed as a follow-up multicenter study. A stratified random sampling technique was used to select a representative sample of recipients who underwent LT between 2001 and December 2010. Recipients aged ⩾ 18 years, with the ability to understand Chinese, who had undergone LT > 6 mo previously and had no severe complications or limited ability for self-expression were eligible for inclusion. A total of 300 recipients were selected; among whom 14 died at the time of investigation, 10 were < 18 years old, eight had received LT < 6 mo previously, five spoke their own ethnic language, six had severe medical complications or rejection, and one was diagnosed with schizophrenia. The resulting study sample included 256 recipients with 66 receiving LDLT and 190 receiving DDLT.

Clinical and demographic data were collected from records of the Chinese Liver Transplant Registry. Self-reported questionnaires (completed by interview or mail) were used to evaluate QoL and psychological outcomes.

Instruments

QoL was assessed using the validated Chinese version of the Medical Outcomes Study SF-36[11]. The SF-36 is a validated self-administered questionnaire used internationally to measure eight domains of health: physical functioning, role-physical, bodily pain, general health, vitality, social functioning, role-emotional, and mental health during the past 12 mo. The raw scores of each subscale were converted to scores that ranged from 0 to 100, with higher scores indicating higher levels of functioning or well-being. The level of HRQoL was assessed by comparing the mean value for the study sample with that for a representative sample of the general population of Sichuan Province[12]. The eight scale scores were aggregated into the norm-based physical and mental

component summary (PCS and MCS) scores that had a population mean of 50 and standard deviation of 10.

Beck anxiety inventory

This is a self-report assessment[13] in which each subscale consists of 21 items that are rated along a four-point Likert scale ("never", "sometimes", "often" or "always"). The participants were required to rate each item in the scale that best represented their current mood, especially during the past 2 wk. The established cut-point of $\geqslant 45$ corresponded to the likelihood of anxiety disorder.

Self-rating depression scale

The Zung *et al*[14] self-rating depression scale (SDS) was used in our study. It was a short self-administered survey to quantify the depressed status of a patient. There were 20 items on the scale that rated the four common characteristics of depression: the pervasive effect, the physiological equivalents, other disturbances, and psychomotor activities. There were 10 positively worded and 10 negatively worded questions. Each question was scored on a scale of 1-4 (based on these replies: "a little of the time", "some of the time", "good part of the time", "most of the time"). The ratio of the raw scores on the test > 80 was coined SDS indices, which are usually applied to assess the severity of the depressive symptoms of a patient. The SDS indices fell into four ranges: (1) < 0.50 normal; (2) 0.50-0.59 minimal to mild depression; (3) 0.60-0.69 moderate depression; and (4) $\geqslant$ 0.70 severe depression.

Ethical consideration

The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and hence was approved by our Hospital Ethics Committee. All participants were asked to sign an informed consent form. There were no organs from prisoners and no subjects were prisoners.

Statistical analysis

Statistical analysis was performed using SPSS statistical software, version 17.0. Scores from recipients were respectively compared with that from the Sichuan general population; from patients with other chronic medical conditions, including type 2 diabetes mellitus[15], chronic hepatitis B[16,17]; and from 125 healthy persons[18]. Between-group differences in QoL were tested with independent-sample Student *t* test, analysis of variance, or nonparametric test as appropriate. Multiple comparisons for observed means were tested using the Student-Newman-Keuls procedure for which equal variances could be assumed and by the Games-Howell procedure when they could not be assumed. Pearson correlation analysis was used to analyze the relationships between the level of QoL and psychological outcomes. A probability value of $P < 0.05$ was taken to represent a significant difference.

HCC: Hepatocellular carcinoma; DDLT: Deceased donor liver transplantation; LDLT: Living donor liver transplantation.

RESULTS

Recipient characteristics

Informed consent for participation was obtained from all recipients and they all completed the validated questionnaires by interview or mail. The results from questionnaires completed by interview versus mail were not significantly different. The demographic and transplant-related characteristics of the study population are listed in Table 1. Most recipients were ⩽ 45 years at the time of transplantation (59.0%), were male (82.4%), had attained a higher education level (52.0%), and suffered from hepatic cirrhosis (55.5%). Many recipients remained or got married after transplantation (94.1%) and earned a salary between 1000 and 3000 RMB/mo (59.8%). Among our participants, 30.5% reported that they experienced early or late post-transplant complications including biliary events, endocrine disorders, physical or psychiatric problems, and 38.3% had received a liver transplant > 5 years ago, three of whom were > 10-year survivors. Roughly equal numbers of recipients

Table 2 Psychological outcomes after transplantation

BAI/SDS scores	Frequency	mean ± SD (%)
BAI		30.26 ± 7.44
< 45	241	94.1
⩾ 45	15	5.9
SDS		0.49 ± 0.11
< 0.5	114	44.5
⩾ 0.5, ⩽ 0.59	104	40.6
⩾ 0.6, ⩽ 0.69	34	13.3
⩾ 0.7	4	1.6

BAI: Beck anxiety inventory; SDS: Self-rating depression scale.

engaged in three post-transplant employment statuses (full-time, part-time and no employment). The majority of recipients (98.4%) insisted on regular follow-up with their regular physicians or community clinics. Approximately 74.2% of the recipients underwent DDLT and 25.8% received LDLT, all of whom were related to their donors.

Post-transplant QoL and psychological outcomes

Beck anxiety inventory (BAI): A mean score of 30.26 was obtained among 256 recipients, 15 (5.9%) of whom scored ⩾ 45 on the BAI, indicating the possibility of post-LT anxiety disorder (Table 2).

SDS: The SDS index reached an average level of 0.49 in our study sample**.** It was suggested that 142 out of 256 study participants exhibited depressive symptoms, with 104 mild, 34 moderate and four severe (Table 2).

Medical outcome study SF-36: In the general health (P = 0.012), role-physical (P = 0.048), role-emotional (P = 0.001), social-functioning (P = 0.003), vitality (P = 0.016), mental health (P = 0.005), PCS (P = 0.013) and MCS (P = 0.016) domains, recipients receiving DDLT scored higher than those undergoing LDLT. Patients aged ⩽ 45 years at the time of transplant scored lower than those > 45 years in vitality (P = 0.020), mental health (P = 0.003) and MCS (P = 0.037). MCS scores were lower in recipients with than without complications (P = 0.017). Recipients who resumed full-time employment scored higher in general health (P = 0.038), physical-functioning (P = 0.003), social-functioning (P = 0.018), bodily pain (P = 0.005), vitality (P = 0.038) and PCS (P = 0.001) than those who undertook part-time jobs or gave up working after transplantation (Table 3).

Scores from recipients were lower in physical-functioning (P < 0.001), role-physical (P = 0.001) but higher in vitality (P = 0.003), mental health (P = 0.001), PCS (P < 0.001) and MCS (P < 0.001) compared with that from Sichuan general population. Recipients had higher scores in general health (P < 0.001), social-functioning (P < 0.001), bodily pain (P < 0.001), vitality (P < 0.001), PCS (P < 0.001) and MCS (P < 0.001) than patients with chronic hepatitis B. In general health (P < 0.001), physical-functioning (P < 0.001), role-physical (P < 0.001), social-functioning (P < 0.001), bodily pain (P < 0.001), mental health (P = 0.001), patients after liver transplantation scored lower that the healthy controls. Compared with patients with type 2 diabetes mellitus, recipients had lower scores in physical-functioning (P = 0.001) and mental health (P < 0.001), as well as higher scores in role-physical (P < 0.001), role-emotional (P < 0.001), social-functioning (P < 0.001), bodily pain (P = 0.023) and vitality (P < 0.001) (Table 4).

The correlation coefficients between PCS and MCS scores of the SF-36 and the scores of BAI or SDS respectively are presented in Table 5. Both PCS and MCS were significantly correlated with the scores of BAI (P < 0.001) as well as the severity of depression based on the SDS (P < 0.001).

DISCUSSION

HRQoL, is a multifaceted construct of physiological and psychosocial aspects of well-being. Integrity of this construct represents an important measure of the success of a medical intervention beyond simple high survival rates, because HRQoL involves every single detail of a person's daily activity and social functioning. As a result, HRQoL of recipients undergoing LT has been increasingly valued. Earlier studies[19-21] have shown that DDLT contributes greatly to improved QoL. Emerging as a life-saving alternative because of organ shortage worldwide, LDLT has also enabled patients to achieve better QoL after than before surgery[22]. The present study aimed to investigate HRQoL in recipients undergoing either DDLT or LDLT.

Established evidence shows that a high level of post-LT anxiety is harmful in the long term to the well-being of the recipients[23], and depressive symptoms after LT are associated with an increased risk of long-term mortality[24]. Fortunately, the incidence of anxiety in our sample was low (5.9%) and those exhibiting severe depressive symptoms after surgery only accounted for a small proportion (4/256). Nevertheless, a high incidence of depressive symptoms (142/256) among recipients should not be underappreciated because of the low incidence of severe depression, because the frequency of depressive symptoms can impair QoL in liver recipients[25]. As a result, longitudinal studies and prolonged follow-up are required to disclose other possible factors that might undermine the psychological health of recipients.

In our study, patients receiving DDLT had significantly higher scores than those undergoing LDLT in the majority of domains on the SF-36. Smaller sample size in LDLT population could be one possible reason. Additionally, it was reported that total comprehensive cost[26], incidence of complications[27-30], rehospitalization rate[27], and HCC recurrence[31,32] were higher in LDLT than DDLT recipients. Higher blood level of tacrolimus in LDLT recipients was also pointed out, which indicated higher incidence of adverse effects[33]. These factors might all contribute to the poorer QoL in LDLT

than DDLT recipients. However, these factors were not considered in the preliminary study design and hence further studies are warranted.

Employment is one measure of the ability to resume normal physical and socializing well-being. It has been shown that lack of disability income coverage prior to transplantation and high physical functioning[4], age and approaching retirement[12] are correlated with post-transplantation occupation. Among our 256 transplant recipients, age and worry about doing harm to the graft were the main reasons for part-time work status and unemployment instead of full-time work. Interestingly, recipients undertaking full-time work enjoyed better physical health than the other two according to the SF-36, regardless of higher scores for bodily pain. Early involvement in social activities and full-time work facilitate recipients normal physical and psychosocial well-being.

Other factors, including age and complications may

affect some QoL subscales. Age > 45 years at the time of transplant and no complications indicated better mental health in recipients. Duffy *et al*[1] have shown that age < 18 years at the time of transplantation was associated with improved long-term survival, and Jin *et al*[12] have concluded that post-transplant medical complications did not affect QoL or psychological outcomes.

In our study, sex, etiology of disease, time since transplant, marital status after transplant surprisingly turned out not to be associated with HRQoL in recipients after transplantation. Our results were in contrast with previous studies[1,12,34].

Regarding the SF-36, our sample had comparable scores in most domains to the Sichuan general population and scored significantly higher in both PCS and MCS. Our results were consistent with earlier studies[2,35,36]. A systematic review demonstrated that liver transplantation recipients experienced improved QoL with reference to the general population and compromised well-being when compared with healthy persons[36]. However, this is inconsistent with our findings. In our study, the LT recipients scored lower in general health, role-physical, bodily pain, mental health and higher in physical-functioning and social-functioning, as well as similarly in other domains when compared with 126 healthy controls.

LT patients are at high risk for cardiovascular events, impaired renal function and diabetes due to life-long immunosuppressive therapy[37]. Thus, there is a necessity to probe the QoL of LT recipients compared with matched controls. Overall HRQoL was significantly better in our LT recipients than patients with chronic hepatitis B or type 2 diabetes mellitus. The result was in accordance with the study of Duffy *et al*[1] about HRQoL of 20-year survivors after LT. Paradoxically, Elliott *et al*[36] have found that symptoms or functional abilities are not different between LT recipients and matched chronic liver disease controls. However, our findings were based on generic QoL instruments, which were not disease-targeted. Therefore, further studies with specific instruments are needed to explored factors contributing to the differences. With respect to the relationship between QoL and psychological outcomes, MCS and PCS scores significantly correlated with the scores of both BAI and SDS. This observation indicated that post-transplant anxiety and depression were potential factors influencing QoL, and our findings were inconsistent with earlier studies[12,38]. Attention should be paid to recipients who had difficulties in psychosocial adjustment after LT.

Generally, in our study recipients undergoing DDLT, age > 45 years, taking full-time work after transplantation, and absence of complications resulted in a favorable QoL. This result could be partly attributable to our follow-up model, which enabled early problem identification and prompt individual intervention as well as HRQoL maintenance and improvement of LT recipients. Telles-Correia *et al*[39] have pointed out that it is useful to design special modes of follow-up to improve patients' medical outcomes. van Ginneken *et al*[40] and Gross *et al*[41] have shared their successful experience of improving QoL of LT recipients by a rehabilitation program and a trial called Mindfulness-Based Stress Reduction.

Our study had several limitations. The findings were based on cross-sectional data, which are less informative than those of a longitudinal study. Nevertheless, our sample was relatively large. The sample size of LDLT patients was small, which could have led to biased results in group comparison. Recipients' anxiety for donors' health should be investigated in future studies because that might affect recipients' post-transplant mental health. Studies with specific instruments are also needed. Moreover, prospective studies are required to explore tailored intervention to help patients through physical and psychological discomfort as well as social disadvantages.

In conclusion, age > 45 years at the time of transplantation, DDLT, full-time working status and no complications after transplantation indicated better QoL in our recipients. Post-transplant anxiety and depression significantly correlated with MCS and PCS. A well-designed follow-up model plays an important role in improving post-LT survival and HRQoL of recipients.

COMMENTS

Background

Living donor liver transplantation (LDLT) is effective treatment for patients with end-stage liver disease, especially in Asian countries where the cadaveric graft supply is markedly limited. The graft and recipient survival rates are excellent and similar to those after deceased donor liver transplantation (DDLT). However, recipients suffer a wide range of physical, mental and psychological difficulties other than the risks inherent to the surgical process. Therefore, the health-related quality of life (HRQoL) of recipients after transplantation should be given priority.

Research frontiers

Currently, discordant conclusions as to HRQoL and psychological health of recipients after LT have been drawn based on varied instruments. Therefore, the study evaluated the HRQoL and psychological outcomes on DDLT or LDLT recipients and identified some underlying factors influencing their HRQoL, as well as delivering the perspectives.

Innovations and breakthroughs

This study is one of the few that have compared HRQoL in liver recipients and those suffering chronic diseases. Furthermore, the authors compared DDLT and LDLT. Additionally, the study was well constructed and was a comprehensive assessment of HRQoL and psychological well-being in recipients after LT.

Applications

The present study provides crucial preliminary findings on research into the recipients' QoL and psychological outcomes. The findings will play an important role in future clinical decision making.

Terminology

LDLT is a procedure in which a living healthy person voluntarily donates part of his/her liver to another without any commercial purposes. DDLT is a procedure in which the donated liver is procured from a cadaver. HRQoL is a multifaceted construct of physiological and psychosocial aspects of well-being.

Peer review

The study is well planned with HRQoL being compared between DDLT and LDLT and also patients with other chronic illnesses, healthy controls, as well as the general population. This was an interesting study in which the authors evaluated HRQoL and mental well being (anxiety and depression) in liver transplant recipients from Sichuan Province, China.

Abstract

AIM: To investigate whether therapeutic treatment with melatonin could protect rats against acute pancreatitis and its associated lung injury.

METHODS: Seventy-two male Sprague-Dawley rats were randomly divided into three groups: the sham operation (SO), severe acute pancreatitis (SAP), and melatonin treatment (MT) groups. Acute pancreatitis was induced by infusion of 1 mL/kg of sodium taurocholate (4% solution) into the biliopancreatic duct. Melatonin (50 mg/kg) was administered 30 min before pancreatitis was induced, and the severity of pancreatic and pulmonary injuries was evaluated 1, 4 and 8 h after induction. Serum samples were collected to measure amylase activities, and lung tissues were removed to measure levels of mRNAs encoding interleukin 22 (IL-22) and T helper cell 22 (Th22), as well as levels of IL-22.

RESULTS: At each time point, levels of mRNAs encoding IL-22 and Th22 were significantly higher ($P < 0.001$) in the MT group than in the SAP group (0.526 ± 0.143 *vs* 0.156 ± 0.027, respectively, here and throughout, after 1 h; 0.489 ± 0.150 *vs* 0.113 ± 0.014 after 4 h; 0.524 ± 0.168 *vs* 0.069 ± 0.013 after 8 h, 0.378 ± 0.134 *vs* 0.122 ± 0.015 after 1 h; 0.205 ± 0.041 *vs* 0.076 ± 0.019 after 4 h; 0.302 ± 0.108 *vs* 0.045 ± 0.013 after 8 h, respectively) and significantly lower ($P < 0.001$) in the SAP group than in the SO group (0.156 ± 0.027 *vs* 1.000 ± 0.010 after 1 h; 0.113 ± 0.014 *vs* 1.041 ± 0.235 after 4 h; 0.069 ± 0.013 *vs* 1.110 ± 0.213 after 8 h, 0.122 ± 0.015 *vs* 1.000 ± 0.188 after 1 h; 0.076 ± 0.019 *vs* 0.899 ± 0.125 after 4 h; 0.045 ± 0.013 *vs* 0.991 ± 0.222 after 8 h, respectively). The mean pathological scores for pancreatic tissues in the MT group were significantly higher ($P < 0.01$) than those for samples in the SO group (1.088 ± 0.187 *vs* 0.488 ± 0.183 after 1 h; 2.450 ± 0.212 *vs* 0.469 ± 0.242 after 4 h; 4.994 ± 0.184 *vs* 0.513 ± 0.210 after 8 h), but were significantly lower ($P < 0.01$) than those for samples in the SAP group at each time point (1.088 ± 0.187 *vs* 1.969 ± 0.290 after 1 h; 2.450 ± 0.212 *vs* 3.344 ± 0.386 after 4 h; 4.994 ± 0.184 *vs* 6.981 ± 0.301 after 8 h). The severity of SAP increased significantly ($P < 0.01$) over time in the SAP group (1.088 ± 0.187 *vs* 2.450 ± 0.212 between 1 h and 4 h after inducing pancreatitis; and 2.450 ± 0.212 *vs* 4.994 ± 0.184 between 4 and 8 h after inducing pancreatitis).

