World Journal of Gastroenterology

Contents

Weekly Volume 18 Number 33 September 7, 2012

EDITORIAL

4457 Role of taxanes in pancreatic cancer
Belli C, Cereda S, Reni M

FIELD OF VISION

4466 Confounding factors affect the pathophysiology of eosinophilic esophagitis
Elitsur Y

4470 Diagnostic criteria for autoimmune hepatitis in children: A challenge for pediatric hepatologists
Ferri PM, Ferreira AR, Miranda DM, Simões e Silva AC

4474 Asymptomatic pancreatic lesions: New insights and clinical implications
Loos M, Michalski CW, Kleeff J

4478 Opposite fates of fructose in the development of metabolic syndrome
Alegret M, Laguna JC

4481 Entry of hepatitis C virus into the cell: A therapeutic target
Del Campo JA, Rojas Á, Romero-Gómez M

TOPIC HIGHLIGHT

4486 Early administration of branched-chain amino acid granules
Ishikawa T

GUIDELINES FOR CLINICAL PRACTICE

4491 Donation after cardio-circulatory death liver transplantation
Le Dinh H, de Roover A, Kaba A, Lauwick S, Joris J, Delwaide J, Honoré P, Meurisse M, Detry O

REVIEW

4507 Surveillance for gastrointestinal malignancies
Tiwari AK, Laird-Fick HS, Wali RK, Roy HK

4517 Management of chronic hepatitis B in pregnancy
Han GR, Xu CL, Zhao W, Yang YF

ORIGINAL ARTICLE

4522 Loss of fragile histidine triad and amplification of 1p36.22 and 11p15.5 in primary gastric adenocarcinomas
Liu YY, Chen HY, Zhang ML, Tian D, Li S, Lee JY

BRIEF ARTICLE

4533 FOLFIRI regimen in metastatic pancreatic adenocarcinoma resistant to gemcitabine and platinum-salts
Neuzillet C, Hentic O, Rousseau B, Rebours V, Bengrine-Lefèvre L, Bonnetain F, Lévy P, Raymond E, Ruszniewski P, Louvet C, Hammel P

4542 Efficacy of a therapeutic strategy for eradication of *Helicobacter pylori* infection
Sereni G, Azzolini F, Camellini L, Formisano D, Decembrino F, Iori V, Tioli C, Cavina M, Di Mario F, Bedogni G, Sassatelli R

4549 Lack of CD44 variant 6 expression in rectal cancer invasive front associates with early recurrence
Avoranta ST, Korkeila EA, Syrjänen KJ, Pyrhönen SO, Sundström JTT

4557 Characteristics of intestinal pseudo-obstruction in patients with mitochondrial diseases
Sekino Y, Inamori M, Yamada E, Ohkubo H, Sakai E, Higurashi T, Iida H, Hosono K, Endo H, Nonaka T, Takahashi H, Koide T, Abe Y, Gotoh E, Koyano S, Kuroiwa Y, Maeda S, Nakajima A

4563 Effect of composite yogurt enriched with acacia fiber and *Bifidobacterium lactis*
Min YW, Park SU, Jang YS, Kim YH, Rhee PL, Ko SH, Joo N, Kim SI, Kim CH, Chang DK

4570 Reduction of gastrointestinal motility by unilateral thyroparathyroidectomy plus subdiaphragmatic vagotomy in rats
Lee JH, Kwon OD, Ahn SH, Choi KH, Park JH, Lee S, Choi BK, Jung KY

4578 Does immunohistochemical staining have a clinical impact in early gastric cancer conducted endoscopic submucosal dissection?
Jeon SR, Cho JY, Bok GH, Lee TH, Kim HG, Cho WY, Jin SY, Kim YS

4585 Spectral analysis of bowel sounds in intestinal obstruction using an electronic stethoscope
Ching SS, Tan YK

4593 Stopping or reducing dietary fiber intake reduces constipation and its associated symptoms
Ho KS, Tan CYM, Mohd Daud MA, Seow-Choen F

4597 Gastric mucin expression in *Helicobacter pylori*-related, nonsteroidal anti-inflammatory drug-related and idiopathic ulcers
Boltin D, Halpern M, Levi Z, Vilkin A, Morgenstern S, Ho SB, Niv Y

4604 What MELD score mandates use of entecavir for ACLF-HBV HBeAg-negative patients?
Yan Y, Mai L, Zheng YB, Zhang SQ, Xu WX, Gao ZL, Ke WM

4610 Side population cells isolated from KATO Ⅲ human gastric cancer cell line have cancer stem cell-like characteristics
She JJ, Zhang PG, Wang X, Che XM, Wang ZM

World Journal of Gastroenterology
Volume 18 Number 33 September 7, 2012

Contents

	4618	7-difluoromethoxyl-5,4'-di-n-octylgenistein inhibits growth of gastric cancer cells through downregulating forkhead box M1 *Xiang HL, Liu F, Quan MF, Cao JG, Lv Y*
CASE REPORT	4627	A case report of abdominal distention caused by herpes zoster *Zhou SR, Liu CY*
ACKNOWLEDGMENTS	I	Acknowledgments to reviewers of *World Journal of Gastroenterology*

Abstract

Pancreatic cancer is one of the most deadly cancers and is characterized by a poor prognosis. Single agent gemcitabine, despite its limited activity and modest impact on disease outcome, is considered as the standard therapy in pancreatic cancer. Most of the combination regimens used in the treatment of this disease, also including the targeted agents, did not improve the outcome of patients. Also, taxanes have been tested as single agent and in combination chemotherapy, both in first line and as salvage chemotherapy, as another possible option for treating pancreatic cancer. The inclusion of taxanes in combination with gemcitabine as upfront therapy obtained promising results. Accordingly, taxanes, and above all, new generation taxanes, appear to be suitable candidates for further testing to assess their role against pancreatic cancer in various clinical settings.

INTRODUCTION

Pancreatic cancer has a very poor prognosis and it still remains as one of the most deadly cancers. At diagnosis, only 10%-20% of patients are considered candidates for a curative resection that is possible only in the absence of distant metastases, peritoneal carcinomatosis, and lack of any involvement of celiac axis and superior mesenteric artery[1]. Around 80% of patients have advanced or metastatic disease and median overall survival (mOS) of this group is very poor ranging from 3 to 6 mo[2]. The first drug used in the treatment of advanced pancreatic cancer was 5-fluorouracil (5-FU) that provided a palliative benefit with a significant improvement in mOS compared to best supportive care (6 mo *vs* 2.5 mo, $P < 0.01$)[3]. When compared to bolus 5-FU, gemcitabine yielded a significantly better response rate (RR) (5.4% *vs* 0%), survival (mOS 5.65 mo *vs* 4.41 mo, $P = 0.0025$) and clinical benefit, which is a composite measure consisting of reduction of pain, analgesic drugs intake and weight loss (23.8% *vs* 4.8%)[4]. Given the modest and disappointing impact on overall survival (OS) achieved with single agent gemcitabine, other agents or drug combinations are continuously tested in advanced pancreatic cancer[5-7]. Among others, taxanes (docetaxel and pacli-

taxel) were tested as single agents or in combination with other chemotherapeutic agents in pancreatic cancer[8-10] because they showed promising activity in other solid tumours[11,12]. Mechanism of action of these drugs consists in enhancing microtubule assembly and inhibiting the depolymerization of tubulin responsible for the formation of bundles of microtubules blocking cell proliferation[13].

This article summarises the main clinical studies conducted in pancreatic cancer with taxanes as first or second line chemotherapy, both as monotherapy and combination therapy, in order to clarify the potential role of this class of drugs for further investigations.

DOCETAXEL

First-line therapy

Single agent: Docetaxel gained researchers' attention for the treatment of pancreatic cancer after a preclinical study showed its effectiveness in a murine model of pancreatic ductal adenocarcinoma[14]. Docetaxel activity as single agent was assessed in phase Ⅱ trials in chemonaïve patients affected by pancreatic cancer at two different dosages, 60 mg/mq[8] and 100 mg/mq[9,15], showing promising activity when used at higher dose (Table 1). With higher doses[9,15], the overall RR ranged from 5% to 15%, the median time to progression (mTTP) was 2.1-5.0 mo, and the mOS was 7-8.5 mo. Neutropenia was the most frequently observed grade 3/4 toxicity in both studies (36%-95%)[9]. Grade 3-4 anemia (9%-16%) and fatigue (9%-23%) were also commonly reported[9]. Given the phase Ⅱ nature of the trials, the small sample size and the selection of patient population, including stage Ⅱ and Ⅲ disease and patients who mainly had a performance status of 0-1, these results should be interpreted with caution. Nevertheless, these trials showed that docetaxel has some activity in the treatment of pancreatic cancer, and warrant further exploration. Docetaxel administered at lower dose failed to demonstrate any activity in pancreatic cancer[8]. In fact, no objective response was observed and both mTTP and mOS were shorter when compared to higher doses[9,15]. Moreover, grade 3-4 toxicity was remarkable with nearly 80% of the patients developing neutropenia, 7% anaemia, and 27% fatigue[8].

Combination chemotherapy: Docetaxel role was also addressed in combination with other drugs (Table 1). *In vitro* and *in vivo* studies have demonstrated that docetaxel yields a synergism with other drugs like capecitabine[16,17], 5-FU[18], gemcitabine[19,20], and cisplatin[21] .

The rationale for the combination of an oral fluoropyrimidine with docetaxel is based on the ability of taxanes to increase the activity in the tumoral tissue of thymidylate phosphorylases, which are key enzymes in the transformation process of capecitabine into its active metabolite 5-FU. The synergism of docetaxel with gemcitabine was observed *in vitro* in several cancer cell lines, but the biological mechanism is not clear. Hypothetically, the combination of these two agents could regulate the apoptotic process by increasing the apoptotic index. Finally, the synergism of docetaxel and cisplatin, observed in cell lines of gastric cancer, could be due to the down-regulation of multi drug resistant proteins by docetaxel thereby increasing cytotoxic index of cisplatin[21].

Several phase Ⅱ clinical trials assessed the activity of these combinations against advanced pancreatic cancer as an upfront therapy[19,20,22-26]. Docetaxel and gemcitabine yielded promising RR ranging from 12% to 40% and mOS ranging from 6 to 9 mo[19,20,23,25]. However, these single arm findings cannot be considered conclusive. Interestingly, the European Organization for Research and Treatment of Cancer (EORTC) group conducted a phase Ⅱ trial in which 96 patients were randomized to receive gemcitabine plus docetaxel or cisplatin plus docetaxel[24]. In 70 patients who were assessable for response, the RR was 19.4% with gemcitabine-docetaxel combination and 23.5% with cisplatin-docetaxel combination. Conversely, survival figures were better in 49 patients treated by the gemcitabine-docetaxel combination [median progression free survival (mPFS) 3.9 mo, mOS 7.4 mo; 1-year OS 30%] compared to those receiving cisplatin-docetaxel (mPFS 2.8 mo, mOS 7.1 mo; 1-year OS 16%). Toxicity was not negligible, consisting of grade 3-4 neutropenia in 47% and 55%, and febrile neutropenia in 9% and 16%, respectively. Altogether, safety profile and survival analysis favoured gemcitabine-docetaxel combination for further evaluation. Another phase Ⅱ trial randomized 259 patients with metastatic pancreatic cancer to receive fixed dose gemcitabine or gemcitabine combined with either docetaxel, cisplatin, or irinotecan[27]. The primary end point of this study was the six months OS that was similar in all four treatment arms: 57% for fixed gemcitabine dose, 53% for gemcitabine plus cisplatin, 54% for gemcitabine plus docetaxel, and 57% for gemcitabine plus irinotecan. The mOS and mTTP were similar in the treatment groups and ranged between 6.4-7.1 mo and 3.3-4.5 mo, respectively. The RRs were also indistinguishable among treatment groups and ranged between 12% to 14%. The cisplatin and docetaxel combination tested in this study gave similar results, in terms of mOS and TTP, to that reported in the EORTC trial[24].

Another drug tested in combination with docetaxel was liposomal doxorubicin starting from preclinical study conducted on xenografted human pancreatic carcinoma in which this drug demonstrated to reduce tumor growth with a low toxicity[28]. In a phase Ⅱ clinical trial, this combination was studied on twenty-one locally advanced and metastatic pancreatic cancer patients[29]. The results in terms of RR (21%) and mOS (10 mo) were similar to those observed with combination of docetaxel with other drugs[19,20,22-26].

The activity of docetaxel, gemcitabine, capecitabine regimen (GTX) was also tested in 43 patients with metastatic disease yielding a RR of 22% and a mOS of 14.5 mo[30]. These results were echoed in a recent retrospective study on 79 chemonaïve patients with locally advanced or metastatic pancreatic cancer who had a mOS

of 25.0 and 11.3 mo, respectively[31].

A four drug combination of cisplatin, docetaxel, capecitabine, and gemcitabine (PDXG) was tested in a randomized phase II trial in which a cisplatin, epirubicin, capecitabine, and gemcitabine (PEXG) regimen was chosen as calibration arm[22]. This choice was based on the fact that a PEFG regimen (cisplatin, epirubicin, fluorouracil, and gemcitabine) was previously shown to be superior to gemcitabine monochemotherapy in terms of progression free survival [PFS; hazard ratio (HR) 0.51; range 0.33-0.78] and OS (HR 0.65; range 0.43-0.99) in a phase III trial of first line therapy of pancreatic cancer[32] and that the use of oral capecitabine was shown to be equivalent to 5-FU in other tumors[33]. Both the radiological and the biochemical RR[34] were better for 53 patients treated with PDXG (60% complete plus partial radiological responses; 41% major biochemical responses; 39% minor biochemical responses) than for 52 patients receiving PEXG (37% complete plus partial radiological responses; 32% major biochemical responses; 32% minor biochemical responses). However, OS and PFS were very similar in the two arms (mOS 10.7 mo *vs* 11.0 mo and mPFS 7.4 mo *vs* 7.6 mo, with PDXG and PEXG regimens, respectively). The safety profile of PDXG regimen was more favourable than that of PEXG regimen in terms of grade 3-4 neutropenia (4% in PDXG group *vs* 13% in PEXG arm).

Overall, these studies suggest that multi-drug associations, in particular triplets and quadruplets, are more active in pancreatic cancer when compared to monochemotherapy.

Salvage therapy

Single agent and combination chemotherapy: Docetaxel was also tested as salvage treatment in pancreatic cancer both as single agent and in combination[31,35-40]

(Table 1). In a phase II trial conducted on 10 patients, no response was obtained, mPFS was 1.5 mo and mOS was 4.0 mo[35].

Combination chemotherapy with taxanes as salvage treatment gave disappointing results with a significant toxicity[37-39]. In these trials, docetaxel combined with capecitabine[37], with irinotecan[38], and with mitomycin plus irinotecan[39] resulted in a RR ranging between 0% to 9.7%, and mOS between 4.5-6.3 mo. The most common toxicity in these studies was grade 3-4 neutropenia observed in around 30%-32% of patients[37-39]. Two retrospective series reported the results of GTX regimen as salvage therapy in patients affected by pancreatic cancer[31,40]. The RR was 12%-15% and mOS was 5.7-6.7 mo[31,40]. Altogether, the response and survival figures observed with docetaxel-based combinations as salvage therapy in advanced pancreatic cancer were in the range reported with other regimens[41-45]. These drug combinations tested in the second line gave RR between 0%-24% and mOS between 3.7-6.2 mo[41,42,44,45]. The PEFG combination was the only regimen that reported a better mOS in second line therapy (8.3 mo) with an acceptable toxicity[43].

PACLITAXEL AND NEW PACLITAXEL FORMULATIONS

First-line therapy

Single agent: Single agent paclitaxel yielded a RR of 3% and a mOS of 5 mo in a series of 45 patients with advanced pancreatic cancer (Table 2)[10], while paclitaxel loaded with polymeric micelle obtained an overall RR of 6.7%, mPFS of 2.8 mo, and mOS of 6.5 mo in 56 patients with advanced pancreatic cancer[46].

Combination chemotherapy: EndoTAG™-1 (ET) is a cationic liposome membrane charging paclitaxel. This particular structure promotes the delivery of the drug in the tumor mass. Tumor endothelium lacks glycocalix which normally covers endothelial cells, so negative charges are exposed on the cell surface. Thus, the positive charges carried by liposomes is exposed and interact with the negative charges present on tumoral cells favouring the internalization of the drug into the tumor[47].

Löhr *et al*[48] tested ET in combination with gemcitabine *vs* gemcitabine alone in a four-arm randomized phase II trial on 212 patients affected by locally advanced or metastatic disease (Table 2). The treatment consisted of seven weekly infusions of standard gemcitabine alone or associated with twice-weekly ET at dosage of 11 (Endo11), 22 (Endo22) or 44 mg/mq (Endo44) for seven weeks. RR was comparable across the four treatment groups (14%-16%), the mPFS was longer in the gemcitabine plus ET arms (4.1, 4.6, and 4.4 for Endo11, Endo22, and Endo44, respectively) compared to gemcitabine group (2.7 mo). Also the mOS appeared to be better in the combination arms (from 8.1 to 9.3 mo) compared to single agent (mOS 6.8 mo). The treatment with gemcitabine and ET was well tolerated with a dose-dependent increase in grade 3-4 thrombocytopenia (from 8% to 14%), neutropenia (from 12% to 22%), and anemia (from 4% to 8%). Grade 3-4 febrile neutropenia was observed in 6% of the patients. No treatment-related neuropathy was observed in this trial. This study suggested that this new formulation of paclitaxel warrants further investigation to define its role in the treatment of pancreatic cancer.

Another paclitaxel formulation known as ABI-007 was tested against pancreatic cancer. ABI-007 (also

known as *nab*-paclitaxel), is a cremophor-free, albumin-bound 130-nm particle form of paclitaxel that does not require the use of cremophor-EL, thus avoiding the severe toxicities associated with this vehicle[49]. The albumin in nab-paclitaxel binds to gp60 (albondin) receptors and to caveolae resulting in the formation of caveoli transporting the drug across the endothelial cells to the tumor interstitial space. In pancreatic tumor stroma, secreted protein acid and rich in cystein (SPARC) protein, which is also called osteonectin, is overexpressed. SPARC interacts with the albumin of nab-paclitaxel enhancing the concentration of this drug into the tumor, which causes "stromal collapse", a phenomenon of depletion and collapsing of stroma, bringing tumor cells closer to each other and to blood vessel. A phase IB-Ⅱ study of ABI-007 in combination with gemcitabine was performed in metastatic pancreatic cancer (Table 2)[50]. The maximum tolerated dose (MTD) was 125 mg/mq for ABI-007 in combination with standard gemcitabine[50]. The PFS for the whole population of patients enrolled into the trial was 6.9 mo and the mOS was 10.3 mo, while in the group of 44 patients treated with ABI-007 at MTD, the mPFS was 7.9 mo and the mOS was 12.2 mo. A phase Ⅲ clinical trial of gemcitabine and ABI-007 combination *vs* standard gemcitabine is currently ongoing in patients with metastatic pancreatic cancer (NCT00844649).

Salvage therapy

Single agent and combination chemotherapy: ABI-007 at 100 mg/mq weekly for three weeks, out of every 4, was also tested as second line chemotherapy in 19 patients with progressive pancreatic cancer after previous gemcitabine-based therapy (Table 2)[51]. One partial response (5.3%) and six stable disease (31.6%) were reported. The mPFS and mOS were 1.6 mo and 7.3 mo, respectively. Grade 3 or 4 neutropenia, neutropenic fever and anemia occurred in 32%, 11% and 11% of patients, respectively.

Paclitaxel in combination with 5-FU was administered as salvage therapy to 28 patients with advanced pancreatic cancer after gemcitabine failure (Table 2)[52]. The RR was 10%, the mTTP 2.5 mo, and the mOS 7.6 mo. This regimen was well tolerated with grade 3-4 neutropenia in 21.4% of the patients, anemia in 3.6%, grade 4 neuropathy in 3.6%, and grade 3 diarrhea in 7.2% of the patients.

TAXANES PLUS RADIOTHERAPY

Pancreatic cancer is characterized by a high rate of both local and systemic failure. Chemoradiation was tested in stage Ⅲ disease with different drugs yielding a mOS between 8 to 11 mo and 1-year survival rate between 25% to 40%[53-55].

Due to their radiation-sensitizing properties[56], taxanes were also tested in combination with radiotherapy in locally advanced[57,58] and in resectable[59] pancreatic cancer. In locally advanced disease, paclitaxel and radiotherapy obtained RR of 26%, mOS of 8-11.2 mo and 1-year OS of 30%-43%[57,58]. These results were in the range reported with other drugs tested in combination with radiotherapy.

Conversely, paclitaxel-based chemoradiation as neoadjuvant therapy in resectable patients yielded disappointing results[59]. In fact, 46% of the patients suffered grade 3 toxicity (hematological, gastrointestinal, asthenia, anorexia, allergic reaction) and the mOS (19 mo) was inferior than expected with 5-FU based chemoradiation (25 mo)[60].

A phase Ⅱ trial randomized 20 patients with resectable and unresectable disease to receive docetaxel plus either continuous 5-FU or weekly cisplatin concomitant to radiotherapy. The enrolment was prematurely concluded due to poor preliminary results[61].

CONCLUSION

Pancreatic cancer is characterized by a dismal prognosis and limited therapeutic progress has been achieved in the past 30 years. Due to its intrinsic or rapidly acquired chemoresistance, the therapeutic armamentarium against pancreatic cancer is limited and there is an urgent need to individuate new active agents or regimens. Single agent gemcitabine, despite poor activity and modest impact on disease outcome, is still considered the standard treatment both in early and advanced stages of the disease[62]. Most combination regimens using gemcitabine-based doublets and including both conventional and targeted agents failed to significantly improve OS over gemcitabine alone[6,7,33,63,64] or yielded a statistically significant but clinically negligible benefit[65]. Interestingly, two phase Ⅲ trials showed that drug combinations including more than two agents may improve OS when compared with gemcitabine alone[32,66] and two clinical practice surveys suggested that the 4-drug regimens may be superior to gemcitabine/platinating-agent doublets[41,67].

In particular, the PEFG regimen and the combination of 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) yielded 1-year OS of 38%-48%[32,66]. The results obtained with these regimens should be generalized with caution due to the lack of confirmatory trials and, in the case of FOLFIRINOX, to the highly selected patients population, which is evident on the basis of the better than expected standard arm outcome and because 4 years occurred to enrol 342 patients in 48 centers (< 2 pts/center per year)[66]. Moreover, while PEFG toxicity profile was favourable[32,68], and the regimen was in fact feasible also in the adjuvant setting[69,70], grade 3-4 toxicity observed with FOLFIRINOX was remarkable particularly in the case of extra-hematological toxicity that may be barely acceptable in the context of a palliative therapy. In fact, the main reason for ending treatment was death in 85 (50%) patients in the FOLFIRINOX arm *vs* 75 in the gemcitabine arm, while fatigue was reported in 24% of the patients, vomiting in 15%, diarrhea in 13%, and neuropathy in 9%[66]. Altogether, these results are encouraging and do suggest that a nihilistic attitude towards pancreatic cancer is no

longer justified and that more aggressive treatment approach may partially overcome chemoresistance. As previously observed with other drugs, like gemcitabine, 5-FU, capecitabine, pemetrexed[4,6,71], the use of taxanes as single agent treatment, both upfront and as salvage therapy, showed moderate activity but did not obtain exciting results[8,9,15,35,36]. Not surprisingly and similarly to fluoropyrimidines and platinating agents, the inclusion of old generation taxanes in doublets with gemcitabine or cisplatin did not appear to produce better results than gemcitabine alone[19,20,23-27,29,37-39]. On the other hand, the inclusion of taxanes in combination with more than 2 drugs[22,30,31,40] seem to be more promising. Worth of note, unexpected radiological and biochemical response was observed in an exploratory subset analysis in patients with stage Ⅲ disease (60% radiological response in PDXG group *vs* 37% in PEXG group and major plus minor biochemical response of 80% *vs* 64%, respectively[22]). Furthermore, more patients in PDXG arm underwent to surgery with radical intent compared to PEXG arm (17% *vs* 6%) and neither resection margin nor nodal involvement was observed in the group treated with docetaxel. Furthermore, the new generation of taxanes, due to their unique chemical structure, are able to penetrate in tumor cell mass in high amount and apparently yields better activity than older taxanes. Accordingly, taxanes, and above all, new generation taxanes, appear to be suitable candidates for further testing to assess their role against pancreatic cancer in various clinical settings.

FUTURE PERSPECTIVES

Apart from the combination of ABI-007 with gemcitabine as first-line therapy in metastatic disease, which is currently being tested in a phase Ⅲ trial (NCT00844649), the role of multiple (i.e., more than two drugs) agents regimens should be addressed. In fact, the hypothesis of stromal depletion induced by ABI-007, if confirmed, may provide a robust rationale for combination polychemotherapy, due to better drug penetration into tumor. Furthermore, a larger effect may be expected in primary tumor where the stroma is more abundant[72-74]. A phase Ⅱ clinical trial is evaluating a combination of ABI-007 with gemcitabine, and GDC-0449, a hedgehog inhibitor, in patients with untreated metastatic pancreatic cancer in order to evaluate the PFS and the safety of this combination (NCT01088815). The hedgehog signalling pathway is involved in embryonic development, but is also activated in pancreatic cancer[75]. In preclinical model the inhibition of this pathway enhanced drug delivery to tumor cells by disrupting the desmoplastic stroma and increasing tumor vascularity[76]. The combination of gemcitabine, ABI-007 and GDC-009 could enhance the stroma collapse and increase the intratumoral concentration of chemotherapeutic drugs. Accordingly, neoadjuvant therapy in patients with stage Ⅲ disease, borderline resectable disease and resectable disease represents a potential field of investigation. Finally, ABI-007 may improve primary tumor oxygenation by inhibiting the formation of novel microvessel and by disrupting established microvessels thus increasing the therapeutic window of concomitant radiation therapy and targeted agents[77,78]. So, the next logical step is to evaluate a combination of anti-angiogenic therapy with ABI-007 in metastatic setting. Furthermore, the identification of new prognostic markers like SPARC could help both in understanding the molecular changes responsible for development and progression of pancreatic cancer and in identifying a subset of patients in which taxane-based therapy may have a more relevant impact on the outcome.

Abstract

Eosinophilic esophagitis is a newly diagnosed esophageal disease in adult and children. The clinical and pathological characteristics of this disease have been established and were recently summarized in the expert clinical guideline published in 2011. In spite of the wide knowledge accumulated on this disease, there are many areas where scientific data are missing, especially in regard to the disease's pathophysiology. Recent publications have suggested that other confounding factors modify the disease and may affect its clinical-phenotypic presentation. Those factors may include place of living, air pollution, race, genetic factors and other. In the present report we discussed and review those confounding factors, the new developments, and what direction we should go to further advance our knowledge of this disease.

INVITED COMMENTARY ON HOT ARTICLES

Eosinophilic esophagitis (EoE) is a chronic esophageal disease associated with allergy in adults and children. The clinical, endoscopic, and histological characteristics of EoE has been described and documented in several expert reports[1,2]. In spite of the knowledge accumulated on this newly discovered disease, double blind placebo control studies have demonstrated that only about 50% of the patients will respond to therapy (biologic, steroids)[3,4], demonstrating the existing gap between the clinical and/or basic knowledge, proposed therapy and the pathophysiology of EoE. The complete story of EoE in children is yet to be unfolded.

In a recent publication, Sperry *et al*[5] compared the clinical presentation of EoE in a cohort of adult and pediatric patients diagnosed with EoE. The authors suggested that African American (AA) patients were younger at diagnosis, presented with failure to thrive (FTT), and were less likely to have esophageal rings compared to the Caucasian (C) patients[5]. The paper has raised the possibility of other unknown confounding factors that may influence the clinical/phenotypic presentation of EoE in adults and children. Indeed, reviewing the

literature of EoE disease suggested that various factors may modify the disease incidence, clinical presentation, and/or clinical response to therapy. Those possible confounding factors are the topic of this paper (Table 1).

Epidemiological studies have showed that the disease's rate is unevenly distributed among adults and children living across the United States. The data showed that the prevalence of the disease in the North-Eastern states is higher in comparison with the South-Eastern states[6-8]. Moreover, further analysis demonstrated that EoE is more prevalent in urban/sub urban areas compared to rural areas[6,8,9]. The data suggested that there are environmental factors that modify EoE, but to date, those modifiers have not been clearly analyzed. The current geographic distribution may implicate air pollution as a modifier factor for EoE[10]. Indeed, animal and clinical studies have confirmed the essential role of aero-allergens in the pathophysiology of the disease[11-13]. Few investigators reported an increase incidence of EoE during the allergy seasons (low during winter, high during spring and fall)[14-16], but those findings were not confirmed by others. For example, in a recent preliminary report, Frederickson *et al*[17] reviewed esophageal biopsies in a cohort of 19 172 patients in Iowa City, IA, of whom 167 adults had EoE. The author reported a comparable monthly rate of EoE with no seasonal variation. Using a national pathology laboratory data base, the seasonal trend of 9995 adult patients was examined by others who reported a similar monthly and seasonal distribution of the patients diagnosed with EoE[18]. Similar results were described by investigators who performed an internet search to look for EoE and seasonal variation[19]. In a recent study, Hurrell *et al*[20] reported a higher prevalence of esophageal eosinophilia in adults who live within the colder geographic zones of the United States compared to those living in the warmer climates. They implicated that the specific flora grow in those areas generate highly potent aeroallergens, and is responsible for their findings. In contrast, the United States governmental environmental agency (Environmental Protection Agency, National Oceanic and Atmospheric Administration, National Park Service) reported the lowest air pollution in the northern geographic areas of the United States, those with colder climate rather than the warmer climate (http//airnow.gov).

In addition to the possible role of aeroallergens and pollution in the pathophysiology of EoE, clinical reports have documented the etiologic role of food allergy in this disease[3,11,21-23]. Indeed, the updated clinical guideline recommended checking food allergy in any patient who is newly diagnosed with EoE[1]. Moreover, in support of this role, eliminating the food allergens alone (i.e., hypoallergenic formula) resolved the clinical symptoms and reversed the histological changes typically seen in EoE[1,24-26]. In patients that would not accept this mode of therapy, topical or systemic steroids are suggested[1]. In a randomized, double-blind, placebo control study, EoE children were treated with Fluticasone propionate[3].

Table 1 Confounding factors and eosinophilic esophagitis

Factor	Ref.
Geographic distribution	[6-9,20]
Air pollution (aeroallergens)	[11-13]
Food allergy	[21-23]
Race (ethnicity)	[27-35]
Gender	[21,26]
Genetic factors	[22,23,39,40]

The authors showed that the children with no allergy had a better response to therapy compared to the children with allergy, pointing towards the role of food allergens as modifiers[3]. Indeed, the role of food allergens in the pathophysiology of EoE has been established, but we are still lacking the exact function of these modifiers. Are all food allergens equal? What about the EoE patients who tested negative for any allergy? Is their disease is more benign? Do they achieve symptom control easier? All these questions are still unanswered and need further investigation.

The different distribution of EoE among various ethnicities has been previously published in adults and children. For example, the clinical presentation of EoE in children reported from several United States centers showed a statistically higher disease rate in C compared to AA or hispanic[21,27-29]. Other reported similar findings in the adult population[5,30,31]. This discrepancy is further accentuated by the epidemiologic data showing that in spite of the wide global distribution of EoE, very few reports from the African continent or from the east Asian countries were reported[1,32-34]. In recent years we have assessed the different clinical presentation of EoE between AA and C children. In that study, we compared between AA children living in urban neighborhoods in New York City and C children who are living in rural West Virginia[35]. We reported that EoE in AA children presented at an earlier age, have more history of atopic features, and presented with significantly lower endoscopic features of EoE compared to the C children. Similarly, Sharma *et al*[36] reported that AA children are more likely to present with FTT, gastroesophageal reflux disease symptoms, and at a younger age compared to the C children at the same cohort. Sperry *et al*[5] compared the clinical presentation of EoE in a cohort of adult and pediatric patients diagnosed with EoE. The authors suggested that when compared with C children, AA children diagnosed at a younger age, present with FTT, and have less esophageal rings[5].

Overall, these data suggest that racial factor does play a role in EoE disease and may serve as a modifier in the disease phenotypic presentation. Further studies will be needed to fully establish the role of ethnicity in the pathophysiology of EoE.

Male sex is the predominant gender in EoE[1]. In large series, the male/female ratio was reported up to 3:1[21,37]. The effect of gender on EoE disease has not been well investigated and studies on this subject are

lacking. Rothenberg *et al*[38] suggested that the predominance of males in EoE may be related to the thymic stromal lymphopoietin receptor resided within the pseudoautosomal region 1 on the X and Y chromosomes (Xp22.3, Yp11.3). The author suggested that this region may explain the higher incident of male gender in EoE.

Similar to many other chronic diseases; i.e., inflammatory bowel disease, celiac disease, asthma, *etc*., genetic factors have a significant influence on the prognosis of EoE. Indeed, several investigators evaluated the genetic factors related to EoE. Few investigators reported that EoE tends to cluster in families[22,23], and other showed by genome-wide microarray expression analysis that EoE patients have a different spectrum of genes compared to children with gastroesophageal reflux disease or normal control[39]. Others showed that specific genes are closely associated with eosinophil's activation and are increased in patients with EoE[1,4,39,40]. In another study, Lu *et al*[41] identified 32 different miRNA which are specific for EoE, of which miRNA-21 and miRNA-223 were the most up-regulated, and decreased post steroid therapy. In a preliminary report, Gonsalves *et al*[42] reported that the esophageal epithelial barrier genes (Desmoglein 1) is lower in adults with EoE who did not respond to dietary therapy, suggesting a dysfunctional, leaking esophageal mucosa. The new data may explain the role of aeroallergens in the disease's pathophysiology, by permitting the absorption of allergens (aeroallergens or food allergens) through the tightly sealed epithelial layer of the esophagus, and/or may explain the quick absorption of topical steroid into the esophageal mucosa during therapy.

Overall, the genetic framework involved in the pathophysiology of EoE is emerging and the genes responsible for activation or suppression of the inflammatory process are slowly uncovered. Nevertheless, we still have a large gap of knowledge left to explain the different response to therapy in EoE patients who belong to a different gender, different ethnicity, or have different allergies.

In summary, eosinophilic esophagitis is a chronic disease of the esophagus with clinical and histological characteristics previously established and described[1]. As in many chronic diseases, the clinical and/or histological presentation may be altered by various environmental or genetic modifiers. Epidemiological and clinical reports have documented the different phenotypic presentation of EoE in different populations, but further investigation is needed to dissect those disease modifiers in order to be able to tailor therapy for the specific patient. In the era of personalized medicine these modifiers play a crucial role in the disease's prognosis, and future studies to address those factors are clearly warranted.

Abstract

Autoimmune hepatitis (AIH) is a progressive inflammatory liver disorder that is rare in children and adolescents. AIH has a broad clinical spectrum and a quick response to treatment with corticosteroids and immunosuppressive medication. The available diagnosis criteria have limitations and should be evaluated in pediatric populations. Recently, some studies reported that the 2008 simplified diagnostic criteria for AIH could be used in children with high sensibility and specificity. In addition, the authors reported that globulin and immunoglobulin G levels can be used interchangeably for diagnostic purposes. They also demonstrated that the 2008 simplified criteria fail in identifying patients with fulminant hepatic failure. Here, we discuss the limitations of the use of these criteria in pediatric patients and the requirement of more studies to improve the diagnosis of AIH in children.

Diagnostic criteria for autoimmune hepatitis in children: A challenge for pediatric hepatologists. *World J Gastroenterol* 2012; 18(33): 4470-4473 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i33/4470.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i33.4470

INVITED COMMENTARY ON HOT ARTICLES

Autoimmune hepatitis (AIH) is particularly aggressive in children and progresses rapidly unless immunosuppressive treatment is promptly started. The recent publication by Mileti *et al*[1] on the validation of simplified diagnostic criteria for autoimmune hepatitis in children caught our attention for its updated theme, with great relevance to pediatrics and hepatologists. We highly recommend reading the manuscript.

AIH is a progressive inflammatory liver disorder that is rare in children and adolescents. It affects patients who have lost immune tolerance to liver self-antigens[2-4]. It predominates in females, and it is serologically characterized by high levels of transaminases and immunoglobulin G (IgG) and the presence of auto-antibodies and histologically characterized by interface hepatitis in the absence of a known etiology[3]. The age of onset of AIH ranges from 6 mo to 75 years; however, it is rare

before 2 years, and the incidence is higher between 10 and 30 years[3].

The clinical spectrum is broad; asymptomatic patients may only have laboratory abnormalities. Patients may also present with clinical symptoms similar to acute viral hepatitis and even severe liver failure (acute, chronic or fulminant)[3]. Auto-antibodies, such as antinuclear antibodies (ANA), anti-smooth muscle antibody (SMA) and anti-liver/kidney microsome type 1 (anti-LKM1), are important for the diagnosis of AIH. Based on the pattern detected, AIH can be classified into two types: type 1, in which ANA and/or anti-SMA are detected, and type 2, in which anti-LKM1 is detected[5].

Some histological findings can suggest the presence of AIH: piecemeal necrosis with periportal/periseptal lymphocytic infiltrate; interface hepatitis with the destruction of hepatocytes at the periphery of the lobule and erosion of the limiting plate; hepatic regeneration with "rosette" formation; and "bridging collapse", in which connective tissue collapses and expands from the portal area into the lobule[6].

Treatment with corticosteroids and immunosuppressive agents is usually efficient in controlling AIH[3]. Prednisone alone or combined with azathioprine is the main treatment, and it is aimed at reducing liver inflammation and inducing clinical remission and better survival rates. The treatment response is characterized by clinical improvement and the reduction of aminotransferase levels to normal or up two times the highest reference value[3].

Given the necessity to standardize the diagnosis and establish early treatment, in 1993, the International Autoimmune Hepatitis Group (IAIHG) created diagnostic criteria for AIH. Those criteria were revised in 1999 to improve specificity and simplify the scoring system, as cited in the discussion section of the manuscript[1,7]. Simplified diagnostic criteria were established in 2008 to make their use in clinical practice easier.

Mileti *et al*[1] selected 37 children under 21 years old with a diagnosis of AIH and 40 children diagnosed with other liver diseases and evaluated the sensitivity and specificity of the diagnostic criteria proposed in 2008. They found a sensitivity of 87% and a specificity of 89% for the 2008 criteria and also observed that these criteria did not rank patients with signs of fulminant hepatic failure (FHF) well. The authors also compared the use of IgG and serum globulin levels to grade the criteria and concluded that they may be used interchangeably without impairing the final score.

The use of 2008 diagnostic criteria might simplify the day-to-day work of hepatologists and might provide an interesting measure for pediatric patients. Based on the cited results and considering that autoimmune hepatitis is important in the differential diagnosis of liver disease in childhood, we discuss some important points that may affect the use of these criteria.

Use of diagnostic criteria in pediatric patients

In general, the adoption of diagnostic criteria is considered to be an attempt to standardize observations and clinical procedures for different centers with the main goal of a "common language". Diagnostic criteria should contain well-defined measures and should be easy to apply in clinical practice to facilitate disease classification, diagnosis and, consequently, treatment. Another important issue concerning diagnostic criteria is the possibility of distinguishing patients who need to be assigned to different therapies or management strategies, even if the diagnosis is not clearly established. This important feature of the diagnostic criteria will certainly allow early treatment, which might improve the outcome of patients.

For many diseases and clinical conditions, we already have diagnostic criteria that were usually established for the adult population and subsequently adapted to pediatric patients. The ideal situation would be that the diagnostic criteria used for children arise from studies on this age group.

Another important point is that diagnostic criteria raise the possibility of a disease, but in most cases, it is difficult to exclude other diagnoses. For example, the diagnosis of rheumatic fever with the criteria originally proposed by Jones[8] in 1944 includes a combination of arthritis, fever, and a high sedimentation rate in the presence of a recent Group A streptococcal infection. However, many children with juvenile arthritis also present with exactly the same features[9].

For AIH, the same problem occurs, with the criteria being initially established for adults and later adopted with changes for pediatric patients. In its first version in 1993, based on consensus from the IAIHG, the diagnosis of AIH in the pediatric population was not considered to require separate diagnostic criteria, as cited by Mileti *et al*[1]. Two other studies attempted to evaluate recent criteria (1999 and the simplified criteria created in 2008) in pediatric populations, and they had controversial results. Those studies are listed and compared with the Mileti *et al*[1] study in Table 1.

The authors generally concluded that the 1999 and 2008 diagnostic criteria could be used in children with good sensitivity and specificity in most cases, but they also showed some limitations. First, in children with the final diagnosis of primary sclerosing cholangitis (PSC), the study of Ebbeson *et al*[10] found that the 1999 criteria adequately scored these patients as "not AIH", while Hiejima *et al*[11] showed that using both criteria, all 5 children with PSC were graded as having AIH. Considering these findings and the possibility of AIH/PSC overlap syndrome in children, the use of gamma-glutamyl transferase could improve the specificity of the 1999 criteria but would not improve the 2008 criteria. Therefore, the recent recommendation of performing cholangiographic evaluation in all children with an initial diagnosis of AIH was added[12,13].

The second issue is the limitation cited by Mileti *et al*[1] regarding the reliability of the 2008 criteria in identifying patients with FHF. The acuteness and severity of FHF

Table 1 Summary of pediatric studies on the validation of diagnostic criteria for autoimmune hepatitis

Authors	Place and date	*n*	Diagnostics	Tested criteria	Results	Conclusions
Mileti *et al*[1]	United States, 2012	68	37 AIH for 1999 criteria/ 31 AIH for 2008 criteria 40 non-AIH	1999 and 2008	1999 criteria: 29 of 31 subjects (94%) as definite AIH; 2 of 31 subjects (6%) as probable AIH Simplified criteria: 25 of 31 subjects (81%) as definite AIH; 2 of 31 subjects (6%) as probable AIH The 2008 diagnostic criteria had a sensitivity of 87% and a specificity of 89% and did not identify 4 patients with AIH and fulminant hepatic failure	The 2008 criteria showed high levels of sensibility and specificity Patients with fulminant hepatic failure need the 1999 criteria Globulin and immunoglobulin G can be used interchangeably
Ebbeson *et al*[10]	Canada, 2004	28	21 AIH 4 PSC 3 ASC	1999	18 of 21 (86%) with AIH scored as definite AIH and 3 of 21 (14%) scored as probable All patients with isolated PSC scored as not AIH	The IAIHG scoring system has a use in children Using the GGT ratio may improve the specificity for children
Hiejima *et al*[11]	Japan, 2011	56	20 AIH 36 non-AIH liver diseases	1999 and 2008	Sensitivity and specificity of the 1999 criteria were 100% and 81%, respectively Sensitivity and specificity of the simplified criteria were 55% and 86%, respectively All 5 children with PSC were graded as having AIH by both criteria	The specificity of the simplified AIH criteria is high Simplified criteria could not differentiate between AIH and PSC and do not seem to be a reliable diagnostic tool in children

AIH: Autoimmune hepatitis; PSC: Primary sclerosing cholangitis; ASC: Autoimmune sclerosing cholangitis; IAIHG: International autoimmune hepatitis group; GGT: Gamma-glutamyl transferase.

demand a rapid and precise diagnostic definition. If the diagnostic criteria provide information in this special situation, treatment with corticosteroids could be started promptly. Thus, further research is important to identify factors or measurements that could improve the diagnosis of FHF.

The third issue is that the auto-antibodies used for diagnosis often have lower titers in children than the cut-off values considered positive in adults and utilized in both diagnostic criteria (1999 and 2008)[4]. The reactivity of ANA, SMA and anti-LKM1 is low; therefore, titers of 1/20 for ANA and SMA and 1/10 for anti-LKM1 can be considered relevant in children[4]. The 2008 and 1999 criteria consider titers above 1/40 to be significant, and the laboratory test is performed with a minimum dilution of 1/40; therefore, children with titers of 1/20 could be false negative for the tested auto-antibody. Therefore, in children with clinical history and a physical examination compatible with AIH, we should not exclude this diagnosis when negative auto-antibody results are obtained.

The fourth issue is the use of histological findings as one point of the diagnostic criteria for AIH. Histology was included in the 1993 and 1999 criteria, and each feature of the liver biopsy was scored as a separate item[7]. In contrast, the simplified criteria utilize only two parameters: histology compatible with AIH and histology typical of AIH[14]. The concern is that a biopsy is not possible at the beginning of follow-up in many pediatric cases because these patients usually exhibit significant liver dysfunction and coagulopathy. Thus, sometimes, clinicians do not have this information and face the necessity of initiating corticosteroid therapy without knowledge of the histological condition. Björnsson *et al*[15] questioned the importance of histology in the diagnosis of typical cases of AIH and concluded that the majority of patients with typical laboratory features of AIH are likely to have compatible liver histology. Not surprisingly, liver biopsy may reveal another hepatic disease that might affect clinical management. We agree that whenever possible, liver biopsy should be performed prior to initiating immunosuppressive therapy in patients with AIH. However, we also believe that if it is not possible to obtain initial histological findings, the initiation of treatment for highly suspected patients should not be delayed. Indeed, for the majority of cases with suggestive clinical features and compatible laboratorial data, the diagnosis of AIH can be reliably established in the absence of liver histology. Ultimately, liver biopsy should be performed, whenever possible, to differentiate other hepatic diseases and according to the guidelines of the American Association for the Study of Liver Disease Practice Guidelines for Autoimmune Hepatitis[13].

The last point to be addressed is the sample size of the Mileti *et al*[1] cross-sectional study, which was composed of just a few individuals classified with both criteria. Similar to other pediatric studies on AIH, the sample size is small. Additional studies should be performed with other populations to establish the best diagnostic criteria for pediatric AIH and to address all other points that require further elucidation in AIH and hepatic-related disorders.

In conclusion, the use of 2008 diagnostic criteria is an important tool in the diagnosis of AIH in children, and the study of Mileti *et al*[1] clearly corroborates this view. However, considering the existing criteria, more studies with larger series seem to be necessary to validate their use in pediatric patients. Finally, we believe that additional pediatric studies on AIH might allow for the clear differentiation between AIH and PSC, include

alternative ways to define fulminant hepatic failure and establish lower auto-antibody titers for pediatric patients.

Abstract

Despite great efforts in experimental and clinical research, the prognosis of pancreatic cancer (PC) has not changed significantly for decades. Detection of pre-invasive lesions or early-stage PC with small resectable cancers in asymptomatic individuals remains one of the most promising approaches to substantially improve the overall outcome of PC. Therefore, screening programs have been proposed to identify curable lesions especially in individuals with a familial or genetic predisposition for PC. In this regard, Canto *et al* recently contributed an important article comparing computed tomography, magnetic resonance imaging, and endoscopic ultrasound for the screening of 216 asymptomatic high-risk individuals (HRI). Pancreatic lesions were detected in 92 of 216 asymptomatic HRI (42.6%). The high diagnostic yield in this study raises several questions that need to be answered of which two will be discussed in detail in this commentary: First: which imaging test should be performed? Second and most importantly: what are we doing with incidentally detected pancreatic lesions? Which ones can be observed and which ones need to be resected?

INVITED COMMENTARY ON HOT ARTICLES

With great interest we noticed the article published by Canto *et al*[1], which investigated the prevalence and characteristics of pancreatic lesions in high-risk individuals (HRI) for pancreatic cancer (PC).

Up to 10% of PC cases are attributed to a familial or inherited predisposition that can substantially increase the risk for PC[2-7]. For example, patients suffering from Peutz-Jeghers syndrome have a 132-fold increased risk for PC[8]. Other genetic predispositions include hereditary pancreatitis (*PRSS1* gene mutations, lifetime risk for PC of up to 40%)[9,10], the familial atypical multiple

mole melanoma syndrome (*p16/CDKN2A* gene mutations, 13-fold to 22-fold increased risk)[11,12], the Lynch syndrome (mismatch repair gene mutations, 8.6-fold increased risk)[13,14], familial adenomatous polyposis (*APC* gene mutations, 4.5-fold increased risk)[15,16], the familial breast-ovarian cancer syndrome (*BRCA1/2* gene mutations, 2.3-fold to 10-fold increased risk)[6,7,17,18], and individuals with a strong history of PC (at least two first-degree relatives with PC, 6.4-fold to 32-fold increased risk)[2,19]. For these, HRI screening programs have been proposed to detect early-stage pancreatic cancers or even pre-invasive lesions, which are potentially curable because once PC progresses into advanced stages the chance for cure decreases abruptly. In the study by Canto *et al*[1], pancreatic lesions were detected in 92 of 216 HRI (42.6%). The confirmed or suspected final diagnosis included branch-duct intraductal papillary mucinous neoplasm (IPMN) (n = 82), combined-duct IPMN (n = 2), main-duct IPMN (n = 4), and pancreatic endocrine tumor (n = 3)[1]. Such a high prevalence of pancreatic lesions is rare but has been reported before by Verna *et al*[20] who detected pancreatic lesions in 11 of 33 HRI (33.3%) and 14 of 31 HRI (45%) by magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS), respectively. A possible explanation for the high diagnostic yield is the high quality of the screening tests and the highly experienced team of radiologists and gastroenterologists involved in the diagnostic work-up in both studies. On the other hand, it is well known that the prevalence of pancreatic lesions increases with age. Therefore, the age at which the screening test was performed is crucial. In the study by Canto *et al*[1], the mean age of HRI at screening was 56.1 years which is comparable to other published studies. When compared to individuals in the general population, the baseline diagnostic yield was significantly higher in HRI. Incidental cystic pancreatic lesions can be found in up to 2.8% in the general population[21] and this number will increase with better imaging tests. These findings point towards the importance of screening initiatives for HRI with high-resolution imaging tests but also illustrate the dilemma we are currently facing. The more diagnostic imaging studies we perform, the more lesions we will find - even in asymptomatic individuals without increased PC risk. The question that remains is what to do with these incidental lesions. How accurate is our interpretation of an incidental pancreatic lesion? Which lesions really represent a precursor of PC and will proceed to invasive cancer? How many of these lesions already carry incipient cancer? In 2006, the Sendai consensus proposed guidelines for the management of cystic lesions including IPMN and mucinous cystic neoplasms (MCN), which have been widely adopted[22]. However, the diagnosis and subsequent recommendation for pancreatic resection are based on imaging in combination with fine needle aspiration from cystic lesions and confirmation of the presumed diagnosis can only be made after surgical resection. A recent study published by Correa-Gallego *et al*[23] reported a series of 330 patients with incidentally discovered cystic neoplasms of the pancreas from a high volume center for diseases of the pancreas. One-hundred-thirty-six patients (41%) were operated on at diagnosis. Preoperative and final histological diagnoses were correlated[23]. The accuracy of preoperative diagnoses was only 64% for presumed branch-duct IPMN (32 of 50 cases)[23]. Ten of the 18 patients (20%) had an extension to the main duct leading to the final diagnosis of combined-duct IPMN[23]. The diagnostic accuracy for presumed MCN was also only 60% (18 of 30 cases)[23]. Of all patients who were operated on, 6 had an invasive carcinoma (2 branch-duct IPMN, 3 main-duct IPMN, and 1 MCN) and 19 patients had a carcinoma in situ (8 main-duct IPMN, 8 cystic pancreatic endocrine neoplasms, and 3 others)[23]. Therefore, correct interpretation of pancreatic lesions is still problematic and even with established guidelines choosing the adequate treatment remains challenging because the final diagnosis can only be verified after surgical resection.

Another problem is that IPMN are usually multifocal which has been addressed by the concept of the field defect of pancreatic duct instability[24-27]. Pancreata which harbour an IPMN are at increased risk of developing carcinoma. Several studies of patients with IPMN reported synchronous or metachronous invasive PC and these cancers were also present in areas distant from the index IPMN[28-30]. The most recent study by LaFemina *et al*[31] analyzed the prevalence and site of PC progression in 157 patients with suspected or confirmed IPMN who were initially selected for radiographic surveillance. After a median length of surveillance of 15 mo (range: 6-193 mo), 97 patients (62%) eventually underwent resection[31]. Surgical pathology confirmed 18 cases of invasive carcinoma (11%), which were diagnosed at a median of 24 mo after the initial diagnosis of IPMN[31]. Ten patients had main-duct IPMN (56%), 5 had branch-duct (28%), and 3 had combined-duct (17%) IPMN[31]. Four patients (22%) developed PC in a region of the pancreas distinct from the radiographically identified IPMN[31]. Miller *et al*[32] followed 153 patients after pancreatic resection for IPMN with clear resection margins. The authors found that 31 patients developed de novo IPMN in the pancreatic remnant and in 3 cases an invasive carcinoma was diagnosed[32]. Therefore, the confirmation of IPMN requires continuous surveillance of the entire pancreatic gland or of the pancreatic remnant after previous resection[32].

In this regard, Canto *et al*[1] attempted to answer the question of which imaging test should be performed for screening HRI and compared computed tomography (CT), MRI and EUS for detecting pancreatic lesions. The authors found that EUS and MRI detected pancreatic lesions better than CT[1]. The baseline diagnostic yield for EUS, MRI, and CT was 42.6%, 33.3% and 11%, respectively[1]. The authors' conclusion that EUS and MRI are currently the best initial tests for detecting early pancreatic lesions is supported by other studies[33-37]. Main limitations of CT include not only its poor sensitivity for small pancreatic lesions (< 10 mm) which

is important for screening for early pancreatic neoplasms but also the use of ionizing radiation which has recently raised concerns regarding the increased risk of radiation-related cancers associated with CT[38]. However, multi-detector CT remains the most widely used imaging modality because of its high accuracy for detecting solid tumors and staging of pancreatic malignancies, its cost effectiveness and its non-invasive nature. Furthermore, EUS and MRI are more cost-intensive and both tests are more dependent on the experience of the performing and diagnosing gastroenterologist and radiologist. Although the invasive nature of EUS as an endoscopic procedure further limits its role in a screening program, the possibility of EUS-guided fine-needle aspiration of pancreatic cystic lesions may be of diagnostic value especially when malignant cells can be detected. Future work with molecular analysis of cyst fluid, direct cystoscopy, and confocal laser endomicroscopy may further enhance its diagnostic accuracy[39].

Based on the high diagnostic yield of modern high-resolution imaging tests, it appears to be reasonable to routinely screen HRI. Based on current evidence, MRI (and EUS) should be the initial imaging tests to be performed. The question at what age screening of HRI should start has yet to be answered.

Although we have learned a lot in the past two decades about the nature especially of pancreatic cystic lesions, we are still facing a great challenge of how to manage incidental pancreatic lesions. Canto *et al*[1] suggest that the goal of PC screening and surveillance programs should be to detect and selectively treat asymptomatic high-grade precursor neoplasms rather than focussing on detection of invasive cancers. However, especially because IPMN constitute a heterogeneous group of pancreatic cystic neoplasms, a better understanding of the natural history of IPMN and its subtypes is necessary to distinguish lesions that need immediate surgical resection and those that can be safely observed. Not only a better understanding of patient characteristics and further progress in imaging tests are needed but also the identification of reliable biomarkers that can be used to identify pancreatic lesions that are about to proceed to PC in asymptomatic individuals.

Abstract

This short review comments on the recently published work of Ishimoto *et al* regarding the opposing effects of fructokinase C and A isoforms on fructose-induced metabolic syndrome in mice. The framework for the commentary is the preexisting background of epidemiological and experimental data regarding the association between ingestion of fructose, as present in sweetened beverages, and the development of metabolic syndrome. The work of Ishimoto *et al* clearly confirms the negative effect of fructose on lipid and glucose metabolism, independently from the amount of energy provided by the ingested sugar. It also confirms the absolute requirement of liver fructose metabolism, driven by fructokinase activity, in order to develop the full spectrum of metabolic syndrome alterations.

INVITED COMMENTARY ON HOT ARTICLES

Non-communicable diseases continue to place an enormous burden on humanity, and have recently surpassed infectious diseases as the primary concern for human health. Among the former, cardiovascular events derived from the development of atherosclerosis associated with chronic metabolic diseases (such as obesity, type 2 diabetes mellitus and metabolic syndrome) are increasing all over the world. Besides genetic predisposition, two lifestyles options that are deeply rooted in affluent Western societies are fuelling this vicious trend: a lack of physical activity and the consumption of hypercaloric diets which tip people's energy balance to an overwhelming excess of ingested, unused energy. Dietary changes favor the consumption of processed, palatable, high-calorie-density foodstuffs over traditional ones. Among the former are the whole spectrum of sweetened beverages (fruit juices, sodas, milk shakes, *etc.*) which are sweetened with High Fructose Corn Syrup or sucrose. In both cases, such beverages offer the ingestion of large amounts of two simple sugars, glucose and fructose, in similar proportions[1,2].

When ingesting calories in liquid form, as in the case of the consumption of sugar-sweetened beverages, there is a lack of an appropriate compensatory response and thus no corresponding adequate reduction in the ingestion of calories provided by solid food. Therefore, it favors an excessive daily intake of calories. However, besides the increase in ingested calories, the particularities of fructose metabolism also need to be considered. Fructose is the carbohydrate with the greatest ability to induce hypertriglyceridemia, in part due to a more marked increase in hepatic lipogenesis than that resulting from a similar intake of glucose[3,4].

After entering liver cells, fructose is rapidly metabolized by the enzyme fructokinase to fructose-1-phosphate. Fructose feeding induces its own metabolism by increasing fructokinase expression. The product of fructokinase (fructose 1-phosphate) is further metabolized by the enzyme aldolase to the triose phosphates glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. The former enters directly into the glycolytic pathway producing pyruvate, which is converted to acetyl-CoA and citrate inside the mitochondria, providing the carbon moiety for de novo synthesis of long-chain fatty acids. Meanwhile, dihydroxyacetone phosphate is converted into glycerol 3-phosphate, which provides the glycerol backbone of triglycerides. Since hepatic fructose metabolism bypasses the main rate-controlling enzyme of glycolysis, phosphofructokinase, a high flux of this carbohydrate to the liver results in a marked increase in lipogenesis and in the production of very low density lipoproteins. In contrast, glucose is first phosphorylated in position 6 by glucokinase, followed by isomerization to fructose-6-phosphate, which is converted by phosphofructokinase into fructose 1, 6-diphosphate before entering the glycolytic pathway. The progression of glucose to complete glycolysis is under the control of phosphofructokinase activity, which is very tightly regulated by the products of the glycolytic pathway, citrate and ATP. Thus, when large amounts of glucose are consumed, there is a feedback inhibition of glycolysis and glucose uptake, limiting pyruvate production, and the lipogenic effect is not as intense as in the case of fructose[5]. Furthermore, research from our laboratory has shown that fructose, but not glucose at a similar energy intake, can down-regulate the liver peroxisome proliferator activated receptor (PPAR) system, impairing fatty acid oxidation, and thus helping the accumulation of fatty acids for triglyceride accretion[6]. At least in male rats, the effect of fructose on the PPARα system is related to the induction of a clear state of liver leptin-resistance[7].

Fructokinase, and its capacity to respond to fructose increasing its expression[8-10] thereby facilitating the incorporation of fructose into liver metabolism, is of paramount importance in the manifestation of metabolic disturbances induced by fructose ingestion. For example, Ouyang *et al*[11] have shown that patients with non alcoholic fatty liver disease consume nearly approximately 2-fold to 3-fold more fructose than controls, primarily in the form of sweetened beverages, and present higher liver expression of fructokinase. In an experimental model of male rats supplemented with 10 % w/v fructose solution, we found that atorvastatin, a hypocholesterolemic drug, counteracts fatty liver and inflammation by reducing the fructose-related liver fructokinase induction[12].

All this background information is capital to clearly appreciate the real importance of the information provided by Ishimoto *et al*[13] in their paper published recently in Proceedings of the National Academy of Sciences. Fructokinase exists in two isoforms, fructokinase A and fructokinase C, with differentiated patterns of tissue expression. Fructokinase C is primarily expressed in liver, kidney and intestines, while the A isoform is expressed ubiquitously[14]. Due to the lower K_m of fructokinase C, this isoform is held to be mainly responsible for fructose metabolism[15]. By cleverly using the knock-out mice that developed themselves for both isoforms (KO-A/C) or only for isoform A (KO-A) and two patterns of fructose supplementation (15% and 30% w/v solutions of fructose in drinking water for 25 wk), Ishimoto *et al*[13] clearly delineated the roles of fructokinase A and fructokinase C in the induction of the manifestations of metabolic syndrome by fructose.

While wild-type mice supplemented with 15% fructose presented almost the full panoply of metabolic syndrome manifestations (obesity, hyperglucemia, hyperinsulinemia, hyperleptinemia and fatty liver), KO-A/C mice supplemented with 30% fructose, despite ingesting equivalent amounts of fructose, presented no manifestations of metabolic syndrome at all. In contrast, KO-A mice supplemented with 30% fructose, although ingesting the same amount of fructose as their matching wild-type controls, presented a more severe manifestation of metabolic syndrome than their wild-type counterparts. Ishimoto *et al*[13] carefully confirmed, by using recombinant fructokinase A, that this isoform, although having a low affinity for fructose, is capable of metabolizing fructose at a range of physiological concentrations.

In our opinion, three clear facts can be derived from the results presented by Ishimoto *et al*[13]: (1) KO-A/C mice were protected from developing metabolic syndrome, despite having a similar fructose intake and energy balance as their wild-type counterparts, which did indeed, develop metabolic syndrome. This experiment clearly demonstrates that the induction of metabolic syndrome by fructose does not depend on the amount of energy ingested (similar in KO-AC and wild-type control mice), instead it depends on the metabolism of ingested fructose, which clearly depends on the presence of fructokinase activity in tissues; (2) The fructokinase A isoform plays a physiological role in the metabolic fate of fructose. Its absence increases fructose concentration in plasma, even in animals ingesting only tap water; and (3) Furthermore, the absence of fructokinase A activity, as in KO-A mice, which shifts the whole metabolism of fructose to the C isoform, worsens the metabolic alterations induced by fructose ingestion. As mentioned above, fruc-

tokinase C is mainly expressed in liver and kidney and, to a lesser extend, intestines. If we consider that, after fructose ingestion, the sugar is rapidly and almost completely extracted by the liver through the glucose transporter 2[16], these results clearly point to the liver as the main target organ of fructose, and the one whose metabolic alteration finally results in the manifestation of metabolic syndrome in the whole organism. It would be very interesting to generate KO-C mice and supplement them with fructose in order to definitely confirm this claim.

While recognizing the problems of directly transposing experimental results obtained from animal models to the everyday-life of human consumption of sweetened beverages, the work of Ishimoto *et al*[13] demonstrates that fructose especial metabolism clearly matters as a key factor in the development of pathologies associated with the metabolic syndrome.

Abstract

Several receptors have been identified as implicated on viral entry into the hepatocyte; and, this interaction between the virus and potential receptors could modulate infection, spontaneous viral clearance, persistence of the infection and the widespread of the virus as outbreak. Nevertheless, the playing role of each of them remains controversial. The Niemann-Pick type C1 like 1 gene (*NPC1L1*) receptor has been recently implicated on hepatitis C virus (HCV) entry into the cell and ezetimibe, an anti-cholesterol drug seems to block that, emerging the idea to control hepatitis C outbreak modulating lipid-related receptors. Hepatitis C infection seems to modulate lipid metabolism according to host genetic background. Indeed, it circulates like a lipoviroparticle. The main aim of this field of vision would be to discuss the role of hepatocyte receptors implicated on virus entry, especially NPC1L1 and the therapeutic options derived from the better knowledge about HCV-lipids- receptors interaction.

INVITED COMMENTARY ON HOT ARTICLES

Viral entry is the first step of virus-host cell interactions and, is a highly orchestrated process involving several viral and host cell factors. Indeed, the virus is able to escape from neutralizing antibodies and promote direct cell-cell transmission. Understanding the mechanisms of viral entry and escape is a prerequisite to define the viral and cellular targets that will give broad protection against hepatitis C virus (HCV) infection. HCV is an enveloped single-strand RNA virus that mainly targets hepatocytes. Due to the difficulty to grow HCV *in vitro* and the species specificity of this virus, surrogate model systems have been developed to study HCV entry into hepatocytes: recombinant envelope glycoproteins[1], HCV-like particles[2], HCV pseudo-particles[3,4] and recombinant infectious HCV[5-7] have been used to study the interactions of the viral envelope with human hepatoma cells or primary human hepatocytes. Four cellular factors have been described as essential for HCV entry (Figure 1): the tetraspanin molecule CD81, the scavenger receptor class B member I and the tight junction proteins claudin-1 and occludin[8]. Interestingly, neutralizing antibodies against CD81 are able to block HCV entry *in vitro* and also in im-

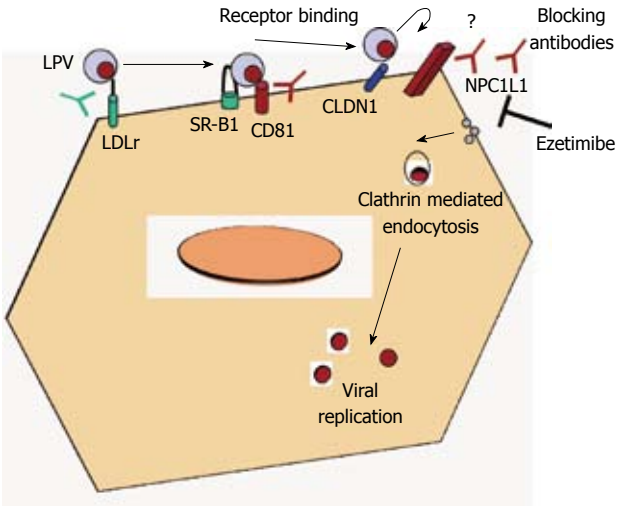

Figure 1 Schematic representation of viral receptors in hepatocytes. Possible mechanisms of viral entry blockade are also depicted by using specific antibodies or inhibitory drugs. LDLr: Low-density lipoprotein receptor; NPC1L1: Niemann-Pick C1-like 1 cholesterol absorption receptor; SR-B1: Scavenger receptor class B type 1; LPV: Lipoviroparticle; CLDN1: Claudin-1.

munodeficient mice transplanted with human hepatocytes, the best currently available small animal model of HCV infection[9]. Neutralizing antibodies against the HCV envelope proteins E1 and E2 could also represent a promising approach to avoid HCV infection, but the main challenge here is the enormous genetic variability of the virus. The requirement for sequential interactions between the viral envelope and key host receptors/co-receptors may provide new drug targets that could be exploited by small-molecule inhibitors. Recently, Syder *et al*[10] discovered and optimized a series of 1,3,5-triazine compounds that are potent, selective and non-cytotoxic inhibitors of HCV entry. Representative compounds fully suppress both cell-free virus and cell-to-cell spread of HCV *in vitro*. To date, only one oral HCV entry inhibitor with a defined mechanism of action, ITX-5061, has entered clinical testing (phase 2a)[11]. ITX-5061 binds directly to SR-B1 and blocks a key post-binding step in the viral entry process. In chronically infected patients we cannot find a single isolate of HCV but rather a population of related yet different viral variants (quasispecies), containing a vast repertoire of preformed variants that allow rapid escape from selective pressures such as neutralizing antibodies or anti-viral drugs. Recently, two well-known molecules have been shown to inhibit HCV entry: the green tea catechin epigallocatechin-3-gallate (EGCG) and the tyrosine kinase inhibitor erlotinib. Erlotinib blocks HCV entry by inhibition of the activity of the epidermal grow factor -receptor which is required for formation of CD81-claudin-1 co-receptor associations[12]. EGCG inhibits viral attachment to the target cell as well as cell-to-cell transmission between adjacent cells.

Role of Niemann-Pick C1-like 1 cholesterol absorption receptor in viral entry

Sainz *et al*[13] have recently discovered a novel surface receptor involved in HCV entry, the Niemann-Pick C1-like 1 cholesterol absorption receptor (NPC1L1), a 13transmembrane-domain cell surface cholesterol-sensing receptor, expressed on the apical surface of intestinal enterocytes and human hepatocytes, including Huh7 cells, is responsible for cellular cholesterol absorption and whole-body cholesterol homeostasis. NPC1L1 was first identified as a homolog of Niemann-Pick C1 protein[14], the deficiency of which causes Niemann-Pick disease type C1, a genetic disorder characterized by intracellular accumulation of unesterified cholesterol in the endosomal/lysosomal system of neurons that causes neurodegeneration and premature death[15,16]. Human *NPC1L1* gene maps to chromosome 7p13, spans 29 kb, encodes a 5 kb mRNA and predominantly produces a protein of 1332 amino acids[17]. NPC1L1 locates to the brush border membrane of the enterocyte and the canalicular membrane of the hepatocyte. Biliary cholesterol, which is secreted into bile by hepatocytes, accounts for more than two thirds of the total amount of cholesterol in the gut lumen. Since the cholesterol is water-insoluble, it is delivered to the brush border membranes by bile salt micelles.

These authors have shown that using NPC1L1-specific antibody, HCV infection was reduced in a similar way that CD-81 specific antibodies did. Ezetimibe is a 2 azetidinone-class drug that has been approved by the Food and Drug Administration as a cholesterol-lowering medication[18]. Sainz *et al*[13] also shown the role of NPC1L1 receptor on HCV infection *in vivo*, using immunodeficiency mice repopulated with human hepatocytes and treated them *via* oral gavage with ezetimibe. They have demonstrated that ezetimibe treatment delayed the establishment of HCV infection in mice pretreated for 2 wk, confirming the ability of this drug to inhibit HCV infection *in vivo*. However, ezetimibe concentration in those experiments was high (30 μmol/L). That means for a 70 kg weight adult to ingest 84 ezetimibe 10 mg tablets per day, when the usual doses for ezetimibe is one 10 mg tablet per day. So far, an ezetimibe based therapy for HCV does not seem suitable. Probably the use of antibodies against NPC1L1 would be a better alternative.

Lipid metabolism and HCV infection

HCV infection is tightly associated with alterations in lipid metabolism and lipids have been shown to play important roles during the viral replication cycle[19,20]. Indeed, recent studies based on transcriptome and proteomic analyses have demonstrated that expression of host genes involved in the biosynthesis, degradation and transport of intracellular lipids is profoundly altered upon infection. The expression of sterol regulatory element binding proteins, which control transcription of genes required for cholesterol biosynthesis, is stimulated by HCV infection. In agreement with this, the expression of fatty acid synthase (FASN) and other genes related to the synthesis and transport of fatty acids is upregulated in infected cells[21,22]. Moreover, the inhibition of FASN

activity blocks HCV RNA replication and production of infectious virus particles[23]. Finally, expression of genes regulating geranylgeranylation of cellular proteins important for HCV replication is also upregulated in HCV infected cells[21] .

HCV from infected patients (sera) can be precipitated with antibodies against lipoproteins (LP), indicating that HCV circulates associated to LP. Removal of LP by apheresis reduced HCV RNA level by 77%, suggesting that most of the viral particles are tightly associated with lipoproteins[24]. Two different studies[25] suggest that infectious HCV particles are highly associated with LP. Lipoproteins are easily endocytosed, supporting the hypothesis that HCV can use this association to LP to adhere the cell and subsequently enter into the host cell by endocytosis rather than direct fusion to the membrane[26].

Lipids droplets are necessary for the lipoviroparticle formation. HCV is hypothesized to initiate assembly in close association with lipid droplets by coating lipid droplets with the core protein and bringing together nonstructural (NS) and structural proteins in a NS2-dependent manner[27-29]. Following capsid assembly, nascent virions bud into the lumen of the endoplasmic reticulum (ER) where the glycoproteins E1/E2 reside in addition to the very low density lipoprotein (VLDL) secretion machinery. HCV is infectious upon envelopment at the ER, and it is thought that apolipoprotein E (ApoE) is acquired early during assembly because knockdown of ApoE reduces intracellular and extracellular virus; also NS5A interacts with ApoE[30,31]. Core proteins disturb microsomal triglyceride transfer protein (MTP) activity in the hepatocyte[32] and it has been described that NS5A could be interfered with MTP function. MTP is an essential chaperone for the assembly of VLDL, which transfers triglyceride, phospholipids, and cholesterol from the hepatocytes. Reduced activity of MTP results in decreased secretion of VLDL, leading to lipid accumulation. This fact could explain development of steatosis.

The low-density lipoprotein receptor (LDLr) was proposed as a potential entry factor for HCV[33], however, its implication in virus entry remains unclear. Moreover, by using HCV particles isolated from patients, a correlation has been shown between the accumulation of HCV RNA into primary hepatocytes, expression of LDLr messenger RNA, and LDL entry[34]. The potential involvement of the LDLr in HCV entry has also been reported in the HCVcc system[35]. Albecka *et al*[36] have shown that HCV particles can interact with the LDLr. However, this interaction does not necessarily lead to a productive infection. Furthermore, those data indicate a role for the LDLr as a lipid-providing receptor, which modulates viral RNA replication.

Quercetin, an abundant flavonoid found in fruits and vegetable, has been implicated in lowering the risk of cardiovascular disease that is often associated with high plasma levels of LDL cholesterol. Quercetin was found to inhibit NS3 activity in a specific dose-dependent manner in an *in vitro* catalysis assay, also inhibiting HCV RNA replication in the subgenomic HCV RNA replicon system and virus production in the HCV infectious cell culture system[37]. Gonzalez *et al*[38] have shown the marked reduction in viral production imparted by heat shock proteins synthesis inhibitor Quercetin. The low toxicity and pharmacokinetics of Quercetin are well known, and it has been approved for other uses in clinical trials. In fact, a phase I study evaluating the safety and tolerability of Quercetin in hepatitis C patients who have contraindications to standard antiviral treatment started last year (www.clinicaltrials.gov).

Administration of the exogenous interferons (IFNs) alpha, beta, and gamma in the setting of treatment for chronic HCV infection and other conditions has been shown to lower LDL cholesterol and raise triglyceride levels in VLDL, concomitant with suppression of lipoprotein lipase[39,40]. Li *et al*[41] have shown an association between rs12979860 genotype and host serum lipid levels, suggesting a relationship between endogenous IFN response and lipids. They hypothesize that the IFN-lambda rs12979860 CC responder genotype, which was associated with both increased likelihood of treatment response and higher LDL cholesterol levels in the studied cohort, is associated with lower IFN-lambda activity or lower intrahepatic IFN signaling gene expression. Our results indicate that LDL and total cholesterol levels were higher in patients infected with HCV genotype 1 harbouring the favourable genotype for interleukin 28B gene (Del Campo *et al*[29] unpublished data). These results suggest that observed associations are directly related to HCV-host interactions instead of a direct effect of this locus on lipid metabolism. At least in part, this host factor could select virus infection and promote chronic infection or spontaneous clearance according to viral genotype and lipid metabolism interplay.

Final remarks

HCV entry is a highly orchestrated process involving several viral and host cell factors, affecting infection, spontaneous viral clearance, persistent infection and widespread, and thereby offering multiple novel targets for antiviral therapy. A recently discovered novel surface receptor involved in HCV entry, NPC1L1, is responsible for cellular cholesterol absorption. This receptor arose as a new therapeutic target for HCV infection, since specific antibodies can block HCV entry. Ezetimibe treatment delayed the establishment of HCV infection in an animal model, emphasizing the relevance of the interaction between the host lipid metabolism and the establishment of a persistent infection, although utilized doses could not be translate to clinical practice. Host and virus genetic variation together with the interaction with hepatocyte receptors were assumed to explain the heterogeneity in HCV outcomes across individuals.

Abstract

The effect of malnutrition on survival in patients with decompensated liver cirrhosis has not been well defined. Nutritional intervention with branched-chain amino acid (BCAA) can increase serum albumin concentration in patients with decompensated cirrhosis but its effects on survival are unclear. The BCAA to tyrosine ratio (BTR) is a surrogate marker (the normal range of BTR is between 4.41 and 10.05, and a Fischer's ratio of 1.8 corresponds to a BTR of 3.5) in patients with decompensated liver cirrhosis, and BCAA inhibits hepatic carcinogenesis in patients with compensated cirrhosis. This review discusses data regarding the effect of early administration of BCAA granules based on the ratio of BCAA to BTR on prognosis in patients with cirrhosis.

INTRODUCTION

The liver plays a key role in nutrient metabolism, and patients with cirrhosis may develop various metabolism and nutrition disorders. In fact, many cirrhosis patients suffer from protein-energy malnutrition (PEM)[1], which is particularly pronounced in the decompensated stage. Correction of PEM can improve prognosis in patients with decompensated cirrhosis[2]. Patients with cirrhosis and decreased plasma branched-chain amino acid (BCAA) levels can develop PEM with increased catabolism[3].

PEM is associated with a high morbidity and mortality due to an increased risk of life-threatening complications, resulting in poor survival and poor quality of life (QoL)[4,5].

SIGNIFICANCE OF BCAA SUPPLEMENTATION

BCAAs are a group of essential amino acids, including valine, leucine, and isoleucine. A low plasma level ratio of BCAAs to aromatic amino acids suggests the presence of liver cirrhosis, and BCAA supplementation was originally developed in order to normalize the patient's amino acid profile and nutritional status[6].

This article summarizes the findings of previous studies to determine whether nutritional intervention with a granulated BCAA preparation can contribute to improved prognosis of patients with PEM and cirrhosis. In Japan, oral BCAA preparations are used in nutritional therapy to correct protein and amino acid abnormalities

in patients with cirrhosis. Moreover, enteral nutrition guidelines published by the European Society for Clinical Nutrition and Metabolism list BCAA supplementation as a grade B recommendation in the treatment of advanced cirrhosis[7].

BCAA supplementation effectively increases Fischer's ratio and improves hypoalbuminemia in patients with liver cirrhosis[8]. In addition, not only does BCAA serve as components of albumin, the activation by *L*-leucine of mammalian target of rapamycin in hepatocytes and the subsequent activation of albumin mRNA transcription and protein synthesis in ribosomes are thought to constitute the mechanism for albumin increase[9,10]. This increase in albumin has been verified in various clinical trials to be effective for improving hypoalbuminemia[8,11].

Oral BCAA preparations come in two dosage forms: enteral nutrition formulas (or elemental diet products) for liver failure and oral BCAA granules. In 1996, an oral BCAA granule product containing valine, leucine, and isoleucine (Val, Leu, Ile) in a composition ratio of 1:2:1.2 was marketed in Japan (Livact®, Ajinomoto Pharmaceuticals, Tokyo, Japan). This product is indicated for decompensated cirrhosis patients who have hypoalbuminemia despite adequate dietary intake.

IMPROVEMENT OF PROGNOSIS AND INHIBITION OF HEPATOCAR-CINOGENESIS

An Italian research group reported a multicenter randomized trial in which a total of 174 patients with advanced liver cirrhosis were given BCAA as a supplement for 1 year and its effects were compared with administration of lactalbumin or maltodextrin[12]. Long-term use of a BCAA granule preparation has been reported to increase serum albumin and to inhibit the incidence of events related to poor prognosis[8,12].

Moreover, Marchesini *et al*[12] analyzed whether oral BCAA might prevent progressive liver failure and improve nutritional parameters and quality of life.

They conclude that long-term nutritional supplementation with oral BCAA is useful to prevent progressive hepatic failure and to improve health status ,and recommend that new formulas are needed to increase compliance. An oral BCAA granule (Livact®, Ajinomoto Pharmaceuticals, Tokyo, Japan) is the form of small uniform granules, which reduces BCAA-induced stimulation of taste buds and contributes to improve compliance.

Kobayashi *et al*[13] conducted a study of patients with compensated cirrhosis caused by hepatitis C. After a mean follow-up of 3.2 years, the authors reported that the incidence of hepatocellular carcinoma (HCC) among men with a baseline serum albumin level of 3.6 to 4.0 g/dL tended to be lower in the BCAA granule treatment group than in the control group. A large-scale postmarketing clinical study conducted at 89 sites in Japan to determine the effects of BCAA granules on the prognosis of cirrhosis patients [Long-term Survival Study (LOTUS)] demonstrated that the onset of complications associated with poor prognosis (i.e., liver failure, ruptured esophageal varices, HCC, and death) was significantly lower among patients in the BCAA granule treatment group than in the dietary therapy group (hazard ratio: 0.67; 95% CI: 0.49-0.93)[8]. Furthermore, stratified analysis of the LOTUS study for groups at high risk for HCC, specifically, patients with a body mass index $\geqslant$ 25 kg/m^2 or elevated alpha-fetoprotein, showed that BCAA granules had an inhibitory effect on the incidence of HCC[14]. Meanwhile, a study by Tsuchiya *et al*[15] on radical therapy for HCC patients reported that long-term treatment with BCAA granules reduced the rate of the third and subsequent relapses of HCC and improved the cumulative rate of survival in patients with baseline serum albumin $\leqslant$ 3.5 g/dL. Sato *et al*[16] undertook a comparative study of dietary control protocols and found that a BCAA granule product and an enteral nutrient for liver failure (or an elemental diet product) had similar effects in terms of improving or maintaining serum albumin and preventing the onset of hepatic encephalopathy. The authors reported that, despite control of the total dietary energy intake, an increase in glycosylated hemoglobin and other markers of abnormal glucose tolerance occurred in the enteral nutrient group, whereas these unfavorable changes were not observed in the BCAA granule treatment group[16].

Moreover, Hayaishi *et al*[17] reported that Oral BCAA supplementation is associated with reduced incidence of HCC in patients with cirrhosis.

Based on these findings, a BCAA granule preparation (Livact®) has been now recommended in the guidelines for the treatment of liver cirrhosis by the Study Group for the Standardization of Treatment of Viral Hepatitis Including from the Ministry of Health, Labour and Welfare in Japan in order to increase serum albumin in cirrhosis patients with the aim of reducing the onset of cancer[18] (Table 1).

IMPORTANCE OF CONTINUED ADMINISTRATION

On the other hand, because some patients do not exhibit any increase in serum albumin after taking BCAA granules, further research has been conducted on the dietary intake and baseline characteristics of these patients. Yatsuhashi *et al*[19] reported that the anti-hypoalbuminemic effect of BCAA granules was not influenced by dietary intake and that continued use of BCAA significantly reduced the incidence of ascites and edema even in patients whose serum albumin did not respond to BCAA granule treatment.

One possible explanation for the significant decline in ascites and edema in the unchanged serum albumin group could be that the BCAA granules improved albumin quality. The sulfhydryl group of the cysteine 34 residue in human serum albumin can exist in a reduced state (reduced albumin) or oxidized state (oxidized albumin). In patients with chronic liver disease, however, the pro-

QoL: Quality of life .

portion of oxidized albumin increases as the condition progresses[20]; this is associated with body fluid retention, such as ascites and edema. Furthermore, BCAA granules reduce the ratio of oxidized albumin in decompensated cirrhosis patients[21]. These findings suggest that the use of BCAA granules is important in maintaining serum albumin and that its continued use can improve the prognosis of patients with decompensated cirrhosis[22-25].

BCAA TO TYROSINE RATIO VALUE, AN IMPORTANT INDICATOR IN EARLY ADMINISTRATION OF BCAA GRANULES

However, the therapeutic effects of BCAA granules can take longer to appear in patients with advanced decompensated cirrhosis, making it important to determine the optimal timing for administration. After examining the biochemical test results of decompensated cirrhosis patients, Kato *et al*[26] identified the following four characteristics of uncompensated cirrhosis, and thus, the proper time to begin administration of BCAA granule preparations: (1) serum albumin $\leqslant$ 3.5 g/dL; (2) BCAA to tyrosine ratio (BTR) $\leqslant$ 3.5; (3) prothrombin activity $\leqslant$ 60%; and (4) platelet count of $\leqslant$ 100 000/mm^3. This in turn led to the search for markers of cirrhosis in order help facilitate determination of the optimal timing to initiate treatment with BCAA granules.

Cirrhosis patients exhibit shifts in their plasma free amino acid concentration, marked declines in BCAA (Val, Leu, Ile), and increases in aromatic amino acids (AAA; tyrosine, phenylalanine) and methionine, whereas their Fischer's ratio (ratio of molar concentrations of BCAA: AAA) or BTR declines in conjunction with disease severity. Fischer's ratio has long been used to analyze plasma free amino acids[27], but the BTR is a simpler method. Azuma *et al*[28] reported that the BTR based on an enzymatic method serves as an alternative to Fischer's ratio and is a potential indicator of liver disorders as well as subsequent chronic liver disease progression.

In the event of malnutrition, the BTR also declines before the serum albumin declines; therefore, determining the BTR is useful for the early detection of potential hypoalbuminemia. In other words, calculating the BTR enables the prediction of serum albumin level changes[29] and therefore allows determination of the appropriate time to administer BCAA granules. Given this time lag between decreases in serum albumin and BTR, monitoring of BTR needs to be done separately from that of albumin when considering prognostic factors for decompensated cirrhosis. The benefits of administering an oral BCAA preparation in patients with decreased BTR have already been reported in a large-scale clinical study[8]. This also implies that the BTR has considerable potential as a prognostic factor of HCC in decompensated cirrhosis patients. In fact, many reports performed the usefulness of BCAA for the treatment of hepatocellular carcinoma[30-39]. So, BTR may be useful as an indicator of prognosis in patients with HCC[40]. Early administration of BCAA granules based on the ratio of BCAA to tyrosine can improve the prognosis of decompensated cirrhosis.

In conclusion, BCAA supplementation for liver disorders may be expected not only to increase serum albumin, but also to exert other effects, such as prolongation of survival among liver cirrhosis patients, prevention of liver cancer, and enhancement of QoL. However, in cases of severe decompensated liver cirrhosis, determination of the timing of administration is also an important issue because BCAA granules take time to take effect. The decrease in BTR precedes reductions in serum albumin. While early therapeutic intervention with BCAA granules can help improve the prognosis of patients with decompensated cirrhosis and low BTR, more research and analysis are needed to fully explore the novel effects of BCAA granule preparations.

Abstract

The renewed interest in donation after cardio-circulatory death (DCD) started in the 1990s following the limited success of the transplant community to expand the donation after brain-death (DBD) organ supply and following the request of potential DCD families. Since then, DCD organ procurement and transplantation activities have rapidly expanded, particularly for non-vital organs, like kidneys. In liver transplantation (LT), DCD donors are a valuable organ source that helps to decrease the mortality rate on the waiting lists and to increase the availability of organs for transplantation despite a higher risk of early graft dysfunction, more frequent vascular and ischemia-type biliary lesions, higher rates of re-listing and re-transplantation and lower graft survival, which are obviously due to the inevitable warm ischemia occurring during the declaration of death and organ retrieval process. Experimental strategies intervening in both donors and recipients at different phases of the transplantation process have focused on the attenuation of ischemia-reperfusion injury and already gained encouraging results, and some of them have found their way from pre-clinical success into clinical reality. The future of DCD-LT is promising. Concerted efforts should concentrate on the identification of suitable donors (probably Maastricht category Ⅲ DCD donors), better donor and recipient matching (high risk donors to low risk recipients), use of advanced organ preservation techniques (oxygenated hypothermic machine perfusion, normothermic machine perfusion, venous systemic oxygen persufflation), and pharmacological modulation (probably a multi-factorial biologic modulation strategy) so that DCD liver allografts could be safely utilized and attain equivalent results as DBD-LT.

INTRODUCTION

The first human liver transplantations (LT) were performed from donation after cardio-circulatory death (DCD) in the 1960s[1-4]. DCD-LT was nonetheless almost universally abandoned in the following two decades, given the well-recognized Harvard brain-dead concept in 1968 and given the better results of LT originating from donation after brain death (DBD)[5]. In 1983, LT was approved as a therapeutic modality for end-stage liver diseases after a long period considered as an experimental procedure. The renewed interest in DCD donors started in the 1990s following the limited success of the transplant community to expand the DBD organ supply and following the request of potential DCD families.

If DCD kidneys are increasingly accepted around the world[6], the use of DCD livers remains limited in experienced transplant centers due to higher risks of primary graft dysfunction and biliary complications as well as a lack of a reliable viability testing prior to liver implantation. However the number of DCD-LT increased rapidly over the past decade. In the United States, 276 DCD liver transplants were performed in 2008 compared to only 23 cases in 1999, making up 5% of the deceased donor (DD) liver transplants[7-10]. The same trend was observed in the United Kingdom[11-13], Spain[14], Netherlands[15] and Belgium[15,16]. Netherlands had the highest rate of DCD- over DD-LT in the world (22.5% in 2008)[15]. France has just initiated its DCD-LT program since 2010[17]. In Japan, although DCD donors were the essential DD source, its use was reserved mainly for kidney, pancreas and islet transplantation[18]. Using a mathematical model to analyze the potential impact of a DCD policy on LT programs, Chaib *et al*[19] reported if 1%, 5% and 10% of deceased individuals became DCD donors, there would be 8%, 27% and 37% relative reductions in the size of waiting list, respectively. The use of DCD livers could increase the supply of transplants by 53%[20]. Centers with active DCD-LT programs usually reported 4%-10% rates of LT from the DCD source[21]. The potential impact of DCD use on the DBD availability is also a controversial issue. Controlled DCD programs might negatively influenced DBD activity in Belgium, Netherlands and United Kingdom while uncontrolled DCD donors seemed to be a clear additional source of organs for transplantation in France and Spain[22].

Most countries use Maastricht-category-3 DCD donors for LT, except France and Spain, where categories 1 and 2 are exclusively used due to legal interdiction of discontinuation of therapy in irreversibly brain-injured individuals[17,23,24]. German law prohibits any DCD organ procurement and transplant activity. In Italy, death of a human being must be declared 20 min after cardiac arrest using continuous electrocardiography. The procedure therefore will enable, at best, retrieval of only a few marginal kidneys and some tissues, and will not be helpful for patients on LT waiting lists[25]. This article is aimed at reviewing mono- and multi-centric DCD-LT outcomes, experimental strategies on animal models to optimize the utilization of this donor source and its future development.

DIFFERENCES BETWEEN DCD AND DBD DONORS PERTINENT TO LT OUTCOMES

Generally results of DCD-LT are inferior to those from DBD-LT with regard to both short-and long-term graft and patient survival as well as post-transplant morbidity. Expected DCD-LT outcomes could be explained by inherent differences between DCD and DBD donors in circumstances of death, warm ischemia time (WIT) and donor cause of death. Consequently, a different strategy of DCD use in terms of logistics of organ retrieval and preservation, allocation and recipient selection appears necessary to guarantee acceptable results. These differences will be briefly discussed prior to considering results of DCD-LT in detail.

Circumstances of death and consequent warm ischemia time

In DCD, donor death is diagnosed on the basis of irreversible cessation of cardio-pulmonary function instead of conventional neurologic criteria. As a result, organs from DCD donors are subjected to a period of hypotension, hypoxia and a circulation prior to organ procurement and this WIT adversely affects tissue viability and graft function after transplantation[26]. An international classification of DCD donors into 4 categories was first proposed in 1995 and widely accepted up to now[27]. New DCD categories have been recently suggested in Spain[28,29], Italy[30] and Belgium[31]. The length of WIT varies greatly according to the type of DCD process. It is longest among uncontrolled categories 1 and 2 (usually 90-120 min) and shorter among controlled categories 3 and 4 DCD donors (usually 20-30 min). In brain death, issues related to donor warm ischemia are eliminated because DBD donors have an effective natural organ perfusion and a potentially well-preserved organ function and WIT is thus nearly equal to zero.

However, WIT is heterogeneously defined among authors[32]. In the controlled DCD context, the commonest definition is the time interval between withdrawal of both ventilator and cardiac support to start of cold flushing of the organ[33,34]. This definition includes the no-touch period and the time of death declaration and is proposed to have two phases (withdrawal and acirculatory phases). Other authors used a blood pressure (BP) or oxygen saturation threshold below which would be defined as the beginning of true WIT (systolic or mean BP < 35-60 mmHg, oxygen saturation < 25%-70% or unreadable)[35-42]. de Vera *et al*[34] did not use a BP threshold to define the start of WIT because tissues are still hypoxic in a DCD donor who maintains a BP but has ceased to ventilate. It is unknown at what BP or oxygen saturation the liver parenchyma and biliary system undergo irrecoverable injury[43]. The first international Non-Heart Beating Donor workshop in Maastricht in 1995

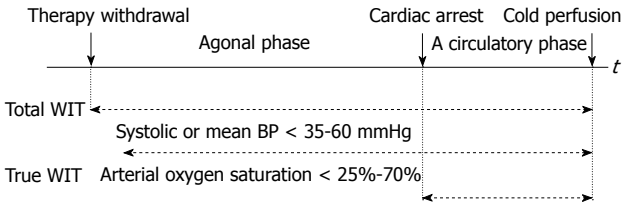

Figure 1 Different ways of warm ischemia time definition in the controlled donation after cardio-circulatory death setting (see text for more details). True warm ischemia time (WIT) is also called complete or functional WIT; Total WIT is also called overall WIT; Agonal phase is also called withdrawal phase. BP: Blood pressure; *t*: Time.

suggested WIT should be calculated from the moment of cardiac arrest until the start of hypothermic flush-out[44]. This definition may be useful for consistency but is inaccurate at the cellular level. Hypoxia starts when the blood flow or oxygenation no longer meets cellular metabolic needs[37]. The start of WIT may be chosen prior to asystole, and the end of WIT may be at or after aortic flushing[45]. Apparently a well-accepted definition of donor organ ischemic times is needed to standardize nomenclature and allow accurate comparisons of individual DCD studies[46,47] (Figure 1).

In transplant practice, WIT should be minimized as much as possible. For controlled DCD donors, the possibility to predict whether a potential donor will or will not expire in a time frame consistent with donation is extremely important, because prolonged time to asystole, likely resulting in suboptimal organ perfusion, is a common reason for non procurement of DCD grafts[48,49]. Time between therapy withdrawal and cardiac arrest usually does not exceed 1 h in most DCD donors. However, if a DCD donor has a period of relatively hemodynamic stability after life-support withdrawal, this period may be extended beyond 1 h without additional warm injury to the organs[50]. Some authors emphasized during the withdrawal phase, time to a systolic BP < 50 mmHg should be < 30 min[20] and the hypotensive period (mean BP < 50 mmHg) < 15 min[51]. Manara *et al*[52] proposed the so-called functional WIT, which is measured from the donor's systolic BP < 50 mmHg, the arterial oxygen saturation < 70%, or both, to the start of cold perfusion, should not exceed 30 min and may be limited to 20 min in suboptimal donors. Several factors have been identified as predictors of rapid death following treatment withdrawal and include the DCD tool of University of Wisconsin[53], donor Glasgow coma scale, inotropic use, BP at treatment discontinuation, high FiO_2 and mode of ventilation[54,55]. Withdrawal of therapy is preferably occurred in the operating room with a donor surgical team immediately available. Prior to cessation of the ventilator and organ perfusion support, the donor may be already prepared and draped, and the surgical instruments, preservation solution and tubing are set up to facilitate rapid organ recovery. The super rapid recovery technique is preferable and organs may be removed *en bloc*[39,50]. For uncontrolled donors, *in vivo* organ preservation techniques, like in-situ intravascular cooling using a double balloon and triple lumen catheter or hypo- and normothermic cardiopulmonary bypass with extracorporeal membrane oxygenation (ECMO), should be employed. With regard to the logistic organization, two frequently mentioned initiatives are the "Maastricht's box" and the "Madrid's rapid identification and response system"[6].

Donor cause of death

DCD donors do not experience the brain dead process. Brain death provokes a cascade of changes in hemodynamics, hormones, and immune response, which negatively affect donor organ viability and transplant outcomes[56,57]. Hemodynamic instability may have deleterious effects on liver function, although the liver has a high tolerance to marked hypotension and a large physiological reserve. Only a few histological changes were observed in the liver both on light and electron microscopic examination during the brain dead process[58,59]. The most important changes are the increased liver immunogenicity with subsequent increased host alloresponsiveness and the occurrence of apoptosis of hepatocytes[60]. Clinical findings in livers from DBD donors revealed significantly higher leukocyte infiltrates, up-regulation of adhesion molecules [intercellular adhesion molecule (ICAM), vascular cell adhesion molecule] and pro-inflammatory cytokines [interleukin-6 (IL-6), IL-10, IL-1β, interferon γ and tumor necrosis factor-alpha (TNF-α)], along with an increased expression of major histo-compatibility complex-Ⅱ relative to livers from living donors[61,62]. The peak time of cytokine expression and cell infiltration is during brain death and organ procurement but not after reperfusion[61]. These changes may amplify ischemia-reperfusion injury (IRI) during the transplant procedure and accelerate graft rejection after transplant[63]. In reality, donor brain-death mechanisms are quite varied and large differences may exist in the degree of impaired organ quality and transplant outcomes. The impact of donor cause of death on transplant outcomes has been recently confirmed in a United Network for Organ Sharing (UNOS) registry analysis, in which the cerebro-vascular accident presented as a predictor of worse graft survival across all organs relative to other donor modes of death[64].

Uncontrolled DCD donors whose cause of death is usually other than neurologic do not undergo the process of brain death, while most controlled DCD donors have sustained irreversible cerebral injuries. As a result, organs from controlled DCD donors are likely to suffer more from the harmful immunologic and inflammatory effects of acute brain injury than those from uncontrolled DCD donors[65].

Allocation policy

It is reported that organs that have already subjected to warm ischemic injury have an increased susceptibility to damage during cold storage[66]. The incidence of primary non-function (PNF) was 2.5 times less in patients with

Table 1 Risk classification for donation after cardio-circulatory death donors and donation after cardio-circulatory death-liver transplantations recipients

Authors		Donors	Recipients
Mateo *et al*[74]	Low risk	Both WIT ⩽ 30 min and CIT ⩽ 10 h	RCRR ⩽ 1.5
	High risk	WIT > 30 min and/or CIT > 10 h	RCRR > 1.5 Re-transplantation and/or On life-support and/or A combination of ⩾ 3 risk factors: Hospitalization or in an intensive care unit Serum creatinine > 2 mg/dL On dialysis Age > 60 yr
Lee *et al*[32]	Low risk	Donors with no identified donor risk factors	Recipients with no identified recipient risk factors
	High risk	Donors with at least one identified donor risk factor: Donor age > 45 yr WIT > 15 min CIT > 10 h	Recipients with at least one identified recipient risk factor: Previous transplantation Life support at transplantation
de Vera *et al*[34]	Low risk	-	MELD scores ⩽ 30
	High risk	-	MELD scores > 30 On life support (mechanical ventilation, hemodialysis)

RCRR: Recipient cumulative relative risk; WIT: Warm ischemia time; CIT: Cold ischemic time; MELD: Model for end-stage liver disease.

cold ischemia time (CIT) ⩽ 8 h *vs* those with CIT > 8 h (5% *vs* 13%)[34]. The incidence of graft failure within 60 d of transplantation was 10.8% if CIT < 8 h and substantially increased to 30.4% and 58.3% if CIT > 8 h and > 12 h, respectively[67]. Proper and rapid allocation of DCD livers thus appears pivotal to minimize CIT. One-year graft survival of DCD livers shared regionally was less good than those shared locally (67% *vs* 77%)[68] and the relative risk of graft failure from nationally shared DCD livers was 31% higher than locally or regionally shared ones[69]. Thus a policy to favor local use of DCD livers seems reasonable[67,68]. However, parallel (backup) offers should also be made to expedite organ placement[33]. The exchange of DCD livers between transplant centers has been successfully done but requires a more efficient and rapid referral system due to a lower tolerance of these allografts to cold storage[70].

Regarding recipient selection criteria, DCD livers could be routinely discussed and offered to all recipients on the waiting list[20,70,71] or selectively reserved to uncomplicated cases to ensure short CIT (by avoiding cases with extensive history of abdominal surgery or portal-vein thrombosis)[20,35]. An expected long surgical procedure exceeding 8 h of CIT, logistical reasons for an extended CIT, combined organ transplantation, recipients with high Model for End-Stage Liver Disease (MELD) scores or a large age difference between donors and recipients could all result in the refusal of a DCD liver[51]. Patients with stable cholestatic liver disease or re-transplantation were also excluded from DCD programs because of problems related to the quality of life in primary biliary cirrhosis and to the fear that pre-existent warm ischemic biliary damage could trigger the recurrence of primary sclerosing cholangitis[72]. Using DCD livers in re-transplanted patients might increase the CIT associated with a difficult hepatectomy. Recently LaMattina has demonstrated the feasibility of simultaneous liver and kidney (SLK) transplantation using DCD donors and shown short-term results comparable to those of SLK transplantation using DBD donors, making it a valid approach to safely expanding the donor organ pool for patients with end-stage liver and kidney disease[73].

It is still controversial whether it is better to transplant such grafts into healthy or sicker recipients (i.e., according to the recipient liver disease severity). UNOS database reviews advocated utilizing DCD livers in "low-risk" recipients[32,67,74]. de Vera *et al*[34] also observed better graft survival when DCD livers were utilized in patients with MELD scores ⩽ 30, but simultaneously could demonstrate that "sicker", high-risk recipients (at MELD scores > 30 or on organ-perfusion support, like mechanic ventilation or hemodialysis) had a greater patient and graft survival benefit from the transplantation of DCD livers compared to patients who are not as critically ill. Risk classification for DCD donors and DCD-LT recipients is summarized in Table 1. Other groups of patients that may have a true survival benefit from DCD-LT include MELD "disadvantaged" patients (hepato-cellular carcinoma patients beyond the Milan criteria or who are listed in areas with long waiting times, patients with low MELD scores that do not adequately reflect their level of illness and their critical need for a transplant)[34,72].

Studies about the effect of DCD liver grafts on hepatitis-C virus positive (HCV+) recipients transplant outcomes were inconsistent. Nguyen *et al*[45] and recently Hernandez-Alejandro *et al*[75] found a negative effect of HCV on DCD livers, but a formal contraindication for the use of DCD liver allografts in HCV+ recipients was not justified except for older donors. In fact, while single-center series reported no significant difference in graft and patient survival rates of HCV+ recipients and graft loss from HCV recurrence between DCD and DBD groups[20,34,76,77], as well as no deleterious effects of DCD liver grafts on the disease progression (fibrosis)

in comparison with DBD liver grafts in HCV+ recipients[77], the most recent UNOS registry data showed inferior graft survival but similar patient survival of HCV+ recipients with DCD donors compared to ones with DBD donors. Furthermore, DCD livers on HCV disease do not fare worse than DCD livers on non-HCV disease. DCD livers thus appeared to be important source of LT for HCV patients[78]. Split livers from DCD donors have also been reported in recent years with acceptable results[79,80].

TRANSPLANT OUTCOMES

Currently one-year patient survival after DBD-LT and to a certain extent after controlled DCD-LT is about 85%-90% in comparison to 60% in the early eighties and around 30% in the early days of LT and at 5 years post-transplant patient survival rate remains over 70%. Medical progress over the past 40 years in the field of organ preservation, surgical techniques, immunosuppressive drugs, treatment of post-transplant complications and organ allocation has permitted DCD to become reality in the modern era. Although there are concerns about the quality of such organs, with evidence that a prolonged WIT causes a raised incidence of PNF and biliary complications as well as suboptimal graft and patient survival when compared to DBD livers, DCD livers may be life-saving for those who would die waiting for a DBD liver[68] and do increase the number of organs available for LT. With careful donor/recipient selection and matching, minimization of ischemia and good post-operative care, acceptable results can be achieved. Essential results of most important publications in the last decade in DCD-LT are presented in Tables 2-4.

PNF

PNF is usually defined as unrecoverable hepato-cellular dysfunction leading to patient death or re-transplantation within the first week post-transplant after excluding other causes of graft failure such as vascular thrombosis, biliary complications, rejection or recurrent disease[81-84]. Initial studies using uncontrolled DCD donors reported a rate of PNF as high as 50%[85]. Currently only a few transplant centers in the world (like Spain, France) used this kind of donors because of aforementioned reasons. By using different *in vivo* organ preservation methods to maintain DCD donors and by strictly applying donor selection criteria, authors in Madrid[71], Barcelona[29] and La Coruña[86-89] could obtain promising results from Maastricht category I and II donors with a PNF rate of 10%-25%. The discard rate nevertheless was high up to 50%-75%[29,71]. In controlled DCD donors, the PNF rates are 0% to 12%. Matched analysis[34,72] and registry data[67,68] showed a higher rate of PNF in controlled DCD than DBD donors, although no difference was found in most comparative studies[20,43,90,91] except one[92]. The increased risk of PNF in DCD-LT recipients was also confirmed in a recent meta-analysis (odds ratio = 3.6, 95% CI: 2.1-6.4)[93]. Case-series reports of controlled DCD-LT also had a rate of PNF between 0% and 10%[42,70,94-97].

PNF is the consequence of severe IRI with the initial period of warm ischemia playing a crucial role. Experimental evidence supported that donor WIT should be less than 30 min to minimize PNF[98]. This warm ischemia (WI) period increases graft susceptibility to damage during cold preservation and CIT was a main contributing factor to PNF[34,67]; therefore, both periods of ischemia must be kept to a minimum. Many laboratory tests have been developed both in animal models and in human to predict the probability of occurrence of PNF post-transplant, but none is yet clinically efficient[99]. Recently Dahaba *et al*[100] proposed bispectral index monitoring as an early intra-operative indicator of early graft dysfunction.

Biliary complications

Since the introduction of LT up to now, biliary complications are always regarded as the "Achilles heel" and a major cause of morbidity and graft failure in patients after LT[101]. The most common biliary complications are bile leakage and bile duct stricture[102,103]. Strictures involving the donor bile duct (> 1 cm above the biliary anastomosis) and requiring endoscopic or radiological dilatation/stenting or surgery in the face of a patent, non-stenotic hepatic artery was referred to as ischemic-type biliary lesions (ITBL), based on the radiologic resemblance of those occurring after hepatic artery thrombosis (HAT)[51,91,103].

Abt *et al*[104] first mentioned the significantly higher incidences of overall biliary complications as well as ITBL in DCD-LT recipients, the finding which was later confirmed in both matched[34,72] and comparative[20,43,51,89,91,104] studies except series of Fujita *et al*[105] and Manzarbeitia *et al*[106]. The rates of overall biliary complications and ITBL were 10.5%- 53% and 8.3%-38%, respectively in DCD-LT compared to 8.3%-22% and 0%-8%, respectively in DBD-LT. Especially Jiménez-Galanes *et al*[71] reported only a 5% incidence of ITBL in their patients receiving livers from uncontrolled DCD donors under normothermic ECMO. A recent meta-analysis revealed that DCD recipients had a 2.4 times increased odds of biliary complications (95% CI: 1.8-3.4) and a 10.8 times increased odds of ITBL (95% CI: 4.8-24.2) *vs* DBD recipients. In average, biliary complications were present in 29% of DCD compared with 17% of DBD recipients and ITBL in 16% of DCD *vs* 3% of DBD recipients[93].

Furthermore DCD recipients who developed ITBL experienced a fairly rapid clinical deterioration, characterized by a relatively short mean time from transplant to first endoscopic retrograde percutaneous cholangiopancreatography (ERCP), from first ERCP to relisting and from relisting to re-transplantation (within 180 d)[36,69]. ITBL results in re-operation, multiple endoscopic and percutaneous biliary interventions, re-transplantation and even patient death with markedly increased medical care costs[107]. The relative risk (RR) of developing graft loss with ITBL formation was 3.02 (95% CI: 1.9-5.3)

DCDc: Controlled donors after cardiac death; DCD_1, DCD_2 and DCD_4: Maastricht category-1, category-2 and category-4 DCD donors; DBD: Donors after brain death; SCD: Standard criteria donors; ECD: Extended criteria donors; WIT: Warm ischemia time; CIT: Cold ischemia time; PNF: Primary non-function; ITBL: Ischemic-type biliary lesions; HAT: Early hepatic artery thrombosis; HAS: Early hepatic artery stenosis. Major symptomatic biliary complications include biliary leak, anastomotic and non-anastomotic stenosis. [1]Numbers denote the statistically significant difference between groups.

and graft survival was significantly decreased in patients with non-anastomotic strictures, compared to patients without it[89]. Up to 50% of all occurrences of ITBL lead to death and/or re-transplantation[108].

ITBL is usually a reflection of severe IRI in relation to various factors. In animal models, irreversible biliary tract damage has been observed after 40 min of cardiac arrest although hepato-cellular function could be preserved[109]. Clinical observations showed that total WIT > 30 min and chaotic donor physiology before asystole may increase the risk of post-transplant biliary stricture[33,110]. The mechanism could come from the stasis of blood and clot formation in the peri-biliary micro-circulation whose blood is solely supplied by the hepatic artery[96]. Many multivariate analysis recognized DCD liver grafts as an independent risk factor for the appearance of ITBL (RR = 47.1)[51,89].

DCDc: Controlled donors after cardiac death; DBD: Donors after brain death; SCD: Standard criteria donors; ECD: Extended criteria donors; WIT: Warm ischemia time; CIT: Cold ischemia time; PNF: Primary non-function; ITBL: Ischemic-type biliary lesions; HAT: Early hepatic artery thrombosis; HAS: Early hepatic artery stenosis. Major symptomatic biliary complications include biliary leak, anastomotic and non-anastomotic stenosis. [1]Numbers denote the statistically significant difference between groups.

Biliary epithelium is also known to be sensitive to cold preservation-reperfusion injury and the correlation between the incidence of ITBL and the duration of cold ischemia has been well documented. Li *et al*[111] demonstrated that the rate of ITBL is significantly increased in livers with increased preservation injury, as reflected by post-transplant peaks in serum transaminases. Other variables implicating in the mechanisms of ITBL may include injury of the peri-biliary vascular plexus, bile salt toxicity and potential immunological etiologies (ABO incompatibility, liver diseases with autoimmune component like autoimmune hepatitis and primary sclerosing cholangitis)[102]. Chan *et al*[43] found donor age > 50 years, donor weight ≥ 100 kg and total ischemia time ≥ 9 h were predictive for the development of ITBL. Patients who underwent LT from DCD donors > 60 years had a markedly high rate of biliary complications (67%), with a RR of 5.6 (95% CI: 0.98-32.2)[34].

Due to serious consequences of ITBL on the patient's quality of life and healthcare cost, preventive measures seem to play a pivotal role in the safe expansion of DCD liver use. Attempts to minimize biliary duct damage may include the use of normothermic ECMO for donor maintenance[29,71,112] and machine perfusion for liver grafts, choice of preservation solutions [histidine-tryptophan-ketoglutarate (HTK) *vs* University of Wisconsin][113-117], use of anticoagulation and thrombolytic agents[96], extensive

DCD: Donors after cardiac death; DBD: Donors after brain death; WIT: Warm ischemia time; CIT: Cold ischemia time; PNF: Primary non-function. Major symptomatic biliary complications include biliary leak, anastomotic and non-anastomotic stenosis. [1]Numbers denote the statistically significant difference between groups.

irrigation of the donor bile duct and pressure perfusion of the hepatic artery during organ retrieval and/or at back table[113,118,119], early porto-caval shunt to reduce portal hypertension in the recipient, choice of reperfusion techniques (concomitant *vs* sequential reperfusion of portal vein and hepatic artery)[120] and certainly the most important thing is always minimizing warm and cold ischemia period[121].

HAT and stenosis

HAT is a thrombo-embolic occlusion of the hepatic artery that can occur early or late after LT. Most authors used the first 30 d post-transplant as a time point to distinguish between early and late HAT[122]. Early HAT results in fulminant hepatic failure, bile duct necrosis and leaks, relapsing bacteremia and ultimately graft loss and recipient death. The frequencies of early HAT after DCD-LT varied from 0% to 16.6% and did not seem significantly higher than those after DBD-LT in most studies[20,29,34,36,43,51,71,72,89,91,104,105] except Yamamoto *et al*[90] (33.3% *vs* 0%). Risk factors for early HAT have been well analyzed in a recent systemic review[123]. Few detailed studies discussed late HAT.

The incidence of hepatic artery stenosis (HAS) was not consistently found higher in DCD than DBD grafts (12.8%-16.6% *vs* 0%-5.4%)[72,91]. It is possible that hepatic arteries are susceptible to WI during DCD organ retrieval, resulting in subsequent scar and stenosis. Moreover the increased susceptibility of DCD livers to post-operative arterial ischemia might be responsible for more biliary strictures in DCD than DBD recipients with HAS (83% *vs* 37%) as well as shorter time to the development of biliary strictures after HAS in the DCD group[91]. Inadequate surgical technique, vascular trauma by clamps, graft rejection, recurrent hepatic disease might also play a role in the mechanisms for HAS[72,124].

Graft and patient survival

Graft survival is defined as the time from transplantation to either re-transplantation or patient death, with "early" and "late" graft failure occurring within and beyond 1 year post-transplant, respectively[34]. Few studies reported experience with LT from uncontrolled DCD donors. Early results were poor with a PNF rate of 50% and one-year graft survival rate of only 17%[85] leading to a scarce usage of this donor category in the United States. Subsequent series in Spain using advanced *in vivo* organ preservation methods showed promising outcomes with one- and five-year graft survival rates of 50%-80% and 49%, and one- and five-year patient survival rates of 70%-85.5% and 62%, respectively[29,71,89]. LT from controlled DCD donors offered better results although they still appeared inferior to DBD-LT in matched studies[34,72], registry data analysis[32,67-69,74,125] and in some comparative studies[36,91,92]. One-, three-, five- and ten-year graft survival rates were 54%-79.5%, 53%-74.5%, 37.5%-71% and 37.5%-44%, respectively. Patient survival rates at corresponding time points were 61.9%-91.5%, 62.8%-89.5%, 42.9%-89.5% and 42.9%-57%, respectively. Transplant outcomes comparable to those obtained from DBD-LT have been sporadically reported in select centers through careful donor selection and optimization of CIT or through invasive techniques designed to optimize recovery before declaration of death[20,43,51,104].

Significant risk factors for DCD liver graft loss have been identified by multivariate Cox regression technique in both single center studies and large data registry analysis[32,67-69,74,126,127]. Among donor risk factors, age > 50 years, total WIT > 30-35 min, CIT > 6 h, body weight > 100 kg and regional or national liver distribution had deleterious effects on graft survival[32,74,127]. There is a stepwise increase in the relative risk of graft failure among donor age, WIT and CIT[32,127]. Strong recipient determinants of

graft failure include age > 55 years, history of previous transplantation, medical status at transplantation [intensive care unit (ICU) or non-ICU hospitalization, life support, dialysis, renal insufficiency], high MELD score (> 30) and positive HCV serology[32,74,127]. In the DBD-LT model, it has been shown that a single risk factor lessened outcome marginally, however, the additive effect of multiple risk factors in a given donor-recipient pair were disastrous[83]. Grafts with ≥ 3 donor risk factors had significantly lower 1-year post-transplant survival than no or only 1 or 2 risk factors (58.3% *vs* 72.6%, 69.2% and 73.9%, respectively). No grafts with 4 risk factors survived within 1 year[128]. The relative risk of allograft failure from LT utilizing DCD donors was 31%-87% higher than LT utilizing DBD donors[67-69,125,126]. Causes of early graft failure included PNF, biliary complications, HAT and deaths from sepsis/multi-organ failure. Late graft failure was often secondary to chronic rejection and recipient death with a functioning graft.

Although DCD livers may not be as good as DBD ones with potential inferior transplant outcomes, there are subgroups of grafts and recipients that could give favorable results through appropriate graft and recipient matching. Low-risk DCD grafts which are transplanted in low-risk patients lead to comparable graft survival rates with DBD livers. Livers from DCD donors transplanted into high-risk recipients fared poorly independent of the allograft quality[74]. Doshi *et al*[68] showed DCD liver grafts were not inferior to DBD livers from older donors (≥ 60 years). Given the ever increasing demand for LT, DCD livers appear to be a reasonable alternative to increasing use of older or split livers and are a reasonable option when death is imminent[68]. Even if graft or/and patient survival is lower with a DCD liver, it is still better than dying because of turning down a DCD offer and continuing to wait for a DBD liver on these d as the patient' s choice is frequently not between marginal livers (including DCD) and standard livers but between marginal livers and no livers[105]. The benefit of earlier access to LT provided by a DCD graft could outweigh the risks of prolonged waiting for a standard graft[77].

Re-transplantation

DCD recipients more often require re-transplantation. Respectively, 21.6%-42% *vs* 8.8%-16% of DCD and DBD recipients were listed for re-transplantation[36,69]. The re-transplantation rate ranged from 7.6% to 31% in DCD-LT compared to 2.5%-12% in DBD-LT[20,29,34,36,51,67-69,71,72,91,92,106]. DCD livers exhibited a 2.1 times greater risk of graft failure, a 2.5 times greater risk of re-listing, and a 3.2 times greater risk of re-transplantation compared with DBD livers[36]. The majority of re-listing and re-transplantation in the DCD group were a consequence of biliary complications, especially ischemic cholangiography, but not due to an increased incidence of PNF, HAT or technical complications[36,69]. Particularly DCD livers had a temporally different failure pattern within the first year post-transplant that limited access to re-transplantation[36,69]: graft failure was more likely to occur within the first 180 d (18.1% *vs* 11.7%[67], 10.2% *vs* 2.5%[72] and 20.5% *vs* 11.5%[69] of DCD and DBD grafts failed within 60, 90 and 180 d, respectively); at re-transplantation, DCD recipients waited longer and received higher risk allografts; and more DCD recipients remained waiting for re-transplantation with fewer removed for death, clinical deterioration, or improvement. Re-transplantation arouses controversy on medical, economic, and ethical grounds: patient and graft survival rates after a second LT are inferior to those after initial grafting, the procedure is more expensive and in the context of organ shortage, re-transplantation inevitably denies organs to first-time recipients[129].

Utilization of DCD allografts for re-transplantation was rare (2.5% of initial DCD *vs* 3.1% of initial DBD) and outcomes from each group were comparable[69]. The general practice is to avoid re-transplantation with a DCD graft[36]. The use of DCD donors in the setting of re-transplantation resulted in an increased risk of recipient death (hazard ratio = 2.1, 95% CI: 1.2-3.6)[129].

Acute rejection

The acute rejection rate did not differ significantly between DCD- and DBD-LT in most studies (1.9%-29% *vs* 0.6%-34%)[20,72,87,89,104]. Foley *et al*[91] reported a one-year rejection rate of 61% in the DCD group similar to that in the DBD group (56%). There were little data looking at the impact of DCD source on the risk of acute rejection.

EXPERIMENTAL STRATEGIES TO IMPROVE DCD-LT OUTCOMES

The progressively increased DCD liver procurement to solve the shortage of DBD organs and to alleviate the waiting-list mortality has raised many challenges to the transplant community and transplant policy makers[110]. A lot of experimental researches have been performed over the past decade, intervening in both donors and recipients at different phases of the transplantation process, at the aim of tackling some of these challenges and providing a deep insight into IRI mechanisms.

Donor pre-treatment

Various cyto-protective substances have been successfully administered into the donor prior to cardiac arrest for prevention of liver microcirculatory disturbance. Microcirculatory disturbance was the main obstacle to successful DCD-LT, which was due to four major mechanisms: deterioration of sinusoidal endothelial cells (SEC) caused by activated Kupffer cells, sinusoidal narrowing caused by some vasoconstrictors and swollen hepatocytes, leukocyte and platelet adhesion, and hyper-coagulability[130]. Up to now, only *Heparin* and *phentolamin* (an anticoagulative substance and alpha-adrenergic antagonist) are allowed in clinical DCD organ procurement[131], other substances remain in animal models. *Tacrolimus,* besides

its powerful immunosuppression, enabled to prevent liver normothermic IRI by multiple mechanisms[132]. *Milrinone*, a type 3 phosphodiesterase inhibitor, attenuated graft injury caused by warm and cold ischemia *via* an increase in intracellular cAMP levels, protection of SEC, relaxation of hepatic stellate cells, inhibition of platelet aggregation and anti-inflammatory effect[133]. *Lazaroids*, an antioxidant designed to inhibit iron-dependent lipid peroxidation, ameliorated SEC viability *via* antioxidant effects and membrane stabilization[134]. *N-acetylcystein* has a direct effect on oxygen free radicals, but its usage had no effect in both graft viability and lipid peroxidation[135].

Animal studies clearly showed the concept of pharmacological modulation of organ donors before procurement is feasible to improve the viability of marginal grafts. Nevertheless there are no definitive recommendations for the use of these drugs. Application of this method to clinical LT would require management of some practical problems and possible ethical conflicts[136].

Organ preservation

Preservation of DCD livers by hypothermic machine perfusion (HMP) was shown superior to static cold storage (SCS) in many experimental studies[137,138].

Nonetheless a putative drawback of HMP for livers is to induce alterations at the vascular endothelial site, especially if HMP was performed for a long time or under suboptimal conditions[139]. Endoplasmic stress activation promoted cellular apoptosis *via* activation of caspase-12[140,141]. The efficiency of HMP was markedly increased by oxygenation of the perfusate[142]. The concern that high oxygenation might favor the generation of oxygen free radicals, which in turn could impair tissue integrity, was not justified. Several investigators could demonstrate the beneficial effect of oxygenated HMP in reducing the liver expression of pro-inflammatory cytokines (TNF-α, IL-8), adhesion molecules (ICAM-1) and major histocompatibility complex class Ⅱ antigens[143-145]. This benefit will likely be more pronounced in marginal grafts such as elderly, steatotic and DCD livers[144]. Cyto-protective agents can be added into the machine perfusion (MP) solution to ameliorate the efficiency of HMP organ preservation[146].

The positive effects of HMP on warm-ischemically pre-damaged livers were observed even after a brief period of MP, before (pre-conditioning) or after SCS (post-conditioning)[143,147] and therefore it was not necessary to require MP over a full preservation period and helped avoid side-effects of HMP on vascular endothelium[141]. The use of HMP as the initial method for organ preservation followed by secondary SCS during transportation combined the advantage of aerobic resuscitation (i.e., restitution of cellular homeostasis) with an ease of SCS for later surveillance and transportation[141]. Manekeller *et al*[148] showed a post-conditioning of 1 h after SCS can ameliorate the viability of marginal livers. The extension or abbreviation of post-conditioning time seems to have no further beneficial effects[148].

Schön *et al*[66] reported advantages of normothermic machine perfusion (NMP) over SCS in pig DCD-LT models. Livers subjected to 1 h of WI and then cold-stored for 4-24 h were rendered completely nonviable while such livers under 4-24 h of oxygenated NMP recovered function to a viable level[149]. Due to the complexity of the logistics of clinical multi-organ recovery and of the NMP device, a period of cold preservation prior to warm perfusion of the liver is unescapable. A brief period of cold preservation (1 h) prior to NMP could maintain the synthetic and metabolic function but resulted in significant hepatocellular damage, sinusoidal endothelial cell dysfunction and Kupffer cell injury[150]. Once this duration was prolonged to 4 h, NMP completely failed to resuscitate porcine livers[151]. Normothermically perfusing DCD livers throughout the preservation period not only replenished cellular substrate, ameliorating the ischemic injury, but also provided a clear assessment of liver function and therefore could permit the use of severely injured organs with reassurance of function[149,152].

Despite the aforementioned benefits of MP over SCS in liver preservation, only SCS is clinically approved up to now, MP is still in the pre-clinical stage and early clinical studies[153]. Tojimbara *et al*[154] showed the impact of viscosity and temperature of initial flushing solutions on graft function. A low viscosity flushing solution was associated with lower vascular resistance, whereas a warm flush solution prevented cold-induced vasospasm and therefore improved the washout effect of the microcirculation[154]. HTK solution possessing a low viscosity and low potassium is more preferable in the DCD setting. The role of aeration of the cold-stored liver was also clarified. Oxygen provided either by surface diffusion (surface oxygenation) or intravascular diffusion (oxygen persufflation) helps improve the energy status of organs thus leading to earlier recovery. Surface oxygenation was not in use any more due to complicated technique, limited efficiency and risk of oxygen intoxication[155]. Venous systemic oxygen persufflation (VSOP) was shown to improve organ viability during hypothermic storage of the grafts and to be a feasible means for reconditioning of warm-ischemically pre-injured livers from DCD donors[155-158]. Experimentally even a short period of VSOP prior to long-term preservation of the liver by SCS may be sufficient for a relevant improvement of liver integrity upon reperfusion[159]. Gaseous persufflation with carbon monoxide was also tested in a DCD-LT rat model with enhanced liver graft viability[160]. However no additive or synergistic effect was noted when livers were persufflated with a mixture of gaseous oxygen and carbon monoxide[161].

Pharmaceutical interventions during SCS aimed at conditioning marginal organs also increasingly gained attention. Different cyto-protective drugs have been added into the flush and/or preservation solution, like vasodilators (phentolamin, epoprosterol, dopamine)[162,163], anti-coagulants (heparin), fibrinolytic agents (strepto-

kinase)[164], antioxydants (superoxide dismutase, edaravone)[165,166], antibiotics, hormones (glucagon, growth factors)[167]. In the DCD setting, vasodilators, anti-coagulants, thrombolytic agents and antibiotics seem particularly necessary because the organs tend to develop vasospasm, thrombus formation in the microcirculation and the risk of colonic bacterial contamination secondary to translocation of organisms during the WI period[168,169].

Viability testing

Due to serious consequences of transplanting a DCD liver with potentially severe IRI (PNF, re-transplantation or even recipient death), it would be ideal if the viability of such livers could be predicted prior to rather than after transplantation. WIT is not always exactly known and thus cannot be a reliable parameter. Light microscopic examination of biopsy specimens was unable to uniformly predict liver function after transplantation[170]. Monbaliu *et al*[171] showed the extent of parenchyma vacuolation predicted pig liver graft viability before LT. Muiesan *et al*[70] applied the mechanical digestion of liver biopsies with collagenase and assessed the viability of hepatocytes by trypan blue exclusion method. However, the test was not helpful and the decision as to whether to use the liver was generally made on gross appearance, ease of perfusion, degree of steatosis and donor characteristics[172].

Another approach is to evaluate the vascular resistance and enzyme release in the perfusate of HMP livers. Resistance index of the portal vein and hepatic artery showed no utility[173]. Biomarkers of liver cell damage, like transaminases, lactate dehydrogenase and liver fatty acid binding protein, correlated well with WI duration and concomitant hepatocyte damage in pig DCD-LT models[174]. Possible other parameters are the ATP content and redox active iron status of the liver during HMP[175]. During NMP, the assessment of liver viability may be easier because the liver is in a normal metabolic state. Bile production was a good viability indicator besides the measurement of other liver functions (detoxification, metabolism or synthesis)[176]. Recently Liu *et al*[177] has tested the utility of magnetic resonance imaging and proton magnetic resonance spectroscopy to evaluate WI livers without success.

Recipient treatment

Pharmaceutical strategies aimed at modulating IRI mechanisms were also applied successfully in animal recipients and generally did not impose ethical problems as donor pre-treatment. Such protocols without donor pretreatment will be favorable in clinical application. Most studies tested a single agent for a specific target of the IRI process. A multi-factorial approach acting on different pathways of the IRI process have been advocated and remarkably ameliorated transplant outcomes[162].

PERSPECTIVES

The future of DCD-LT is promising. Concerted efforts should concentrate on the identification of suitable donors (probably Maastricht category Ⅲ DCD donors), better donor and recipient matching (high risk donors to low risk recipients), use of advanced organ preservation techniques (oxygenated HMP and NMP, VSOP), and pharmacological modulation (probably a multi-factorial biologic modulation strategy) so that liver procurement and transplantation from DCD donors could be widely expanded and attain equivalent results as DBD-LT.

Abstract

Gastrointestinal (GI) malignancies are notorious for frequently progressing to advanced stages even in the absence of serious symptoms, thus leading to delayed diagnoses and dismal prognoses. Secondary prevention of GI malignancies through early detection and treatment of cancer-precursor/premalignant lesions, therefore, is recognized as an effective cancer prevention strategy. In order to efficiently detect these lesions, systemic application of screening tests (surveillance) is needed. However, most of the currently used non-invasive screening tests for GI malignancies (for example, serum markers such as alpha-fetoprotein for hepatocellular carcinoma, and fecal occult blood test, for colon cancer) are only modestly effective necessitating the use of highly invasive endoscopy-based procedures, such as esophagogastroduodenoscopy and colonoscopy for screening purposes. Even for hepatocellular carcinoma where non-invasive imaging (ultrasonography) has become a standard screening tool, the need for repeated liver biopsies of suspicious liver nodules for histopathological confirmation can't be avoided. The invasive nature and high-cost associated with these screening tools hinders implementation of GI cancer screening programs. Moreover, only a small fraction of general population is truly predisposed to developing GI malignancies, and indeed needs surveillance. To spare the average-risk individuals from superfluous invasive procedures and achieve an economically viable model of cancer prevention, it's important to identify cohorts in general population that are at substantially high risk of developing GI malignancies (risk-stratification), and select suitable screening tests for surveillance in these cohorts. We herein provide a brief overview of such high-risk cohorts for different GI malignancies, and the screening strategies that have commonly been employed for surveillance purpose in them.

INTRODUCTION

Malignancies originating in the gastrointestinal (GI) tract are responsible for about one third of global cancer burden[1]. In the United States, of estimated 1 529 560 new cancer cases and 569 490 cancer deaths in 2010, approximately 274 330 new cases (approximately 18% of total) and 139 580 deaths (approximately 25% of total) could be attributed to GI malignancies[2]. One of the reasons behind relatively high mortality rate for GI cancers is their visceral location, which requires highly invasive endoscopy to directly visualize early-stage lesions, leading to diagnoses at advanced incurable stages in most cases.

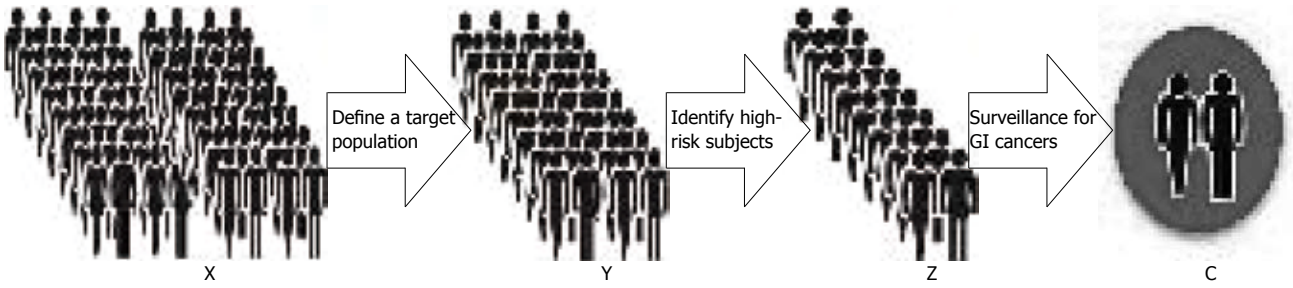

Figure 1 Risk stratification is a step-wise approach towards identifying high-risk individuals where surveillance for gastrointestinal cancers is truly needed in order to detect any neoplastic growth at early stages. The initial step is to define a target population (Y) in the general population (X) where screening strategies would be applied. Based upon findings of the screening tests in target population, subjects deemed to be at high-risk for developing a gastrointestinal (GI) malignancy (Z) would need repeated screening tests at suitable intervals (surveillance), and this would result in detection of potentially curable early stage cancerous lesions in certain individuals (C).

Secondary prevention through systemic application of screening tests (surveillance) to detect cancer-precursor/premalignant lesions is regarded an effective prevention strategy, and arguably also promotes positive life-style changes[3]. However, only a small proportion of total population is indeed at a credible risk of developing GI malignancy in future and needs surveillance. Identifying these high-risk cohorts (risk-stratification) is therefore crucial for the success of any surveillance program[4] (Figure 1). Such an approach is not only mandatory from an economic perspective but also spares the general population of repeated invasive screening tests to detect cancer precursor lesions. Screening tests detect the end-point of increased genetic/environmental predisposition (that is precursor lesions), and therefore constitute the most important arm of any risk-stratification strategy.

CANCER BIOMARKERS, SURROGATE MARKERS, LEAD-TIME BIAS AND OVERDIAGNOSIS BIAS

Biomarker is a variable that directly relates to cancer progression and/or final biological outcome (such as death), and is measured by a screening test[5]. The ease of procuring the material for biomarker analysis is an important question for visceral organs such as those in GI tract. Intraepithelial neoplasia or dysplasia remains the most reliable marker of impending malignancy, but is associated with a number of inherent limitations, including the need for invasive procedures to obtain tissue and inter-pathologist variability in interpretation of histopathological features[6]. Moreover, although endoscopic techniques have evolved over the years[7], their regular use for risk-stratification in average risk populations is economically unviable at this point. Surrogate markers, which variably correlate with cancer progression, can usually be measured through non-invasive means such as in serum or stool and therefore represent attractive tools for screening, but have limitations such as poor sensitivity and/or specificity[8]. It should be noted that surveillance programs are recommended only if an effective treatment is known to exist should any precursor/premalignant lesion be detected upon screening. This is important in order to avoid the possibility of lead-time bias (early diagnosis of cancerous lesions leading to increased number of years patient survives without actual shift in age at death) and overdiagnosis bias (diagnosis of cancerous lesions that won't have progressed, meaning they won't have caused death in first place)[9].

ESOPHAGEAL CANCER

In the United States, more than four fifth of patients diagnosed with esophageal cancer in 2010 are estimated to have a cancer death[2]. Esophageal adenocarcinoma (EA) and squamous cell carcinoma (ESCC) together account for more than 95% of esophageal cancer cases: ESCC being responsible for the bulk of cases worldwide and EA being more common in western countries, particularly among Caucasian males[10]. Due to such stark differences in the epidemiology of ESCC and EA, there is greater emphasis on risk-stratification for ESCC in developing countries, as compared to EA and its precursor lesion, Barrett's esophagus (BE), in developed countries. However, with increasing westernization of developing countries, the incidence of EA is surely on the rise in these countries too.

EA

Nearly all the cases of EA evolve through BE→Dysplasia→EA sequence[11]; and therefore, BE subjects represent a high-risk cohort where surveillance could be considered depending upon mucosal changes detected on endoscopic biopsy (reviewed in detail in reference[12]). The challenging part, however, is to identify individuals who could have BE in first place. Long-standing gastroesophageal reflux disease (GERD) patients are clearly at-risk for developing BE, but a significant proportion of BE cases can exist and progress to EA even without GERD symptoms. Furthermore, high prevalence of GERD symptoms in general populations (> 20% of adult population[13]) and extremely low rate of progression from GERD to BE to EA (approximately 0.5% and 1.0% per year respectively[14,15]) means that endoscopic screening for BE in all GERD patients would not be cost-effective[16]. However, certain subsets of GERD patients can clearly benefit from screening for BE on

an individual basis; for example, first-degree relatives of BE patients are more likely to harbor BE in presence of GERD symptoms as compared to other GERD patients with no such family history[17,18]. This increased risk could be related to genetic polymorphism of cyclin D1 and glutathione S-transferase genes which have been implicated in development of BE[19-21]. However, it's important to emphasize that there is no evidence of clear benefit of screening in asymptomatic persons (no GERD symptoms) with a positive family history of BE/EA. Overall, screening recommendations for BE remain controversial, and > 95% of EA cases are still diagnosed in patients without any prior diagnosis of BE[22]. The risk of EA (as well as ESCC) is also increased in hereditary conditions such as Peutz-Jeghers syndrome (PJS), but endoscopic surveillance in such cases is recommended for the whole upper GI tract and is not esophagus-specific.

A recent single cohort study demonstrated promising results of non-endoscopic screening for BE using an ingestible esophageal sampling device (Cytosponge) coupled with immunocytochemistry for trefoil factor 3[23]. However, non-endoscopic screening is still tested only on a limited scale, and serum markers have not been shown to be effective for screening for BE/EA as yet. Therefore, standard endoscopy with biopsy remains the "gold" standard for detecting BE. However, apart from the need of invasive endoscopy, low positive predictive value (about 34%) associated with index endoscopy[24] and need for multiple biopsies (at least 8 biopsies[25]) to diagnose metaplasia needed to define BE have been major drawbacks of endoscopy based screening. Recent advancements in endoscopic GI mucosa imaging (reviewed in reference[26]) have largely improved lesion detection capabilities, and enabled targeted biopsy of the dysplastic areas. Current recommendations for the need and frequency for EA surveillance in BE patients are largely based upon the degree of dysplasia in the BE mucosa (reviewed in detail by Badreddine *et al*[12]). In summary, after screening endoscopy in suspected BE patients (such as GERD patients over 50), detection of no dysplasia leads to repeat confirmatory endoscopy after 6-12 mo followed by endoscopic surveillance every 3 years; detection of low grade dysplasia leads to repeat confirmatory endoscopy in 6 mo followed by yearly endoscopic surveillance; and detection of high grade dysplasia needs confirmation by two expert pathologists and either 3 monthly surveillance combined with multiple biopsies spaced at every 1 cm *vs* endoscopic ablation *vs* esophageal resection.

ESCC

Currently, surveillance for ESCC is mandated only in two conditions-Tylosis palmaris (an obscure skin condition often associated with internal malignancies) and Lye ingestion[27]. However, co-existence of multiple ESCC risk factors could prompt surveillance in certain circumstances. For example, alcohol, smoking, flushing response to alcohol, Asian ethnicity, inactivating aldehyde dehydrogenase 2 allele polymorphism and personal history of any other malignancy of aerodigestive tract (UADT-which includes oral cavity, larynx, pharynx and esophagus) are all independent risk factors for ESCC[28-31]; and although none of them warrants surveillance for ESCC on its own, it would be worthwhile to consider screening for precursor lesions in persons with multiple risk factors, especially in case of Asian ethnicity, on an individualized basis. Some other conditions such as achalasia and Plummer-Vinson syndrome that are known to increase the risk of ESCC warrant endoscopic interventions for symptomatic treatment (such as for dysphagia) but not for screening[32]. Most of the reports on the impact of screening on ESCC incidence and mortality, and associated cost-effectiveness analyses have come from geographically high-risk countries. In two such studies conducted in China, investigators concluded that screening general population with exfoliative balloon cytology (EBC) was an effective tool for risk stratification and could have favorable impact on ESCC incidence and mortality[33,34]. However, United States-based Veterans' Affairs (VA) studies conducted in relatively high-risk population due to personal history and (or) symptoms produced conflicting results; and it was concluded that because of the low prevalence of ESCC in the United States and the difficulty of diagnosing malignancy in the setting of active esophagitis, EBC was probably not a cost-effective screening strategy in Western world[35]. Therefore, internationally, endoscopy aided biopsy therefore remains the standard test for ESCC screening and surveillance currently, albeit only in a limited cohort of subjects at high-risk for ESCC.

GASTRIC CANCER

Gastric cancer (GC) is the second leading cause of cancer deaths worldwide, and remains a major public health burden in Asia-pacific countries such as China, Japan and Korea where the age-standardized incidence rate for GC is > 20 per 100 000 subjects (defining criterion for high-risk areas)[1]. Gastric adenocarcinoma is the most common gastric malignancy (> 90% cases), with two subtypes: Intestinal (more common form and prevalent in high-risk areas) and diffuse type. Due to stark geographical differences in the prevalence of gastric cancer worldwide, the strategies and significance attached with screening for this cancer are highly variable.

The individuals migrating from high-risk areas remain at-risk even in low-risk countries such as the United States; however, their offspring tend to have risk levels comparable to that of the local population[36]. Geographical origin and location is therefore an extremely important consideration for any surveillance strategy against GC. Universal screening for GC has been considered only in certain high-risk countries such as Japan, South Korea and Matsu Island in Taiwan (China)[37]. On the other hand in average/low-risk countries, screening is recommended only in the presence of a well-characterized familial predisposition to GC (responsible for 1%-3% of GC cases), such as in case of hereditary

diffuse gastric cancer (HDGC) syndrome, familial adenomatous polyposis (FAP), PJS and Lynch syndrome. HDGC is the most common inherited form arising due to germline mutation in *E-cadherin* gene (*CDH1*) with the carrier of the mutations having more than 80% lifetime risk of developing GC[38]. However, surveillance or genetic testing is not considered for poorly-characterized familial cases (responsible for 8%-10% of GC cases) which are believed to be associated with more common but less penetrant defects such as polymorphism in pro-inflammatory interleukin-1 (*IL-1*) gene clusters and toll-like receptors 4 (TLR 4) + 896A > G[37,39,40]. Additionally, TLR 4 + 896A > G polymorphisms in TLR 4, a pattern recognition receptor that activates pro-inflammatory signaling pathways in response to microbes, has been associated with presence of GC and its precursors which indicates the relevance of TLR 4 polymorphism during gastric carcinogenesis[41]. A meta analysis of the role of IL-1b and IL-1 receptor antagonist gene polymorphisms in gastric cancer risk showed an association in Caucasians, but not in Asians[40]. Similarly, a metaanalysis by Huang *et al*[42] concluded that *cag A* seropositivity significantly increased the risk for gastric cancer and could be used for identifying populations at risk for GC. However, despite high prevalence of *cagA* in Asia-Pacific regions, the currently known *cagA* genotypes in Asia are not associated with increased GC risk[43]. Other high-risk subgroups considered for screening on a case-to-case basis are elderly patients with atrophic gastritis or pernicious anemia, patients with partial gastrectomy, patients with the diagnosis of sporadic adenomas, and immigrant ethnic populations from GC high-risk countries.

Over ninety percent of GC cases are sporadic, and most are linked to *Helicobacter pylori* (*H. pylori*) infection[44,45]. A meta-analysis of six major studies on *H. pylori* eradication demonstrated that *H. pylori* "screen-and-treat" strategy reduced the incidence of GC[46]. Based on this, the Asia-Pacific Gastric Cancer Consensus Conference in 2008 concluded that it might perhaps be the right time for a population-based screening and treatment of *H. pylori* infection (by using locally approved screening tests for *H. pylori,* such as serum or stool antibody/antigen detection), particularly in high-risk areas as a part of GC prevention program[37]. Interestingly, Ford *et al*[47] have proposed that even in western countries where better sanitation, low-salt intake and effective treatment of *H. pylori* infection has led to gradual decline in GC incidence over decades, a "screen and treat" strategy for *H. pylori* could reduce the dyspepsia-related health care costs over a longer (10 years or more) follow-up duration. However, prospective trials on a global scale are needed to validate such observations; and currently, no screening for *H. pylori* is recommended for asymptomatic individuals in geographically low/average-risk areas. Gastric cancer phenotype initiated due to *H. pylori* is characterized structurally by a corpus predominant gastritis, multifocal gastric atrophy, intestinal metaplasia, and physiologically by high gastrin, low acid secretion, low pepsinogen I and pepsinogen I / Ⅱ ratio, and hypo-and achlorhydria[48-50]. All these findings have been used to design screening tests for GC, such as serum pepsinogen I levels and pepsinogen I / Ⅱ ratios that have been investigated in high-risk areas, but have limited usefulness on a global scale[51]. Currently, endoscopy aided with advanced imaging techniques and biopsy (at least 5) to look for precursor lesions remains the main tools for screening and surveillance for GC.

PANCREATIC CANCER

Pancreatic cancer (PC) is the most aggressive GI malignancy that silently progresses to untreatable metastatic disease in most cases, and is generally fatal within six mo of diagnosis[2]. However, interestingly, a study from Japan has demonstrated that resection of all pancreatic lesions < 1 cm in size can achieve about 100% cure rates[52], suggesting that a thorough surveillance program for PC could potentially be useful. However, this approach leads to unnecessary high-risk surgical resection of many benign lesions that won't have progressed to malignancy in first place. Therefore, identifying high-risk cohorts where such pancreatic lesions are more likely to be malignant is definitely a better-refined strategy for prevention. Such high-risk cohorts for PC (defined as having > 10-fold increased risk of PC as compared to the general population) include familial and/or syndromic cases (3%-16% of total cases) where screening is routinely recommended (Figure 1)[53-56]. However, screening strategy for individuals at 5- to 10-fold increased risk of pancreatic cancer (e.g., those with just one or two affected first-degree relatives) is unclear. Clearly, in such cases, most centers take individualized approaches depending upon the cost and other considerations. Future studies are needed to establish the risk threshold at which screening is likely to be most cost-effective.

Notably, conditions such as chronic pancreatitis, diabetes mellitus and smoking history have strong associations with PC, but none of them increases the risk to an extent that could warrant screening.

Screening for PC faces a unique challenge in terms of incidental radiological findings in the pancreas due to rampant use of computerised tomography (CT) scan in patient-care. Because many of these lesions are non-lethal, it's important to establish their malignancy potential in order to guide their management and avoid over-enthusiastic and sometimes unwarranted surgeries that could ensue otherwise[57]. The most common of these lesions are intraductal papillary mucinous neoplasms (IPMNs). IPMNs which involve the main duct have a 70% risk of containing a malignancy at the time of diagnosis and need to be resected[58], while those involving the branch ducts have 25% risk of containing malignancy and 15% risk of malignant transformation during follow-up, and they can be safely observed with continued surveillance[57,58]. Certain other features however necessitate immediate resection, such as diameter ⩾ 3 cm, a mural nodule appearance, main pancreatic duct dilation ⩾ 6 mm, progressively changing lesion characteristics,

or presence of symptoms[57,58]. In general, the approach is usually much more aggressive if such lesions are present in high-risk individuals[55].

Another variety of PC precursor lesions, although not detectable by routine imaging tests in a clinical setting, are pancreatic intra-epithelial neoplasia (PanIN)[59]. PanIN is a histological diagnosis where pro-cancerous genetic and epigenetic aberrations have been noticed. PanIN-3 lesions are essentially treated as PC and resected whereas PanIN-1 lesions have very small risk of malignancy, and can be safely followed-up[60]. The management of PanIN-2 lesions is controversial and recommendations depend upon co-existing conditions and cost-considerations.

Currently, endoscopic ultrasonography (EUS) is most efficient screening test for PC; it accurately identifies pancreatic cysts and IPMNs, and has the advantage of detecting structural changes somehow predictive of PanIN lesions[61]. Other screening modalities like CT and endoscopic retrograde cholangiopancreatography have fallen out of favor mainly due to low sensitivity and radiation exposure and high incidence of pancreatitis respectively. However, magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRCP), especially secretin-enhanced MRCP, is still an acceptable alternative to EUS[62]. In the absence of any clear guidelines for the frequency and starting age for screening for pancreatic cancer, recommendations are highly institutionalized based upon factors such K-ras mutations, family history *etc*.[63-66].

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is the most common primary liver malignancy, and is increasing in incidence in the United States[2]. In general, 5-year survival is less than 10% if diagnosed in symptomatic patients, but HCC diagnosis prior to appearance of symptoms offers the curative opportunities through resection of tumor[67]. Although extremely rare in asymptomatic populations, HCC is a dreaded long-term complication of most chronic liver diseases (CLD); and therefore, CLD patients constitute the obvious target population for risk-stratification. However, the level of HCC risk varies in different CLDs; and due to the generally protracted course of CLDs and high cost of repeated screening, cost-considerations are very important in formulating surveillance strategies in these patients. Among CLD patients, diagnosis of cirrhosis is a strong predictor of the risk of progression to HCC, and advent of cirrhosis often marks the starting point for surveillance recommendations in these patients. Chronic viral hepatitis (hepatitis B and C) is the most common etiology behind HCC. Hepatitis B and C carriers have an HCC incidence rate of 0.2%-0.6% per year, and 3%-11% per year respectively[68,69]. Hepatitis B can particularly be deceptive because HCC can occur even in non-cirrhotic hepatitis B virus (HBV) carriers, and the risk seems to be variable. Asian ethnicity, viral replication status, and seropositivity for hepatitis B surface antigen and anti-HBe antigen differentially influence the risk of development of HCC in HBV carriers, and therefore have an important impact on surveillance program (reviewed in references[70-73]). On the other hand, the risk of HCC in long-term hepatitis C carriers is independent of factors such as ethnicity and viral replication status[71,74], and largely depends upon the extent and severity of cirrhosis. Based upon this, the first European association for study of the liver conference on HCC recommended screening for HCC in chronic hepatitis C patients with at least stage 3 fibrosis (METAVIR)[75]. Another puzzling question is whether surveillance for HCC should continue in successfully treated chronic viral hepatitis patients? Evidence has been conflicting for hepatitis B carriers with mostly Western and some Asian studies suggesting a significant reduction in HCC risk after successful treatment[76-78], and a non-randomized, but match controlled Asian study following a large cohort for longer periods suggesting continued risk of HCC post treatment[79]. Thus, given the higher risk associated with Asian ethnicity, it seems prudent to continue HCC surveillance in Asian hepatitis B carriers with cirrhosis even after successful seroconversion. However, the same can't be said about non-cirrhotic western populations. In contrast, continued surveillance for HCC is recommended for hepatitis C infected population because even after successful treatment (i.e., sustained virological response), the risk of HCC in cirrhotic hepatitis C carriers remains sufficiently high to warrant surveillance[74]. Additionally, co-existing risk factors like old age, viral genotype, viral replication status, aflatoxin exposure, co-infection and other CLDs, diabetes and human immunodeficiency virus also need to be taken into account in deciding the surveillance protocol for HCC in viral hepatitis carriers. Additionally, there are some non-viral cirrhotic conditions as well where surveillance could be considered (Table 1).

For screening purposes, ultrasonography (USG) and serum alpha-fetoprotein levels are often used. Serial USG (at 6-12 mo interval[80,81]) has by far been superior to any other screening test for HCC (65%-80% sensitivity and 90% specificity), and can detect nodules of 1 cm size, which are essentially curable[82]. However, USG needs to be aided with biopsies to differentiate between benign cirrhotic and dysplastic/malignant nodules. Conversely, evidence suggests that serum alpha-fetoprotein measurement has no role in HCC screening (although it can still have some utility in HCC diagnosis and follow-up), and should be no longer used for screening purposes. Other serological markers such as alpha flucosidase, glypican-3 and desgamma carboxyprothombin have already been discredited[83].

COLORECTAL CANCER

Colorectal cancer (CRC) is the third most common cancer in both men and women[2]. Over the years, its incidence has constantly been decreasing, largely due to colonoscopic screening. As less than one third of CRC cases are as-

Table 1 At-risk cohorts for considering surveillance for gastrointestinal malignancies

Esophageal cancer
Barrett's esophagus
Tylosis palmaris
Lye ingestion
Head and Neck tumors patients with flushing response/inactive ALDH1 allele
Gastric cancer
Hereditary diffuse gastric cancer
Lynch syndrome
Peutz-Jeghers syndrome
Juvenile polyposis syndrome
Li-Fraumeni syndrome
Atrophic gastritis/pernicious anemia
Post-partial gastrectomy
Sporadic adenoma
18-60 yr old Inhabitants of high-risk areas
Pancreatic cancer
Hereditary pancreatitis
Peutz-Jeghers syndrome
Familial pancreatic cancer kindred (≥ 1 first-degree relative and ≥ 3 first, second or third degree relative with pancreatic cancer)
Familial atypical multiple mole melanoma
Familial breast-ovarian cancer
Hereditary nonpolyposis colorectal cancer (Lynch syndrome)
Familial adenomatous polyposis (FAP)
Cystic fibrosis
Fanconi anemia
Ataxia telangiectasia
Incidentally discovered IPMN/PanIN lesions
Hepatocellular carcinoma
Hepatitis B carriers (Asians and Africans)
Hepatitis B cirrhosis
Family history of HCC (mainly Asians and Africans)
Treated hepatitis B cirrhosis (Asians)
Hepatitis C cirrhosis
Treated hepatitis C cirrhosis
Alcoholic cirrhosis
Genetic hemochromatosis
Alfa1-antitrypsin deficiency
Primary biliary cirrhosis
Colorectal cancer
Familial adenomatous polyposis
Attenuated FAP (AFAP)
Hereditary nonpolyposis colorectal cancer (Lynch syndrome)
Peutz-Jeghers syndrome
Juvenile polyposis syndrome
MUTYH-associated polyposis
Hyperplastic polyposis
Patients with long-standing IBD
Acromegaly patients
Positive findings on index colonoscopy (at 50 yr) such as three or more tubular adenomas, tubular adenoma > 10 mm, adenoma with villous histology, adenoma with high-grade dysplasia, after surgical removal of invasive cancer, incomplete removal of neoplastic lesion

IPMN: Intraductal papillary mucinous neoplasms; PanIN: Pancreatic intraepithelial neoplasia; HCC: Hepatocellular carcinoma; IBD: Inflammatory bowel disease; ALPH1: Aldehyclen dehydrogenase 1; MUTYH: Human MutY homolog.

sociated with any kind of familial predisposition and even lesser proportions (< 5%) belong to well-defined inherited syndromes (such as Lynch syndrome, FAP *etc*.[84]), screening colonoscopy at age 50 (also called index colonoscopy) is the main tool of CRC risk-stratification in general[85]. Presence of adenomas on index colonoscopy is a strong predictor of the risk of development of additional adenomas (30%-50% detection rate at follow up after clearance colonoscopy[86]) and CRC in future. However, most adenomas don't progress to cancer (the life-time cumulative incidence of CRC is 5.5%, and prevalence of colonic adenomas at age 60 is 30%-40%[87]), and therefore their size, numbers, morphology and histopathological characteristics are used to assess the relative risk of progression to cancer and the need of follow-up surveillance/treatment strategies.

In individuals with familial predisposition, the average life-time risk of CRC varies from 100% in FAP to 20% in persons with first and/or second degree relatives with CRC[88], due to difference in penetrance of the inherited genetic defects. It is estimated that only 5% of CRC cases are associated with highly penetrant inherited mutations with well-characterized clinical presentation such as FAP, Lynch syndrome *etc*. whereas rest belong to less penetrant but far more common genetic defects such a polymorphisms in CYP450 family, glutathione-S-transferase family, insulin-like growth factor binding protein-3, ornithine decarboxylase-1 and transforming growth factor-beta receptor 1 genes[84]. However, currently the genetic testing is recommended only if a well-characterized familial syndrome (e.g., Lynch syndrome, FAP) is suspected, because the epidemiological data of the relative-risk of CRC associated with gene polymorphisms is still limited.

Two other well-established high-risk cohorts where surveillance for CRC is recommended are patients with long standing inflammatory bowel disease (IBD) and acromegaly patients. Recent reports suggest that both ulcerative colitis and Crohns' disease patients are at comparable cumulative risk of CRC if the extent and duration of the disease are the same (in case of ulcerative colitis, risk of CRC stands at 1.6% at 10 years, 8.3% at 20 years and 18.4% at 30 years[89,90]). For IBD patients with colonic disease, screening is recommended after 10 years of disease history, and involves endoscopic evaluation of inflammatory changes in the mucosa combined with multiple biopsies to detect dysplasia[91]. Acromegaly patients, on the other hand, seem to have increased incidence as well as propensity for malignant transformation of adenomas, especially right-sided ones, as compared to the general population (odds ratio: 2.4 for adenoma, 7.4 for CRC[92]). This could possibly be attributed to the presence of elevated serum insulin growth factor-1 level (seen in > 90% of acromegaly patients), which has been shown to increase the risk of CRC in non-acromegalic population[93]. Additionally, colonoscopic screening starting at age 40 is recommended to detect precursor lesions in such patients.