CONCLUSION: Melatonin protects rats against acute pancreatitis-associated lung injury, probably through the upregulation of IL-22 and Th22, which increases the innate immunity of tissue cells and enhances their regeneration.

Melatonin attenuates acute pancreatitis-associated lung injury in rats by modulating interleukin 22. *World J Gastroenterol* 2012; 18(36): 5122-5128 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i36/5122.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i36.5122

INTRODUCTION

Severe acute pancreatitis (SAP) is an inflammatory disease characterized by tissue edema, acinar necrosis, hemorrhage, and fat necrosis in the pancreas. Subsequent entry of proteolytic enzymes and vasoactive mediators into the systemic circulation always leads to multi-organ complications[1]. Pulmonary dysfunction is the most prominent manifestation of extra-abdominal organ dysfunction in pancreatitis, and its severity ranges from mild oxygenation abnormalities to severe acute respiratory distress syndrome (ARDS)[2]. Respiratory failure is associated with approximately 60% of the deaths that occur within the first week of pancreatitis[3,4]. Thus, the success of efforts to identify new therapeutic strategies for SAP will likely depend largely on understanding the molecular pathogenesis of damage to both the pancreas and the lungs.

Interleukin 22 (IL-22) is a member of the IL10 family of cytokines. It is an important effector of activated IL-22-producing T helper cells 22 (Th22), Th1 cells, and Th17 cells, as well as cytotoxic T-cell subsets, γδT cells, natural killer (NK), and NKT cells[5-7]. Activated T cells and NK cells are major sources of IL-22, and the highest levels of IL-22 expression have been detected in CD4+ memory cells. In contrast, IL-22 is not produced by either resting or activated monocytes, or B cells[8]. Like all other members of the IL10 family, IL-22 exerts its biological effects *via* heterodimeric transmembrane receptor complexes that each comprise of a type-1 and a type-2 receptor chain. These receptor chains belong to the cytokine receptor family class 2[5,9].

Since its discovery in 2000, several research groups have studied the unique biological activities of IL-22 and its significance in diseases. IL-22 protects tissues from damage, enhances tissue repair, maintains tissue integrity, increases innate immunity, and promotes anti-microbial defenses[5,10]. Therapy involving IL-22 improves liver regeneration after 70% hepatectomy[11] and also ameliorates high-fat diet-induced liver lipogenesis and hepatic steatosis[12]. Similarly, therapy with IL-22 counteracts the destructive nature of inflammatory bowel disease and ulcerative colitis[13] and prevents lung inflammation and fibrosis[14].

The recently discovered Th22 subset of T cells, which differs from Th17 and other known T-cell subsets based on its unique function[15], produces cytokines such as IL-22, IL26, and IL13. Th22 cells express several fibroblast growth factors, are associated with epidermal repair responses, and synergize with tumor necrosis factor α to induce a characteristic Th22 signature in keratinocytes[15]. Moreover, Th22 cells may regulate epidermal responses in inflammatory skin diseases and could be involved in unknown pathways that control tissue immunity and remodeling[15].

Although most melatonin is produced by the pineal gland, it can also be secreted by extrapineal organs and tissues such as the gastrointestinal tract, the retina and lens, skin, immune and hematopoietic cells, and some reproductive organs[16,17]. Several studies have demonstrated the beneficial effects of melatonin on SAP. As early as 1999, melatonin was reported to attenuate pancreatic edema and lipid peroxidation in caerulein-induced SAP[18]. Subsequent studies confirmed that pretreatment with melatonin significantly decreases all investigated inflammatory parameters associated with SAP[18]. Moreover, melatonin exerts an anti-inflammatory effect by inhibiting nuclear factor kappa B, a transcription factor with a central role in the development of inflammatory diseases. The present study was undertaken to examine the role of IL-22 in the pathogenesis of AP-induced lung damage, as well as the capacity of melatonin to protect against AP-associated lung injury.

MATERIALS AND METHODS

Animals

A total of 72 clean-grade healthy adult male Sprague-Dawley (SD) rats, each weighing 200-250 g, were obtained from the Experimental Animal Center of Wenzhou Medical College, Wenzhou, China. All animals were fed standard rat chow and had unlimited access to water under conditions that provided a constant room temperature of 25 ℃ and a 12-h/12-h day/night cycle. All animals were acclimated for at least a week before experimentation. Animals were deprived of rat chow for 12 h before experimentation but were allowed unlimited access to water throughout the experimental period. All procedures were performed in accordance with the guidelines for animal experiments of Wenzhou Medical College, Wenzhou, China.

Animal groups and procedures

SD rats were anesthetized by intraperitoneal (i.p.) injection of 10% chloraldurate (2 mL/kg; Solarbio, Beijing, China) and were randomly assigned to a sham operation group (SO group; n = 24), a SAP group (n = 24), or a melatonin treatment group (MT group; n = 24). For each animal in the SAP group, a laparotomy was performed through a midline incision, and 1 mL/kg of 4% sodium taurocholate (Sigma, St. Louis, United States) was retrogradely injected into the biliopancreatic duct through the papilla using a segmental epidural catheter *via* a microinjection pump at a rate of 0.2 mL/min. A microclip was placed in the hepatic portion of the biliopancreatic duct to avoid reflux before injection of sodium taurocholate.

Rats in the SO group were subjected to the same surgical procedure but without infusion of 4% sodium taurocholate. In the MT group, melatonin (50 mg/kg body weight; Sigma) was administered i.p. 30 min before the injection of taurocholate. After each operation, the abdomen of each rat was closed in two layers. All surgical procedures were performed using sterile techniques.

The rats were killed by exsanguination at defined time points (1, 4 and 8 h; $n = 8$ for each time point) after the surgical procedure. Postcava puncture was used to obtain 3 mL blood from each animal to assay levels of serum amylase. The concentration of serum amylase (U/L) was assayed using a fully automatic biochemical analyzer (Hitachi, Tokyo, Japan). Lung tissues were harvested immediately before death, and tissue samples were fixed in 4% paraformaldehyde for immunohistochemical analysis. Other tissues were removed and stored in liquid nitrogen for the determination of IL-22 and Th22 mRNA levels using real-time reverse-transcription polymerase chain reaction and IL-22 protein levels using enzyme-linked immunosorbent assay (ELISA).

Histological analysis and pathological scores of pancreatic tissues

Samples of lung and pancreatic tissues were fixed in 40 g/L formaldehyde, embedded with paraffin wax, sectioned (4 μm thick), stained with hematoxylin and eosin (H and E), and observed using light microscopy. Tissue alteration was assessed (20 fields/section) by an experienced histologist who was blinded to the experimental protocol. Ten randomly selected visual fields in each pathological section were observed (H and E staining; × 400) using a high-powered microscope (CX31, Tokyo, Japan) and scored by two experienced pathologists using established standards[19], respectively. The maximum possible score for each visual field was 12, and the pathological score for each section was determined by calculating the mean of the scores from the two pathologists for the 10 visual fields.

Real-time, fluorescence-based quantitative polymerase chain reaction

Total RNA was extracted from lung tissues using TRIzol reagent (Invitrogen, Carlsbad, United States), and cDNA was synthesized using the first strand cDNA synthesis kit (MBI Fermentas, Burlington, Canada). mRNAs encoding IL-22 and Th22 were detected using the PCR mix kit (Daweike, Shanghai, China), and real-time quantitative PCR was performed using the ABI 7500 Sequence Detection System (Applied Biosystems Inc, Carlsbad, United States). For PCR, we used the following primers for IL-22 (forward: 5'-GCCAGCTGCCTGCTTCTCGT-3', reverse: 5'-CTGGCCTCCTTGGCCAGCAT-3'), Th22 (forward: 5'-GGGCTTCCAGGGTGCTTCGC-3', reverse: 5'-CCTCAGTTCACCGAGAACCCCA-3'), and β-actin (forward: 5'-GCGTCCACCCGCGAGTACAA-3', reverse: 5'-CGACGACGAGCGCAGCGATA-3'; Generay, Shanghai, China). The cDNA was denatured at 95 ℃ for 5 min and amplified over the course of 40 cycles, each involving 95 ℃ (15 s), 60 ℃ (45 s), and 72 ℃ (60 s), with a final extension at 72 ℃ (5 min). The samples were tested in triplicate, and the expression of IL-22 and Th22 mRNA was calculated using the $2^{-\Delta\Delta CT}$ method.

Sandwich enzyme-linked immunosorbent assays

Concentrations of IL-22 were measured using commercially available sandwich ELISA kits (all from R and D Systems, Rapidbio, United States). IL-22 levels were assayed using microtiter wells coated with purified rat IL-22 and a solid-phase IL-22-specific antibody. The horseradish peroxidase (HRP)-labeled secondary antibody was detected with the tetramethylbenzidine substrate solution, which creates a blue reaction product. The HRP enzyme-catalyzed reaction was terminated by the addition of a sulfuric acid solution, and the color change was measured spectrophotometrically at a wavelength of 450 nm. The concentration of IL-22 in the samples was then determined by comparing the $A_{450\ nm}$ of the samples to a standard curve.

Statistical analysis

Statistical analysis were carried out using the SPSS software (ver. 15.0; SPSS Inc., Chicago, IL, United States). All data are expressed as the mean ± SD. One-way analysis of variance were used to investigate differences among the SO, SAP, and MT groups at each time point, and post hoc comparisons were performed between samples in the SO and SAP groups to check for statistical significance. Differences were considered significant at $P < 0.05$.

RESULTS

Histopathological examination of lung tissues and pathological scores of pancreatic tissues after SAP induction

The appearance of lung tissue samples collected 1 h (Figure 1A), 4 h (Figure 1B), and 8 h (Figure 1C) after the induction of SAP was much more severely affected than the appearance of tissue from animals in the SO group (Figure 1D), which tended to remain morphologically normal even 8 h after surgery. Microscopic examination of lung tissue from animals in the SAP group provided extremely clear evidence of edema, hemorrhage complicated by microthrombosis, cell degeneration, and inflammation (Figure 1A-C). The extent of damage observed in the lungs of SAP animals was largely alleviated in lung tissues of animals in the MT group (Figure 1E-G).

Pancreatic tissue samples were also collected and analyzed from each group of animals. At each time point, the mean pathological score for pancreatic tissues in the MT group was significantly higher ($P < 0.01$) than for samples in the SO group, but significantly lower ($P < 0.01$) than for samples in the SAP group at each time point. The severity of SAP increased significantly over time in

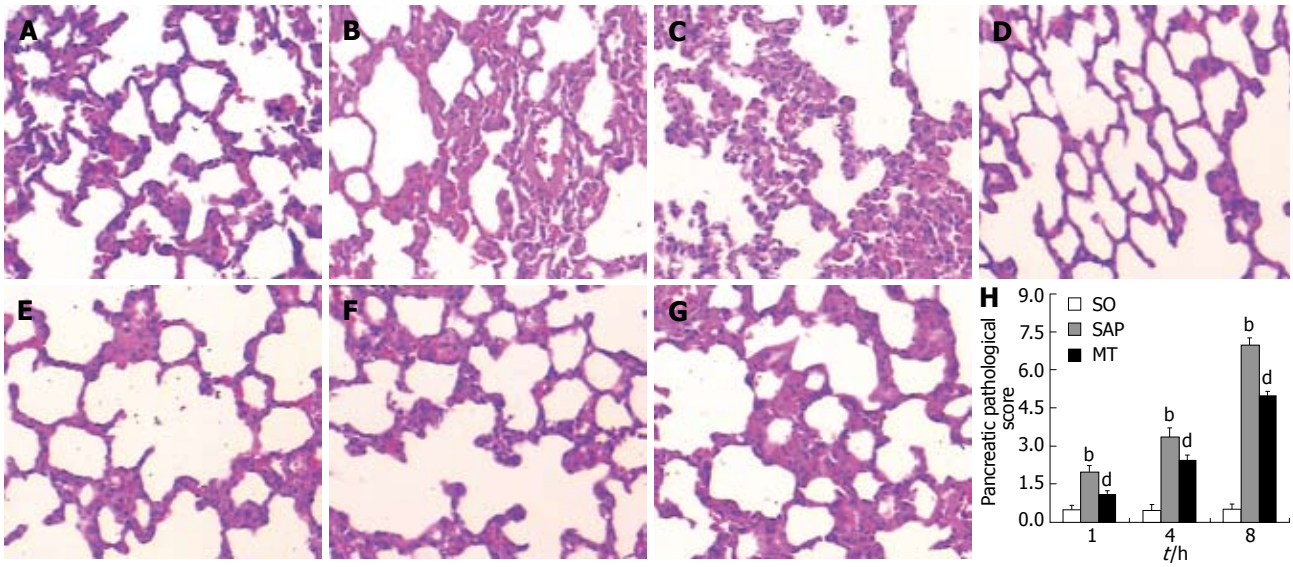

Figure 1 Histology of pulmonary tissues and pathological scores of pancreatic tissues from rats in the sham operation, severe acute pancreatitis, and melatonin treatment groups. A-C: Histological changes of pulmonary tissues in the SAP group (A) 1 h, (B) 4 h, and (C) 8 h after experimental induction of SAP; D: Histological changes of pulmonary tissues in the SO group 8 h after mock induction of SAP; E-G: Histological changes of pulmonary tissues in the MT group (E) 1 h, (F) 4 h, and (G) 8 h after experimental induction of SAP (hematoxylin and eosin stain; ×200). H: Pathological scores of pancreatic tissues (n = 8). $^{b}P < 0.01$ *vs* the MT group; $^{d}P < 0.01$ *vs* the SO and MT groups. SO: Sham operation; SAP: Severe acute pancreatitis; MT: Melatonin treatment.

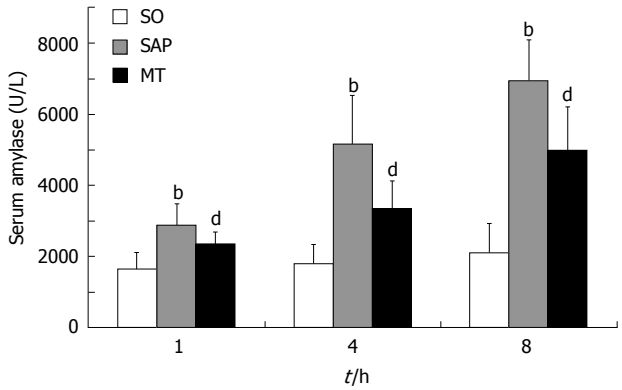

Figure 2 Changes in serum amylase levels from rats in the sham operation, severe acute pancreatitis, and melatonin treatment groups over time. Serum amylase levels differed significantly ($P < 0.01$) between each pair of time points in the SAP group, but not at different levels in the SO group (n = 8 rats per group). $^{b}P < 0.01$ *vs* the SO group; $^{d}P < 0.05$ *vs* the SO and SAP groups. SO: Sham operation; SAP: Severe acute pancreatitis; MT: Melatonin treatment.

the SAP group ($P < 0.01$, Figure 1H).

Serum amylase levels after SAP induction

Levels of serum amylase at each time point were markedly elevated in the SAP group relative to the SO ($P < 0.01$) and MT ($P < 0.05$) groups (Figure 2). In addition, the levels of amylase in the MT group increased compared with those in the SO group. In the SAP group, amylase levels increased over time, indicating the development of SAP. There was no significant difference between the levels of serum amylase at the three time points in the SO group (Figure 2).

Expression of IL-22 and Th22 mRNAs after SAP induction

Levels of the IL-22 and Th22 mRNAs in lung tissues were significantly decreased within 1 h after the induction of SAP ($P < 0.01$; Figure 3A and B), and levels of both mRNAs remained low during the remaining time points. Importantly, this decrease in both mRNAs in the SAP group relative to the SO group was partly rescued in the MT group. Differences between levels in the SAP group and the MT group were significant ($P < 0.01$), and expression differed significantly between the MT group and the SO group ($P < 0.01$, Figure 3A and B).

Levels of IL-22 in lung tissue after SAP induction

The level of IL-22 in lung tissue in the MT group was significantly lower than that in the SO group and significantly higher than that in the SAP group at each time point ($P < 0.01$; Figure 4). The level of IL-22 in the lung tissue samples decreased significantly over time in the SAP group ($P < 0.01$), although IL-22 levels did not differ significantly between each pair of time points in the SO group.

DISCUSSION

Patients with SAP and the associated multiple-organ failure in which it frequently results[20], require admission to a high-dependency or intensive-care unit. Despite recent progress in revealing the mechanisms that underlie SAP, which include inflammation, cell injury, and cell death, the exact pathogenesis of SAP is not fully understood. The uncontrolled generation of reactive oxygen species (ROS) during SAP causes oxidative damage, both in the pancreas and distant organs. The lung is especially vulnerable to damage by ROS because it possesses the largest endothelial surface area of any organ in the body[21].