From a screening test perspective, non-invasive screening tests such as stool tests (occult blood and DNA tests), imaging (CT, Barium enema) and sigmoidoscopy are only occasionally used, and a full-length colonoscopy despite its several limitations remains the most effective and preferred screening test for CRC (reviewed in details in reference[85]). Current guidelines recommend

screening colonoscopy in average risk individuals at age 50, a significant deviation from earlier practice of colonoscopic screening only in high-risk individuals[94]. The rationale for colonoscopic surveillance has always been based on the high detection rate of colorectal adenomas at follow up (30%-50%) after a complete clearance colonoscopy[86]. However, the main object of colonoscopic surveillance is the prevention of subsequent colorectal cancer rather than the detection and removal of adenomas, most of which will not become malignant. Adenomas with advanced pathology (> 1 cm, with villous elements or severe dysplasia) have a much higher malignant potential, and the main objective of screening is to ensure that such lesions are detected before they become invasive. Therefore, individuals with 1-2 small polyps < 1 cm size and no villous morphology at index colonoscopy are considered low-risk and need no modification in surveillance protocol. However, certain findings on index colonoscopy (as mentioned in the Table 1) indicate high-risk of CRC and necessitate enhanced surveillance.

FUTURE PERSPECTIVE

Currently, surveillance for GI malignancies is challenging because of the general lack of inexpensive screening tests and potent biomarkers that could efficiently identify high-risk cohorts. Recently, there has been a surge in interest in using a panel of biomarkers (gene expression signatures) for screening purposes, but their impact on cancer mortality remains to be tested in large-scale studies[95,96]. Another new class of biomarkers under investigation these days are miRNAs, a type of non-coding RNAs that are endogenous silencers of target genes[97,98]. Unfortunately, many biomarkers/screening tests with initial promise indeed fail to meet the Early Detection Research Network-outlined criteria for their validation[99], and therefore are not used clinically. From a futuristic perspective, we are standing at the crossroads of a major change in our approach towards cancer prevention. With completion of the human genome project, rapid advances in deep sequencing technology and better understanding of the genetic landscape of different tumors (including GI cancers), it is being expected that it would be possible to assess the cumulative predisposition to different cancers in every individual in a cost-effective manner, leading to a highly individualized treatment and preventive care (Personalized Medicine) in coming years[100].

SEARCH STRATEGY AND SELECTION CRITERIA

References for this review were identified through searches of PubMed with the following search terms: "Gastrointestinal malignancies", "risk stratification", "gastrointestinal cancer screening/surveillance", "cancer biomarker", and "cancer prevention" published before December 2011. Articles were also identified through searches of the authors' own files. The final reference list was generated on the basis of relevance to the broad scope of this review; and only articles published in English were reviewed, and considered for inclusion in the reference list based upon the further reading opportunity they offered.

Abstract

Pregnancy associated with chronic hepatitis B (CHB) is a common and important problem with unique challenges. Pregnant women infected with CHB are different from the general population, and their special problems need to be considered: such as the effect of hepatitis B virus (HBV) infection on the mother and fetus, the effect of pregnancy on replication of the HBV, whether mothers should take HBV antiviral therapy during pregnancy, the effect of these treatments on the mother and fetus, how to carry out immunization of neonates, whether it can induce hepatitis activity after delivery and other serious issues. At present, there are about 350 million individuals with HBV infection worldwide, of which 50% were infected during the perinatal or neonatal period, especially in HBV-endemic countries. Currently, the rate of HBV infection in the child-bearing age group is still at a high level, and the infection rate is as high as 8.16%. Effective prevention of mother-to-child transmission is an important means of reducing the global burden of chronic HBV infection. Even after adopting the combined immunization measures, there are still 5%-10% of babies born with HBV infection in hepatitis B e antigen positive pregnant women. As HBV perinatal transmission is the main cause of chronic HBV infection, we must consider how to prevent this transmission to reduce the burden of HBV infection. In this population of chronic HBV infected women of childbearing age, specific detection, intervention and follow-up measures are particularly worthy of attention and discussion.

INTRODUCTION

Chronic hepatitis B (CHB) in pregnancy is an important and pervasive issue with unique challenges. However, for pregnant women with chronic hepatitis B virus (HBV) infection, unlike the general population, many special

problems need to be considered, such as the influence of HBV infection on the mother and fetus, influence of pregnancy on HBV replication, effects of antiviral treatment on maternal and neonatal outcomes, immunization of newborns and the possible flare of hepatitis after delivery. Approximately 350 million people are infected with HBV worldwide and 50% of them have acquired their infection in the perinatal or neonatal period, especially in countries where HBV has a high prevalence[1,2]. In these countries, women of childbearing age have a higher hepatitis B e antigen (HBeAg)-positive rate and a higher probability of mother-to-infant transmission, the younger they are when infected with HBV, the higher the risk of developing CHB[1,3,4]. The rate of HBV infection among women of childbearing age is still at a high level (7.18%) in China[5-7], which leads to an increased risk of HBV vertical transmission and damage due to CHB in the mother and fetus in pregnancy. Therefore, the effective prevention of vertical transmission of HBV is an important approach in reducing the global burden of CHB. Specific hepatitis B immunoglobulin (HBIG) is available for passive protection and is normally used in combination with hepatitis B vaccine to confer immediate cover (passive immunity) and long-lasting protection (active immunity) in newborns, which is administered as an effective prophylactic measure to prevent mother-to-infant transmission of HBV, however, 5%-10% infants of HBeAg-positive mothers are still infected with HBV[8-10].

PREGNANCY AND CHRONIC HBV INFECTION

Overall, no severe effects due to CHB are found in pregnancy. Studies have shown that chronic HBV infection is associated with gestational diabetes mellitus, antepartum hemorrhage, threatened premature labor and lower Apgar score. Mothers with seriously abnormal liver function complications are prone to postpartum hemorrhage, puerperal infection, low body weight infants, fetal distress, premature birth, fetal death and neonatal asphyxia[11-21]. A series of physiological changes occur during pregnancy, including vigorous metabolism and increased nutrient consumption. These changes occur to promote the metabolic needs of the mother as well as the needs of the growing fetus. Abundant sex hormone produced by the mother needs to be metabolized and inactivated in the liver, and metabolism and detoxification in the fetus also depend on the mother's liver, which correlates with aggravation of pre-existing liver diseases and exacerbation of liver damage[22,23]. Alanine aminotransferase (ALT) in late pregnancy and the postpartum period shows an increasing tendency, however, HBV replication in the gestational period is not noticeably different[24-28]. Some women appear to undergo HBeAg seroconversion in the initial months after delivery if immune activation occurs, with a seroconversion rate of 12.5% to 17%, which is correlated with an obvious decrease in adrenal cortex hormone[29,30]. Although HBV infection during pregnancy can often be tolerated, severe hepatitis and hepatic failure induced by perinatal hepatic flare reactions still occur, and can have an unfavorable outcome[29].

PERINATAL MANAGEMENT OF CHB

As relatively safe assays for the diagnosis of HBV infection are available and effective treatment strategies for CHB have been developed, the screening of HBV infection in the perinatal period has become standard care, which can identify newborns that require prophylaxis with hepatitis B vaccine and HBIG as well as pregnant women who require antiviral therapy. In addition, it is beneficial to advise patients with hepatitis B about sexual and family contacts. Screening and vaccination are key factors in the successful prevention and control of HBV infection.

Women with CHB should actively plan their pregnancy and undergo baseline evaluations, such as hepatitis B surface antigen (HBsAg), HBeAg, antibody to HBeAg (anti-HBe), HBV DNA, severity of liver disease and the presence of other viral infections, are suggested before pregnancy. The ability to sustain pregnancy and the risk of vertical transmission of HBV in women with CHB should also be evaluated. All pregnant women should be screened for HBV infection at the first prenatal examination, and HBsAg-positive patients should be transferred to hospitals with experience in the management of CHB for easier monitoring of mothers in pregnancy, delivery and the postpartum period as well as newborns, and appropriate prevention of mother-to-infant transmission of HBV based on an individual's condition should be conducted.

PREVENTION AND TREATMENT OF CHRONIC HBV INFECTION IN PREGNANCY

The treatment goals for CHB in pregnancy are to achieve stabilization of liver function in mothers and prevent HBV infection in newborns. Regular monitoring of liver function and HBV DNA level should be performed in the gestational period to determine whether liver disease is progressing and antiviral therapy is needed in mothers. Sinha *et al*[11] from India made several suggestions aimed at Asian HBV carriers when planning a pregnancy: First, in patients with lower HBV DNA level at baseline (HBV DNA $< 10^6$ copies in HBeAg-positive patients and HBV DNA $< 10^5$ in HBeAg-negative patients) and no obvious fibration, antiviral therapy may be delayed, but monitoring should be performed during pregnancy. In patients with HBV DNA $> 10^7$ copies/mL repeated in the late trimester of pregnancy, or prior delivery history of a HBV-positive infant and HBV DNA $> 10^6$ copies/mL, antiviral therapy should be administered; Second, in patients with higher HBV DNA level at baseline and obvious fibration, but without liver cirrhosis, antiviral

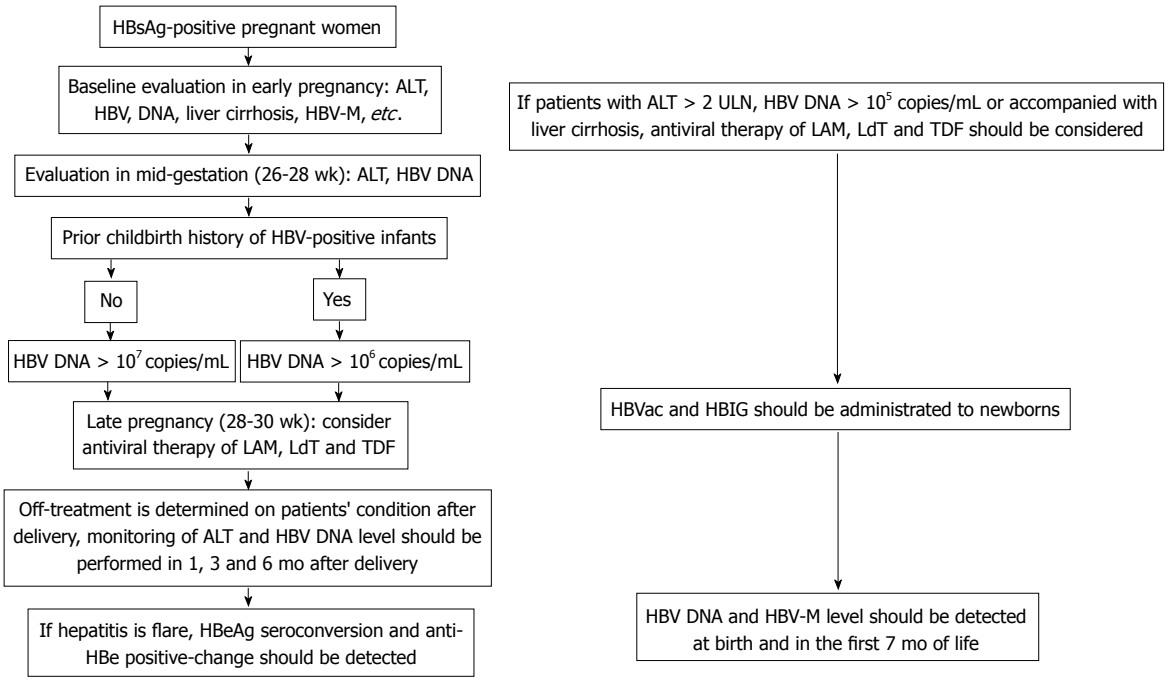

Figure 1 Management of chronic hepatitis B in pregnancy. HBsAg: Hepatitis B surface antigen; ALT: Alanine aminotransferase; HBV: Hepatitis B virus; LAM: Lamivudine; LdT: Telbivudine; TDF: Tenofovir; HBeAg: Hepatitis B e antigen; Anti-HBe: Antibody to HBeAg; ULN: Upper limits of normal; HBVac: Hepatitis B vaccine; HBIG: Hepatitis B immunoglobulin.

therapy is suggested. If a response is sustained after off-treatment, pregnancy is feasible, monitoring should be performed, and management is the same as that outlined in the first scenario; If a response is not sustained after drug withdrawal, management is the same as the third scenario; Third, If patients have liver cirrhosis before pregnancy, antiviral therapy [lamivudine (LAM), tenofovir (TDF) or telbivudine (LdT)] is suggested first, and one of these drugs should be continued during pregnancy, and monitoring should also be conducted.

To effectively prevent HBV infection in infants, delivery methods are also believed to be potential risk factors for mother-to-infant transmission[31,32], however, there is no clear evidence to show that delivery methods are correlated with reduced vertical transmission of HBV[33-35]. Immediate vaccination with HBVac in combination with HBIG in infants born to CHB mothers can effectively prevent infection in the labor and postnatal period, but has no effect on intrauterine infection[36-38], which is the primary cause leading to failure of vaccination. As both HBV intrauterine and perinatal transmission is significantly correlated with HBV DNA level in pregnant women[39-45], currently most attention is focused on oral antiviral drugs in late pregnancy, which reduce HBV intrauterine transmission by decreasing HBV DNA titers in peripheral blood before delivery[46-48].

PROBLEMS CORRELATED WITH ANTIVIRAL THERAPY DURING PREGNANCY

The current difficulty in preventing mother-to-infant transmission of HBV is the prevention of intrauterine transmission. High HBV DNA level is the most important independent risk factor for intrauterine transmission, thus pregnant woman can take oral antiviral drugs in late pregnancy to reduce HBV DNA titers in peripheral blood before delivery and decrease HBV intrauterine transmission.

Selection of antiviral drugs

Due to inhibition of cell proliferation, interferon is contraindicated in pregnant women. For patients using interferon, pregnancy is practicable after discontinuation of interferon for 6 mo. LdT and TDF are authorized category B antiviral drugs by the Food and Drug Administration for use in pregnancy. After reviewing the increasing safety data on LAM in clinical practise[49-52], LAM was elevated to a category B antiviral drug in pregnancy by NIH, that is, the category B antiviral drugs in pregnancy include LAM, LdT and TDF[33,53].

Indication for antiviral therapy

For HBsAg-positive pregnant women by screening, baseline evaluation, such as HBV-M (HBsAg, HBeAg, anti-Hbe), HBV DNA, hepatitis activity and severity of hepatic fibrosis/liver cirrhosis, are suggested in early pregnancy[54-56]. In patients with higher HBV DNA level and hepatitis activity (ALT > 2 upper limit of normal, HBV DNA > 10^5 copies/mL) at baseline or accompanied by liver cirrhosis, antiviral therapy should be administered during early pregnancy. For patients with normal liver function, ALT and HBV DNA level should be reevaluated in mid-gestation (26-28 wk). For patients with HBV DNA > 10^7 copies/mL or prior delivery his-

tory of HBV-positive infants and HBV DNA > 10^6 copies/mL, antiviral therapy (LAM, TDF or LdT) should be given at 28-30 wk until 4 wk after delivery, then it should be determined whether the above therapy is to be continued on the basis of the patient's condition; otherwise antiviral therapy should not be given[57]. ALT and HBV DNA level should be monitored in all HBsAg-positive pregnant women at 1, 3 and 6 mo after delivery. In a hepatitis flare, HBeAg seroconversion and anti-Hbe positive-change should be detected[58]. Active-passive immunization should be performed in all newborns on schedule; HBV-M (HBsAg, HBeAg, anti-HBe) and HBV DNA level should also be detected at birth and in the first 7 mo of life in newborns[59]. In patients with liver cirrhosis before pregnancy, antiviral therapy (LAM, TDF or LdT) are suggested first, one of these drugs should be continued during pregnancy, and monitoring should also be conducted (Figure 1).

Individualized management of CHB in pregnancy

For women with an unplanned pregnancy during the course of antiviral therapy for CHB, individualized management is performed according to the actual condition of the patient. There are two options for patients: one is temporal off-treatment and whole course monitoring of HBV DNA and ALT level, in addition, antiviral therapy is based on the patient's actual condition after pregnancy, which is suitable for patients with mild hepatitis and a lower risk of recurrence and disease progression; the other option is sequential use of LAM, TDF or LdT as antiviral therapy during the whole course[11,36]. Although active-passive immunity should be given to all newborns of HBsAg-positive pregnant women, breast feeding does not increase the risks of HBV infection. However, there is not enough safety data on these drugs with regard to newborn exposure during breast feeding to assess whether patients receiving antiviral therapy should breastfeed their children [57].

Overall, HBV perinatal transmission is a major cause of chronic HBV infection. To reduce the burden of HBV infection, we must consider how to prevent HBV transmission. For women of childbearing age, HBV detection and intervention deserves special attention and investigation.

Abstract

AIM: To investigate the genomic copy number alterations that may harbor key driver genes in gastric tumorigenesis.

METHODS: Using high-resolution array comparative genomic hybridization (CGH), we investigated the genomic alterations of 20 advanced primary gastric adenocarcinomas (seventeen tubular and three mucinous) of Chinese patients from the Jilin province. Ten matching adjacent normal regions from the same patients were also studied.

RESULTS: The most frequent imbalances detected in these cancer samples were gains of 3q26.31-q27.2, 5p, 8q, 11p, 18p, 19q and 20q and losses of 3p, 4p, 18q and 21q. The use of high-resolution array CGH increased the resolution and sensitivity of the observed genomic changes and identified focal genetic imbalances, which included 54 gains and 16 losses that were smaller than 1 Mb in size. The most interesting focal imbalances were the intergenic loss/homozygous deletion of the fragile histidine triad gene and the amplicons 11q13, 18q11.2 and 19q12, as well as the novel amplicons 1p36.22 and 11p15.5.

CONCLUSION: These regions, especially the focal amplicons, may harbor key driver genes that will serve as biomarkers for either the diagnosis or the prognosis of gastric cancer, and therefore, a large-scale investigation is recommended.

INTRODUCTION

Gastric cancer is one of the leading causes of cancer-related death worldwide. Although its incidence has gradu-

ally decreased in many Western countries, the incidence of gastric cancer still remains high in South and Central America and is highest in Eastern Asia, specifically in China, South Korea and Japan[1,2]. The most common gastric malignancy is adenocarcinoma[3], which is characterized by multiple genetic instabilities, as are other adenocarcinomas. One of these genetic instabilities is chromosomal instability, a common consequence of a chromosomal or chromosome-segment abnormality, that causes DNA copy number changes during tumor progression. These alterations may lead to a loss of function of tumor suppressor genes (inactivation) and/or a gain of function of oncogenes (activation). High-level DNA copy number changes (amplification/amplicons) in tumors are frequently restricted to certain chromosomal regions containing well-known oncogenes that are also overexpressed or activated[4,5]. Some oncogenes, such as *NMYC*, *LMYC* and *GLI*, were originally discovered because of their genomic amplification in human tumors[4]. An analysis of the composition of DNA amplifications showed that human cancer can be classified *via* DNA copy number profiling because such amplifications are non-randomly selected with respect to the biological backgrounds of cancer[6]. Therefore, the detection and discovery of unidentified or incompletely described amplicons and relevant genes located within these amplicons can lead to the identification of genes putatively involved in growth control and tumorigenesis.

Recently available whole-genome array comparative genomic hybridization (CGH), a high-throughput genomic technology, facilitates the accumulation of high-resolution data of genomic imbalances associated with disease. In this study, we identified possible candidate genes that could provide insight into the pathology of gastric adenocarcinoma through the integration of genomic copy number changes.

MATERIALS AND METHODS

Tumor samples

This study included seventeen tubular and three mucinous adenocarcinomas of advanced primary stomach cancer samples from Jilin Province in North-Eastern China (Table 1). Of the twenty samples studied, thirteen were from males and seven were from females. The mean age was 62.1 (ranging from 52 to 76) years. The stage of each tumor was classified according to the tumor node metastasis classification of the International Union Against Cancer. The histopathological grades were as follows: Grade 1 (well-differentiated/low grade adenocarcinoma), no cases; Grade 2 (moderately differentiated/intermediate-grade adenocarcinoma), five (tubular) cases; and Grade 3 (poorly differentiated/high-grade adenocarcinoma), 15 (12 tubular and three mucinous) cases. Unfortunately, we were unable to obtain information concerning postsurgical pathological stages. Tumor samples were obtained surgically in the First Hospital of Jilin University; paired adjacent normal tissue was also collected as a control for comparison with the tumor. All patients had negative histories of exposure to either chemotherapy or radiotherapy before surgery, and there were no other diagnosed cancers. An informed consent with approval of the ethics committee of the First Hospital of Jilin University was obtained from all participating patients.

Twenty tumor samples and ten paired adjacent normal tissues were snap-frozen after surgical resection and stored at -80 ℃. DNA was isolated from the tumor tissue by proteinase K digestion followed by phenol-chloroform extraction according to standard protocols.

Array CGH assay

Array CGH was performed according to the manufacturer's protocol with minor modifications on a 385k oligonucleotide chip (Roche/NimbleGen Systems Inc., Madison, WI). Commercially available pooled normal control DNA (Promega Corporation, Madison, WI) was used for reference. The patient DNA and the reference DNA were labeled with either cyanine 3 (Cy-3) or cyanine 5 (Cy-5) by random priming (Trilink Biotechnologies, San Diego, CA) and then hybridized to the chip *via* incubation in the MAUI hybridization system (BioMicro Systems, Salt Lake City, UT). After 18-h hybridization at 42 ℃, the slides were washed and scanned using a GenePix 4000B (Molecular Devices, Sunnyvale, CA).

Statistical analysis

Profile smoothing and breakpoint detection were performed with NimbleScan version 2.4 and SignalMap version 1.9 (NimbleGen Systems). If a smoothed copy number $\log_2$ ratio was above 0.15 or below -0.15 across five neighboring probes, it was defined as a gain or a loss, respectively. Amplifications were defined as those with a smoothed DNA copy number ratio above 0.5.

RESULTS

Overview of genomic imbalances in 20 primary gastric adenocarcinomas

An overview of genomic imbalances in the twenty advanced primary gastric adenocarcinomas is shown in Figure 1. Genomic copy number changes (gains, losses, amplifications or homozygous deletions) were detected in all cases except one. Net gains (15 cases) of genetic material were more frequent than net losses (4 cases). The sizes of the net genomic imbalances per sample ranged from a loss of 122.2 Mb (4.1% of genome) to a gain of 336.9 Mb (11.2% of genome) (Table 1). The mean number of gains per case was 9.0, ranging from 0 to 40, and the mean number of losses per case was 3.5, ranging from 0 to 14. The gain sizes ranged from 56.3 kb to 158.6 Mb, and the loss sizes ranged from 150.1 kb to 131 Mb. Approximately 28% (70/250) of the genomic imbalances were smaller than 1 Mb; from this subset, 21.6% (54/250) of the total imbalances were gains, and 6.4% (16/250) were losses. The most frequent

[1]Signet ring cell; [2]Percent of net imbalances calculated based on 3000 Mb of genome size. F: Female; M: Male; T: Tumor; N: Node; M: Metastasis ; CR: Cardiac region; GF: Gastric fundus; GB: Gastric body; AA: Antral area; P: Pylorus; Y: Yes; N: No.

genomic imbalances detected in these cancer samples were gains of 3q26.31-q27.2 (6/20), 5p (5/20), 8q [12/20: 8q22.2-q22.3 (10), 8q24.13-q24.22 (12)], 11p (6/20), 18p (4/20), 19q (8/20) and 20q (8/20) and losses of 3p14.2 (6/20), 4p15.1 (6/20), 18q21.2-q22.1 (4/20) and 21q21.1-q21.2 (4/20). However, no genomic imbalances were detected in the ten paired adjacent tissues, demonstrating that these genomic imbalances are tumor related.

Genomic regions with amplification: Possible diagnostic marker loci

The most prominent feature in this study was the amplicons of 11q13 (two tubular and one mucinous), 18q11.2 (three tubular) and 19q12 (three tubular), as well as the novel amplicons 1p36.22 (two tubular) and 11p15.5 (three tubular) (Table 2 and Figure 2). Amplification of 11q13 had the smallest region of overlap (SRO) of 343.7 kb, which included the *CCND1*, *ORAOV1* and *FGF19* genes. Amplification of 18q11.2 had an SRO of 625.0 kb, which included the *GATA6* and *CTAGE* genes. Amplification of 19q12 had an SRO of 1.4 Mb, which included nine genes: *LOC148145*, *LOC10050583*, *UQCRFS1*, *LOC284395*, *VSTM2B*, *POP4*, *PLEKHF1*, *C19orf12* and cyclin E1 (*CCNE1*). The SRO of the novel amplification 1p36.22 was 418.7 kb and included *FEX14*, *CASZ1*, *C1orf127* and *TARDBP*. The SRO of the other novel amplification, 11p15.5, was 343.7 kb and included *MUC5B*, *LOC255512*, *TOLLIP*, *BRSK2*, *HCCA2*, *DUSP8* and *LOC338865*. Other regions in which amplification was detected were 8p23.1, 8q24.21, 10q26.12q26.13, 11q13, 12p12.1, 12q15, 17q12 and 20q13.2; these regions are summarized in Table 2.

The most common losses involved the fragile histidine triad/FRA3B and PDCH7 genes

Six cases had a loss of the fragile histidine triad (*FHIT*) gene, which maps to the common fragile site 3p14.2. Five of these were intergenic losses of the *FHIT* gene,

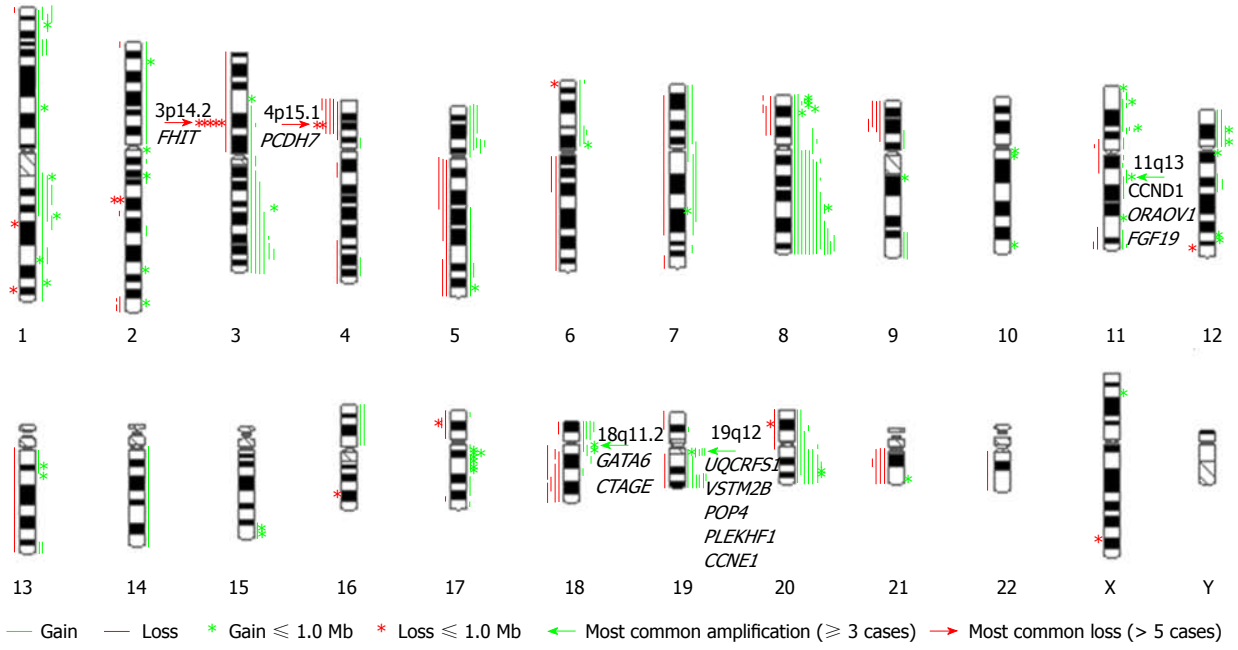

Figure 1 An overview of genomic imbalances in 20 primary gastric adenocarcinomas. The total number of gains was 180 (54 ⩽ 1 Mb), and the total number of losses was 70 (16 ⩽ 1 Mb). Partial or whole gains of 8q (12/20), 19q (8/20), and 20q (8/20) were most frequent. The most common amplicons were of the 11q13, 18q11.2 and 19q12 regions (green arrows). The loss of the *FHIT* gene and the partial loss of 4p with the smallest region of overlap including the *PCDH7* gene were the most frequent losses (red arrow).

and one of these five cases (T38) showed a homozygous deletion. The sizes of these losses ranged from 88.3 kb to 762.5 kb (Table 3 and Figure 3). Another common loss identified in all six cases was the 4p15.1 region (Table 3 and Figure 3). Two cases (TW789 and TW782) had an intergenic loss of the *PDCH7* gene.

DISCUSSION

In this study, we investigated gene/segmental genomic copy number alterations in twenty advanced primary gastric adenocarcinomas (seventeen tubular and three mucinous) *via* whole-genome array CGH. We observed that the total number of gains/amplifications (180) was 2.6 times the total number of losses (70). Nineteen out of the 20 cases had genomic imbalances; fifteen of these had net genomic gains (3.4-336.9 Mb), and four of these had net genomic losses (0.06-122.2 Mb), indicating that genomic gains are more common than losses (Figure 1). These findings are compatible with previous findings determined *via* conventional CGH[7-51]. However, we discovered cryptic genomic imbalances smaller than 1.0 Mb in 28% (70/250) of the total imbalances (with an average of 3.5 per case) and narrowed down the SROs of losses or of gains/amplifications to those including interesting genes or focal genomic segments. These findings are explained by the resolution of the array that we used. The most interesting cryptic imbalances were losses of 3p14.2 and 4p15.1 (Figure 3) and amplifications of 1p36.22, 11p15.5, 11q13, 18q11.2 and 19q12 (Figure 2).

The loss of 3p14.2 in six of our cases encompassed the *FHIT* gene, which was discovered at the FRA3B locus on the short arm of chromosome 3 and is the most active common chromosome fragile site in the human genome. *FHIT*'s loss of function as a tumor suppressor gene due to breakage, allelic loss, occasional homozygous deletion and promoter hypermethylation has been evaluated in different types of epithelial tumors, including gastric cancer, which is strongly associated with direct or indirect exposure to environmental carcinogens[52-54]. The FHIT protein is absent in more than 50% of the observed cases, both in gastric cancer cell lines and in primary gastric adenocarcinomas, irrespective of any specific histotype, indicating that alterations of the *FHIT* gene can play a role in tumorigenicity as an important and preliminary genetic alteration in the cell[55]. However, subsequent additional genetic changes involving other tumor suppressor genes or oncogenes may be necessary for tumor progression. In our six cases who had lost the *FHIT* gene, five showed an intergenic loss of *FHIT*, ranging in size from 150 kb to 762.4 kb. One case had a homozygous deletion of part of the *FHIT* gene (case T36); however, no deletion of this region was found in the normal adjacent tissue of the same case (date not shown). This finding suggests that *FHIT* loss, not normal copy number variation, is clearly linked to tumorigenicity. However, copy number variations, particularly losses including the *FHIT* gene, have been reported in the normal population[56], raising the question of whether constitutional copy number loss of the *FHIT* gene increases tumorigenicity susceptibility.

The other most common loss was of 4p15.1, detected in six cases and encompassing the *PDCH7* gene. PDCH7 is an integral membrane protein that is thought

[1]Novel amplicon; [2]Gene and references that are overexpressed when amplified in gastric cancer; [3]Genes (and references) that are overexpressed when amplified in types of cancer other than gastric cancer; [4]Underexpression has been reported in gastric cancer. SRO: Smallest region of overlap; N/A: Not available.

to function in cell-cell recognition and adhesion. Loss of heterozygosity (LOH) or deletion of this region has been reported in hepatocellular carcinoma (HCC) and in some head and neck squamous cell carcinomas[57,58]. Recently, a genome-wide analysis revealed a single-nucleotide polymorphism in *PDCH7* whose risk allele affects overall survival in early-stage non-small-cell lung cancer[59].

Gene/chromosomal segment amplifications are thought to reflect genetic instabilities in solid-tumor cells[60]. Such amplifications commonly consist of double minutes (DMs) or homogeneous staining regions or are dispersed at the genomic level; they are usually correlated with protein levels of genes[61]. It has been proposed that the activation of proto-oncogenes by amplification plays an important role in the development of many human solid tumors. Therefore, detection of specific gene amplifications in tumor cells can lead to the identification of genes putatively involved in growth control and tumorigenesis. In our study, we identified the novel amplicons 1p36.22 and 11p15.5 as well as prominent amplicons 11q13, 18q11.2 and 19q12 (≥ 3 cases with amplification).

LOH or the loss of the short arm of chromosome 1, which includes band p36, has been reported in vari-

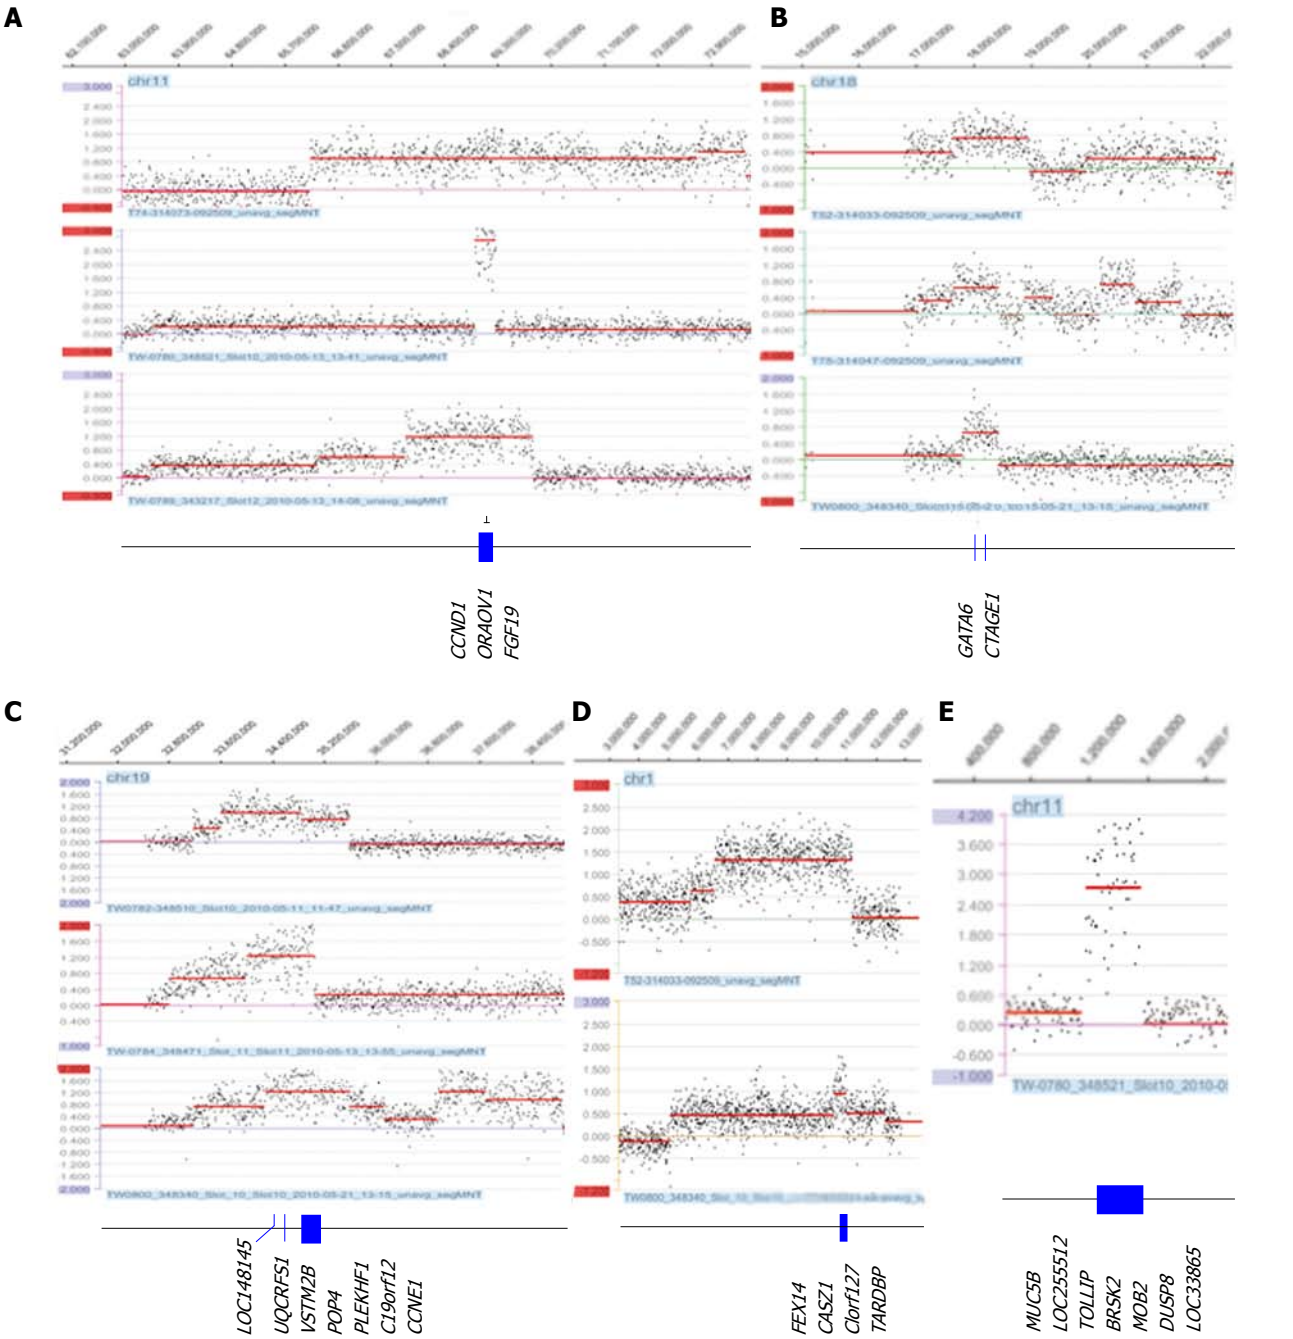

Figure 2 Representative amplifications detected by array comparative genomic hybridization and the genes that are located in the smallest region of overlap. The most common amplicons at 11q13 (A), 18q11.2 (B) and 19q12 (C) and novel amplicons at 1p36.22 (D) and 11p15.5 (E) region (log2 > 0.5). The x-axis indicates the genomic location, and the y-axis indicates the log2 ratio.

ous cancers[62], supporting the possibility that this region encompasses at least one tumor suppressor gene, as opposed to one or more oncogenes. The *CASZ1* gene on 1p36, which was amplified in our cases, has been implicated as a candidate tumor suppressor gene in neuroblastomas[63]. However, our study revealed three cases with a gain of 1p36.22. Of these, two cases with high-level amplification of a 418.7 kb SRO, which includes the *PEX14*, *CASZ1*, *C1orf127* and *TARDBP* genes, had not previously been reported. Further studies could determine whether this amplification induces overexpression of proteins. The other novel amplicon, found in one case, was the 11p15.5 region, which is 343.7 kb and includes the *MUC5B*, *TOLLIP*, *BRSK2*, *HCCA2*, *DUSP8* and *LOC33865* genes. The *MUC5B* gene encodes a member of the mucin family of proteins, which are highly glycosylated macromolecular components of mucus secretions. This family member is the major gel-forming mucin in mucus. The expression of this gene has been associated with a type of gastric carcinoma but not with the clinical-biological behavior of the tumors[64,65]. The *TOLLIP* gene encodes a ubiquitin-binding protein that interacts with several toll-like receptor (TLR) signaling cascade components. The TOLLIP

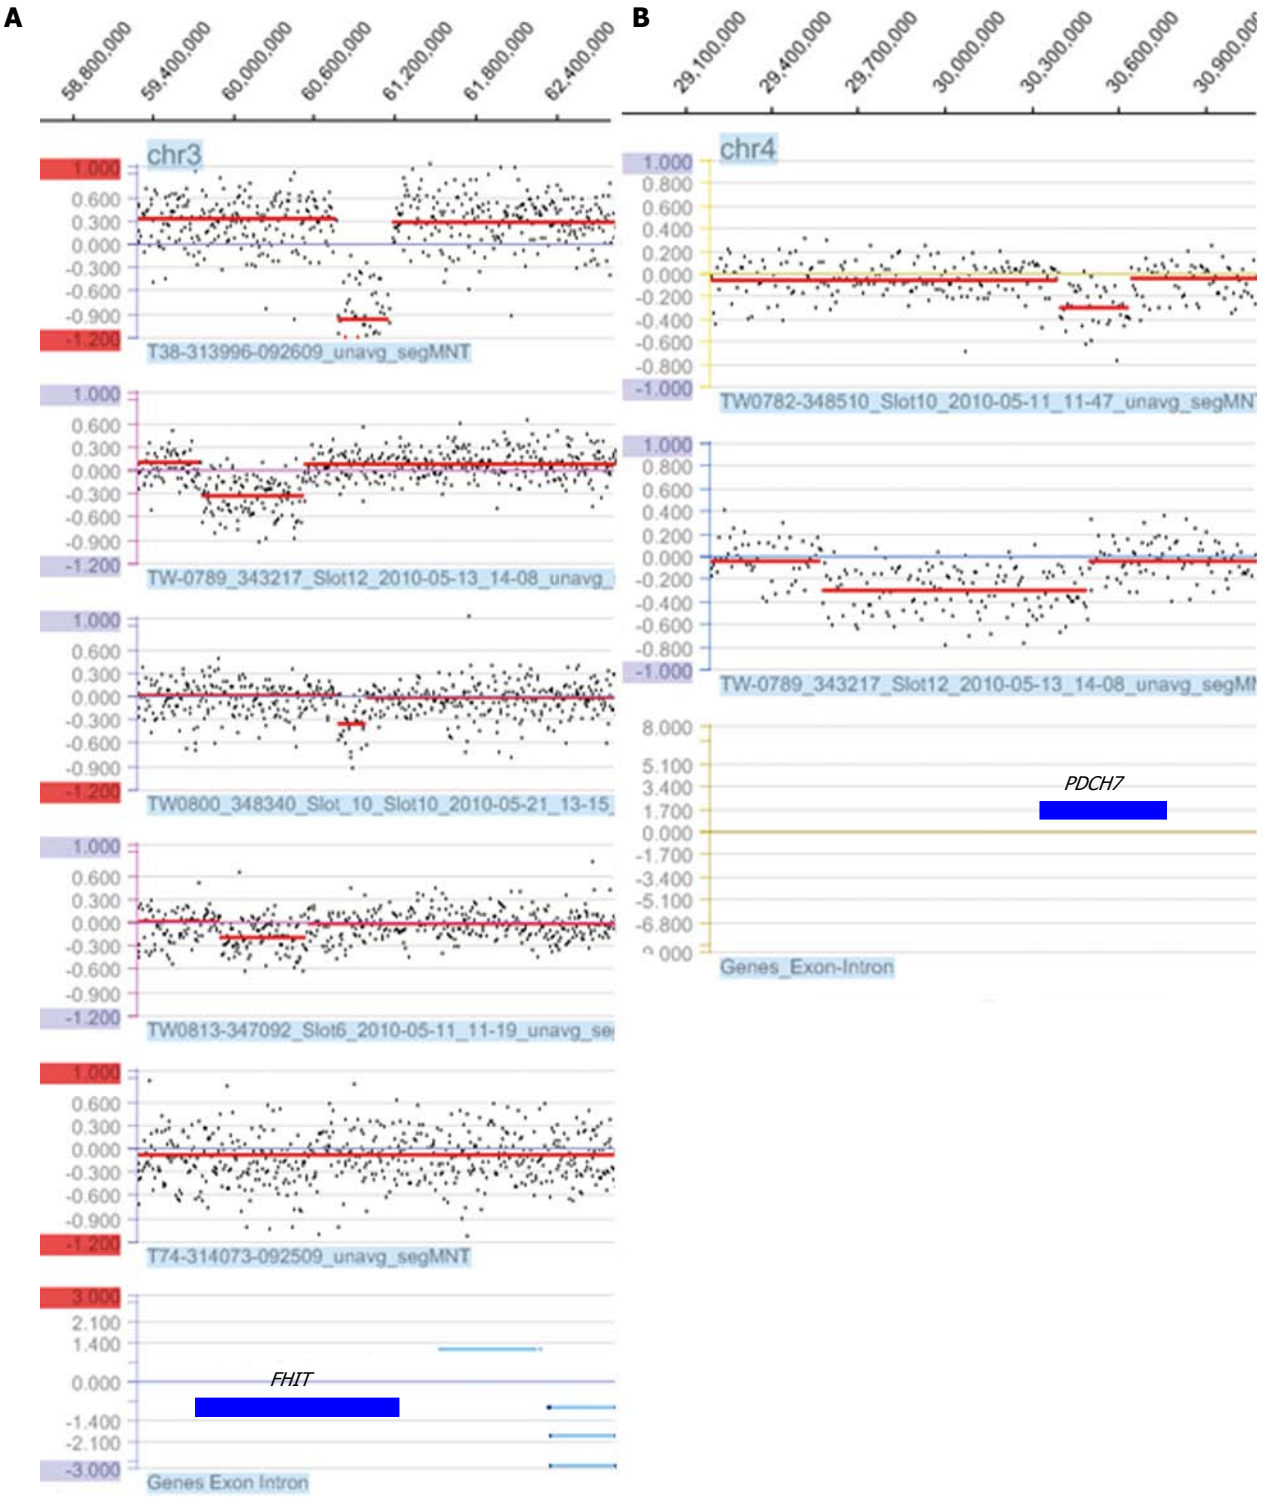

Figure 3 Intergenic loss of *FHIT*/FRA3B on 3p14.2 (A) and *PDCH7* on 4p15.1 (B) detected by array comparative genomic hybridization. The x-axis indicates the genomic location, and the y-axis indicates the log2 ratio.

protein regulates inflammatory signaling and is involved in interleukin-1 receptor trafficking and the turnover of the IL1R-associated kinase; a possible association with human cancer development has been suggested[66]. The BR serine/threonine kinase 2 (*BRSK2*) gene acts as a checkpoint kinase upon DNA damage induced by UV irradiation or methyl methane sulfonate[67]. Clinical implications of *BRSK2* expression in pancreatic ductal adenocarcinoma have been suggested[68]. The hepatocellular carcinoma-associated gene 2 (*HCCA2*) gene was initially identified as a HCC-specific protein. It was subsequently found to interact with *MAD2L2* and might function in cell cycle regulation[69]. The dual specificity phosphatase 8 (*DUSP8*) gene is a member of the *DUSP* subfamily.

Table 3 Summary of losses of *FHIT* at 3p14.2 and of *PDCH7* at 4p15.1

HD: Homozygous deletion.

DUSPs inactivate their target kinases by dephosphorylating both the phosphoserine/threonine and phosphotyrosine residues. These genes negatively regulate members of the mitogen-activated protein kinase (MAPK) superfamily (MAPK/ERK, SAPK/JNK, p38), which are involved in cellular proliferation and differentiation. The roles of the DUSPs in the regulation of MAPK activities have been highlighted as part of the oncogenic process[70]. Overall, any of the genes in this region are likely to play an important role in the progression of cancer.

The amplification of 11q13 ranged from 343.7 kb to 20.5 Mb and had an SRO of 343.7 kb, which included the *CCND1*, *ORAOV1* and *FGF19* (*BLC6*) genes. The variously sized 11q13.3 amplicon containing *CCND1* is one of the most frequent amplification events in human tumors. Computational genome-wide approaches to identify driver genes have reported *CCND1* as one of the most common somatic focal amplifications in human cancers[5]. As shown in our 11q13 amplification, the *ORAOV1* and *FGH19* genes lie within 15 kb of *CCND1*, and they are invariably co-amplified with *CCND1*. However, the limited data show that their expression levels depend on the type of tumor, indicating that the driver gene can be tissue-type dependent/specific. The co-expression of *FGH19* with or without *CCND1* has been found in HCC, but an absence of *FGH19* expression has been found in breast cancer and oral cancer[27]. Future work can determine whether *FGH19* is co-expressed with *CCND1* in primary gastric adenocarcinoma, even given that recently published whole-genome expression data did not show a significant correlation or co-expression of amplification/expression of *CCND1* and *FGH19*[35,43]. *ORAOV1* overexpression has been found in all amplified HCCs; however, *ORAOV1* does not promote tumorigenicity in $p53^{-/-}$; Myc hepatoblasts, nor is it cooperative with *FGFR1* or *CCND1*[27]. A total of four cases in this study had a gain of the 18q11.2 region. Of these, three cases had amplifications ranging from 625.0 kb to 1.3 Mb with an SRO of 625.0 kb, which includes the *GATA6* and *CTAGE* genes. This 18q11.2 amplification, along with expression and epigenetic studies, supports the oncogenic function of *GATA6* in esophageal carcinoma, colon cancer and pancreatic cancer[40,42,71,72] but not in gastric adenocarcinoma. Upregulation of *GATA6* has been reported in the transition from normal esophageal epithelium to Barrett adenocarcinoma and adenocarcinoma[42,71]. A 0.36 kb amplification including *GATA6* and *CTAGE1* has been found in pancreatic carcinoma[40,41], and dysregulation (overexpression) of *GATA6* contributes to colorectal tumorigenesis and tumor invasion[72]. Moreover, in that study *GATA6* was overexpressed not only in the cases with an amplification of *GATA6* but also in the cases without amplification[72]. However, *CTAGE* was rarely overexpressed, indicating that *GATA6* is the driver in this amplicon[41] and suggesting that *GATA6* overexpression may play a role in the early stages of tumor development. A contradictory result showing underexpression of the *GATA6* gene has been reported in gastric adenocarcinoma[36], demonstrating that the oncogenic function of *GATA6* in gastric adenocarcinoma needs to be investigated. Our observed amplification of 19q12 with an SRO of 1.4 Mb includes the nine genes *LOC148145*, *LOC10050583*, *UQCRFS1*, *LOC284395*, *VSTM2B*, *POP4*, *PLEKHF1*, *C19orf12* and *CCNE1*. This 19q12 amplification has been found in gastric cancer and esophageal adenocarcinoma[12,44,45]. Of these genes, *CCNE1*, an E type cyclin, has traditionally been considered the target of the 19q amplification, which is also one of the most common amplification products in various tumor types[5,12]. However, a comprehensive analysis of the 19q12 amplification in gastric cancer has revealed clustered overexpression of *CCNE1* as well as *UQCRFS1*, *POP4*, *C19orf12* and *RMP*, indicating potential functions of other genes in this region in tumor development[45]. In ovarian cancer, it has been suggested that the *CCNE1* gene is the key driver in this 19q12 amplicon and is correlated with the gain in the 20q11 region that includes the *TPX2* gene[73]. It is not clear whether the *CCNE1* gene is a key driver in other types of tumors, including gastric cancer tumors, because no detailed study has been conducted; it is also possible that this gene is tissue specific, as shown in 19q12. However, the gain of the 20q11 region is one of the most

common findings in gastric cancer, and the correlation between 19q12 and 20q11 in gastric cancer needs to be investigated.

Other amplifications found were 1q21.2 (1 amp/3 gains), 8p23.1 (2 amps/3 gains), 8p23.1 (2 amps/3 gains), 8q24.21 (1 amp/11 gains), 10q26.12q26.13 (1 amp), 11p13 (2 amps/1 gain), 12p12.1 (2 amps/2 gains), 12q15 (2 amps), 17q12 (2 amps/1 gain) and 20q13.2 (1 amp/6 gains). We summarized these amplifications and the expression of the gene(s) corresponding to these amplicons in various primary epithelial tumor and cell lines (Table 2). *MCL1* on 1q21.1, *MYC* on 8q24.21, *KRAS* on 12p12.1, *MDM2* on 12q15, *ERBB2* on 17q12 and *ZNF217* on 20q13.2 are well-acknowledged oncogenes in several tumors[5]. Recently published data suggest that the same amplifications do not necessarily induce the same gene expression in different tissue types[27], implying that driver genes can be tissue-type specific and making it necessary to acquire and investigate both amplification and overexpression information for different tumor types, even in the case of well-validated oncogenes.

In summary, the array CGH technique allows for comprehensive, rapid and reliable analysis of the whole genome of primary gastric adenocarcinomas and enables the refined and detailed study of amplifications and regions of recurrent copy number change. This approach makes it possible to identify putative oncogenes and tumor suppressor genes that may deserve further investigation. In this context, we identified candidate target genes/genomic segments of amplification that may help to direct therapeutics against gastric cancer.

COMMENTS

Background

Gastric cancer is one of the leading causes of cancer-related death worldwide. Although its incidence has gradually decreased in many Western countries, the incidence of gastric cancer still remains high in South and Central America and is highest in Eastern Asia, specifically in China, South Korea and Japan. Searching for biomarkers for gastric cancer has proven to be quite challenging.

Research frontiers

Cancer is a genetic disease that involves multiple genetic alterations. Understanding the molecular profile of tumor tissue is crucial for efficiently targeting cancer cells. In this study, the authors identified possible candidate target genes that could provide insight into the pathogenesis of gastric adenocarcinoma through the integration of genomic copy number changes.

Innovations and breakthroughs

Recent reports have highlighted the oncogenic addiction associated with oncogene amplification as a driver gene in carcinogenesis and target treatments. In this research paper, the authors identified novel amplicons that have not been published previously and that could be new target sites for potential diagnosis, prognosis and treatment.

Applications

To learn how these new amplicons are induced and change gene expression, this study may represent a future strategy for therapeutic intervention in the treatment of patients with gastric adenocarcinoma.

Peer review

The paper was designed to be a proof of principle for using cytogenomic microarrays on a larger study to ascertain biomarkers for various gastric neoplasms. The authors did a very thorough analysis of the genetic alterations and of the discussion of the possible genes involved. As claimed, they showed the power of the cytogenomic microarray in detecting common genetic alterations in various gastric tumors. The study was organized in a very clear manner and each common abnormality was compared in a thoughtful manner.

Abstract

AIM: To evaluate the efficacy and safety of the FOLFIRI regimen in patients with metastatic pancreatic adenocarcinoma (PAC) after the failure of gemcitabine and platinum salts.

METHODS: All consecutive patients with histologically confirmed, metastatic PAC and World Health Organization performance status (PS) $\leqslant$ 2 received FOLFIRI-1 [irinotecan 180 mg/m^2 on day 1 and leucovorin 400 mg/m^2 followed by 5-fluorouracil (5-FU) 400 mg/m^2 bolus, then 5-FU 2400 mg/m^2 as a 46-h infusion, biweekly] or FOLFIRI-3 (irinotecan 100 mg/m^2 on day 1 and leucovorin 400 mg/m^2, then 5-FU 2400 mg/m^2 as a 46-h infusion and irinotecan 100 mg/m^2 repeated on day 3, biweekly) after failure of gemcitabine and platinum-based chemotherapies as a systematic policy in two institutions between January 2005 and May 2010. Tumor response, time to progression (TTP), overall survival rate (OS) and grade 3-4 toxicities were retrospectively studied. Subgroup analyses were performed to search for prognostic factors.

RESULTS: Sixty-three patients (52.4% male, median age 59 years) were analyzed. Among them, 42.9% were PS 0, 38.1% were PS 1 and 19.0% were PS 2. Fifty one patients (81.0%) had liver metastases. Before the FOLFIRI regimen, patients had received 1 line (n = 19), 2 lines (n = 39) or 3 lines (n = 5) of chemotherapy. Median TTP obtained with the line before FOLFIRI was 3.9 mo (95% CI: 3.4-5.3 mo). A total of 480 cycles was completed (median: 6 cycles, range: 1-51 cycles). The main reason for discontinuing FOLFIRI was tumor progression (90.3%). Tumor control was achieved in 25 patients (39.7%) (partial response: n = 5, stable disease: n = 20) with FOLFIRI. Median TTP was 3.0 mo (95% CI: 2.1-3.9 mo) and median OS was 6.6 mo (95% CI: 5.3-8.1 mo). Dose adaptation was required in 36 patients (57.1%). Fifteen patients (23.8%) had grade 3-4 toxicities, mainly hematological (n = 11) or digestive (n = 4). Febrile neutropenia occurred in 3 patients. There was no toxic death. PS 2 was significantly associated with poor TTP [hazard ratio (HR): 16.036, P < 0.0001] and OS (HR: 4.003, P = 0.004).

CONCLUSION: The FOLFIRI regimen had an acceptable toxicity and an interesting efficacy in our study, limited to patients in good condition (PS 0-1).

INTRODUCTION

Pancreatic adenocarcinoma (PAC) accounts for 2%-3% of all cancers but is the fourth leading cause of cancer death in Western countries[1]. More than 80% of patients present with unresectable disease and most of those with operable tumors who undergo resection have local relapse or metastases[2]. The overall prognosis of metastatic PAC remains poor, with a 5-year survival rate of less than 5%[3].

Gemcitabine became the reference regimen as first-line chemotherapy in patients with metastatic PAC after a randomized trial showed significant improvement in median overall survival (OS) compared with 5-fluorouracil (5-FU) (5.6 mo *vs* 4.4 mo, $P = 0.002$)[4]. Over the past decade, multiple phase Ⅱ and Ⅲ studies have attempted to improve these results using various combinations of gemcitabine with other agents but no significant benefit on survival has been found compared with gemcitabine alone, except for erlotinib which resulted in a modest but significant improvement in OS (6.2 mo *vs* 5.9 mo, $P = 0.038$)[5,6]. A phase Ⅲ trial comparing the FOLFIRINOX regimen (folinic acid/5-FU, irinotecan and oxaliplatin combination) to gemcitabine as first-line treatment for metastatic PAC showed that this combination was superior to gemcitabine (OS: 11.1 mo *vs* 6.8 mo, $P < 0.001$)[7].

In clinical practice, about half of metastatic PAC patients with disease progression under gemcitabine treatment remain in acceptable clinical condition and thus may receive subsequent line(s) of chemotherapy. A retrospective series of 117 patients evaluated the feasibility and benefits of second- and third-line chemotherapies in patients with metastatic PAC after the failure of gemcitabine[8]. Fifty three (45%) received two lines and 24 (21%) received three or more lines. Median time to progression (TTP) and OS from the beginning of the second line were 2.3 mo and 4.7 mo, respectively. The FFCD 0301 phase Ⅲ trial was the first randomized study to evaluate a chemotherapy strategy with a second line of treatment in the treatment plan. It compared the combination of folinic acid/5-FU and cisplatin followed by gemcitabine or the reverse sequence in metastatic PAC[9]. The second line of therapy was administered at disease progression to 68% of patients who received folinic acid/5-FU and cisplatin as a first line treatment and to 55% in the gemcitabine arm (non-significant). Median progression-free survival (PFS) and OS in the two arms were not significantly different. Although there is no standard regimen in this setting, two randomized studies have indicated that the combination of folinic acid/5-FU and oxaliplatin appeared to be superior to both best supportive care (4.9 mo *vs* 2.3 mo, $P = 0.008$) and folinic acid/5-FU alone (6.0 mo *vs* 3.0 mo, $P = 0.014$) as a second line of treatment[10]. Other regimens have been tested in non-randomized phase Ⅱ studies, but the samples were small and information on World Health Organization (WHO) performance status (PS) and disease stage were often lacking[11].

Preclinical studies have shown that the camptothecin analog irinotecan has significant activity in both cultured pancreatic tumor cells and in xenograft models[12,13]. Irinotecan monotherapy in previously untreated PAC patients yielded response rates (RR) of 9%-27%[14-16]. *In vitro* studies have suggested that there is a synergistic effect between irinotecan and 5-FU[17-19]. A multicenter phase Ⅱ study with folinic acid/5-FU and irinotecan day 1/day 3 combination (FOLFIRI-3 regimen) showed promising activity in chemotherapy-naive patients with locally advanced or metastatic PAC, with a median PFS and OS of 5.6 mo and 12.1 mo, respectively, and a manageable toxicity profile[20]. A randomized phase Ⅱ study has compared modified FOLFIRI-3 and a modified FOLFOX schema (folinic acid/5-FU and oxaliplatin combination) as second-line chemotherapy in that setting[21]. The efficacy was similar, with 6-mo OS rate of 27% and 30%, respectively. An Italian group reported a retrospective series of 40 patients with gemcitabine-resistant locally advanced or metastatic PAC treated with a standard FOLFIRI (FOLFIRI-1, folinic acid/5-FU and irinotecan day 1 combination) regimen[22]. Median TTP was 3.7 mo and median OS was 6 mo.

Because no data exist on the efficacy of the FOLFIRI regimen after the failure of both gemcitabine and platinum salts, we performed a retrospective study to evaluate the efficacy and safety of this regimen in patients with advanced PAC in that setting. As locally advanced PAC may have a more favorable natural history than metastatic PAC, we decided to exclude locally advanced PAC patients from the study to have a homogeneous population.

MATERIALS AND METHODS

Patients

All patients with histologically confirmed, metastatic PAC, after failure (progression or major toxicity) of gemcitabine and platinum-based chemotherapies, re-

ceived an irinotecan-based regimen as a systematic policy after discussion during a weekly multidisciplinary meeting in our institutions (Saint Antoine Hospital, Paris and Beaujon Hospital, Clichy), if they met the following criteria: previous treatment with gemcitabine and platinum salt (combined or given in consecutive lines); WHO PS ≤ 2; at least one bidimensionally measurable lesion according the Response Evaluation Criteria in Solid Tumors (RECIST); absence of severe uncontrolled cardiovascular, metabolic, infectious or renal disease; serum bilirubin level < 1.5 times the upper limit of normal; polynuclear neutrophil count > 1500/mm^3; platelet count > 100 000/mm^3.

Chemotherapy regimen

The FOLFIRI-1 regimen consisted of irinotecan 180 mg/m^2 administered as a 90-min infusion on day 1, together with leucovorin 400 mg/m^2 for 2 h followed by an 5-FU 400 mg/m^2 bolus, then a 46-h infusion of 5-FU 2400 mg/m^2. The FOLFIRI-3 regimen consisted of irinotecan 100 mg/m^2 administered as a 60-min infusion on day 1, together with leucovorin 400 mg/m^2 for 2 h, then a 46-h infusion (without bolus administration) of 5-FU 2400 mg/m^2 and irinotecan 100 mg/m^2 repeated on day 3 at the end of 5-FU infusion. Only FOLFIRI-3 (intensified) regimen has been evaluated in phase II studies in PAC[20,21]. However, the FOLFIRI-1 regimen is extensively used in clinical practice for treatment of other gastrointestinal cancers and seems to be less toxic. Thus, the choice between the FOLFIRI-1 or FOLFIRI-3 regimen was left up to the discretion of the investigator. The chemotherapy cycles were repeated every two weeks if the clinical and biochemical assessment was compatible (as mentioned above).

Patients who developed a cholinergic syndrome received preventive treatment with atropine (0.25 mg subcutaneously) during all subsequent cycles. Late-onset diarrhea was treated using high-dose loperamide. When severe neutropenia occurred and/or did not recover to grade ≤ 1 on day 14, a granulocyte-colony stimulating factor was given.

The irinotecan and the 5-FU dosages were reduced by 20% when any grade 3-4 toxicity occurred; other dose adjustments were decided on an individual basis. Treatment was stopped when the tumor progressed or severe toxicity occurred, or at the patient's request. Further treatments are discussed on an individual basis.

Assessment of therapeutic efficacy

Treatment efficacy was assessed on a clinical evaluation, carbohydrate antigen (CA) 19-9 serum levels and thoraco-abdominal computed tomography (CT). Assessment of treatment efficacy was performed every 2 mo (four cycles) or earlier in patients with clinically suspected progression. Tumor response was assessed using CT according to RECIST[23]. A complete response (CR) was defined as complete disappearance of all assessable disease, partial response (PR) as a decrease of > 30% in the sum of the largest diameters of target lesions, stable disease (SD) as a decrease of < 30% or an increase of < 20% in measurable lesions, and progressive disease (PD) as an increase of > 20% in measurable lesions or the appearance of new malignant lesions. Patients who were not assessable by CT but who presented clinical and/or biochemical (CA 19-9 serum level elevation) evidence of disease progression or who died from a cancer-related cause were also considered as PD. The sum of CR, PR and SD was reported as the tumor control rate (TCR). The sum of CR and PR was reported as overall RR (ORR). OS was defined as the time from the first day of the FOLFIRI regimen to the date of death (all causes) or last follow-up. TTP was defined as the time from the first day of the FOLFIRI regimen to the date of disease progression. Patients without progression were censored at the last follow-up.

Safety

Toxicity was assessed before each cycle with the National Cancer Institute Common Toxicity Criteria (version 3.0). A complete physical examination was performed and a full blood count and serum bilirubin, aminotransferases, alkaline phosphatase and creatinine assays were obtained before each treatment cycle.

Data collection

The following patient data were collected and analyzed retrospectively: age; gender; primary tumor location; stage at the time of diagnosis; previous surgery and/or radiotherapy; previous lines of chemotherapy; TTP with the previous line; reasons for stopping previous line; presence or absence of liver metastases at the beginning of FOLFIRI regimen; PS at the beginning of FOLFIRI regimen; type of FOLFIRI regimen (FOLFIRI-1 or FOLFIRI-3); number of cycles administered; best tumor response; grade 3-4 toxicities; dose adaptation; TTP and OS from the beginning of FOLFIRI regimen; reasons for stopping FOLFIRI regimen; further treatments.

Statistical analysis

All analyses were performed using Stata software (version 11.0; StataCorp). All statistical tests were two sided with an alpha type one error of 5%. TTP and OS were estimated using the Kaplan-Meier method and described using median or rate of TTP/OS at a specific time point with 95% CI. Log-rank tests were used to compare survival curves.

Univariate and multivariate Cox proportional hazard model analyses were performed with the following variables: stage at diagnosis; previous treatment by radiotherapy; number of previous chemotherapy lines; presence or absence of liver metastases; PS at the beginning of FOLFIRI regimen.

For exploratory purposes, subgroup analyses were performed according to the following variables: primary tumor location; stage at the diagnosis; previous treatment by surgery or radiotherapy; number of previous

RESULTS

Patients

Between January 2005 and May 2010, 63 patients with metastatic PAC fulfilled the criteria for this study. Their characteristics are shown in Table 1. Median age was 59 years (range: 24-81 years). Thirty three patients (52.4%) were male. The primary tumor was located in the head of the pancreas in 32/50 patients (64.0%). Twenty three patients (36.5%) had undergone prior surgery and 16 patients (25.4%) had received chemoradiotherapy. Twenty-seven patients (42.9%) were WHO PS 0, 24 patients (38.1%) were PS 1 and 12 patients (19.0%) were PS 2 at the beginning of the FOLFIRI regimen. Fifty one patients (81.0%) had liver metastases.

Before receiving the FOLFIRI regimen, patients had received one line (gemcitabine-oxaliplatin: n = 19, 30.2%), two lines (gemcitabine then FOLFOX regimen: n = 39, 61.9%) or three lines (n = 5, 7.9%) of chemotherapy. The previous line had been stopped for tumor progression in 55 patients (87.3%) and due to toxicity (oxaliplatin-related neuropathy) in the remaining 8 patients (12.7%).

Study treatment and drug delivery

Fifty five patients (87.3%) received the FOLFIRI-1 regimen and 8 patients (12.7%) received the FOLFIRI-3 regimen. A total of 480 cycles was completed (median: 6 cycles per patient, range: 1-51 cycles per patient).

The reasons for discontinuing the FOLFIRI regimen was progression in 56/62 patients (90.3%), toxicity in one patient (febrile neutropenia: n = 1, 1.6%), a tumor control ⩾ 6 mo or at the patient's request in 4 patients (6.5%), surgery in one patient (1.6%) who had a major response. Sixteen patients (25.4%) who remained in good condition at the time of FOLFIRI withdrawal received a subsequent line following the multidisciplinary proposal.

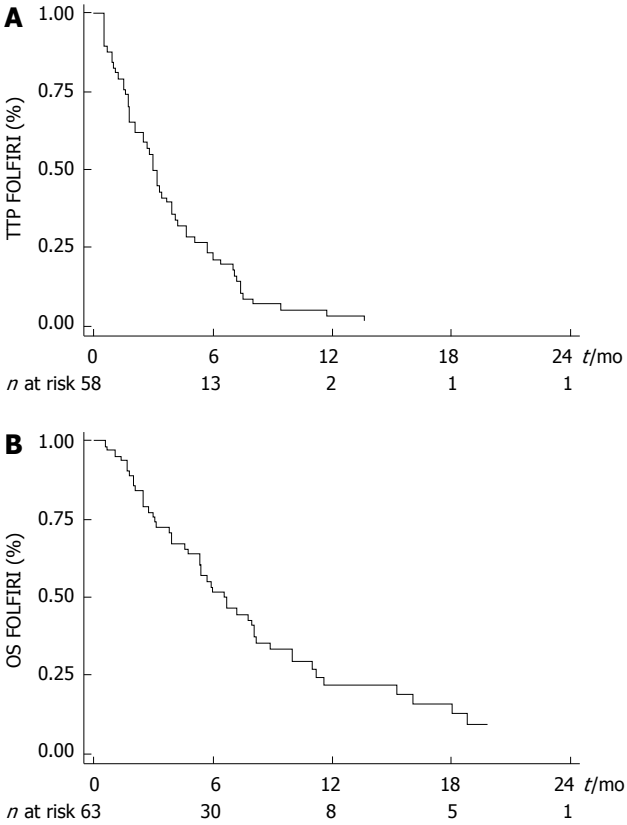

Figure 1 Time to progression (A) and overall survival (B) from the beginning of FOLFIRI for the 63 patients. TTP: Time to progression; OS: Overall survival.

Tumor response and survival

Median TTP obtained with the last line of chemotherapy before FOLFIRI was 3.9 mo (95% CI: 3.4-5.3 mo). Tumor control was obtained with the FOLFIRI regimen in 25 patients (39.7%) (CR: n = 0; PR: n = 5, 7.9%; SD: n = 20, 31.8%). ORR was 7.9% (5/63). Median TTP was 3.0 mo (95% CI: 2.1-3.9 mo) and median OS was 6.6 mo (95% CI: 5.3-8.1 mo) (Figure 1A and B).

Subgroup analysis

WHO PS was the only variable that was significantly associated with TTP and OS (Tables 2 and 3). Median TTP was 4.2 mo (95% CI: 3.2-7.0 mo) in PS 0 patients, 3.0 mo (95% CI: 1.8-4.1 mo) in PS 1 patients and 0.7 mo (95% CI: 0.5-1.5 mo) in PS 2 patients (Figure 2A). Median OS after the beginning of FOLFIRI was 8.2 mo (95% CI: 6.7-11.0 mo) in PS 0 patients, 5.4 mo (95% CI: 3.0-16.1 mo) in PS 1 patients and 2.5 mo (95% CI: 0.7-3.1 mo) in PS 2 patients (Figure 2B). PS 2 was significantly associated with a poor TTP [hazard ratio (HR) = 16.036, $P < 0.0001$] and OS (HR = 4.003, $P = 0.004$) in univariate analysis and in multivariate analysis also. No significant association was found between other variables and survival, except for the number of previous lines with TTP in multivariate analysis (Tables 2 and 3).

Dose adaptation and safety

Dose adaptation was required in 36 patients (57.1%).

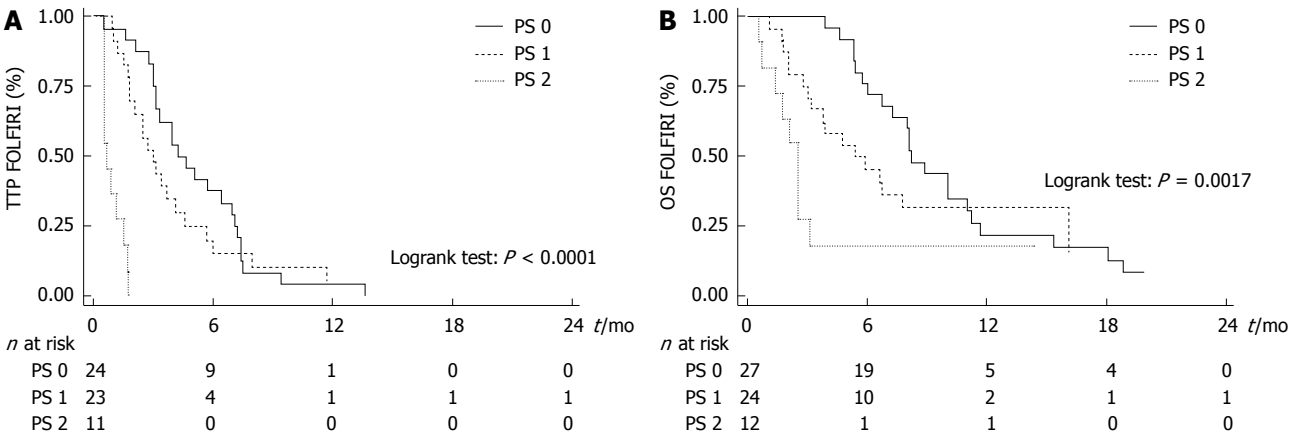

Figure 2 Subgroup analysis according to the World Health Organization performance status. A: Time to progression (TTP) according to World Health Organization (WHO) performance status (PS); B: Overall survival (OS) according to WHO PS.

The initial dose was reduced in 20 patients (31.7%) (19 patients who received the FOLFIRI-1 regimen and one patient who received the FOLFIRI-3 regimen) for the following reasons: cholestasis (n = 11), PS 2 (n = 8) or age > 75 years (n = 2), pre-existent diarrhea (n = 2) or mucositis (n = 1), and an episode of grades 3-4 hematological toxicity during previous chemotherapy (n = 1). A subsequent reduction was proposed in 19 patients (30.2%) (18 patients who received the FOLFIRI-1 regimen and one patient who received the FOLFIRI-3 regimen). Fifteen (23.8%) of these patients had grade 3-4 toxicities, mainly hematological (n = 11, 17.5%) and/or digestive with diarrhea and/or mucositis (n = 4, 6.3%). Febrile neutropenia occurred in 3 patients (4.8%). There were no related deaths.

DISCUSSION

We have evaluated the efficacy and safety of the FOLFIRI regimen after the failure of both gemcitabine and platinum salts in 63 patients with metastatic PAC treated in two centers. Tumor control was obtained in 39.7% of

patients. The median TTP was 3.0 mo and the median OS after the beginning of FOLFIRI was 6.6 mo. Toxicity was frequent with the FOLFIRI regimen (grade 3-4 toxicities in 23.8% of patients, mainly hematological and digestive) but manageable as only one patient had to stop treatment. In the subgroup analysis, the WHO PS was the only variable that was significantly associated with TTP (HR = 16.036, $P < 0.0001$) and OS (HR = 4.003, $P = 0.004$). Patients with WHO PS 2 may not benefit from this regimen.

Irinotecan-based chemotherapies have previously been tested in advanced PAC. Irinotecan was tested as a single agent in the first line setting in three phase Ⅱ trials with interesting results, showing an ORR of 9%-27% and a median OS of 5.2-7.3 mo[14-16]. However, two phase Ⅲ trials that tested irinotecan combined with gemcitabine as first-line chemotherapy did not show a significant benefit in TTP (2.8-3.5 mo) and OS (6.4-6.6 mo), despite a higher response rate than with standard gemcitabine (ORR: 15%-16%)[24,25]. A randomized phase Ⅱ study confirmed that the antitumoral activity of the combination of gemcitabine and irinotecan is similar to a regimen of fixed dose gemcitabine, gemcitabine/cisplatin or gemcitabine/docetaxel[26]. Thus, the gemcitabine/irinotecan combination does not seem to be synergistic. In contrast, the efficacy of the combination of irinotecan and 5-FU has been shown to be interesting with acceptable toxicity (Table 4)[20,27-29]. This is supported by *in vitro* and *in vivo* data showing synergy between these two drugs[17-19]. These regimens have not yet been tested in a phase Ⅲ trial compared with gemcitabine. Recently, a phase Ⅲ trial comparing the FOLFIRINOX regimen (folinic acid/5-FU, irinotecan and oxaliplatin combination) to gemcitabine as first-line treatment for metastatic PAC showed a significant improvement in survival with the FOLFIRINOX regimen with a median PFS and OS of 6.8 mo and 11.1 mo, respectively[7]. Toxicity was significant (grade 3-4 in 54% the patients) but manageable, and no toxic death occurred. Patients included in this study were in good condition (WHO PS 0-1). In addition, an absence of cholestasis was required for inclusion which probably explains the unusually high rate of body/tail tumor localization.

Irinotecan as a single agent has been shown to be a well-tolerated but marginally effective regimen in gemcitabine-pretreated patients. ORR was less than 10% and median OS did not exceed 4-6.6 mo[30,31]. The results with irinotecan-based combination regimens in gemcitabine-resistant advanced PAC were conflicting (Table 4)[32-37]. Data on irinotecan and 5-FU combination regimens in this setting are scarce. A randomized phase Ⅱ study evaluated modified FOLFIRI-3 *vs* modified FOLFOX (folinic acid/5-FU and oxaliplatin combination) in patients with gemcitabine-resistant advanced PAC. Efficacy was comparable with both regimens with a 6-mo OS rate of 27% (95% CI: 13%-46%) and 30% (95% CI: 15%-49%), respectively[21]. An Italian group reported a retrospective series of 40 patients with gemcitabine-

Table 4 Phase Ⅰ-Ⅱ studies of regimens as first and second lines chemotherapy in advanced pancreatic cancer

resistant locally advanced or metastatic PAC treated with the standard FOLFIRI-1 regimen[22]. As in our series, most patients were PS 0-1 (82.5%); 17.5% of patients had locally advanced PAC, while all patients in our series were metastatic. The efficacy was quite similar to our series: TCR: 50%, ORR: 15%, median TTP: 3.7 mo and median OS: 6 mo. In contrast, toxicity was higher, with 27% and 32% of grades 3-4 hematological and digestive toxicities respectively. Toxicity was more frequent in PS 2 patients (71%) than in PS 0-1 patients (45%). The difference in the incidence of severe toxicity between the two series was not due to a difference in the proportion of PS 2 patients (17.5% *vs* 19%). One explanation might be that the initial dose was frequently adapted in our series (31.7%), particularly in PS 2 patients (8/12, 66.7%). In contrast, there was no tumor control at 6 mo in a study using a combination of irinotecan and fluoropyrimidine (mostly capecitabine) in 34 patients, most of whom where PS 0-1, and only 6% of patients were alive 1 year after the beginning of this chemotherapy regimen[38]. Most patients (97%) had been pretreated with capecitabine. This suggests that the different dose intensity and administration schedule for fluoropyrimidine, as in the XELIRI regimen, and the synergy of capecitabine and irinotecan could not overcome possible acquired resistance to this drug.