IL-22 is a member of the IL-10 cytokine family, which additionally comprises IL-10, IL-19, IL-20, IL-24,

IL-26, IL-28α, IL-28β and IL-29[22-24]. IL-22 is a key player in antimicrobial defenses, tissue regeneration, and protection against damage that may serve either protective or highly pathogenetic roles in chronic inflammatory disorders, depending on the nature of the affected tissue and the local cytokine milieu[5]. IL-22 targets cells from the skin, liver, and kidney and from organs of the respiratory and gastrointestinal systems. The effects of IL-22 in AP are mediated by direct and/or indirect inhibition of the activities and/or production of cycloxygenase-2, prostaglandin E2, IL-1β, and monocyte chemoattractant protein-1, all of which contribute to the progression of SAP[25]. In fact, IL-22 is a potential therapeutic target for the treatment of chronic inflammatory diseases, and treatment with recombinant cytokine or delivery of IL-22 by gene therapy may alleviate tissue destruction during inflammatory responses[26]. Experimental delivery of IL-22 has been efficacious in treating autoimmune disorders such as experimental autoimmune myocarditis in rats[27,28]. Western blotting for IL-22 in bronchoalveolar lavage fluid revealed lower levels of IL-22 in patients with ARDS[29]. This is the first study to suggest the protective actions of IL-22 in a rat model of pancreatitis-associated lung injury.

In this study, we measured the levels of mRNAs encoding IL-22 and Th22 in rat pulmonary tissues to explore the mechanism of acute pancreatitis-associated lung injury. We also examined the effects of SAP, with and without prior treatment with melatonin, on IL-22 protein levels. The reduced levels of IL-22 and Th22 mRNAs that accompanied taurocholate-induction of SAP suggest that downregulation of mRNAs encoding IL-22 and Th22 contribute to the pathogenesis of pancreatitis-associated lung injury. However, future studies are needed to determine more precisely the underlying mechanisms by which downregulation of IL-22 and Th22 contributes to acute pancreatitis-associated lung injury.

Melatonin is a hormone that can cross all body barriers as well as the placenta[30,31]. It is not stored and is rapidly released into the general circulation immediately after its synthesis. Melatonin is useful not only for the acute treatment of ischemic stroke and neurodegenerative disease[32] but also as a prophylactic treatment against stroke[33]. Melatonin is a more highly efficient ROS scavenger than other ROS scavengers and general antioxidants such as glutathione and ascorbic acid, which protect DNA, lipids, and proteins from oxidative damage[34,35]. The previous results have indicated that melatonin prevents or attenuates the severity of experimental SAP[18], but few published studies have examined the relevance between the effect of melatonin and IL-22 or Th22. The main finding of this study was the demonstration that the ameliorative effect of melatonin on pancreatitis-associated lung injury is correlated with an elevation in the levels of IL-22 and Th22, and IL-22 has been demonstrated to protect tissues against caerulein-induced SAP by their anti-inflammatory effects[25].

The levels of mRNAs encoding IL-22 and Th22 were lower in rats with SAP and gradually decreased with the progression of SAP. The levels of IL-22 and Th22 mRNAs in pulmonary tissues from the MT group were, however, partially restored to the levels seen in the SO group, and histopathological examination indicated that the damage to pulmonary tissues from the MT group was reduced relative to that of the SAP group. This sug-

gests that the alleviation of acute pancreatitis-associated lung injury by melatonin is mediated, at least in part, by upregulation of IL-22 and Th22 activities.

In summary, this study indicates, for the first time, that the downregulation of pulmonary IL-22 and Th22 may be associated with the pathogenesis of acute pancreatitis-associated lung injury. Melatonin, functioning as a protectant and antioxidant, may reduce lung injury by increasing IL-22 and Th22 activity.

COMMENTS

Background

Severe acute pancreatitis (SAP) is a potentially serious disease for which there are limited specific therapies. Pulmonary dysfunction is the most prominent manifestation of extra-abdominal organ dysfunction in pancreatitis. Previous studies assessed the therapeutic efficacy of interleukin 22 (IL-22) and melatonin for the treatment of SAP in a rat model of the disease, although the exact mechanism(s) by which melatonin mediates its effects remains obscure.

Research frontiers

Previous research indicated that therapy involving recombinant IL-22 markedly attenuates the severity of SAP in rats. The study has found that melatonin, which can reduce pancreatic damage in rats with SAP, has a protective effect on the lungs of rats with SAP. This protection is associated with increases in the levels of mRNAs that encode IL-22 and T helper cell 22 (Th22) and increased levels of IL-22 protein. Further research is needed to explore the mechanism by which melatonin upregulates IL-22 and Th22 and how IL-22 and Th22 mediate their protective effects on the lungs of animals with SAP.

Innovations and breakthroughs

The mechanism(s) responsible for the previously proposed anti-inflammatory effects of IL-22 and melatonin during SAP remains to be elucidated. The authors studied the effect of melatonin on levels of mRNAs encoding IL-22 and Th22 and the level of IL-22 in lung tissues from rats with SAP. The results indicated that the downregulation of pulmonary mRNAs encoding IL-22 and Th22 in animals with SAP may be associated with the pathogenesis of acute pancreatitis-associated lung injury, and melatonin is potentially capable of reducing lung injury by increasing IL-22 and Th22 activities. This paper provides a plausible explanation of the mechanism underlying the therapeutic effects of melatonin in the treatment of SAP.

Applications

Given the established therapeutic efficacy of melatonin for treating SAP, elucidation of the underlying mechanism involved is the primary obstacle to translation of this approach to clinical practice. The results suggest that the therapeutic effects of melatonin in reducing acute pancreatitis-associated lung injury can potentially be attributed to increased IL-22 and Th22 activities.

Terminology

SAP is principally caused by autodigestion of the pancreas, and pulmonary dysfunction is the most pertinent manifestation of extra-abdominal organ dysfunction in patients with pancreatitis. IL-22 is a member of the IL10 family of cytokines and represents an important effector molecule of activated IL-22-expressing Th22 cells, Th1, and Th17 cells. Melatonin, which is secreted by the pineal gland, prevents or attenuates the severity of experimental SAP.

Peer review

The authors of this study focus on the value of melatonin in alleviating the severity of acute pancreatitis-associated lung injury and the possible molecular mechanism that underlies this effect. The results suggest that the down-regulation of pulmonary IL-22 and Th22 may be associated with the pathogenesis of acute pancreatitis-associated lung injury and that melatonin is potentially capable of reducing lung injury by increasing IL-22 and Th22 activity.

Abstract

AIM: To investigate the association between the CpG island methylator phenotype (CIMP) and serum *Helicobacter pylori* (*H. pylori*) levels for clinical prediction of gastric cancer (GC) progression.

METHODS: We analyzed the serum CIMP status of 75 patients with GC using a methylation marker panel and a methylation-specific polymerase chain reaction. Serum samples from 40 healthy persons were examined at the same time. The genes examined were *APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK* and *E-cad*. *H. pylori* infection in serum was assayed with an anti-*H. pylori* immunoglobulin G antibody test and a rapid urease test.

RESULTS: The frequencies of high-level methylation in GC tissues for the seven genes were: 48% for *APC*, 57.33% for *WIF-1*, 56% for *RUNX-3*, 50.67% for *DLC-1*, 52% for *SFRP-1*, 54.67% for *DKK*, and 48% for *E-cad*. The frequencies in GC serum were 30.67% for *APC*, 34.67% for *WIF-1*, 37.33% for *RUNX-3*, 29.33% for *DLC-1*, 33.33% for *SFRP-1*, 32% for *DKK*, and 26.67% for *E-cad*. CIMP+ (defined as $\geqslant$ 3 methylated genes) was associated with 47 (62.67%) GC tissue samples and 44 (58.67%) GC serum samples. CIMP+ was not associated with non-neoplastic mucosal tissues or the serum of healthy persons. Of the 75 GC cases, 51 (68%) were *H. pylori*+, and 24 (32%) were *H. pylori*-. Of the 51 *H. pylori*+ cases, 36 were CIMP+ and 15 were CIMP-. In contrast, for the 24 *H. pylori*- cases, 11 were CIMP+, and 13 were CIMP-. The difference was significant between the *H. pylori*+ and *H. pylori*- groups (χ^2 = 4.27, P < 0.05). Of the 51 *H. pylori*+ GC patients, 34 were CIMP+ and 17 were CIMP-, while among the 24 *H. pylori*- GC cases, 10 were CIMP+ and 14 were CIMP-. The difference was significant between the *H. pylori*+ and *H. pylori*- groups (χ^2 = 4.21, P < 0.05). A 2-year follow-up showed significant difference in the rates of metastasis and recurrence between *H. pylori*+/CIMP+ cases and the *H. pylori*+/CIMP- cases or CIMP- cases associated with *H. pylori* assayed in serum (P < 0.05). However, there were no significant differences in survival rates between the two groups.

CONCLUSION: *H. pylori*+/CIMP+ cases are associated with higher rates of metastasis and recurrence than *H. pylori*+/CIMP- cases. Serum may be useful for examining CIMP status.

INTRODUCTION

Gastric cancer (GC) is one of the most common human tumors and is the second-leading cause of cancer-related deaths worldwide[1]. GC remains a major clinical challenge because it has a poor prognosis and limited treatment options due to its relative resistance to radiotherapy and chemotherapy[2].

DNA methylation is an enzyme-mediated chemical modification that occurs in cytosine-guanine dinucleotide-rich areas (CpG islands) in gene promoter regions. Aberrant promoter hypermethylation leads to loss of gene function in tumors[3]. In several types of cancers, including GC, global hypomethylation and promoter hypermethylation in specific genes are associated with genomic instability and inactivation of tumor-suppressor genes[4]. The methylation pattern(s) of multiple genes can provide useful information regarding global epigenetic alterations[5]. The hypermethylated subtype associated with tumors, denoted that the CpG island methylator phenotype (CIMP) for which multiple genes are concurrently methylated, is a novel marker of tumor progression[6-8].

Helicobacter pylori (*H. pylori*) infection of the stomach is associated with an increased risk for gastric carcinoma[9]. Several studies have demonstrated that *H. pylori* infection is associated with gene promoter hypermethylation and gene-type-specific methylation profiles involved in the multistep process of carcinogenesis[10,11]. *H. pylori* infection may induce methylation of the Trefoil factor family 2 and E-cadherin promoters in GC[12]. Certain studies have shown that methylation levels in GC patients are one to two orders of magnitude greater in *H. pylori*+ individuals than in *H. pylori*- individuals[13]. In infected mucosae, aberrant methylation and subsequent silencing of tumor suppressor genes, including *p16*, *E-cadherin*, and *hMLH1*, are strongly correlated with subsequent cancer risk[14].

In the present study, we focused on the relationship between *H. pylori* infection and CIMP status in GC risk. We did not specifically study the relationship between CIMP and *H. pylori* infection or the clinical value of evaluating CIMP associated with *H. pylori* infection.

We analyzed the relationship between serum CIMP of 75 GC patients and *H. pylori* infection in GC. The examined genes were *APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK*, and *E-cad*, which were selected because they had been found to be frequently methylated in GC and other malignancies The aim of this study was to evaluate the clinical significance of serum CIMP and *H. pylori*-infection levels for the prediction of GC progression.

MATERIALS AND METHODS

Patients and specimens

Between 2008 and 2009, tumor samples, adjacent non-neoplastic tissues, and sera from 75 Chinese GC patients were collected during surgical resection at the Nantong Tumor Hospital. Samples from 40 healthy people were used as matched controls. The controls had no self-reported history of cancer and could frequently be matched to the cases in age (± 5 years), gender, and residential area. After resection, tissue specimens were immediately frozen in liquid nitrogen and stored at -70 ℃. Patients consisted of 53 men and 22 women, ranging in age from 31 to 76 (52 ± 7) years. Questionnaire data and blood samples were also collected from all patients and controls. After centrifugation, isolated serum samples were stored at -70 ℃. The diagnosis of GC was confirmed by pathological examination and magnetic resonance imaging and/or computerized tomography. Tumor-node-metastasis (TNM) stage was classified according to the 6th edition TNM classification of the American Joint Committee on Cancer. Written informed consent was obtained from each patient and healthy control, and the local ethics committee approved the study protocol.

DNA extraction and sodium bisulfite

DNA from serum (200 μL per sample) and tissue samples was treated with proteinase K and then extracted with phenol-chloroform according to the manufacturer's instructions (Shanghai ShineGene Molecular Biotech, Inc., Shanghai, China) and stored at -20 ℃. A final elution volume of 50 μL was collected. The extracted DNA was treated with sodium bisulfite using EZ DNA Methylation kit reagents (Zymo Research, Orange, CA, United States) to convert all unmethylated cytosines to uracils. Bisulfite-modified DNA was suspended in 10 μL of elution buffer and stored at -20 ℃ until methylation-specific polymerase chain reaction (PCR) (MSP) was performed.

MSP

MSP was used to determine the methylation status of CpG islands in genes after bisulfate treatment[15,16]. The methylation status of the promoters of *APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK*, and *E-cad* was determined with a two-step amplification/detection MSP protocol. PCR products were electrophoresed through 2% agarose gels, stained with ethidium bromide, and visualized with ultraviolet illumination. All experiments were performed in duplicate. Table 1 lists the sequences of the PCR primers used.

H. pylori assay

H. pylori infection was assayed with the reagents of a serum anti-*H. pylori* immunoglobulin G (IgG) antibody test (PBM, PRINCETON, United States) and a rapid urease test (Fujian Sanqiang Biological and Chemical Co., Ltd,

Sanming, China). The sensitivities of the serum anti-*H. pylori* IgG antibody test and rapid urease test have been reported to be ≥ 90% of the culture test[13].

Follow-up examination

Patients were followed up to 2 years after surgery. The last follow-up was on September 12, 2010. Patients had not received chemotherapy prior to surgery. The median follow-up period was 17.5 mo (range, 8-28 mo). Patients were given a physical examination, abdominal ultrasonography, and chest X-ray, and serum was collected and tested for associated tumor markers. During the first year, local recurrence and the development of distant metastasis were monitored every 3 mo with computerized tomography and/or magnetic resonance imaging. Of the 75 patients, 13 (18.67%) died from cancer-related causes. We tracked all but three of the remaining patients during the entire study period. Seventeen patients (22.67%) had GC recurrence found on computerized tomography Fourteen patients (18.67%) had GC metastases. Sixty-two patients were still alive at the time of the last follow-up report.

Statistical analysis

The SPSS 13.0 software package (SPSS, Inc., Chicago, IL, United States) was used for statistical analysis. Values for the clinical and biological characteristics of the patients are expressed as mean ± SD. Comparison was done with the Student's *t* test. The χ^2 test was used to compare the incidence of methylation. All *P* values are two-sided, and a *P* value < 0.05 was considered statistically significant.

[a]*P* < 0.05 *vs* the number of methylated gene promoters for tumor and non-neoplastic tissue samples with the χ^2 test. GC: Gastric cancer.

RESULTS

Clinical data

The median tumor size was 3.8 cm (range 2.5-9.6 cm). According to the Edmondson-Steiner classification system, six cases were classified as grade Ⅰ, 22 as grade Ⅱ, 40 as grade Ⅲ, and seven as grade Ⅳ. According to the 6th edition TNM classification of the American Joint Committee on Cancer, 24 cases were classified as grade Ⅰ, 31 as grade Ⅱ, and 20 as grade Ⅲ.

Methylation of tumor-associated genes in GC

We examined the methylation status of seven tumor-associated genes (*APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK* and *E-cad*) from tissue and serum samples of GC patients and from serum samples of controls. The overall results are summarized in Table 2. No methylated gene promoters from control serum were detected. Methylation occurred more frequently in the GC DNA than in adjacent non-neoplastic mucosal tissues, and the same relationship was observed for serum samples and non-neoplastic tissues. Methylation was detected in one or more of the genes in 69 (92%) of the 75 cases. The frequencies of high-level methylation in GC tissue and serum were ≥ 15% for the seven genes: 48% for *APC*, 57.33% for *WIF-1*, 56% for *RUNX-3*, 50.67% for *DLC-1*, 52% for *SFRP-1*, 54.67% for *DKK*, and 48% for *E-cad* in tissue. In serum, the frequencies were 30.67% for *APC*, 34.67% for *WIF-1*, 37.33% for *RUNX-3*, 29.33% for *DLC-1*, 33.33% for *SFRP-1*, 32% for *DKK*, and 26.67% for *E-cad*.

According to the criteria used in a related study[17], the CIMP status of our 75 GC samples was classified as CIMP+ (≥ 3 methylated genes) or CIMP- (two or fewer methylated genes). In this study, because the cutoff value was 3, the average number of methylated genes found

Table 3 CpG island methylator phenotype associated with *Helicobacter pylori* infection in 75 gastric cancer tissue and serum samples

CIMP	*H. pylori* infection in tissue samples		*H. pylori* infection in serum samples

was 3.6 in tumor tissue and 2.0 in serum. For tumor tissue samples, 47 (62.67%) were classified as CIMP+, and 28 (37.33%) were classified as CIMP-. For serum samples, 44 (58.67%) were classified as CIMP+, and 31 (41.33%) were classified as CIMP-. No non-neoplastic tissues or serum from healthy controls were classified as CIMP+.

H. pylori in GC

We determined how many of the 75 GC patients were infected with *H. pylori* and found 51 (68%) to be *H. pylori*+ and 24 (32%) to *H. pylori*-.

Of the 51 *H. pylori*+ GC cases examined in tissues, 36 were CIMP+ and 15 were CIMP-. In contrast, of the 24 *H. pylori*- GC cases, 11 cases were CIMP+ and 13 were CIMP-. There was a significant difference between the *H. pylori*+ and *H. pylori*- groups ($\chi^2 = 4.27$, $P < 0.05$). When the sera from the 51 *H. pylori*+ GC cases were examined, 34 were CIMP+ and 17 were CIMP-. In contrast, of the 24 *H. pylori*- GC cases, 10 were CIMP+ and 14 were CIMP-. There was a significant difference between the two groups ($\chi^2 = 4.21$, $P < 0.05$). The overall results are summarized in Table 3.

Prognostic significance of CIMP associated with H. pylori infection in GC

After the two-year follow-up, the metastasis rates were found significantly different between the *H. pylori*+/CIMP+ and the *H. pylori*+/CIMP- cases when analyzed in serum ($P < 0.05$). The tumors of *H. pylori*+/CIMP+ patients frequently metastasized. The recurrence rates were significantly higher in the *H. pylori*+/CIMP+ group than in the *H. pylori*+/CIMP- group when serum was examined ($P < 0.05$). There were no differences in survival rates between *H. pylori*+/CIMP+ cases and *H. pylori*+/CIMP- cases examined in serum ($P > 0.05$). The overall results are summarized in Table 4.

DISCUSSION

Epigenetic alterations have been suggested to be significant initiating events in tumorigenesis[18]. Aberrant methylation of promoter DNA regions rich in CpG islands is the key step in epigenetic gene silencing. Abnormal gene expression may be an early event in tumorigenesis and a potential biomarker for early detection[19]. In several studies, aberrant DNA methylation in gastric biopsies from *H. pylori*+ patients was found to be correlated with a greater gastric cancer risk[13,20]. Methylation level of promoters in several genes in the gastric mucosa is 5-300 times higher in infected than in uninfected individuals. In infected mucosae, the aberrant methylation and subsequent silencing of tumor suppressor genes has been strongly correlated with subsequent cancer risk[14].

Notably, the term "CIMP" has been used in a variety of ways in the context of gastric carcinoma[21]. The hypermethylator phenotype may be related to patient-specific factors, such as exposure to carcinogens or genetic predisposition[22]. The relationship between *H. pylori* and methylation of multiple genes has been demonstrated, but little attention has been paid to the association of CIMP and *H. pylori* with respect to gastric cancer or the relationship between CIMP in serum and the presence of *H. pylori* in gastric cancer.

We collected tissue and serum samples from GC patients and healthy controls to examine the methylation status of seven tumor-associated genes (*APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK*, and *E-cad*). We found that the promoters of these genes from healthy control serum were not methylated. The frequencies of high-level methylation in GC tissue and serum were at least 15% for these seven genes. Thus, examining the methylation status of multiple genes may help diagnose early GC. We also found that promoter methylation in serum DNA was highly specific for the cancer-related genes and that the results in serum samples were similar to tissue samples. We also determined the CIMP status of 75 GC samples and found a good concordance between serum and tumor CIMP status.

Of the 75 GC cases, 51 (68%) were *H. pylori*+ and 24 (32%) were *H. pylori*-. Thus, *H. pylori* infection was substantial in GC, suggesting that eradicating *H. pylori* infection may be essential to prevent or treat GC.

The prognostic roles of CIMP status have been evaluated in several cancer types. In esophageal adenocarcinoma, CIMP is associated with a poor prognosis[16]. In GC, concordant methylation of multiple genes/loci (CIMP-H)

is associated with a better survival, but is not an independent predictor of prognosis in resected GC[2].

H. pylori infection is also a factor in the prognosis of GC. We found that CIMP was associated with *H. pylori* infection. At the end of the 2-year follow-up, we found that the rates of metastasis differed significantly between *H. pylori*+/CIMP+ and *H. pylori*+/CIMP- cases when examining the serum ($P < 0.05$). The tumors of *H. pylori*+/CIMP+ cases frequently metastasized. The recurrence rates were also significantly higher in the *H. pylori*+/CIMP+ cases than in the *H. pylori*+/CIMP- cases when serum was examined ($P < 0.05$). There were no significant differences in survival rates between *H. pylori*+/CIMP+ and *H. pylori*+/CIMP- cases examined in serum ($P > 0.05$). Therefore, aberrant DNA hypermethylation may be frequently associated with chronic inflammation, but not with *H. pylori* infection. Modulation levels of pleiotropic regulators suggested that DNA methylation plays an important role in host response to *H. pylori* infection. *H. pylori* promotes genetic instability via decreasing expression of DNA repairing genes[22,23]. We observed that CIMP+ in conjunction with *H. pylori* infection was associated with metastasis and recurrence of GC, but not the survival rate after the 2-year follow-up period.

In summary, our study shows that promoter methylation in serum DNA was highly specific and that serum and tissue samples yielded similar results. Therefore, CIMP detection in serum, rather than in tumor tissues, may be used as a reliable index for predicting the clinical course of patients with GC.

This study is limited by a relatively small number of patients, cancer-related genes, as well as follow-up period of less than 2 years. Thus, larger-scale multi-gene studies with an extended follow-up period are needed to validate our results.

COMMENTS

Background

Gastric cancer (GC) is one of the most common human tumors and is the second-leading cause of cancer-related deaths worldwide. GC remains a major clinical challenge because it has a poor prognosis and limited treatment options due to its relative resistance to radiotherapy and chemotherapy. Aberrant DNA methylation in gastric biopsies from *Helicobacter pylori* (*H. pylori*)+ patients has been shown to be correlated with a greater GC risk. The relationship between *H. pylori* and methylation of multiple genes has been demonstrated, but little attention has been paid to the association of the CpG island methylator phenotype (CIMP) and *H. pylori* with respect to GC or the relationship between CIMP in serum and the presence of *H. pylori* in GC.

Research frontiers

DNA methylation is an enzyme-induced chemical modification that occurs in cytosine-guanine dinucleotide-rich areas (CpG islands) in the gene promoter regions. Aberrant promoter hypermethylation is an important mechanism for loss of gene function in tumors including GC. The methylation pattern of multiple genes can provide useful information and an overall picture of epigenetic alterations. The hypermethylated subtype in tumors is termed as the CIMP, where multiple genes are concurrently methylated. *H. pylori* infection is found associated with gene promoter hypermethylation and gene-type-specific methylation profiles that are involved in the multistep process of carcinogenesis. Methylation levels in patients with GC are one to two orders of magnitude greater in *H. pylori*+ individuals than in *H. pylori*- individuals.

Innovations and breakthroughs

In the present study, the authors focused on the relationship between *H. pylori* infection and CIMP status in GC risk. The authors analyzed the relationship between serum CIMP of 75 patients with GC and *H. pylori* infection in GC. The examined genes were *APC*, *WIF-1*, *RUNX-3*, *DLC-1*, *SFRP-1*, *DKK*, and *E-cad*, which were selected because they had been found to be frequently methylated in GC and other malignancies. This study evaluated the clinical significance of serum CIMP and *H. pylori*-infection levels for the prediction of GC progression.

Applications

It was found in this study that *H. pylori*+/CIMP+ cases were associated with higher metastasis and recurrence rates than *H. pylori*+/CIMP- cases. CIMP detection in serum, rather than in tumor tissues, may be used as a reliable index for predicting the clinical course of patients with GC.

Terminology

Epigenetic changes: Heritable changes in gene structure without changing the gene sequence; CpG islands: CpG rich areas located in the promoter regions of many genes; CpG island methylation: The addition of a methyl group to a cytosine residue that lies next to guanine within CpG dinucleotides; CIMP: The hypermethylated subtype in tumors, where multiple genes are concurrently methylated.

Peer review

This manuscript was well designed and executed, and data were summarized well.

Abstract

Ulcerative jejunoileitis is an uncommon clinical syndrome consisting of abdominal pain, weight loss associated with diarrhea, and multiple inflammatory ulcerations and strictures of the small bowel. Ulcerative jejunoileitis can complicate established celiac disease or develop in patients *de novo*. Increased levels of tumor necrosis factor-alpha (TNF-α) in the small intestine of patients with untreated celiac disease are associated with a role in the immune pathogenesis of this disorder. No specific therapy has been shown to change the course of ulcerative jejunoileitis. We report a case of severe ulcerative jejunoileitis previously unresponsive to traditional therapies, including high dose corticosteroids and cyclosporine. The patient had a dramatic resolution of symptoms and a complete normalization of endoscopic findings after anti-TNF-α monoclonal antibody, infliximab (Remicade®).

INTRODUCTION

Ulcerative jejunoileitis, also termed chronic nongranulomatous enteritis or idiopathic chronic ulcerative jejunoileitis, is a clinical syndrome consisting of abdominal pain, diarrhea, and multiple inflammatory ulcerations of the small bowel, especially the jejunum[1]. Ulcerative jejunoileitis can complicate established celiac disease or occur in patients *de novo*[1,2]. It is uncommon and largely a diagnosis of exclusion.

CASE REPORT

A 62-year-old man presented in May 2009 with a 20-year history of intermittent abdominal pain, diarrhea, weight loss, and gastrointestinal bleeding. In 2008, he was admitted at another institution with abdominal pain, and found to have a perforated jejunum with an interloop abscess requiring small bowel resection. There was no evidence of granulomas or histologic Crohn's disease in the resected specimen, and no history of diverticulum at the site of perforation. He was hospitalized several times with pain, bleeding, and intussusception in the postoperative period. He had been started on 25 mg prednisone per day preoperatively because of possible Crohn's disease and continued on this medication.

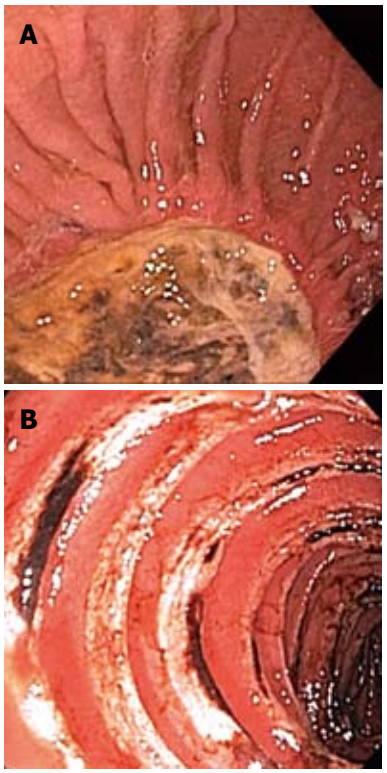

Figure 1 Enteroscopic appearance of the lesions. A: A 4-cm chronic cavity consistent with chronic perforation at the jejunal anastomosis; B: More distal jejunal ulcerations.

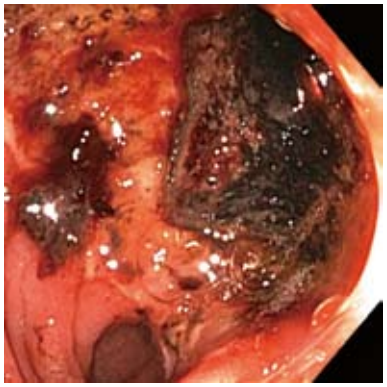

Figure 2 Endoscopy showing bleeding from an anastomotic ulcer.

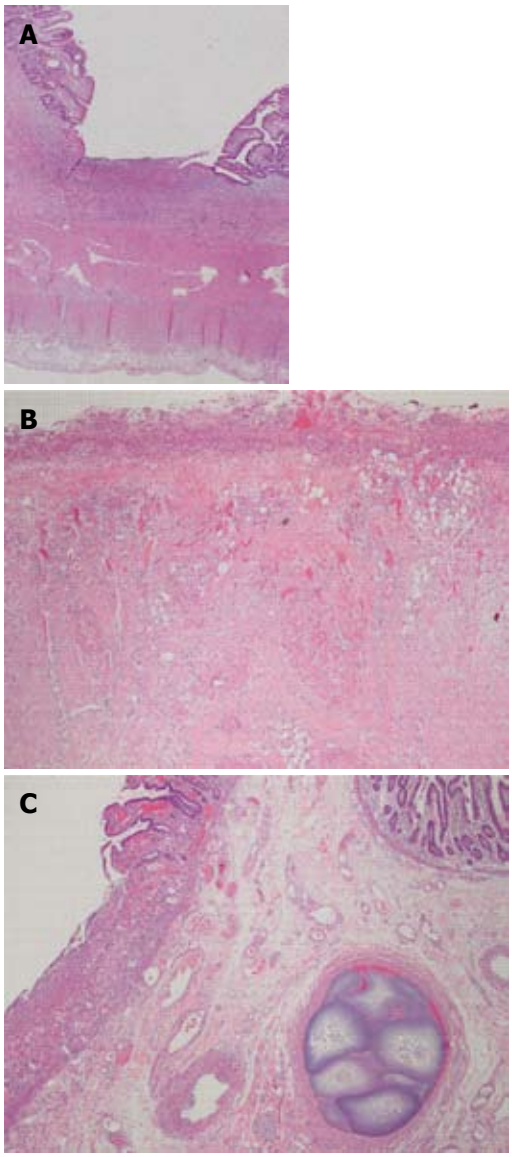

Figure 3 Surgically resected jejunum. A: Full thickness small bowel section showing ulcerated small intestinal mucosa; B: Ulcer bed showing acute and chronic inflammation, granulation tissue and overlying fibrinopurulent exudate, no granulomas are seen; C: Intravascular embolization material in submucosal blood vessel.

Physical examination revealed a chronically ill, tremulous man. His prednisone was increased to 40 mg/d, but the patient continued to have abdominal pain and bloody bowel movements. Enteroscopy showed circumferential ulceration and a stricture of the distal esophagus with a clot, severe duodenal ulceration, a stricture and a 4-cm ulcer cavity at the jejunal anastomosis as well as more distal ulceration (Figure 1A and B). Computerized tomography (CT) of the abdomen demonstrated a long segment of inflamed jejunum and mesenteric adenopathy. Serum gastrin level was normal. Despite parenteral nutrition, 60 mg/d of prednisone and 8 mg/kg per day of oral cyclosporine, the patient continued to have refractory diarrhea and bleeding. Repeat endoscopies demonstrated deep anastomotic and multiple distal ulcerations.

Because of relapsing bleeding and steroid-dependence, infliximab was initiated at 5 mg/kg dose at 0, 2 and 6 wk, followed by every eight-week intervals in conjuction with cyclosporine and prednisone. One month after initial infusion, he was admitted with rebleeding from the anastomotic ulcer (Figure 2). Angiography was negative for active bleeding. An exploratory laparotomy was performed with distal duodenal and proximal jejunal resection and revealed a chronic 5 cm jejunal ulcer at the jejunojejunostomy site associated with microperforation and an inflammatory mass with matted lymph nodes. Full thickness biopsies of the jejunum demonstrated multiple ulcerations but no features of Crohn's, celiac disease, ischemia, lymphoma, vasculitis, neoplasm, or infectious etiology (Figure 3A-C). After the surgery, prednisone was

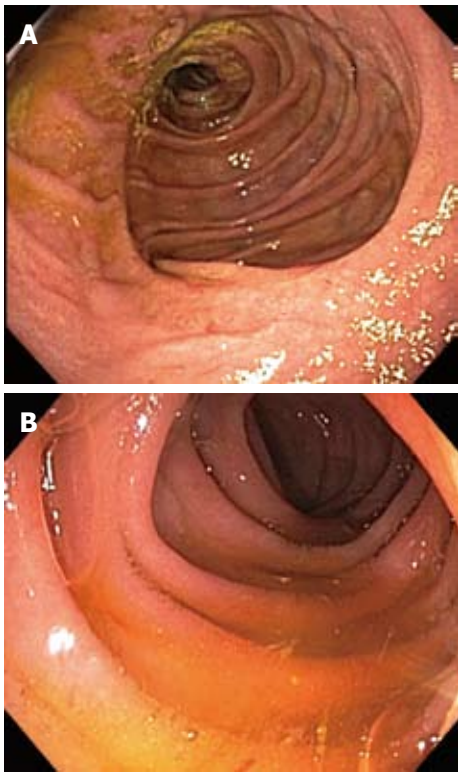

Figure 4 Complete improvement on endoscopic findings after infliximab therapy. A: Jejunojejunostomy; B: Distal jejunum.

tapered and discontinued 6 mo postoperatively.

To date (30 mo), the patient is stable on every eight week infliximab infusion. His PPI has been discontinued, and there is no evidence of ulceration, enteritis, or lymphoma on follow-up enteroscopy (Figure 4A and B), colonoscopy, or abdominal CT.

DISCUSSION

Although pathophysiology of ulcerative jejunoileitis is poorly understood, it may be related to mucosal infiltration by activated T-cells. A molecular analysis of mucosal T-cell populations has previously shown that monoclonal T-cells exist in ulcers and normal mucosa, suggesting a fundamental role of T-cells in ulcer pathogenesis[3]. Another study demonstrated that the cytotoxic capability of T-cells is responsible for the development of the ulcers with preference for mucosa-associated lymphoid tissue localization[4]. Tumor necrosis factor alpha (TNF-α) plays a pivotal role in Crohn's disease[5]. Increased levels of interleukin-6 and TNF-α in the lamina propria and epithelium of patients with untreated celiac disease also support their role in the development of the mucosal damage observed in celiac disease[6]. Infliximab therapy results in a reduction in the activated T lymphocytes that accumulate within the lamina propria in Crohn's disease, and neutralization of TNF is effective in induction and maintenance of remission in Crohn's disease[7]. Case reports using infliximab in patients with refractory celiac disease have shown improvement in symptoms, and duodenal histology[8,9]. One additional case of ulcerative jejunoileitis complicating refractory celiac disease has been published, demonstrating improvement in fecal output and small bowel histology[10]. However, a complete recovery was not achieved and parenteral nutritional support continued. Seven months later, the patient developed a stenosis of the distal ileum and surgical resection demonstrated enteropathy-associated T-cell lymphoma.