Our current study is the largest retrospective series on chemotherapy with a combination of irinotecan and 5-FU in metastatic PAC after the failure of gemcitabine and platinum salts. It was a bi-center study with a homogenous population (metastatic, not locally advanced, PAC) and selection bias was reduced by the systematic treatment policy in both centers. However, patients were heterogeneous regarding the number of previous lines of chemotherapy or the type of FOLFIRI regimen. We could not compare the efficacy of the two FOLFIRI regimens due to the unequal distribution of patients between the two groups, with only 8 patients receiving the FOLFIRI-3 regimen. Moreover, this study included selected patients treated in high volume centers with teams that were experienced in the management of pancreatic tumors and their complications. Endoscopic procedures for the treatment of jaundice, a classic exclusion criteria for irinotecan (40%-60% of PAC), were easily accessible. Another possible bias was the high rate of previous surgery (32.9%). The natural history of operated patients might be more favorable than that of patients with unresectable PAC at diagnosis. The toxicity of the FOLIFIRI regimen was manageable, although dose adaptation was required in more than half of patients (57.1%). Only patients who are PS 0-1 seem to benefit from this regimen.

In conclusion, the FOLFIRI regimen is a valuable option in patients with metastatic PAC after failure of gemcitabine and platinum salts but should be considered for patients in good condition (WHO PS 0-1). Further studies are needed to determine whether FOLFIRI is a valuable option as first line therapy in advanced PAC.

ACKNOWLEDGMENTS

The authors thank Ms. Mélanie Gauthier for her help in the statistical analysis.

COMMENTS

Background

Pancreatic adenocarcinoma (PAC) is the fourth leading cause of cancer death in the Western countries. The overall prognosis of metastatic PAC remains poor with a 5-year survival rate of less than 5%. Gemcitabine is the reference first-line regimen for metastatic PAC treatment. About half of patients with metastatic PAC whose disease progresses under gemcitabine are eligible for subsequent line(s) of chemotherapy and there is no standard regimen in that setting. Preclinical and clinical studies have suggested that the combination of 5-fluorouracil (5-FU) and irinotecan (FOLFIRI regimen) may be beneficial in PAC. The research aimed to evaluate the efficacy and safety of FOLFIRI regimen in patients with metastatic PAC after the failure of gemcitabine and platinum salts.

Research frontiers

Tumor response rate, toxicity of irinotecan-based regimen, time to progression and overall survival were determined for the FOLFIRI regimen.

Innovations and breakthroughs

This is a homogeneous study of consecutive metastatic PAC patients treated by two experienced teams in the management of patients with pancreatic cancer. The present paper suggests that whereas the combination of gemcitabine and irinotecan was not effective enough, that of 5-FU and irinotecan appears to be beneficial regarding both efficacy and tolerability. In addition, the study series

provides original data about the appropriate target population for the irinotecan-based regimen, particularly taking into account the PS status.

Applications

Recently, the FOLFIRINOX schema, combining 5-FU, irinotecan and oxaliplatin, was shown to be superior to gemcitabine in a first-line setting, with an overall survival of 11.1 mo (95% CI: 9-13.1 mo) *vs* 6.8 mo (95% CI: 5.5-7.6 mo, hazard ratio = 0.57) ($P < 0.0001$), respectively, in selected patients (performance status 0-1, absence of cholestasis). However, due to the hematological toxicity of this combination, many patients are not eligible for first-line therapy. The sequence FOLFOX then FOLFIRI (or the reverse) may be an alternative and should be considered as being better tolerated.

Terminology

For treatment purposes, pancreatic tumors are generally classified as resectable, locally advanced, or metastatic. A locally advanced pancreatic cancer is a tumor involving the arterial axis (celiac trunk, mesenteric artery) and thus is not resectable despite no detectable metastases. This form of cancer should be distinguished from metastatic tumors as the prognosis is different (slightly better, and some patients can have surgical treatment in case of a good tumor response after chemotherapy) and separate analyses are needed. Thus, locally advanced PAC patients were excluded from the study.

Peer review

This is an interesting study in which authors evaluate the efficacy and safety of this regimen in patients with metastatic PAC after the failure of gemcitabine and platinum salts. The results are convincing and suggest that FOLFIRI regimen had an acceptable toxicity and an interesting efficacy in our study, limited to patients in good condition.

Abstract

AIM: To determine the efficacy of our therapeutic strategy for *Helicobacter pylori* (*H. pylori*) eradication and to identify predictive factors for successful eradication.

METHODS: From April 2006 to June 2010, we retrospectively assessed 2428 consecutive patients (1025 men, 1403 women; mean age 55 years, age range 18-92 years) with gastric histology positive for *H. pylori* infection referred to our unit for 13-C urea breath test (UBT), after first-line therapy with proton pump inhibitor (PPI) *b.i.d.* + amoxicillin 1 g *b.i.d.* + clarithromycin 500 mg *b.i.d.* for 7 d. Patients who were still positive to UBT were recommended a second-line therapy (PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + tinidazole 500 mg *b.i.d.* for 14 d). Third choice treatment was empirical with PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + levofloxacin 250 mg *b.i.d.* for 14 d.

RESULTS: Out of 614 patients, still *H. pylori*-positive after first-line therapy, only 326 and 19 patients respectively rechecked their *H. pylori* status by UBT after the suggested second and third-line regimens. "Per protocol" eradication rates for first, second and third-line therapy were 74.7% (95% CI: 72.7%-76.4%), 85.3% (95% CI: 81.1%-89.1%) and 89.5% (95% CI: 74.9%-103%) respectively. The overall percentage of patients with *H. pylori* eradicated after two treatments was 97.8% (95% CI: 97.1%-98.4%), *vs* 99.9% (95% CI: 99.8%-100%) after three treatments. The study found that eradication therapy was most effective in patients with ulcer disease ($P < 0.05$, $P = 0.028$), especially in those with duodenal ulcer. Smoking habits did not significantly affect the eradication rate.

CONCLUSION: First-line therapy with amoxicillin and clarithromycin produces an *H. pylori* eradication rate comparable or superior to other studies and second-line treatment can still be triple therapy with amoxicillin and tinidazole.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a bacterium that colonizes the stomach of about half the world's population and is considered the main cause of peptic ulcer[1,2] and mucosa-associated lymphoid tissue lymphoma[3,4]; furthermore it is an important risk factor for gastric adenocarcinoma[5,6] and also an associated factor for many gastric and non-gastric diseases[7]. *H. pylori* eradication is strongly recommended[8,9] in many clinical situations[10]. Different treatments have been proposed as effective[11,12] and meta-analyses are available comparing their results[13-15]. Prevalence of antibiotic resistance was found to be an important factor in the choice of the preferred regimen[16-19].

In particular, clarithromycin resistance is the strongest predictor of treatment failure[20,21]: in fact the eradication rate decreases below the recommended 80% threshold, when the prevalence of clarithromycin resistance reaches 15%-20%. On the other hand *in vitro* resistance to metronidazole may not accurately reflect resistance *in vivo*, and does not significantly affect the eradication rate[22]. In Northern Italy primary resistance to clarithromycin and metronidazole is reported to be 16.6% and 25.1% respectively[23].

The American College of Gastroenterology guidelines recommend first-line eradication with triple therapy consisting of a proton pump inhibitor (PPI), amoxicillin and clarithromycin. The European (Maastricht Ⅲ Consensus) guidelines recommend first-line eradication with triple therapy on account of clarithromycin/metronidazole resistance. According to both guidelines, second-line therapy should be a bismuth-based quadruple treatment while third-line treatment should be based on antimicrobial susceptibility testing[24].

Our Trust policy is to suggest an antibiotic regimen to outpatients referred to our unit for 13-C urea breath test (UBT), or esophagogastroduodenoscopy (EGD) with assessment of the *H. pylori* status and found to be *H. pylori*-positive. We do not usually prescribe a bismuth-based second-line therapy and we do not base the choice of the third-line therapy on antimicrobial susceptibility testing. The aim of the present study is to determine the efficacy of this strategy for *H. pylori* eradication.

MATERIALS AND METHODS

Setting

Our UBT outpatient clinic is the only existing one in the Health District of Reggio Emilia, serving about 500 000 people in North Italy. EGD is performed in six different public hospitals and in several private practices.

Patients

Our policy was to suggest an eradication therapy to the general practitioners of outpatients found to be *H. pylori*-positive after EGD or 13-C UBT performed at our Unit. Before examination (EGD or UBT), a brief medical history was obtained, including reason for investigation, allergy, past and ongoing treatments, and smoking habits. In patients undergoing EGD, if *H. pylori* status assessment was indicated, it was obtained by histology, according to the Sydney classification.

UBT was performed using an isotope ratio mass spectrometer (Breathmat, Bremen). A delta value > 3.5 over baseline was considered a positive result. All patients *H. pylori*-positive after EGD or UBT received a letter for their general practitioner reporting the result of the test, the recommended antibiotic regimen and the suggestion to further submit the patient to our UBT outpatient clinic to confirm *H. pylori* eradication, at least 8 wk after the end of treatment. Standard first-, second- and third-line antibiotic regimens are shown in Table 1. Alternative antibiotic regimens were suggested to patients with known allergy to a particular antibiotic. Each patient also received a form, where she/he was instructed to mark consumption of the drugs and to record any suspected adverse effect. Compliance with the proposed treatment and adverse effects were checked, on the occasion of the resubmission of the patient. Nevertheless no attempt was made to contact patients, who did not return to our UBT outpatient clinic and no information about them was actively sought. Data about patients and treatments were prospectively collected in a purpose-built database.

In the present observational retrospective study, we included 2428 outpatients (Table 2 shows their characteristics), who underwent UBT from April 2006 to June 2010, after positive histological assessment of *H. pylori* status and after first-line eradication therapy with PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + clarithromycin 500 mg *b.i.d.* for 7 d.

Ethics and endpoints

The study was conducted according to the declaration of Helsinki. All patients consented to UBT. Although patients were informed about the purpose and potential side effects of the suggested treatments, a formal consensus about therapy was not obtained, because the therapy was always finally prescribed by the general practitioner after further evaluation and discussion with the patient. Furthermore none of the medications were prescribed as part of a clinical trial and therefore there was no need for study approval by the ethics committee at our hospital. The primary endpoints of the study were eradication rates of the suggested antibiotic regimens, as calculated per protocol in patients, who were referred to our UBT outpatient clinic after each line of treatment. Secondary endpoints were: (1) percentage of patients, still *H. pylori*-positive after first-line therapy, who achieved

Table 1 Antibiotic regimens suggested by our unit and eradication rates per protocol

	Patients	*H. pylori* eradicated and eradication rate per protocol (95% CI)	Patients treated and cumulative effect (95% CI)
First-line: PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + clarithromycin 500 mg *b.i.d.* for 7 d	2428	1814 74.7 (72.7-76.4)	
Second-line: PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + tinidazole 500 mg *b.i.d.* for 14 d	326	278 85.3 (81.1-89.1)	2140 97.8 (97.1-98.4)
Third-line: PPI *b.i.d.* + amoxicillin 1 g *b.i.d.* + levofloxacin 250 mg *b.i.d.* for 14 d	19	17 89.5 (74.9-103)	2111 99.9 (99.8-100)

PPI: Proton pump inhibitor; b.i.d.: Twice daily; *H. pylori*: *Helicobacter pylori*. Standard dosages for PPIs are as follows: lansoprazole 30 mg, omeprazole 20 mg, pantoprazole 40 mg, rabeprazole 20 mg, esomeprazole 20 mg.

Table 2 Characteristics of patients who underwent urea breath test after treatment (%)

Patients characteristics	UBT after first-line therapy (2428 patients)	UBT after second-line therapy (326 patients)	UBT after third-line therapy (19 patients)
Women	1403 (58)	202 (62)	13 (68)
Men	1025 (42)	124 (38)	6 (32)
Mean age (range), yr	55 (18-92)	54 (21-86)	53 (27-80)
Peptic ulcer disease	202 (8.2)[1]	23 (7.1)	0
Previous gastric surgery and/or neoplasm	6 (0.2)[2]	3 (0.9)	0
Smokers	424/1082 (43.8)	59/287 (20.6)	3/17 (7.6)

[1]172 and 23 patients were found to be affected respectively by duodenal and gastric ulcer. 7 patients were affected by both gastric and duodenal ulcer; [2]1 patient was affected by low-grade mucosa-associated lymphoid tissue. Among the patients with a history of previous gastric surgery, 1 patient had undergone surgery for cancer, the others for peptic ulcer disease. UBT: Urea breath test.

H. pylori eradication, proved by UBT, at the end of study; and (2) factors predictive of successful eradication.

Statistical analysis

The data was analysed with SPSS v.18.0 (Chicago, Illinois United States). The significance level is 0.05. The data is summarized by the primary measures of central tendency and dispersion, as well as with frequencies and percentages with 95% CI. Pearson's Chi square and Fisher's exact test were used to compare frequencies, where appropriate.

RESULTS

The study flow chart is shown in Figure 1. Six hundred and fourteen patients (25.3%) were found to be *H. pylori*-positive to UBT, after the first-line antibiotic regimen.

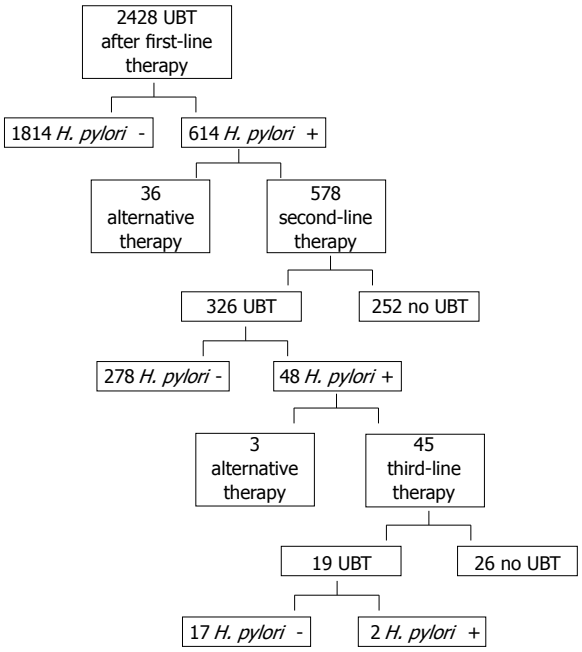

Figure 1 Flow chart of the study. UBT: Urea breath test; *H. pylori*: *Helicobacter pylori*.

Out of these patients, 326 (53.1%) were referred again to our unit to check eradication after second-line standard therapy. Out of the 48 still *H. pylori*-positive after second-line therapy, only 19 underwent UBT (39.6%).

An antibiotic regimen alternative to the second or third-line standard therapy was suggested by us, or by their general practitioner, to 40 patients (6.5%). Among the patients, who were referred to us for UBT, a small number reported a non-complete compliance with the received standard antibiotic regimen, because of side effects: this was the case in 13 patients (0.5%, 11 tested *H. pylori*-negative and 2 positive) during first-line therapy and in 9 patients (2.7%, all eradicated) during second-line therapy. Three out of 21 reported a previously unknown allergy to penicillin; all other side effects were minor (diarrhea, headache, metallic taste).

Eradication rates of the antibiotic regimen, as calculated in patients who subsequently checked *H. pylori* status by UBT, are reported in Table 1. The two patients who were still positive after the third treatment were advised to take bismuth-based quadruple therapy for 14 d and *H. pylori* was finally eradicated.

As shown in Table 3, peptic ulcer disease, but not smoking habits, was found to be predictive of successful eradication during first-line therapy. Stratifying patients according to the number of cigarettes smoked per day (data not shown), the eradication rate decreased proportionally to the increase in the number of cigarettes, though statistical significance was only borderline ($P = 0.056$).

Table 4 compares that characteristics of the patients who rechecked (297, 48.4%) or not (278) their *H. pylori* status, until the achievement of an UBT-proved *H. pylori*-negative status, or after the completion of third-line therapy, whichever came first.

Table 3 Factors investigated as potentially predictive of successful eradication (%)

Risk factor	Eradication rate	
	First-line antibiotic regimen	Second-line antibiotic regimen
Women	1029/1403 (73.3)	172/202 (85.1)
Men	785/1025 (76.6)	106/124 (85.5)
Peptic ulcer disease	167/206 (81.1)[1]	22/24 (91.7)
Non-ulcer disease	1647/2222 (74.1)[1]	54/71 (76.1)
Smokers	302/424 (71.2)	50/57 (94.7)
Non-smokers	1346/1 778 (75.7)	192/230 (83.5)

[1]Difference of frequencies: 6.9% (95% CI: 1%-12.8%, $P < 0.05$). If patients affected by duodenal ulcers is compared with patients with non-ulcer disease, the difference is 8.3% (95% CI: 2.3%-14.4%, $P < 0.05$).

Table 4 Characteristics of patients who rechecked or not their *Helicobacter pylori* status (%)

Patients characteristics	Rechecked their *H. pylori* status[1] (297 patients)	No recheck of their *H. pylori* status (278 patients)
Women/men	185 (62)/112 (38)	170 (61)/108 (39)
Mean age (range), yr	55 (21-86)	50 (20-92)
Peptic ulcer disease	21 (7)	17 (6)
Previous gastric surgery and/or neoplasm	2 (0.6)	1 (0.3)
Smokers	53 (20)	69 (27)

[1]Patient who rechecked their *Helicobacter pylori* (*H. pylori*) status, until the achievement of an urea breath test-proved *H. pylori*-status, or after the completion of the third-line therapy, whichever came first. Patients treated with alternative second and third-line antibiotic regimens are excluded.

DISCUSSION

In our study, patients were treated with first-line PPI-amoxicillin-clarithromycin therapy for 7 d only. A recent meta-analysis showed a minimal advantage of longer treatment[25].

All the different PPIs (omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole) are shown to be equally effective in combination with antibiotic therapy[26] and higher H2 receptor antagonists (ranitidine)[27]: therefore we left the choice of PPI to the general practitioner. We also advised general practitioners to prescribe the double dose of PPI, because it has proved more effective in a recent meta-analysis[28].

The eradication rate after first therapy was 74.7%. This rate is comparable to the 76% achieved by the same regimen (for 10 d of treatment) in a recent study from Greece[29] and it is higher than the 56% found in a study with 14 d of PPI-clarithromycin-metronidazole[30,31].

The European and American guidelines recommend a bismuth-based quadruple treatment as second-line therapy; according to Maastricht guidelines, a PPI-amoxicillin-metronidazole therapy could be used if bismuth is not available.

In Italy bismuth salts are often available, but we preferred to recommend PPI-amoxicillin-tinidazole as second-line therapy, because the bismuth-based quadruple regimen is associated with a relatively high incidence of side effects and a worse compliance than the triple regimen; although a recent meta-analysis shows no statistically significant differences[32]. The PPI-amoxicillin-metronidazole regimen was reported to be effective as second-line therapy to achieve eradication rates of 89% and 64% for metronidazole susceptible and resistant strains, respectively[33]. In our study, this second-line regimen obtained an eradication rate of 85.3%. These results are superior to data reported by others after unsuccessful first-line treatment for the same regimen, for the bismuth-based quadruple combination[34] and also for a levofloxacin-based therapy[35].

The Consensus Conference recommended third-line rescue treatment based on antimicrobial susceptibility testing. We preferred not to perform susceptibility testing, choosing an empirical triple therapy with levofloxacin.

Two meta-analyses have suggested that levofloxacin-based rescue regimen is more effective and safer than quadruple therapy[35,36]. Levofloxacin resistance develops rapidly and it is one of the most effective antibiotics in the treatment of respiratory tract infections. For these reasons, we reserved its use for third-line therapy. In our study, levofloxacin-based third-line therapy achieved an eradication rate of 89.5%. Although we observed these excellent results in a small group of patients, our findings are consistent with other experiences[29,36] and support the use of a levofloxacin-based regimen as empirical third-line therapy of *H. pylori* infection.

The overall eradication rate after two and three treatments, respectively, is proved to be 97.8% and 99.9%. These results confirm the data already published in literature (Table 5).

During first-line treatment, the efficacy of therapy in patients with peptic ulcer disease was higher (81.1%) than in patients with non-ulcer disease (74.1%). This finding is in agreement with others experiences[37-39] and could be explained by a larger number of antibiotic-resistant *H. pylori* strains in non-ulcer disease patients.

The study also assessed the influence of smoking on treatment: the eradication rate was moderately higher in non-smokers (75.7% *vs* 71.2%). Recent studies demonstrated that smoking affects the eradication rate[40,41]; in our larger report the trend is negative but not yet statistically significant.

It should be noted that our study is not a clinical trial, but a retrospective revision of our practice. This may explain its major limitation; that is the high number of patients (45.3%), who did not have their *H. pylori* status rechecked after failure of first-line therapy. We do not know whether these patients did not undergo any further treatment, or they stopped therapy because of adverse effects, or decided not to repeat UBT after completion of the suggested regimen. Nevertheless the regimens suggested in our studies are usually relatively well tolerated and we do not believe that the high percentage of our patients lost at follow up was due to adverse effects. In the setting of an open-access UBT facility,

Table 5 Studies reporting eradication rates and cumulative effect of different therapeutic strategies

	% Eradication rate (number of patients)				
	First-line	Second-line	Third-line	Cumulative effect (Ⅱ to Ⅲ line)	Antimicrobial susceptibility testing before third-line
Gasbarrini *et al*[41] 2000	86 (2413)	82 (329)	77 (39)	99	Yes
Beales[42] 2001	73 (469)	70-73 (66)	65 (20)	94-98	Yes
Qasim *et al*[40] 2005	77 (3280)	56 (270)	38 (28)		
Gisbert *et al*[32] 2008	70 (500)	74 (343)	76 (136)	99.5	No
Rokkas *et al*[28] 2009	76 (540)	73 (120)	70 (30)	98	No
Present study	75 (2428)[1,2]	85 (326)	89 (19)	97.8-99.9	No

[1]172 and 23 patients were found to be affected respectively by duodenal and gastric ulcer. 7 patients were affected by both gastric and duodenal ulcer; [2]1 patient was affected by low-grade mucosa-associated lymphoid tissue. Among the patients with a history of previous gastric surgery, 1 patient had undergone surgery for cancer, the others for peptic ulcer disease. UBT: Urea breath test.

Qasim *et al*[40] reported that only 25% of their patients *H. pylori*-positive after first-line therapy, were proved to have eradication of *H. pylori* after second-line therapy or have rechecked their *H. pylori* status by UBT after third-line therapy. A high compliance with repeated courses of therapy is reported in prospective clinical trials[29,41], but it is conceivable that it may be difficult to replicate these good results in common clinical practice. Data are lacking about strategies useful to reinforce compliance with *H. pylori* eradication therapy in this setting. It should be noted that a high percentage of our patients did not achieve a proved *H. pylori*-negative status, despite the fact that our policy avoided invasive testing (EGD) to obtain antimicrobial susceptibility testing and regimens requiring assumption of a lot of pills, such as bismuth-based quadruple therapy.

We believe that efforts to introduce new effective antibiotic regimens, should parallel not only the emergence of new resistance, but also the efforts to target appropriate antibiotic regimens to the majority of patients requiring *H. pylori* eradication therapy. Our policy to suggest to the general practitioner an antibiotic regimen for each patient found to be *H. pylori*-positive may be criticized and it could be not generally applicable. Nevertheless different models of collaboration between gastroenterologists and general practitioners should be tested to improve effectiveness of *H. pylori* infection therapy in current practice.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) is considered an important risk factor for many gastric and non-gastric diseases. Different treatments have been proposed as effective for *H. pylori* eradication and meta-analyses are available comparing their results. Prevalence of antibiotic resistance was found to be an important factor in the choice of the preferred regimen.

Research frontiers

The European (Maastricht Ⅲ Consensus) and American (American College of Gastroenterology) guidelines recommend a therapeutic strategy for *H. pylori* eradication with clarithromycin and metronidazole for 7-14 d or amoxicillin and clarithromycin for 10-14 d as first-line therapy. They also suggest bismuth-based quadruple second-line therapy and third-line therapy based on antimicrobial susceptibility tests.

Innovations and breakthroughs

In the present study, about 75% of patients were cured with first-line therapy (proton pump inhibitor + amoxicillin + clarithromycin), 97.8% after the second-line therapy (proton pump inhibitor + amoxicillin + tinidazole) and 99.9% after the third-line therapy (proton pump inhibitor + amoxicillin + levofloxacin). No statistical differences in eradication rates in smokers and non-smokers were found, even if there is a negative trend. Patients with ulcer disease had an eradication rate superior to that of patients with non-ulcer disease. This study was conducted in an open access setting and showed only about half of the patients still *H. pylori*-positive after first-line therapy were finally proved to have successful eradication of *H. pylori*.

Applications

The high eradication rates of this study suggest that a regimen simpler than quadruple drug therapy may be preferred as second-line therapy at least in some patients and in some regions; furthermore the antimicrobial susceptibility test (and the esophagogastroduodenoscopy involved) would not be necessary after two failed treatments. The fact that nearly half of our patients still *H. pylori*-positive after first-line therapy did not reach a urea breath test (UBT)-proved *H. pylori*-negative status, despite the use of effective antibiotic regimens, suggests that strategies should be devised and implemented to improve the access of patients to appropriate therapies and to strengthen the compliance of patients to these treatments.

Terminology

H. pylori is a bacterium that colonizes the stomach of about half the world's population and is considered the main cause of peptic ulcer and mucosa-associated lymphoid tissue lymphoma; furthermore it is an important risk factor for gastric adenocarcinoma and also an associated factor for many gastric and non-gastric diseases. *H. pylori* infection can be detected by esophagogastroduodenoscopy (a biopsy is taken during endoscopy and it is sent to the hospital laboratory to be examined for histology) or UBT. In the 13-C UBT, person fast for about 6 h. A baseline breath sample is collected (person blow into a test tube), then person drink a solution of Carbon-13-urea in water. A second breath sample is taken after 30 min and analyzed by a mass spectrometer. If *H. pylori* is present in the stomach the Carbon-13-urea will be broken down and Carbon-13 will appear in the breath.

Peer review

These authors conducted a retrospective epidemiology study on over 2428 patients who were positive for *H. pylori* looking to determine the efficacy of a therapeutic strategy for *H. pylori* eradication based on first-line therapy with amoxicillin and clarithromycin and second-line treatment with amoxicillin and tinidazole. The authors found that the eradication therapy was most effective in patients with ulcer disease, especially with duodenal ulcer during first-line therapy.

Abstract

AIM: To investigate the prognostic value of CD44 variant 6 (CD44v6), a membranous adhesion molecule, in rectal cancer.

METHODS: Altogether, 210 rectal cancer samples from 214 patients treated with short-course radiotherapy (RT, *n* = 90), long-course (chemo) RT (*n* = 53) or surgery alone (*n* = 71) were studied with immunohistochemistry for CD44v6. The extent and intensity of membranous and cytoplasmic CD44v6 staining, and the intratumoral membranous staining pattern, were analyzed.

RESULTS: Membranous CD44v6 expression was seen in 84% and cytoplasmic expression in 81% of the cases. In 59% of the tumors with membranous CD44v6 expression, the staining pattern in the invasive front was determined as "front-positive" and in 41% as "front-negative". The latter pattern was associated with narrower circumferential margin (P = 0.01), infiltrative growth pattern (P < 0.001), and shorter disease-free survival in univariate survival analysis (P = 0.022) when compared to the "front-positive" tumors.

CONCLUSION: The lack of membranous CD44v6 in the rectal cancer invasive front could be used as a method to identify patients at increased risk for recurrent disease.

INTRODUCTION

In 2008, approximately 1.2 million new cases of colorectal cancer (CRC) were diagnosed globally[1]. Preoperative radiotherapy (RT) for rectal cancer has improved local control rates[2], but patients may still present with fairly differing clinical responses and prognoses[3]. To improve

disease predictability, strong expectations have been placed on tumor markers.

CD44 is a family of transmembrane glycoproteins serving as a major receptor for hyaluronate, an important component of the extracellular matrix (ECM)[4]. *CD44* has been suggested to act both as a tumor-suppressing cofactor and as a growth- and invasiveness-promoting molecule[5] through its participation in many important cellular processes, including adhesion, growth regulation, survival, differentiation and motility[6]. Of the several isoforms produced by alternative splicing of the CD44 gene[7], variant 6 (CD44v6) has been intensely studied in relation to CRC progression and outcome[8].

Induction in CD44v6 expression is suggested to represent an early event in colorectal carcinogenesis[9], and has in some studies been related to disease progression, metastatic potential[7,9,10], and poor disease outcome[11]. Instead, in some other studies, stronger CD44v6 expression has been reported in adenomas than in carcinomas, as well as in primary carcinomas compared to metastatic tumors[12], and has been shown to have favorable[8,13] or no[14] effect on CRC outcome. Furthermore, strong expression has been shown to indicate more favorable response to chemotherapy[15].

In most of the previous studies on CD44v6 expression in colorectal tumors, both colonic and rectal carcinomas have been included. There is, however, some evidence that proximal and distal colonic lesions differ in their expression of CD44v6[16]. In those few studies including solely rectal tumors[17-19], CD44v6 has not been considered in relation to RT. In the present study, we examined the expression of CD44v6 immunohistochemically in a cohort of 214 primary rectal carcinomas treated with or without preoperative (chemo)radiotherapy. Considering the fundamental role of the tumor invasive front in tumor-host interaction[20], as well as the discrepant data on the prognostic value of the extent of CD44v6 expression in CRC[8,11,14], intratumoral staining pattern of this protein was also systematically assessed. We hypothesized that this aspect could offer additional information of the significance of CD44v6 expression in rectal cancer.

MATERIALS AND METHODS

Patients and study material

The material of this study consisted of formalin-fixed, paraffin-embedded tissue samples from 214 patients operated upon for rectal cancer at Turku University Hospital between 2000 and 2009. Operative samples were retrieved from the archives of the Department of Pathology, Turku University Hospital. To ensure a biologically and therapeutically homogeneous study population, only tumors of the middle and lower rectum were included. Superficial tumors treated with excision only, as well as patients with distant metastases at the time of diagnosis, were excluded. The use of archival tissue material was approved by the National Supervisory Authority for Welfare and Health (permission No. Dnro 1709/32/300/02, May 13th 2002).

Tumor staging was done according to the tumor node metastasis classification of malignant tumors, 2002[21]. Selection of treatment was based on preoperative tumor staging which included computed tomography (CT) or magnetic resonance imaging of the rectum, CT of the abdomen, and X-ray or CT of the chest. According to the common clinical guidelines[22], patients were treated either with short-course preoperative RT (n = 90), long-course preoperative (chemo) RT (n = 53), or received no treatment before surgery (n = 71). Short-course RT consisted of five 5-Gy fractions during 1 wk, with surgery on the following week. Long-course RT was given in 1.8-Gy fractions to a total dose of 50.4 Gy over a 6-wk period, with (n = 44) or without (n = 9) concomitant chemotherapy, and operation was performed at 5-7 wk after RT. Chemotherapy regimens were either bolus 5-fluorouracil (n = 5) or capecitabine (n = 39). Anterior resection was performed in 118 cases (55%), and abdominoperineal resection in 92 cases (43%). In four cases (2%), some other technique, such as low Hartmann's procedure, was used. The presence of vascular invasion was assessed in 159 cases, in which cancer cells could be detected in 47 cases (30%), either in the extramural lymphatic or blood vessels. Postoperative adjuvant chemotherapy was given to patients with lymph node positive or high-risk lymph node negative tumors according to the standard clinical practice[22]. The median follow-up time was 45.5 mo. In 61 patients (29%), local or distant disease recurrence was seen. Of them, 39 (64%) were treated with chemotherapy with or without biological treatments. Among these 39 cases, progression-free survival (PFS) was retrospectively defined from the medical records, and the median PFS was 20.7 mo. The key demographic and clinical characteristics of the patients are summarized in Table 1.

Immunohistochemistry

Four tumors with T0 after long-course RT were not stained, and accordingly, the actual study material consisted of 210 samples. The most representative blocks were selected and cut into 5-μm sections. Antigen retrieval was performed by heating in a microwave oven in 10 mmol/L sodium citrate, pH 6.0 two times for 7 min. Endogenous peroxidase activity was blocked by incubating the slides in 0.3% hydrogen peroxide in Tris-buffered saline. The sections were subjected to immunohistochemical staining with monoclonal antibody for CD44v6 (concentration 1:1000; Bender MedSystems, Vienna, Austria) and monoclonal mouse anti-cytokeratin (Ck-Pan) (clone: AE1/AE3, concentration 1:50; Zymed Laboratories, South San Francisco, CA, United States) using EnVision + Dual Link System - HRP (Dako, Denmark).

Evaluation of immunohistochemistry for CD44v6

Immunohistochemistry (IHC) staining was individually evaluated by two observers (Avoranta ST and Sundström

[1]Differences between the three treatment groups using Fisher's exact test; mean age with analysis of variance; [2]Includes the T3 tumors with threatened circumferential margin involvement; [3]Circumferential margin, data available in 164 cases. RT: Radiotherapy.

JTT) blinded to clinical data. Squamous basal cells of anal epithelium included in some of the cases were used as a positive control for CD44v6. Using 5×, 10× and 20 × objectives, the immunostaining of CD44v6 in every slide was assessed using the following parameters: (1) the extent of expression (membranous and cytoplasmic staining scored separately); (2) the intensity of expression (membranous and cytoplasmic staining scored separately); and (3) the intratumoral pattern of membranous CD44v6 expression. The extent of expression within the whole tumor area was analyzed using four categories: 1 for immunopositivity < 5%, 2 for 5%-20%, 3 for 21%-50% and 4 for > 50%. The intensity of expression was analyzed using four categories: 1 for negative staining; 2 for weak staining (a faint immunopositivity in the membrane or cytoplasm); 3 for moderate staining (a clear immunopositivity in the membrane or cytoplasm); and 4 for strong staining (a pronounced immunostaining in the membrane or cytoplasm equivalent to that of the basal cells of anal squamous epithelium). The intratumoral pattern of membranous CD44v6 expression was classified into three categories: 1 for immunopositivity mainly in the tumor invasive front; 2 for immunopositivity mainly in the tumor central areas; and 3 for heterogenous immunopositivity (no apparent difference in CD44v6 expression between the invasive front and central areas of tumor).

For statistical purposes, categories 1 and 2 were studied as one group and categories 3 and 4 as another group when analyzing the extent and intensity of expression. With regard to the intratumoral pattern of membranous staining, categories 1 and 3 were studied as one group ("front-positive"), and category 2 as in its own group ("front-negative").

Evaluation of tumor growth pattern

In order to evaluate tumor growth pattern, hematoxylin-eosin and Ck-Pan stainings were scrutinized in each operative sample. Using the Jass' classification of the tumor growth pattern, tumours were appointed as "expanding" when the invasive margin was pushing or reasonably well circumscribed, and "infiltrating" when the tumor invaded in a diffuse manner with widespread penetration into adjacent normal tissues[23].

Evaluation of tumor regression grade

Tumor regression grade (TRG) after long-course RT was defined by a pathologist (Sundström JTT) as poor, moderate or excellent according to the modified Dworak and Rödel scales, as described recently[24]. Briefly, poor TRG was defined as minimal or no tumor regression after (chemo) RT. In case of poor response, many tumor cells remained after treatment. In tumors with moderate response, there were only some tumor cells or tumor cell groups left in the primary tumor, lymph nodes or perirectal fat. In tumors with excellent response, few or no tumor cells could be detected.

Statistical analysis

Statistical analysis were run using IBM SPSS® Statistics 19.0.1 for Windows software. Frequency tables were analyzed using the χ^2 test, with the likelihood ratio (LR) or Fisher's exact test for categorical variables. 2 × 2 tables were used to calculate odds ratio and 95% CI using the exact method. Fisher's exact test, Spearman's correlation and LR were used to assess the significance of the correlation between individual variables in univariate analysis. Inter-observer reproducibility of the assessments was tested using weighted κ. It was calculated using the intraclass correlation coefficient (ICC) test, in parallel mode with a two-way random model, using consistency assumption and the average-measures option to interpret the ICC (95% CI). The ICC of assessments was very good with weighted κ ranging from 0.70 to 0.90.

Univariate survival analysis for disease-free survival (DFS) and disease-specific survival (DSS) was based on the Kaplan-Meier method where stratum-specific outcomes were compared using log-rank (Mantel-Cox) statistics. To adjust for the covariates, a Cox proportional

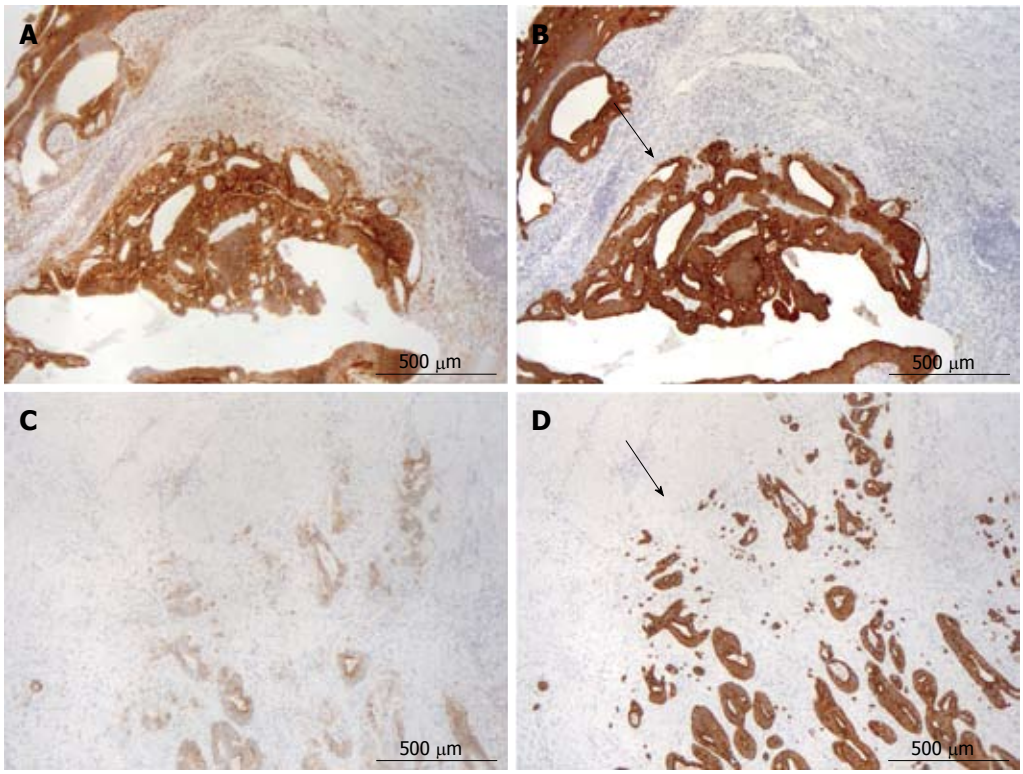

Figure 1 The immunohistochemistry for CD44 variant 6 and Pan-cytokeratin. A: The same tumor with "front-positive" membranous staining of CD44 variant 6 (CD44v6); B: Expanding growth pattern as shown with Pan-cytokeratin (Ck-Pan) staining; C: The same tumor with "front-negative" membranous staining of CD44v6; D: Infiltrating growth pattern as shown with Ck-Pan staining. Invasive front is indicated with arrows.

hazards regression model was used, covariates (as listed separately) being inserted using the enter mode. Of the variables significant in univariate analysis, two (circumferential margin, vascular invasion) were not included in the multivariate model because the data were incomplete. All statistical tests were two-sided and declared significant at a P value of < 0.05.

RESULTS

CD44v6 expression in tumors

Altogether, 177 out of 210 tumors (84%) showed membranous and 170 (81%) cytoplasmic CD44v6 expression. Both the extent and intensity of membranous and cytoplasmic staining were closely correlated ($r = 0.4$; $r = 0.31$, $P < 0.001$ for both). Of the 177 tumors with membranous CD44v6 positivity, 105 (59%) were "front-positive" (Figure 1A), usually showing an expanding growth pattern (Figure 1B), and 72 (41%) were "front-negative" (Figure 1C), usually showing an infiltrating growth pattern (Figure 1D).

Tumor growth pattern

In 206 tumors, a proper invasive front could be detected to evaluate tumor growth pattern. Altogether, 99 (48%) showed an expanding (Figure 1B) and 107 (52%) an infiltrating growth pattern (Figure 1D).

CD44v6 related to treatment groups and TRG

Only the extent of cytoplasmic staining was related to treatment group. Patients in the long-course RT group had less cytoplasmic CD44v6 expression in their tumors as compared to patients in the control group ($P = 0.002$). Within the long-course RT group, no differences in CD44v6 expression were seen according to concomitant chemotherapy. TRG after long-course RT, as analyzed also from the four tumors without IHC for CD44v6, was poor in 27 cases (51%), moderate in 14 cases (26%) and excellent in 12 cases (23%). No significant differences were seen in CD44v6 expression, as related to TRG.

CD44v6 related to clinicopathological variables

No significant differences were seen in the extent or intensity of CD44v6 expression concerning the variables listed in Table 1. With regard to the intratumoral pattern of membranous staining, "front-negative" was associated with narrower circumferential margin ($P = 0.01$), infiltrative tumor growth pattern ($P < 0.001$), and a greater risk for disease recurrence ($P = 0.01$ overall) as demonstrated in Table 2. No difference was seen in the number of patients receiving postoperative adjuvant chemotherapy between "front-positive" and "front-negative" groups ($P = 0.65$). Of the "front-positive" tumors, 37% were diagnosed before and 63% after 2005; the corresponding proportions for "front-negative" tumors being 22% and 78%, respectively ($P = 0.035$). No other significant correlations were seen between the staining pattern and clinicopathological variables, including PFS.

Recurrence and survival analysis

In univariate survival (Kaplan-Meier) analysis, no differences in DFS or DSS were seen according to the extent or intensity of CD44v6 expression, neither membranous nor cytoplasmic (data not shown). DFS ($P = 0.022$), but not DSS ($P = 0.68$), in patients with "front-negative" tumors was significantly shorter than in patients with "front-positive" tumors (Figure 2A and B). The same trend/difference was also seen in the short-course RT and control groups ($P = 0.058$ and $P = 0.024$ for difference in DFS, respectively) when analyzing treatment subgroups separately. With regard to tumor growth pattern, infiltrating tumors had shorter DFS ($P = 0.015$), and a tendency towards a shorter DSS ($P = 0.14$), as compared to expanding tumors.

The results of multivariate analysis are summarized in Table 3. The independent adverse prognostic factors for DFS were male sex, high postoperative T and the presence of positive lymph nodes, and those for DSS were patient age, postoperative T4, poor differentiation grade and disease recurrence.

DISCUSSION

Loss and gain of adhesive functions play an essential role in the progression of epithelial neoplasms[25]. In the present study, the expression of CD44v6, a cell surface mediator of cell-to-ECM adhesion[4], was systematically studied in a cohort of 214 primary rectal carcinomas treated with or without preoperative RT. The actual extent of CD44v6 expression was not associated with disease progression or outcome, but the analysis of its intratumoral staining pattern showed that patients with "front-negative" staining pattern had a significantly shorter DFS.

In our series, both membranous and cytoplasmic staining of CD44v6 was present in most cases, with a strong mutual correlation as reported earlier[8]. We found that preoperative RT affected cytoplasmic but not membranous CD44v6 expression. Although membranous CD44v6 is known to bind extracellular hyaluronate and growth factors[5], the biological significance of cytoplasmic CD44v6 is rather unknown[8]. In some studies it has been considered to have no functional roles[8], whereas in others, it has been related to neoplastic transformation[12,26] suggesting a role in loss of differentiation[26]. As preoperative RT has been shown to cause remarkable histological alterations[27], the reason for a decrease in cytoplasmic CD44v6 expression after RT could reflect these histological changes. However, further studies are required to elucidate this suggestion.

The prognostic value of CD44v6 expression, regarding the extent of expression, has been studied with inconclusive results in CRC[8,11,14]. In accordance with Morrin *et al*[14], we found no differences in disease progression indicators and patient outcome according to the

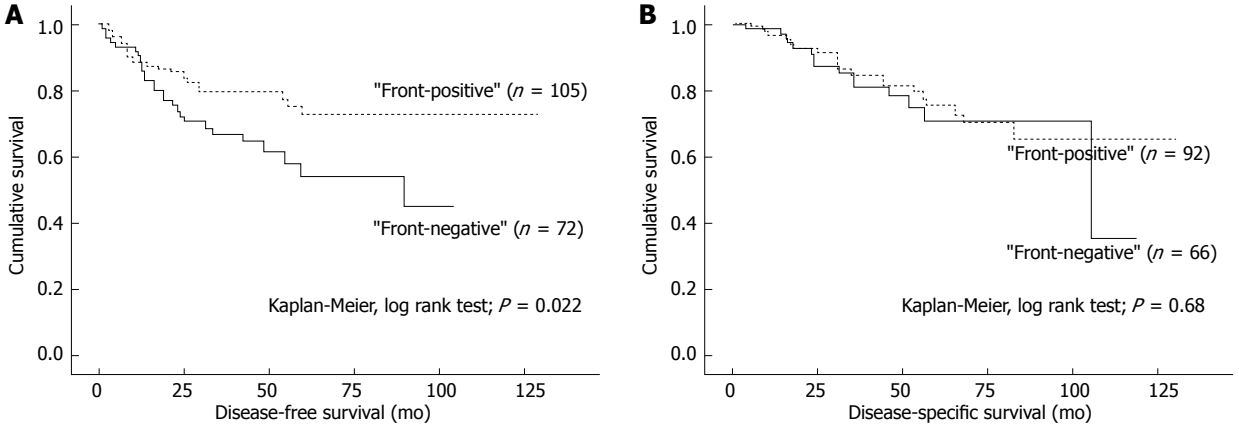

Figure 2 CD44 variant 6 related to disease-free and disease-specific survival in univariate analysis. Disease-free survival (A) and disease-specific survival (B) according to "front-positive" and "front-negative" membranous staining pattern of CD44 variant 6.

extent of CD44v6 expression. This finding is in contrast with some recent studies on rectal tumors, in which high membranous CD44v6 expression was shown to be associated with local recurrence[19] as well as shorter DFS[17-19] and DSS[17,18]. In contrast to these studies, we also included preoperatively treated tumors in our study to assess the possible relation of CD44v6 expression to TRG. This dissimilar study design may explain some of the discrepancy even though we found no differences in membranous CD44v6 expression parameters between the treatment or TRG-groups. In addition, the discrepancy may originate from differences in antibodies, cut-off points as well as disease subtypes in different studies as earlier discussed by Naor *et al*[28].

In addition to the extent of CD44v6 expression, we also assessed the intratumoral staining pattern of membranous expression. Given that tumor-host interaction at the invasive CRC front is thought to represent a dynamic interface between pro- and antitumor factors[20], it is not surprising that abnormalities in cell adhesion functions are seen in this compartment[29,30]. Although loss of membranous CD44v6 expression towards the CRC invasive front has been reported[8,12], our study is, to our knowledge, the first to assess the relation of membranous CD44v6 staining pattern to rectal cancer outcome. Furthermore, some of the previous studies are based on tissue microarray analyses, questioning the reliability of invasive front detection. Interestingly, "front-negative" tumors were related to more narrow postoperative circumferential margin and infiltrative tumor growth pattern as compared to "front-positive tumors" with apparent CD44v6 expression in the invasive front. Previously, Ishida[31] and Zlobec *et al*[8] with their co-workers have shown weak/negative CD44v6 expression to be related to infiltrating growth pattern, as assessed by its overall extent irrespective of its localisation. Our results may indicate that more important than the actual quantity of CD44v6 expression is, indeed, its localisation within the tumor. It is possible that "front-negative" tumors are more difficult for surgeon to resect with wide margins as they grow in a more diffuse manner, explaining the more narrow margins seen in these lesions.

Our observations lend support to the view of Zlobec *et al*[8], and Coppola *et al*[12], suggesting that the loss of membranous CD44v6 at the advancing edge of the tumor results in defective binding of the tumor cells to ECM, increasing their mobility and metastatic potential[8,12]. Further supporting this view, treatment with hyaluronic acid has recently been shown to delay the growth of residual colon carcinoma cells after chemotherapy[32]. Indeed, CD44v6 is known to have a higher affinity for hyaluronate, as compared to standard CD44[33], and, CD44v6-expressing tumors cells could be more effectively entrapped within the hyaluronic acid at the primary site[12]. In addition to binding with extracellular hyaluronate, membranous CD44v6 expression in the invasive front may also be important due to its intercellular adhesion properties, because loss of CD44v6 expression has been correlated to the loss of E-cadherin expression[8].

Importance of the localization of CD44v6 expression was further supported by the fact that "front-negative" tumors more often developed recurrent disease with shorter DFS as compared to patients with "front-positive" tumors. This was also observed in the subgroup analysis for the control group, and with a similar trend in the short-course RT group. No such appearance was seen in the long-course RT group, possibly due to the smaller number of cases available for this assessment. In some of the long-course RT cases, few tumor glands were left after treatment, and for this reason, no evident invasive front could be detected. However, despite this evident difference in DFS between the patients with "front-positive" and "front-negative" tumors, these two groups had practically identical DSS, which, due to the differences in the year of diagnoses between these two groups, could reflect the improvements in the treatment of recurrent rectal cancer.

The staining pattern of CD44v6 lost its significance in multivariate analysis. As in a number of other studies[34], we also found infiltrating tumor growth pattern to suggest an adverse DFS and a tendency towards a shorter DSS. The close correlation of CD44v6 staining

pattern with this prognostic factor may at least partly explain the lack of CD44v6 as an independent prognostic factor in our study. In addition, the other functions of this protein, such as binding of growth factors[35], may subvert the advantage of "front-positive" tumors.

Taken together, we found that tumors with "front-negative" CD44v6 membranous staining pattern were strongly related to invasive behavior. Our results substantiate the hypothesis that the lack, rather than overexpression, of membranous CD44v6 in the invasive tumor front contributes to rectal cancer progression. Although associated with a shorter DFS in univariate analysis, "front-negative" phenotype did not prove to be an independent prognostic factor in multivariate analysis, possibly confounded by other prognostic factors, including tumor growth pattern. We propose that analyzing the intratumoral staining pattern of membranous CD44v6 could offer a simple tool to predict the patients at increased risk for disease recurrence and thus in need of more aggressive postoperative treatment approaches and close monitoring.

COMMENTS

Background

Colorectal cancer is a common malignancy. Radiotherapy alone or in combination with chemotherapy has been used to lower the risk of local recurrence. Still, a significant proportion of patients comes down with disease recurrence that is challenging to treat and causes harmful symptoms. New prognostic markers are constantly being studied to identify better the patients who need more aggressive treatment approaches in addition to surgery. CD44 variant 6 (CD44v6), a cell membrane receptor binding extracellular components, has been demonstrated to associate with rectal cancer progression and prognosis, but with discrepant results.

Research frontiers

In many studies, CD44v6 has been suggested to play a role in tumor progression and metastasis. The important area in the work was to study whether there is a difference in rectal cancer prognosis according to the intratumoral staining pattern of CD44v6. In contrast to previous studies, authors also included patients treated with radiotherapy before surgery.

Innovations and breakthroughs

The previous studies on the percentage and intensity of CD44v6 expression in rectal cancer have not been conclusive with regard to prognosis, because the overexpression of this protein has been associated with both favorable and adverse survival. Although alteration of CD44v6 expression in tumor invasive front has been demonstrated, its association with rectal cancer prognosis has not been studied in detail. Interestingly, the authors found that the patients with tumors showing CD44v6 expression in the invasive front presented with a longer disease-free survival time than did the patients whose tumors expressed protein more centrally. Moreover, the latter "front-negative" type was associated with infiltrating tumor growth and narrow tumor-free margin, both known to be adverse prognostic factors. Instead, the authors did not find the percentage and intensity of CD44v6 staining to be related to disease prognosis. The authors concluded that for rectal cancer progression and prognosis, more important than the actual amount of CD44v6 might be its distribution within the tumor.

Applications

The study suggests that patients with "front-negative" rectal cancer may need more aggressive treatment and monitoring after surgery.

Terminology

Prognostic factor is a situation or a condition, or a characteristic of a patient, that can be used to estimate the chance to recover from a disease or the risk for the disease recurring. Invasive front is the interface of tumor and host tissue; the deepest rim of cancerous tissue grown in adjacent non-cancerous tissues.

Peer review

In this work, the authors investigated the prognostic value of CD44v6 in patients treated with/without preoperative radiotherapy. The results are interesting and suggest that the lack of membranous CD44v6 in the rectal cancer invasive front could be used as a method to identify patients at increased risk for recurrent disease. The article is generally well written.

Abstract

AIM: To reveal the frequency, characteristics and prognosis of chronic intestinal pseudo-obstruction (CIP) in mitochondrial disease patients.

METHODS: Between January 2000 and December 2010, 31 patients (13 males and 18 females) were diagnosed with mitochondrial diseases at our hospital. We conducted a retrospective review of the patients' sex, subclass of mitochondrial disease, age at onset of mitochondrial disease, frequency of CIP and the age at its onset, and the duration of survival. The age at onset or at the first diagnosis of the disorder that led to the clinical suspicion of mitochondrial disease was also examined.

RESULTS: Twenty patients were sub-classified with mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS), 8 with chronic progressive external ophthalmoplegia (CPEO), and 3 with myoclonus epilepsy associated with ragged-red fibers (MERRF). Nine patients were diagnosed with CIP, 8 of the 20 (40.0%) patients with MELAS, 0 of the 8 (0.0%) patients with CPEO, and 1 of the 3 (33.3%) patients with MERRF. The median age (range) at the diagnosis and the median age at onset of mitochondrial disease were 40 (17-69) and 25 (12-63) years in patients with CIP, and 49 (17-81) and 40 (11-71) years in patients without CIP. During the survey period, 5 patients (4 patients with MELAS and 1 with CPEO) died. The cause of death was cardiomyopathy in 2 patients with MELAS, cerebral infarction in 1 patient with MELAS, epilepsy and aspiration pneumonia in 1 patient with MELAS, and multiple metastases from gastric cancer and aspiration pneumonia in 1 patient with CPEO.

CONCLUSION: Patients with CIP tend to have disorders that are suspected to be related to mitochondrial diseases at younger ages than are patients without CIP.

Characteristics of intestinal pseudo-obstruction in patients with mitochondrial diseases. *World J Gastroenterol* 2012; 18(33): 4557-4562 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i33/4557.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i33.4557

INTRODUCTION

Intestinal pseudo-obstruction was first reported by Dudley *et al*[1] in 1958, and refers to an uncommon disabling motility syndrome characterized by severe symptoms and signs of intestinal obstruction (abdominal pain, abdominal distention, nausea, and vomiting) and radiographic evidence of a dilated bowel in the absence of any mechanical obstruction. Pseudo-obstruction is primarily considered a small-intestine motility disorder, but it may occur in any portion of the gastrointestinal tract[2-6]. Furthermore, pseudo-obstruction may occur as an acute disease (Ogilvie syndrome[7]) or as a chronic remitting or persistent disorder, and chronic intestinal pseudo-obstruction (CIP) can be caused by and complicate many disorders[2]. Primary CIP can be sub-classified into visceral myopathy, visceral neuropathy and idiopathic CIP based on its histopathological manifestations. According to its etiology, secondary CIP can be categorized as disease-induced (such as connective tissue disorders, muscular dystrophies, infiltrative diseases, mitochondrial diseases, generalized nerve disease, endocrine disease, metabolic disease and others)[8-12] or drug-induced (antidepressant and anti-anxiety drugs, phenothiazines and others)[13-16].

Although an algorithm for the diagnosis of CIP was proposed by Rudolph *et al*[2] in 1997, diagnostic criteria for CIP have not yet been established in Japan or worldwide. Recently, Iida *et al*[17] proposed the diagnostic criteria for CIP shown in Table 1 and reported a diagnostic sensitivity of 85.9%.

Mitochondrial diseases are a heterogeneous group of disorders associated with mutations or deletions of nuclear or mitochondrial DNA[18-22]. Genetic mutations or deletions result in multisystem involvement associated with defects in the oxidative phosphorylation system and impaired production of ATP. The degree of organ dysfunction is contingent on the energy requirement of the organ and the proportion of mutated mitochondrial DNA in the organ[18]. Encephalomyopathy and cardiomyopathy are frequently encountered manifestations of mitochondrial diseases, and recently, gastrointestinal dysmotility has received attention[23-26]. Chinnery *et al*[27] reported that over 15% of patients with mitochondrial diseases complain of dysphagia or constipation, and a small percentage of the cases with constipation develop intestinal pseudo-obstruction. Although Amiot *et al*[28] reported that 19% of 80 patients with CIP had mitochondrial defects, the relationship between CIP and mitochondrial disease has not yet been conclusively established.

The aim of this study was to determine the frequency, characteristics, and prognosis of CIP in patients with mitochondrial diseases.

MATERIALS AND METHODS

Between January 2000 and December 2010, 33 patients were diagnosed with mitochondrial diseases at the Yokohama City University School of Medicine. Their clinical and treatment data were collected from their medical records and 2 patients were excluded due to insufficient clinical data.

Diagnosis of mitochondrial disease

The plasma and cerebrospinal fluid levels of lactate and pyruvate were measured at rest and then re-evaluated under exercise stress to ensure that the levels were within the normal ranges. Muscle biopsies and genetic analyses were performed in all patients. Examinations for other component disorders of mitochondrial dysfunction, such as glucose intolerance, electrocardiography, echocardiography, and brain magnetic resonance imaging were performed as needed.

Ethical approval

This study was conducted in accordance with the declaration of Helsinki, and with the approval of the Ethics Committee of Yokohama City University School of Medicine. We obtained written informed consents from each of the patients.

Statistical analysis

We conducted a retrospective review of each patient's sex, subclass of mitochondrial disease, age at the onset of mitochondrial disease, age at the establishment of the diagnosis of mitochondrial disease, frequency of CIP and the age at onset, and the duration of survival. The age at onset or at the first diagnosis of the disorder that led to the clinical suspicion of mitochondrial disease was also examined. As controls, we collected the data of 57 patients who were diagnosed with progressive muscular dystrophy at the Yokohama City University School of Medicine between January 2007 and December 2011. Five of the patients were excluded due to insufficient clinical data.

RESULTS

Thirty-one patients with mitochondrial diseases underwent detailed assessment (Table 2). The subjects comprised 13 males and 18 females and were sub-classified as having mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS; $n = 20$), chronic progressive external ophthalmoplegia (CPEO; $n = 8$), or myoclonus epilepsy associated with ragged-red fibers

Table 1 Criteria for the diagnosis of chronic intestinal pseudo-obstruction

Must include
One or more symptoms of ileus[1] onset at least 6 mo prior to diagnosis
One or both of following for the last 12 wk: (1) Abdominal pain; (2) Abdominal bloating
Dilatation and/or air-fluid levels of the intestine on abdominal X-ray, echo and/or computed tomography imaging
No evidence of structural disease (including findings of upper endoscopy, lower endoscopy, computed tomography, barium enema, and small-bowel follow-through) that could explain dilatation and/or air-fluid levels of the intestine
Supportive criteria
Congenital and/or onset under 15 years old must be excluded. Only adult onset is included
Surgical history within the 6 mo prior to diagnosis must be excluded to rule out Ogilvie syndrome, except surgery for CIP
To define CIP at two levels: Primary CIP or secondary CIP. Primary CIP consists of three types: the muscular type, neurogenic type and idiopathic type; Secondary CIP consists of two types: the systemic sclerosis (SSc) type and unclassified type
Family accumulation may exist
Neuropathy such as problems with urination may exist
Some psychosocial disorder may be present

[1]Symptoms of ileus include: Abdominal pain, nausea, vomiting, abdominal bloating, abdominal fullness, lack of defecation and/or passing gas. CIP: Chronic intestinal pseudo-obstruction.

Table 2 Age at the oncet of mitochondrial disease and chronic intestinal pseudo-obstruction

Sex	Subclass	Age at the onset of mitochondrial disease, yr	Age at the diagnosis of mitochondrial disease, yr	Age at the diagnosis of CIP, yr
F	MELAS	Difficulty in walking at 40	40	40
M	MELAS	Glucose intolerance at 13	57	46
M	MERRF	Difficulty in walking at 41	50	50
F	CPEO	Palpebral ptosis at 71	81	-
F	MELAS	Impaired hearing at 45	54	-
M	MELAS	Impaired hearing at 24	29	-
M	CPEO	Palpebral ptosis at 40	69	-
F	CPEO	Impaired eye movement at 30	52	-
F	MELAS	Impaired hearing at 25	40	43
M	CPEO	Palpebral ptosis at 49	49	-
F	MERRF	Muscular weakness at 46	54	-
M	MELAS	Impaired hearing at 47	52	-
M	MELAS	Epilepsy at 11	18	-
M	CPEO	Glucose intolerance at 40	67	-
M	MELAS	Impaired hearing at 24	31	-
F	MELAS	Impaired hearing at 12	17	25
F	MELAS	Impaired hearing at 54	60	-
F	MELAS	Epilepsy at 40	44	-
M	MELAS	Glucose intolerance and impaired hearing at 18	18	-
F	MELAS	-	23	-
F	MELAS	Chronic diarrhea at 26	40	-[1]
F	MELAS	Epilepsy at 18	18	26
F	MELAS	Difficulty in walking and hearing at 63	69	69
F	MELAS	Glucose intolerance at 33	42	55
M	CPEO	Palpebral ptosis at 16	44	-
M	MELAS	Epilepsy at 29	29	-
F	CPEO	Palpebral ptosis at 13	17	-
F	CPEO	Palpebral ptosis at 59	59	-
M	MELAS	Epilepsy at 21	21	34
F	MELAS	Glucose intolerance at 46	48	-
F	MERRF	Difficulty in walking at 20	50	-

[1]This patient died of uncontrolled epilepsy and aspiration pneumonia 5 mo after the onset of intestinal pseudo-obstruction and did not fulfill the diagnostic criteria. M: Male; F: Female; CIP: Chronic intestinal pseudo-obstruction; MERRF: Myoclonus epilepsy associated with ragged-red fibers; MELAS: Mitochondrial encephalopathy with lactic acidosis and stroke-like episodes; CPEO: Chronic progressive external ophthalmoplegia.

(MERRF; n = 3). Of the 31 patients, 9 (28.1%) were diagnosed with CIP based on Nakajima's criteria, including 8 of the 20 (40.0%) patients with MELAS, 0 of the 8 (0.0%) patients with CPEO, and 1 of the 3 (33.3%) patients with MERRF. One patient died of uncontrolled epilepsy and aspiration pneumonia 5 mo after the onset of intestinal pseudo-obstruction and did not fulfill the diagnostic criteria.

The confirmable outcomes were as follows: in December 2010, 14 patients were receiving outpatient treatment, 12 patients had been transferred to chronic care facilities, and 5 patients (4 patients with MELAS and 1 with CPEO) had died. The cause of death was cardiomyopathy in 2 patients with MELAS, cerebral infarction in 1 patient with MELAS, epilepsy and aspiration pneumonia in 1 patient with MELAS, as previously described, and multiple metastases from gastric cancer and aspiration pneumonia in 1 patient with CPEO.

In radiographic examinations for the 9 patients with CIP, small intestinal distention was observed in 6 patients, and large intestinal distention was observed in 1 patients. Both small and large intestinal distention was observed in 2 patients.

The median age (range) at the establishment of the diagnosis of mitochondrial disease was 40 (17-69) years in patients with CIP and 49 (17-81) years in patients without CIP. The median age (range) at the onset or at the first diagnosis of the disorder that led to the suspicion of mitochondrial disease was 25 (12-63) years in patients with CIP and 40 (11-71) years in patients without CIP.

The symptoms of CIP were treated with laxative agents, antidiarrheal drugs, antiflatulence agents, mosapride, dimethicone, pantothenic acid, daikenchuto (Chinese herbal medicine), neostigmine or distigmine, and none of the patients required surgery (Table 3).

As controls, we collected the data of 57 patients with progressive muscular dystrophy (Table 4). The patients consisted of 2 patients with Duchenne muscular dystrophy, 7 patients with Becker muscular dystrophy, 4

Table 3 Characteristics of chronic intestinal pseudo-obstruction in patients with mitochondrial diseases

Sex	Subclass	Type of abdominal discomfort	Area of dilated intestine	Treatment
F	MELAS	Nausea, vomiting, diarrhea, constipation	Small intestine	PEG, neostigmine
M	MELAS	Diarrhea	Small intestine	Antidiarrheal drug
M	MERRF	Pain, diarrhea, distension	Small and large intestines	Mosapride, dimethicone, antiflatulent, daikenchuto, pantothenic acid
F	MELAS	Diarrhea, constipation, distension	Small and large intestines	Mosapride, daikenchuto, magnesium oxide
F	MELAS	Nausea, vomiting, diarrhea, constipation, pain	Small intestine	PEG, antiflatulent, magnesium oxide, antidiarrheal drug
F	MELAS	Nausea, vomiting, constipation, pain	Small intestine	Prostarmon, magnesium oxide, dimethicone, daikenchuto, mosapride, neostigmine, sodium picosulfate hydrate
F	MELAS	Nausea, vomiting, distension	Small intestine	Magnesium oxide, daikenchuto
F	MELAS	Nausea, vomiting	Large intestine	Daikenchuto, sennoside
M	MELAS	Nausea, vomiting, diarrhea, distension	Small intestine	Daikenchuto, mosapride, magnesium oxide, lansoprazole, neostigmine, dimechicone

M: Male; F: Female; CIP: Chronic intestinal pseudo-obstruction; MERRF: Myoclonus epilepsy associated with ragged-red fibers; MELAS: Mitochondrial encephalopathy with lactic acidosis and stroke-like episodes; PEG: Polyethylene glycol.

Table 4 Characteristics of chronic intestinal pseudo-obstruction in patients with progressive muscular dystrophy

Subclass	No. of patients	No. of females	Age at the onset[1]	Age at the diagnosis[1]
Duchenne muscular dystrophy	2	0	1	2 (1-3)
Becker muscular dystrophy	7	0	10 (1-30)	19 (6-43)
Limb-girdle muscular dystrophy	4	1	22.5 (5-40)	49 (10-53)
Facio-scapulo-humeral muscular dystrophy	1	1	NS	NS
Myotonic dystrophy	38	18	30 (5-62)	39 (12-67)
Total	52	20	25 (1-62)	34.5 (1-67)

[1]Data is presented as median age (range). NS: Not stated. None of the patients with progressive muscular dystrophy in this study fulfilled the diagnostic criteria of chronic intestinal pseudo-obstruction.

patients with limb-girdle muscular dystrophy, 1 patient with facio-scapulo-humeral muscular dystrophy and 43 patients with myotonic dystrophy (5 patients were excluded due to insufficient clinical data). The median age (range) at the establishment of the diagnosis of progressive muscular dystrophy was 34.5 (1-67) years and the median age (range) at the onset of progressive muscular dystrophy was 25 (1-62) years. Only 2 of the patients died, while the others were alive at the last hospital visit. Although progressive muscular dystrophy has been considered as one of the etiologies of CIP, none of the patients with progressive muscular dystrophy in this study fulfilled the diagnostic criteria of CIP.

DISCUSSION

Although mitochondrial diseases have been considered as a potential cause of secondary CIP, the frequency of CIP in patients with mitochondrial diseases has not yet been well established. Gastrointestinal dysmotility (including CIP) may be caused by the accumulation of intracellular long-chain fatty acids, activation of extramitochondrial fatty acid oxidation pathways and excessive generation of reactive oxygen species leading to visceral myopathy, possibly as a result of impaired mitochondrial beta-oxidation[29]. Betts *et al*[30] reported that profound COX deficiency was found in the smooth muscle layers of all regions of the gastrointestinal tract in patients with the m.3243A>G mutation despite scarce evidence of morphologic abnormalities within the gastrointestinal tissues of these patients. Parsons *et al*[31] also reported that 80% of patients with MELAS and more than 60% of m.3243A>G carriers have 1 or more autonomic symptoms; gastrointestinal symptoms were especially common in the MELAS group, occurring in 66% of these patients and in almost 40% of the mutation carriers. In mitochondrial diseases, mitochondrial neurogastrointestinal encephalopathy (MNGIE), which is an uncommon autosomal recessive syndrome caused by the reduced activity of thymidine phosphorylase due to a mutation of the nuclear DNA, has also been reported to be particulary associated with CIP along with other symptoms such as malnutrition, progressive external ophthalmoplegia, ptosis, peripheral neuropathy, and leukoencephalopathy[32-34]. Although we have never encountered patients with MNGIE, this study revealed that patients with mitochondrial diseases develop complicating CIP at a relatively high frequency (28.1%), especially patients with MELAS (40.0%). We also examined the clinical data of patients with progressive muscular dystrophy, which is also a known cause of CIP, as controls and found that CIP occurs less frequently in patients with progressive muscular dystrophy than in patients with mitochondrial diseases (0% *vs* 28.1%).

Patients with CIP tend to have disorders, such as glucose intolerance, epilepsy, hearing impairment and palpebral ptosis,that are suspected to be related to mitochondrial diseases at younger ages than are patients without CIP. None of the patients in our study presented with CIP as the initial symptom of mitochondrial disease. This trend indicates that some patients with mitochondrial dysfunction will develop gastrointestinal dysmotility with disease progression, eventually leading

to the development of CIP.

The frequency of CIP among patients with relatively mild mitochondrial dysfunction who do not need advanced treatment at a hospital may also be smaller than that noted in this study. Most patients with mitochondrial diseases die of cardiomyopathy and encephalopathy before the development of severe CIP, and this finding is consistent with a previous report indicating that the degree of organ dysfunction depended on the energy requirement of the organ. Although CIP was not a major cause of death in patients with mitochondrial diseases, it often resulted in impaired oral intake or tube feeding and eventually the critical loss of the activities of daily life. Early detection and treatment of gastrointestinal dysmotility, including CIP, and the maintenance of the nutritional status may be efficacious in the management of patients with mitochondrial diseases.

There is still no sufficiently effective treatment for CIP today. A number of medicines were used in this study, and none were especially effective when comparing these treated patients with CIP patients without mitochondrial diseases. Surgery has been reported to be effective in patients with normal small intestinal motility[35], although surgery was not performed in this study (8 of 9 patients with CIP in this study had small intestine dysmotility).

Selection bias is one of the major limitations of our study. Patients receiving outpatient treatment at a university hospital like ours may have more severe symptoms than general patients presenting to primary care practitioners may have. This limitation could have resulted in an over-estimation of the CIP prevalence in patients with mitochondrial diseases. In addition, the 31 patients with mitochondrial diseases in this study included 20 patients with MELAS (64.5%), 8 patients with CPEO (25.8%) and 3 patients with MERRF (9.7%), indicating a larger prevalence of MELAS patients in our study compared with that from an epidemiological study conducted in Japan (64.5% *vs* 25.5%)[36]. This selection bias may also have contributed to an over-estimation of the CIP prevalence. Moreover, patients with MELAS often use antiepileptic drugs regularly, which may cause drug-induced intestinal pseudo-obstruction. In our study, 5 patients with CIP regularly used antiepileptic drugs (phenytoin, carbamazepine, carbamazepine and sodium valproate, and for 2 patients, carbamazepine and clonazepam). Although it may be difficult to precisely distinguish between mitochondrial and drug-induced gastrointestinal symptoms, the regular use of these antiepileptic drugs alone rarely results in CIP, and mitochondrial dysfunction was considered the main cause of the severe intestinal dysmotility of these 5 patients.

In conclusion, patients with mitochondrial diseases (especially MELAS) sometimes develop CIP. In cases characterized by the adequate control of fetal mitochondrial dysfunctions such as cardiomyopathy and encephalopathy, CIP may present as a prominent problem. The possibility of the development of gastrointestinal dysmotility, including CIP, should be considered at all stages of the clinical course of all patients with mitochondrial diseases.

COMMENTS

Background

Chronic intestinal pseudo-obstruction (CIP) is characterized by severe symptoms and signs of intestinal obstruction without mechanical obstruction. Although mitochondrial diseases have been considered as a potential cause of secondary CIP, the frequency, characteristics, and prognosis of CIP in patients with mitochondrial diseases has not yet been well established.

Research frontiers

Mitochondrial diseases are a heterogeneous group of disorders associated with mutations in or deletions of nuclear or mitochondrial DNA. The degree of organ dysfunction depends on the energy requirements of the organ and on the proportion of mitochondrial DNA in the organ. In the treatment of mitochondrial patients with CIP, current research now focuses on how mitochondrial dysfunction develops into CIP and what the differences between the patients with CIP and without CIP are.

Innovations and breakthroughs

The relationship between CIP and mitochondrial diseases has not yet been firmly established. In the present study, authors conducted a retrospective review of each patient's sex, subclass of mitochondrial disease, age at the onset of mitochondrial disease, age at the establishment of the diagnosis of mitochondrial disease, frequency of CIP and the age at its onset, and the duration of survival. The age at the onset or at the first diagnosis of the disorder that led to the clinical suspicion of mitochondrial disease was also examined.

Applications

The study results suggest that patients who have certain disorders, such as glucose intolerance, epilepsy, hearing impairment and palpebral ptosis, that are suspected to be related to mitochondrial diseases at younger ages tend to develop gastrointestinal dysmotility with disease progression, eventually leading to the development of CIP.

Terminology

CIP is an uncommon disabling motility syndrome characterized by severe symptoms and signs of intestinal obstruction (abdominal pain, abdominal distention, nausea and vomiting) and radiographic evidence of dilated bowels in the absence of any mechanical obstruction; Mitochondrial diseases are a heterogeneous group of disorders associated with mutations in or deletions of nuclear or mitochondrial DNA.

Peer review

This is a good descriptive study in which the authors retrospectively reviewed the frequency, characteristics and prognosis of chronic intestinal pseudo-obstruction in mitochondrial patients. The study revealed that patients with CIP tend to have disorders that are suspected to be related to mitochondrial diseases at younger ages than patients without CIP.

Abstract

AIM: To investigate whether composite yogurt with acacia dietary fiber and *Bifidobacterium lactis* (*B. lactis*) has additive effects in irritable bowel syndrome (IBS).

METHODS: A total of 130 patients were randomly allocated to consume, twice daily for 8 wk, either the composite yogurt or the control product. The composite yogurt contained acacia dietary fiber and high-dose *B. lactis* together with two classic yogurt starter cultures. Patients were evaluated using the visual analog scale *via* a structured questionnaire administered at baseline and after treatment.

RESULTS: Improvements in bowel habit satisfaction and overall IBS symptoms from baseline were significantly higher in the test group than in the control group (27.16 *vs* 15.51, $P = 0.010$, 64.2 ± 17.0 *vs* 50.4 ± 20.5, $P < 0.001$; respectively). In constipation-predominant IBS, improvement in overall IBS symptoms was significantly higher in the test group than in the control group (72.4 ± 18.4 *vs* 50.0 ± 21.8, $P < 0.001$). In patients with diarrhea-predominant IBS, improvement in bowel habit satisfaction from baseline was significantly higher in the test group than in the control group (32.90 *vs* 7.81, $P = 0.006$).

CONCLUSION: Our data suggest that composite yogurt enriched with acacia fiber and *B. lactis* has greater therapeutic effects in patients with IBS than standard yogurt.

INTRODUCTION

Irritable bowel syndrome (IBS) is a functional bowel disorder characterized by symptoms of abdominal pain or discomfort associated with disturbed defecation, and is one of the most common gastrointestinal problems[1-3]. The pathogenesis of IBS is incompletely understood but over the past few years, there has been an emergence of new etiological hypotheses. These include gastrointestinal infection, low-grade infiltration and activation of mast cells in the intestinal mucosa with consequent release of bioactive substances, modification of small bowel and colonic microflora, changes related to the brain-gut axis, and altered serotonin metabolism[4-8]. These new views of the pathogenesis of IBS have changed the approach to IBS treatment[9]. Among several treatment options, the use of probiotics seems to be promising[10].

Probiotics are live microorganisms with a vast array of therapeutic potential for gastrointestinal disease[11,12]. They have been studied and used in many gastrointestinal disorders, with growing evidence for use in pouchitis, *Clostridium difficile* colitis, antibiotic-associated diarrhea, inflammatory bowel disease, and IBS. The emerging multifactorial pathophysiological paradigm of IBS may create adjunctive probiotic therapeutic opportunities[10,13,14]. The most widely studied organisms are *Bifidobacterium lactis* (*B. lactis*) and *Lactobacillus spp.*[15]. *B. lactis* survives complete transit through the digestive tract and is recovered live in stools in large quantities relative to the quantity initially ingested[16,17]. Daily consumption of fermented milk containing *B. lactis* was reported to improve gastrointestinal transit and digestive comfort, alleviate bloating, and increase stool frequency[18,19].

Acacia gum is extensively used as a food additive. It is a complex polysaccharide, that is primarily indigestible, not degraded in the intestine, but fermented in the colon[20]. Acacia fiber is made from acacia gum. Recently, its prebiotic properties, meaning it selectively stimulates the intestinal flora, were described and a synergy for bifidogenicity was observed with the combination of other prebiotics (fructo-oligosaccharide) and acacia gum. In addition, because acacia fiber is slowly fermented, it may attenuate the side effects of fermentation. Intestinal gas production resulting from fermentation can induce abdominal symptoms[21]. Dietary fiber is also commonly used in the treatment of patients with IBS[22]. Although dietary fiber does not appear to be useful as a sole treatment of IBS, it may have a limited role in empiric therapy, especially if constipation is the most significant symptom[23,24].