In contrast, we have demonstrated that infliximab plays a key role in the management of ulcerative jejunoileitis and should be considered a treatment option for patients with this disorder.

Abstract

Scrub typhus is an acute febrile disease caused by *Orientia tsutsugamushi* (*O. tsutsugamushi*). We report herein the case of a woman who presented with fever and elevated serum levels of liver enzymes and who was definitively diagnosed with scrub typhus by histopathological examination of liver biopsy specimens, serological tests and nested polymerase chain reaction. Immunohistochemical staining using a monoclonal anti-*O. tsutsugamushi* antibody showed focally scattered positive immunoreactions in the cytoplasm of some hepatocytes. This case suggests that scrub typhus hepatitis causes mild focal inflammation due to direct liver damage without causing piecemeal necrosis or interface hepatitis. Thus, scrub typhus hepatitis differs from acute viral hepatitis secondary to liver damage due to host immune responses, which causes severe lobular disarray with diffuse hepatocytic degeneration, necrosis and apoptosis as well as findings indicative of hepatic cholestasis, such as hepatic bile plugs or brown pigmentation of hepatocytes.

INTRODUCTION

Scrub typhus is an acute febrile disease caused by *Orientia tsutsugamushi* (*O. tsutsugamushi*) that occurs when *O. tsutsugamushi* is transmitted to humans through the bites of chiggers (*Leptotrombidium*)[1]. Previous reports from Taiwan have revealed that 97% of hospitalized scrub typhus patients have high serum levels of aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase as well as subsequent abnormal liver function[2,3]. However, only a few studies have evaluated the histopathological features of patients with scrub typhus hepatitis[4]. We report herein the case of a woman who presented with fever and elevated serum levels of liver enzymes and who was definitively diagnosed with scrub typhus by a histopathological examination of liver biop-

sy specimens, serological tests and a nested polymerase chain reaction (PCR).

CASE REPORT

A 63-year-old woman presented at our clinic with a 5-d history of fever. Five days previously, the patient had visited a primary care clinic due to fever, chills, headache, myalgia, anorexia and diarrhea. She was transferred to our clinic because of her unusually high serum levels of liver enzymes and low platelet count. She was a housewife by occupation and had worked in the field every day for 3 wk prior to her illness. She presented with the following clinical parameters: blood pressure, 100/60 mmHg; pulse rate, 84/min; respiratory rate, 20/min; and body temperature, 38.1 ℃. Hematochemical tests revealed the following: white blood cell count, 2.97/L (neutrophils 59%, lymphocytes 25%); hemoglobin, 12.4 g/dL; platelets, 117/L; erythrocyte sedimentation rate, 22 mm/h; C-reactive protein, 5.05 mg/dL; aspartate aminotransferase (AST)/alanine aminotransferase (ALT), 426/299 U/L; gamma-glutamyltransferase (γ-GTP)/alkaline phosphatase, 368/299 U/L; total bilirubin, 1.12 mg/dL; and lactate dehydrogenase/creatinine phosphokinase, 172/110 U/L (normal range, 180-460/26-20 U/L). The patient was negative for antibodies against acute hepatitis viruses A, B, D and E and for immunoglobulin M (IgM) against Epstein-Barr virus capsid antigen. PCR for cytomegalovirus and antigenemia tests were also negative. Antibodies involved in connective tissue diseases were absent. Specimens for immunohistochemical staining were obtained by ultrasound-guided needle aspiration to accurately evaluate the increased serum levels of liver enzymes. For immunohistochemical staining, we used a monoclonal anti-*O. tsutsugamushi* antibody that targets a recombinant 56 kDa protein of a clinical *O. tsutsugamushi* Boryong strain. Immunolocalization was performed using a polyvalent horseradish peroxidase polymer detection system according to the manufacturer's protocol (Lab Vision, Fremont, CA, United States)[5].

On the third day of hospitalization, a fever was evident (≥ 38 ℃), chills and headache persisted, and maculopapular rashes occurred. Thus, we conducted serological tests for scrub typhus, leptospirosis and hemorrhagic fever with renal syndrome (HFRS) as well as PCR for scrub typhus and leptospirosis. Hematoxylin and eosin staining of the biopsy specimens revealed mild inflammation with a small number of eosinophils and a dominance of lymphocytes in the portal areas. Piecemeal necrosis and interface hepatitis were not evident in the portal tract (Figure 1). Mild degrees of lobular disarray and ballooning degeneration of hepatocytes were observed in addition to the necrosis of isolated hepatocytes. However, there were no clusters of necrotic hepatocytes, bridging necrosis, intracanalicular bile plugs or intrahepatic cholestasis. Immunohistochemical staining using a monoclonal anti-*O. tsutsugamushi* antibody showed scattered positive immunoreactions in the cytoplasm of some hepatocytes (Figure 1D). Serological tests for *O. tsutsugamushi* performed on the third day of hospitalization revealed anti-*O. tsutsugamushi* IgM and immunoglobulin G (IgG) antibody titers of 1:40 and 1:1024, respectively. Nested PCR using the blood buffy coat was positive for the gene encoding the 56 kDa protein of *O. tsutsugamushi*. Serological tests were negative for HFRS and leptospirosis. Based on these findings, a comprehensive physical examination was conducted, which revealed an eschar on one of her labia minora. The patient reported that she had urinated during field work. Finally, she was definitively diagnosed with scrub typhus. A 5-d course of doxycycline improved the symptoms of fever, chills and headache and her unusually high levels of liver enzymes and low platelet count. She was discharged from the hospital without any complications. At the time of discharge, serological tests showed anti-*O. tsutsugamushi* IgM and IgG titers of 1:5120 and 1:16 384, respectively.

DISCUSSION

Fever, headache and skin rash are potential indicators of rickettsial diseases[6]. In the present case, the patient presented with fever, diarrhea and elevated serum levels of liver enzymes without a typical skin rash or eschar suggestive of scrub typhus. We initially considered infections caused by hepatitis virus, other infectious diseases such as tuberculosis and autoimmune hepatitis. Serological tests, serum protein electrophoresis and the use of antinuclear antibodies all yielded negative results, but immunohistochemical staining of a biopsy specimen revealed hepatocytes positive for *O. tsutsugamushi*. Because a maculopapular skin rash developed during hospitalization and because positive immunohistochemical staining was confirmed, a thorough history and a comprehensive physical examination were conducted, which confirmed an eschar on a labium minus and a history of urination during field work. These results reflect the importance of a thorough physical examination that includes the genitalia[7].

Although many studies have reported increases in liver enzymes in patients with scrub typhus[2], there have been only a few reports on the histopathological features of this disease[4]. In this case, the primary lesion was portal triad inflammation, which is consistent with the results of a previous study indicating that *Rickettsia* and *Orientia* species mainly cause such inflammation due to tropism for the vascular endothelium[8]. Rickettsioses cause focal lesions in various organs but do not cause extensive hepatic lesions that are sufficient to cause organ failure[9]. In addition, although Rocky Mountain Spotted Fever causes the focal death of some hepatocytes and increases in the serum levels of liver enzymes due to hepatic infection, hepatic failure does not occur[8]. In our case, immunohistochemical staining showed scattered focal positive immunoreactions. *O. tsutsugamushi* hepatitis is speculated to cause primarily intrahepatic sinusoidal endothelial vasculitis and to increase the serum levels of

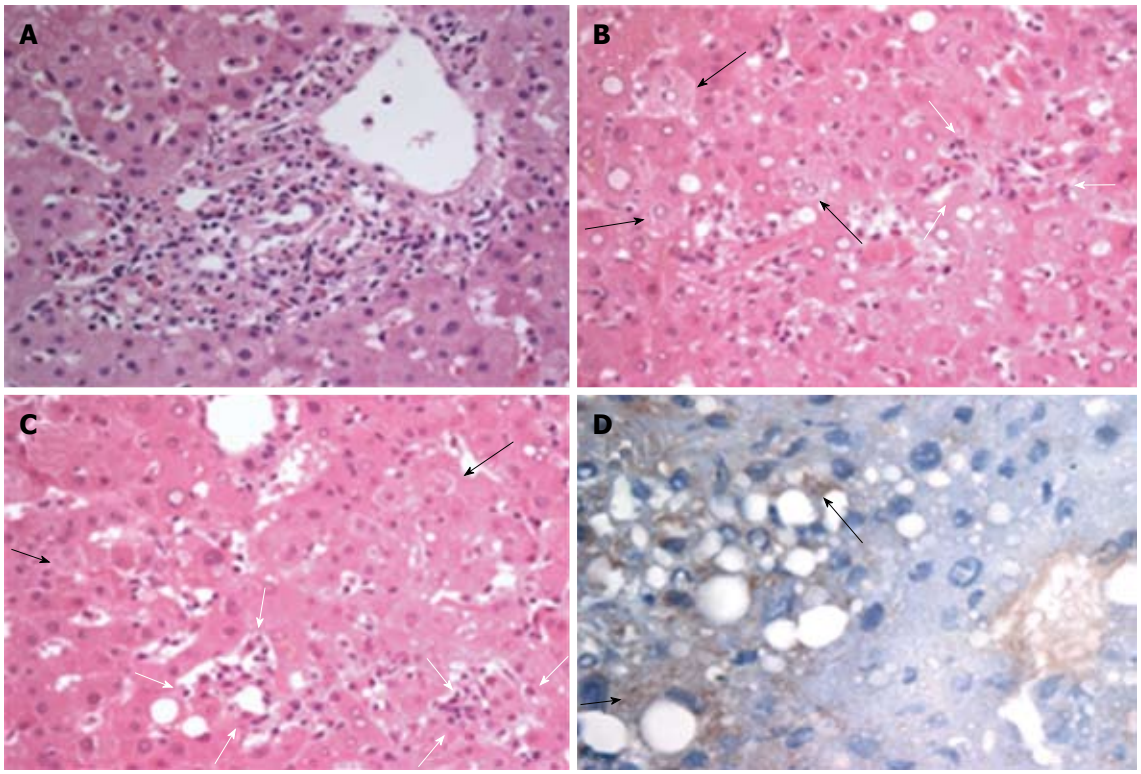

Figure 1 Histopathological analysis of a liver specimen from a patient with scrub typhus. A: Portal inflammation showing lymphocytes and some eosinophils devoid of distinct interface hepatitis; B, C: The degeneration of individual hepatocytes (black arrows), mild ballooning changes with lobular disarray and small clusters of mononuclear cell infiltration (white arrows) identified in the lobules. Neither cholestasis nor hepatocyte apoptosis are evident (hematoxylin and eosin stain, ×400 magnification); D: Immunohistochemical staining for *Orientia tsutsugamushi* demonstrating scattered positive immunoreactions (arrows) in the cytoplasm of the hepatocytes (labeled streptavidin-biotin method, counterstained by hematoxylin, ×400 magnification).

AST, ALT and γ-GTP due to direct cytopathic liver damage[10]. In contrast, host immune responses have been shown to cause viral hepatitis-induced liver damage[11,12]. The hepatitis virus multiplies within the cytoplasm of hepatocytes, causing non-cytopathic inflammation and hepatocellular damage as well as the destruction of infected hepatocytes through human leukocyte antigen-restricted, hepatitis A virus-specific CD8+ T lymphocytes and natural killer cells. Because hepatocyte degeneration, necrosis and apoptosis are more severe in acute viral hepatitis, it is conceivable that the serum levels of AST and ALT would be significantly higher in acute viral hepatitis than in scrub typhus hepatitis. Unlike patients with scrub typhus hepatitis, patients with viral hepatitis exhibit hepatic cholestasis, including intracanalicular bile plugs or the brown pigmentation of hepatocytes; this hepatic cholestasis can markedly increase the serum levels of γ-GTP and alkaline phosphatase[13,14]. Further studies are needed to confirm the relationship between the laboratory and histopathological findings.

Although granuloma formation in the liver is a characteristic finding in patients with scrub typhus, our patient did not have granulomatous hepatitis. It is thought that granulomatous hepatitis can be observed in some patients with scrub typhus.

In summary, this case has 2 clinical implications. First, our patient was diagnosed early with scrub typhus by immunohistochemistry using a monoclonal antibody for *O. tsutsugamushi*. The immunohistochemical analysis showed scattered focal positive immunoreactions in the cytoplasm of some hepatocytes. Second, our report supports previous findings demonstrating that scrub typhus hepatitis causes mild portal inflammation and lobular activities without causing significant interface hepatitis or intralobular hepatocyte death due to focal direct liver damage. In contrast, acute viral hepatitis secondary to host immune response-induced liver damage causes severe lobular disarray with diffuse hepatocyte degeneration, necrosis and apoptosis as well as findings of hepatic cholestasis, including intracanalicular bile plugs and the brown pigmentation of hepatocytes.

Abstract

Air in the main pancreatic duct has been reported only rarely and might be associated with either a spontaneous or a surgically induced alteration of the anatomy of the biliary tract. We report a case of "innocent" air found incidentally in the main pancreatic duct. To our knowledge, this is only the third such case reported. A 54-year-old woman presented with hemoptysis that had lasted for 3 d. She underwent a chest computed tomography scan, which revealed not only focal bronchiectasis in the left lower lobe, but also air in the main pancreatic duct and dilatation of the common bile duct. She was managed conservatively for the hemoptysis and no further problems developed. She had no specific gastrointestinal symptoms and had no history of surgery or medication. Her laboratory parameters were normal. Magnetic resonance cholangiopancreatography also demonstrated air in the main pancreatic duct and a dilated common bile duct (CBD). Duodenoscopy revealed separate biliary and pancreatic orifices with patulous openings and some air bubbles appearing in the pancreatic orifice. Endoscopic retrograde cholangiopancreatography (ERCP) showed the dilated CBD and pancreatic duct with some air bubbles, but no other abnormal lesions. She was discharged with no further problems. Most patients with air in the main pancreatic duct have had a pancreatobiliary disease, or a history of pancreatobiliary disease, pancreatobiliary surgery or sphincterotomy. If the air is innocent, as in our case, ERCP should be performed to evaluate any altered sphincteric function or anatomy such as patulous openings.

INTRODUCTION

Air in the pancreas is unusual and is usually related to an abscess, emphysematous pancreatitis or a pancreatic fistula[1,2]. There have been several cases reported, including one case series of air in the main pancreatic duct rather than in the pancreas itself[3-9].

This phenomenon has been reported in a child with biliary and pancreatic ascariasis with liver abscesses and a pancreatic pseudocyst[3], in an adult patient with cystic dilatation of the main pancreatic duct limited to the

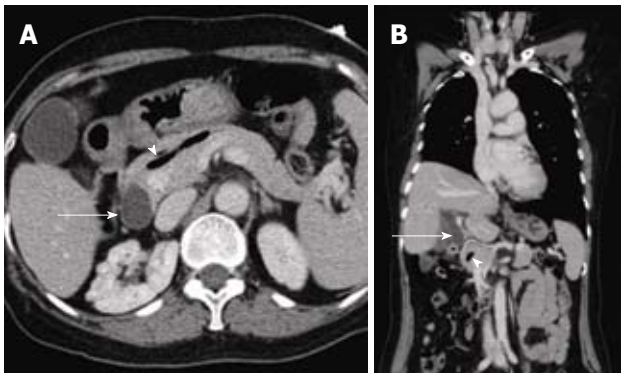

Figure 1 Computed tomography scans revealed air in the main pancreatic duct (arrowhead) and dilatation of the common bile duct (arrow). A: Axial scan; B: Coronal scan.

Figure 3 Endoscopic retrograde cholangiopancreatography showed dilatations of the common bile duct and pancreatic duct with some air bubbles (arrowheads), but no other abnormal lesions.

head of the organ[4], in a patient after transampullary septectomy[5], in 11 patients with various acute or chronic pancreatic and/or biliary diseases[6], in three infants with a congenital duodenal obstruction[7], in a middle-aged man with a history of acute pancreatitis[8], and in a young woman with acute pancreatitis and a pseudocyst[9]. Among these patients, most had a pancreatobiliary disease, or a history of pancreatobiliary disease, pancreatobiliary surgery or sphincterotomy, whereas only two patients had no such background.

We report a case of "innocent" air in the main pancreatic duct found incidentally. The patient had no history of a pancreatobiliary disease and had no pancreatic or biliary symptoms.

CASE REPORT

A 54-year-old woman presented at our hospital's division of pulmonology with hemoptysis that had lasted for 3 d. She underwent a chest computed tomography (CT) scan, which revealed not only focal bronchiectasis in the left lower lobe, but also air in the main pancreatic duct (arrowhead in Figure 1) and dilatation of the common bile duct (CBD; arrow in Figure 1). She was managed conservatively for the hemoptysis and no further problems developed. She was referred to the gastrointestinal (GI) division for an evaluation. She had no specific GI symptoms such as abdominal pain and had no history of surgery or medication. Her laboratory parameters were normal (hemoglobin, 14.8 g/dL; white blood cell, 6400/mm^3; aspartate aminotransferase/alanine aminotransferase, 17/16 IU/L; total bilirubin, 1.14 mg/dL; alkaline phosphatase, 182 IU/L; γ-glutamyl transpeptidase, 31 IU/L; amylase, 94 IU/L). To better evaluate the pancreatic ductal system, magnetic resonance cholangiopancreatography (MRCP) was carried out. This also demonstrated air in the main pancreatic duct and the dilated CBD. To further evaluate the ampulla of Vater and the pancreatobiliary ductal system, endoscopic retrograde cholangiopancreatography (ERCP) was carried out. A duodenoscopic examination revealed separate biliary (arrow in Figure 2) and pancreatic orifices with patulous openings and some air bubbles appearing in the pancreatic orifice (arrowhead in Figure 2). The ERCP showed the dilated CBD and pancreatic duct with some air bubbles (Figure 3), but no other abnormal lesions. She was discharged with no further problems.