The aim of this study was to investigate whether a composite yogurt enriched with acacia dietary fiber and *B. lactis* had additive therapeutic effects in patients with IBS when compared with standard yogurt.

MATERIALS AND METHODS

Study population

A total of 130 patients were recruited at Samsung Medical Center, Seoul, South Korea. They were male and female patients between 18 and 70 years of age who met the Rome Ⅲ criteria[25] for the diagnosis of IBS.

Exclusion criteria were as follow: (1) endocrine disorders, neurological disorders, cardiovascular disorders, inherited neuromuscular disorders, malignant tumors, renal failure (serum creatinine ≥ 3.0 mg/dL), and liver cirrhosis (child class B and C); (2) current use of medications that potentially influence bowel habits such as medications for constipation, antidiarrheal drugs, and medications that can cause constipation, including anticholinergic drugs (e.g., anticonvulsants, antihistamines, antipsychotic and neuroleptic agents, anti-Parkinson agents, and antidepressants), narcotic pain medications (e.g., codeine), resins (e.g., cholestyramine), and metal ions and inorganic compounds (e.g., aluminum-, calcium-, and iron-containing antacids); (3) age > 55 years without a history of a sigmoidoscopy or colonoscopy performed in the previous 5 years; (4) abnormal results on a sigmoidoscopy or colonoscopy and abdominal radiological tests performed in the previous 2 years; and (5) any previous abdominal surgery.

Study protocol

This was a randomized, double-blind, controlled trial. Simple randomization was performed using a random number table. Potentially eligible patients answered a structured questionnaire at baseline. At that time, they were provided with a standardized explanation of questions and symptom definitions. In addition, patients were evaluated *via* a full review of their clinical history including complete blood count, serum chemistry, and thyroid function test. Clinically significant abnormalities in any of the latter tests resulted in exclusion from the study. Thereafter, eligible patients were randomly allocated to consume two bottles daily (one at breakfast, one at dinner) for 8 wk of either the composite yogurt (test product) or the control product. At the end of the study, patients were again administered a questionnaire. The use of any medication that potentially influences bowel habits was prohibited for 7 d prior to consumption of the products.

The study protocol was conducted in accordance with the Declaration of Helsinki and approved by the Institutional Review Board at Samsung Medical Center, Seoul, South Korea (No. 2010-07-223). All subjects provided written informed consent before inclusion in the study.

Study products

The test product was a yogurt containing high-dose *Bifidobacterium animalis subsp. lactis Bb-12* (*B. animalis subsp. lactis Bb-12*) (≥ 10^{11} cfu/bottle), *Bifidobacterium* enhancer, and acacia dietary fiber, together with the two classic yogurt starter cultures, *Streptococcus thermophilus* (≥ 3×10^9 cfu/bottle) and *Lactobacillus acidophilus* (*L. acidophilus*) (≥ 10^9 cfu/bottle).

The control product was a traditional yogurt contain-

ing *B. animalis subsp. lactis Bb-12* ($\geq 10^{10}$ cfu/bottle), no extra-functional ingredients (*Bifidobacterium* enhancer and acacia dietary fiber), and two yogurt starter cultures, *Streptococcus thermophilus* ($\geq 3 \times 10^{9}$ cfu/bottle) and *L. acidophilus* ($\geq 1 \times 10^{9}$ cfu/bottle). Both the test and control products were without added flavor and had similar appearance, color, texture, and taste. Each bottle contained either 150 mL of test or control product and was provided by the Namyang Dairy Products Co. Ltd. (Seoul, South Korea).

Assessments

Each patient was evaluated using a structured questionnaire at baseline and after 8 wk treatment. At baseline, the questionnaire assessed age, sex, height, body weight, IBS subtype[26], abdominal symptoms (abdominal pain/discomfort, abdominal distension/bloating, and flatulence), and bowel habits (frequency and duration of defecation, urgency, straining, feeling of incomplete defecation, stool consistency, bowel habit satisfaction, and discomfort related to daily life). Abdominal pain/discomfort, abdominal distension/bloating, bowel habit satisfaction, and discomfort related to daily life were evaluated using the visual analog scale (VAS, 0 = no symptoms, 25 = mild, 50 = moderate, 75 = severe, and 100 = very severe). Abdominal pain/discomfort, flatulence, and defecation were assessed by frequency. The stool consistency was determined using the Bristol stool scale[27].

At the end of the treatment, abdominal symptoms and bowel habits were assessed by the self-administration of the questionnaire that had the same questions as the one at baseline. In addition, the improvement of overall IBS symptoms was evaluated using the VAS (0 = aggravated, 25 = no change, 50 = slightly improved, 75 = much improved, 100 = very much improved).

Statistical analysis

It was determined that 50 patients per group were required for a power of 85% and two-sided significance at 5% in detecting a between-group effect of 0.2 in the improvement of overall IBS symptoms. To ensure the inclusion of at least 50 patients per group, 65 per group were ultimately recruited in order to account for a potential withdrawal rate of 25%.

Baseline demographic data were compared between groups using Student's *t* test, Pearson's χ^2 test, or Fisher's exact test, as appropriate. Changes in the symptom scores after treatment for each group were assessed using a paired *t* test, McNemar's test, and a generalized estimating equation. A two-sided *P* value < 0.05 was considered statistically significant. Statistical analysis was performed using PASW Statistics 18 for Windows (SPSS, Inc, Chicago, IL, United States).

RESULTS

Baseline characteristics and response to treatment

A total of 130 patients were enrolled and randomized either to the test group ($n = 65$) or the control group ($n = 65$). Thirteen patients discontinued the study and were lost to follow-up, and 117 (58 in the test group and 59 in the control group) completed the study. Using the Rome Ⅲ criteria, 35.0% of patients were classified as constipation-predominant IBS (IBS-C), 29.9% as diarrhea-predominant IBS (IBS-D), 8.5% as mixed IBS (IBS-M), and 26.5% as unsubtyped IBS. Table 1 shows baseline characteristics and symptom scores of patients in the test and control groups. At baseline, the distributions of age, sex, body mass index, and IBS subtype were similar between the groups, and the baseline scores for abdominal symptoms and bowel habits did not differ.

Table 2 summarizes the changes in the study parameters after 8 wk treatment in both the test and control groups and differences between the groups. Bowel habit satisfaction improved more in the test group than in the control group (change from baseline of 27.16 *vs* 15.51, $P = 0.010$), and the improvement in overall IBS symptoms was significantly higher in the test group than in the control group (64.2 ± 17.0 *vs* 50.4 ± 20.5, $P < 0.001$). The scores for abdominal pain/discomfort, abdominal distension/bloating, and discomfort related to daily life also improved more in the test group than in the control group, but the improvements did not significantly differ between the groups. The improvements in straining and feeling of incomplete evacuation did not differ between the groups. Defecation duration and frequency, flatulence, and urgency did not improve after treatment. The change in stool consistency was different in the two groups. Stool consistency did not change in the test group but became softer in the control group. There were no significant adverse events reported throughout the study.

Analysis by IBS subtype

A subgroup analysis was performed to determine the effects of the test product on each IBS subtype. In the IBS-C group (Table 3), the improvement in overall IBS symptoms was significantly higher in the test group than in the control group (72.4 ± 18.4 *vs* 50.0 ± 21.8, $P < 0.001$), and the difference between the two groups was greater than that between the test and control groups including all of the study patients (64.2 ± 17.0 *vs* 50.4 ± 20.5, $P < 0.001$). However, bowel habit satisfaction did not differ between the two groups. Defecation frequency and feeling of incomplete evacuation, which did not improve in the study patients overall, improved in the test and control groups (change from baseline of 1.79, $P = 0.002$ and 1.96, $P = 0.032$; change from baseline -42.1%, $P = 0.021$ and -31.8%, $P = 0.016$, respectively) although the improvements did not significantly differ between the groups. Stool consistency became softer in both groups without a significant difference between the test and control groups (change from baseline of 0.789 *vs* 1.09, $P = 0.386$). In the IBS-D group (Table 4), bowel habit satisfaction improved more in the test group than in the control group (change from baseline of 32.90 *vs*

7.81, P = 0.006), and the difference between the two groups was greater than the difference between patients in the overall analysis (change from baseline of 27.16 *vs* 15.51, P = 0.010). However, the improvement in overall IBS symptoms did not differ between the two groups. Abdominal pain/discomfort scores improved more in the test group than in the control group, and the improvement was nearly significant (change from baseline of -23.68 *vs* -9.38, P = 0.050). Stool consistency became harder in both groups without a significant difference between the test and control groups (change from baseline of -1.26 *vs* -0.63, P = 0.738). In the IBS-M group, the improvements in abdominal symptoms, bowel habits, and overall IBS symptoms did not significantly differ between the test and control groups.

DISCUSSION

Several clinical studies have demonstrated the efficacy of probiotics for the treatment of patients with IBS. Some studies have also been performed in populations of certain IBS subtypes. A study by Kim *et al*[28] evaluated the effect of VSL#3, a combination of probiotics that contains live bacteria including *Bifidobacterium*, *Lactobacillus*, and *Streptococcus salivarius ssp. thermophilus,* on gastrointestinal transit and symptoms in IBS-D. With VSL#3 treatment, the decrease in bloating was of borderline significance, but there was no effect on gastrointestinal transit

or other individual IBS symptoms. A study by Guyonnet *et al*[19] assessed the effects of fermented milk containing *B. animalis* DN-173 010 in IBS-C and reported improvements in the health-related quality-of-life discomfort score and bloating symptoms, as well as increased stool frequency. Another study demonstrated the effects of a fermented milk product containing *B. lactis* DN-173-010 on abdominal distension and gastrointestinal transit in IBS-C[29]. In the present study, the therapeutic effect of the composite yogurt differed according to IBS subtype; in IBS-C, overall IBS symptoms were improved, and in IBS-D, the improvement in bowel habit satisfaction was prominent. However, irrespective of IBS subtype, the new composite yogurt had additive therapeutic effects on bowel habit satisfaction and overall IBS symptoms among the entire IBS study sample when compared with standard yogurt.

Lactobacilli and *bifidobacteria*, alone or in combination, have been used for the treatment of IBS in many clinical studies. A study by Sinn *et al*[14] reported that 4 wk treatment with *L. acidophilus*-SDC 2012, 2013 was associated with a reduced score for abdominal pain or discomfort compared to baseline. O'Mahony *et al*[30] performed a study in patients with IBS and grouped them into three different treatment arms. The patients received *Lactobacillus salivarius* UCC4331, *Bifidobacterium infantis* (*B. infantis*) 35624, or placebo, but only *B. infantis* alleviated IBS symptoms. This was associated with a normalization of the anti-inflammatory to proinflammatory cytokine ratio (interleukin-10/interleukin-12), suggesting an immune-modulating role for *B. infantis*. A larger study by Whorwell *et al*[31] evaluating different doses of *B. infantis* 35624 was performed in 362 women with IBS. The participants were randomized to receive either the placebo or encapsulated *B. infantis* at a dose of 10^6, 10^8 or 10^{10} cfu for 4 wk. *B. infantis* at a dose of 10^8 cfu was significantly superior to placebo and all other doses in improving IBS symptoms. However, the 10^{10} dose was associated

with significant formulation problems. From only these two studies, it is not possible to determine which strain is most effective and the optimal dose. Nevertheless, to date, *Bifidobacterium* seems to be one of the most important probiotics, and a *B. infantis* dose of at least 10^8 cfu may be appropriate for the treatment of IBS. Given this fact, it can be deduced that at a *Bifidobacterium* dose > 10^8 cfu, the therapeutic effects would increase in proportion to the dose up to a certain point. In this study, we used *B. lactis*, which has been shown to have therapeutic effects in IBS in several studies[18,19,29,32]. Our results also showed that the new composite yogurt (containing > 10 times the *B. lactis* of the control product and *Bifidobacterium* enhancer) was associated with a significant improvement in bowel habit satisfaction and overall IBS symptoms, although acacia fiber was also added to the test product and it was difficult to attribute the results to one or the other component. To determine the optimal dosage, another trial evaluating the effects of yogurt containing *B. lactis* at different dosages is necessary.

Dietary fiber accelerates whole gut transit time and increases daily stool weight and the proportion of unformed stool, and its efficacy in alleviating constipation has been confirmed in patients with IBS[33]. Therefore, dietary fiber is frequently recommended for IBS[22]. A study by Choi *et al*[24] evaluated the additive effects of probiotic fermented milk containing dietary fiber in IBS-C patients, compared to plain probiotic fermented milk, and dietary fiber had additive benefits for the symptoms of constipation, especially in IBS-C. However, in a study by Francis *et al*[34], fiber was found to exacerbate all symptoms of IBS. Dietary fiber is classified into soluble and insoluble fiber, which have different effects on global IBS-related symptoms[35]. Soluble fiber delays gastric emptying and nutrient absorption from the small bowel; it is used to delay gastric emptying and improve glycemic control in diabetes, as well as to alleviate constipation. Insoluble fiber has little effect on gastric emptying and small bowel transit; it markedly accelerates colonic transit and is frequently used as a laxative[36]. For our study, we used acacia fiber, which is soluble, and that is thought to be the reason the composite yogurt containing acacia fiber was associated with improvement in IBS symptoms among IBS-C patients.

The present study had some limitations. First, the follow-up period was relatively short. It would have been useful to know how participants were faring after using the composite yogurt for 6 and 12 mo. Next, this study was limited by the lack of a placebo group because the control product was not a placebo. Finally, we did not investigate participants' dietary factors, which may be more prevalent in IBS-D. Nevertheless, this was a well-designed trial with an appropriate number of patients. Furthermore, additive effects of high-dose *B. lactis* and acacia dietary fiber were clearly noted with respect to bowel habit satisfaction and overall IBS symptoms. Among IBS subtypes, overall IBS symptoms were more improved in IBS-C; in IBS-D, bowel habit satisfaction was more improved. In conclusion, a new composite yogurt had greater therapeutic effects in patients with IBS than standard yogurt had. Further studies are needed to determine the most effective probiotic strain, dosage, and duration of therapy.

COMMENTS

Background

Irritable bowel syndrome (IBS) is one of the most common gastrointestinal problems. The new views of the pathogenesis of IBS have changed the approach to IBS treatment. Among several treatment options, the use of probiotics seems to be promising. Dietary fiber is also commonly used in the treatment of patients with IBS.

Research frontiers

The authors investigated whether a composite yogurt enriched with acacia dietary fiber and *Bifidobacterium lactis* (*B. lactis*) had additive therapeutic effects in patients with IBS when compared with standard yogurt.

Innovations and breakthroughs

This study was a well-designed prospective clinical trial with an appropriate number of patients. Additive effects of acacia dietary fiber and high-dose *B. lactis* were clearly noted with respect to bowel habit satisfaction and overall IBS symptoms.

Applications

The study results suggest that composite yogurt enriched with acacia fiber and *B. lactis* has greater therapeutic effects in patients with IBS than standard yogurt has.

Terminology

Probiotics are live microorganisms with a vast array of therapeutic potential for gastrointestinal disease.

Peer review

This study is very informative for clinicians because IBS is one of the most common gastrointestinal problems and clinicians frequently encounter problems with treating IBS patients. In addition, the results have scientific relevance for understanding the pathogenesis of the disease.

Abstract

AIM: To investigate whether the combined methods of unilateral thyroparathyroidectomy (TPX) and subdiaphragmatic vagotomy (VAX) can be adapted for rats and used as a reliable method to produce a rat model of long-term reduction of gastrointestinal (GI) motor function.

METHODS: Male Sprague-Dawley rats were randomly divided into 3 groups, normal, sham-operated and unilateral TPX plus VAX. The TPX plus VAX rats received VAX 7 d after application of TPX, and dietary intake and fecal output were then measured daily for 1 wk. After completion of the experiments, gastric emptying and small bowel transit were measured *in vivo*, and the contractile responses of colonic strips to excitatory and inhibitory neurotransmitters were estimated using isometric force transducers *in vitro*.

RESULTS: In comparison with normal and sham-operated rats, rats which received unilateral TPX plus VAX showed a significant decrease in body weight and in fecal pellet number and weight throughout the entire week. Application of TPX plus VAX to rats markedly delayed gastric emptying and small bowel transit. In TPX plus VAX rats, the longitudinal muscles of the proximal colon showed a significant reduction in contractile responses to acetylcholine (5×10^{-6} mol/L), and a dramatic attenuation of contractile responses was also observed in both the longitudinal and circular muscles of the distal colon. However, the spontaneous contractility of the colonic strips from TPX plus VAX rats was not significantly affected by treatment with *N*-nitro-*L*-arginine-methyl ester (0.1 mol/L).

CONCLUSION: The results indicate that unilateral TPX plus VAX reduced the motor function of the GI tract in rats, and the reduced gut motility is likely mediated, at least in part, by inhibition of the excitatory neurotransmitter system.

INTRODUCTION

Vagal nerves and thyroid hormones regulate the physiological functions of the gastrointestinal (GI) tract. The subdiaphragmatic vagal nerve and its branches innervate the GI tract from the lower esophageal sphincter to the upper GI tract in humans[1,2], and the extensive distribution of vagal nerves to the gut plays an important role in the regulation of many digestive functions including food intake, gastric accommodation and GI motility[1,3]. Therefore, abnormalities in the subdiaphragmatic vagal nerves pathologically mediates the development of several GI diseases including dyspepsia and constipation[1,3,4]. In addition, hyper- and hypo-thyroidism also gives rise to a variety of GI symptoms including abnormal gastric secretion and GI motility[5,6]. The effects of hypothyroidism on the GI tract seem to be multi-factorial with alterations in neuroregulation, and a reduction in peristaltic activity being the most frequent GI complaint in patients with hypothyroidism[7].

It has been suggested that the vagal nerves predominantly act on the stomach and small intestine rather than the lower GI tract, and that subdiaphragmatic vagotomy (VAX) results in a transient slowing of the rate of gastric emptying and transit of the upper small intestine[8-10]. In our preliminary studies, rats which received subdiaphragmatic VAX transiently showed delayed gastric emptying and small bowel transit after surgery. Additionally, it has been reported that a complete depletion of thyroid hormones by bilateral thyroparathyroidectomy (TPX) in rats can induce a severe tetany which has a high mortality rate[11]. We also observed a similar phenomenon in preliminary studies, where bilateral TPX caused an extremely high fatality rate $\geqslant$ 90%) of rats within 48 h after surgical application. Taken together, we consider that bilateral TPX or subdiaphragmatic VAX alone is not a reliable and reproducible method to induce a long-term reduction in upper GI motility.

Therefore, we hypothesized that in comparison with bilateral TPX or subdiaphragmatic VAX, a combined method (TPX plus VAX) of unilateral TPX and subdiaphragmatic VAX might be a better strategy to provide a long-term reduction in spontaneous motility of the entire GI tract, but with reduced postoperative mortality. To examine this hypothesis, this study measured the effects of unilateral TPX plus VAX on the alteration of GI motility using rats, which are not only a popular laboratory animal for biomedical research, but also are a good model for studying the pharmacological properties of medicines, and for investigating the pathophysiological characteristics of human GI dysfunction[12,13].

MATERIALS AND METHODS

Animals and experimental groups

Male Sprague-Dawley rats (6-wk old) were obtained from Samtako BioKorea (Kyungki, South Korea) and acclimatized for 1 wk with free access to a solid normal rodent diet (Samyang Co., Kyungki, South Korea) and drinking water under a temperature of 23 ℃ ± 2 ℃, a relative humidity of 50%-60% and a 12-h/12-h dark-light cycle. After acclimatization, rats were randomly divided into 3 groups: normal, sham-operated and unilateral TPX plus VAX groups. Each group comprised 7-9 rats. The experimental procedures employed in this study are illustrated in Figure 1. All experiments were conducted in accordance with the institutional guidelines established by the Wonkwang University Commolittee for the Care and Use of Laboratory Animals.

Unilateral thyroparathyroidectomy

Unilateral TPX was carried out according to the previous method with a slight modification[14]. In brief, rats (7-wk old) were anesthetized using chloropent (5 mg/kg *ip*) for deep anesthesia, and thyroparathyroid glands on the right side were exposed by a mid-line incision of the neck under aseptic conditions and excised under stereomicroscopic observation. For sham-operated rats, the operation was performed using the same procedures except with no dissection of the thyroparathyroid glands. After surgery, animals were individually housed for 1 wk in cages with bedding of wood shavings.

Subdiaphragmatic vagotomy

At 7 d after unilateral TPX, subdiaphragmatic VAX was carried out according to a previous report with a slight modification[15]. Briefly, rats (8-wk old) were anesthetized using chloropent (5 mg/kg *ip*), and the abdomen around the stomach was opened under aseptic conditions. The ventral and dorsal branches of the subdiaphragmatic vagal nerves were cut (0.5 cm above the gastroesophageal junction). In sham-operated rats, the vagal trunks were similarly exposed, but without cutting of the vagal nerves. At the end of surgery, the completeness of VAX was verified by gastric responses to electrical stimulation, and inspection of the vagal nerve endings using a stereomicroscope as described in previous reports[8,15]. After dissecting the vagal nerves, animals were individually acclimatized for 1 d in wood-bedded cages and then housed in stainless-steel metabolic cages throughout the entire experimental period. Body weight, dietary intake, and fecal pellet number and weight were measured daily (9:00 am) for 7 d.

Measurement of gastric emptying

Gastric emptying was measured according to the previous method with a slight modification[16]. At 8 d after subdiaphragmatic VAX, rats were starved overnight but with drinking water available *ad libitum*. Each animal was sacrificed by cervical dislocation 10 min after oral ad-

ministration of a test meal (1 mL) containing 0.05% (w/v) phenol red in aqueous carboxymethyl cellulose (4.5%, w/v), and the stomach was immediately removed, followed by clamping of the gastro-esophageal and gastro-duodenal junctions. The stomach was rinsed with phosphate-buffered saline (PBS, pH 7.4) and dissected in 20 mL 0.1 mol/L NaOH. The stomach, containing phenol red solution, was shaken for 30 min and centrifuged at 3000 *g* for 10 min. To precipitate proteins, 0.5 mL of supernatant was added to 20% trichloroacetic acid (50 mL) and mixed vigorously. The samples were centrifuged at 10 000 *g* for 30 min, and 0.3 mL supernatant was mixed with 0.5 mol/L NaOH (0.4 mL) to develop the color. The absorbance of samples at 558 nm wavelength was measure with a spectrophotometer (U-2000; Hitachi, Tokyo, Japan). Gastric emptying was estimated from the following formulation: (amount of residual phenol red/phenol red present in stomach immediately after administration) × 100.

Measurement of small bowel transit

To examine the spontaneous motility of the small intestine, a small bowel transit test was measured an established method[17]. Briefly, rats at 8 d after application of subdiaphragmatic VAX were starved overnight but with drinking water available *ad libitum*. Each animal was orally administered 1 mL of a charcoal meal, 10% (w/v) activated charcoal in aqueous Arabic gum (5%, w/v), and sacrificed by cervical dislocation 20 min later. The gastro-duodenal and ileo-cecal junctions were tied, and the entire small intestine was then quickly removed to avoid stretching. After rinsing the intestine with PBS, small bowel transit was estimated by comparing the distance travelled by the charcoal meal from the pyloric sphincter to the total length of the small intestine from the pyloric sphincter to the ileo-cecal junction. The distance travelled by the charcoal meal was expressed as a percentage of the total length of the small intestine.

Preparation of colonic strips

At 8 d after subdiaphragmatic VAX, rats were starved overnight but with drinking water available *ad libitum* and sacrificed by CO_2 asphyxiation and cervical dislocation. The entire proximal and distal colons were removed, and the luminal contents were flushed out using Krebs-Ringer bicarbonate buffer (composition 118 mmol NaCl, 4.7 mmol KCl, 1.2 mmol KH_2PO_4, 1.2 mmol $MgSO_4$, 2.6 mmol $CaCl_2$, 25 mmol $NaHCO_3$ and 11.5 mmol *D*-glucose, pH 7.4). Strips (1 cm length) of proximal colon at a distance of 1 cm from the ileo-cecal junction and distal colon and at a distance of 1 cm from the anus were dissected. The intact colonic strips were longitudinally or circularly mounted in an organ bath (10 mL) containing Krebs-Ringer bicarbonate buffer bubbled with 5% CO_2/95% O_2 and maintained at 37 ℃. One end of each colonic strip was tied with suture silk and fixed to the bottom of the organ bath, and the other end was connected to an isometric force transducer (Grass Technologies, West Warwick, RI).

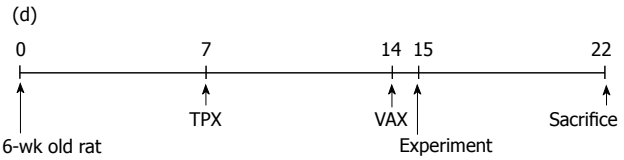

Figure 1 Schematic diagram of experiments to examine gastrointestinal motility after sequential application of unilateral thyroparathyroidectomy and subdiaphragmatic vagotomy. TPX: Thyroparatyroidectomy; VAX: Subdiaphragmatic vagotomy.

Measurement of colonic contractility

Colonic contractility was measured as described in our previous report[18]. Briefly, after the colonic strips were allowed to equilibrate for 30-60 min with washout every 10 min, 1 g of tension was slowly applied to the tissues before starting the experiments. The strips were treated with 0.5 mol of acetylcholine (ACh) or 0.1 mmol of *N*-nitro-*L*-arginine methyl ester (L-NAME) for 10 min, and the contractile responses of the colonic strips prepared from the unilateral TPX plus VAX rats to ACh and L-NAME were estimated and compared with the colonic contractility in strips of normal animals. Isometric contractile responses from the force transducer were measured by a biological recording system equipped with an amplifier (PowerLab 4/25, AD Instruments, Colorado Springs, CO, United States). The mean tensions and amplitudes of colonic contraction produced under resting and drug-treated conditions were measured over a period of 10 min.

Measurement of serum thyroxine contents

To estimate the change of serum thyroxine (T_4) level caused by unilateral TPX, total serum T_4 level at 15 d after application of unilateral TPX were measured using the T_4 enzyme-linked immunosorbent assay kit (GenWay Biotech; San Diego, CA, United States). Blood samples were collected from the abdominal vein at the time of sacrifice, and serum was obtained by centrifugation at 3000 *g* for 10 min. Serum samples were stored at -70 ℃ until T_4 analysis.

Statistical analysis

All results are presented as mean ± SE. One-way analysis of variance was performed to compare the statistical significance of multi-groups, followed by *post hoc* analysis by the Student-Newman-Keuls test for comparison of 2 groups. $P < 0.05$ was considered statistically significant.

RESULTS

General observation and serum thyroxine levels

No deaths occurred in the rats which received unilateral TPX plus VAX. In these rats, an obvious dilatation of the stomach and significant residual luminal content in the GI tract were found, but marked morphological changes

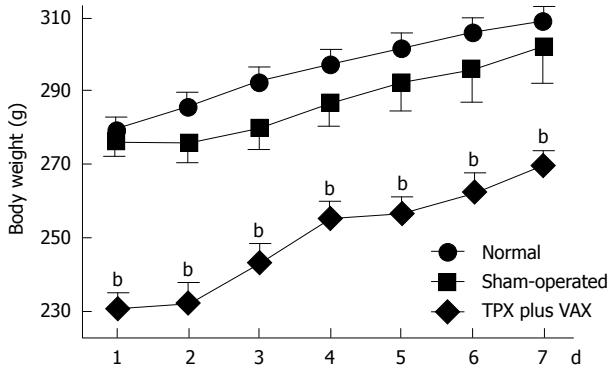

Figure 2 Effects of unilateral thyroparatyroidectomy plus subdiaphragmatic vagotomy on body weight gain in rats. Body weights were measured for 7 d from the day after subdiaphragmatic vagotomy (VAX). Each point represents the mean ± SE of 7-9 rats. $^{b}P < 0.01$ *vs* normal and sham-operated groups. TPX: Thyroparatyroidectomy.

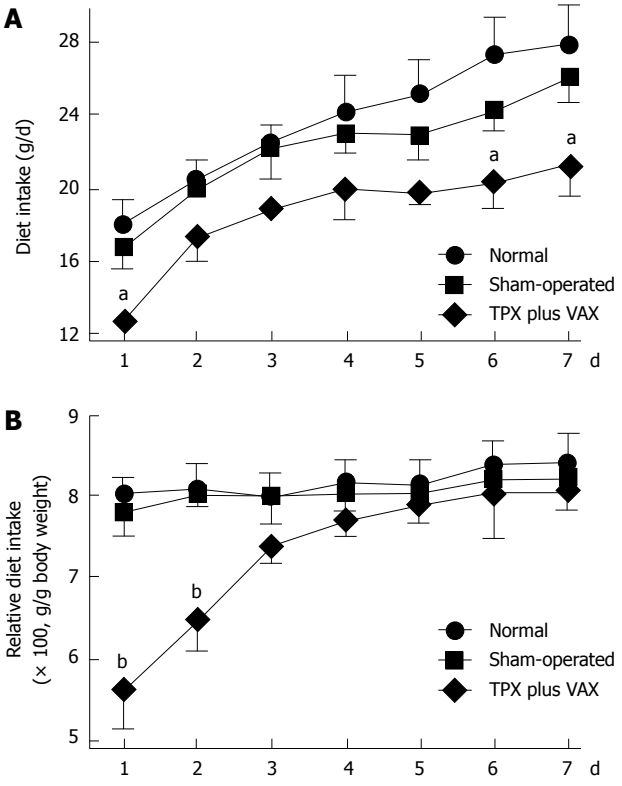

Figure 3 Changes in daily dietary intake in the thyroparatyroidectomy plus subdiaphragmatic vagotomy rats. Daily dietary intake (A: Absolute; B: Relative to body weight) was measured for 7 d from the day after subdiaphragmatic vagotomy (VAX). Each point represents the mean ± SE of 7-9 rats. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* normal and sham-operated groups. TPX: Thyroparatyroidectomy.

of the gut were not observed. There were no significant differences in visible features and behaviors among the normal (4.74 ± 0.85 g/dL), sham-operated (4.97 ± 1.14 g/dL) and unilateral TPX plus VAX rats (2.86 ± 0.98 g/dL). Serum T_4 levels in the unilateral TPX plus VAX rats were not significantly lower than those in the normal and sham-operated animals.

Body weight and dietary intake

As shown in Figure 2, body weights of unilateral TPX plus VAX rats were significantly lower than those of normal and sham-operated animals throughout the entire experimental period. However, there was no significant difference in body weights between normal and sham-operated rats. Daily dietary intake of the unilateral TPX plus VAX rats was not significantly lower than in normal and sham-operated animals throughout the entire experimental period (Figure 3A). The relative daily dietary intake in unilateral TPX plus VAX rats transiently decreased, but almost completely returned to normal levels after 4 d (Figure 3B).

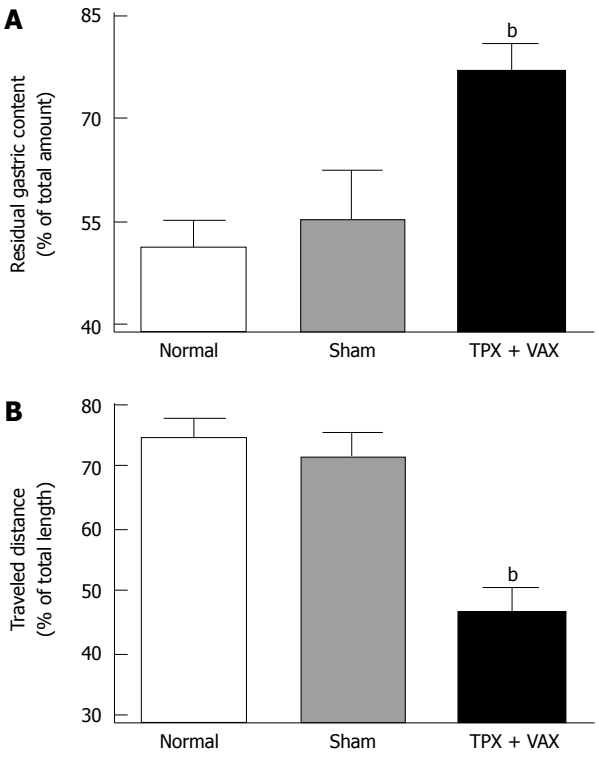

Figure 4 Effects of thyroparatyroidectomy plus subdiaphragmatic vagotomy on gastric emptying and small bowel transit in rats. Gastric emptying (A) and small bowel transit (B) was measured 8 d after subdiaphragmatic vagotomy (VAX). Each point represents the mean ± SE of 7-9 rats. $^{b}P < 0.01$ *vs* normal and sham-operated groups. TPX: Thyroparatyroidectomy.

Gastric emptying and small bowel transit

The motor functions of upper GI tracts were estimated by the gastric emptying test and small bowel transit *in vivo*, and the obtained results are shown in Figure 4. In comparison with normal and sham-operated rats, the residual gastric contents of unilateral TPX plus VAX rats were significantly elevated (Figure 4A), and the traveled distances of the luminal content in the small intestines of unilateral TPX plus VAX rats were markedly shortened (Figure 4B).

Defecatory function

Defecatory function was determined by measuring fecal pellet numbers and weights, and the obtained results are shown in Figure 5. In comparison with normal and sham-operated rats, daily fecal pellet numbers of unilateral TPX plus VAX rats were significantly reduced

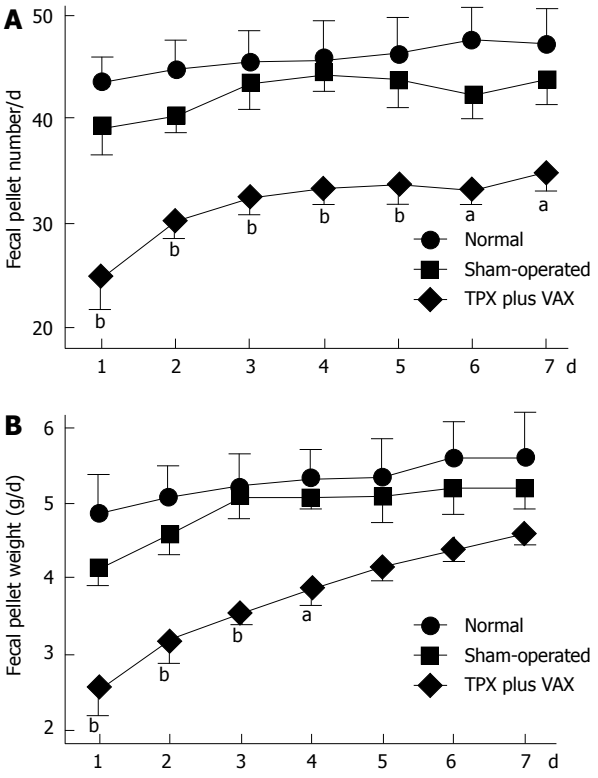

Figure 5 Effects of thyroparatyroidectomy plus subdiaphragmatic vagotomy on defecation of rats. Fecal pellet numbers (A) and weights (B) were measured for 7 d from the day after subdiaphragmatic vagotomy (VAX). Each point represents the mean ± SE of 7-9 rats. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* normal and sham-operated groups. TPX: Thyroparatyroidectomy.

throughout the entire experimental periods (Figure 5A), and their daily fecal weights were markedly reduced for the first 4 d of the experimental period (Figure 5B).

Colonic contractility

To examine changes in the spontaneous contractility of colonic smooth muscles, the contractile responses of intact colonic strips to ACh (0.5 mol) and L-NAME (0.5 mmol) were measured. The representative tracings obtained for proximal and distal colons are shown in the Figures 6A and 7A, respectively. In comparison with normal rats, the contractile responses to ACh (0.5 mol), both tension and amplitude, of the proximal colon longitudinal muscles prepared from the unilateral TPX plus VAX rats were significantly attenuated, whereas no significant changes were observed in the circular muscles (Figure 6B). L-NAME-induced contractility of the proximal colon did not significantly differ between the normal and unilateral TPX plus VAX rats (Figure 6C). Additionally, ACh-induced contractions of the distal colonic longitudinal and circular muscles prepared from the unilateral TPX plus VAX rats were significantly reduced compared with those of normal animals (Figure 7B), whereas the contractile responses of colonic strips to L-NAME did not significantly differ between normal and unilateral TPX plus VAX rats (Figure 7C).

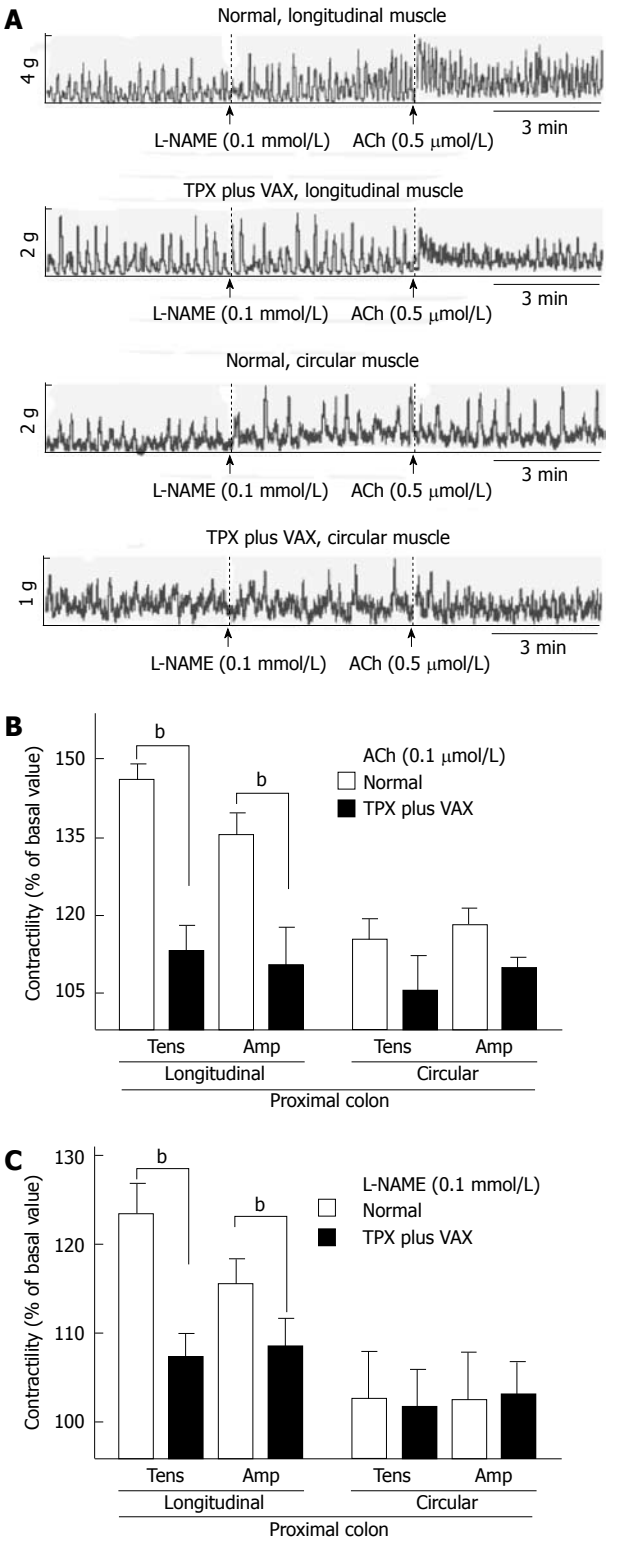

Figure 6 Reduced contractile activity of the proximal colonic muscles in the thyroparatyroidectomy plus subdiaphragmatic vagotomy rats. Animals were sacrificed at 8 d after subdiaphragmatic vagotomy (VAX), and intact proximal colonic strips prepared from the age-matched normal and thyroparatyroidectomy (TPX) plus VAX rats were longitudinally or circularly mounted in a 10 mL organ bath. The contractile responses of colonic strips to acetylcholine (Ach) and *N*-nitro-*L*-arginine methyl ester (L-NAME) were measured by isometric force transducers. Figures show the representative tracings (A) and contractile responses to ACh (B) and L-NAME (C). Each point represents the mean ± SE of 7-9 rats. $^{b}P < 0.01$ *vs* normal and sham-operated groups.

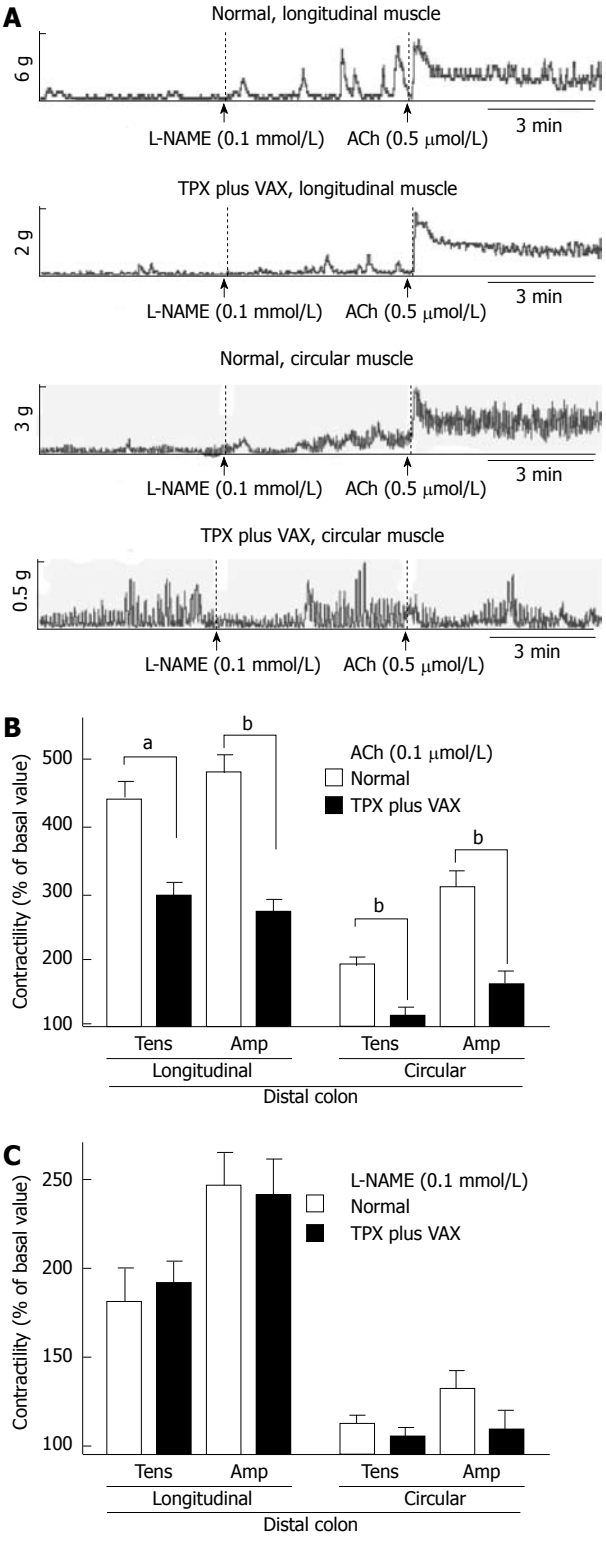

Figure 7 Reduced contractile activity of distal colonic muscles in the thyroparatyroidectomy plus subdiaphragmatic vagotomy rats. Animals were sacrificed at 8 d after subdiaphragmatic subdiaphragmatic vagotomy (VAX), and intact distal colonic strips prepared from the age-matched normal and thyroparatyroidectomy (TPX) plus VAX rats were longitudinally or circularly mounted in a 10 mL organ bath. The contractile responses of colonic strips to acetylcholine (Ach) and N-nitro-L-arginine methyl ester (L-NAME) were measured by isometric force transducers. Figures show the representative tracings (A) and contractile responses to ACh (B) and L-NAME (C). Each point represents the mean ± SE of 7-9 rats. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* normal and sham-operated groups.

DISCUSSION

To produce a rat model of a long-term reduction of the physiological motility of the entire GI tract, a partial depletion of thyroparathyroid hormones and denervation of subdiaphragmatic vagal nerves were sequentially applied to rats. In the rats receiving unilateral TPX plus VAX, an obvious dilatation of the stomach and significant residual luminal contents of GI tracts were found without marked morphological changes of the gut, and gastric emptying and small bowel transit were significantly delayed. The rats also showed a significant retardation of defecatory function. Additionally, we observed a significant reduction in distal colonic contractile responses to ACh, but not to L-NAME. These findings possibly indicate that a partial depletion of thyroparathyroid hormones and denervation of subdiaphragmatic vagal nerves decrease the spontaneous motility of the entire GI tracts through a reduction in the physiological activity of excitatory neurotransmitter systems. These dysfunctions are likely the pathological characteristics of the GI diseases related to reduced GI motility in humans.

Although a variety of animal models has been developed to examine the pathological mechanisms involved in the reduction of GI motility and to evaluate the pharmacological properties of drugs[19-22], it is unfortunately difficult to translate the findings of these animal models to human GI diseases. Although pathological characteristics of the bilateral TPX- or subdiaphragmatic VAX-induced animal models have been intensively investigated[1,3,6], the precise values for the combined method of unilateral TPX and subdiaphragmatic VAX are entirely, to our knowledge, lacking. Moreover, in the preliminary studies, we observed several scientific and methodological limitations of bilateral TPX or subdiaphragmatic VAX alone. A complete depletion of thyroparathyroid hormones by bilateral TPX caused an extremely high fatality rate (≥ 90%) within 48 h after surgery, and subdiaphragmatic VAX transiently (less than 3 d after surgery) reduced only gastric emptying and small bowel transit, but not colonic transit. These results led us to consider that bilateral TPX or subdiaphragmatic VAX may not be a reliable and reproducible method to produce animal models of GI diseases induced by long-term functional reduction of GI motility in humans.

It has been reported that subdiaphragmatic VAX in guinea pigs increased daily food intake and weight gain, whereas the reverse occurred in rats[23,24], and a pathological depletion of thyroid hormones causes a reduction in normal weight gain in rats[14]. These findings are partially in accord with our findings, indicating that unilateral TPX plus VAX significantly decreases body weight gain, but not daily dietary intake. We carefully consider that these may be related to the experimental methods used, which may differently regulate the physiological functions of gut including gastric secretion and bowel motility, resulting in different magnitudes of food intake and weight gain. This is supported by previous reports[1,25],

suggesting that alteration of food intake and weight gain following bilateral TPX and subdiaphragmatic VAX is absolutely dependent on the ability of the GI tract to digest food.

The delayed gastric emptying in some patients with hypothyroidism is likely to result from reduced muscle contractility of the antrum[26], and vagal nerves are involved in the regulation of contractile patterns during gastric phase Ⅲ[27]. In rats, chronic hypothyroidism or hyperthyroidism alters the expression patterns of cholinergic muscarinic receptors distributed in the ileal muscles[28], and administration of carbachol obviously increases ileal transit decline by vagal denervation[8]. These suggestions are well in accord with our results, indicating that unilateral TPX plus VAX markedly delays gastric emptying and small bowel transit. Although this study did not evaluate the cellular mechanisms implicated in the unilateral TPX plus VAX-induced reduction of upper GI motility, the results found in this study likely suggest that unilateral TPX plus VAX may be a reliable and reproducible method to produce a rat model characterized by a long-term reduction in gastric emptying and small bowel transit.

A previous report[8] suggested that colonic transit was delayed soon after subdiaphragmatic VAX, but returned to essentially normal levels at a later time. We also observed a similar effect of subdiaphragmatic VAX on defecatory function. Importantly, a reduction in defecatory function was maintained for 7 d when unilateral TPX and subdiaphragmatic VAX were sequentially applied to rats. These results clearly indicated that unilateral TPX plus VAX obviously reduces the colonic motor activity which propels the luminal contents, and the reduced propulsive activity of the upper and lower GI tract is maintained for long time periods compared with subdiaphragmatic VAX alone. Moreover, it is considered that a significant decrease in the daily numbers of fecal pellets is possibly caused by a reduction in the defecatory function of the colon, and this likely reflects the reduction in motor function of colonic smooth muscle observed in patients with constipation and defecatory disorders[25].

It has been well known that ACh[29] is the major excitatory neurotransmitter, and nitric oxide[30] is the major non-adrenergic, non-cholinergic inhibitory neurotransmitter in the regulation of colonic motility. Therefore, to assess the alteration in excitatory and inhibitory neurotransmitter systems by unilateral TPX plus VAX, we examined the contractile responses of colonic strips to ACh and L-NAME. In comparison with colonic strips of normal rats, the colonic strips prepared from unilateral TPX plus VAX rats exhibited a markedly impaired contractile response to ACh, but the contractile response to L-NAME was not significantly altered. We also found that unilateral TPX plus VAX did not significantly affect the contractile properties of adrenergic and purinergic inhibitory mechanisms (data not shown). These results are possibly suggestive of cholinergic neuronal remodeling during a partial depletion of thyroparathyroid hormones and disruption of subdiaphragmatic vagal nerves, resulting in functional reduction in colonic motility leading to pathological conditions such as constipation. Findings comparable with our results have previously been reported, suggesting that depletion of thyroparathyroid hormones reduces GI motility through a reduction in excitatory neurotransmitter activity[6]. Therefore, the results found in this study suggest that, in addition to dysfunction of vagal nerves regulating GI motility, the reduced colonic contractility may result from enteric excitatory neuronal loss associated with a decrease in thyroparathyroid hormones. However, further studies are needed to investigate the detailed cellular mechanisms involved in the unilateral TPX plus VAX-induced reduction of GI motility.

Taken together, sequential application of unilateral TPX and subdiaphragmatic VAX to rats may be a reliable method to produce a model of delayed gastric emptying and defecatory disorders in rats. In comparison with bilateral TPX or subdiaphragmatic VAX alone, TPX plus VAX showed valuable advantages, including no animal deaths and long-term persistence of reduced GI motility. Rats sequentially undergoing unilateral TPX and subdiaphragmatic VAX may be taken into consideration as a putative animal model for disorders of GI motility such as dyspepsia and constipation.

COMMENTS

Background

The prevalence of dyspepsia and constipation in humans continues to increase throughout the world. Although attenuation of gastric and colonic motility is widely considered as the primary causal factors for the occurrence of dyspepsia and constipation, respectively, there are still many questions to be answered, and a useful animal model to evaluate the pathophysiological mechanisms responsible for the reduction of gut motility remains to be developed.

Research frontiers

Thyroid diseases affect gastrointestinal (GI) functions including disturbance of gut motility, and the most common GI complaints in patients with hypothyroidism are nausea, vomiting, constipation and abdominal pain. The vagal nerves are extensively distributed in the digestive tracts from the upper esophageal sphincter muscles to the transverse colon in humans, and the extensive distribution of vagal nerves to the gut provides a key bi-directional link with the brain, which regulates GI behavior such as food intake, gastric accommodation and muscle contractility.

Innovations and breakthroughs

It has been demonstrated in our study using rats that complete depletion of thyroparathyroid hormones by thyroparathyroidectomy caused an extremely high fatality rate, and the disturbance of vagal activity by thyroparathyroidectomy produced a transient, less than 3 d, reduction of gastrointestinal motility. However, in comparison with thyroparathyroidectomy or vagotomy alone, application of both unilateral thyroparathyroidectomy and subdiaphragmatic vagotomy to rats had several advantages, including no deaths of the animals and a long-term, at least 7 d, reduction in gut motility. In the present study, the authors suggest for the first time that both unilateral thyroparathyroidectomy and vagotomy may be reliably applied to produce a rat model of GI disorders characterized by long-term reduction in GI motility.

Applications

Rats subject to both unilateral thyroparathyroidectomy and subdiaphragmatic thyroparathyroidectomy may provide an animal model of dyspepsia and constipation, and may be usefully used in studies of new drugs to reverse the reduced motility of the GI tract.

Terminology

Dyspepsia: A condition of impaired gastric digestive function associated with gastritis and gastroesophageal reflux. The common symptoms of dyspepsia are upper abdominal fullness, bloating, nausea, heartburn or feeling full earlier than expected.

Peer review

The authors have attempted to develop a novel animal model for reducing gastrointestinal motility in aid of studies examining dyspepsia and constipation. This is a straightforward study that addresses an important issue.

Abstract

AIM: To evaluate clinicopathologic parameters and the clinical significance related lymphovascular invasion (LVI) by immunohistochemical staining (IHCS) in endoscopic submucosal dissection (ESD).

METHODS: Between May 2005 and May 2010, a total of 348 lesions from 321 patients (mean age 63 ± 10 years, men 74.6%) with early gastric cancer (EGC) who met indication criteria after ESD were analyzed retrospectively. The 348 lesions were divided into the absolute (n = 100, differentiated mucosal cancer without ulcer ≤ 20 mm) and expanded (n = 248) indication groups after ESD. The 248 lesions were divided into four subgroups according to the expanded ESD indication. The presence of LVI was determined by factor Ⅷ-related antigen and D2-40 assessment. We compared LVI IHCS-negative group with LVI IHCS-positive in each group.

RESULTS: LVI by hematoxylin-eosin staining (HES) and IHCS were all negative in the absolute group, while was observed in only the expanded groups. The positive rate of LVI by IHCS was higher than that of LVI by HES (n = 1, 0.4% *vs* n = 11, 4.4%, P = 0.044). LVI IHCS-positivity was observed when the cancer invaded to the mucosa 3 (M3) or submucosa 1 (SM1) levels, with a predominance of 63.6% in the subgroup that included only SM1 cancer (P < 0.01). In a univariate analysis, M3 or SM1 invasion by the tumor was significantly associated with a higher rate of LVI by IHCS, but no factor was significant in a multivariate analysis. There were no cases of tumor recurrence or metastasis during the median 26 mo follow-up.

CONCLUSION: EGCs of the absolute group are immunohistochemically stable. The presence of LVI may be carefully examined by IHCS in an ESD expanded indication group with an invasion depth of M3 or greater.

INTRODUCTION

The incidence of early gastric cancer (EGC) has increased in Asia, and particularly in South Korea and Japan[1]. Endoscopic submucosal dissection (ESD) can be used for *en bloc* and complete resection (CR), and is widely applied for the curative treatment of EGC[2-4]. Studies comparing the long-term results of EGC treatment have demonstrated no significant increase in the five-year survival rate of patients following ESD[2,5,6]. However, these techniques are necessary for proper diagnosis of tumor histology to check whether the tumor has been completely removed or has recurred and to predict the possibility of lymph node (LN) metastasis, thereby determining the need for additional surgery.

Assessment of lymphovascular invasion (LVI) is usually performed on the basis of conventional hematoxylin-eosin staining (HES), sometimes lacks objectivity possibly because of the inability to distinguish lymphatics from blood vessels[7]. Although the clinical significance of molecular-based methods using immunohistochemical staining (IHCS) of resected tissues is controversial, IHCS has been used to evaluate the presence of LVI, which a risk factor for LN metastasis[8-10]. Thus, we evaluated possible correlations between IHCS and other clinicopathologic parameters in ESD specimens and the clinical significance of IHCS.

MATERIALS AND METHODS

Study design and patients

Data were retrospectively collected from patients who underwent ESD at a single, tertiary-care, academic medical center. Between May 2005 and May 2010, a total of 348 lesions (321 patients) that met the absolute and expanded indication criteria after ESD were included. This study was approved by our hospital ethics committee and institutional review board. Written informed consent was obtained from all patients prior to the procedure.

Pre-ESD evaluation

The pre-ESD assessment of tumor size and depth of invasion was performed by conventional endoscopy and endoscopic ultrasonography. Contrast-enhanced computed tomography was also performed in all patients before treatment to exclude involvement of lymph nodes or distant metastasis.

ESD and pathologic analysis

ESD was performed as reported previously[11,12]. All ESD specimens were examined by an experienced pathologist (Jin SY). Resected specimens were fixed in 10% formalin and sectioned serially in 2-mm intervals, then subjected to histological analysis. All slices were embedded in a paraffin block. The section margin, depth of invasion, and LVI were observed carefully. A one-piece resection was defined as an *en bloc* resection. The definition of CR was: (1) *en bloc* resection or complete reconstruction in two piecemeal resection cases; (2) being free of cancer at both the vertical (VM) and lateral margins (LM); (3) no submucosal invasion deeper than 500 μm from the muscularis mucosa; and (4) no evidence of vascular or lymphatic invasion. Incomplete resection was defined as resections that did not meet the curative criteria. Incompletely resected lesions confined to the mucosa with positive LM were scheduled for an additional ESD procedure, argon plasma coagulation, or surgery.

In pathology specimens obtained by ESD, the absolute indication criteria for ESD was intramucosal differentiated adenocarcinoma without ulceration $\leqslant$ 20 mm in diameter. The expanded indication criteria for ESD were: (1) intramucosal differentiated adenocarcinoma without ulceration > 20 mm in diameter; (2) intramucosal differentiated adenocarcinoma with ulceration $\leqslant$ 30 mm in diameter; (3) submucosa 1 (SM1) differentiated adenocarcinoma $\leqslant$ 30 mm in diameter; and (4) intramucosal undifferentiated adenocarcinoma without ulceration $\leqslant$ 20 mm in diameter. In this order, the expanded indication group was divided into four subgroups (groups 1, 2, 3 and 4).

Immunohistochemical staining

Serial sections (4 μm-thick) were deparaffinized in xylene. Samples were rehydrated in a graded alcohol series, and heated for 10 min in a microwave oven. This procedure was repeated twice after immersion in a citrate buffer solution to increase the reproducibility of endogenous antigens. To detect endogenous peroxidase, the samples were placed in 3% hydrogen peroxide solution for 10 min and rinsed with phosphate-buffered saline (PBS). Nonspecific binding sites were blocked by incubation in 3% normal non-immune serum for 10 min. Then the slides were washed with PBS and incubated with biotinylated polyvalent secondary antibody at room temperature for 15 min. After washing with PBS, the slides were incubated with streptavidine peroxidase for 15 min and washed a second time. Immunoreactive proteins were visualized by incubation with amine-ethyl carbazole for 3 to 5 min. The samples were counterstained with Mayer's HE and mounted using crystal mount (Biomeda, Foster City, CA, United States).

Primary antibodies specific for the mucin and gastric phenotypic markers, MUC5AC (CLH2, Novocastra Lab. Ltd, Newcastle, United Kingdom) and MUC6 (CLH5, Novocastra Lab. Ltd, Newcastle, United Kingdom), the intestinal phenotypic marker MUC2 (CCP58, Biogenx, San Ramon, CA, United States), and CD10 (56C6, Signet Lab. Oakland, CA, United States) were used. Samples that were positive for MUC5AC or MUC6 were classi-

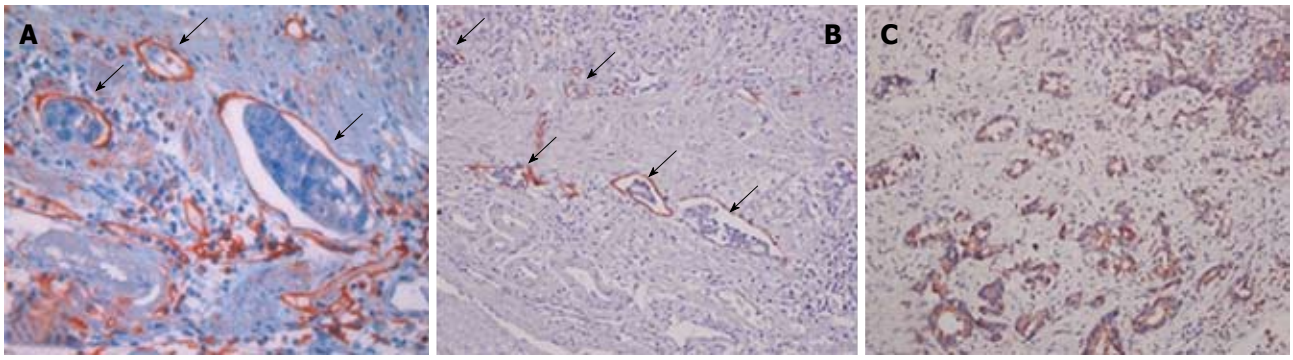

Figure 1 Immunohistochemical findings of early gastric cancers. A: Three foci of vascular invasion of tumor cells (arrows) are seen (factor Ⅷ related antigen, × 400); B: Multiple foci of lymphatic invasion (arrows) are found in the both mucosa and submucosa (D2-40, ×200); C: Positive staining is noted in the cytoplasm of neoplastic glands (vascular endothelial growth factor, ×200).

fied as having a gastric phenotype, and those positive for MUC2 or CD10 were classified as having an intestinal phenotype. Samples that were positive for at least one marker of both phenotypes were considered to have a mixed phenotype, and samples showing no marker immunoreactivity were considered to be an unclassified phenotype.

Lymphovascular-related markers and IHCS analysis

For the vascular endothelial marker, primary antibodies against factor Ⅷ-related antigen (FⅧRAg, 1:3000; DAKO, Carpenteria, CA, United States) were used. For the lymphatic endothelial marker, primary antibodies against D2-40 (1:200; LI-D, Covance Inc., Cumberland, VA, United States) were used. Primary antibodies against vascular endothelial growth factor (VEGF) (1:50; SC-152, Santa Cruz Biotechnology, Santa Cruz, CA, United States) were also applied. Vascular or LVI was indicated by clusters of tumor cell in vessels or lymphatic vasculature, the endothelia of which stained positive for FⅧRAg or D2-40, respectively. VEGF was considered positive when anti-VEGF antibodies stained the tumor cytoplasm. High microvessel density (MVD) and lymphovascular density (LVD) were detected by increased intra-tumor staining of factor Ⅷ and D2-40 (Figure 1).

Post-ESD follow-up

Endoscopic follow-up examinations were performed routinely at 1, 3, 6 and 12 mo, and then annually after ESD to assess the completeness of resection and to detect metachronous lesions. During the follow-up period, biopsy samples were taken from the ESD ulcer scar or other suspicious mucosal abnormalities. If a residual lesion or metachronous lesion was noted, additional ESD or surgery was planned.

Statistical analysis

Statistical analyses were performed using the SPSS software (version 15.0; SPSS, Chicago, IL, United States). Categorical variables were analyzed by the Chi-square test or Fisher's exact test and non-categorical variables were analyzed by the *t* test to verify the relationship between IHCS and other clinicopathological parameters. Non-categorical variables were compared among the four groups using an analysis of variance test. A multivariate analysis was conducted using a logistic regression method. *P* values $\leqslant$ 0.05 indicated statistical significance.

RESULTS

Endoscopic and pathologic characteristics

In the absolute group, the mean age of the 100 patients (100 lesions) was 62.2 years (range: 33-86 years) and included 70 men (70%). In the expanded group, the mean age of the 221 patients (248 lesions) was 62.9 years (range: 33-91 years) and included 189 men (76.2%). The dominant tumor location in both groups was the lower third of the stomach. Macroscopically, the flat/depressed type was most common (n = 131, 52.8%), and ulcers were observed in 64.9% (n = 161) of patients in the expanded group.

Of 248 lesions in the expanded group, 238 (96%) were differentiated and 10 (4%) were poorly differentiated adenocarcinoma. Twenty-eight lesions (11.3%) were SM1 cancer. The mean tumor size was 21.2 mm (range: 3-86 mm). Twenty-four (9.7%) were LM-positive two (0.8%) were VM-positive. The mixed mucin phenotype (n = 90, 36.3%) was predominant. A total of 72 (29%) were VEGF positive and 59 (23.8%) exhibited a high MVD/LVD. The CR rate by IHCS was significantly lower than that by HES (84.3% *vs* 88.3%, $P < 0.01$). The endoscopic and histopathologic characteristics of the lesions in the absolute and expanded groups are summarized in Table 1.

Subgroup analysis in the expanded indication

As mentioned above, the 248 lesions were divided into four groups according to the expanded ESD indication. Groups 1, 2, 3 and 4 contained 71 (28.6%), 140 (56.4%), 27 (10.8%) and 10 (4.7%) lesions, respectively. LVI HES-positivity was also defined as when LVI was positive by HE staining, and LVI IHCS-positivity was also defined as when LVI was positive by IHCS. Of a number of clinicopathological factors, only LVI IHCS-positivity showed significant differences between subgroups. LVI

M: Mucosa; SM: Submucosa; VEGF: Vascular endothelial growth factor; MVD: Microvessel density; LVD: Lymphatic vessel density; LVI: Lymphovascular invasion; HES: Hematoxylin-eosin staining; IHCS: Immunohistochemical staining.

HES-positivity was observed only in group 4, which included undifferentiated carcinoma. While LVI IHCS-positivity was observed in all subgroups, there was a predominance of 63.6% (7/11) in group 3, which included only SM1 cancer ($P < 0.001$) (Table 2).

Comparison of LVI in the immunohistochemically negative and positive groups in the expanded indication

LVI HES-positivity was confirmed by LVI IHCS; however, of 11 lesions identified as LVI IHCS-positive, only one was also LVI HES-positive (100% *vs* 9.1%, $P = 0.044$) (Table 3).

The association between LVI IHCS and various clinicopathological factors and IHCS markers was analyzed (Table 4). In this statistical analysis, we combined the three tumor location and depth of invasion categories into two "upper + corpus" and "lower + angle", and "mucosa 2 (M2)" and "M3 + SM1", respectively. Phenotype was categorized into intestinal and non-intestinal type. LVI IHCS-positivity was detected in 4.4% (11/248). In a univariate analysis, M3 or SM1 invasion of the tumor, and the presence of VEGF and a high LVD/MVD were factors significantly associated with a higher rate of LVI by IHCS. However, there were no significant as-

sociations between LVI by IHCS and age, sex, location, macroscopic type, endoscopic ulcer, resection pieces, histology, tumor size, lateral margin, vertical margin, or phenotype. In a multivariate analysis, there were no significant associations between LVI in IHCS and these factors (Table 4).

Follow-up

Of the 321 patients who underwent ESD, 5 (1.6%) required additional surgery (Table 5). The reasons for additional surgery were an insufficient gap between the tumor and LM or VM in four patients and patient need in one. No lesions exhibited LN metastasis. Two of the five patients had a residual tumor in the gastric wall. There were no cases of tumor recurrence or metastasis after ESD, including those patients who underwent additional surgery, during the median 26 mo follow-up.

DISCUSSION

LVI and increased LVD detected by IHCS are associated with LN metastasis in gastric cancer[13-18], and are correlated with an unfavorable prognosis in other types of cancer[19-23]. However, detection of LVI by HES is difficult for several reasons. Primarily, the distinction between blood vessels and lymphatic vessels is subjective. Furthermore, artifacts or artificial spaces formed during sample preparation may mimic the tubular structure of vasculature[7]. Antibodies to FⅧRAg help to distinguish true vascular endothelial cells therefore increasing the sensitivity of detection of vascular invasion[24,25] whereas the monoclonal antibody D2-40 specific for lymphatic endothelial cells enhances detection of lymphatic invasion[26-28]. In a previous study using post-operative specimens to diagnose lymphatic invasion, D2-40 was more sensitive for detection of lymphatic invasion (positive rate 44% *vs* 27% for D2-40 *vs* HE)[27]. Thus, we evaluated the clinical significance of IHCS, using for example FⅧRAg and D2-40, in patients with the expanded indication criteria after ESD. To the best of our knowledge, no study has evaluated the possible correlations between IHCS and other clinicopathological parameters in the expanded indication of ESD.

IHCS: Immunohistochemical staining; M: Mucosa; SM: Submucosa; VEGF: Vascular endothelial growth factor; LVD: Lymphatic vessel density, MVD: Microvessel density.

In this study, 11 lesions in the only expanded indication group, but not the absolute indication group, displayed LVI-positivity. This is likely because lymphatics existed only in the deep mucosa and abundant microvessels were found in the muscularis mucosa[27]. Differentiated mucosal cancer, which belongs to the absolute indication group was LVI-negative. Because the EGCs of the absolute indication group were immunohistochemically stable, the clinical implication of IHCS in this group is insignificant.

In the expanded indication, comparing the LVI IHCS-negative and LVI IHCS-positive groups, M3 or SM1 invasion of the tumor and the presence of VEGF and a high LVD/MVD were factors significantly associated with a higher rate of LVI by IHCS. However,

Table 5 Clinicopathological characteristics of the five patients who underwent surgical resection after endoscopic submucosal dissection

Sex/age (yr)	Type	Site	Ulcer	Pathology	Size (mm)	LM/VM	Depth	LVI HES	LVI IHCS	Residual tumor	LN

Female/64	Ⅲ	Middle	+	MD	19	+/-	M	-	-	-	-
Female/54	Ⅰ	Middle	-	MD	68	+/-	M	-	+	+	-
Male/35	Ⅰ	Middle	-	MD	22	-/-	M	-	-	-	-

LM: Lateral margin; VM: Vertical margin; LVI: Lymphovascular invasion; HES: Hematoxylin-eosin staining; IHCS: Immunohistochemical staining; LN: Lymph node; MD: Moderately differentiated; WD: Well differentiated; M: Mucosa.

there were no significant associations between LVI by IHCS and these factors in a multivariate analysis. This may be because, first, the number of patients in the LVI IHCS-positive group was too small compared to the LVI IHCS-negative group. Second, although the specimens were examined by a highly experienced pathologist, the interpretation of the IHCS results was not always accurate. Nonetheless, we must not overlook the fact that LVI-positivity was observed when the cancer invaded the M3 or SM1 layer in the LVI IHCS-positive group. Resected specimens examined by HES showed an LVI false-negative rate of 4% and a false-positive rate of 0%. The positive rate of LVI by IHCS was significantly higher than that of LVI by HES (4% *vs* 0.4%, $P = 0.044$). In other words, 10 tumors, which had been diagnosed as no LVI by HES, were correctly diagnosed as having LVI after IHCS. Only 1 of 11 (9%) LVI, confirmed by IHCS, was correctly diagnosed by HES. These results suggest that LVI cannot be predicted by HES alone and also that IHCS is somewhat more helpful than HES for identifying LVI. Therefore, the presence of LVI should be carefully examined by IHCS when invasion with a depth of M3 or greater has been detected in an expanded indication.

The major limitations of this study are its retrospective design, the relatively short follow-up period and the limited number of patients with LVI by IHCS. Because the number of LVI by IHCS was small and additional surgical treatment was not provided to all patients who were LVI-positivity by IHCS, we were unable to explain the association between LVI IHCS-positivity and LN metastasis. According to the Japanese classification of gastric carcinoma[29], resected specimens were cut thinner (*vs* surgical specimens; 2 mm *vs* 4 mm). Therefore, the quality of pathologic interpretation of resected specimens was better than that of surgical specimens. We found no case of metastasis in the LVI IHCS-positive group during the median 26 mo follow-up. However, because a previous study reported that LN metastasis was confirmed in 89% of D2-40 positive cases, compared to 41% of suspected cases of metastasis based on HES[14], a future large and long-term follow-up study is needed to assess via IHCS the relationship of LVI with LN metastasis, tumor recurrence, and patient survival.

Examination by IHCS may be required because LVI can be undetected in an ESD expanded indication group with an invasion depth of M3 or greater if we rely only on HES.

COMMENTS

Background

Lymphovascular invasion (LVI) detected by immunohistochemical staining (IHCS) is associated with lymph node (LN) metastasis in gastric cancer. The clinical significance of IHCS in early gastric cancer (EGC) in association with endoscopic submucosal dissection (ESD) is controversial. No study has evaluated the possible correlations between IHCS and other clinicopathological parameters in ESD specimens.

Research frontiers

Relationships between LN micrometastasis and clinicopathological findings based on D2-40 and factor Ⅷ-related antigen (FⅧRA) IHCS in gastric cancer have been reported. Several studies have reported that IHCS is more sensitive for detection of LVI.

Innovations and breakthroughs

LVI by hematoxylin-eosin stain (HES) and IHCS were all negative in an ESD absolute group; this group was immunohistochemically stable. However, in an ESD expanded group, the LVI IHCS-positive rate was significantly higher than that of LVI by HES. LVI IHCS-positivity was observed when the cancer invaded the mucosa 3 (M3) or submucosa 1 (SM1) levels. Therefore, the presence of LVI should be carefully examined by IHCS in an expanded group with an invasion depth of M3 or SM1.

Applications

In an ESD expanded indication group with an invasion depth of M3 or greater, IHCS should be used because LVI-positivity can remain undetected by HES. However, a large-scale prospective study is required.

Terminology

ESD, a method that can be used for *en bloc* and complete resection of EGC, is widely applied for the curative treatment of EGC. IHCS is widely used in the diagnosis of abnormal cells using specific molecular markers, such as D2-40 and FⅧRA.

Peer review

Because the number of LVIs detected by IHCS was small and additional surgical treatment was not provided to all patients who were LVI-positive by IHCS, it was unable to explain the association between LVI IHCS-positivity and LN metastasis. However, this study implies the clinical significance of IHCS in an ESD expanded indication group, and reports a useful methodology.

Abstract

AIM: To determine the value of bowel sounds analysis using an electronic stethoscope to support a clinical diagnosis of intestinal obstruction.

METHODS: Subjects were patients who presented with a diagnosis of possible intestinal obstruction based on symptoms, signs, and radiological findings. A 3M™ Littmann® Model 4100 electronic stethoscope was used in this study. With the patients lying supine, six 8-second recordings of bowel sounds were taken from each patient from the lower abdomen. The recordings were analysed for sound duration, sound-to-sound interval, dominant frequency, and peak frequency. Clinical and radiological data were reviewed and the patients were classified as having either acute, subacute, or no bowel obstruction. Comparison of bowel sound characteristics was made between these subgroups of patients. In the presence of an obstruction, the site of obstruction was identified and bowel calibre was also measured to correlate with bowel sounds.

RESULTS: A total of 71 patients were studied during the period July 2009 to January 2011. Forty patients had acute bowel obstruction (27 small bowel obstruction and 13 large bowel obstruction), 11 had subacute bowel obstruction (eight in the small bowel and three in large bowel) and 20 had no bowel obstruction (diagnoses of other conditions were made). Twenty-five patients received surgical intervention (35.2%) during the same admission for acute abdominal conditions. A total of 426 recordings were made and 420 recordings were used for analysis. There was no significant difference in sound-to-sound interval, dominant frequency, and peak frequency among patients with acute bowel obstruction, subacute bowel obstruction, and no bowel obstruction. In acute large bowel obstruction, the sound duration was significantly longer (median 0.81 s *vs* 0.55 s, $P = 0.021$) and the dominant frequency was significantly higher (median 440 Hz *vs* 288 Hz, $P = 0.003$) when compared to acute small bowel obstruction. No significant difference was seen between acute large bowel obstruction and large bowel pseudo-obstruction. For patients with small bowel obstruction, the sound-to-sound interval was significantly longer in those who subsequently underwent surgery compared with those treated non-operatively (median 1.29 s *vs* 0.63 s, $P < 0.001$). There was no correlation between bowel calibre and bowel sound characteristics in both acute small bowel obstruction and acute large bowel obstruction.

CONCLUSION: Auscultation of bowel sounds is non-specific for diagnosing bowel obstruction. Differences in sound characteristics between large bowel and small bowel obstruction may help determine the likely site of obstruction.

INTRODUCTION

Auscultation of bowel sounds is a traditional technique for evaluating patients with abdominal symptoms. It is simple, but generally empirical and too subjective. Bowel sounds show wide variations from person to person and even from the same person at different times. The interpretation of a person's bowel sounds by different clinicians may also vary[1,2]. There is a distinct lack of clinical research within the literature to support any discussion on the value of auscultation for bowel sounds[3]. Many practitioners pay little attention to this physical examination and some have even abandoned their stethoscope. The question has been raised as to whether auscultation for bowel sounds is of any clinical value.

Recently, recording of bowel sounds with objective evaluation has become possible with commercially available electronic stethoscopes; however, bowel sounds in intestinal obstruction have not been extensively studied since the introduction of these stethoscopes.

The aim of this study is to determine the value of objective assessment of bowel sounds provided by an electronic stethoscope in supporting a clinical diagnosis of intestinal obstruction. Correlation with radiological and operative findings and clinical outcome is made to identify characteristic bowel sounds that will improve the diagnostic accuracy for bowel obstruction.

MATERIALS AND METHODS

The electronic stethoscope used for this study was the 3M™ Littmann® Model 4100 with Version 2.0 sound analysis software (3M Health Care, St. Paul, MN 55144, United States). Three frequency modes are available for auscultation: bell (20-200 Hz), diaphragm (100-500 Hz), and extended range (20-1000 Hz). Bowel sounds are best heard in the diaphragm mode, which selectively filters in sounds of higher frequency range, thus omitting the low frequency sounds transmitted from the heart or lungs. Other features of the electronic stethoscope include the ability to amplify sounds several times compared with a conventional stethoscope, and digital signal processing over the entire acoustic range. A maximum of six distinct tracks of up to 8 s each can be recorded and stored in the stethoscope. The recorded sound tracks are then transmitted to a computer via an infrared link.

The Local Ethics Committee approved this study. The subjects were patients admitted to our institution with a diagnosis of possible intestinal obstruction during the period July 2009 to January 2011. Clinical data were prospectively collected. The presenting complaints and findings from physical examination were reviewed following admission to the ward. Verbal consent was obtained from the patients for recording of their bowel sounds. The patients were positioned lying supine on a bed. Six 8-s recordings were taken from each patient with the stethoscope positioned on the lower abdomen (two at the right iliac fossa, two at the suprapubic region, and two at the left iliac fossa). The reason for recording sounds from the three different areas of the lower abdomen was to position the stethoscope as far away from the heart and lungs as possible to reduce the interference by sounds arising from the heart and lungs. For the purpose of this study, no attempt was made to compare the sounds at different recording sites as a previous study showed that the frequency and intensity of bowel sounds were equal throughout all four quadrants[4]. The diagnosis of each of the patients was determined by clinical follow-up, clinical evolution, and by radiological and operative findings. The recorded sound tracks were analysed by the main investigator using the supplied software. The investigators were not blinded to the results of other tests such as radiological imaging or intraoperative findings.

When analyzing the sound tracks, the tracks were played back in the "diaphragm" mode. The overall quality of recording was determined by the level of ambient background noise that was actually present at the time of recording, and the presence of a constant "hissing" machinery noise (not present in the environment during recording), which could sometimes occur during playback of some of the tracks. This "ghost sound" phenomenon was noticeably more common when the entire track lacked actual bowel sounds and it was thought that the recording system compensates for the lack of sound by automatic over-amplification of the baseline machine noise. The waveform view displays the raw input signal as a continuous waveform line, where each wave is a pulse of sound. The maximum arbitrary amplitude (range 0% to 100%) of the bowel sounds was identified from each track (Figure 1).

Classification of bowel sounds

The sounds were described as "isolated" when they occurred in isolation and did not last for more than 0.5 s in duration and were more than 0.2 s apart. The spike of the isolated sound is shown as a single vertical line over a very short duration (Figure 1). The sounds were described as "clustered" when they occurred continuously for more than 0.5 s and recognised audibly as a run of individual "popping" effects (Figure 1), and "prolonged" when they occurred continuously for longer than 4 s[5]. The interval between sounds was determined by the period between the end of one sound and the start of the next sound. For the purpose of computation, when there were more than two distinct bowel sounds on a single track the shortest interval between two distinct bowel sounds was taken as the interval between sounds for that track. The spectrum view displays the frequency

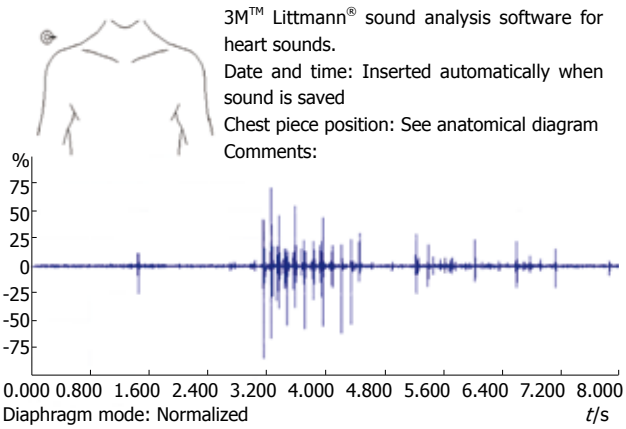

Figure 1 Example of bowel sound recording displayed in the "waveform" view. The y-axis indicates the relative sound amplitude and the x-axis indicates recording time elapsed in seconds. This recording was taken from a patient with a small bowel obstruction. Note the isolated sound on the left side followed by two clusters of sound in the middle and on right side of the strip.

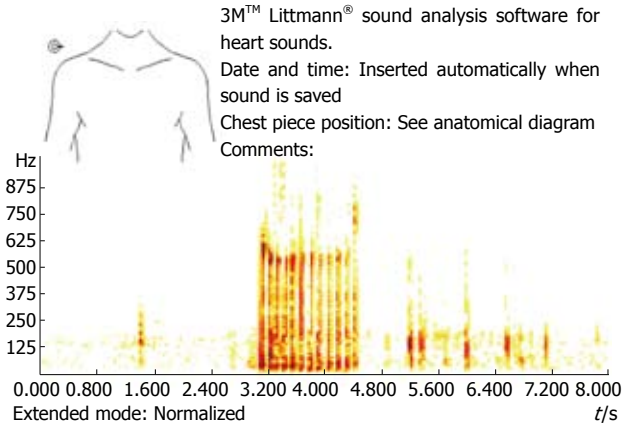

Figure 2 Example of bowel sound recording displayed in the "spectrum" view. This chart shows the sound frequency spectrum and the relative intensity of each sound frequency (darker colour indicates higher sound intensity at the frequency indicated along the y-axis) for the same recording used for Figure 1.

distribution as vertical bars, each bar represents a group of frequencies, and the more prominent frequencies have darker colour tones than the less prominent frequencies (Figure 2). The highest dominant frequency from each track was determined by first identifying the most dominant sound frequency across the spectrum at each point of time when bowel sounds were present. The highest dominant frequency over the entire duration of the track was then identified and used for analysis. The peak frequency was determined by the highest value dominant frequency among the six tracks for each individual patient.

X-rays and computed tomography (CT) imaging of the abdomen and pelvis were reviewed for evidence of intestinal distension. The calibre of the small bowel and large bowel at the widest points were determined using the measuring tool in the Amalga IMS 5.1 radiology image viewing system installed on our institution's computers. The point of transition was identified if bowel obstruction was present on CT images. Any operative intervention performed for the patients was also documented. The cause of obstruction, as identified from radiological imaging and/or during surgery, was recorded.

The following definitions were used to compare bowel sounds between patients with acute bowel obstruction *vs* subacute obstruction *vs* no obstruction[6-8]:

Acute bowel obstruction: Dilated bowel calibre (> 3 cm for small bowel, > 6 cm for large bowel) with symptoms of vomiting (for small bowel pathology) or no flatus/bowel motion for > 24 h (for large bowel pathology) and with CT/operative evidence of complete or high grade mechanical obstruction with a discrete transition point, collapsed distal segment, and little or no colonic gas present distal to the obstruction.

Subacute obstruction: Dilated bowel calibre (> 3 cm for small, > 6 cm for large bowel), with or without symptoms as per acute obstruction, but no CT/operative evidence of complete or high-grade mechanical obstruction (a poorly defined transition zone, incomplete collapse of distal bowel segment, and moderate colonic gas distal to the obstruction).

Acute (complete) or subacute (partial) mechanical obstruction of the bowel may be caused by herniation, adhesions, volvulus, intussusception, foreign body, phytobezoar, strictures, neoplasia, or wall oedema due to inflammatory conditions. Partial obstruction allows some liquid contents and gas to pass through the point of obstruction, whereas complete obstruction impedes passage of all bowel contents.

No obstruction: No clinical/CT/operative/endoscopic evidence of mechanical obstruction and other diagnosis was observed during the clinical course of the patient. Diagnoses such as constipation colic, faecal impaction, paralytic ileus, chronic megacolon, and pseudo-obstruction will be classified under this category.

Statistical analysis

Statistical analysis was performed using SPSS Version 12.0.1 (SPSS Inc. Chicago, Illinois, United States). Continuous non-parametric data were analysed using Mann-Whitney *U* test. A χ^2 test was used to correlate the type of bowel sounds with the presence of obstruction. Pearson correlation was used to correlate bowel calibre with sound duration, sound-to-sound interval, dominant frequency, and peak frequency. Continuous data was presented as median values with inter-quartile ranges.

RESULTS

Seventy-one patients were recruited and had their bowel sounds recorded during the period July 2009 to January 2011. These patients had been admitted to our institution with abdominal symptoms, physical signs, or radiological

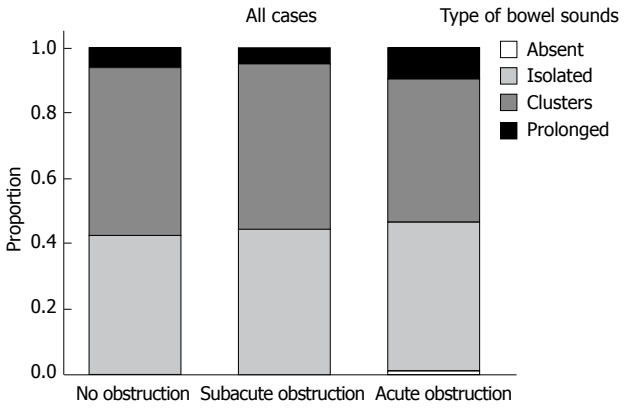

Figure 3 Distribution of different types of bowel sounds recorded for patients with no obstruction, subacute obstruction, and acute obstruction.

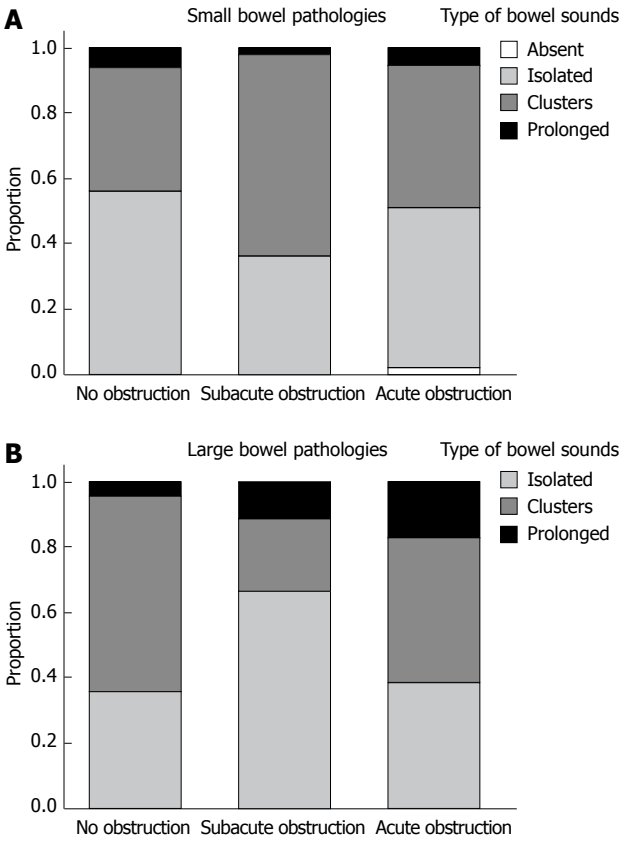

Figure 4 Distribution of different types of bowel sounds recorded for patients with small bowel pathologies (A) and large bowel pathologies (B).

findings suggestive of possible bowel obstruction.

There were 43 male and 28 female patients with age range from 22 to 93 years (mean 68 ± 16 years). Sixty-nine percent of patients presented with abdominal pain and 70.4% had a history of vomiting. Abdominal distension was present in 90.1% of the patients and abdominal tenderness was present in 33.8%. All patients had radiological imaging of the abdomen and pelvis. Plain film radiography was performed in all patients and CT was performed in 85.9% of patients.

Acute bowel obstruction was diagnosed in 40 patients (56.3%). Of these, 27 occurred in the small bowel and 13 occurred in the large bowel. Eleven patients (15.5%) had subacute bowel obstruction, of which eight occurred in the small bowel and three occurred in the large bowel. Twenty patients (28.2%) had no bowel obstruction. The diagnoses made for the non-obstructive conditions were ileus, pseudo-obstruction, gastritis, gastroenteritis, ileitis, colitis, constipation, cholecystitis, and bowel ischemia. Surgical intervention was performed in 25 patients (35.2%) during the same admission for the acute abdominal conditions.

Four hundred and twenty-six recordings were made from the 71 patients, of which 6 were of poor quality and were not used for analysis.

All types of bowel sounds were heard in all three groups of patients. Overall, isolated and clustered bowel sounds were heard most frequently in approximately equal proportions in all three groups of patients and prolonged sounds comprised 9.3% in the group with acute bowel obstruction (Figure 3).

The cases were further analysed separately in subgroups of patients with small bowel pathologies and patients with large bowel pathologies. In the subgroup of patients with small bowel pathologies, the incidence of prolonged sounds were 6%, 2% and 6% with no obstruction, subacute obstruction and acute obstruction, respectively, and were not significantly different (P = 0.208) (Figure 4A). In the subgroup of patients with large bowel pathologies, the incidence of prolonged sounds increased significantly from 4% with no obstruction to 11% with subacute obstruction, and 17% with acute obstruction (P = 0.025) (Figure 4B).

Among the groups of patients with no bowel obstruction, subacute obstruction, and acute obstruction, the distributions of dominant frequencies were similar, with the highest number of recordings with a dominant frequency in the 100 to 300 Hz range (Figure 5A). None of the recordings showed a dominant frequency of over 1000 Hz.

There was no significant difference between the sound characteristics in terms of sound duration (Figure 5B), sound-to-sound interval (Figure 5C), dominant frequency (Figure 5D), and peak frequency (Figure 5E) when comparisons were made among the groups of patients with acute bowel obstruction, subacute bowel obstruction, and no bowel obstruction. The results are summarised in Table 1.

In the patient subset with acute bowel obstruction (n = 40), 27 patients had a small bowel obstruction and 13 had a large bowel obstruction. The sound characteristics in acute small and large bowel obstruction were compared (Table 2). The sound duration was significantly longer (P = 0.021) and the dominant frequency significantly higher (P = 0.003) in the large bowel obstruction group. The median peak frequency was about 100 Hz higher in the large bowel obstruction group, but the difference did not reach statistical significance (P = 0.060).

Comparison was made between patients with acute large bowel obstruction and the three patients with

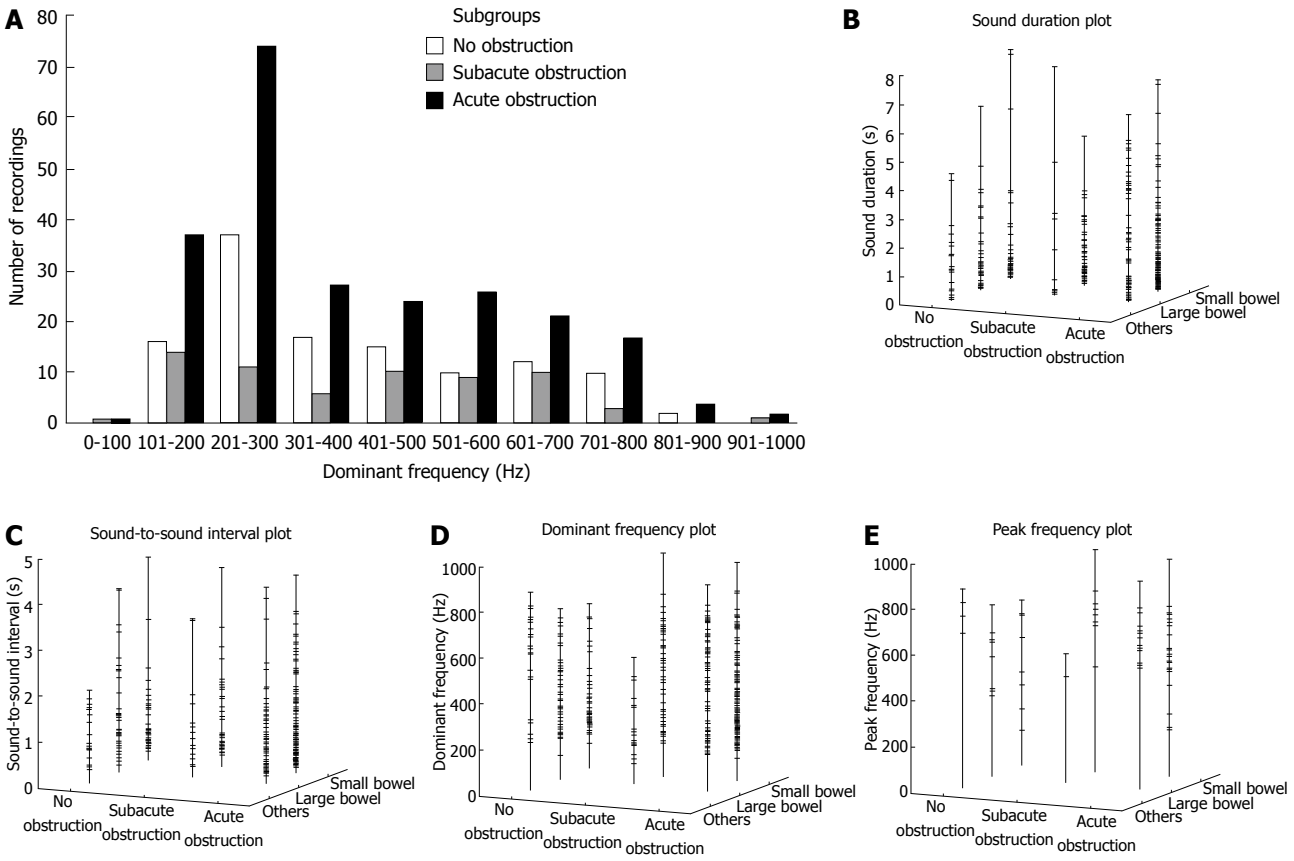

Figure 5 Distribution of the dominant frequencies of bowel sounds (A), sound duration (B), sound-to-sound interval (C), dominant frequency (D), and peak frequency (E) in patients with no obstruction, subacute obstruction, and acute obstruction, *etc*.

Table 1 Sound characteristics of acute bowel obstruction *vs* subacute bowel obstruction *vs* no obstruction

	No obstruction (n = 20)	Subacute obstruction (n = 11)	Acute obstruction (n = 40)	P value
Sound duration (s)	0.64 (0.20-1.57)	0.63 (0.23-1.67)	0.69 (0.19-2.10)	> 0.05
Sound-to-sound interval (s)	0.72 (0.46-1.27)	0.70 (0.47-1.67)	0.75 (0.41-1.41)	> 0.05
Dominant frequency (Hz)	325 (225-530)	405 (218-565)	315 (225-545)	> 0.05
Peak frequency (Hz)	595 (378-713)	655 (465-735)	585 (530-706)	> 0.05

Data are presented as the median (inter-quartile range).

Table 2 Sound characteristics of acute small bowel obstruction *vs* acute large bowel obstruction

	Small bowel obstruction (n = 27)	Large bowel obstruction (n = 13)	P value
Sound duration (s)	0.55 (0.17-1.67)	0.87 (0.27-3.60)	0.021
Sound-to-sound interval (s)	0.72 (0.41-1.40)	0.78 (0.44-1.42)	0.621
Dominant frequency (Hz)	288 (220-479)	440 (250-643)	0.003
Peak frequency (Hz)	560 (480-695)	660 (578-740)	0.060

Data are presented as the median (inter-quartile range).

pseudo-obstruction of the large bowel (Table 3). There was no significant difference in the sound characteristics between the two groups. Comparison between patients with a small bowel obstruction and a pseudo-obstruction (Table 4) showed significantly longer sound duration, longer sound-to-sound interval, and higher dominant frequency in patients with a pseudo-obstruction.

Analysis was performed on the 35 patients with a small bowel obstruction (27 acute obstruction and eight subacute obstruction included). Twenty-six patients (74%) with a small bowel obstruction were caused by (or presumed to be caused by) adhesions when there was a previous history of abdominal operation(s), CT (performed on 30 patients) did not find any mass lesion causing the obstruction, or the diagnosis confirmed during surgical exploration. Other causes of obstruction were small bowel volvulus (n = 3), bowel non-rotation (n = 1), femoral hernia (n = 1), parastomal hernia (n = 1), omental mass invasion (n = 1), and unknown (n = 2). The bowel sounds characteristics were compared between those who were treated conservatively (n = 25) *vs* those who were operated on (n = 10) (Table 5). The dominant frequency and peak frequency between non-operated and operated groups were not significantly different. The sound duration in the operated group was

Table 3 Sound characteristics of acute large bowel obstruction *vs* large bowel pseudo-obstruction

	Large bowel obstruction (n = 13)	Large bowel pseudo-obstruction (n = 3)	P value
Sound duration (s)	0.87 (0.27-3.60)	1.24 (0.53-2.64)	0.686
Sound-to-sound interval (s)	0.78 (0.44-1.42)	1.08 (0.68-2.23)	0.061
Dominant frequency (Hz)	440 (250-643)	488 (389-679)	0.174
Peak frequency (Hz)	660 (578-740)	630 (525-750)	0.638

Data are presented as the median (inter-quartile range).

Table 4 Sound characteristics of acute small bowel obstruction *vs* large bowel pseudo-obstruction

	Small bowel obstruction (n = 27)	Large bowel pseudo-obstruction (n = 3)	P value
Sound duration (s)	0.55 (0.17-1.67)	1.24 (0.53-2.64)	0.048
Sound-to-sound interval (s)	0.72 (0.41-1.40)	1.08 (0.68-2.23)	0.041
Dominant frequency (Hz)	288 (220-479)	488 (389-679)	0.001
Peak frequency (Hz)	560 (480-695)	630 (525-750)	0.446

Data are presented as the median (inter-quartile range).

longer than the non-operated group, but the difference did not reach statistical significance. The sound-to-sound interval was significantly longer in the operated group (P < 0.001).

Analysis of bowel sounds was made in relation to bowel dilatation in acutely obstructed bowel. There was no correlation between the small bowel calibre (4.8 ± 1.6 cm) and the sound duration (r = -0.046, P = 0.567), sound-to sound interval (r = -0.020, P = 0.817), dominant frequency (r = 0.025, P = 0.753), and peak frequency (r = -0.208, P = 0.298) for acute small bowel obstruction. Similarly, for acute large bowel obstruction, there was no correlation between the large bowel calibre (8.2 ± 1.7 cm) and sound duration (r = -0.103, P = 0.372), sound-to-sound interval (r = -0.077, P = 0.535), dominant frequency (r = -0.022, P = 0.847), and peak frequency (r = -0.028, P = 0.927).

DISCUSSION

Bowel sounds are generated by contractions of the alimentary tract, and mixing of gaseous and liquid contents[9]. The quality of bowel sounds varies according to the state of bowel activity[10,11]. Bowel sounds are complex, and each sound comprises a mixture of tones and is often a sequence of closely connected sounds. Common descriptions of bowel sounds include gurgling or rattling or rustling noise heard in a normal person, rumbling explosions heard with gastroenteritis, succussion splash heard in gastric outlet obstruction, diminished, i.e., infrequent, and soft sounds, and prolonged tinkling or high-pitched metallic sounds that may be heard in bowel obstruction. Very diminished or absent bowel sounds may be caused by bowel obstruction, intestinal ischemia, paralytic ileus, and peritonitis.

Table 5 Sound characteristics of non-operated and operated patients with small bowel obstruction

	Small bowel obstruction, non operated (n = 25)	Small bowel obstruction, operated (n = 10)	P value
Sound duration (s)	0.55 (0.21-1.45)	1.00 (0.25-2.26)	0.100
Sound-to-sound interval (s)	0.63 (0.39-1.13)	1.29 (0.61-1.82)	< 0.001
Dominant frequency (Hz)	360 (225-560)	265 (210-455)	0.084
Peak frequency (Hz)	625 (535-713)	525 (400-738)	0.432

Data are presented as the median (inter-quartile range).

The published literature on auscultation of bowel sounds has been rather scarce over the past century. Since Cannon described the rhythmic sounds produced by the stomach and intestines more than 100 years ago, very few papers have been published on this subject[12].

Advances in technology have allowed various systems to be developed for the objective analysis of bowel sounds. Spectral analysis of bowel sounds was first described by Horn *et al*[13] in 1966. The spectrogram that their apparatus produced was a complex record, which was difficult to understand, and the frequency range of their apparatus was too small. Work by Watson *et al*[14] in 1967 found that bowel sounds have a frequency range of at least 150 Hz to 5000 Hz, with peaks detected at frequencies of up to 2000 Hz. These very high frequencies were not seen in our study, where the peak dominant frequency of bowel sounds recorded never reached above 1000 Hz in any of our recordings.

Yoshino *et al*[15] in 1990 attempted a computer analysis of bowel sounds in intestinal obstruction. The number of subjects studied was small (n = 21). The peak frequency of patients with intestinal obstruction in the subgroup of patients that required surgery (612 ± 86 Hz, n = 5) was significantly higher compared with the subgroup that did not require surgery (273 ± 64 Hz, n = 3). The authors concluded that computer analysis of bowel sounds of mechanical obstruction could provide a very objective assessment of severity, and could help determine the treatment regimen (conservative or operative) of each patient. However, our data on patients with small bowel obstruction showed that the subgroup that subsequently underwent surgery (n = 10) did not have any significant difference in the dominant or peak frequencies when compared with the subgroup that did not undergo surgery (n = 25). Instead, there was a significantly longer sound-to-sound interval in the subgroup that underwent surgery compared with the subgroup that was treated conservatively. The explanation for this is difficult, but it may be that in situations

where the small bowel obstruction does not resolve and subsequently requires surgery, the affected bowel is more prone to ischemia and fatigue, becoming more distended and resulting in less frequent peristaltic activities and recordable sounds[10,16].

The study by Sugrue *et al*[17] in 1994 compared characteristics of bowel sounds in controls (n = 63) and patients with acute appendicitis (n = 25), acute cholecystitis (n = 15), and bowel obstruction (n = 21). This study compared sound number, duration, interval, and amplitude but not frequency of bowel sounds. It was found that in bowel obstruction, the sound duration, interval, and amplitude all significantly increased when compared to control subjects. However, in our current study, there was no significant difference in the sound duration and sound-to-sound interval between obstructed and non-obstructed bowel.

The current study is, so far, the largest series of patients with intestinal obstruction investigated for bowel sounds (n = 51). This study has shown objectively that bowel sound characteristics, in general, are not significantly different between patients with acute, subacute, or no intestinal obstruction using the commonly compared parameters, including sound duration, sound-to-sound interval, and dominant and peak frequencies. However, the obstructed large bowel has significantly longer sound duration (median 0.87 s *vs* 0.56 s) and higher dominant frequency (median 440 Hz *vs* 288 Hz) when compared to obstructed small bowel. The possible explanations for these differences are that movements within the colon usually involve less frequent peristalsis but larger volume shift with each peristalsis and, therefore, in the presence of an obstruction, a longer time elapses when fluid and gas are forced to pass through a tight stenosis. The higher sound frequency in large bowel obstruction can be explained by the fact that the majority of ileocecal valves are competent[18,19]. In the event of large bowel obstruction, the pressure rises within the "closed loop" segment of the colon proximal to the point of obstruction. Progressive distension of the colon increases the tension on the colonic wall, as well as thinning of the wall; hence, vibration is produced at a higher frequency. In small bowel obstruction, the pressure within the obstructed segment of bowel is usually limited by reflux of the small bowel contents back into the stomach (except in the presence of certain uncommon situations causing a closed loop obstruction), hence the common presentation of vomiting in small bowel obstruction.

In the small group of patients with large bowel pseudo-obstruction, the sound characteristics were similar to those with large bowel obstruction. This is not surprising, because in both conditions the large bowel can be grossly distended. The point of "obstruction" in patients with pseudo-obstruction is often caused by a high resting anal sphincter tone, which impedes the evacuation of flatus and faeces. This can be identified by digital rectal examination and the findings of a tight anus, which precludes easy entry of the examining finger. Upon entry of the finger, the rectum can be felt to be capacious and mainly gas and fluid filled.

The intrinsic difficulty with the study of bowel sounds is that it is never possible to hear or record exactly the same pattern of bowel sounds with exactly same amplitude, frequency, duration and interval repeatedly and consistently as compared to the consistent sounds produced from the heart, which has a set rhythm and sound characteristics over time. The bowel sounds heard from the same patient will also differ at different times when the patient is re-examined. Therefore intrasubject reproducibility of repeat recording was not evaluated in this study. The wide range of physiological variations means that the clinical significance of bowel sounds is limited. There is no clear evidence that high-pitched bowel sounds have clinical pertinence[20]. The recording of bowel sound yields only the sum of the motility of all areas of the alimentary track, so no statements are possible about the activity of any particular segment by comparison of sounds at different recording sites[21].

In this study, the recording of six 8-second tracts of bowel sounds performed over a few minutes may not be representative of the overall pattern over a longer period. The technical ability to perform continuous recording over a longer period is more likely to provide better representation of the whole picture, as well as improving intrasubject reproducibility. Recent biomedical engineering experimental studies have utilised bowel sounds to assess bowel motility and their techniques have shown good potential for monitoring and estimation of bowel motility[22-25]. Incorporation of these technologies into a portable electronic stethoscope might improve the recording, analysis, and interpretation of clinical data.

COMMENTS

Background

Auscultation of bowel sounds is a traditional technique for evaluating patients with abdominal symptoms. It is simple, but is generally empirical and too subjective. There is a distinct lack of clinical research to support the value of auscultation for bowel sounds.

Research frontiers

Recording of bowel sounds with objective evaluation has become possible with commercially available electronic stethoscopes. In this study, the authors aimed to determine the value of objective assessment of bowel sounds provided by an electronic stethoscope in supporting a clinical diagnosis of intestinal obstruction. Correlation with radiological and operative findings, and clinical outcome was made to identify characteristic bowel sounds that will improve the diagnostic accuracy for bowel obstruction.

Innovations and breakthroughs

This is the largest study examining bowel sounds for intestinal obstruction using a commercially available electronic stethoscope. Bowel sounds recorded for different conditions, including acute and subacute obstruction of the small bowel and large bowel, pseudo-obstruction of large bowel, and patients with no bowel obstruction were compared using measurable parameters, such as sound duration, sound-to-sound interval, dominant frequency, and peak frequency. The most important breakthroughs from this study are that large bowel obstruction has a significantly longer sound duration and higher dominant frequency than small bowel obstruction. Furthermore, bowel sounds in pseudo-obstruction of the large bowel mimic acute large bowel obstruction; therefore, auscultation is of less value in differentiating between these two conditions. Small bowel obstruction that resolved with conservative management had shorter sound-to-

sound interval than those that eventually needed surgery.

Applications

By understanding the differences in bowel sound qualities among various acute obstructive conditions of the bowel, practitioners can use their past experience and clinical judgement when auscultating and interpreting bowel sounds in an acute abdomen.

Terminology

Bowel sound duration, sound-to-sound interval, dominant frequency, and peak frequency are the main parameters used to analyse bowel sounds. The reasons for the observed differences among conditions, including acute and subacute obstruction, small and large bowel obstruction, were discussed.

Peer review

The authors assessed the value of objective analysis of bowel sounds in a unique group of patients who presented with a common, yet challenging, abdominal condition. The data presented in this study showed that auscultation of bowel sounds, seemingly so simple to perform, becomes very complex when subjected to a scientific study. Bowel sounds on their own may not be specific enough to provide a diagnosis of bowel obstruction. The combination of clinical and radiological assessments remains the standard for diagnosing bowel obstruction.

Abstract

AIM: To investigate the effect of reducing dietary fiber on patients with idiopathic constipation.

METHODS: Sixty-three cases of idiopathic constipation presenting between May 2008 and May 2010 were enrolled into the study after colonoscopy excluded an organic cause of the constipation. Patients with previous colon surgery or a medical cause of their constipation were excluded. All patients were given an explanation on the role of fiber in the gastrointestinal tract. They were then asked to go on a no fiber diet for 2 wk. Thereafter, they were asked to reduce the amount of dietary fiber intake to a level that they found acceptable. Dietary fiber intake, symptoms of constipation, difficulty in evacuation of stools, anal bleeding, abdominal bloating or abdominal pain were recorded at 1 and 6 mo.

RESULTS: The median age of the patients (16 male, 47 female) was 47 years (range, 20-80 years). At 6 mo, 41 patients remained on a no fiber diet, 16 on a reduced fiber diet, and 6 resumed their high fiber diet for religious or personal reasons. Patients who stopped or reduced dietary fiber had significant improvement in their symptoms while those who continued on a high fiber diet had no change. Of those who stopped fiber completely, the bowel frequency increased from one motion in 3.75 d (± 1.59 d) to one motion in 1.0 d (± 0.0 d) ($P < 0.001$); those with reduced fiber intake had increased bowel frequency from a mean of one motion per 4.19 d (± 2.09 d) to one motion per 1.9 d (± 1.21 d) on a reduced fiber diet ($P < 0.001$); those who remained on a high fiber diet continued to have a mean of one motion per 6.83 d (± 1.03 d) before and after consultation. For no fiber, reduced fiber and high fiber groups, respectively, symptoms of bloating were present in 0%, 31.3% and 100% ($P < 0.001$) and straining to pass stools occurred in 0%, 43.8% and 100% ($P < 0.001$).

CONCLUSION: Idiopathic constipation and its associated symptoms can be effectively reduced by stopping or even lowering the intake of dietary fiber.

INTRODUCTION

Lack of fiber in the diet was first postulated in 1971

as the cause of diseases such as diverticulosis, hemorrhoids and colorectal cancer[1]. Since then, partly due to widespread media publicity, it is now widely accepted that dietary fiber is a necessary component of a healthy diet and is required for normal bowel movement[2-5]. It is popularly used in the management of constipation by the public and by many doctors. Insoluble fiber is known to increase stool weight and decrease colonic transit time[6,7]. Fiber is said to aid in water retention in the colon and results in stools that are less dry and easier to evacuate. However, the reality is that stool moisture content remains at 70%-75% regardless of the amount of fiber and water consumed[7,8].

There is recent evidence that low fiber intake does not equate to constipation[9]. Patients with chronic constipation also have similar fiber intake to controls[10-13]. Patients with chronic constipation may also have worsening symptoms when dietary fiber intake is increased[14]. Another study found that lactulose was more effective in easing constipation when compared with fiber[15].

It has also been our experience that many patients with constipation are already consuming a large amount of fiber before they seek medical attention.

We therefore carried out a prospective longitudinal case study to investigate the effect of decreasing dietary fiber in patients with idiopathic constipation.

MATERIALS AND METHODS

Constipation was defined clinically in patients who presented either with symptoms of straining to expel bulky large stools or a bowel frequency of less than one motion per 3 d over a period of at least 3 mo. Patients who presented to the clinic with symptoms of constipation, abdominal distension, pain or bloating, difficulty in evacuation with or without symptoms of rectal bleeding were considered for the study. For the purpose of this study, we did not distinguish between slow colonic transit type or obstructed defecation type of constipation nor did we attempt to classify the patients according to irritable bowel syndrome subtypes. All the patients underwent colonoscopy to exclude colonic lesions. Patients who had colorectal cancer, previous colonic surgery, melanosis coli or thyroid disorders were excluded. Patients with anal conditions such as severe prolapsed hemorrhoids, chronic anal fissure or any other condition that required surgery were also excluded.

Sixty-three consecutive patients after normal colonoscopy were enrolled into the study from May 2008 to May 2010. Each patient was to act as their own control. The physiology of the gastrointestinal tract and the bulking effects of dietary fiber were explained to the patients[16,17]. Patients were then instructed to completely stop their intake of dietary fiber, including vegetables, cereals, fruits, wholemeal bread and brown rice for 2 wk. Those who were vegetarians were asked to eat white rice instead of unpolished rice, white bread instead of whole meal bread, and to take processed bean products for protein. They were to continue their normal quantities of carbohydrates and proteins. Sieved fruit juices and clear vegetable soups were allowed. Patients were instructed not to take any laxatives during these 2 wk. After 2 wk, patients were asked to continue on with as little fiber in their diet as they were comfortable with for the long term. Patients were followed up at 1 mo and 6 mo intervals and final results were analyzed at 6 mo.

Data collected included age, sex, general dietary fiber intake, symptoms of constipation, difficulty in evacuation of stools, anal bleeding, abdominal bloating or abdominal pain. Constipation was recorded as the interval in days between bowel movements. Difficulty in evacuation was a subjective measure and patients were asked to choose from one of 3 degrees (no straining, occasional or moderate straining and severe straining or straining most of the time).

Statistical analysis

All data was entered into a secured database, and accessed only by the authors. The paired samples *t* test was performed using SPSS for Windows (SPSS Inc., Chicago, United States), version 17.0 on an IBM personal computer. Results are expressed as mean ± SD.

RESULTS

There were 16 males (25.6%) and 47 (74.4%) females, median age 47 years (range, 20-80 years) included in the study. At the commencement of the study, all patients were already on a high fiber diet or taking fiber supplements. After 2 wk of a no fiber diet, patients were asked to continue on as little fiber in the diet as they were able to follow if this were to give them relief from their symptoms.

At 6 mo, 41 patients continued on a no fiber diet and 16 were on a reduced fiber diet. The remaining 6 patients continued on a high fiber diet for various reasons including being vegetarians or inability to stop consuming dietary fiber for religious or personal reasons.

The median age of patients who stayed on a no fiber diet was 46 years (range, 21-80 years), on a reduced fiber diet was 45 years (range, 20-65 years) and on a high fiber diet was 59 years (range, 28-75 years). There was no statistical significant difference in age between the 3 groups. There was also no statistical difference in sex between the 3 groups (Table 1).

At 6 mo follow-up, the interval between bowel movements decreased with the reduction in fiber intake ($P < 0.001$). Forty one patients who completely stopped fiber intake had their bowel frequency increased from one motion in 3.75 d (± 1.59 d) to one motion in 1.0 d (± 0.00 d) ($P < 0.001$). Of 16 patients who reduced their dietary fiber intake, 12 patients had daily bowel movement, 3 had one bowel movement every 2 to 3 d and one had a bowel movement every 4 to 6 d, giving one motion per 1.9 d (± 1.21 d) on a reduced fiber diet compared with 1 motion per 4.19 d (± 2.09 d) on a high fiber diet ($P < 0.001$). There was no change in the frequency of bowel movement for patients who continued with high dietary fiber intake, with one motion per 6.83 d (± 1.03 d) before and after consultation ($P = 1.00$).

Table 1 Age and sex of all patients, segregated by post-consultation dietary fiber intake

Variable	General (n = 63)	No fiber (n = 41)	P value	Reduced fiber (n = 16)	P value	High fiber (n = 6)	P value
Age (yr), mean (range)	47 (20-80)	46 (21-80)	0.864	45 (20-65)	0.459	59 (28-75)	0.052
Sex[1] n (%)	16 (25.4)	15 (36.6)	0.258	1 (6.25)	0.034	0 (0)	< 0.01

[1]Numbers of male in each group. Corresponding P values for the age and sex of each category to the overall mean are provided.

Table 2 Symptoms at presentation and at 6 mo following change in dietary fiber intake

Symptom	Symptoms at presentation (n = 63)	High dietary fiber (n = 6)	P value	Reduced dietary fiber (n = 16)	P value	No dietary fiber (n = 41)	P value
Anal bleeding	31	4	1	4	0.216	0	< 0.001
Constipation	63	6	1	12	0.041	0	< 0.001
Bloatedness	33	6	1	5	0.041	0	< 0.001
Strain in bowel opening	63	6	1	9	0.004	0	< 0.001
Abdominal pain	13	3	1	2	0.164	0	0.012

There was also a difference between the groups in the proportion of patients with associated symptoms. For symptoms of bloating, all of those on a high fiber diet continued to be symptomatic, while only 31.3% in the reduced fiber group and none of the no fiber group had symptoms (0%, $P < 0.001$) (Table 2).

With regards to straining, all those on a no fiber no longer had to strain to pass stools. Of those who reduced dietary fiber, 7 of 16 showed improvement while the symptoms remain unchanged in those who remained on a high fiber diet ($P < 0.001$ between groups).

Symptoms of abdominal pain only improved in patients who stopped fiber completely while those who continued on a high fiber diet or reduced fiber diet did not show any improvement (Table 2). In addition, those on a no dietary fiber diet no longer had symptoms of anal bleeding.

DISCUSSION

This study has confirmed that the previous strongly-held belief that the application of dietary fiber to help constipation is but a myth. Our study shows a very strong correlation between improving constipation and its associated symptoms after stopping dietary fiber intake. However whilst there was no significant difference between the mean age of the 3 groups with different post-consultation dietary fiber intake, older patients seemed less likely to stop dietary fiber, although this did not reach significance. We did not survey the actual reasons for resuming dietary fiber. The clinical impression during consultation however was that some of these patients were vegetarians, some felt uneasy not eating any fiber, whilst others could not completely discontinue fiber due to constant media and peer pressure to increase dietary fiber.

Constipation is often mistaken by the layman as the state of not passing stool, with the subsequent false notion that making more feces will allow easier defecation. In truth, constipation refers to the difficulty in evacuating a rectum packed with feces, and easier defecation cannot possibly be affected by increasing dietary fiber which increases bulky feces. In this paper, we looked at constipation both as the number of days before each motion as well as the ease of defecation.

It is well known that increasing dietary fiber increases fecal bulk and volume. Therefore in patients where there is already difficulty in expelling large fecal boluses through the anal sphincter, it is illogical to actually expect that bigger or more feces will ameliorate this problem. More and bulkier fecal matter can only aggravate the difficulty by making the stools even bigger and bulkier. Several reviews and a meta-analysis had already shown that dietary fiber does not improve constipation in patients with irritable bowel diseases[18-21].

The role of dietary fiber in constipation is analogous to cars in traffic congestion. The only way to alleviate slow traffic would be to decrease the number of cars and to evacuate the remaining cars quickly. Should we add more cars, the congestion would only be worsened. Similarly, in patients with idiopathic constipation and a colon packed with feces, reduction in dietary fiber would reduce fecal bulk and volume and make evacuation of the smaller and thinner feces easier. Adding dietary fiber would only add to the bulk and volume and thus make evacuation even more difficult.

Whilst it is often stated in physiology textbooks that bulking agents improve peristalsis, there is no proof of this in practice nor experimentally. Regardless of the food ingested, small intestinal and right mid colonic contents are fluid and all ingestible dietary fiber is suspended therein. Dietary fiber, therefore, cannot act as solid boluses for the initiation of peristalsis. In fact, dietary fiber had been shown to retard peristalsis and hold up gaseous expulsion in human experiments[22].

Dietary fiber is also associated with increased bloatedness and abdominal discomfort[22]. Insoluble fiber was reported to worsen the clinical outcome of abdominal pain and constipation[18-20]. In our recent study, patients who followed a diet with no or less dietary fiber intake showed a significant improvement, not just in their constipation,

but also in their bloatedness. Patients who completely stopped consuming dietary fiber no longer suffered from abdominal bloatedness and pain. These symptoms are caused by the fermentation of dietary fiber by colonic bacteria, which produces hydrogen, carbon dioxide and methane[23]. Gases that are trapped by peristaltic colon exert pressure on the walls, causing the abdominal pain experienced by patients. This was previously observed in a prior study on younger patients, when dietary fiber had been shown not to be effective in the management of children with recurrent abdominal pain or bloating[21].

Stools only become well-formed in the sigmoid colon and rectum and by this time, especially in constipated subjects, more stools result in more evacuation problems. It is not logical to increase both the volume and size of stool in patients with idiopathic constipation and indeed for anybody with difficulty in passing stools, e.g., due to anismus or anal spasm from anal stricture, fissure or pelvic outlet disorders. We have shown that decreasing the bulk and volume of feces immediately enables the easier evacuation of smaller and thinner stools through the anal sphincter mechanism. This eliminates the need to strain in passing stools, and prevents the tearing of the anal sphincter and bleeding due to large and bulky fecal loads. None of our patients experienced anal bleeding or straining following complete abstinence from dietary fiber.

The results of this study should lead us to reexamine popular beliefs in benefits of dietary fiber and more studies should be undertaken to confirm or repudiate these results.

In conclusion, contrary to popularly held beliefs, reducing or stopping dietary fiber intake improves constipation and its associated symptoms.

COMMENTS

Background

It is a widely accepted view that dietary fiber is essential for gut health and to promote bowel movements. However, most patients with chronic constipation seen by the authors were already taking high fiber diet with no improvement in their symptoms.

Research frontiers

The role of dietary fiber in patients with chronic constip is reevaluated.

Innovations and breakthroughs

The authors showed that reducing dietary fiber intake may actually improve symptoms of chronic constipation.

Applications

This could bring relief to millions of people suffering from chronic constipation in that reducing their dietary fiber intake may relieve their symptoms and suffering.

Peer review

This paper is a preliminary study looking at the effects of dietary fiber on the symptoms of constipation on a small cohort of cases. The discussion provided an overview of the evidence available in the literature on this topic and gave a fresh perspective on the benefits or harm of excessive dietary fiber. All in all, this is an interesting preliminary study that warrants publication and further research.

Abstract

AIM: To determine the pattern of secreted mucin expression in *Helicobacter pylori* (*H. pylori*)-related, nonsteroidal anti-inflammatory drug (NSAID)-related and idiopathic gastric ulcers.

METHODS: We randomly selected 92 patients with *H. pylori*-associated (n = 30), NSAID-associated (n = 18), combined *H. pylori* and NSAID-associated gastric ulcers (n = 24), and patients with idiopathic gastric ulcers (n = 20). Immunohistochemistry for T-cell CD4/CD8, and for mucin 5AC (MUC5AC) and mucin 6 (MUC6), was performed on sections of the mucosa from the ulcer margin. Inflammation score was assessed according to the Sydney system.

RESULTS: MUC5AC was expressed on the surface epithelium (98.9%) and neck glands (98.9%) with minimal expression in the deep glands (6.5%). MUC6 was strongly expressed in the deep glands (97.8%), variable in the neck glands (19.6%) and absent in the surface epithelium (0%). The pattern of mucin expression in idiopathic ulcer margins was not different from the expression in ulcers associated with *H. pylori*, NSAIDs, or combined *H. pylori* and NSAIDs. CD4/CD8 ratio was higher in *H. pylori*-positive patients (P = 0.009). Idiopathic ulcers are associated with hospitalized patients and have higher bleeding and mortality rates.

CONCLUSION: Idiopathic ulcers have a unique clinical profile. Gastric mucin expression in idiopathic gastric ulcers is unchanged compared with *H. pylori* and/or NSAID-associated ulcers.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection and non-steroidal anti-inflammatory drugs (NSAIDs) are the leading causes of peptic ulcer[1-5]. However, in up to 39% of cases neither of these risk factors is identified[6]. While it may be prudent to exclude rarer causes of gastric ulcer such as malignancy, Zollinger-Ellison syndrome or systemic mastocytosis, in many cases *H. pylori*/NSAID-negative ulcers are apparently idiopathic.

Mucins are high-molecular-weight glycoproteins, which are heavily decorated with O-linked oligo-saccharides and n-glycan chains, linked to a protein backbone. There are 21 mucin (*MUC*) genes known in the human genome. These genes encode 2 groups of mucins: secreted mucins and membrane-bound mucins. The main mucins expressed in the stomach are MUC 1 (membrane-bound) and MUC5AC and MUC6 (secreted mucins). It has been proposed that defects in gastric mucin quality or quantity play a role in the pathogenesis of *H. pylori*/NSAID-negative ulcers[7]. MUC5AC, forming the bulk of the adherent unstirred mucous layer, is secreted by surface foveolar cells, whereas MUC6 is secreted by neck and gland cells, and both are strongly expressed in normal gastric mucosa[8]. These two mucin proteins remain segregated within the mucous gel in a laminated linear arrangement[9]. NSAIDs disrupt the production of prostaglandin-E2 which mediates mucin secretion. *H. pylori* similarly decreases mucin synthesis *via* inhibition of galactosyltransferase[10], this despite mucin's inherent antibacterial properties[11].

The pattern of mucin secretion in idiopathic peptic ulcer disease has yet to be determined. The aim of the present study is to identify the clinical and endoscopic features, and gastric mucin secretion patterns, in peptic ulcer disease positive and negative for *H. pylori* infection and/or NSAID therapy.

MATERIALS AND METHODS

Patients

Approval was granted by the ethics committee of Rabin Medical Center. Non-consecutive patients who underwent routine or emergency upper endoscopy at the Department of Gastroenterology, Rabin Medical Center, Beilinson Hospital, and who were assigned an endoscopic diagnosis of gastric ulcer, between 2003 and 2009, were randomly identified using an established computerized endoscopy reporting system. Clinical parameters were recorded, including patient age and gender, major indication for upper endoscopy, concomitant diseases and the use of aspirin and NSAIDs in the previous 3 mo. Endoscopic parameters were recorded, including ulcer site, size and number. *H. pylori* status was determined *via* histological detection on biopsies taken from the ulcer margins, gastric body or antrum and/or the rapid urease test and/or ^{13}C-urea breath test performed within 3 mo. Exclusion criteria included cases where no biopsies were taken from the ulcer margin, and where biopsies revealed neoplasia. Patients with clinical or histological evidence of Zollinger-Ellison syndrome, gastrointestinal malignancy, eosinophilic gastroenteritis, systemic mastocytosis, and patients receiving bisphosphonates, potassium salts or iron, were excluded.

Tissue samples

Formalin-fixed, paraffin-embedded tissue samples from ulcer margins were obtained from the Pathology Department. Where additional biopsies of gastric body or antrum were taken at endoscopy, these too were obtained. Paraffin-embedded blocks were cut into 4 μm thick sections. Slides were deparaffinized in xylene and rehydrated using a graded ethanol series. Antigen was retrieved by boiling the slides in a microwave oven for 15 min in 0.01 mol/L citrate buffer (pH 6.0). Endogenous peroxidase was blocked with a 3% H_2O_2-methanol solution, and the slides were incubated in 10% normal goat serum for 30 min to prevent nonspecific staining. The tissue sections were then incubated overnight at 4 ℃ with primary antibody (MUC5AC or MUC6, 1:100; Santa Cruz, CA). The standard biotin-streptavidin-peroxidase method was then used, and the sections were lightly counterstained with hematoxylin. Histologically normal gastric biopsies were used as positive controls for MUC5AC and MUC6. The sections incubated with phosphate-buffered saline (0.01 mol/L, pH 7.4) instead of primary antibody were used as negative controls. Cytoplasm staining was assessed in at least 10 high-power fields by two blinded observers at 3 sites: the foveola, the mucous neck cells, and the glands. The range of cytoplasmic staining (0: 0%-5%; 1: 6%-30%; 2: 31%-60%; and 3: 61%-100%) and the intensity of staining (0: No staining; 1: Weak staining; 2: Intermediate staining; 3: Strong staining) were assessed, and averages of the grades were taken. The final staining score was defined as the product of scores for the range and intensity of cytoplasmic staining. Staining was defined as negative if the staining score was 0 or 1, intermediate for 2, 3 or 4, and high for 6 or 9[12]. All specimens were scored blindly.

Immunohistochemistry with monoclonal antibodies to T-cell CD4 and CD8 antigens was performed for 5 cases from each group using a technique previously described[13]. Tissue sections were cut 4 μm thick from routinely processed formalin-fixed and paraffin-embedded blocks. The slides were oven dried overnight at 60 ℃. The slides were then put inside the Ventana (Benchmark, United States). The Ventana was activated by loading the pre-programmed recipe file for the appropriate antibody. For CD4 we used polyclonal antibody (Spring, CA, United States), and for CD8 a monoclonal antibody, clone SP16 (DBS, CA, United States). Immunohistochemical staining was performed by the I-view DAB detection kit of Ventana. Dark brown staining was defined as positive, and no staining was defined as negative. Staining was scored as follows: 0 (no detectable staining); 1 (1%-10% positive cells); 2 (11%-50%); 3 (51%-80%); and 4 (more than 80%). In cells with positive staining, the staining was intense and uniform, so intensity was not factored

[1]Number of patients with comorbidities as listed; [2]Fever unknown origin, gastric outlet obstruction, and surveillance following resection of gastric and esophageal carcinoma (1 case for each indication); [3]Inflammatory bowel disease; [4]Hemodialysis; [5]Inflammatory bowel disease, sepsis, cirrhosis (2 cases), tetraplegia following trauma. *H. pylori*: *Helicobacter pylori*; NSAID: Non-steroidal anti-inflammatory drugs; ASCVD: Atherosclerotic cardiovascular disease; COPD: Chronic obstructive pulmonary disease; GERD: Gastro esophageal reflux disease; GI: Gastrointestinal. +: Positive; -: Negative.

into the scoring. The ratio of CD4/CD8 intraepithelial/mucosal lymphocytes was assessed for ten low-power microscopic fields. Inflammation score was measured according to the Sydney system, and compared between the groups[14]. Sydney score for inflammation is the sum of 5 criteria: *H. pylori* status, atrophy, intestinal metaplasia, lymphocytic infiltration and polymorphonuclear cell infiltration. Every criterion has 0 to 3 score (none exists, mild, moderate, severe) thus the range is 0 to 15.

Statistical analysis

Statistical analysis was performed using statistical package for the social sciences software 19.0 (SPSS, Inc.). Patient groups were compared using the Pearson χ^2 test, *F* test and Duncan test. *P* values were considered significant when $\leqslant 0.05$.

RESULTS

Ulcer biopsies from 92 patients were included in the final set analysis, including 30 *H. pylori*-associated ulcers, 18 NSAID-associated, 24 associated with combined *H. pylori*/NSAID and 20 idiopathic, neither associated with *H. pylori* nor NSAID use. Patient characteristics are summarized in Table 1.

Forty-four patients were male, with no significant differences between the 4 groups ($P = 0.24$). Mean age was 66.6 years. Patients with *H. pylori*-associated ulcers not receiving NSAIDs were significantly younger compared to the other 3 groups ($\alpha = 0.05$, Duncan test). There was no significant difference in the patients' origin between the groups. Although significant co-morbidities were observed in all groups, 80% (16/20) of patients with *H. pylori*/NSAID-negative ulcers were inpatients at the time of their endoscopy, compared to 45.8% (33/72) in other groups ($P = 0.007$). Furthermore, idiopathic ulcers were associated with decreased survival, where 25% (5/20) died within 12 mo, compared to 9.7% (7/72) in other groups (all cause mortality, $P = 0.04$).

Patients with *H. pylori*/NSAID-negative ulcers more often presented with upper gastrointestinal bleeding: 45% (9/20) compared with 26.4% (19/72) in the other groups ($P = 0.11$). Subacute and asymptomatic presentations (iron deficiency anemia, weight loss, fecal occult blood and screening) were less common in those with *H. pylori*/NSAID-negative ulcers (2/20, 10%, compared to 34/72,

47.2%, $P = 0.003$).

No difference between groups was observed regarding ulcer number or size. *H. pylori*-negative/NSAID-positive ulcers tended to be more often located in the gastric body: 6/18 (33.3%) compared with other groups 19/74 (25.7%) ($P = 0.51$). The presence of intestinal metaplasia did not differ between groups (Table 2).

Virtually all biopsies had positive (intermediate or high) staining for MUC5AC in the surface and neck cells (Figure 1). Staining for MUC5AC was minimal in gland cells (Tables 3 and 4). Although no significant difference between groups was observed there was a trend towards

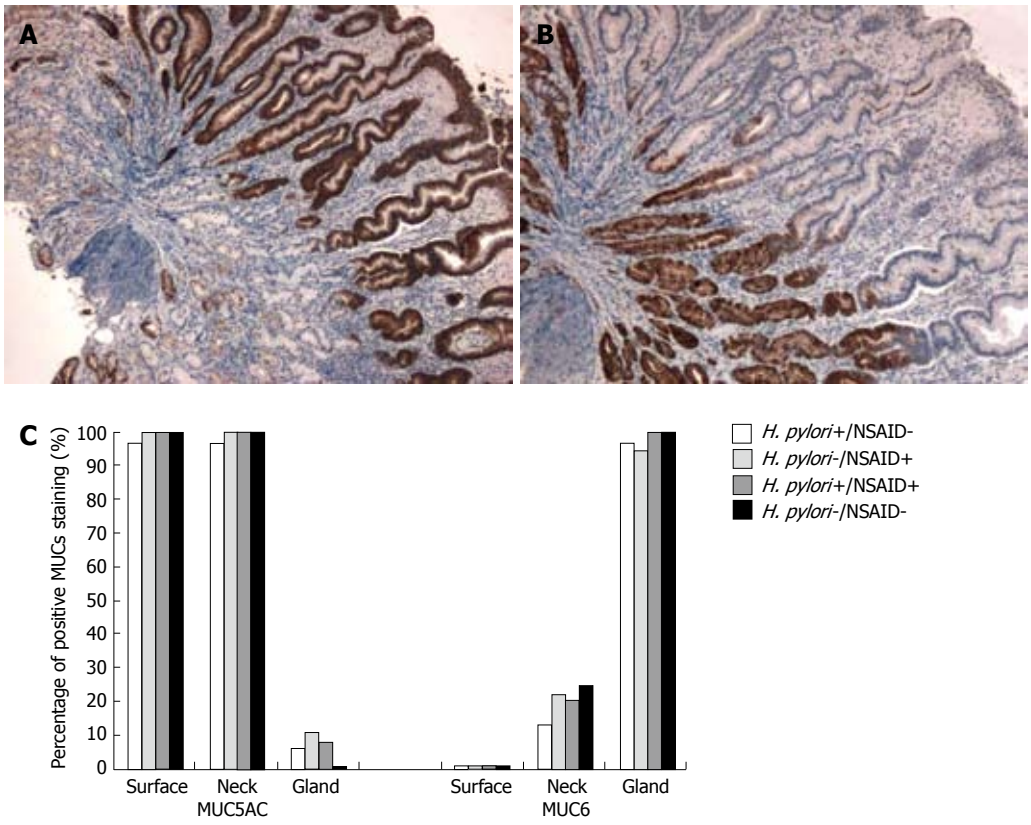

Figure 1 Mucin 5AC and mucin 6 expression in gastric ulcers. A: Immunohistochemical stain showing strong expression of mucin 5AC (MUC5AC) in surface and neck cells (× 10) of gastric mucosa from the ulcer edge of a patient with *Helicobacter pylori* (*H. pylori*)/non-steroidal anti-inflammatory drugs (NSAID)-negative gastric ulcer; B: Immunohistochemical stain showing strong expression of MUC6 in deep gland cells (× 10) of gastric mucosa from the ulcer edge of a patient with *H. pylori*/NSAID-negative gastric ulcer; C: Percentage of positive MUCs staining according to *H. pylori* and NSAID status. Positive stain defined as a stain extent and intensity score product ⩾ 2.

Table 5 Intraepithelial/mucosal T-cell populations (n = 20)

Group	CD4+/CD8+	CD8+/HPF	CD4+/HPF
H. pylori+/NSAID-	3.15	22.0 ± 4.4	69.6 ± 38.2[a]
H. pylori-/NSAID+	0.55	14.0 ± 9.4	8.4 ± 12.5
H. pylori+/NSAID+	2.99	26.6 ± 20.9	50.0 ± 25.2
H. pylori-/NSAID-	1.15	29.0 ± 11.4	38.0 ± 27.7

[a]P = 0.009 *vs H. pylori*-/NSAID+ group. *H. pylori*: *Helicobacter pylori*; NSAID: Non-steroidal anti-inflammatory drugs; HPF: High-power field.

decreased expression of MUC5AC in the deep glands of idiopathic ulcers (P = 0.09). Including for analysis only cells with high mucin expression (extent and intensity score products of 6 or 9), and separate analyses of staining extent and intensity, did not significantly alter the results. All but two biopsies stained positively (intermediate or high) for MUC6 in the gland cells (Figure 1), and staining was uniformly negative in the surface cells. Staining for MUC6 was variable in the neck cells. Again, including only cells with high mucin expression (extent and intensity score products of 6 or 9), and separate analyses of staining extent and intensity, did not significantly alter the results.

T-cell CD4/CD8 ratio was significantly lower in the NSAID-positive groups when compared to the *H. pylori*-positive groups (P = 0.009, Table 5). As expected, the Sydney inflammation score was significantly lower in the *H. pylori*-negative/NSAID-negative group than in the *H. pylori*-positive/NSAID-negative group (P = 0.017, Table 6).

DISCUSSION

Gastric secreted mucin expression has not been previously studied in the setting of the idiopathic ulcer. In the present study, the distribution of immunohistochemical staining for MUC5AC and MUC6 in the margins of *H. pylori*/NSAID-negative ulcers did not significantly differ from staining patterns in the margins of ulcers associated with *H. pylori* and/or NSAIDS.

H. pylori interacts with gastric mucins in various manners, in order to facilitate its colonization. It has been established that *H. pylori* disrupts the assembly of the mucin molecule *via* inhibition of galactosyltransferase[10,12]. Furthermore, *H. pylori* reduces gastric mucous viscosity by elevating pH through urease secretion, thereby enhancing its motility within gastric mucous[15]. Kobayashi *et al*[16] demonstrated that BabA and SabA adhesins on *H. pylori* bind to Lewis B blood group antigens on MUC5AC, facilitating colonization.

On the other hand, gastric mucins have antimicrobial properties which are directed against *H. pylori*. Kawakubo *et al*[11] demonstrated that unique O-glycans in MUC6 inhibit bacterial biosynthesis of cholesteryl-α-*D*-glucopyranoside,

Table 6 Inflammation score according to the Sydney system (n = 20)

Group	*H. pylori*	Atrophy	Intestinal metaplasia	Lymphocytes	PMN	Score
H. pylori+/NSAID-	2.20 ± 0.44	0.60 ± 0.54	0.40 ± 0.54	1.80 ± 0.83	1.20 ± 1.30	6.20 ± 2.48[a]
H. pylori-/NSAID+	0.00 ± 0.00	0.40 ± 0.54	0.60 ± 1.34	1.40 ± 0.89	0.20 ± 0.44	2.60 ± 2.19
H. pylori+/NSAID+	1.80 ± 1.09	0.80 ± 0.83	0.40 ± 0.89	2.00 ± 0.70	1.40 ± 0.89	6.40 ± 3.13
H. pylori-/NSAID-	0.00 ± 0.00	0.20 ± 0.44	0.20 ± 0.44	1.40 ± 0.54	0.40 ± 0.54	2.20 ± 1.64

[a]P = 0.017 *vs H. pylori*-/NSAID- group. PMN: Polymorphonuclear cells; *H. pylori*: *Helicobacter pylori*; NSAID: Non-steroidal anti-inflammatory drugs.

a major cell wall component. Lindén *et al*[17] suggest that mucins decorated with Le^b (the binding site for the *H. pylori* BabA adhesin) effectively bind *H. pylori*, thereby impairing its colonization of the mucosal surface. Similarly, in *Trichuris muris* infection MUC5AC is aberrantly expressed in the intestine and plays a key role in expulsion of the nematode[18]. Byrd *et al*[19] demonstrated that gastric biopsies from *H. pylori*-related gastritis patients frequently expressed the aberrant location of MUC6 staining in the surface foveolar cells. In the present study, cytoplasmic mucin staining of ulcers associated with *H. pylori* was unchanged. One reason for this discrepancy is the fact that the present study only included patients with gastric ulcers, and sampled gastric mucosa immediately adjacent to the edge of a gastric ulcer. These patients represent a distinct subgroup of patients with *H. pylori* infection, and our findings imply that alterations in secreted gastric mucins do not play a role in the pathogenesis of gastric ulcer in patients with *H. pylori* infection. This is supported by Marques *et al*[20] who found that although topographic expression of MUC5AC and MUC6 mucins was altered in *H. pylori*-related gastritis, the expression of these mucins was unchanged in mucosa adjacent to patients with *H. pylori*-related gastric ulcer.

An interesting finding in our study was that many patients with *H. pylori*/NSAID-negative ulcers had multiple comorbidities, were more often inpatients at the time of endoscopy, had fewer subacute presentations, and had a poorer survival. This concurs with Chan *et al*[21] who noted that three-quarters of patients with acutely bleeding *H. pylori*/NSAID-negative ulcers have significant comorbidity including major organ failure and malignancy. A large prospective study found that concomitant diseases and the absence of epigastric pain are independent risk factors for *H. pylori*/NSAID-negative ulcers in the duodenum[22]. A higher number of comorbidities were associated with increased ulcer size and depth, and more bleeding complications. Furthermore, our data are consistent with previous findings that idiopathic ulcer is an independent risk factor associated with long-term mortality[23,24].

In this study, *H. pylori*/NSAID-negative gastric ulcers were associated with underlying systemic disease, which could be severe. This association has been reported previously in idiopathic ulcers[24], and suggests the possible role of ischemic or non-specific inflammatory factors in their pathogenesis[25]. Despite the heterogeneity of possible pathogenic factors of these idiopathic *H. pylori*/NSAID-negative cases, our results indicate virtually no difference in qualitative MUC5AC and MUC6 staining in these ulcers compared with definite *H. pylori*-positive, NSAID-positive, and combined *H.pylori*/NSAID-positive gastric ulcers .

H. pylori-positive ulcer is associated with a high inflammation rate, thus groups 2 and 4 had significantly lower Sydney inflammation score than groups 1 and 3 (P = 0.017). In addition, we found a low ratio of T-cell CD4/CD8 in the groups negative for *H. pylori*; but when NSAID use was also negative the result did not reach significance. Similar findings were described by Strömberg *et al*[26]. In peptic ulcer patients positive for *H. pylori*, the number of intraepithelial T-cell CD4+ was higher than in patients with *H. pylori* infection but without ulcer or in healthy controls negative for *H. pylori*. Thus, *H. pylori* infection recruits CD4+ lymphocytes.

A limitation of our study is the retrospective nature of the data collection, which precluded elimination of false negative tests for *H. pylori* (probably due to proton pump inhibitor, bismuth or antibiotics), and cases of surreptitious or unreported NSAID use, which would result in misclassification of ulcers as *H. pylori*/NSAID-negative. This could only be overcome using a prospective study design, by performing multiple tests for *H. pylori* and assaying serum salicylate and plasma thromboxane, respectively.

In conclusion, patterns of mucin secretion in *H. pylori*/NSAID-negative ulcers need to be further studied in well-designed, prospective studies which minimize cross-contamination of groups. Idiopathic peptic ulcers are an increasingly encountered entity, with unique clinical and endoscopic features. Future efforts should focus on identifying genetic and epigenetic factors which regulate mucin secretion in this setting, as well as characterizing a potential role of the membrane-bound mucins and other mucosal protective factors.

COMMENTS

Background

In health, a mucin layer protects the stomach from the harmful effects of gastric acid and ulceration. The main causes of peptic ulcer disease are *Helicobacter pylori* (*H. pylori*) infection and aspirin or nonsteroidal anti-inflammatory drug (NSAID) therapy. However, up to 39% of peptic ulcer disease is idiopathic. Idiopathic ulcers are often associated with poorer outcomes.

Research frontiers

Alterations in secreted gastric mucins have been described in *H. pylori* infection and NSAID treatment, and may have a role in ulcer pathogenesis. This is the first study to look at gastric mucin secretion in idiopathic ulcers.

Innovations and breakthroughs

Mucin 5AC (MUC5AC) and MUC6 are equally expressed by *H. pylori*-induced,

NSAID-induced and idiopathic ulcers. The number of CD4 and CD8 lymphocytes is highest in *H. pylori*-induced ulcers reflecting a greater inflammatory component. Inflammation score is lowest in NSAID-associated ulcers.

Applications

Idiopathic peptic ulcer disease is more aggressive than peptic ulcer disease induced by *H. pylori* or NSAIDs. Elucidating the pathogenesis of idiopathic ulcers will lead the way to finding appropriate therapies.

Terminology

Mucin is the major component of gastric mucous and is synthesized and secreted by specialized cells. The two primary gastric mucin molecules are coined MUC5AC and MUC6; *H. pylori* is a ubiquitous bacterium which may cause gastric ulcer; NSAIDs include a range of over-the-counter medications commonly used for analgesia and rheumatic disease, and similarly cause gastric ulceration. Idiopathic ulcers are ones with no identifiable cause.

Peer review

The manuscript is interesting and has potential to enhance understanding on MUC5AC and MUC6 expression in gastric mucosa in *H. pylori*-, NSAID- and idiopathic-ulcers.

Abstract

AIM: To investigate optimal timing for therapeutic efficacy of entecavir for acute-on-chronic hepatitis B liver failure (ACLF-HBV) in hepatitis B e antigen (HBeAg)-negative patients.

METHODS: A total of 109 inpatients with ACLF-HBV were recruited from the Department of Infectious Diseases of the Third Affiliated Hospital, Sun Yat-sen University from October 2007 to October 2010. Entecavir 0.5 mg/d was added to each patient's comprehensive therapeutic regimen. Patients were divided into three groups according to model for end-stage liver disease (MELD) score: high ($\geqslant$ 30, 20 males and 4 females, mean age 47.8 ± 13.5 years); intermediate (22-30, 49 males and 5 females, 45.9 ± 12.4 years); and low ($\leqslant$ 22, 28 males and 3 females, 43.4 ± 9.4 years). Statistical analysis were performed using SPSS 11.0 software. Data with normal distribution were expressed as mean ± SD and comparisons were made with Student's *t* tests. A value of $P < 0.05$ was considered statistically significant. Viral loads were related exponentially and logarithmic data were used for analysis.

RESULTS: For 24 patients with MELD score $\geqslant$ 30, treatment lasted 17.2 ± 16.5 d. Scores before and after treatment were significantly different (35.97 ± 4.87 and 40.48 ± 8.17, respectively, $t = -2.762$, $P = 0.011$); HBV DNA load was reduced (4.882 ± 1.847 copies $\log_{10}$/mL to 3.685 ± 1.436 copies $\log_{10}$/mL); and mortality rate was 95.83% (23/24). Of 54 patients with scores of 22-30, treatment lasted for 54.0 ± 43.2 d; scores before and after treatment were 25.87 ± 2.33 and 25.82 ± 13.92, respectively ($t = -0.030$, $P = 0.976$); HBV DNA load decreased from 6.308 ± 1.607 to 3.473 ± 2.097 copies $\log_{10}$/mL; and mortality was 51.85% (28/54). Of 31 patients with scores $\leqslant$ 22, treatment lasted for 66.1 ± 41.9 d; scores before and after treatment were 18.88 ± 2.44 and 12.39 ± 7.80, respectively, ($t = 4.860$, $P = 0.000$); HBV DNA load decreased from 5.841 ± 1.734 to 2.657 ± 1.154 copies $\log_{10}$/mL; and mortality was 3.23% (1/31).

CONCLUSION: For HBeAg-negative patients with ACLF-HBV, when entecavir was added to comprehensive therapy, a MELD score $\geqslant$ 30 predicted very poor prognosis due to fatal liver failure.

INTRODUCTION

Currently, there are only four commercially available nucleoside analogs for the treatment of hepatitis B virus (HBV). These include lamivudine, adefovir dipivoxil, entecavir and telbivudine; all efficient antiviral agents that can reduce the HBV DNA load to the lower limit of detection in 72%, 51%, 90% and 88% of hepatitis B e antigen (HBeAg)-negative chronic hepatitis B (CHB) patients, respectively, after 1 year of treatment[1-5]. However, these drugs seem to be ineffective for some patients with acute-on-chronic hepatitis B liver failure (ACLF-HBV), for whom even comprehensive therapy in combination with antiviral treatment cannot reduce a high mortality rate[6,7]. When compared with HBeAg-positive CHB patients, the proportion of HBeAg-negative CHB patients has been increasing during recent years, and the age of these patients is relatively advanced. Although the HBV-DNA load is relatively low, this form of hepatitis is active, prone to fluctuation, and positively correlated with the degree of inflammation and necrosis of the liver[8,9]. Furthermore, cirrhosis and hepatocellular carcinoma are more prevalent among these patients. In a previously reported study, 71.74% of patients with ACLF-HBV were negative for HBeAg[6]. Here, we evaluated the efficacy of entecavir, a potent antiviral nucleoside analog, in ACLF-HBV patients having different model for end-stage liver disease (MELD) scores, and suggest a new method for guiding the therapeutic decision-making process.

MATERIALS AND METHODS

Patients

A total of 109 inpatients with ACLF-HBV were recruited from the Department of Infectious Diseases of the Third Affiliated Hospital, Sun Yat-sen University from October 2007 to October 2010. Diagnosis was based on the Guidelines for Diagnosis of Liver Failure (2006)[10] and included the presence of two or more of the following: prothrombin time/international normalized ratio (PT-INR) $\geqslant$ 1.5; serum total bilirubin > 10 times the upper limit of normal; ascites; hepatic encephalopathy; decreased liver size; or the hepatorenal syndrome. The standard serum creatinine (Cr) was defined as the normal median (31.8-93.7 μmol/L), and MELD scores were $\geqslant$ 16.1. All patients were hepatitis B surface antigen (HBsAg)-positive, HBeAg-negative, hepatitis B e antibody (HBeAb)-positive and hepatitis B core antibody (HBcAb)-positive. There were 97 male (89.0%) and 12 female (11.0%) patients with a mean age of 45.61 ± 11.90 years (range: 25-73 years). Patients were divided into three groups according to MELD score: high ($\geqslant$ 30, 20 male and 4 female, mean age 47.8 ± 13.5 years); intermediate (22-30, 49 male and 5 female, 45.9 ± 12.4 years); and low ($\leqslant$ 22, 28 male and 3 female, 43.4 ± 9.4 years). There were no marked differences in age and sex among the three groups. Patients co-infected with hepatitis A, C or E virus or human immunodeficiency virus were excluded. None had been treated with regular pegylated interferon, nucleoside analogs, or thymosin. Entecavir 0.5 mg/d was added to each patient's comprehensive therapeutic regimen as the sole antiviral agent.

Detections

HBV DNA levels were determined by real-time polymerase chain reactions with commercial diagnostic kits (Da-an GeneCo., Guangzhou, China). The lower detection limit was 500 copies/mL. HBsAg, HBsAb, HBeAg, HBeAb and HBcAb were detected with an automatic rapid immunoassay system (AxSYM; Abbott, United States). Total bilirubin and Cr and were measured using an automatic biochemical analyzer (AU 640; Olympus, Japan); normal ranges were 4-17.1 μmol/L and 31.8-93.7 μmol/L, respectively. PT-INR = (prothrombin time/reference prothrombin time) ISI. Prothrombin time was measured using detection reagent STA-Neoplastine(r) CI PLUS with an automatic coagulometer (STA-R) (Diagnostica Stago, France). Sample collection, transportation, preservation and processing were performed according to the manufacturer's instructions.

Calculations of MELD scores

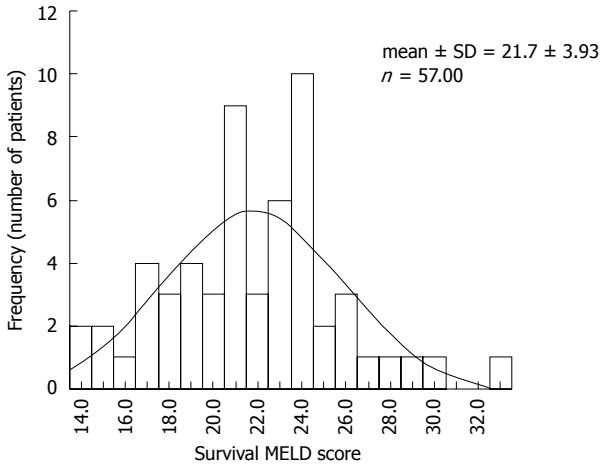
MELD score = 3.8 × $\log_e$ [serum bilirubin (μmol/L) × 0.058] + 11.2 × $\log_e$ (PT-INR) + 9.6 × $\log_e$ [serum Cr (μmol/L) × 0.011] + 6.4 × (0 or 1) (cholestatic or alcoholic cirrhosis: 0; other liver diseases: 1)[11].

Definitions of therapeutic efficacy

Survival: patients discharged with no evidence of liver failure; death: progression of disease leading to death in spite of comprehensive therapy and entecavir treatment.

Statistical analysis

Statistical analysis were performed using SPSS 11.0 software. Data with normal distribution were expressed as mean ± SD and comparisons were made with Student's *t* tests. A value of $P < 0.05$ was considered statistically significant. Viral loads were related exponentially and logarithmic data were used for analysis.



RESULTS

The mortality rate was > 95% in patients with MELD score > 30, and > 95% of patients survived with MELD

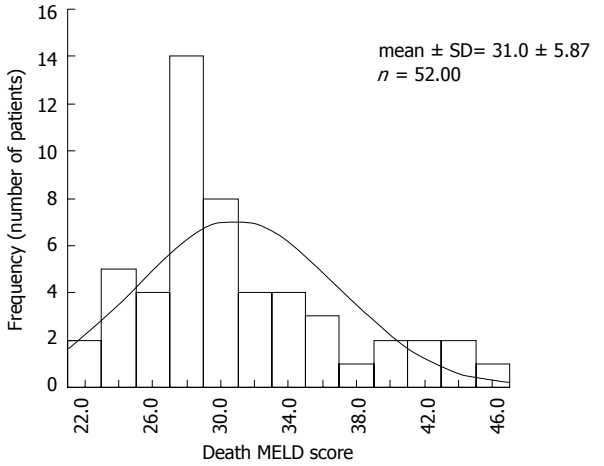

Figure 1 Frequency distribution of model for end-stage liver disease scores of patients receiving entecavir who survived (A) or succumbed (B). Death occurred in 95% of patients with MELD score > 28.63, 96% with score > 29.39 and 97% with score > 30.69; and in 5% with score < 22.85, 4% with score < 22.26, and 3% with score < 21.97. The mortality rate was > 95% in patients with MELD score > 30, and > 95% patients survived with MELD score < 22. MELD: Model for end-stage liver disease.

score < 22. Frequency distribution of MELD scores of patients receiving entecavir who survived or succumbed is described in Figure 1.

Of the 24 patients with high MELD scores (≥ 30), 23 (95.83%) died. Antiviral treatment was administered for 17.2 ± 16.5 d. Comparing measurements taken before antiviral treatment and before death, there were no marked differences in HBV DNA load, total bilirubin, INR and prothrombin activity (PTA), but Cr and MELD scores increased significantly (P = 0.003 and 0.011, respectively) (Table 1).

Of the 54 patients with intermediate MELD scores, 28 (51.85%) died and 26 survived. Antiviral treatment was administered for 54.0 ± 43.2 d. The MELD scores before and after antiviral treatment were not significantly different (25.87 ± 2.33 and 25.82 ± 13.92, respectively; t = -0.030, P = 0.976), but the HBV DNA load decreased significantly, by 2.918 ± 1.811 copies $\log_{10}$/mL (P = 0.000). Liver function results and outcomes are presented in Table 1.

There were 31 patients with low MELD scores; one (3.23%) died and 30 survived. Antiviral treatment was administered for 66.1 ± 41.9 d. Total bilirubin decreased and PTA increased significantly during antiviral treatment (P < 0.05), and decreases in MELD score (18.88 ± 2.44 to 12.39 ± 7.80; t = 4.860, P = 0.000) and HBV DNA levels (by 3.185 ± 1.740 copies log10/mL, P = 0.000) were also significant (Table 1).