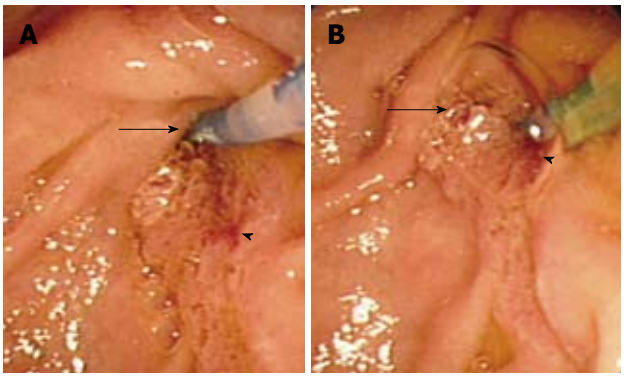

Figure 2 Duodenoscopy revealed separate biliary and pancreatic orifices. A: A catheter inserted into the biliary orifice (arrow); B: A catheter inserted into the pancreatic orifice (arrowhead). The pancreatic orifice was patulous with some air bubbles appearing in it.

DISCUSSION

Here, we report a case of "innocent" air found incidentally in the main pancreatic duct. The patient had no pancreatobiliary disease or history of it. She had separate biliary and pancreatic orifices with patulous openings but displayed no pancreatic or biliary symptoms. To our knowledge, this is only the third case reported of innocent air in the main pancreatic duct[4,6].

This phenomenon has been reported only rarely and might be associated with either a spontaneous or surgically induced alteration of the anatomy of the biliary tract. The origin of such air is not known, but there have been two possible explanations given[6,10]. First, it is likely that air in the pancreatic duct is the result of biliary-pancreatic reflux in patients who have received biliary-enteric anastomoses or have undergone sphincterotomy. Second, in patients who have not undergone

such operations, the likely cause of pancreatic duct air is a duodenal-pancreatic duct reflux. This possibility arose from the observation that six of 11 patients with air in the pancreatic duct had undergone previous biliary or pancreatic surgery or had undergone sphincterotomy; these patients all had pneumobilia[6]. However, these patients comprised only 5% of all who had received biliary anastomoses or had undergone sphincterotomy, so this mechanism seemed to operate only in a minority of such patients. Duodenal-pancreatic duct reflux occurring in patients who have not undergone pancreatobiliary surgery or sphincterotomy could be explained by the animal experiment of DiMagno *et al*[10]. That is, during duodenal phase Ⅲ motor activity of the interdigestive period, the mean duodenal pressure at times exceeds the mean pancreatic pressure, and reflux of duodenal contents into the pancreatic duct can occur. Generally, the sphincter of Oddi plays a major role in regulating secretory flow and preventing such reflux, but patients who have undergone a sphincterotomy or have had papillitis might have altered sphincter function so that reflux could occur more commonly. However, in three patients with a common channel, air was present only in the pancreatic duct and not in the biliary system[6]. This could be explained neither by a biliary-pancreatic reflux nor by a duodenal-pancreatic duct reflux. Further investigations on the presence of air in the pancreatic duct are needed.

In all previous reports, air in the pancreatic duct was demonstrated by CT scans[3,4,8,9] or ultrasonography[5-7]. CT is known to be sensitive for detecting small amounts of gas. Generally, air in the pancreatic duct is never demonstrated on plain radiographs. In our case, air in the pancreatic duct was found first by a CT scan and then found in MRCP and ERCP studies. In a previous case series, nine of 11 patients underwent a second ultrasound examination and air in the pancreatic duct was only confirmed in five[6]. In another case, air in the pancreatic duct found first on CT scans was not shown in the second MRCP[8]. This spontaneous disappearance of air seemed to be related to the cyclically variable diameter of the pancreatic duct associated with air expulsion or the phasic motor activity of the sphincter of Oddi[6]. As in our case, why air in the pancreatic duct persisted was not understood fully. However, in our case, the major duodenal papilla had separate biliary and pancreatic orifices with patulous openings. This anatomy could have been one cause of air in the pancreatic duct that also affected the persistence of air. Why there was no pneumobilia and the CBD was dilated is also not understood fully; possibly the degree of altered sphincteric function differed between the separate biliary and pancreatic orifices.

In most cases reported in the literature, the patients had a history of biliary and/or pancreatic disease, such as pancreatitis or cholangitis, or a history of pancreatobiliary surgery or sphincterotomy[3,5-9]. Two patients had no history of pancreatobiliary disease or surgery and no pancreatobiliary symptoms[4,6]. Our patient also had no history of pancreatobiliary disease or surgery and no related symptoms. Therefore, this appears to be the third reported case of innocent air in the pancreatic duct. Separate duct orifices with patulous openings might be related to the presence of air in the pancreatic duct and the dilated CBD, but how such patulous openings formed is not known.

In summary, when air in the pancreatic duct is discovered, the physician should investigate a history of pancreatobiliary disease, a history of pancreatobiliary surgery and sphincterotomy and any related symptoms. If the air is innocent, as in our case, ERCP should be performed to evaluate any altered sphincteric function or anatomy such as patulous openings.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/esps/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

The progress of tissue-engineering technology has realized development of new therapies to treat various disorders by using cultured cells. Cell- and tissue-based therapies have been successfully applied to human patients, and several tissue-engineered products have been approved by the regulatory agencies and are commercially available. In the review article, we describe our experience of development and clinical application of cell sheet-based regenerative medicine. Endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) have been shown to be useful for removal of gastrointestinal neoplasms with less invasiveness compared with open surgery, especially in esophageal surgery. However, postoperative inflammation and stenosis are major complications observed after intensive mucosal resection. Therefore, we have developed novel regenerative medicine to prevent such complications and promote wound healing of esophageal mucosa after EMR or ESD. Transplantable oral mucosal epithelial cell sheets were fabricated from patients' own oral mucosa. Immediately after EMR or ESD, fabricated autologous cell sheets were endoscopically transplanted to the ulcer sites. We performed a preclinical study with a canine model. In human clinical settings, cell culture and cell sheet fabrication were performed in clean rooms according to good manufacturing practice guidelines, and pharmaceutical drugs were used as supplements to culture medium in place of research regents used in animal study. We believe that cell-based regenerative medicine would be useful to improve quality of life of patients after EMR or ESD.

INTRODUCTION

Endoscopic mucosal resection (EMR) is one of the standard techniques for removing superficial early-stage cancers in the gastrointestinal tract with low invasiveness compared with open surgery[1,2]. In the case of the esophagus, EMR is a useful operation for removing m1 (epithelial cancers restricted to the intraepithelial layer) and m2 (mucosal cancers with invasion of intermediate depth) carcinomas without esophageal reconstruction. To permit large *en bloc* resection of cancerous lesions without technical restriction of EMR, endoscopic submucosal dissection (ESD) was developed as a new mucosal resection technique with development of endoscopic devices[3-5]. Early-stage esophageal cancers are removed using a hook-knife, which is an endoscopic device used to perform ESD[6]. ESD is a more impressive operative procedure than EMR for reducing the recurrence of esophageal squamous cell carcinoma[7]. Although these developments of endoscopic surgery contribute low invasive cancer resection for patients suffering from esophageal cancer, there are some postoperative complications after ESD. Esophageal stenosis is a major complication caused by endoscopic resection, and the stenosis is significantly associated with the mucosal defect involving over three-fourths circumference of the esophagus lumen[8]. The esophageal stenosis caused by aggressive ESD considerably affects the patient's quality of life, since the patient has to receive treatment with balloon dilation or temporary stents to expand the esophageal stricture with further inflammation and postoperative pain. These physical dilations carry a risk of perforation[9]. Treatment with anti-inflammatory drugs after endoscopic resection may be an effective therapy for preventing stricture after ESD[10,11].

With recent progression of tissue engineering and regenerative medicine, there are some reports proposing new technologies using biological scaffolds[12] or cell suspensions[13,14] for preventing the esophageal stenosis caused by mucosal defects. We have developed a novel method of endoscopic transplantation of autologous epithelial cell sheets immediately after ESD to prevent the postoperative complications[15]. Transplantable tissue-like epithelial cell grafts are fabricated by cell sheet technology. On the basis of results obtained with canine and porcine models, we have used this technology with human patients since 2008.

CELL SHEET TECHNOLOGY FOR REGENERATION OF ESOPHAGEAL MUCOSA

Tissue engineering by using cell sheet technology

The concept of tissue engineering was originally proposed by Langer *et al*[16]. Conventionally, biodegradable polymer scaffolds have been used to reconstruct tissue architecture, and cells are seeded on them. The technique should be useful to reconstruct bone and cartilage, having a large amount of extracellular matrices (ECM) and few cells. However, scaffold-based tissue engineering would not be optimal for the regeneration of parenchymal tissues filled with a huge amount of cells and faint ECM. Therefore, we have proposed an alternative method of tissue reconstruction by using transplantable cell sheets to eliminate biodegradable scaffolds.

In order to fabricate transplantable cell sheets without any scaffolds, we employ temperature-responsive culture surfaces, onto which poly (N-isopropylacrylamide) is covalently immobilized to control cell adhesion/detachment with a simple temperature change[17]. Cells adhere, spread, and proliferate on temperature-responsive surfaces at 37 ℃, which is the normal temperature for mammalian cell culture. By reducing temperature below 32 ℃, cells spontaneously detach from the surfaces without proteolytic enzyme such as trypsin, since the grafted polymer becomes hydrophilic. When the temperature is reduced after cells reach confluence, all the cells are harvested as a single contiguous cell sheet. Because this technique eliminates trypsin for cell harvest, all the cell membrane proteins including growth factor receptors, ion channels and cell-to-cell junction proteins are intact even after cell and cell sheet harvest. Furthermore, ECM deposited during cell culture is retained under cell sheets[18]. Therefore, cell sheets easily integrate to transplanted sites. With this technique, many types of epithelial cell sheets are fabricated and subjected to regenerative medicine of skin[19], cornea[20], urinary bladder[21], and trachea[22].

Cultured epithelial cells for clinical application

Cultured autologous epidermal keratinocytes have been used as cell grafts to treat burns as the first therapy using cultured cells[23]. A transplantable epidermal cell graft is fabricated using murine 3T3 feeder layer cells[24]. Human keratinocytes co-cultured with 3T3 feeder cells proliferate and show stratification as *in vivo* with characteristics of native epithelial tissues including tonofilaments and desmosomes. Interestingly, human epidermal keratinocytes can be serially cultured to more than 150th passages *in vitro*[25]. The cultivation of human keratinocytes achieved clinical treatments for severe burns[26] and giant congenital nevi[27] by transplantation of cultured autologous keratinocyte grafts. Moreover, allogeneic keratinocyte grafts are also used for skin ulcers[28]. In these cases, keratinocyte sheets are harvested with bacteria-derived dispase treatment.

Oral mucosal epithelium is also stratified squamous epithelium, and on the basis of the feeder layer method, the epithelial cells have been used as a cell source to fabricate transplantable epithelial cell grafts for treating oral mucosa[29-31]. Moreover, since extraction of oral mucosal tissue is easy, cultured human oral mucosal epithelial cells are selected as useful cell grafts for ectopic transplantation, such as skin[30,32]. We have successfully applied cultured autologous oral mucosal epithelial cell sheets fabricated on temperature-responsive culture inserts to treat human patient cornea suffering from limbal epi-

thelial stem cell deficiency[33,34]. Furthermore, we utilized cultured autologous oral mucosal epithelial cell sheets for bladder reconstruction by the transplantation onto a demucosalized gastric flap in a canine model[35]. We believe that cultured oral mucosal epithelial cell sheets fabricated on temperature-responsive surfaces are useful for treatment of many types of epithelial diseases as well as reconstruction of defective tissues.

Fabrication of transplantable oral mucosal epithelial cell sheets in the clinical setting

To promote healing of esophageal ulcers after ESD for the prevention of postoperative complications, we performed endoscopic transplantation of cultured autologous oral mucosal epithelial cell sheets in the clinical setting. From the safety view point, animal-derived materials, such as bovine serum and 3T3 feeder cells should be eliminated as much as possible. For example, human embryonic stem cells cultured under a typical culture condition using animal-derived serum replacements and mouse feeder layer express an immunogenic nonhuman sialic acid[36]. Moreover, cells co-cultured with a mouse feeder layer are classified as xenogeneic products by United States Food and Drug Administration.

We reported that oral mucosal epithelial cells make transplantable stratified cell sheets on temperature-responsive cell culture inserts having micropores to supply culture medium from the basal cell surfaces even without a 3T3 feeder layer and allogeneic serum[37]. The method can, in principle, permit the cultured human oral mucosal epithelial cell sheets to be used as an autologous epithelial cell sheet graft for human patients[38]. Therefore, the autologous epithelial cell sheets are not, in principle, rejected after transplantation onto the esophageal ulcer and may be replaced by native epithelium in the esophagus. Moreover, the culture medium for the preparation of cultured oral mucosal epithelial cell sheets is modified to exclude laboratory reagents as much as possible for the clinical use[39].

Transplantable epithelial cell sheets are fabricated in a cell-processing center (CPC) with clean rooms according to the good manufacturing practice guideline in the clinical study. The cleanliness of the CPC is controlled by air conditioning systems using high efficiency particulate air filters, and standard operation procedures (SOP) are documented to keep a sterile environment of cell culture rooms in the CPC. The environment of the CPC is continuously monitored with various monitors including aerosol particles, temperature, and humidity, and various sterilization tests are performed to validate the cleanliness of the environment. In these tests culture rooms in the CPC were successfully kept sterile[40,41]. SOP of the culture method was also documented for the prevention of human error of operators to fabricate cell sheets highly reproducibly. Consequently, transplantable human epithelial cell sheets were successfully fabricated in a clinical study to treat ten human patients, and validation tests to demonstrate the quality assurance were performed one day before the ESD and transplantation.

From the average yield of the cells isolated from excised human oral mucosal tissues of healthy volunteer donors, we concluded that approximately 0.3 cm^2 of oral mucosal tissue is needed to fabricate one transplantable epithelial cell sheet having an area of 2.8 cm^2 (Figure 1A and B). The degree of cell stratification is an important point to enable reproducible cell sheet harvesting from temperature-responsive culture inserts. Figure 1C and D show the growth of seeded human oral mucosal epithelial cells. These cells became confluent on the surface of temperature-responsive culture inserts, and elevation of cell density accompanied with cell stratification was observed after a further 5 d.

Endoscopic transplantation of epithelial cell sheet onto esophageal ulcer immediately after ESD

Since 2008, we have performed a clinical study using cultured autologous human oral mucosal epithelial cell sheets to treat esophageal ulcer after endoscopic resection of a mucosal neoplasm. Endoscopic transplantation of the cultured epithelial cell sheets is performed using a support membrane to grasp by endoscopic forceps[42]. Epithelial cell sheets transplanted onto esophageal ulcer with a support membrane in a swine model are shown in Figure 2. One epithelial cell sheet fabricated on temperature-responsive culture insert (23 mm in diameter) covers the ulcer surface involving approximately one-third circumference of the esophagus lumen (Figure 2A and B), and three or four epithelial cell sheets were needed to cover the full circumferential ulcer (Figure 2C and D).

Although more research is needed for understanding the mechanism and correlation between ulcer size and number of transplanted epithelial cell sheets for preventing inflammation and postoperative stenosis, serial cultivation is a useful method of preparation of epithelial cells from small tissue for fabricating cell grafts to transplant onto a large ulcer after aggressive ESD. Serial culture using low calcium concentration medium (LCM) is a useful method to amplify a cell number of stratified squamous epithelial cells without using 3T3 feeder cells[43,44]. Interestingly, although normal human epidermal keratinocytes cultured in LCM show some mesenchymal-like phenotype, the keratinocytes can express the differentiation marker and stratify in differentiation-inducing culture conditions[45]. Since the conventional culture medium for serial cultivation of epithelial cells typically includes animal-derived material, the medium is not useful for clinical use. The modification of the LCM would be important for fabricating epithelial cell sheets to transplant onto large esophageal ulcers after aggressive ESD without any complications.