DISCUSSION

Providing comprehensive treatment is the main therapeutic strategy for patients with ACLF; when possible other treatment options include use of bioartificial liver support systems and liver transplantation. Comprehensive treatment can only prolong survival for the fraction of patients having a potential for liver regeneration. When antiviral treatment is added, prolonged survival times can be achieved at low cost. It remains controversial whether comprehensive therapy with bioartificial liver support systems is translated into a survival benefit. Liver transplantation is usually limited by high cost, insufficient donors, and unclear effects on long-term survival. In recent years, treatment of liver failure with stem cell transplantation has achieved favorable outcomes in preclinical studies, but this strategy has not been approved and its

Table 1 Models for end-stage liver disease score group: Liver function, hepatitis B virus DNA load, length of treatment and mortality rate

n = 24	Total bilirubin (μmol/L)	INR	Prothrombin activity (%)	Blood creatinine (μmol/L)	MELD score	HBV DNA loads (copies log10/mL)	Treatment course (d)	Mortality (%)
High model (*n* = 24)

therapeutic efficacy remains to be confirmed. At present, treatment with nucleoside analogs has been applied in the treatment of ACLF-HBV and has been confirmed effective, but not all patients can survive[12-16]. When is the right time to add nucleoside analogs for treatment of ACLF-HBV patients? Therefore, it is imperative to investigate the therapeutic efficacy of comprehensive therapy in combination with antiviral treatment.

For HBeAg-negative and -positive CHB patients, there are differences in indication for treatment with nucleoside analogs, their therapeutic efficacy, and criteria for discontinuation of treatment. In the natural course of CHB, the HBV viral load significantly increases once the host immune function is compromised, which may induce acute cellular immune responses, resulting in ACLF. Therefore, maximizing long-term inhibition or elimination of HBV DNA may prevent the occurrence of ACLF in HBeAg-negative patients[17]. Nucleoside analogs can rapidly inhibit the replication of HBV and minimize propagation of the virus between hepatocytes. In addition, antiviral treatment can reduce target antigens on hepatocytes, thereby reducing attacks by cytotoxic T cells, thus attenuating the extent of damage and subsequent necrosis.

Entecavir is a cyclopentyl guanosine analog that can significantly inhibit HBV DNA polymerase, which then suppresses initiation of DNA replication and extension, resulting in reduction of viral load[18-20]. Among four commercially available nucleoside analogs, entecavir is the most potent antiviral drug, and it has the lowest frequency of resistance (1% after 4 years)[21,22]. The US Guidelines for Diagnosis and Treatment of Chronic Hepatitis B recommends entecavir as the first-line antiviral drug for treatment of patients with HBV-related liver failure[23]. Therefore, the present study aimed to investigate the efficacy of entecavir in combination with comprehensive therapy of ACLF-HBV, according to MELD score.

In 2003, Malinchoc *et al*[11] analyzed clinical information of 231 patients undergoing transjugular intrahepatic portosystemic stent shunt procedures. They applied Cox proportional hazards regression to establish the MELD score, which was then used to evaluate the risk of death among patients with liver diseases of any cause, achieving favorable reliability. A 2002 study revealed that MELD scores were given priority in making the decision to perform liver transplantation[24]. In addition, MELD score is also a sensitive indicator of the severity of liver failure.

In the present study, mean scores in the high MELD score group increased significantly before death, and mortality was 95.83% (23/24). Therapeutic failure in this group may be attributed to the fact that suppression of viral replication requires a relative long period of time; a previous study has determined that treatment with entecavir can significantly reduce the viral load within 4 wk[25]. However, treatment in this group lasted on average only 17.2 d, in the setting of fatal liver failure. In addition, ACLF pathogenesis is complex; the rapid increase in HBV replication is only one factor contributing to liver failure. Once liver failure is initiated, additional antiviral treatment is not adequate to prevent progression.

No significant differences in scores were observed before and after antiviral treatment in the intermediate MELD score group, which may account for the difference in outcome [48.15% (26/54) recovered and 51.85% (28/54) died]. Death in this group may be related to late-stage ACLF or to deteriorating liver function in the early or intermediate stages. In this CHB condition, massive liver necrosis may occur from induction of potent cellular immune responses; as a result, antiviral treatment may not be effective. Survival of 48.15% (26/54) of these patients may be attributed to the potential for liver regeneration, even if several parameters suggest liver failure. In this group, the course of treatment was 54.0 d, so HBV DNA replication was significantly suppressed, and fur-

ther liver necrosis was prevented.

In the low MELD score group, scores were significantly decreased by antiviral treatment, and the mortality was 3.23% (1/31). The majority of patients recovered, possibly because they had early-stage ACLF, a low risk for development of cellular immune responses, and the potential for compensatory liver regeneration. The mean length of treatment was 66.1 d; enough time for entecavir to accomplish an antiviral effect, which, together with effective liver regeneration, promotes recovery from liver failure.

We suggest that timely administration of an antiviral agent may improve prognosis for HBeAg-negative ACLF patients, and that prognosis can be predicted by the MELD score. When the score is $\leqslant$ 22, most patients may survive if given comprehensive therapy in combination with antiviral treatment. When the MELD is 22-30, survival, if given antiviral treatment, will depend on the severity of liver failure, the developmental trend of the disease, and whether comprehensive therapeutic interventions provide enough time for antiviral drugs to exert their effects. When the MELD score is $\geqslant$ 30, the vast majority of patients will not recover with comprehensive plus antiviral therapy. These patients are at high risk for death and liver transplantation should be considered.

COMMENTS

Background

In the natural course of chronic hepatitis B, the hepatitis B virus (HBV) viral load significantly increases once the host immune function is compromised, which may induce acute cellular immune responses, resulting in acute-on-chronic liver failure (ACLF). Therefore, maximizing long-term inhibition or elimination of HBV DNA may prevent the occurrence of ACLF in hepatitis B e antigen (HBeAg)-negative patients.

Research frontiers

In previous studies, treatment with nucleoside analogs has been used for acute-on-chronic hepatitis B liver failure (ACLF-HBV) and has been confirmed as effective. When is the right time to add nucleoside analogs to treatment of ACLF-HBV patients? The present study investigated the optimal timing, according to model for end-stage liver disease (MELD) score, for therapeutic efficacy of entecavir for ACLF-HBV in HBeAg-negative patients.

Innovations and breakthroughs

For HBeAg-negative patients with ACLF-HBV, when entecavir was added to comprehensive therapy, patients with different MELD scores may have a different outcome; a MELD score $\geqslant$ 30 predicted very poor prognosis due to fatal liver failure.

Peer review

This issue is of great interest and is offering a new method of deciding the optimal timing for therapeutic efficacy of entecavir to treat ACLF-HBV in HBeAg-negative patients according to MELD score.

Abstract

AIM: To investigate whether the side population (SP) cells possess cancer stem cell-like characteristics *in vitro* and the role of SP cells in tumorigenic process in gastric cancer.

METHODS: We analyzed the presence of SP cells in different human gastric carcinoma cell lines, and then isolated and identified the SP cells from the KATO Ⅲ human gastric cancer cell line by flow cytometry. The clonogenic ability and self-renewal were evaluated by clone and sphere formation assays. The related genes were determined by reverse transcription polymerase chain reaction. To compare tumorigenic ability, SP and non-side population (NSP) cells from the KATO Ⅲ human gastric cancer cell line were subcutaneously injected into nude mice.

RESULTS: SP cells from the total population accounted for 0.57% in KATO Ⅲ, 1.04% in Hs-746T, and 0.02% in AGS (CRL-1739). SP cells could grow clonally and have self-renewal capability in conditioned media. The expression of *ABCG2*, *MDRI*, *Bmi-1* and *Oct-4* was different between SP and NSP cells. However, there was no apparent difference between SP and NSP cells when they were injected into nude mice.

CONCLUSION: SP cells have some cancer stem cell-like characteristics *in vitro* and can be used for studying the tumorigenic process in gastric cancer.

INTRODUCTION

Cancer stem cells (CSC) have the characteristics of longevity, self-renewal and proliferation. It is believed that cancer stem cells are responsible for the heterogeneity and relapse of certain cancers. Flow cytometric analysis of cell surface antigens has served as the main tool to characterize CSC. CSC populations have already been identified in several solid tumors, including breast cancer[1], brain tumor[2], prostate cancer[3], melanoma[4], retinoblastoma[5], lung cancer[6], and colon cancer[7]. CSC often expresses the multi-drug resistant 1 (MDR1) or adenosine-triphosphate (ATP)-binding cassette (ABC) transporter genes, which help promote chemoresistance, a phenotype of side population (SP) cells[8].

SP cells can efflux the DNA-binding dye Hoechst33342 through an ABC membrane transporter. SP cells were initially investigated as part of the hematopoietic stem cells, and harbored stem cell-like characteristics[9]. Although conflicting results have been recently reported[10,11], most studies that investigated cell lines and tumors such as Cal-51[12], human breast carcinoma (MCF7)[13], human glioma (U373)[14], mouse ovarian carcinoma (MOVCAR 7)[15], human nasopharyngeal carcinoma (CNE-2)[16], Huh7 and PLC/PRF/5 hepatocellular carcinoma[15,16], 4T1 and NXS2 murine carcinoma[17] showed that these cell lines or tissues possessed SP cells, which were described to have stem cell-like fractions. Most studies suggested that SP cell analysis can be used to identify cancer stem cell populations[18].

Gastric cancer is the second most common cancer in the world. A total of 21 000 new cases of gastric cancer were diagnosed in the United States in 2010 with a projected five-year mortality rate exceeding 65%[19]. Aggressive surgery followed by chemotherapy resulted in a clinical response of 20%-35%. However, a majority of patients relapse and become drug-resistant. Various types of ABC transporters, especially ABC transporter genes 2 (*ABCG2*), contribute to drug resistance in cancers including gastric cancer, by pumping chemotherapeutic drugs out of cancer cells[20]. Therefore, SP cells could be used as a therapeutic target and for preventing relapse and drug-resistance in gastric cancer as well.

In this study, we analyzed the percentage of SP and non-side population (NSP) cells from several gastric cancer cell lines. By doing so, we sorted SP and NSP cells separately from the KATO Ⅲ cell lines and estimated whether the SP cell fraction possessed cancer stem cell-like characteristics *in vitro*.

MATERIALS AND METHODS

SP and NSP presentation

The human gastric cancer cell lines including KATO Ⅲ (ATCC NO: HTB-103), Hs-746T (HTB-135) and AGS (CRL-1739) were procured from American Type Culture Collection. KATO Ⅲ and Hs-746T were grown in DMEM supplemented with 100 mL/L fetal bovine serum (FBS) and penicillin/streptomycin at 37 ℃ in a humidified atmosphere with 50 mL/L CO_2. AGS was grown in RPMI-1640 supplemented with 100 mL/L FBS and penicillin/streptomycin at 37 ℃ in a humidified atmosphere with 50 mL/L CO_2. To analyze SP and NSP cell fractions, the cells were removed from their dishes with 2.5 g/L trypsin and 0.5 g/L ethylenediaminetetraacetic acid, centrifuged, washed with PBS and resuspended at 37 ℃ in Hank's balanced salt solution (HBSS) containing 20ml/L FBS. Cells (1×10^6) were labeled in HBSS with 5.0 mg/L Hoechst33342 dye (Sigma, St. Louis, MO) either alone or in combination with 50 mol/L verapamil (Sigma, St. Louis, MO) at 37 ℃ for 90 min. After washing three times with PBS, the cells were resuspended in HBSS containing 20 mL/L FBS and 1mmol/L 4-(2-hydroxyethyl)-1-piperazine ethanesulphonic acid (HEPES), passed through a 40-μm mesh filter, then maintained at 4 ℃ until flow cytometric analysis. Then, 1×10^6 viable cells were analyzed and sorted using a FACS Vantage SE Cell Sorter (BD Biosciences, CA). The Hoechst dye was excited with a UV laser and its fluorescence was measured with both 675/20 (Hoechst Red) and 424/44 filters (Hoechst Blue). The analysis was repeated three times.

Clone formation assays

Following melting 10 g/L agar (DNA grade) in the microwave and warming 2 × Dulbecco's modified eagle medium (DMEM) supplemented with 200 mL/L FBS to 40 ℃ in a water bath, equal volumes of the two solutions were mixed to yield a new solution of 5 g/L agar, 1 × DMEM and 100 mL/L FBS. Next, 1.0 mL of mixed solution was added to each well of a 6-well plate to form the base agar. Then, 7 g/L agar (DNA grade) was melted in the microwave and cooled to 40 ℃ in a water bath; similarly, 2 × DMEM and 200 mL/L FBS were warmed to the same temperature. Freshly sorted SP and NSP cells from KATO Ⅲ were passed through a 40-μm filter to provide a single cell suspension and were counted. Three mL DMEM, 1.5 mL 2 × DMEM containing 200 mL/L FBS and 1.5 mL agar including 400 cells were then mixed together, and a 1.5 mL cell suspension of this solution was placed into each well of a 6-well plate as the top agar. Finally, 100 cells were seeded into each well, and were incubated at 37 ℃ in a humidified incubator for 2-3 wk. Colonies were either left unstained, or were stained with 5 g/L MTT (Sigma, St. Louis, MO) for no more than one hour, and counted under a dissecting microscope. The procedure was repeated three times. After SP cells were seeded in soft agar assays, colonies containing more than 50 cells (primary colony) were removed from soft agar with sterile Pasteur pipettes, treated with trypsin and mechanically dissociated into single cells. Then, 100 cells were seeded into each well at 37 ℃ in a humidified incu-

bator for another 2-3 wk. Colonies (secondary colony) were stained with 5 g/L MTT for no more than one hour, and counted under a dissecting microscope. The procedure was repeated three times.

Lentivirus infection

Plasmid DNA was kept at a 3:3:1 ratio [Vector (EGFP): Δ8.91: VSV-G] according to the lipofectamine protocol (Invitrogen). Next, 2.5 μg plamid DNA was diluted in 500 μL serum-free DMEM for each well, and 2.5 μL Mix PLUS reagent and 6.25 μL Lipofectamine™ LTX reagent were added to the diluted DNA and incubated for 30 min at room temperature. Then, approximately 500 μL of the DNA-Lipofectamine™ LTX complex was added to each well containing 293FT cells, which were 40%-50% confluent. The cells were incubated at 37 ℃ in a CO_2 incubator for six hours and the medium was changed for transfected cells. After 24 h, the media from 293FT cells was collected, and 8 mg/L polybrene was added and transferred to target cells. The transfer of media from 293 FT to KATO Ⅲ cells was repeated after 24 h and 48 h.

Sphere formation assays

To test sphere formation in suspension, sorted SP and NSP cells from KATO Ⅲ were passed through a 40-μm filter to provide a single cell suspension. Next, 4 mL medium containing 100 cells were added to the 6-well plates with serum-free media including F12 with EGF (10 μg/L), insulin (20 mg/L) and basic fibroblast growth factor (bFGF) (10 μg/L). Aliquots of epidermal growth factor (EGF), insulin and bFGF were added twice a week. After 10-14 d, plates were visually assayed for the formation of floating spheres. To assess the ability of primary spheres to form secondary spheres, colonies containing more than 30 cells were collected by centrifugation and trypsinized to yield single cells. After passing through a 40-μm filter, 4 mL serum-free media containing 100 cells were added to each 6-well plate and were cultured 10-14 d for secondary sphere formation. Spheres were counted under a dissecting microscope.

Gene expression detection

1×10^5 SP and NSP cells from the KATO Ⅲ total population were collected in a separate centrifuge tube with 350 μL RLT buffer containing 10 g/L 2-mercaptoethanol, total RNA was extracted from these cells using a RNeasy Mini Kit (Qiagen, CA) according to the protocol provided by the manufacturer. RNA was transcribed into cDNA using the SuperScript First-Strand Synthesis System (Invitrogen, CA). RT-PCR was performed using a SuperScript One-Step kit (Invitrogen, CA). The primers were as follows: Glyceraldehyde-3-phosphate dehydrogenase, 5-CTG CAC CAC CAA CTG CTT AG-3 and 5-AGG TCC ACC ACT GAC ACG TT-3; *ABCG2*, 5-GGG TTC TCT TCT TCC TGA CGA CC-3 and 5-TGG TTG TGA GAT TGA CCA ACA GAC C-3; *MDR1*, 5-GCC TGG CAG CTG GAA GAC AAA TAC-3 and 5-ATG GCC AAA ATC ACA AGG GTT AGC-3; B-cell-specific Moloney murine leukemia virus insertion site 1 (*Bmi-1*), 5-AGC AGA AAT GCA TCG AAC AA-3 and 5-CCT AAC CAG ATG AAG TTG CTG A-3; Octamer-binding transcription factor 4 (*Oct-4*), 5-GAG AAT TTG TTC CTG CAG TGC-3 and 5-GTT CCC AAT TCC TTC CTT AGT G-3. The PCR products were separated by electrophoresis on a 20 g/L agarose gel.

Tumor formation assays

Sorted SP and NSP cells from KATO Ⅲ were resuspended in 50 μL HBSS, ranging in density from 10^4 cells to 10^3 cells, and then mixed with 50 μL Matrigel (Becton Dickinson, NJ) to prevent injected cell dispersion and loss. Then, cells were subcutaneously injected into 6- or 7-wk old nude mice on the day of sorting. Nude mice were obtained from the Animal Institute of the Xi'an Jiaotong University, China (XJTU). All experiments were approved by the Animal Care Committee of XJTU. Mice were monitored every day to assess tumor formation for 6-8 wk after transplantation.

Statistical analysis

All values were expressed as mean ± SD. Any significant difference among mean values was further evaluated by the Student's *t* test.

RESULTS

Identification of SP in gastric cancer cell lines

SP was identified through their fluorescence profile in a dual-wavelength analysis by flow cytometry (Hoechst red 675/20; Hoechst blue 424/44), and were shown as a characteristic tail separated from the complete population.

The percentage of SP cells in human gastric cancer cell lines was 0.57% in KATO Ⅲ, 1.04% in Hs-746T, and 0.02% in AGS (Figure 1). SP cells decreased in number following treatment with verapamil, an inhibitor of the ABC transporter. To further investigate the function of SP and NSP cells in these gastric cancer cell lines, *in vitro* and *in vivo* tumorigenicity was studied mainly among KATO Ⅲ cells.

Clone formation

The clonogenic ability of SP and NSP cells were examined when seeded as single cells. The clonogenic efficiency of SP cells was significantly higher than NSP cells in soft agar assays (Figure 2A and B). Moreover, most SP cells could divide into colonies of more than 50 cells in soft agar after three weeks. There was no apparent difference between NSP cells and the complete population. The self-renewal ability of SP cells was also examined in serial soft agar assays. There was an increase in clonogenic efficiency from primary to secondary colonies. Moreover, secondary colonies were similar in size to the primary colonies, thus demonstrating that SP cells can maintain and expand themselves in serial soft agar assays.

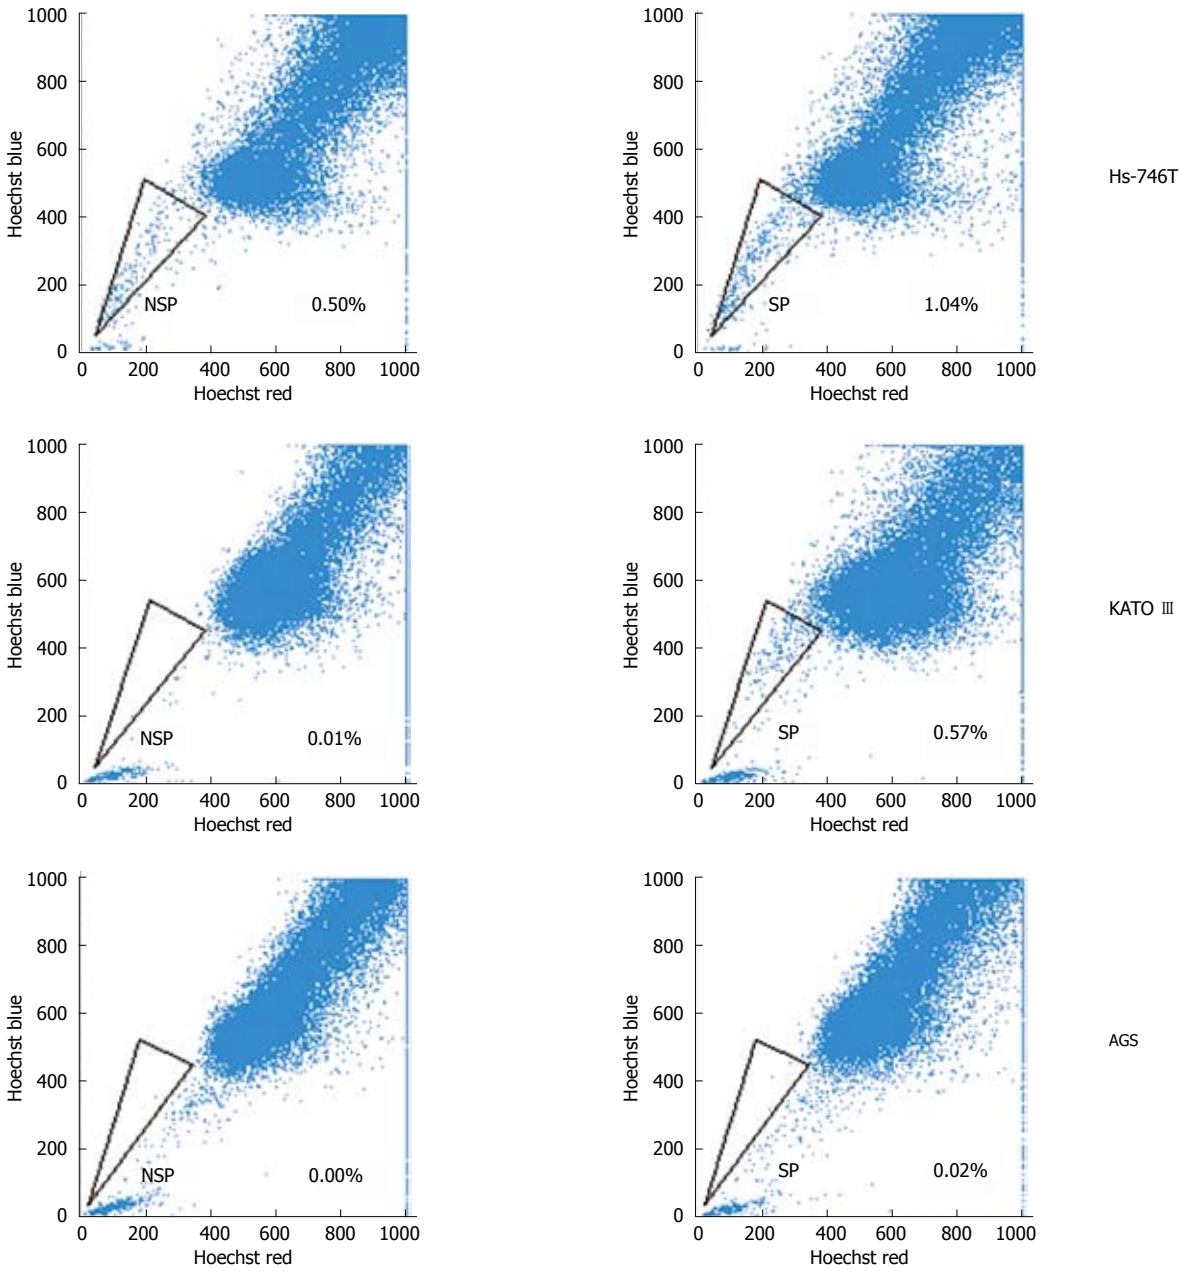

Figure 1 Side population and non-side population cells from several human gastric cancer cell lines were analyzed through uptake of the DNA binding dye Hoechst33342 with or without the presence of verapamil. NSP: Non-side population; SP: Side population.

To ascertain whether the colony comes from a single cell, KATO Ⅲ was infected with enhanced green fluorescent protein-expressing (EGFP) lentivirus and equal numbers of KATO Ⅲ-GFP and KATO Ⅲ cells were seeded from primary to second passage into serial soft agar assays. It was revealed that KATO Ⅲ-GFP cells expressed strong green fluorescence and showed a similar growth rate compared to non-infected KATO Ⅲ. Moreover, there were no mixed colonies (Figure 2C), indicating that the colonies came from single cells.

Sphere formation

The ability of SP and NSP cells to generate spherical clones and self-renewal was evaluated by sphere formation assays (Figure 3A). It was difficult to observe floating spheres from NSP cells (Figure 3B). SP cells started to form floating spheres after 2-3 d of seeding, and became primary spheres of more than 30 cells after 10-14 d (Figure 3C). The secondary sphere occurred slightly more quickly and frequently than the primary spheres, suggesting that SP cells have self-renewal ability.

Gene expression

First, the expression of ABC transporters, including *ABCG2* and *MDR1*, was observed, which was significantly higher in SP than in NSP cells (Figure 4). To further

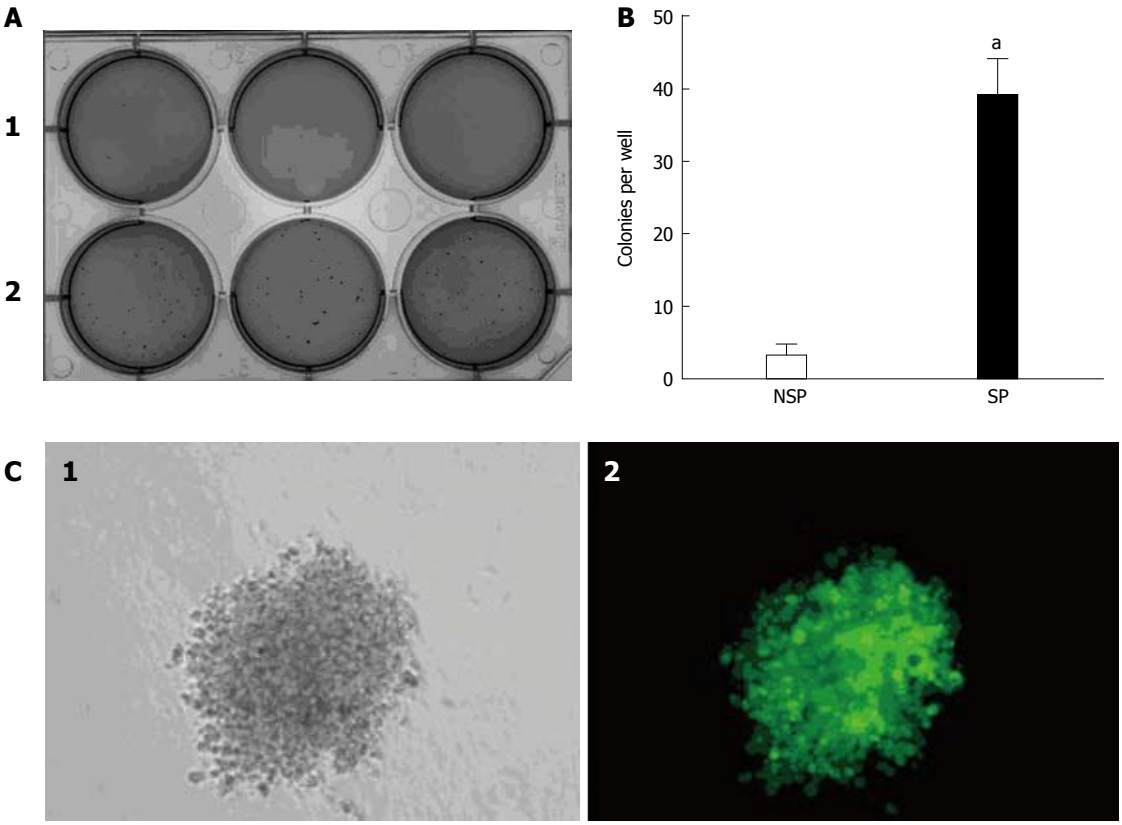

Figure 2 Soft agar assays and fluorescence for KATO Ⅲ-green fluorescent protein cells. A: Side population (SP) cells (A-2) were more clonogenic than non-side population (NSP) cells (A-1); B: The assay was repeated 3 times, and the column diagram indicated that there was a statistically significant difference in clonogenic efficiency between SP and NSP cells ($^aP < 0.05$ *vs* NSP cells); C: KATO Ⅲ-green fluorescent protein (GFP) cells expressed strong green fluorescence in regular culture, with no mixed colonies resulting from a single KATO Ⅲ-GFP cell. C-1 was observed under white light, while C-2 was observed under fluorescent light.

determine whether SP cells have stem cell-like characteristics, SP and NSP cells were examined for their expression of stem cell markers. The results demonstrated that the expression of *Oct-4* and *Bmi-1* in SP cells was higher than in NSP cells (Figure 4), suggesting that SP cells had some of the characteristics of undifferentiated stem cells.

Tumor formation

To compare tumorigenic ability, SP and NSP cells from the KATO Ⅲ human gastric cancer cell line were subcutaneously injected into the nude mice. Each mouse was individually injected with different amounts of SP and NSP cells. Six weeks after injection, although tumor diameter was smaller in NSP than in SP cells, four out of six mice could form tumors when injected either with SP or NSP cells (Table 1). All remaining mice could form tumors after eight weeks.

DISCUSSION

To our knowledge, there has been no report identifying SP cells from the gastric cancer cell lines. As such, in this paper we analyzed SP and NSP cells in the KATO Ⅲ, Hs-746T and AGS human gastric cancer cell lines. In the KATO Ⅲ and Hs-746T cell lines, which have a high tumorigenic ability, SP cells accounted for 0.57% and 1.04% of the total population, moreover, they occupied 0.02% in the high tumorigenic AGS cell line. Therefore, it is challenging to draw a conclusion from the percentage of SP cells in different cell lines to compare their tumorigenic ability. These data are consistent with the C6 glioma cell line, which was mainly composed of cancer stem cells, although many of these cells were neither CD133+ nor a side population[21]. Further studies are therefore needed to compare the relationship between SP prevalence and tumorigenicity.

Single cells that grow anchorage-independently in soft agar are known to be malignant. Thus, cell lines should contain those cells which could form colonies and those that did not form colonies in soft agar assays. As such, soft agar assays can be used to investigate this tumorigenic ability *in vitro*. By seeding the mixed cells of KATO Ⅲ-GFP and KATO Ⅲ into soft agar, we could conclusively determine that colonies came from single cells. The clonogenic ability of SP cells isolated from KATO Ⅲ was higher than that of NSP cells in soft agar and sphere forming assays. This is in agreement with the reports for the MCF7[13] and ARO[11] cell lines. In original animal transplant experiments, SP of KATO Ⅲ were injected into nude mice subcutaneously, ranging in density from 10^4 to 10^2 cells. The tumor forms in mice by injecting 10^4 (2 out of 2) and 10^3 cells (2 out of 2) SP in 6 wk. The other mice did not form tumor by injecting 5×10^2 (0 out of 2) and 1×10^2 cells (0 out of 2) SP until week

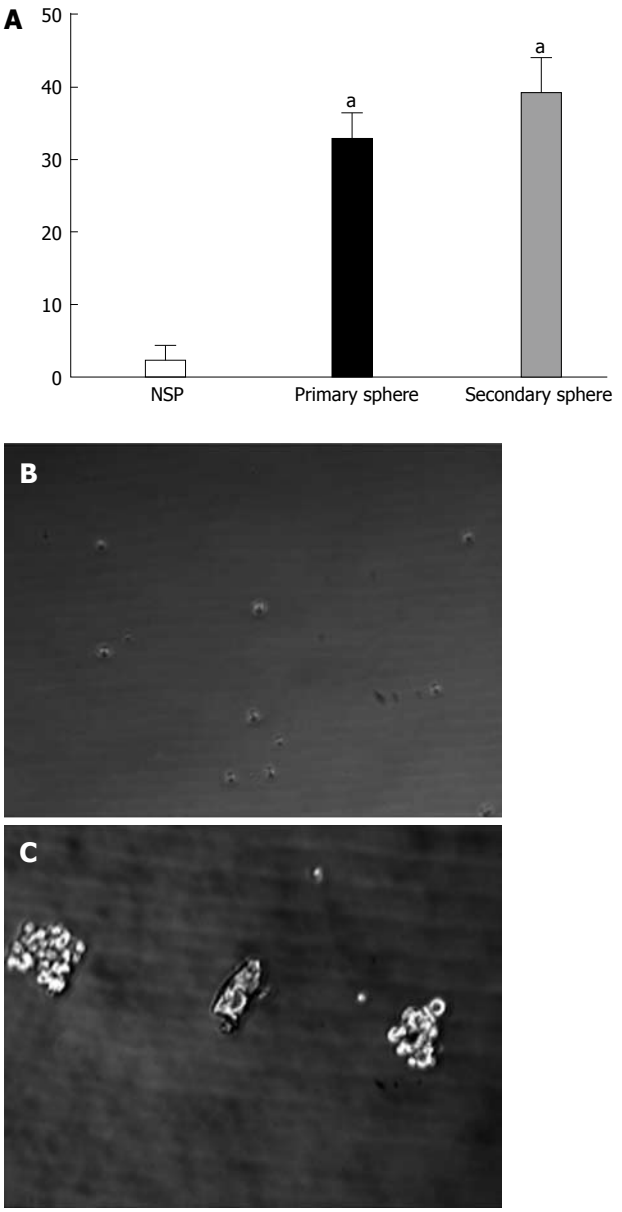

Figure 3 Serial sphere assays. A: The assay was repeated 3 times, and the column diagram indicated a statistically significant difference in clonogenic efficiency between non-side population (NSP) and side population (SP) cells in primary and secondary sphere assays ($^aP < 0.05$ *vs* NSP cells); however, there was no significant difference between primary and secondary sphere assays; B: Sphere assay for NSP cells; C: Sphere assay for SP cells.

SP: Side population; NSP: Non-side population.

10. In tumor formation assays, SP and NSP of KATO Ⅲ ranging from 10^4 to 10^3 cells were injected. In our study, 12 injection sites for SP cells could form tumors in six weeks. However, 12 injection sites for NSP cells could also form tumors as well, although the observation period had to be increased to eight weeks. There was no significant difference in tumorigenicity *in vivo* between SP and NSP cells, which suggested that although *CSC* was enriched in SP cells, it may contain both SP and NSP cells.

Indefinite self-renewal is one of the essential properties of stem cells. A stem cell could undergo asymmetric division continuously, producing one cell that retains self-renewal ability and differentiates into a mature cell. Stem cells and progenitor cells have the property of

anchorage-independent growth[22]. Therefore, soft agar and sphere formation assays can be used to test the self-renewal ability of stem cells *in vitro*[23,24]. In serial soft agar and sphere formation assays, single cells isolated from primary colonies coming from SP cells could form a secondary colony, suggesting that SP cells have the self-renewal capacity.

Bmi-1 is a transcriptional repressor belonging to the polycomb group of transcription factors. It has been shown to be important in the self-renewal of both normal and leukemic stem cells, as well as neuronal stem cells[25]. Oct-4 is a POU homeodomain transcription factor that is a key regulator of self-renewal in embryonic stem cells[26]. Cellular expression of Oct-4 is believed to have the capacity for self-renewal[27]. Moreover, the self-renewal ability of cancer stem cells could drive tumorigencity[28]. Oct-4 and Bmi-1 overexpression in SP cells isolated from KATO Ⅲ was observed, which might reflect the property of self-renewal of SP cells.

While ABCG2 can efflux the DNA binding dye Hoechst 33342, which could induce an SP phenotype, MDR1 is the best-studied member of the ABC transporter superfamily of genes[29]. The expression level of *ABCG2* and *MDR1* mRNA was higher in SP than in NSP cells as determined by RT-PCR analysis, which contributes to the chemotherapeutic resistance of SP cells, and thus may be a target for cancer therapy.

COMMENTS

Background

Gastric cancer is the second leading cause of cancer-related deaths worldwide. Cancer stem cells have the characteristics of longevity, self-renewal and proliferation. It is believed that cancer stem cells are responsible for the heterogeneity and relapse of certain cancers including gastric cancer.

Research frontiers

Side population (SP) cells can efflux the DNA-binding dye Hoechst33342 through an adenosine-triphosphate-binding cassette (ABC) membrane transporter and harbor stem cell-like characteristics. Recent studies suggested that SP cell analysis can be used to identify cancer stem cell populations. However, there has been no report identifying SP cells from the gastric cancer cell lines.

Innovations and breakthroughs

This is the first study to analyze SP and non-side population (NSP) cells in several human gastric cancer cell lines. The clonogenic ability of SP cells isolated from KATO Ⅲ was higher than that of NSP cells in soft agar and sphere forming assays. *Oct-4* and *Bmi-1* overexpression in SP cells isolated from KATO Ⅲ might reflect the property of self-renewal of SP cells. Moreover, *ABCG2* and *MDR1* overexpression contributes to the chemotherapeutic resistance of SP cells, and thus may be a target for cancer therapy.

Applications

SP cells could be used as a therapeutic target and for preventing relapse and drug-resistance in gastric cancer.

Terminology

Cancer stem cells are characterized by its self-renewal capacity, differentiation potential, and cancer-initiating ability. Side population cells expressing the ABC transporter were distinguished from whole cell population. Recent studies demonstrated that SP cells could be characterized as cancer stem cells in primary tissues and tumor cell lines, therefore, it was postulated to be responsible for tumor development and recurrence.

Peer review

Overall, this paper is very well written with good English and solid methodology. The biggest issue is that the content is not new. Basically, what the authors did was to confirm and characterize the side population cells in gastric cancer cell lines, which is not surprising. With that said, it is believed no one has done it in these cells, and it still may somewhat be informative to readers.

Abstract

AIM: To investigate whether the 7-difluoromethoxyl-5, 4′-di-n-octylgenistein (DFOG), a novel synthetic genistein analogue, affects the growth of gastric cancer cells and its mechanisms.

METHODS: A series of genistein analogues were prepared by difluoromethylation and alkylation, and human gastric cancer cell lines AGS and SGC-7901 cultured *in vitro* were treated with various concentrations of genistein and genistein analogues. The cell viability was measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. The cells were incubated by DFOG at different concentrations. The growth inhibitory effects were evaluated using MTT and clonogenic assay. The distribution of the phase in cell cycle was analyzed using flow cytometric analysis with propidium iodide staining. The expression of the transcription factor forkhead box M1 (FOXM1) was analyzed by reverse transcription-polymerase chain reaction and Western blotting. The expression levels of CDK1, Cdc25B, cyclin B and $p27^{KIP1}$ protein were detected using Western blotting.

RESULTS: Nine of the genistein analogues had more effective antitumor activity than genistein. Among the tested analogues, DFOG possessed the strongest activity against AGS and SGC-7901 cells *in vitro*. DFOG significantly inhibited the cell viability and colony formation of AGS and SGC-7901 cells. Moreover, DFOG efficaciously arrested the cell cycle in G2/M phase. DFOG decreased the expression of FOXM1 and its downstream genes, such as CDK1, Cdc25B, cyclin B, and increased $p27^{KIP1}$ at protein levels. Knockdown of FOXM1 by small interfering RNA before DFOG treatment resulted in enhanced cell growth inhibition in AGS cells. Up-regulation of FOXM1 by cDNA transfection attenuated DFOG-induced cell growth inhibition in AGS cells.

CONCLUSION: DFOG inhibits the growth of human gastric cancer cells by down-regulating the FOXM1 expression.

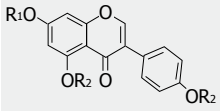
INTRODUCTION

Genistein, 5,7,4'-trihydroxylisoflavone, as one of the active constituents of soybean products, has been reported to possess anti-cancer activities[1,2]. But probably because of its low solubility in both water and organic solvent, genistein has a very low bioavailability. The introduction of the fluorine or fluoride-bearing alkyl such as CF_3 or HCF_2 into organic molecules dramatically changes their physiological, physical and chemical properties[3]. To our best knowledge, the introduction of fluorine moiety into the aryl part of the flavonoid molecule can enhance their biological activities, including anti-bacterial, anti-fungal and anti-viral activities[3]. Fluorinated 3, 4-dihydroxychalcones have illustrated interesting biological activities, including anti-peroxidation and antitumor activity *in vitro*[4]. We have previously reported that introduction of CF_3 or HCF_2 group into chrysin (5,7-dihydroxylflavone) molecule can improve their anticancer activities[5-7]. Recently, we synthesized a series of difluoromethoxylated genistein analogues and determined their protective effects against vascular endothelial cells[8]. However, there are few studies which reported the anti-cancer effect of fluorinated genistein analogues.

Gastric cancer is one of the most common malignancies in the world and its incidence and mortality rank first in China[9]. Recent data indicate that the mortality of gastric cancer in China tends to increase and it severely threatens the health and life of people[10]. At present, surgery and chemotherapy remain as the main modalities in the management of gastric cancer, but the curative effect of the existing chemotherapeutic drugs is not satisfactory, which cause numerous side effects. Therefore, it has been a focus to search for new drugs capable of preventing and treating gastric cancer and other malignancies. Gastric cancer has been shown to have activated forkhead box protein M1 (FOXM1) signaling pathway[11]. The FOXM1 belongs to a family of evolutionary conserved transcriptional regulators that were characterized by the presence of a DNA-binding domain called the forkhead box or winged helix domain[12]. It has been shown that FOXM1 signaling plays an important role in cellular developmental pathways, and activation of FOXM1 signaling is associated with carcinogenesis[13]. FOXM1 signaling is frequently up-regulated in cancers, including lung, breast, pancreatic and gastric cancer[11,14-16]. Moreover, FOXM1 has been shown to regulate transcription of cell cycle genes, including Cdc25B, CDK1, cyclin B and $p27^{KIP1}$[13,17]. Recently, it has been reported that FOXM1 expression could serve as an independent predictor of a poor survival of gastric cancer patients[11]. Studies by Wang *et al*[18] have shown that genistein may inhibit FOXM1 activation in pancreatic cancer cells, leading to apoptotic cell death. Therefore, it is believed that the targeted inactivation of FOXM1 could represent a promising strategy for the development of novel selective anti-cancer therapies.

In the present study, we investigated whether the growth inhibitory effects of genistein and the novel synthetic genistein analogue 7-difluoromethoxyl-5,4'-di-n-octylgenistein (DFOG) on gastric cancer cells could be attributed to modulation of FOXM1 activity. We found that DFOG and genistein down-regulated the FOXM1 expression and its downstream genes, including cdc25B, CDK1, cyclin B and up-regulated $p27^{KIP1}$, resulting in the growth inhibition of gastric cancer cells. These results provide strong evidences to support that FOXM1 is a rational target in gastric cancer, and the targeted inactivation of FOXM1, especially by genistein and its analogue DFOG, may provide new insight into the strategy development for better prevention of tumor progression and/or treatment of gastric cancer.

MATERIALS AND METHODS



Cell culture and reagents

Human gastric cancer cell lines AGS and SGC-7901 were purchased from China Center for Type Culture Collection (CCTCC, Wuhan, China). Cells were maintained in RPMI 1640 medium (Invitrogen, Carlsbad, CA, United States) supplemented with 10% fetal bovine serum, 2 mmol/L glutamine, 100 mg/L penicillin, and 100 mg/L streptomycin, and incubated in a humidified atmosphere of 5% CO_2 at 37 ℃. The difluoromethoxylated genistein analogues 2,4a-4h were prepared by the method described elsewhere[8] (Table 1). Primary antibodies for FOXM1, CDK1, cyclin B, $p27^{KIP1}$ and Cdc25B were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, United States). Anti-β-actin antibody and Horseradish peroxidase-conjugated rabbit anti-mouse secondary antibody were purchased from Santa Cruz Biotechnology. Lipofectamine 2000 was purchased from Invitrogen. Protease inhibitor cocktail, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and all other chemicals were obtained from Sigma (St. Louis, MO, United States). Genistein (Sigma) and the difluoromethoxylated genistein analogues were dissolved in dimethyl sulfoxide (DMSO) to make a 10 mmol stock solution and were added directly to the media at different concentrations before use.

MTT assay

Cells were seeded in a 96-well plate at a density of 5000 cells/well as described previously[19]. After incubation for 24 h to allow cell attachment, different concentrations of genistein and genistein analogues (0.1, 0.3, 1.0, 3.0, 10.0 and 30.0 μmol/L) were added to each well and cultured for 24 h. Medium was removed and then incubated with 5.0 mg/mL MTT for 4 h. Then supernatant was removed after centrifugation. Finally, 100 μL of DMSO was added and absorbance at 570 nm wavelength (A_{570}) was measured by means of an Enzyme-labeling instrument (ELX-800 type; Bio-Tek, Shanghai, China). Relative cell proliferation inhibition rate = (1 - average A_{570} of the experimental group/average A_{570} of the control group) × 100%. The IC_{50} (defined as the drug concentration which 50% cell viability was inhibited) was as-

Table 1 Structures of genistein and its difluoromethylated derivatives

	Compound	R1	R2
1	Genistein (5,7,4′-trihydroxylisoflavone)	H	H
2	7-difluoromethyl genistein	CHF_2	H
4a	7-difluoromethyl-5,4′-dimethyl genistein	CHF_2	CH_3
4b	7-difluoromethyl-5,4′-diethyl genistein	CHF_2	CH_3CH_2
4c	7-difluoromethyl-5,4′-di-n-propyl genistein	CHF_2	n-C_3H_7
4d	7-difluoromethyl-5,4′-di-benzyl genistein	CHF_2	$C_6H_5CH_2$
4e	7-difluoromethyl-5,4′-diheptyl genistein	CHF_2	n-C_7H_{15}
4f	7-difluoromethyl-5,4′-di-n-octyl genistein	CHF_2	n-C_8H_{17}
4g	7-difluoromethyl-5,4′-didecyl genistein	CHF_2	n-$C_{10}H_{21}$
4h	7-difluoromethyl-5,4′-diisobutyl genistein	CHF_2	iso-C_4H_9

sessed from the dose-response curves using GraphPad Prism program (Version 4, GraphPad Software).

Clonogenic assay

Cells were plated in 24-well plates at a density of 300 cells/well for 24 h, prior to the addition of various concentrations of DFOG (1, 5 and 10 μmol/L) and 10 μmol/L genistein. After 48 h of treatment, the drug-containing medium was removed and replaced with complete growth medium. Medium was changed every 3 d for 8-10 d until visible colonies formed. Colonies were simultaneously fixed and stained with 0.5% crystal violet in methanol, and manually counted. Individually stained colonies in each well were counted and the colony formation fraction was calculated as follows: colony number/(number of cells seeded × plating efficiency), where plating efficiency is equivalent to the colony number divided by the number of cells seeded in the drug-free medium.

Cell cycle analysis by flow cytometry

Cells were plated in 6-well plates at a density of 1 000 000 cells/well for 24 h, prior to the addition of various concentrations (1, 5 and 10 μmol/L) of DFOG and 10 μmol/L genistein. After 24 h of treatment, cells were harvested, and DNA content was stained for 15 min at 37 ℃ with a solution containing 0.4% Triton X-100 (Sigma), 50 μg/mL of propidium iodide (Sigma), and 2 μg/mL of DNase-free RNase (Roche, United States). The cells were then analyzed for cell cycle perturbation using a FACSCalibur (FACS 420, Becton Dickinson, United States). The CellQuest program was used to quantitate the distribution of cells in each cell cycle phase: G1, S and G2/M.

Reverse transcription-polymerase chain reaction

Total RNA was extracted using Trizol reagent (Life Technologies, Gaithersburg, MD, United States). The integrity of the RNA was checked by 2% agarose gel electrophoresis. Approximately 2 μg RNA was reversely transcribed following the protocol of the Super Script™ first-strand synthesis system (Invitrogen Corporation, Carlsbad, CA, United States). The cDNAs encoding FoxM1 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) genes were amplified by polymerase chain reaction (PCR) as follows: denaturation at 94 ℃ for 30 s, annealing at 63 ℃ for 30 s and elongation at 72 ℃ for 45 s. Primer sequence was designed using Primer. For FoxM1, the forward primer was 5'-AACCGCTACTTGACATTGG-3' and reverse primer 5'-GCAGTGGCTTCATCTTCC-3'. A housekeeping gene, GAPDH was used as the internal control. The forward primer was 5'-ACCCAGAAGACTGTGG ATGG-3', and the reverse primer was 5'-TGCTGTAGCCAAATTCGTTG-3'. PCR products were analyzed by agarose (2%) gel electrophoresis.

Plasmids and transfections

FOXM1 small interfering RNA (siRNA) and control siRNA were obtained from Santa Cruz Biotechnology. The FOXM1 cDNA plasmid was purchased from OriGene Technologies Inc (Rockvile, MD, United States). Human gastric cancer AGS cells were transfected with FOXM1 siRNA and cDNA, respectively, using Lipofectamine 2000 (Invitrogen) as described by Wang *et al*[20].

Western blotting analysis

Western blotting analysis was carried out as previously described[21]. Cells were lysed in lysis buffer by incubation for 20 min at 4 ℃. The protein concentration was determined using the Bio-Rad assay system (Bio-Rad, Hercules, CA, United States). Total proteins were fractionated using sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred onto Polyvinylidene fluoride membrane (Millipore, United States). Anti-FOXM1, anti-CDK1, anti-cyclin B, anti-$p27^{KIP1}$, anti-cdc25B and anti-β-actin rabbit polyclonal antibodies were used as primary antibodies. The signals were detected using an ECL Advance Western blotting analysis system (Amersham Pharmacia Biotech Inc., Piscataway, NJ, United States).

Statistical analysis

The SPSS 15.0 software package (SPSS Inc, Chicago, IL, United States) was used for the statistical analysis. Data were expressed as mean ± SD. The means of multiple groups were compared with one-way analysis of variance, after the equal check of variance, and the pairwise comparisons among the means were performed using the least significant difference method. Statistical comparison was also performed with two-tailed *t* test when appropriate. A $P < 0.05$ was considered as statistically significant.

RESULTS

Effects of genistein and genistein analogues on the cell viability of gastric cancer cells

First, we examined the effects of genistein and the genistein analogues on the viability of AGS and SGC-7901

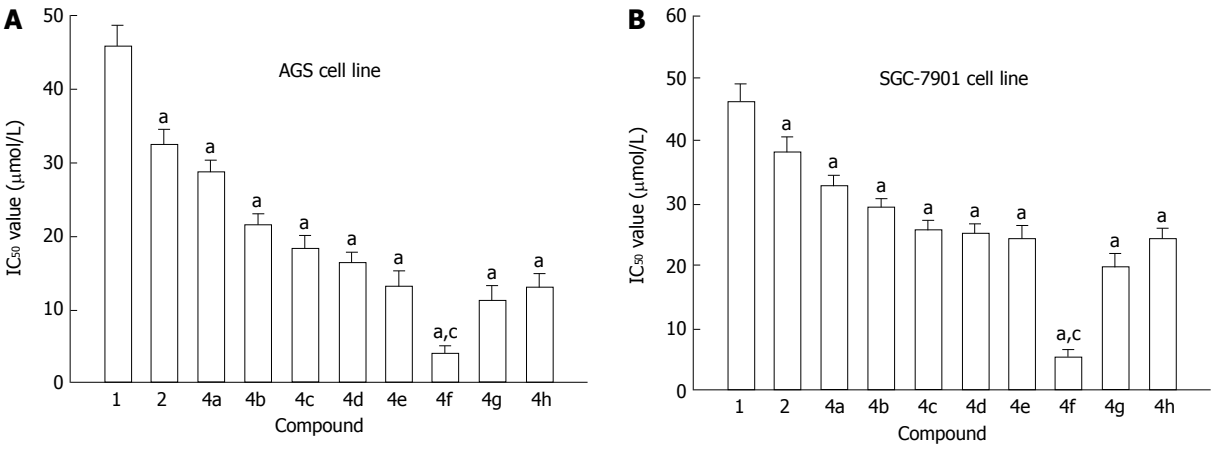


Figure 1 Inhibition of cell viability by genistein and genistein analogues. A: AGS cell line; B: SGC-7901 cell line. $^{a}P < 0.05$ *vs* treatment with genistein; $^{c}P < 0.05$ *vs* treatment with genistein or other genistein analogues. 1: Genistein (5,7,4'-trihydroxylisoflavone); 2: 7-difluoromethyl genistein; 4a: 7-difluoromethyl-5,4'-dimethyl genistein; 4b: 7-difluoromethyl-5,4'-diethyl genistein; 4c: 7-difluoromethyl-5,4'-di-n-propyl genistein; 4d: 7-difluoromethyl-5,4'-di-benzyl genistein; 4e: 7-difluoromethyl-5,4'-diheptyl genistein; 4f: 7-difluoromethyl-5,4'-di-n-octyl genistein; 4g: 7-difluoromethyl-5,4'-didecyl genistein; 4h: 7-difluoromethyl-5,4'-diisobutyl genistein.

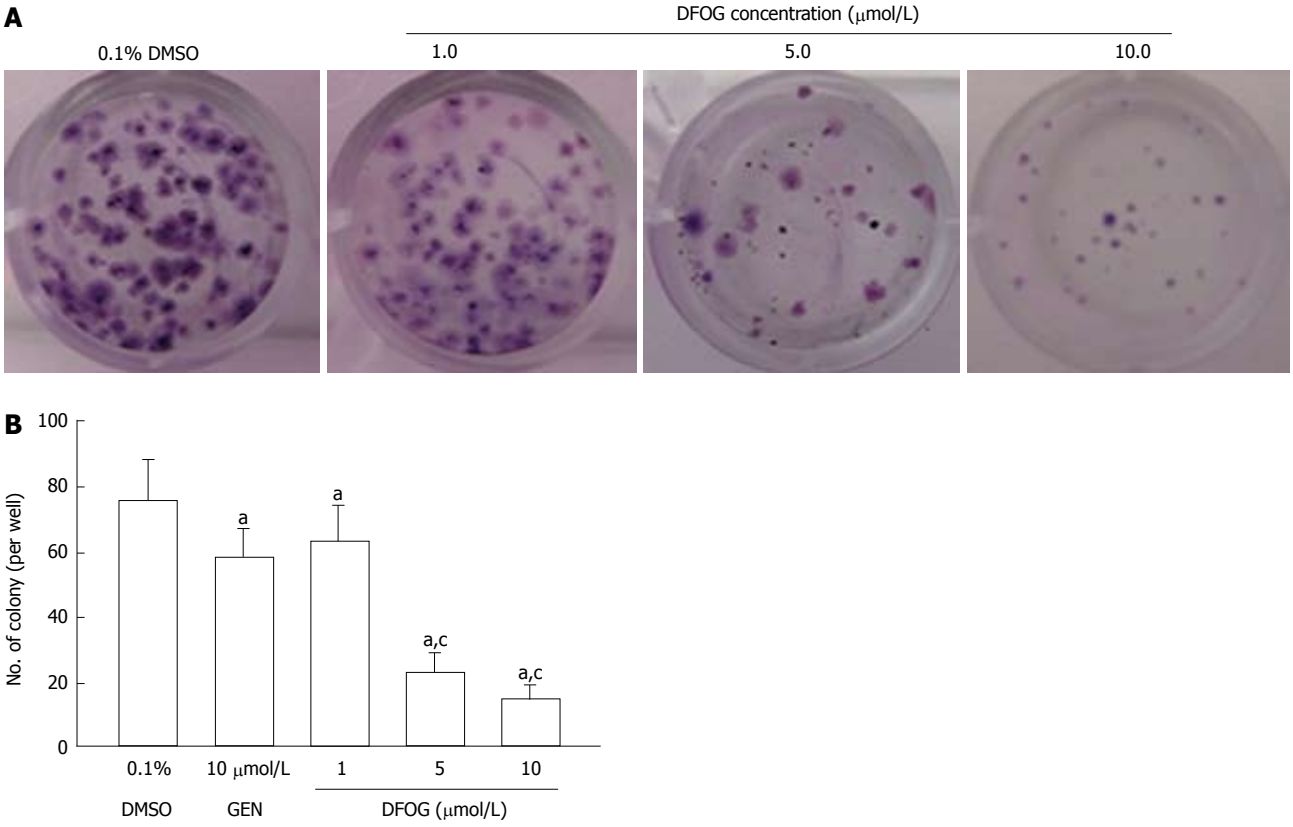

Figure 2 Decrease of colony number and inhibition of colony formation by 7-difluoromethoxyl-5,4'-di-n-octylgenistein. A: Decrease of colony number by 7-difluoromethoxyl-5,4'-di-n-octylgenistein (DFOG); B: Inhibition of colony formation by DFOG and genistein in AGS cell line. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with 10 μmol/L genistein (GEN) or 1 μmol/L DFOG.

cells using MTT assay. Nine of difluoromethylated genistein analogues had higher effective antitumor activities than genistein. Among the aforementioned analogues, DFOG showed the strongest activity against AGS and SGC-7901 *in vitro* (Figure 1A and B). IC_{50} of DFOG was 3.9 μmol/L for AGS cells and 5.2 μmol/L for SGC-7901 cells, the potency of DFOG was 11.7 and 8.9 as much as that of the lead compound, genistein (IC_{50} was 45.9 μmol/L for AGS cells and 46.3 μmol/L for SGC-7901 cells).

Effects of DFOG on the colony formation of gastric cancer cells

Next, we tested the effects of DFOG on cell growth by clonogenic assay. DFOG treatment resulted in a significant inhibition of colony formation of AGS cells

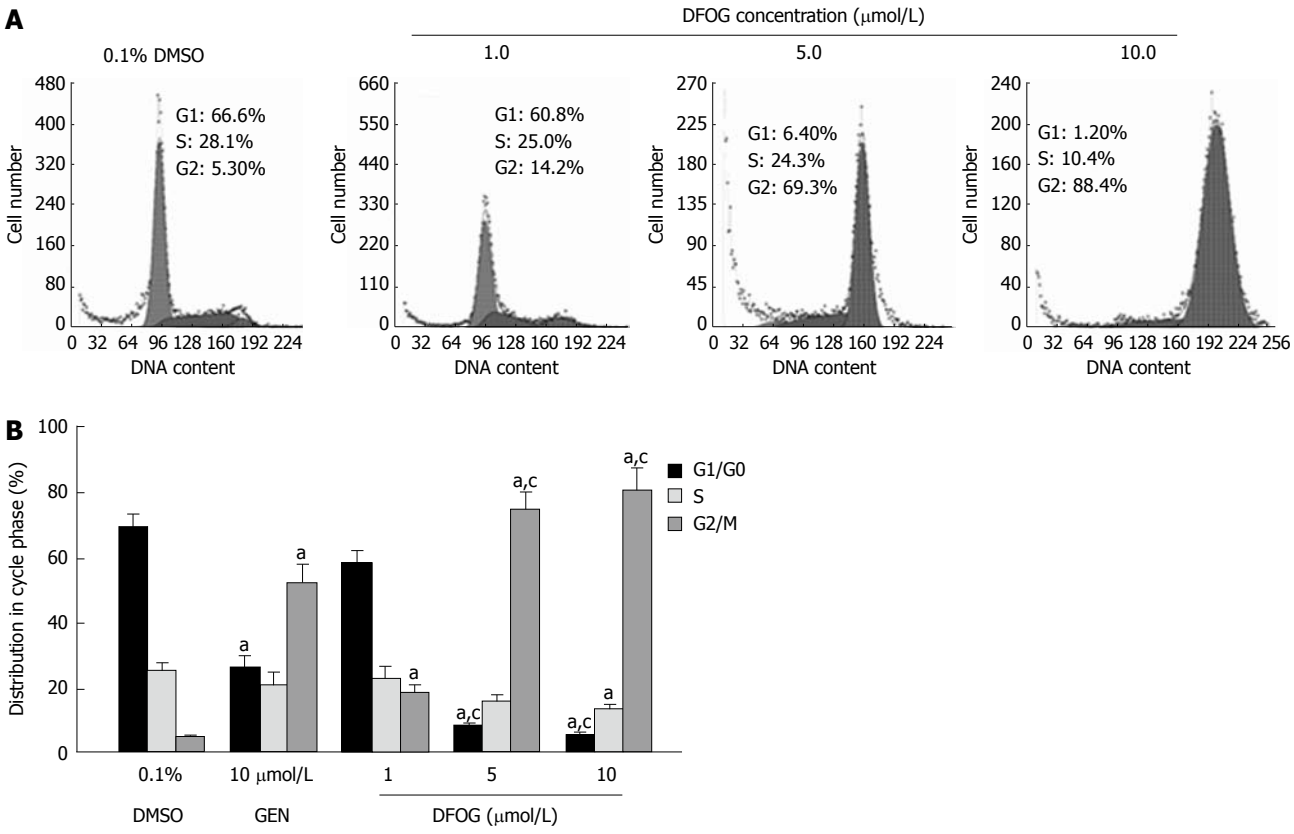

Figure 3 Increase of cells in G2/M phase and induction of cell cycle arrest in G2/M phase by 7-difluoromethoxyl-5,4'-di-n-octylgenistein. A: Increase of cells in G2/M phase by 7-difluoromethoxyl-5,4'-di-n-octylgenistein (DFOG); B: Induction of cell cycle arrest in G2/M phase by DFOG and genistein in AGS cell line. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with 10 μmol/L genistein (GEN) or 1 μmol/L DFOG.

compared with controls (Figure 2A and B). Similar results were observed in SGC-7901 cells (data not shown). These data suggests that DFOG inhibits the growth of gastric cancer cells.

Effects of DFOG on the distribution of cell cycle phase in gastric cancer cells

To assess whether the loss of cell survival could in part be attributed to the induction of cell cycle arrest, we evaluated the effects of DFOG treatment on the distribution in cell phase using flow cytometry with propidium iodide staining. As shown in Figure 3A and B, in gastric cancer cell line AGS, DFOG treatment caused a significant accumulation of cells in the G2/M phase and a marked decrease in the G1/G0 phase compared with control cells. Similar results were observed in SGC-7901 cells (data not shown). These results provided convincing data that DFOG could induce the growth inhibition and arrest of cell cycle in G2/M phase in gastric cancer cells.

Effects of DFOG on FOXM1 expression in gastric cancer cells

The studies by Wang *et al*[18] have shown that FOXM1 signaling is over-expressed in pancreatic cancer and is involved in promotion of cell growth, and thus considered as a putative target for drug development. Therefore, we investigated whether DFOG could regulate FOXM1 signaling pathway. FOXM1 mRNA and protein expression in AGS cell line treated with DFOG and genistein for 24 h were decreased in a concentration-dependent manner (Figure 4A and B). We also found that FOXM1 protein expression was down-regulated by DFOG and genistein in SGC-7901 cells (Figure 4C).

Effects of DFOG on the expression of FOXM1 downstream target genes in gastric cancer cells

It is well known that FOXM1 has several downstream target genes, such as CDK1, Cdc25B, cyclin B, and $p27^{KIP1}$. We used Western blotting analysis to determine the expression of these genes, and found that DFOG and genistein inhibited the expression of CDK1, Cdc25B, cyclin B, and increased $p27^{KIP1}$ at the protein levels in AGS and SGC-701 cells (Figure 5A and B).

Effects of down-regulation of FOXM1 expression by siRNA on DFOG-induced cell growth inhibition in AGS cells

Down-regulation of FOXM1 by siRNA transfection showed less expression of FOXM1 protein in AGS cells, as confirmed by Western blot (Figure 6A).The down-regulation of FOXM1 expression significantly inhibited cell viability induced by DFOG (Figure 6B). DFOG plus FOXM1 siRNA inhibited cell growth to a greater degree compared with DFOG alone. FOXM1 siRNA transfection induces arrest of cell cycle in G2/M phase in AGS cells (Figure 6C). These results provide some molecular evidences suggesting that the DFOG-induced inhibition

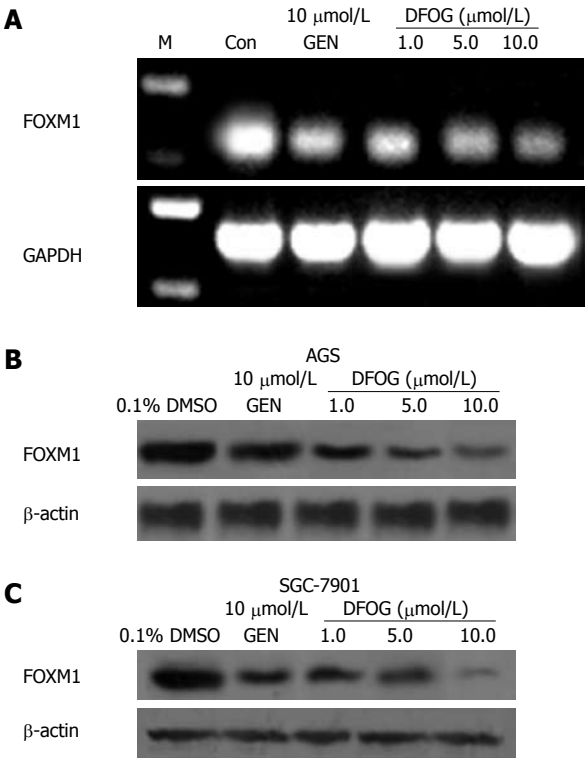

Figure 4 Down-regulation of forkhead box M1 expression by 7-difluoromethoxyl-5,4'-di-n-octylgenistein and genistein in AGS and SGC-7901. A: mRNA level using reverse transcription-polymerase chain reaction in AGS cell line; B: Protein level using Western blotting in AGS cell line; C: Decrease of forkhead box M1 (FOXM1) protein expression in SGC-7901 cell line. DMSO: Dimethyl sulfoxide; GEN: Genistein; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

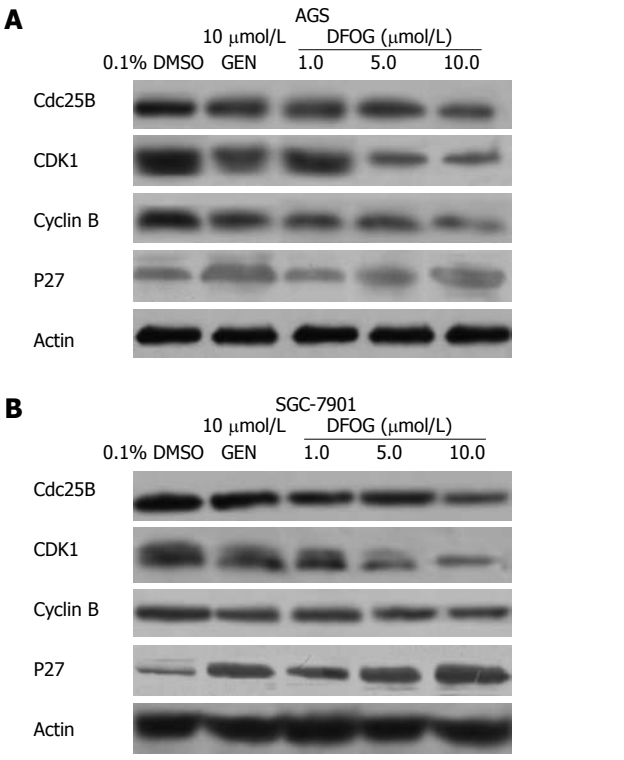

Figure 5 Modulation of the protein expressions of forkhead box M1 downstream target genes by 7-difluoromethoxyl-5,4'-di-n-octylgenistein and genistein. A: AGS cell line; B: SGC-7901 cell line. DMSO: Dimethyl sulfoxide; GEN: Genistein; DFOG: 7-difluoromethoxyl-5,4'-di-n-octylgenistein.

of the growth is mediated *via* inactivation of FOXM1 in gastric cancer cells.

Effects of over-expression of FOXM1 by cDNA transfection on DFOG-induced cell growth inhibition in AGS cells

Up-regulation of FOXM1 by cDNA transfection showed over-expression of FOXM1 protein in AGS cells, as confirmed by Western blotting (Figure 7A). The over-expression of FOXM1 rescued DFOG-induced cell viability inhibition to a certain degree (Figure 7B). These findings suggested that DFOG-inhibited cell growth is in part attributed to inactivation of FOXM1 signaling pathway in gastric cancer cells.

DISCUSSION

FOXM1 signaling has been demonstrated to maintain a balance between cell proliferation, differentiation and apoptosis, suggesting that abnormal activation of *FOXM1* gene is one of the characteristics of human cancers[22]. Increasing studies have shown over-expression of *FOXM1* gene in human cancer cells and tissues[14,23,24]. Thus, the development of agents targeting FOXM1 is likely to have a significant therapeutic impact on the treatment of human cancers, including gastric cancer. FOXM1 could be down-regulated by some drugs, such as antibiotic thiazole compound Siomycin A, thiostrepton, and epidermal growth factor receptor inhibitor gefitinib[25-27]. These observations clearly suggest that chemical compounds that target FOXM1 may act as anti-cancer drugs[27]. Wang *et al*[18] have shown that genistein may inhibit FOXM1 activation in pancreatic cancer cells, leading to apoptotic cell death. In the present study, we used two human gastric cancer cell lines, AGS and SGC-7901, which have high expression of FOXM1, and found that DFOG, a novel synthetic genistein analogue, and genistein could induce significant growth inhibition in the two cell lines, as evidenced by both MTT and clonogenic assay. Furthermore, DFOG and genistein inhibited the expression of FOXM1 and its target genes. Therefore, DFOG and genistein could mediate the cell growth inhibition partly *via* inactivation of FOXM1. Down-regulation of FOXM1 by siRNA together with DFOG treatment inhibited cell growth to a greater degree in AGS cells as compared with DFOG treatment alone. Up-regulation of FOXM1 by cDNA transfection showed over-expression of FoxM1 protein as confirmed by Western blotting analysis, and this over-expression in FOXM1 attenuated DFOG-induced cell growth inhibition in AGS cells. In view of these findings, we strongly believe that inactivation of FOXM1 by DFOG and genistein results in the down-regulation of its target genes, which are mechanistically linked with DFOG and genistein induced cell growth inhibition.

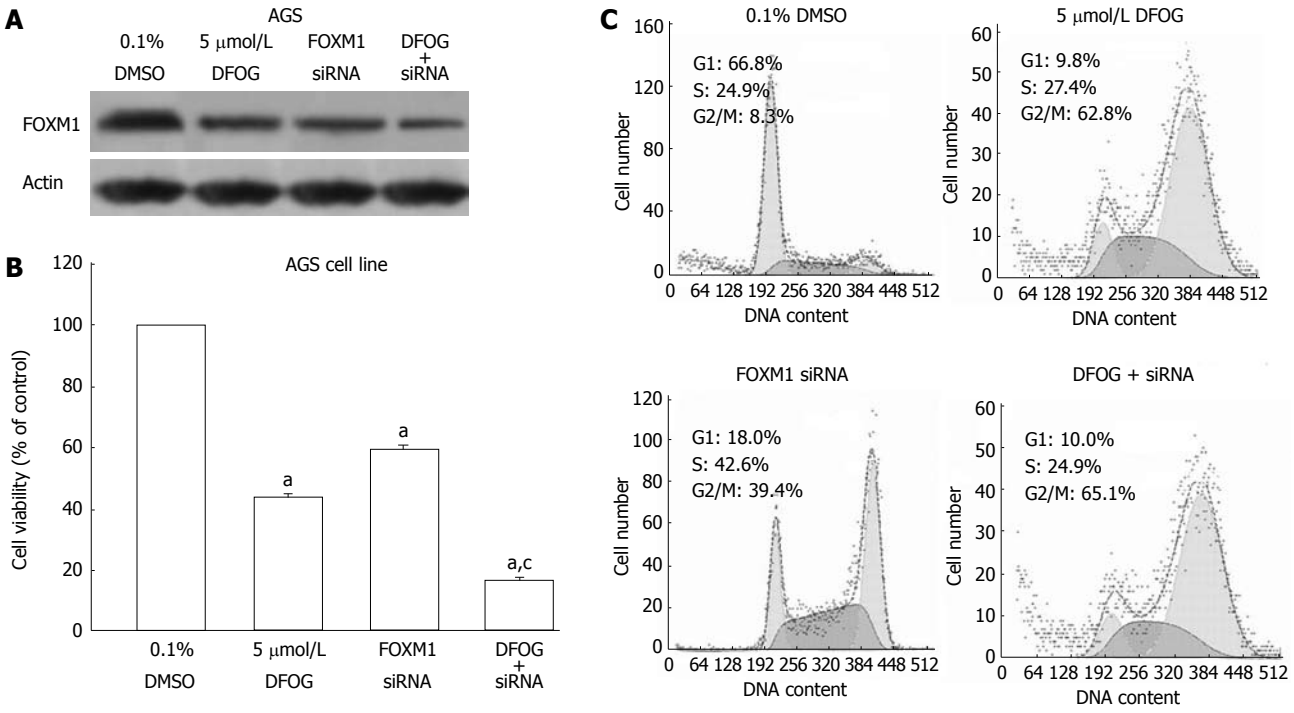

Figure 6 Forkhead box M1 small interfering RNA enhances the down-regulation of forkhead box M1 protein expression by 7-difluoromethoxyl-5,4'-di-n-octylgenistein and effects of forkhead box M1 small interfering RNA transfection or 7-difluoromethoxyl-5,4'-di-n-octylgenistein in AGS cell line. A: Western blotting analysis; B: The cell viability inhibitory effects of 7-difluoro methoxyl-5,4'-di-n-octylgenistein (DFOG) by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenylte trazolium bromide assay; C: Both on cell cycle distribution in AGS cells. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with 5 μmol/L DFOG or forkhead box M1 (FOXM1) small interfering RNA (siRNA) alone.

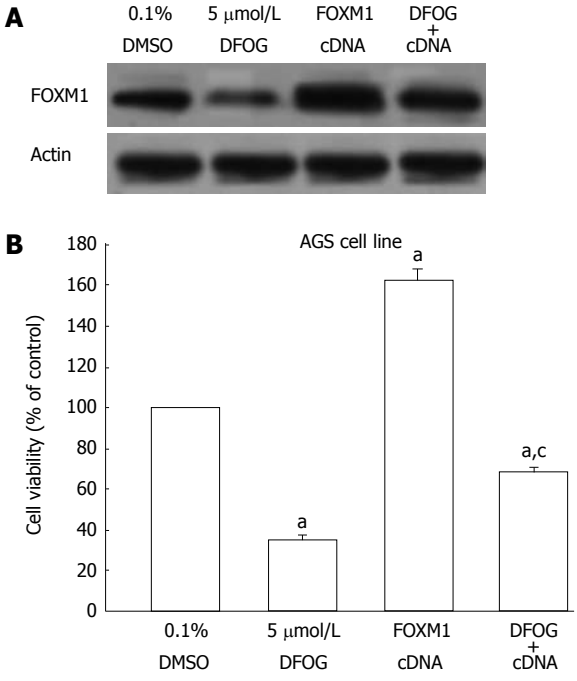

Figure 7 Forkhead box M1 cDNA transfection reduces the down-regulation of forkhead box M1 protein expression by 7-difluoromethoxyl-5,4'-di-n-octylgenistein in AGS cell line. A: Western blotting analysis; B: The cell viability inhibitory effects of 7-difluoro methoxyl-5,4'-di-n-octylgenistein (DFOG) by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenylte trazolium bromide assay. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with 5 μmol/L DFOG or forkhead box M1 (FOXM1) cDNA transfection alone.

Genistein has been found to induce G2 arrest and inhibit proliferation in a variety of cancer cell lines[28]. Because down-regulation of FOXM1 by DFOG reduced cell growth, we postulated that cell growth inhibition might result from cell cycle arrest in any specific phase of the cell cycle. We did find that FOXM1 down-regulation increased cell population in the G2/M phase and decreased cells in the G1/G0 and S phase. We also observed a marked reduction in cyclin B, Cdc25B and CDK1 expression in DFOG-treated cells. It is known that Cdc25B, cyclin B and CDK1 are the major effectors of the G2/M checkpoint response[29]. Diminished G1-S progression and growth rate was associated with increased expression of the *Cdk*I protein $p21^{CIP}$ and $p27^{KIP1}$, which have negative effects on cell cycle machinery by binding to various cyclin-Cdk complexes and inhibiting their activities[24,30]. In our study, the decreased cyclin B, cdc25B and Cdk1 and the increased expression of CdkI proteins, $p27^{KIP1}$, were strongly correlated with the altered cell cycle distribution phenotype and growth suppression. These results suggest that FOXM1 affects the gastric cancer cell cycle by regulating the expression levels of some cyclins (cyclin B), CDK (CDK1), CDK modulator (cdc25B) and CDK inhibitors ($p27^{KIP1}$).

In summary, we presented experimental evidence which strongly supports the role of DFOG, a novel synthetic genistein analogue, as an anti-tumor agent mediated through inactivation of FOXM1 signaling pathway.

However, further in-depth studies are needed to identify how DFOG could regulate the FOXM1 pathway, and to assess the anti-tumor activity mediated by the inactivation of FOXM1 either by genistein and DFOG or other synthetic compounds in pre-clinical animal models for the successful treatment of gastric cancer in the future. It is also tempting to speculate that the inactivation of FOXM1 together with the treatment of gastric tumor cells with conventional agents could be a useful strategy toward better treatment of human malignancies, especially gastric cancer.

COMMENTS

Background

Gastric cancer is one of the most common malignancies in the world and its incidence and mortality rank first in China. Recent data indicate that the mortality of gastric cancer in China tends to increase and it severely threatens the health and life of people. New therapeutic agents for this malignant disease are urgently needed.

Research frontiers

Genistein, 5,7,4'-trihydroxylisoflavone, a major component of soybean products, has been reported to possess anticancer activities. The authors synthesized a series of difluoromethoxylated genistein analogues and determined their protective effects against vascular endothelial cells. There have been few studies focusing on the anticancer effect of fluorinated genistein analogues.

Innovations and breakthroughs

The authors investigated whether the inhibitory effects of genistein and the novel synthetic genistein analogue 7-difluoromethoxyl-5, 4'-di-n-octylgenistein (DFOG) on the growth of gastric cancer cells could be attributed to modulation of Forkhead Box M1 (FOXM1) activity. It was found that DFOG and genistein down-regulated the FOXM1 expression and its downstream genes, including Cdc25B, CDK1, cyclin B and up-regulated $p27^{KIP1}$, resulting in the inhibition of gastric cancer cell growth.