CONCLUSION

This article introduces cell sheet technology to fabricate stratified epithelial cell sheet grafts for preventing postoperative inflammation and stenosis after endoscopic re-

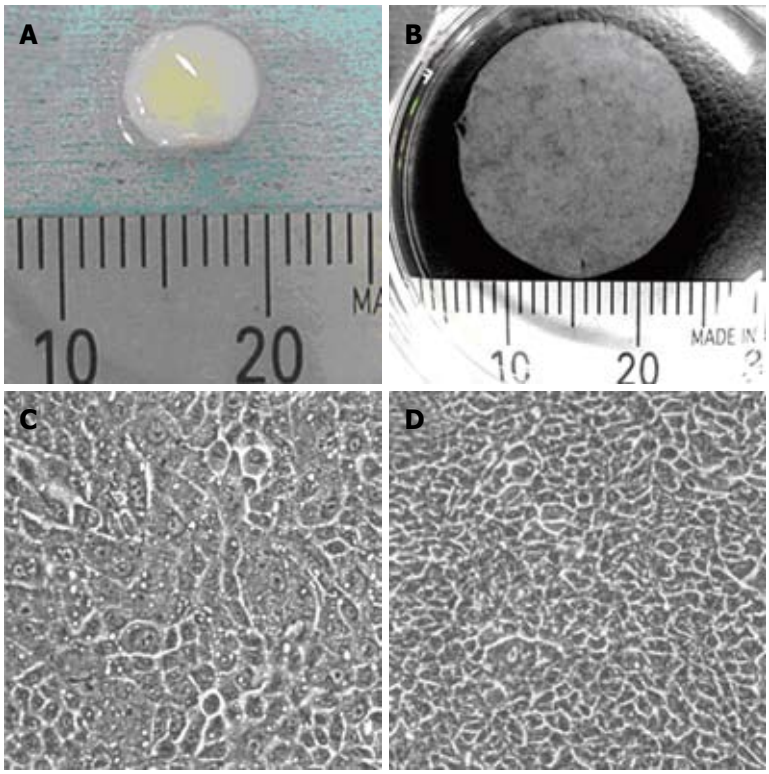

Figure 1 Transplantable oral mucosal epithelial cell sheet. section for removing early-stage cancers from the esophagus. The efficacy of the oral mucosal epithelial cell sheet has been demonstrated, and the method for fabricating the cell sheet has also developed to use the cell graft as a clinical application for treating esophageal ulcers. This new therapy has been developed by integration of endoscopic technology and cell sheet technology. We believe that cell sheet technology will meet new technology and then the integration will create new therapies for treating patients without any specific therapies.

Abstract

Irritable bowel syndrome (IBS) is a common gastrointestinal (GI) disorder that considerably reduces the quality of life. It further represents an economic burden on society due to the high consumption of healthcare resources and the non-productivity of IBS patients. The diagnosis of IBS is based on symptom assessment and the Rome Ⅲ criteria. A combination of the Rome Ⅲ criteria, a physical examination, blood tests, gastroscopy and colonoscopy with biopsies is believed to be necessary for diagnosis. Duodenal chromogranin A cell density is a promising biomarker for the diagnosis of IBS. The pathogenesis of IBS seems to be multifactorial, with the following factors playing a central role in the pathogenesis of IBS: heritability and genetics, dietary/intestinal microbiota, low-grade inflammation, and disturbances in the neuroendocrine system (NES) of the gut. One hypothesis proposes that the cause of IBS is an altered NES, which would cause abnormal GI motility, secretions and sensation. All of these abnormalities are characteristic of IBS. Alterations in the NES could be the result of one or more of the following: genetic factors, dietary intake, intestinal flora, or low-grade inflammation. Post-infectious IBS (PI-IBS) and inflammatory bowel disease-associated IBS (IBD-IBS) represent a considerable subset of IBS cases. Patients with PI- and IBD-IBS exhibit low-grade mucosal inflammation, as well as abnormalities in the NES of the gut.

INTRODUCTION

Irritable bowel syndrome (IBS) affects as many as 5%-20% of individuals worldwide (Figure 1)[1-31]. The annual incidence of IBS is between 196 and 260 per 100 000[32,33], with IBS occurring more often in women than in men, and being more commonly diagnosed in patients younger than 50 years of age[14,34-44]. IBS symptoms range from diarrhoea to constipation, or a combination of the two, with abdominal pain or discomfort existing alongside abdominal distension[45]. The degree of symptoms varies in different patients from tolerable to severe, and the time pattern and discomfort varies immensely from patient to patient[14,34-44]. Some patients complain of daily symptoms, while others report intermittent symptoms at intervals of weeks or months. IBS is not known to be associated with the development of serious disease or with excess mortality[46,47]. However, IBS causes a reduced quality of life with the same degree of impairment as major chronic diseases, such as diabetes, congestive heart failure, renal insufficiency and hepatic cirrhosis[48-50]. Although a minority (10%-50%) of IBS patients seek healthcare, they generate a substantial workload in both primary and secondary care[51-53]. The annual costs in the United States, both direct and indirect,

for the management of patients with IBS are estimated at 15-30 billion USD[37,54,55].

The treatment options for IBS have included pharmacological symptomatic relief of symptoms such as pain, diarrhoea or constipation. Evidence of the long-term benefit of pharmacological agents has been sparse, and new agents that have proven to be effective have raised issues concerning safety[56,57]. Alternative therapies, such as cognitive behavioural therapy and gut-directed hypnotherapy, have been used with good results[58]. Other non-pharmacological approaches have been also tried with proven effects on symptoms and the quality of life in patients with IBS[58].

The present review is an attempt to give an update on the diagnosis and pathogenesis of IBS, and to discuss some controversial issues in both the diagnosis and pathogenesis of IBS.

DIAGNOSIS

There is currently no biochemical, histopathological or radiological diagnostic test for IBS, with the diagnosis of IBS being based mainly on symptom assessment. Over the last few years, Rome working parties have generated detailed, accurate, and clinically useful definitions of the syndrome. As a result, the Rome criteria (Ⅰ, Ⅱ and Ⅲ) have been established (Table 1)[59,60]. In addition to these criteria, warning symptoms or red flags, such as age over 50 years, a short history of symptoms, nocturnal symptoms, weight loss, rectal bleeding, anaemia, and the presence of markers for inflammation or infections, should be excluded. IBS patients are sub-grouped on the basis of differences in the predominant bowel pattern as diarrhoea-predominant (IBS-D), constipation-predominant (IBS-C), or a mixture of both diarrhoea and constipation (IBS-M), and un-subtyped IBS in patients with an insufficient abnormality of stool consistency to meet the criteria for IBS C, D or M (Table 2). It has been reported that around one third of patients have IBS-D, one third have IBS-C, and the remainder have IBS-M[61-63]. The division of IBS patients into subtypes is useful for clinical practice and symptomatic treatment, but it is common for IBS patients to switch from one subtype to another over time. These patients are known as "alternators". More than 75% of IBS patients change to either of the other 2 subtypes at least once over a 1-year period[63].

The majority of gastroenterologists believe that a symptom-based diagnosis, such as that based on the Rome Ⅲ criteria, without red flags is enough for the diagnosis of IBS and that no further investigations are needed. The use of red flags in combination with Rome criteria has been found to be highly specific, but not particularly sensitive[64]. The American College of Gastroenterology Task Force does not recommend routine colonoscopy in patients younger than 50 years of age without any associated alarming symptoms[65]. The guidelines of the of the British Society of Gastroenterology go further, however, by recommending an examination of the colon earlier if there is a first degree relative affected by colorectal cancer who is younger than 45 years, or two first degree relatives of any age[66]. The British Society Of Gastroenterology also recommended further investigations in IBS-D due to the overlap with other diarrhoea diseases, such as coeliac and inflammatory bowel disease (IBDs)[66]. These recommendations seem to be suitable for detecting and diagnosing colorectal cancer in this group of patients, but not in other organic gastrointestinal (GI) diseases. It is rather difficult to clinically distinguish IBS from adult-onset coeliac disease (CD)[67-73], as the breadth of the spectrum of symptoms associated with IBS results in a potential for overlap of IBS and CD symptomatologies. The situation is further complicated by the fact that the abdominal symptoms of both IBS and CD patients are triggered by the ingestion of wheat products. In CD patients, this is due to a gluten allergy, while in IBS the effect is attributed to the long sugar polymer fructan in the wheat[74]. The prevalence of CD in IBS varies in different studies and varies from 0.04% to 4.7%[72,73,75-84]. Regardless of the number of CD patients among patients diagnosed with IBS, I believe that IBS patients from all subtypes should be routinely screened for CD, which is in line with current opinions in the field[84-86]. Distinguishing IBD from IBS, especially with mild disease activity, can be difficult[87]. Furthermore,

Table 1 Rome Ⅲ criteria for the diagnosis of irritable bowel syndrome[1]

Recurrent abdominal pain or discomfort with onset at least 6 mo prior to diagnosis, associated with 2 or more of the following, at least 3 d/mo in the last 3 mo
Improvement with defecation
Onset associated with change in frequency of stool
Onset associated with change in form (appearance) of stool
Symptoms that cumulatively support the diagnosis are:
Abnormal stool frequency (greater than 3 bowel movements per day or less than 3 bowels movements per week)
Abnormal stool form (lump/hard or loose/watery stool)
Abnormal stool passage (straining, urgency or feeling of incomplete evacuation)
Passage of mucous
Bloating or feeling of abdominal distension

[1]Adapted from reference [1] with the permission from Nova Science Publisher, Inc.

Table 2 Subtyping of irritable bowel syndrome[1]

IBS with constipation-hard or lumpy stools > 25% and loos or watery stools < 25% of bowel movements
IBS with diarrhea-loos or watery stools > 25% and hard or lumpy stools stools < 25% of bowel movements
Mixed IBS-loos or watery stools > 25% and hard or lumpy stools stools > 25% of bowel movements
Unsubtyped IBS-insufficient abnormality of stool consistency to meet criteria for IBS-C,D or M

IBS-like symptoms are frequently reported before the diagnosis of IBD[87-90]. Microscopic colitis (MC) and IBS have similar symptoms and a normal endoscopic appearance[91-101], and the diagnostic overlap between IBS, IBD and MC is important because of a potentially different treatment for each disorder. The prevalence of IBD in patients that fulfilled the Rome criteria without alarming symptoms varies between 0.4% and 1.9%[96-100], and MC from 0.7% to 1.5%[90-97]. It is conceivable, therefore, to conclude that symptom-based diagnosis of IBS may lead to a number of other GI disorders that require quite different management than IBS being missed. Sigmoidoscopy in IBS patients might be insufficient, however, as a considerable number of MC patients may not be identified without mucosal biopsies from the right colon[101]. Moreover, performing a sigmoidoscopy would not exclude Crohn's disease lesions in the terminal ileum, making ileocolonoscopy prefered, especially in IBS-D patients. This seems, at first sight, to add more economic burden to healthcare, which is already suffering from a lack of resources. IBS patients are already consuming a large amount of healthcare resources. However, performing an ileocolonoscopy would reassure IBS patients and prevent them from seeking a new examination, which would not increase the economic burden of this patient group on society, but instead use the existing resources effectively.

Several biomarkers for the diagnosis of IBS have been considered, but only gut transit measured by radio-isotope markers meets the criteria for reproducibility and availability[102]. However, radio-isotope tests themselves are expensive and of limited availability[102]. It has been reported that the chromogranin A-containing cell density is low in the duodenum of IBS patients (Figure 2)[103,104]. As chromogranin A is a general marker for endocrine cells[105,106], this finding indicates a general reduction in small intestinal endocrine cells in these patients. It has been proposed that the quantification of duodenal chromogranin A cell density could be used as a histopathological marker for the diagnosis of IBS[103,104]. Receiver-operator characteristic curves for chromogranin A cell density in the duodenum is given in Figure 3. The sensitivity and specificity at the cut-off < 31 cells/mm^2 in the duodenum are 91% and 89%, respectively. Screening of IBS patients for CD is now widely accepted. Thus, gastroscopy with duodenal biopsies can be used for excluding or confirming CD instead of blood tests, and the same biopsies can be used for the diagnosis of IBS. The duodenal endocrine cell types affected and their role in the pathogenesis of IBS is discussed in the next section.

PATHOGENESIS

Patients with IBS typically present with GI complaints for which physicians can find no organic cause. It is natural and understandable to make comparisons with hysteria, which is also predominant in women. Hysteria has been replaced in modern psychiatry by somatisation disorders and conversion disorders. The notion that IBS is a psychiatric disorder is deeply rooted in clinical practice.

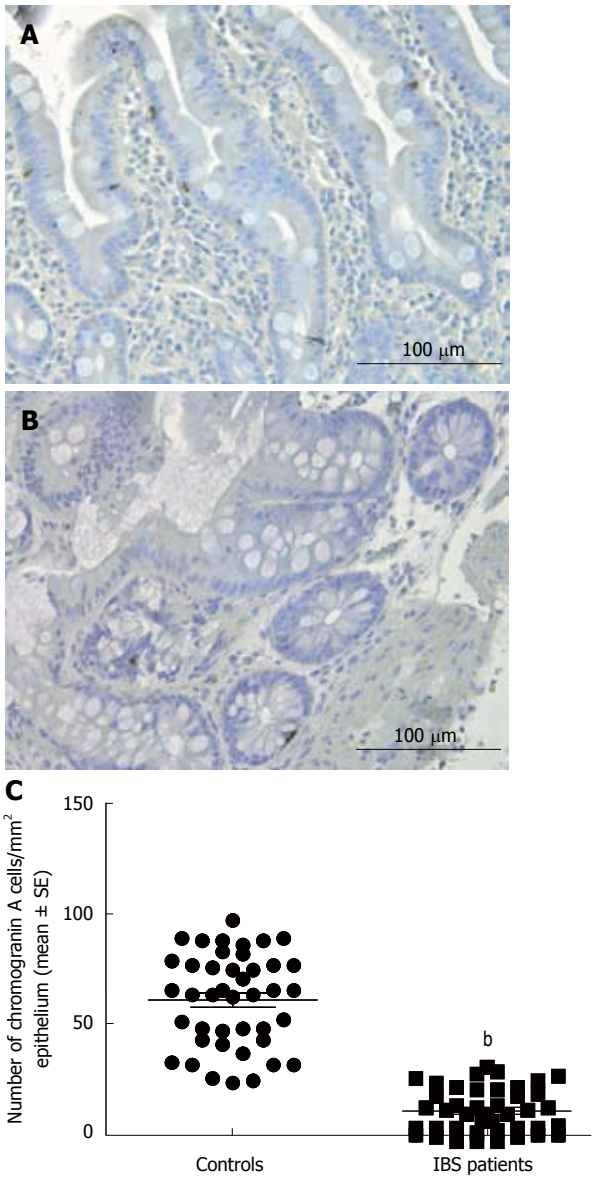

Figure 2 Chromogranin A cells in the duodenum. A: A healthy subject; B: A patient with irritable bowel syndrome (IBS); C: Controls and IBS patients. Reproduced from reference [1] with permission from Nova Science Publisher, Inc. $^{b}P < 0.01$ *vs* control group.

This situation was not improved by the huge number of publications on a selected group of IBS patients, which show that IBS patients are more likely to be psychiatrically ill and sexually or physically abused than the general population[107-121]. Many patients with IBS ignore their symptoms and regard them as a normal part of everyday life. IBS patients with anxiety, depression, somatisation or hypochondria are more liable to seek healthcare than other IBS patients. Unless this is borne in mind, incorrect conclusions can be drawn. A hospital-based case-control study showed that patients with IBS have a comparable health-related quality of life, level of psychological distress and occurrence of recent stressful life events to age-matched IBD patients[122]. These findings are interesting as IBD patients receive effective treatment and are treated with sympathy, understanding and support by their doctors as well as society. In contrast, IBS patients are offered non-effective treatments, are treated with mistrust and neglect by their doctors, feel that they are labelled as hypochondriacs and believe that they receive no support from society. It could be expected that IBS patients would be more anxious and depressed than IBD patients, but this is not the case. Two percent of patients diagnosed with IBS among the adult residents of Olmsted County, Minnesota, United States, were found to suffer from depression compared to the 16.2% incidence of depression in the entire population of the United States[122,123]. In conclusion, there is no convincing evidence to show that psychological factors play a role in the onset and/or progression of IBS[66].

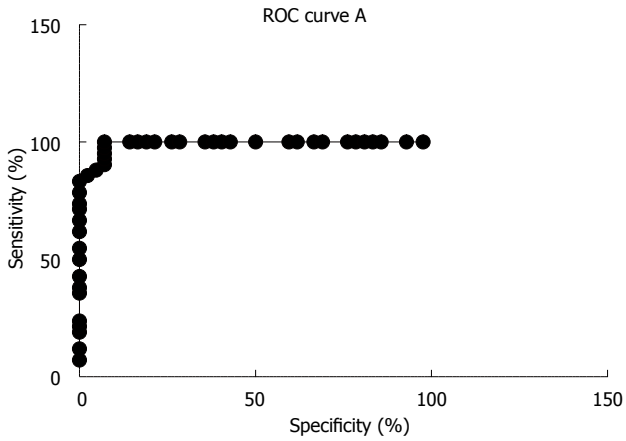

Figure 3 Receiver-operator characteristic for chromogranin A cell density in the duodenum. Reproduced from reference [1] with permission from Nova Science Publisher, Inc. ROC: Receiver-operator characteristic.

The pathogenesis of IBS appears to be multifactorial. There is evidence to show that the following factors play a central role in the pathogenesis of IBS: heritability and genetics, environment and social learning, dietary or intestinal microbiota, low-grade inflammation and disturbances in the neuroendocrine system (NES) of the gut.

Heritability and genetics

Up to 33% of patients with IBS had a family history of IBS compared to 2% of the controls[124]. In a study of a family cluster from Olmsted County, United States, a significant association was reported between having a first degree family member with bowel symptoms and presenting with IBS. In contrast, those who reported having a spouse with bowel symptoms were no more likely to present with IBS than the general population[125]. It was further shown that the prevalence of IBS was 17% in the relatives of patients compared to 7% in the relatives of spouses[126]. Another study showed that patients with IBS were more likely to present a family history of IBS than controls (33.9% and 12.6%, respectively). Moreover, 21.1% of IBS non-consulter patients reported a family history of IBS, in comparison with 12.6% of the control subjects[127].

In twin studies, a higher rate of IBS was reported in monozygotic twins than in dizygotic twins (33.3% *vs*

13.3%). Moreover, 56.9% of the variance was attributed to additive genetic factors, indicating a substantial genetic component in IBS[128-132]. In contrast, a study performed on British twin pairs did not show any significance in the rates of IBS between monozygotic and dizygotic twins[133].

The serotonin transporter (*SERT*) gene encoding the SERT protein is located on chromosome 17q11.1-q12. A functional polymorphism is the insertion or a deletion of 44 base pairs in the *SERT*-gene-linked polymorphic region[134]. An association was reported between a functional polymorphism in the *SERT* gene and diarrhoea-predominant IBS[135,136]. Individuals with a long allele genotype of the *SERT* gene have been shown to be vulnerable to developing IBS with constipation[137]. Other studies, however, did not show such association between *SERT*-gene polymorphism and IBS[136]. A polymorphism in the CCK1 receptor *CCKAR* gene (779T>C) has also been found to be associated with IBS[138,139].

Environment and social learning

Parental modelling and the reinforcement of illness behaviour can contribute to the causes of IBS[140-144]. Having a mother with IBS has been shown to account for as much variance as having an identical set of genes as a co-twin who has IBS. This suggests that the contribution of social learning to IBS is at least as great as the contribution of heredity[144].

Dietary and intestinal flora

Patients with IBS believe that their diet has a significant influence on their symptoms and they are interested in finding out which foods they should avoid[145-148]. About 60% of IBS patients report a worsening of symptoms following food ingestion: 28% within 15 min after eating and 93% within 3 h[148]. Many IBS patients report specific foods as triggers, most commonly implicating milk and dairy products, wheat products, onion, peas and beans, hot spices, cabbage, certain meats, smoked products, fried food and caffeine as the offending foods[149]. However, dietary composition among IBS patients in the community does not differ from community controls[150-153]. In a recent study, IBS patients were reported to have made a conscious choice to avoid certain food items, some of which belong to fermentable oligosaccharides, disaccharides, monosaccharides and polyols (FODMAPs). However, they reported a higher consumption of other food items that are rich in FODMAPs. Patients also reportedly avoided other food sources that are important for health, which result in a low intake of calcium, phosphorus and vitamin B2[153].

There is no documented evidence showing that a food allergy or intolerance plays a role in IBS symptoms[1]. The reaction of IBS patients to certain food items has been attributed to a number of short-chain carbohydrates that are poorly absorbed so that a significant portion of the ingested carbohydrates enters the distal small bowel and colon. Once there they increase the osmotic pressure and provide a substrate for bacterial fermentation with the production of gas, distension of the large intestine and abdominal discomfort or pain. These carbohydrates are FODMAPs and include fructose, lactose, fructans, galactans and sugar alcohols, such as sorbitol, maltitol, mannitol, xylitol and ismalt. Fructose and lactose are present in apples, pears, watermelon, honey, fruit juices, dried fruits, milk and dairy products. Polyols are used in low calorie food products. Galactans and fructans are present in common dietary constituents, such as wheat, rye, garlic, onions, legumes, cabbage, artichokes, leeks, asparagus, lentils, inulin, soy, Brussels sprouts and broccoli[78,147].

A deficiency in dietary fibre was widely believed to be the primary cause of IBS[154]. Although increasing the amount of dietary fibre continues to be a standard recommendation for patients with IBS, clinical practice has shown that increased fibre intake in these patients increases abdominal pain, bloating and distension. IBS patients assigned to the fibre treatment showed persistent symptoms or no improvement in symptoms after treatment compared to patients taking the placebo or a low-fibre diet. Other studies have shown that whilst a water-insoluble fibre intake did not improve IBS symptoms, soluble-fibre intake was effective in improving overall IBS symptoms[155,156]. It is noteworthy that the role of FODMAPs and fibre on IBS symptoms is associated with intestinal flora. The presence of bacteria that break down FODMAPs and fibre and produce gas, such as *Clostridia spp.*, can cause distension of the large intestine with abdominal discomfort or pain.

Most bacteria in the GI tract exist in the colon. The colon of each individual contains between 300 and 500 different species of bacteria[1], and each person has his own unique intestinal flora. The intestinal flora is affected by several factors, such as diet, climate changes, stress, illness, aging and antibiotic treatment[1]. The intestinal flora in IBS patients has been found to differ considerably from that of healthy controls, as IBS patients have fewer *Lactobacillus* and *Bifdobacterium spp.* than healthy subjects[157]. These bacteria bind to epithelial cells and inhibit pathogen binding as well as enhancing barrier functioning[158]. Furthermore, these bacterial species do not produce gas upon fermenting carbohydrates, which is an effect that would be amplified as they also inhibit the *Clostridia spp.*[158]. Probiotics alter colonic fermentation and stabilise the colonic microbiota, and several studies on probiotics have shown improvements in flatulence and abdominal distension, with a reduction in the composite IBS symptom score[158-160].

Low-grade inflammation

In a subset of IBS patients GI symptoms appear following gastroenteritis, with about 25% of patients showing IBS-D symptoms 6 mo post-infection and approximately 10% developing persistent symptoms[161-164]. Post-infectious (PI)-IBS has been reported after viral, bacterial, protozoa and nematode infections[1], with the incidence of PI-IBS varying between 7% and 31%, although the largest studies suggest this number is about 10%[161-164]. One study showed that 6% to 17% of sporadic (un-

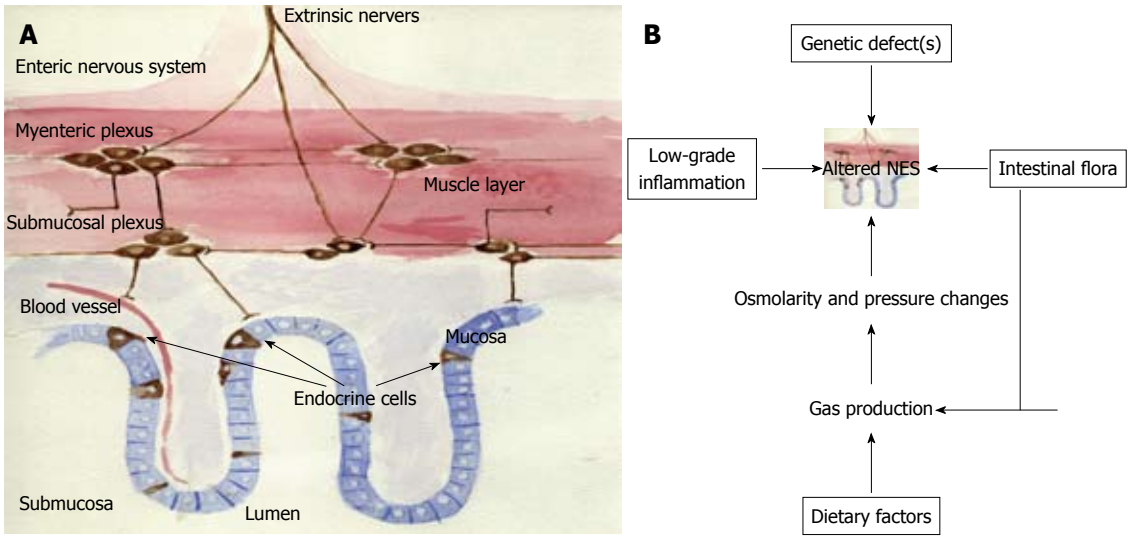

Figure 4 Schematic drawing to illustrate the neuroendocrine system of the gut and the possible pathogenesis of irritable bowel syndrome. A: Schematic drawing of neuroendocrine system; B: Possible pathogenesis of irritable bowel syndrome. Reproduced from reference [1] with permission from Nova Science Publisher, Inc. NES: Neuroendocrine system.

selected) IBS patients believed that their symptoms began with an infection[1]. Following infection, the initial inflammatory response shows an increase in CD3 lymphocytes, CD8 intraepithelial lymphocytes and calprotectin-positive macrophages[161]. These changes rapidly decrease in most subjects but a small number with persistent symptoms fail to show this decline[165]. Furthermore, the number of serotonin cells was shown to increase in subjects with persistent symptoms[165]. There are several pieces of evidence showing that inflammation and immune cells affect the NES of the gut, which controls and regulates GI motility and sensitivity[166]. Thus, serotonin secretion by enterochromaffin (EC) cells can be enhanced or attenuated by the secretory products of immune cells such as CD4+T[167]. Furthermore, serotonin modulates the immune response[167]. The EC cells are in contact with or very close to CD3+ and CD20+ lymphocytes, and several serotonergic receptors have been characterised in lymphocytes, monocytes, macrophages and dendritic cells[168]. Moreover, immune cells in the small and large intestine show receptors for substance P and vasoactive intestinal polypeptide[169].

IBS occurs in 32%-46% of patients with ulcerative colitis (UC) and in 42%-60% of Crohn's disease patients who are in remission[170-174]. Faecal calprotectin has been found to be significantly elevated in UC and Crohn's disease patients with criteria for IBS, compared to those without IBS-type symptoms, indicating the presence of occult inflammation[174].

Abnormalities in the NEC of the gut in IBS

The NES of the gut consists of two parts: endocrine cells scattered among the epithelial cells of the mucosa facing the gut lumen, and peptidergic, serotonergic and nitric oxide-containing nerves of the enteric nervous system (ENS) in the gut wall (Figure 4A)[1]. This system regulates several functions of the GI tract, such as motility, secretion, absorption, microcirculation in the gut, local immune defence and cell proliferation[1]. This regulatory system includes a large number of neuroendocrine peptides/amines, which exert their effects *via* a number of actions: an endocrine mode of action, by circulating in the blood to reach distant targets, an autocrine/paracrine mode, which is a local action, and *via* synaptic signalling or *via* neuroendocrine means, which involve the release from synapses into the circulating blood. The different parts of this system interact and integrate with each other and with afferent and efferent nerve fibres of the central nervous system, in particular the autonomic nervous system. There are at least 14 different populations of endocrine or paracrine cells in the GI tract[1]. The ENS comprises a large variety of neurotransmitters and associated receptors. Almost every known neurotransmitter can be found in the ENS, and most of the receptors associated with these neurotransmitters are also expressed there[1].

In the stomach of patients with IBS, the density of ghrelin-immunoreactive cells in the oxyntic mucosa was found to be significantly lower in IBS-constipation patients and significantly higher in IBS-diarrhoea patients compared to healthy controls[175]. However, the levels of total or active ghrelin in plasma and stomach tissue extracts from IBS patients did not differ from those of healthy subjects[175,176]. Ghrelin is a 28-amino acid peptide hormone that was originally isolated from the stomach[177]. Ghrelin mostly originates from endocrine cells in the oxyntic mucosa of the stomach, but small amounts are expressed in the small intestine, large intestine and in the arcuated nucleus of the hypothalamus[177]. Ghrelin has several functions, including a role in regulating growth hormone (GH) release from the pituitary, where it acts synergistically with the GH-releasing hormone[178,179]. Ghrelin also increases appetite and feeding and plays a major role in energy metabolism[178-181]. Furthermore, this hormone has been found to accelerate gastric and

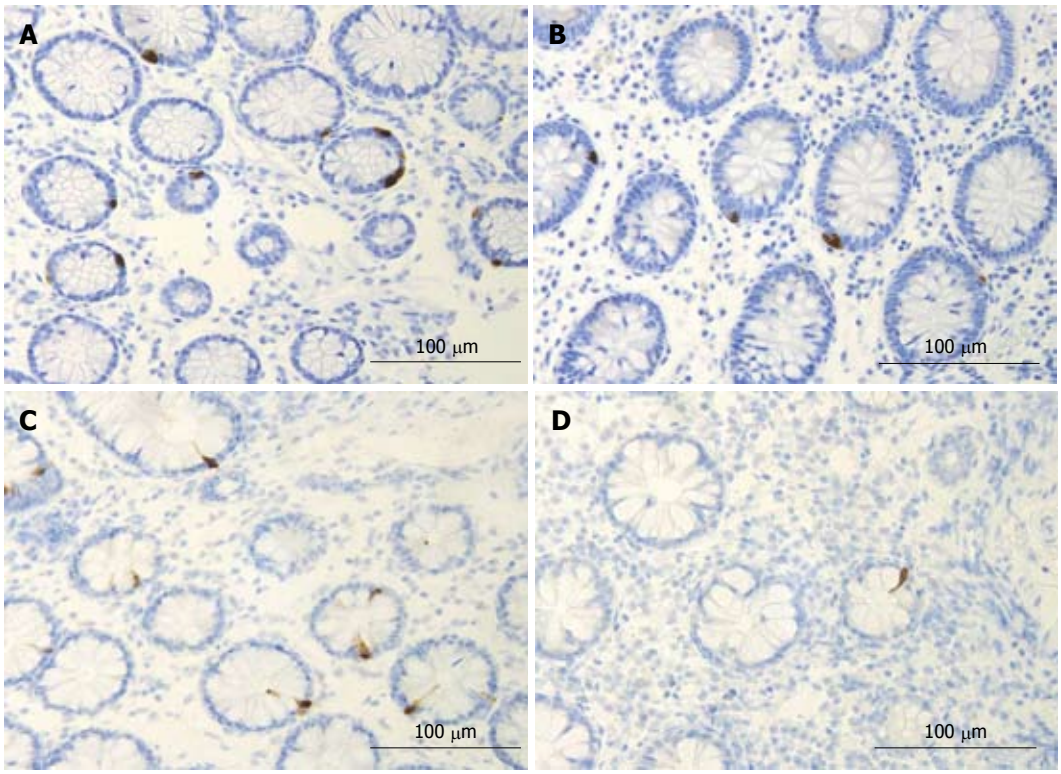

Figure 5 Serotonin cells and polypeptide YY immunoreactive cells in the colon. small and large intestinal motility[181-192], as well as having anti-inflammatory actions and protecting the gut against a wide range of insults. The density of neuropeptide-expressing cells is altered in the small intestine of IBS patients. Thus, the density of cells expressing gastric inhibitory polypeptide and somatostatin is decreased in patients with both diarrhoea- and constipation-predominant IBS subtypes[193]. The densities of secretin and cholecystokinin (CCK)-expressing cells are decreased in the diarrhoea-predominant subtype, but not in the constipation-predominant subtype. Serotonin cell density has also been found to be unchanged in the duodenum of IBS patients, regardless of the subtype[193], which is interesting as serotonin cells were previously reported to be affected in the small intestine of IBS patients[194-196]. These peptides all play important roles in secretion and gastric motility. In the large intestine, serotonin and polypeptide YY (PYY) cell densities have been found to be low in both IBS-constipation and IBS-diarrhoea patients (Figure 5)[197]. Furthermore, the mucosal 5-HT concentration has also been reported to be low in IBS patients[197], which is in line with current observations. In PI-IBS, the number of CCK and serotonin cells has been reported to be increased in the small intestine[198], and serotonin and PYY cell numbers were found to be increased in the large intestine[199-202].

HYPOTHESIS

As described above, abnormalities in the neuroendocrine peptides/amines of the gut have been reported. These abnormalities could cause disturbances in digestion, GI motility and visceral hypersensitivity. These abnormalities appear to contribute to symptom development and could play a central role in the pathogenesis of IBS. Genetic differences have been found between IBS patients and healthy subjects in genes controlling the serotonin signalling system and CCK. Moreover, differences in the diet, intestinal flora and inflammation affect the NES of the gut. The release of different gut hormones depends on the composition and quantity of ingested food, as the food content of FODMAPs and fibre, intestinal flora and the subsequent fermentation can increase intestinal osmotic pressure. This change in intestinal pressure can stimulate hormonal release, such as the release of serotonin. Likewise, inflammation and the release of secretory products from immune cells effects hormonal release and the proliferation of gut endocrine cells.

Therefore, it is feasible to hypothesise that the cause of IBS is an altered NES (Figure 4B). An altered NES would cause abnormal GI motility, secretion and sensation, all of which are characteristic of IBS[203-216]. The alteration in NES could be a result of one or more of the following: genetic factors, dietary intake, intestinal flora or low-grade inflammation.

CONCLUSION

The diagnosis of IBS is based on symptom assessment and the Rome Ⅲ criteria. Whereas the latter has been

widely used in scientific studies and in GI congresses in the past 10 years, it is not, however, used by most clinicians consulted by IBS patients[217-220]. This is not because these clinicians are unaware of the Rome Ⅲ criteria, but because of the reality in the clinic. IBS patients that seek advice from a doctor are worried and want to be investigated, and are rarely satisfied until this is done, so they will repeatedly seek healthcare until they are investigated. I believe, therefore, that the Rome Ⅲ criteria should be combined with a physical examination, blood tests, gastroscopy, duodenal biopsies and colonoscopy with segmental biopsies. These examinations and tests, in addition to the Rome Ⅲ criteria, would reassure the patient and exclude CD, IBD, MC and cancer. Furthermore, performing these examinations and tests would remove the pressure applied by some patients to perform these examinations repeatedly, as the need for further investigations can always be argued against if there are no new symptoms. Duodenal chromogranin A cell density also appears to be a promising biomarker for the diagnosis of IBS.

The pathogenesis of IBS appears to be multifactorial. There is evidence to suggest that the following factors play a central role in the pathogenesis of IBS: heritability and genetics, dietary and intestinal microbiota, low-grade inflammation and disturbances in the NEC of the gut. Several authors have tried to connect these factors in a logical cause-effect pattern, but it is my belief that the proposed hypothesis presented in this review is the most logical.