Applications

These results provide strong evidences for the first time to support that FOXM1 is a rational target in gastric cancer, and the targeted inactivation of FOXM1, especially by genistein and its analogue DFOG, and provided new insight into strategies for better prevention of tumor progression and/or treatment of gastric cancer.

Terminology

Genistein, 5,7,4'-trihydroxylisoflavone, as one of the active constituents of soybean products, has been reported to possess anti-cancer activities. The DFOG is a novel synthetic genistein analogue.

Peer review

The novel anti-cancer drugs are mandatory to overcome cancer cells resistant to conventional anti-cancer drugs. In this paper the authors identified DFOG to be a good anti-cancer drug in gastric cancer cells. In addition, they also obtained the results to show FOXM1 as one of target molecules of DFOG. All data presented in this paper is acceptable.

Abstract

Gastrointestinal complications caused by herpes zoster are extremely rare. Here, we described a case of abdominal distention caused by herpes zoster. The patient was a 59-year-old female who suffered from unexplained paroxysmal and a burning pain on the right part of her waist and abdomen, accompanied by abdominal distention. Intestinal pseudo-obstruction was diagnosed by abdominal radiography. Distention of the right abdominal wall was still apparent after one month. In this report, we found that recovery from abdominal distention caused by herpes zoster is difficult and may require surgical intervention.

Zhou SR, Liu CY. A case report of abdominal distention caused by herpes zoster. *World J Gastroenterol* 2012; 18(33): 4627-4628 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i33/4627.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i33.4627

INTRODUCTION

Herpes zoster is a viral disease that typically manifests as a dermatological condition, marked by an irritating skin rash with blisters that is often limited to one side of the body; although rare, it has also been implicated in unusual gastrointestinal complications[1]. We treated a patient with abdominal distention caused by herpes zoster and report it below.

CASE REPORT

A 59-year-old female patient suffered from unexplained paroxysmal and a burning pain on the right part of her waist and abdomen for 2 wk. An erythra appeared on the affected area one week ago and the pain was exacerbated, interrupting the patient's sleep. A diagnosis of herpes zoster was made and the patient was administrated with valaciclovir (0.3 g *bid*), vitamin B_{12} (0.5 mg im *qd*), and ibuprofen and codeine phosphate sustained tablets (50 mg *bid*) for 3 wk. The patient had abdominal distention accompanied by dyspepsia, abdominal bloating and constipation, which showed no apparent changes after motilium treatment. Upon physical examination, laminal erythema was found on her left waist and abdomen accompanied by papulovesicles and small vesicles. The erythra showed zonal distribution not exceeding the midline. The abdomen was asymmetric with left distention, a lax abdominal wall and hyperalgesia. Two air-fluid levels appeared on the abdominal radiograph, which was diagnosed as intestinal pseudo-obstruction by surgical consultation. After treatment with fasting, fluid infusion,

enema and moxifloxacin (1 tablet *qd* × 3), the symptoms were relieved after 5 d. The diagnosis was modified as intestinal pseudo-obstruction caused by herpes zoster. Continued treatment included mecobalamin (1 tablet *tid*) to nourish the nerve and for heat-clearing and a detoxifying soft capsule (2 pills *tid*) to clear away heat and toxic materials and relax the bowels. After 15 d, the red spots disappeared, and the vesicles dried up, changed to scabs and dropped off, leaving anomalous pigmentation of the skin. At the same time, the pain was apparently alleviated, but the distention of the right abdominal wall and constipation persisted. On follow-up one month later, the distention of the right abdominal wall was still apparent, but the partial sense of pain decreased and the constipation was relieved.

DISCUSSION

Herpes zoster is a herpetic skin disease caused by varicella-zoster virus (VZV) infection, which can infect the surrounding sensory and motor nerves and their dominated skin areas. When the abdomen is involved, the infection can cause paralysis of the abdominal wall muscle[2], which may involve the autonomic nerve, the myenteron and small intestine smooth muscles, leading to the manifestation of intestinal pseudo-obstruction (Ogilvie's syndrome)[1]. The present patient was an overweight, middle-aged female. Due to two pregnancies, her abdomen became flabby. VZV infection in this area may cause nerve paralysis, a decrease in abdominal muscle tonus and abdominal distention. Simultaneously, indigestion, constipation and intestinal pseudo-obstruction appear due to the involvement of the autonomic nerves. Further consultation after one month showed no improvement of the abdominal wall distention. As recovery from this type of nerve paralysis is difficult, surgical intervention is sometimes necessary.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/esps/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

The pathogenesis of inflammatory bowel disease (IBD) is complex and largely unknown. Until recently, research has focused on the study of protein regulators in inflammation to reveal the cellular and molecular networks in the pathogenesis of IBD. However, in the last few years, new and promising insights have been generated from studies describing an association between an altered expression of a specific class of non-coding RNAs, called microRNAs (miRs or miRNAs) and IBD. The short (approximately 22 nucleotides), endogenous, single-stranded RNAs are evolutionary conserved in animals and plants, and regulate specific target mRNAs at the post-transcriptional level. MiRNAs are involved in several biological processes, including development, cell differentiation, proliferation and apoptosis. Furthermore, it is estimated that miRNAs may be responsible for regulating the expression of nearly one-third of the genes in the human genome. Thus, miRNA deregulation often results in an impaired cellular function, and a disturbance of downstream gene regulation and signaling cascades, suggesting their implication in disease etiology. Despite the identification of more than 1900 mature human miRNAs, very little is known about their biological functions and functional targets. Recent studies have identified dysregulated miRNAs in tissue samples of IBD patients and have demonstrated similar differences in circulating miRNAs in the serum of IBD patients. Thus, there is great promise that miRNAs will aid in the early diagnosis of IBD, and in the development of personalized therapies. Here, we provide a short review of the current state-of-the-art of miRNAs in IBD pathogenesis, diagnostics and therapeutics.

MicroRNAs in inflammatory bowel disease - pathogenesis, diagnostics and therapeutics. *World J Gastroenterol* 2012; 18(34): 4629-4634 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i34/4629.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i34.4629

INTRODUCTION

Inflammatory bowel disease (IBD), whose incidence is

increasing[1], comprises a number of intestinal chronic relapsing inflammatory disorders[2-4], among which ulcerative colitis (UC)[5] and Crohn's disease (CD)[6] are the two main entities. The pathogenesis of IBD remains largely unknown[7,8], but involves a complex interaction between genetic, environmental, and immunological factors[9,10]. In this context, research on microRNAs (miRs or miRNAs) is a promising new research, providing novel insights into the pathogenesis of IBD, biomarker identification, and treatment. Since their discovery and initial characterization in 1993[11,12], the number of miRNA sequences deposited in the miRBase database (Sanger Database) has grown continuously[13]. Numerous investigations have uncovered the key roles of miRNAs in several physiological networks[14-18]. Given their ability to target mRNAs and their predicted regulation of the expression of nearly one-third of all human transcripts, miRNAs have been linked to critical processes underlying development and tissue homoeostasis. Thus, dysregulation of miRNAs is implicated in the pathogenesis of several human diseases[18-26], including gastrointestinal disorders, such as cancer and inflammation[27-29]. Actually, loss of intestinal miRNAs in mouse models has been shown to impair differentiation of intestinal cells and epithelial barrier function, resulting in inflammation[30].

The discovery and role of miRNAs in IBD, particularly their role in cell signaling, seems to offer a new way of understanding this chronic disease and gives rise to new diagnostic tools and potential therapeutic strategies. Thus, it is possible that some miRNAs could serve as biomarkers for IBD, aiding early diagnosis, and lead to the development of personalized therapies.

Here we provide a short review of the current research in miRNAs in IBD; including pathogenesis, diagnostics and therapeutics.

MiRNA BIOGENESIS

MiRNAs are a recently discovered class of short (18-24 nucleotides in length), endogenous, non-coding single-stranded RNAs that regulate gene expression by controlling the stability and translation of protein-coding mRNAs[26,31,32]. A number of biological processes are regulated by miRNAs, including cell differentiation, proliferation, apoptosis, and cell cycle control[30,33,34]. Long primary miRNA transcripts (pri-miRNA) are initially transcribed by RNA polymerase Ⅱ or Ⅲ in the nucleus, and are then cleaved to precursor hairpin (pre-miRNA) by the microprocessor complex, Drosha and DiGeorge syndrome critical region gene 8[35-37]. Next, the pre-miRNAs are exported into the cytoplasm and further cleaved to mature miRNAs by the RNase Ⅲ endonuclease, Dicer, in a complex with a trans-activator RNA binding protein[38-40]. One RNA strand from the mature miRNA is incorporated into the RNA-induced silencing complex, and guides this complex to the 3' untranslated regions of "target" mRNA sequences, which in mammalian cells induces target mRNA degradation and suppresses protein expression[31,32,41-44].

ABBERANT EXPRESSION OF MiRNAS IN INFLAMMATORY BOWEL DISEASE

In 2008, Wu *et al*[45] were the first to report miRNA expression in colonic mucosa samples from IBD patients. They identified 11 miRNAs that were differentially expressed in active UC *vs* controls (Table 1)[45] and demonstrated an inverse relationship between macrophage inflammatory peptide-2α (previously shown to be implicated in IBD[46]) and miR-192. Similarly, Bian *et al*[47] found miR-150 to be significantly upregulated in inflamed colonic mucosa of UC patients, as compared to controls (Table 1), and they established an inverse correlation between miR-150 and its target, *c-Myb*[48], a proto-oncogene that is involved in apoptosis. Consequently, these two studies have exposed new and important insights into the pathogenesis of IBD.

In 2010, three studies[49-51] identified altered miRNA expression in IBD tissue but without concomitant functional analyses. In a cohort of 12 controls and 12 active UC patients, Takagi *et al*[49] reported miR-21 and miR-155 to be significantly upregulated in inflamed colonic UC tissue (Table 1). In a second study, Wu *et al*[50] assayed the expression of 467 miRNAs in patients with sigmoid CD and in patients with active terminal ileal CD. They found five miRNAs to be associated with active sigmoid CD, and four miRNAs were significantly increased in active ileal CD, as compared to control tissues (Table 1)[50]. These reports were followed by a similar study by Fasseu *et al*[51] evaluating the expression of more than 300 miRNAs in colonic tissue samples of UC and CD patients using quantitative real-time polymerase chain reaction analysis. Several miRNAs were differentially expressed in accordance with disease type, but with a large number in common to both groups (Table 1). They identified a set of eight miRNAs (miR-26a, miR-29a, miR-29b, miR-30c, miR-126*, miR-127-3p, miR-196a, and miR-324-3p) defining quiescent IBD *vs* controls, and a distinct subset of 15 miRNAs that could differentiate between quiescent UC and CD (n = 16) (Table 1)[51]. These three studies illustrate the potential use of miRNAs as biomarkers and the possibilities of developing miRNA profile-based diagnostic tools.

Other recent studies have focused on certain specific miRNAs and their association with target genes. Hence, Pekow *et al*[52] reported an inverse correlation of the tumor suppressors miR-143 and miR-145 with their target genes, *IRS-1* (miR-145), and *K-RAS*, *API-5* and *MEK-2* (miR-143). Similarly, Nguyen *et al*[53] demonstrated decreased levels of miR-7 in inflamed CD colonic tissue, where expression of its target, CD98, was upregulated compared with control tissue. Dysregulation of CD98 interferes with the natural proliferation and differentiation of enterocytes. These two studies[52,53] not only provided new information on the pathophysiology of the well known, but poorly understood, inflammation-driven neoplastic progress in the colonic mucosa of UC, but also provided targets for future therapeutic interventions.

Some studies have focused on single miRNAs and their relation to single-nucleotide polymorphisms (SNPs). Brest *et al*[54] found increased expression of miR-196 re-

stricted to intestinal epithelial cells within inflamed CD as compared to controls. They showed that miR-196 binds to, and correlates with, a decreased expression of the immunity-related GTPase M (*IRGM*) protective variant (c.313C) during inflammatory conditions, but not with the *IRGM* c.313C>T polymorphism, $IRGM^T$, which is strongly associated with CD in European populations[55]. In a similar study, Zwiers *et al*[56] found that the mutation (rs10889677 C>A) in the *IL-23R* gene, associated with IBD, results in loss of its binding sites for let-7e and let-7f miRNAs, leading to sustained *IL-23R* expression *in vitro*, which contribute to the chronicity of IBD. Thus, these studies indicate that single SNPs located at miRNA-binding sites are likely to affect the expression of their targets and that they might contribute to the pathogenesis of IBD.

In a semi-invasive approach and with diagnostic intentions, few studies have used whole blood instead of colonic tissue. As a proof of concept, Wu *et al*[57] performed a microarray-based study on whole blood from IBD patients and found a panel of differentially expressed miRNAs (Table 2) that enabled them to distinguish active IBD subtypes from each other and from controls. In a similar study by Zahm *et al*[58], higher concentrations of 11 miRNAs (Table 2) were found in the sera of pediatric CD patients *vs* controls. Receiver operating characteristic analyses resulted in a diagnostic sensitivity above 80% for CD[58]. Recently, Paraskevi *et al*[59] identified that 11 circulating miRNAs that were differentially expressed in blood samples from active CD *vs* controls, and identified a set of six miRNAs that were significantly elevated in active UC *vs* healthy controls (Table 2). Similarly, Duttagupta *et al*[60] found seven circulating miRNAs that were differentially expressed in UC patients *vs* controls (Table 2).

Although these studies are preliminary, they demonstrate the possibilities of developing a much-needed semi-invasive test based on differentially expressed peripheral blood miRNAs.

FUTURE USE IN DISEASE DIAGNOSTICS AND THERAPEUTICS

The studies described above have significantly increased our knowledge regarding the pathogenesis of IBD and have demonstrated the usefulness of miRNAs, not only as potential biomarkers, but also as latent targets for therapeutic interventions. However, a range of obvious challenges lie ahead, especially as identification of new miRNAs is an ongoing process. In 2008, Wu *et al*[45] used a miRNA microarray containing 553 known human miRNA genes, but currently more than 1900 human miRNA sequences are known[13], and new ones are identified on an almost daily basis. Consequently, this area of research is in its infancy, and future studies in the field of IBD need to focus on miRNA sequencing and using

larger cohorts to address two important challenges: (1) identification of all of the miRNAs that are consistently dysregulated in IBD; and (2) to identify all of the targets of the miRNAs involved in IBD. If these challenges are met, the subsequent possibilities regarding diagnostics and therapeutics seem endless.

The potential clinical use of miRNAs is best illustrated by the most investigated and well-described miRNA, miR-21, also classified as an "oncomiR"[61,62]. The almost omnipresent overexpression of miR-21 in human cancers[62-64], including colorectal cancer, provides new options for cancer therapy[65]. Interestingly, as listed in Tables 1 and 2, miR-21 is the only miRNA commonly found to be upregulated in inflamed tissue or sera of IBD patients[45,49-51,58]. Thus, miR-21 is a potential biomarker for active IBD. It may also be of significant importance for the pathogenesis of IBD, as expression of miR-21 is mediated by nuclear factor-κB[66] - a key transcription factor involved in the pathogenesis of various human diseases, including IBD[67,68]. Unfortunately, the importance of these miRNA pathways in disease pathogenesis is unknown. Thus, functional studies are needed to address the role of miRNAs in IBD and particularly their role in cell signaling.

CONCLUSION

Currently, several clinical trials are testing the therapeutic efficacy of miRNA-based therapies; one such miRNA-target drug is "miravirsen"[69], a specific inhibitor of miR-122 that is currently in phase II clinical trials for Hepatitis C infections[70]. Within the next several years, further studies will undoubtedly provide a basis for more successful clinical trials and provide more insights in to the efficacy of miRNA-based therapeutics, including IBD.

Abstract

Acute pancreatitis is the most common serious complication of endoscopic retrograde cholangio-pancreatography (ERCP) and its incidence may exceed 25% in some high-risk patient subsets. In some patients, pancreatitis may follow a severe course with pancreatic necrosis, multiorgan failure, permanent disability and even death. Hence, approaches which minimize both the incidence and severity of post-ERCP pancreatitis are worth pursuing. Pancreatic stents have been used with some success in the prevention of post-ERCP, while so far pharmacological trials have yielded disappointing results. A recent multicenter, randomized, placebo-controlled, double-blind trial has shown that rectally administered indomethacin is effective in reducing the incidence of post-ERCP pancreatitis, the occurrence of episodes of moderate-to-severe pancreatitis and the length of hospital stay in high-risk patients. These results together with the demonstration that rectal administration of indomethacin is not associated with enhanced risk of bleeding strongly support the use of this drug in the prophylaxis of post-ERCP pancreatitis.

INTRODUCTION

Physicians sometimes make a strenuous effort to cope with illnesses which develop de novo following diagnostic and/or therapeutic interventions. One example of such a struggle is the management of complications occurring in patients undergoing endoscopic retrograde cholangiopancreatography (ERCP), a procedure used to both diagnose and treat diseases of the pancreaticobiliary tree[1-4]. Indeed despite recent advances in technology and experience of gastroenterologists, the use of ERCP can be accompanied by perforation, bleeding and pancreatitis[5,6]. Pancreatitis is the most common complication of

ERCP[5,7-10]; its frequency varies between 1% and 10% in average risk patients[6,7,11-13] but can exceed 20% in high-risk patient subset[14-16].

DIAGNOSIS, SEVERITY AND RISK FACTORS OF POST-ERCP PANCREATITIS

The diagnosis of post-ERCP pancreatitis is based on the presence of pancreatic-type abdominal pain, increase in serum amylase at least 3 times above the upper limit of normal 24 h after the procedure and need of hospitalization or prolongation of a planned hospital admission[7]. Although various criteria have been used to define the severity of pancreatitis[17-21], the length of hospitalization is now considered a major factor in the evaluation of disease severity. Mild pancreatitis is defined as need for an unplanned hospital stay or an extension of a planned hospital stay by 2-3 d; moderate pancreatitis requires 4-10 d of hospitalization and severe pancreatitis results in a hospitalization of > 10 d. Additionally, pancreatitis can be defined severe if it leads to the development of pancreatic necrosis or pseudocyst, or requires percutaneous or surgical intervention[7]. While most patients develop a mild pancreatitis with rapid and full recovery, a small percentage may follow a severe course with pancreatic necrosis, multiorgan failure, permanent disability, and even death[7,11,12,22]. Hence, approaches which minimize both the incidence and severity of post-ERCP pancreatitis are worth pursuing. Some patient-related (i.e., known or suspected dysfunction of sphincter of Oddi, female gender and previous pancreatitis) and procedure-related (i.e., precut sphincterotomy, pancreatic injection, ampullectomy) characteristics are definite independent risk factors for post-ERCP pancreatitis and may be useful for the stratification of patients into low-risk or high-risk categories[23]. Further factors which may influence the outcome of ERCP and the risk of post-ERCP pancreatitis include availability of equipment and adequacy of endoscopic, radiologic and nursing support[23].

PATHOGENESIS AND PREVENTION OF POST-ERCP PANCREATITIS

Various types of injury (i.e., mechanical injury to the papilla from cannulation, chemical injury due to ionic contrast agents, hydrostatic injury as a result of excessive contrast injection and thermal injury from electrocautery), developing during the procedure, can impair the drainage from the pancreas and favor activation of factors that cause tissue damage[24,25]. Although the exact mechanism driving post-ERCP pancreatitis is not fully understood, circumstantial evidence suggests that, once activated, the pathways of inflammation promote intraluminal activation of proteolytic enzymes, autodigestion of the organ, impaired acinar secretion, and then massive synthesis of chemokines and proinflammatory cytokines, which amplify the ongoing inflammatory process[25-29]. Strategies that interrupt one or more of these critical steps could help prevent post-ERCP pancreatitis. There is a wide consensus among gastroenterologists that the ideal pharmacological agent for preventing post-ERCP pancreatitis should have a short administration time, be well tolerated with a low side-effect profile and cost-effective.

The anti-inflammatory activity of indomethacin was first described in 1963, and the drug has been used to treat several rheumatological conditions including osteo- and rheumatoid arthritis[30,31]. Indomethacin shares important pharmacological properties with other non-steroidal anti-inflammatory drugs (NSAIDs), particularly aspirin, and inhibits cyclooxygenase, phospholipase A2 and neutrophil-endothelial interactions, which are supposed to play a major role in the pathogenesis of pancreatitis[32-35]. Previous reports have shown that NSAIDs, including indomethacin, reduce experimental pancreatitis-driven lethality in rodents[36] and rectal indomethacin decreases the number of d with pain and number of opiate injections in patients with acute pancreatitis[37]. Moreover, three recent meta-analyses[38-40] of four prospective randomized placebo-controlled trials showed that rectal administration of 100 mg diclofenac immediately after the procedure or 100 mg indomethacin immediately before the procedure was effective in reducing pancreatitis, with a pooled relative risk after administration of 0.36 (95% CI: 0.22-0.60)[15,41-43]. Further analysis showed that prevention of post-ECRP pancreatitis by NSAIDs occurred in patients with either low-risk or high-risk. In particular, Murray *et al*[42] showed that 100 mg of rectal diclofenac administered to high-risk patients (i.e., patients undergoing pancreatography or with manometrically documented sphincter of Oddi dysfunction) upon arrival in the recovery area significantly reduced the incidence of post-ERCP pancreatitis [7/110 (6.4%) *vs* 17/110 (15.5%) in the placebo group]. Similarly, Khoshbaten *et al*[43] showed that 100 mg of rectal diclofenac administered to high-risk patients upon arrival in the recovery area was superior to placebo in reducing the incidence of post-ERCP pancreatitis [2/50 (4%) *vs* 13/50 (26%) in the placebo group]. Along the same line is the paper published by Elmunzer *et al*[44] in a recent issue of *The New England Journal of Medicine* and showing that rectally administered indomethacin significantly reduces the incidence of post-ERCP pancreatitis in high-risk patients. The authors performed a multicenter, randomized, placebo-controlled, double-blind trial in which 602 patients were assigned to receive a single dose of rectal indomethacin (100 mg) or placebo immediately after ERCP[44]. The selected patients showed an increased baseline risk of post-ERCP pancreatitis on the basis of patient- and procedure-related independent risk factors (i.e., sphincter of Oddi dysfunction, a history of post-ERCP pancreatitis, pancreatic sphincterotomy and ampullectomy). Overall 79/602 (13.1%) patients developed post-ERCP pancreatitis and this complication was more frequent in patients receiving placebo [52/307 (16.9%)] than in those treated with indomethacin [27/295 (9.2%)]. Moreover, indomethacin reduced the occurrence of episodes of moderate-to-severe pancreatitis [13 (4.4%)

vs 27 (8.8%) in the placebo group]. Consequently, the median length of hospital stay was 0.5 d shorter in the group of patients treated with indomethacin[44]. Interestingly, in accordance with previous studies evaluating NSAIDs in the prevention of post-ERCP pancreatitis[6,45], the benefit of rectal administration of indomethacin was not associated with enhanced risk of bleeding, as this event was documented in 4 patients receiving the active drug and 7 of those receiving placebo[44].

As mentioned above, a known or suspected dysfunction of sphincter of Oddi is an independent risk factor for post-ERCP pancreatitis[29,46,47]. The term sphincter of Oddi dysfunction is used to define motility abnormalities caused by stenosis or dyskinesia of the sphincter of Oddi. Both alterations can account for obstruction to flow through the sphincter of Oddi thereby promoting retention of bile in the biliary tree and pancreatic juice in the pancreatic duct and clinical manifestations[48,49]. Dysfunction of sphincter of Oddi can be classified as biliary types Ⅰ, Ⅱ and Ⅲ and pancreatic types Ⅰ, Ⅱ and Ⅲ[50]. The features of biliary-type I include biliary-type abdominal pain, liver enzyme elevation and common bile duct dilation > 9 mm. Patients with biliary-type Ⅱ dysfunction have pain and only one of the remaining criteria, while biliary-type Ⅲ patients have only recurrent biliary-type abdominal pain. Patients with pancreatic-type I dysfunction have pancreatic-type abdominal pain and a dilated pancreatic duct and elevated pancreatic enzymes, or recurrent acute pancreatitis. Pancreatic-type Ⅱ dysfunction is defined as pancreatic-type abdominal pain and a dilated pancreatic duct or elevated pancreatic enzymes, while type Ⅲ patients have recurrent pancreatic-type pain alone. Elmunzer *et al*[44] showed that indomethacin was effective in preventing post-ERCP pancreatitis regardless of whether patients had sphincter of Oddi dysfunction and that the treatment was protective in all the 3 subtypes of sphincter of Oddi dysfunction. However, 82% (495/602) of patients enrolled into the trial had clinical suspicion of sphincter of Oddi dysfunction and more than half of them had manometric alterations compatible with sphincter hypertension. Since this high rate of sphincter of Oddi dysfunction is not representative of most ERCP populations, further experimentation should be performed on large numbers of patients with no sphincter of Oddi dysfunction in order to ascertain whether indomethacin is really effective in this subset of patients. The protective effect of indomethacin did not appear to be influenced by the necessity of performing pancreatic stenting, as well as by additional patient-related (age < 45 years, female gender, history of post-ERCP pancreatitis, history of recurrent pancreatitis), procedure-related (i.e., difficult cannulation, precut sphincterotomy, pancreatic sphincterotomy, pancreatic acinarization, biliary sphincterotomy, ampullectomy) and operator-related (i.e., trainee involved in stanting) characteristics. Other issues which need to be clarified relate to the time of administration and dose of the drug. The Elmunzer's study shows that the number of patients who need to be treated with indomethacin to prevent one episode of pancreatitis is 13[44]. This could reflect the fact that the time of administration was not appropriate. The indomethacin suppositories were administered immediately after ERCP[44]. Plasmatic peak of NSAID concentrations occurs within 30 min from rectal administration, a time-frame which could be sufficient to trigger pancreatitis by ERCP. Previous studies have documented a positive result in post-ERCP pancreatitis reduction even when rectal indomethacin was administered immediately pre-procedure[15,41]. We can thus speculate that a double administration of the drug, both before and after ERCP, may be more effective than a single administration. Moreover, dose-response studies would also be necessary as so far all the studies have been performed using 100 mg of drug.

CONCLUSION

Data of the present study advance our understanding of how we can prevent post-ERCP pancreatitis, even though additional studies are needed to optimize the dose and time of administration of indomethacin and verify whether the prophylactic effect of the drug can be generalized to all patients with elevated baseline risk of pancreatitis or restricted to particular subgroups.

Abstract

Chronic complications of symptomatic gallstone disease, such as Mirizzi syndrome, are rare in Western developed countries with an incidence of less than 1% a year. The importance and implications of this condition are related to their associated and potentially serious surgical complications such as bile duct injury, and to its modern management when encountered during laparoscopic cholecystectomy. The pathophysiological process leading to the subtypes of Mirizzi syndrome has been explained by means of a pressure ulcer caused by an impacted gallstone at the gallbladder infundibulum, leading to an inflammatory response causing first external obstruction of the bile duct, and eventually eroding into the bile duct and evolving to a cholecystocholedochal or cholecystohepatic fistula. This article reviews the life of Pablo Luis Mirizzi, describes the earlier and later descriptions of Mirizzi syndrome, discusses the pathophysiological process leading to the development of these uncommon fistulas, reviews the current diagnostic modalities and surgical approaches and finally proposes a simplified classification for Mirizzi syndrome intended to standardize the reports on this condition and to eventually develop a consensual surgical approach to this unexpected and seriously dangerous condition.

INTRODUCTION

Chronic complications of symptomatic gallstone disease, such as Mirizzi syndrome, are rare in Western developed countries with an incidence of less than 1% a year[1]. These currently bizarre complications, are being encountered in 1% to 2% of patients with symptomatic cholelithiasis according to some recent series[1,2]. However, in underdeveloped countries; particularly in Latin-America, Mirizzi syndrome is a more common condition with a reported incidence ranging from 4.7% to 5.7%[3,4]. The importance and implications of this condition are related to their associated, and potentially serious, surgical complications such as bile duct injury, and to its modern management when encountered during laparoscopic cholecystectomy[5,6]. The pathophysiological process leading to the subtypes or stages of Mirizzi syndrome, has been explained as an inflammatory phenomenon secondary to a pressure ulcer caused by an impacted gallstone at the gallbladder infundibulum. The impacted gallstone together with the inflammatory response, causes first external obstruction of the bile duct, and eventually erodes into the bile duct evolving into a cholecystocholedochal or cholecystohepatic fistula with different degrees of communication between the gallbladder and bile duct[4,7,8].

Based on this knowledge, and after an extensive experience treating this uncommon condition, a new concept regarding Mirizzi syndrome and gallstone ileus have been developed relating both conditions and modifying the classic Csendes classification[4,7,8].

WHO WAS PABLO LUIS MIRIZZI?

Pablo Luis Mirizzi was a surgeon from Argentina, born in the city of Cordoba on January 25, 1893 and deceased in the same city on August 28, 1964 (Figure 1). Mirizzi, graduated from the Medical Sciences School at the National University of Cordoba in 1915; and in 1916 at 23 years of age defended his "Tesis Doctoral" entitled "Anemia Esplénica Cirrógena". Mirizzi was a brilliant young doctor studying under the most prominent Argentinean surgeons of their time. At the age of 25 years; in 1918, he was appointed Assistant Professor of Surgery at the same university where he had studied. During the next few years, Mirizzi traveled abroad and visited the most important and renowned surgical centers of his time in the United States of America and Europe. After he returned to Argentina, he developed his professional, scientific and academic career and in 1926 he became Full Professor of Surgery[9,10]. On June 18, 1931 Mirizzi performed the first operative cholangiography which is considered his main contribution to modern biliary surgery[9-11]. The first description made by Mirizzi compatible with the syndrome that bears his name, was published in 1940 in an article dealing with a "physiologic sphincter of the hepatic duct"[12]; The most known and cited description of his syndrome was published in 1948 postulating the functional spasm of the "common hepatic duct sphincter", which he believed existed within the common hepatic duct, as the cause of the obstructive jaundice in patients with chronic or acute gallstone disease[13]. The syndrome that Mirizzi described, consisted of an uncommon and benign cause of obstructive jaundice, caused by a gallstone impacted at the Hartmann's pouch, gallbladder infundibulum or the cystic duct and its associated inflammatory process, thereby causing obstruction of the common hepatic duct[9,10,12,13]. Mirizzi, believed that the obstruction of the common hepatic duct was rather functional, and that the mechanical obstruction of the gallbladder infundibulum and consequent inflammatory process predisposed to the contraction of a "muscular sphincter" located in the common hepatic duct[9,10,12-14]. However, current knowledge has dismissed the presence of any sphincter, or even smooth muscle, in the common hepatic duct[10,14,15]. Pablo Luis Mirizzi was recognized during his lifetime as a great surgeon, a great teacher, and a great humanitarian physician. In 1955 he was named Honorary Professor of the National University of Cordoba, and in 1956, the "Sociedad Argentina de Cirugía" honored him the title "Cirujano Maestro". Afterwards, numerous surgical academies and societies around the world awarded him honorary memberships as well as many other honors. In 1957, the Assembly of the International Society of Surgery named

Figure 1 Professor Pablo Luis Mirizzi (1893-1964).

Professor Mirizzi as President of the International Surgical Congress that was to be celebrated in Munich in 1959; this was the first time that a Latin-American surgeon had received such a high honor. Pablo Luis Mirizzi died in his city, Cordoba, on August 28, 1964. Besides his great contributions to surgery, he left his art collection to the "Museo Provincial de Bellas Artes Emilio Caraffa", donated his medical library to the Medical Sciences School of the National University of Cordoba, and established a biennial traveling surgical scholarship in biliary surgery to be awarded to distinguished young surgeons from Cordoba, Argentina[9,10].

EARLY AND LATEST DESCRIPTIONS OF THE "MIRIZZI SYNDROME"

The most common complications of chronic gallstone disease are acute cholecystitis, acute pancreatitis and acute cholangitis[1]. Other benign complications are unusual and include Mirizzi syndrome and gallstone ileus among others[1,8]. The bizarre complications of gallstone disease described in the surgical literature of the late XIX century and early XX century are seldom found today due to the widespread use and availability of ultrasonography, which have led to early diagnosis and early treatment for patients with gallstone disease, consequently avoiding the development of those late complications[4,8]. Professor Mirizzi, however, was not the first to describe the characteristics of benign obstruction of the bile duct with resultant jaundice. Partial duct obstruction secondary to an impacted gallstone and its associated inflammatory process was first described by Kehr[16] in 1905 and by Ruge[17] in 1908. Mirizzi[12] reported his syndrome for the first time in 1940, and in 1941 Levrat *et al*[18] reported other cases. Finally the famous article that established the eponym of Mirizzi[13] for this condition was published in 1948. At the same time, other authors began to report other forms of complications related to long-standing gallstone disease, and in 1942, Puestow[19] reported the first fistula between the gallbladder and the choledochus in a series of 16 patients with "spontaneous internal biliary fistulas", he described fistulas between the gallbladder and other abdominal and thoracic organs such as stomach, duodenum, colon and bronchus.

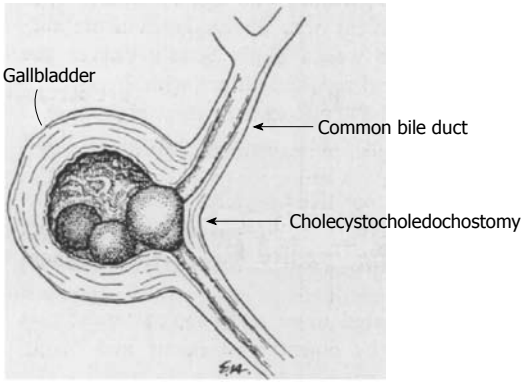

Figure 2 Albert Behrend described this case that corresponded to Mirizzi syndrome type Ⅳ according to the Csendes classification. The gallstone surrounded by an inflammatory process was clearly dilating the cystic duct fusing the gallbladder to the bile duct (original drawing from *Annals of Surgery* 1950; 132, page 300)[20].

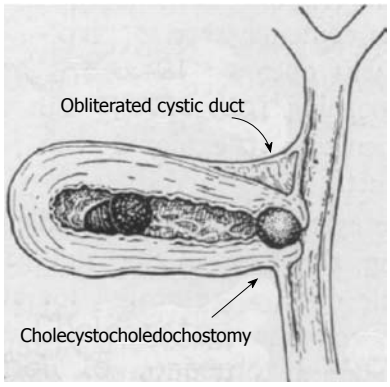

Figure 3 Another case described by Behrend. The cystic duct has become obliterated due to a chronic inflammatory process and the gallstones have eroded the gallbladder wall and formed a cholecystobiliary fistula corresponding to Mirizzi syndrome type Ⅱ according to the Csendes classification (original drawing from *Annals of Surgery* 1950; 132, page 300)[20].

Another important and overlooked article was published in 1950 by Behrend *et al*[20], in this publication they described 3 patients with cholecystobiliary fistulas; the first patient had a gallstone eroding through a much dilated cystic duct (Figure 2). The second patient had a fistula between the gallbladder wall and the choledochal wall with the cystic duct obliterated (Figure 3). The third patient had a double fistula between the gallbladder and the common hepatic duct, and between the gallbladder and the duodenum through the gallbladder wall (Figure 4), constituting the first description of what is currently known as Mirizzi Syndrome type V[4]. Soon, other authors described other cases of cholecystobiliary fistulas, Patt *et al*[21] in 1951 reported two cases, also Mirizzi[22] in 1952 reported on another four cases, and by 1975 Corlette *et al*[23] reported on another 24 cases. In 1982 McSherry *et al*[24] and in 1989 Csendes *et al*[7], published seminal articles describing the pathophysiological process involved in the development of Mirizzi syndrome, including the initial external compression of the bile duct by impacted gallstones until the erosion of

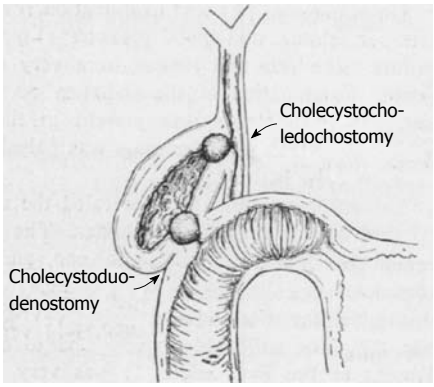

Figure 4 This illustration by Behrend clearly depicts Mirizzi syndrome type Ⅴ according to Csendes. The continuous inflammatory process affecting the gallbladder has obliterated the cystic duct, and the gallstones compressed inside the gallbladder, have produced pressure ulcers over the gallbladder walls eroding into the bile duct and the duodenum (original drawing from *Annals of Surgery* 1950; 132, page 300)[20].

the gallstones through the gallbladder wall into the bile duct. Both authors proposed similar classifications for this syndrome. Recently, the Mirizzi syndrome classification originally described by Csendes *et al*[7] was expanded to include bilioenteric fistulae; this addition was recently validated by Beltran *et al*[4].

PATHOPHYSIOLOGY

The current concept of Mirizzi syndrome, includes the external compression of the bile duct and the later development of cholecystobiliary and cholecystoenteric fistulas as different stages of the same disease process[4,7,8]. Mirizzi syndrome can be caused by an acute or chronic inflammatory condition secondary to a single large gallstone or multiple small gallstones impacted in the Hartmann's pouch or in the gallbladder infundibulum and cystic duct[1,4,7,8,14,25-37]. A long cystic duct; parallel to the bile duct, and a low insertion of the cystic duct into the bile duct, have been regarded as predisposing factors for the development of Mirizzi syndrome[1,25,31,32]. Recurrent impaction of gallstones will lead to repeated episodes of acute cholecystitis and will render the gallbladder initially distended with thick inflamed walls. Eventually the gallbladder will become contracted and atrophic, having thicker fibrotic walls if contracted. When the gallbladder becomes atrophic, it will degenerate into thick or thin atrophic walls; and in some cases the walls would be intimately adherent to the contained gallstones[1,2,25,27,37]. The close proximity of the acutely or chronically inflamed gallbladder to the bile duct could eventually lead to the fusion of their walls by edematous inflammatory tissue that in time will become fibrotic contributing to the external compression of the bile duct and leading to the characteristic obstructive jaundice seen with this condition[1,2,7,8,37], this late process could be acute or chronic[1,4,7,8,14,25-37].

The cholecystobiliary fistula has been explained by two mechanisms. The first mechanism, proposes that the

impacted gallstone and its secondary inflammatory process will lead to complete obliteration of the cystic duct, the impacted gallstone seeking to pass into the bile duct will develop a pressure ulcer that ultimately will erode the gallbladder wall and bile duct wall forming a communication between both lumens[1,8,23,27,37]. The second mechanism proposes that the impacted gallstone at the gallbladder infundibulum progressively dilates the cystic duct, leading to shortening, contraction and fibrosis of this duct and finally forming a large communication between the gallbladder and bile duct[2,23,27,37]; and even fusing the gallbladder to the adjacent bile duct[14,27,37]. If the inflammatory process continues or if a chronic inflammatory process becomes established, the gallstones will cause a pressure ulcer and necrosis, eroding into the bile duct and producing a cholecystobiliary fistula[1,2,4,8,23,27,37]. In some cases, the gallstones will also cause other pressure ulcers and concomitantly with the cholecystobiliary fistula a cholecystoenteric fistula will form[2,4,8,20].

Some characteristics of this distorted anatomy can be consistently found in Mirizzi syndrome. Consequently, based on over 70 years of publications on the subject, we may describe certain "anatomy" of Mirizzi syndrome. First, an atrophic gallbladder with either thick or thin walls[25,26,37], with impacted gallstones at the infundibulum or at the Hartmann's pouch, occasionally found firmly attached to the gallbladder wall[26,30,32,37]. Second, an obliterated cystic duct which is frequently found[2,25,30,37]. Third, a long cystic duct running parallel to the common bile duct with low insertion which has been described as a risk factor for Mirizzi syndrome[1,25,26,30,31,34]. Fourth, another anatomic variation thought to predispose to Mirizzi syndrome has been related to a normal short cystic duct[2,26,30]. Fifth, partial obstruction by external compression of the bile duct or by a gallstone eroding into the bile duct originating from the gallbladder. Sixth, a normal caliber distal bile duct with normal thickness walls[2,25,32]. Seventh, a dilated proximal bile duct with thick inflamed walls[2,25,32]. Eighth, an anomalous communication between the gallbladder and the bile duct[28]. Finally, an anomalous communication between the gallbladder and the stomach, duodenum, colon, or other abdominal viscera[4,8,28] (Table 1).

SYMPTOMATOLOGY AND OTHER CLINICAL MANIFESTATIONS

Patients with Mirizzi syndrome present with a mean age varying from 53 to 70 years, and are female with a frequency of around 70% of all cases[2,4,5,7,25,26,28,32,36]. However, it may occur at any age and in any patient with gallstones[4,27,32]. Long-standing gallstone disease, with a median of 29.6 years of disease, has been reported for patients with Mirizzi syndrome[4].

Mirizzi syndrome frequently presents in an acute form; however, the chronic form is equally or an even more common form of presentation[35]. Although the clinical presentation of Mirizzi syndrome is unspecific, the most common form of clinical presentation of Mirizzi syndrome is obstructive jaundice (60%-100%), accompanied by abdominal pain over the right upper abdominal quadrant (50%-100%), and fever in the context of a patient with known or suspected gallstone disease[1,14,26-33,35-37]. A previous recent history of jaundice can sometimes be elicited. Frequently, patients with Mirizzi syndrome present in the setting of acute cholecystitis, acute cholangitis or acute pancreatitis[1,2,27,28,33,35]. Recently, Mirizzi syndrome in the setting of gallstone ileus has been described and validated as another clinical presentation that surgeons must bear in mind[4,8].

The most common laboratory finding present in these patients is hyperbilirubinemia. Other laboratory abnormalities are elevated aminotransaminase levels and leukocytosis, frequently seen when acute cholecystitis, cholangitis or pancreatitis is present[1,25,26,28,29,33,35]. Recently, extremely high levels of the malignancy marker, CA19-9, have been consistently found in patients with Mirizzi syndrome type II or higher[38-40]. Consequently, the CA19-9 must be interpreted cautiously in patients with suspected biliary malignancy, because if Mirizzi syndrome is not ruled out, the patient would be incorrectly labeled as having biliary tract or gallbladder cancer and could miss the opportunity for curative surgery.

The differential diagnosis of Mirizzi syndrome includes any other benign or malignant cause of obstructive jaundice, such as gallbladder cancer, cholangiocarcinoma, pancreatic cancer, sclerosing cholangitis, metastatic disease, and others[1,27,31,37].

DIAGNOSIS

Preoperative diagnosis of Mirizzi syndrome followed by thoughtful surgical planning is of utmost importance[6]. The incidence of bile duct injuries in patients operated on with Mirizzi syndrome without preoperative diagnosis could be as high as 17%[14]. Preoperative diagnosis of Mirizzi syndrome is difficult and can be made in only 8% to 62.5% of patients[26,29,37,41]. If preoperative diagnosis is not made, intraoperative recognition and proper management is essential. Inadequate recognition of this condition leads to high preoperative morbidity and mortality[14]. The diagnosis of Mirizzi syndrome is based in the clinical characteristics previously described and a high index of suspicion or surgical intuition, which might be complemented by radiological images and endoscopic procedures.

Ultrasonography

A contracted gallbladder with thick or extremely thin walls with one large gallstone or multiple smaller gallstones impacted in the infundibulum may be appreciated[32]. The hepatic duct would be dilated in its extra and intrahepatic portions above the level of the obstruction site, and the common bile duct would be within normal size under the level of obstruction[1,14,28,32]. The reported diagnostic accuracy for ultrasonography in Mirizzi syn-

Table 1 Mirizzi syndrome "anatomy"

Gallbladder	Cystic duct	Bile duct	Fistulas
Thick or thin atrophic walls[25,26,37]	Obliterated cystic duct[2,25,37]	Partial obstruction by external compression or by a gallstone eroding into the bile duct	Cholecystocholedochal fistula[28]
Impacted gallstones at the infundibulum or at the Hartmann's pouch[26,30,32,37]	Occasional absence of cystic duct[2,25,30]	Normal caliber distal bile duct with walls of normal thickness[2,25,32]	Cholecystoenteric fistula[4,8,28]
	A long cystic duct running parallel to the common bile duct with low insertion[1,25,26,30,31,34]	A dilated proximal bile duct with thick inflamed walls[2,25,32]	
	A normal short cystic duct[2,26,30]		

drome is 29%[29], with a reported sensitivity varying from 8.3% to 27%[33,41].

Computed tomography

Abdominal computed tomography (CT) can identify the gallbladder and measure its wall thickness and the bile duct dilatation. However, the presence of periductal inflammation can be misinterpreted as gallbladder cancer[27]. The radiological signs elicited by CT are not specific. The main utility of CT would be the exclusion of malignancy in the porta hepatis area or in the liver[1,14,32].

Magnetic resonance

Cholangioresonance or magnetic resonance cholangiopancreatography (MRCP) is a useful tool to demonstrate extrinsic compression of the bile duct and to determine whether a fistula is present or not. Moreover, it is useful to rule out choledocholithiasis and other causes of bile tract obstruction. Some typical features of Mirizzi syndrome can be shown by MRCP such as the extrinsic narrowing of the common hepatic duct, a gallstone in the cystic duct, dilatation of the intrahepatic and common hepatic ducts, and a normal choledochus. Magnetic resonance imaging can also show the extent of the inflammatory process surrounding the gallbladder and has the advantage of avoiding the complications associated with endoscopic cholangiography[14]. However, the diagnostic accuracy for MRCP is 50%[29].

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is an invasive procedure not only useful to confirm the presence of Mirizzi syndrome with or without cholecystobiliary or cholecystoenteric fistulae, but also for therapeutic means allowing stone retrieval, stent placement and other procedures[1,14,28,41]. The diagnostic accuracy of Mirizzi syndrome with this method reaches around 55% to 90%[29,41], with a failure rate ranging from 5% to 10%[33,41]. The features of ERCP in Mirizzi syndrome include a narrowing or curvilinear extrinsic compression involving the lateral portion of the distal common hepatic duct with proximal ductal dilatation and normal distal caliber[14,27,32,41].

Intraoperative diagnosis

Over 50% of patients with Mirizzi syndrome are diagnosed during surgery[29]. Surgical characteristics include the presence of a shrunken gallbladder with distorted anatomy or a dilated gallbladder with thick walls and a large stone, or multiple gallstones, impacted at the gallbladder neck or infundibulum, an obliterated Calot's triangle, a dense fibrotic mass at the Calot's triangle, and dense adhesions at the subhepatic space. Intraoperative cholangiography could be useful and help to confirm the diagnosis, determine the location and size of the fistula, detect bile duct stones, and detect whether there is any loss of integrity of the bile duct wall[14]. However, intraoperative cholangiography may be difficult to perform and persistent dissection at the Calot's triangle area may result in a bile duct injury. Intraoperative ultrasonography has been reported to be a useful tool to identify the anatomy of the biliary tree and help with an accurate dissection of the bile duct in an inflamed area[14,28].

GALLSTONE ILEUS AND MIRIZZI SYNDROME

The first description of gallstone ileus was made by the notable anatomist Thomas Bartolin in 1654 as a disease of elderly and debilitated people. In 1890 Courvoisier[42] described 131 cases with a surgical mortality rate approaching 50%. Gallstone ileus is classically described as the impaction of one or more gallstones in the small bowel, frequently at the distal ileum[43]. However, an interesting form of gallstone ileus is the obstruction of the duodenum by an impacted gallstone causing gastric retention syndrome, first described in 1770 by Beaussier, and later by Bonnet in 1841 and by Bouveret[44] in 1896. Gallstone ileus accounts for 1% to 4% of all mechanical small bowel obstructions and for up to 25% of small bowel obstructions in patients older than 65 years, with a female preponderance[43]. The pathophysiology of gallstone ileus resembles that of Mirizzi syndrome. An episode of acute cholecystitis triggers a chronic inflammatory process causing a pressure ulcer by the offending gallstones and eventually eroding through the gallbladder wall into the bowel wall forming a cholecystoenteric fistula and allowing the passage of a single or multiple gallstones[1,2,4,7,8]. These similar pathological processes between cholecystoenteric fistula and Mirizzi syndrome with cholecystocholedochal fistula, were related in 2005 by Beltrán *et al*[8], constituting the basis for the addition by Csendes of a

fifth grade to his widely known classification[7], which was later validated in 2008 by Beltrán *et al*[4]. An interesting fact regarding this relationship between Mirizzi syndrome and cholecystoenteric fistula, is that many authors have previously described Mirizzi syndrome associated to fistulas communicating the gallbladder with the duodenum, colon, stomach or jejunum, failing to describe an association between these two conditions[28,45,46].

CLASSIFICATION

Before recognition of external compression of the bile duct and cholecystobiliary fistula as different evolving stages of the same disease process during the decade of 1980; in 1975, Corlette *et al*[23] classified the cholecystocholedochal fistulas in two types. Type Ⅰ was defined when the fistula involved the Hartmann´s pouch and the bile duct. Type Ⅱ was defined when the gallstone dilated and eroded the cystic duct into the bile duct. McSherry *et al*[24] in 1982, classified the Mirizzi syndrome into two types based on ERCP findings. Type Ⅰ involves the external compression of the bile duct by a large stone or stones impacted in the cystic duct or in the Hartmann' s pouch. Type Ⅱ consists of a proper cholecystobiliary fistula, caused by a gallstone or gallstones that have eroded into the bile duct. In 1989 Csendes *et al*[7], modified the classification of McSherry by dividing Mirizzi syndrome into four types. Csendes classification (Figure 5) further categorized the cholecystobiliary fistula according to the extent of bile duct destruction. Csendes type Ⅰ corresponds to McSherry type Ⅰ, the external compression of the bile duct by an impacted gallstone in the gallbladder infundibulum or cystic duct. Mirizzi syndrome type Ⅱ consists of a cholecystobiliary fistula resulting from erosion of the bile duct wall by a gallstone, the fistula must involve less than one-third of the circumference of the bile duct. Mirizzi syndrome type Ⅲ consists of a cholecystobiliary fistula involving up to two-thirds of the bile duct circumference. Mirizzi syndrome type Ⅳ is a cholecystobiliary fistula with complete destruction of the bile duct wall with the gallbladder completely fused to the bile duct forming a single structure with no recognizable dissection planes between both biliary tree structures. In 2007, Csendes added one more type to his classification that was later validated by Beltran and Csendes in 2008[4]; the Mirizzi type Ⅴ, which includes the presence of a cholecystoenteric fistula together with any other type of Mirizzi. Furthermore, Mirizzi type Va includes a cholecystoenteric fistula without gallstone ileus and Mirizzi type Vb refers to a cholecystoenteric fistula complicated by gallstone ileus[4]. A simple historical comparison between the most well-known Mirizzi syndrome classifications is depicted in Table 2. Other lesser known classification systems have been described over the last 25 years; such as acute *vs* chronic variant, anatomic variant of cystic duct *vs* no anatomic variant of cystic duct, and obstruction due to gallstones *vs* obstruction due to inflammation[14,30,35]. The incidence of the different types of Mirizzi syndrome according to Beltrán and Csendes[4] is detailed in Table 3. Mirizzi type Ⅰ is fairly common (10.5% to 51%) and Mirizzi Ⅳ is rather uncommon (1% to 4%). Mirizzi Ⅴ, however, could be present in up to 29% patients with any other type of Mirizzi. Recently, some authors have used the new addition to the former Csendes classification to describe their patients with complex cholecystobiliary fistulas and associated cholecystoenteric fistulas[47].

TREATMENT

Patients with Mirizzi syndrome constitute a formidable challenge and their surgical treatment a test to any surgeon's ability and dexterity[8]. The treatment of Mirizzi syndrome is surgical. Mirizzi syndrome is important to surgeons because preoperative diagnosis is not always possible and because the surgical treatment of this condition is associated with a significantly increased risk of bile duct injury[48-56]. Besides, the severe inflammatory process with thick dense hard adhesions and associated edematous tissues distort the anatomy[37,48,51,53,55]. Additionally, the presence of a cholecystobiliary fistula further increases the risk of biliary duct injury[48,52,53]. During the operation, dissection of the Calot's triangle may lead to bile duct injury or excessive bleeding and other morbidity

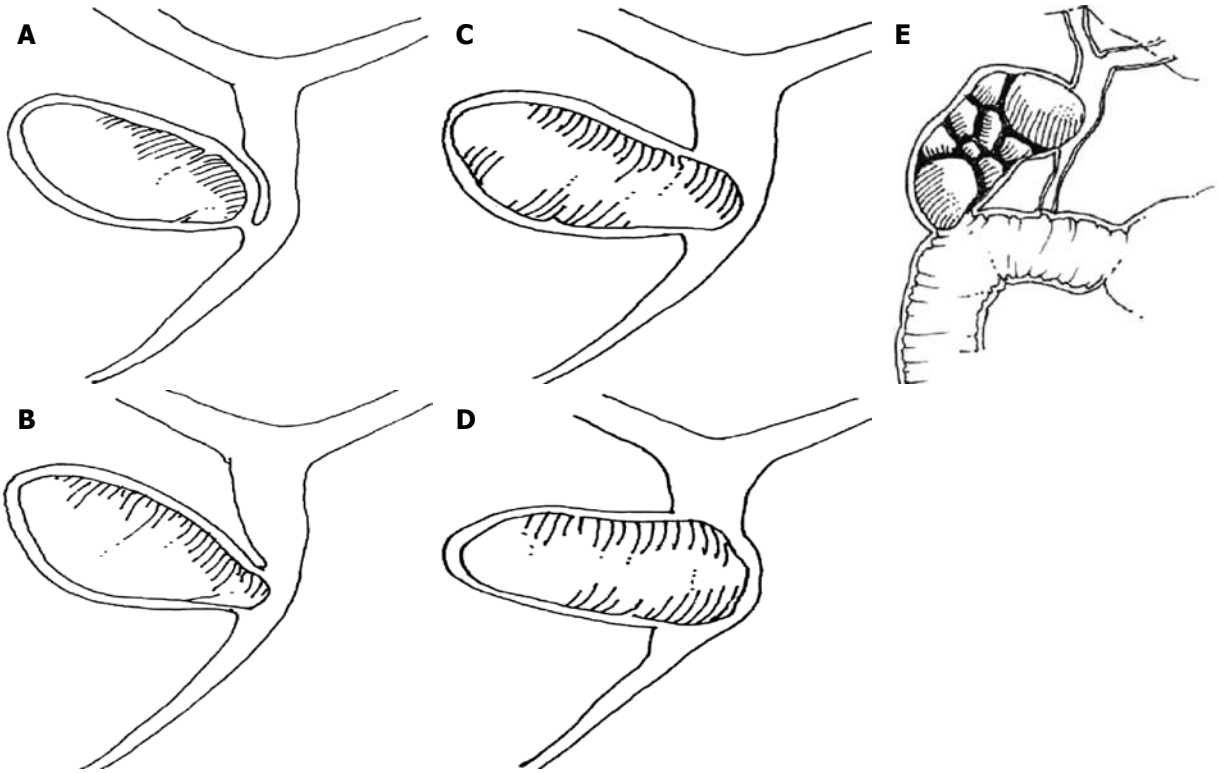

Figure 5 Mirizzi syndrome type Ⅰ to type Ⅴ. A: Mirizzi type Ⅰ is the extrinsic compression of the common bile duct by an impacted gallstone; B: Mirizzi type Ⅱ consists of a cholecystobiliary fistula involving one third of the circumference of the bile duct; C: In Mirizzi type Ⅲ, the cholecystobiliary fistula compromises up to two-thirds of the circumference of the bile duct; D: In Mirizzi type Ⅳ, the cholecystobiliary fistula has destroyed the bile duct wall, and comprises the whole circumference of the bile duct; E: Mirizzi type V corresponds to any type of Mirizzi associated with a bilioenteric fistula with or without gallstone ileus (original drawings from *World Journal of Surgery* 2008; 32, pages 2239 to 2241)[4].

such as sepsis, delayed bile duct stricture, and secondary biliary cirrhosis[14,26,28,48,53]. The surgical treatment of Mirizzi syndrome avoids a truly standardized approach and must be individualized depending on the stage of the disease and the expertise of the surgical team[55]. However, some guidelines could be drawn and have been used during the last few years.

Open surgery

Subtotal cholecystectomy may be the best treatment for Mirizzi type I and most cases of Mirizzi type Ⅱ and Ⅲ[48-57]. Subtotal cholecystectomy was described in 1985 by Bornman *et al*[58] for difficult open cholecystectomy in patients with severe cholecystitis associated with liver cirrhosis and portal hypertension. Since then, this technique has been also applied to cases of Mirizzi syndrome. Recently, subtotal cholecystectomy has been described in laparoscopic cholecystectomy, following the same technical details described for the open technique[59]. After identification of the anatomical repairs and having determined the presence of Mirizzi syndrome, the gallbladder is approached by an incision running from the fundus to the Hartmann's pouch, or if possible in selected cases, directly over the Hartmann's pouch to remove the impacted gallstone[14,26,27,32,33,37,48,49,51,54-59]. The reflux of bile indicates the presence of a fistula between the gallbladder and the bile duct, because the cystic duct is usually occluded[48-55]. If no fistula is macroscopically evident or diagnosed by intraoperative cholangiography, a partial cholecystectomy leaving the gallbladder neck or infundibulum is performed and the gallbladder stump is closed with absorbable monofilament sutures over the bile duct. However, it must be kept in mind that sometimes a classic cholecystectomy could be performed. If a fistula is present (Mirizzi Ⅲ and Ⅳ), besides partial cholecystectomy, a biliary-enteric anastomosis could sometimes be performed between the duodenum and bile duct or between the bile duct and a loop of jejunum *en-Y-de-Roux*[7,14,29,33,37,48,51,55]. The rationale for a biliary-enteric anastomosis is that because of the continued inflammation of the gallbladder flap, strictures can develop, with an even greater risk for large cholecystocholedochal fistulas or badly damaged bile ducts[55]. Baer *et al*[48] have advocated an anastomosis between the partially resected gallbladder and the duodenum which they called "cholecysto-choledocho-duodenostomy" for patients with Mirizzi Ⅱ or higher, claiming satisfactory results and decreased risk of bile duct injury. A variation of the Baer anastomosis is the "cholecysto-choledocho-jejunostomy" proposed by Safioleas *et al*[54], for patients with Mirizzi Ⅱ or higher. Others have proposed a standardized surgical approach based on the grade of Mirizzi encountered, which seems to be a logical and appropriate management; however, not always plausible[4,7,52]. The bile duct should be explored for the presence of stones through a different incision over the common hepatic duct or the choledochus, because common bile duct stones are a common

occurrence in Mirizzi syndrome and have been found in 25% to 40% of cases[26,53]. The common bile duct suture must be protected with a Kehr tube placed through a different hepaticotomy or choledochotomy proximal or preferable distal to the fistula[7,28,30,33,37,41,52]. Operative cholangiography through the Kehr tube should be performed in all patients with Mirizzi syndrome before concluding the surgical procedure[26-33,51,53].

Treatment of Mirizzi syndrome type I

Acute and chronic presentation of Mirizzi syndrome type I could be adequately resolved by classic cholecystectomy[1-37,48,50,52,53,56]. Those cases with extensive chronic or acute inflammation of Calot's triangle area could be securely operated on with subtotal cholecystectomy with excellent outcomes[48-57,59]. The approach to the gallbladder in subtotal cholecystectomy begins by choosing a convenient site, more commonly the fundus and in selected cases the Hartmann´s pouch or even over the impacted gallstone, to open the gallbladder wall[49,50,54,55,57-59]. The gallstone or gallstones are then emptied and the gallbladder is removed starting the dissection at the fundus[57]. Sometimes, the gallstones are firmly adhered to the gallbladder wall and must be extracted with mucosa or whole wall, on other occasions the gallstones are loosely attached to the wall and are easily removed. The cystic duct is identified from inside the open gallbladder and explored seeking residual gallstones. In some cases, the cystic duct is obliterated and no attempt should be made to open it. Finally, the cystic duct is secured without further dissection. If the bile duct is to be explored this must be done through a separate incision and protected by a Kehr tube[7,14,26-30,53].

Treatment of Mirizzi syndrome type II

The initial approach to patients with cholecystobiliary fistula involves a subtotal cholecystectomy starting the dissection from the gallbladder fundus towards the Hartmann´s pouch. Most cholecystobiliary fistulas are diagnosed during surgery, and not during the preoperative study. The gallbladder should be removed leaving a remnant of gallbladder wall measuring about 5 mm around the cholecystobiliary fistula in order to aid in the closure of the destroyed bile duct[52,54]. Mirizzi syndrome type II can be successfully treated with this technique[55,56]. The exploration of the bile duct should always be undertaken using a separate incision distal to the fistula and protected by a Kehr tube[30]. Placing the Kehr tube through the fistula increases the risk of bile leakage and bile duct stricture[7,14,30,50].

Treatment of Mirizzi syndrome type III

Most cases of Mirizzi syndrome type III can be treated by subtotal cholecystectomy leaving a flap of gallbladder wall measuring at least 1 cm to repair the bile duct[52,53]. However, some cases with an important inflammation of the gallbladder wall will need another procedure such as a bilioenteric anastomosis to the duodenum or a hepaticojejunostomy *en-Y-de-Roux*[7,27,36,37,48,50,51,54-56].

Treatment of Mirizzi syndrome type IV

The treatment of this type of Mirizzi with extensive destruction of the bile duct wall consists on a bilioenteric anastomosis. A hepaticojejunostomy *en-Y-de-Roux* is preferred[7,27,3,37,46,50-56].

Treatment of Mirizzi syndrome type V

Mirizzi type V can be associated with an acute serious condition or with chronic active or inactive bilioenteric fistulae; consequently the treatment differs accordingly. Mirizzi syndrome type Va should be treated with division and simple suture with an absorbable material of the bilioenteric fistulae over the implicated viscera (duodenum, stomach, colon or small bowel) and cholecystectomy, either total or subtotal according to the presence of a cholecystobiliary fistula or simple external compression of the bile duct. Mirizzi syndrome type Vb is a matter of controversy, nonetheless, it seems advisable to treat the acute condition first (gallstone ileus) and at a second time after the patient has recovered from surgery (3 or more months later), approach the gallbladder according to the presence or absence of external compression of the bile duct or cholecystobiliary fistula[8].

Laparoscopic surgery

Laparoscopic cholecystectomy can be dangerous for the bile duct[6,60,61]. Some conditions increase the risk of bile duct injuries in laparoscopic cholecystectomy: uncommon pathology such as Mirizzi syndrome, difficult or distorted anatomy, and technical problems[5,6,60,62,63]. Severe inflammation in the triangle of Calot area makes dissection of the cystic duct and cystic artery hazardous[5,6,60,62]. It has been suggested that preoperative diagnosis of Mirizzi syndrome decreases the rate of conversion and complications, thus a stronger emphasis should be given to the preoperative diagnosis of this syndrome[6]. Currently, and despite various studies reporting the feasibility of laparoscopic surgery in Mirizzi syndrome, laparoscopic cholecystectomy for this condition is considered controversial and technically challenging, placing the patient at a probably unnecessary increased risk of bile duct injuries; as a consequence, laparoscopic cholecystectomy for Mirizzi syndrome cannot currently be recommended as a standard procedure[6]. Also, besides being technically demanding, the surgical laparoscopic treatment of Mirizzi syndrome requires some technology still not widely available such as intraoperative ultrasonography, laparoscopic choledocoscopy or the use of laparoscopic staplers[4,5,62]. Furthermore, careful analysis of the reports on laparoscopic surgery for Mirizzi syndrome have revealed increased complication rates compared to open cholecystectomy[33,35]. Laparoscopic subtotal cholecystectomy and dissection of the gallbladder from the fundus towards the infundibulum have been described to reduce the risk of bile duct injury and conversion to open surgery rates[5,59,64]. Probably laparoscopic cholecystectomy could be carefully undertaken in selected patients with Mirizzi syndrome type I [5,50,61-64]. However, it is not recommended for patients with Mirizzi syndrome type II or high-

er[5,60]. Moreover, successful laparoscopic cholecystectomy in patients with Mirizzi type I can be predicted based in the visualization of the cystic duct during the initial dissection over the Calot's triangle[63]. A series reporting laparoscopic cholecystectomy in Mirizzi syndrome had a conversion rate as high as 31% to 100%, with a complication rate of 0% to 60%, bile duct injury of 0% to 22% and mortality ranging from 0% to 25%[6,28,55,56,61].

A step-by-step approach to the laparoscopic management of Mirizzi syndrome summarizing much of the current knowledge has been proposed by Rohatgi *et al*[62], highlighting the initial section of the gallbladder fundus and retrieval of the impacted gallstones to identify the gallbladder infundibulum and cystic duct from within the gallbladder and facilitate the subtotal cholecystectomy; they also emphasize the importance of operative cholangiography. The identification of some steps and associated anatomic landmarks would make laparoscopic cholecystectomy on these patients safer, these steps and anatomic landmarks have been proposed by Singh *et al*[65]. This proposal consists of the initial approach to the gallbladder that must be kept close to the liver margin, early definition of the gallbladder neck, early definition of the gallbladder-cystic duct junction, identification of the cystic lymph node as a landmark between the cystic duct and cystic artery, appropriate and careful dissection of the Calot's triangle, identification of the Rouviere's sulcus as a landmark to the plane of the common bile duct, and continuous localization and identification of the common bile duct during surgery.

ERCP

ERCP besides being diagnostic allows the performance of a sphincterotomy for stone extraction and facilitates other interventions such as the placement of stents or a nasobiliary tube or other procedures[29,35,41,49,50,51,55,56,61]. Poor surgical candidates may have an attractive option with the use of ERCP to relieve the obstruction of the bile duct caused by Mirizzi syndrome. Patients with associated cholangitis will benefit from preoperative biliary drainage as a temporary measure before a definitive operation. In general, endoscopic management includes both, biliary drainage and stone removal, and eventually stent insertion. Standard stone removal techniques are usually used and include baskets, balloons, and mechanical and electro-hydraulic lithotripsy. However, ERCP has known associated morbidity and mortality and its risks must be weighed against its benefits in patients suspected of having Mirizzi syndrome.

GALLBLADDER CANCER AND MIRIZZI SYNDROME

Mirizzi syndrome constitutes one differential diagnosis of gallbladder carcinoma. It has been reported that 6% to 28% of patients with preoperative diagnosis of Mirizzi syndrome actually had gallbladder cancer[14,61]. Gallbladder cancer has been associated with various degrees of Mirizzi syndrome with an incidence varying between 5.3% and 28% of patients[66-69]. Gallbladder cancer is found associated with Mirizzi syndrome mainly in patients with Mirizzi syndrome type Ⅱ or higher[66,68]. Moreover, patients with Mirizzi syndrome and biliary-enteric fistulas (Mirizzi type Ⅴa) associated with gallbladder cancer have been reported[66]. Mirizzi syndrome and gallbladder cancer share the same risk factor in their etiology: long-standing gallstone disease with stasis. Consequently, Mirizzi syndrome must be considered a risk factor for gallbladder cancer[67,68]. There are no clinical features to distinguish Mirizzi syndrome from gallbladder cancer, except that patients with gallbladder cancer are a decade older than patients with Mirizzi syndrome alone[67]. Measurement of the tumor marker, CA19-9, could help to differentiate between Mirizzi syndrome and gallbladder cancer, although CA19-9 is moderately elevated in benign diseases associated with obstructive jaundice including Mirizzi syndrome[38-40], this marker is markedly elevated with levels over 800 UI/mL in patients with gallbladder cancer[68]. Nonetheless, it must be kept in mind that high levels of CA19-9 have been found in some patients with Mirizzi syndrome[38-40]. Patients with suspected Mirizzi syndrome must undergo extensive preoperative study with CT and magnetic resonance cholangiography to rule out gallbladder cancer[66-69]. Tomographic findings suggesting gallbladder cancer and not Mirizzi syndrome are the presence of a mass filling or replacing the gallbladder which is seen in 40% to 60% of patients, local liver involvement, and focal protrusion of the anterior surface of the liver[66]. During the operation, frozen section biopsy must be performed in all patients with Mirizzi syndrome to definitively rule-out gallbladder cancer. If a surgically resectable gallbladder cancer is diagnosed, a radical cholecystectomy with hepatic wedge resection and lymph node dissection must be performed. The diagnosis of gallbladder cancer must be ruled out before or during surgery and an appropriate surgery must be performed because a second surgery to perform oncologic surgery has a poorer prognosis and outcome than a one-stage radical surgery[14]. Nonetheless, long-term survival in patients with Mirizzi syndrome and gallbladder cancer can be attained[67].

A PROPOSITION FOR A SIMPLIFIED CLASSIFICATION

Despite numerous attempts to standardize the surgical treatment of Mirizzi syndrome, no consensus has been reached and none of the proposed algorithms has been accepted by the world surgical community. The main reasons for the failure to establish a standard surgical approach to Mirizzi syndrome are the rarity of this condition and its unexpected presentation during surgery; these reasons preclude the design and performance of controlled randomized trials to test the proposed surgical approaches. Besides, there are no international publications in the English language reporting long-term outcomes of the surgical treatment of any type of Mirizzi syndrome.

Table 4 New proposed classification and suggested surgical treatment for Mirizzi syndrome

Type of Mirizzi	Description	Treatment
Ⅰ	External compression of the bile duct	Open cholecystectomy Open subtotal cholecystectomy Laparoscopic cholecystectomy Laparoscopic subtotal cholecystectomy
Ⅱa	Cholecystobiliary fistula < 50% the diameter of the bile duct	Open cholecystectomy Open subtotal cholecystectomy
Ⅱb	Cholecystobiliary fistula > 50% the diameter of the bile duct	Open subtotal cholecystectomy Biliary-enteric derivation: Side-to-side to the duodenum *En-Y-de-Roux* to the Jejunum
Ⅲa	Cholecystobiliary fistula and cholecystoenteric fistula without gallstone ileus	Simple closure of the fistula and treatment of the gallbladder according to the presence of Mirizzi Ⅰ, Ⅱa or Ⅱb
Ⅲb	Cholecystobiliary fistula and cholecystoenteric fistula with gallstone ileus	Treatment of the gallstone ileus and deferred treatment of the gallbladder according to the presence of Mirizzi Ⅰ, Ⅱa or Ⅱb

Consequently, no conclusions can be drawn regarding the real utility of the currently used and proposed surgical techniques for Mirizzi syndrome.

The importance and ultimate goal of all classification systems for Mirizzi syndrome is to enable the surgeon to tailor the surgical approach to the individual case[61]. This goal has not been entirely fulfilled by the current published classifications. Moreover, the recognition of cholecystoenteric fistulae associated with Mirizzi syndrome and the consequent addition of a new grade of Mirizzi to the classic classification of Csendes has further complicated the correct diagnosis, classification, and treatment of patients with Mirizzi syndrome. In 2009, Solis-Caxaj suggested that the classification of Mirizzi syndrome should be simplified taking into account the recent addition by Csendes[70], he proposed that the classification should have only 3 types. The proposition of Solis-Caxaj makes sense and given the current knowledge on Mirizzi syndrome, which is well established, I believe that a more simple classification should be proposed as follows: Mirizzi Ⅰ, external compression of the bile duct by a chronic or acute inflammatory process and a gallstone impacted at the Hartmann pouch or at the gallbladder infundibulum. Mirizzi Ⅱa, cholecystobiliary fistula less than 50% the diameter of the bile duct. Mirizzi Ⅱb, cholecystobiliary fistula more than 50% the diameter of the bile duct. Mirizzi Ⅲa, cholecystobiliary fistula associated with a concurrent cholecystoenteric fistula without gallstone ileus. Mirizzi Ⅲb cholecystobiliary fistula associated with a concurrent cholecystoenteric fistula with gallstone ileus. Based on this proposed classification and the published world-wide experience, a standardization of the surgical treatment could be suggested (Table 4).

CONCLUSION

Mirizzi syndrome continues to be a fascinating subject of study, this fascination arises due to the challenge it represents and the unexpectedness of its presentation complicating an assumedly simple surgery as some currently consider being the cholecystectomy. Even though more than 60 years have passed since the description of Pablo Luis Mirizzi, it seems that the last word on this subject is yet to be pronounced. The approach to patients with suspected Mirizzi syndrome should be cautious and sound. Every effort should be made to establish a preoperative correct diagnosis, and if encountered during surgery every effort should be made to perform an accurate and cautious surgery trying to identify the type of Mirizzi and perform the most adequate treatment for each particular case. This article extensively reviews the current knowledge on Mirizzi syndrome and based on this knowledge proposes a simplified classification suggesting the surgical approach according to each type of Mirizzi.

Abstract

The liver is an important site for iron and lipid metabolism and the main site for the interactions between these two metabolic pathways. Although conflicting results have been obtained, most studies support the hypothesis that iron plays a role in hepatic lipogenesis. Iron is an integral part of some enzymes and transporters involved in lipid metabolism and, as such, may exert a direct effect on hepatic lipid load, intrahepatic metabolic pathways and hepatic lipid secretion. On the other hand, iron in its ferrous form may indirectly affect lipid metabolism through its ability to induce oxidative stress and inflammation, a hypothesis which is currently the focus of much research in the field of non-alcoholic fatty liver disease/non-alcoholic steatohepatitis (NAFLD/NASH). The present review will first discuss how iron might directly interact with the metabolism of hepatic lipids and then consider a new perspective on the way in which iron may have a role in the two hit hypothesis for the progression of NAFLD *via* ferroportin and the iron regulatory molecule hepcidin. The review concludes that iron has important interactions with lipid metabolism in the liver that can impact on the development of NAFLD/NASH. More defined studies are required to improve our understanding of these effects.

ROLE OF IRON IN HEPATIC LIPID METABOLISM: A BRIEF OVERVIEW

The liver is a major site for the storage of iron and the metabolism of lipids and is therefore an important site for interaction between these two metabolic pathways. One role of iron in the pathogenesis of diseases associated with hyperlipidemia and lipid deposition is likely to include an ability to induce oxidative stress and inflammation in the liver. In the setting of lipid deposition in the liver, iron overload has been associated with increased fibrosis and progression of non-alcoholic fatty liver disease and non-alcoholic steatohepatitis (NAFLD/NASH)[1-3]. Iron in its ferrous form can generate free radicals *via* the Fenton reaction, resulting in oxidative stress and lipid peroxidation. These effects can, in turn, stimulate hepatic

stellate cells to increase production of collagen and progression of fibrosis in patients with NAFLD and NASH. Notwithstanding these indirect effects, there are also recent and archival studies to show that iron has direct effects on lipid metabolism. Variations in hepatic iron stores result in inappropriate lipogenesis for lipid storage and secretion. For example, iron deficiency is associated with increased hepatic lipogenesis and lipemia[4,5]. Since the liver co-ordinates iron and lipid metabolism, and under conditions of stress is the site of excessive deposition of both these nutrients, this review will focus on the role of iron in the metabolism of hepatic lipids. In particular, it examines the role of different enzymes, receptors and transporters, as well as the effects of proteins involved in lipogenesis and lipoprotein secretion as sites for interaction between iron and lipids. The review then addresses the way in which iron may function in the progression of NAFLD. To begin, a brief overview of normal hepatic lipid metabolism is provided.

HEPATIC LIPID METABOLISM

Hepatic steatosis occurs whenever there is an imbalance among the uptake, synthesis, oxidative and secretory pathways of fatty acid metabolism. Sources of fatty acids for hepatic triglyceride (TG) synthesis are those derived from the plasma non-esterified fatty acids (NEFA) pool and those from within the liver through *de novo* lipogenesis (DNL), mainly from glucose (Figure 1). The hepatic uptake of fatty acid from the plasma is not regulated and is therefore directly related to the concentration of plasma NEFAs. Adipose tissue by its TG lipolysis is the main contributor to the plasma NEFA pool. The remaining NEFAs come from peripheral lipolysis of lipoproteins [chylomicrons (CM), very low density lipoprotein (VLDL)] and dietary fatty acids in the circulation. The hepatic uptake of fatty acids occurs by fatty acid binding protein and fatty acid translocase. Once in the hepatocyte, fatty acids undergo oxidation or they may be detoxified by re-esterification with glycerol and cholesterol to form TG and cholesteryl esters (CE), respectively. The TG and CE are then secreted as VLDL into the plasma or, if in excess, are stored in the cytoplasm as lipid droplets. Adipose differentiation-related protein (ADRP) is expressed in hepatocytes and is involved in cytosolic lipid storage[6].

The partitioning of hepatic TG into different pools under normal conditions of fasting/feeding and dietary variations, i.e. carbohydrate or fat diet, involves different hormonal and metabolic regulatory mechanisms. Insulin is a fat-sparing hormone and a major metabolic factor in the regulation of fat metabolism. In the liver, insulin increases TG synthesis by the hepatocytes and restricts its secretion by partitioning the newly synthesized TG into cytosolic stores[7]. In addition, insulin also inhibits lipolysis in the hepatocyte[8], decreases the assembly of VLDL by impairing the association of apoB-100 with TG[9], inhibits the translation of apoB-100 mRNA in human hepatocellular carcinoma (HepG2) cells[10] and stimulates the degradation of newly synthesized apoB[11], which collectively decrease VLDL-TG secretion. These actions coupled with insulin-stimulated expression of ADRP promotes lipid droplet assembly[12]. Furthermore, insulin also activates sterol regulatory element binding protein-1c, which transcriptionally activates nearly all genes involved in DNL[13].

EFFECTS OF IRON DEFICIENCY ON HEPATIC LIPIDS

There is evidence to suggest that lipoprotein uptake pathways are affected by iron.

Anaemia/hypoxia is associated with decreased fat uptake by the liver, but increased fat accumulation by the liver. Decreased fat uptake may either be due to impaired peripheral lipolysis or decreased uptake of CM and VLDL remnants, leaving the lipoproteins to accumulate in the circulation. Rat models of chronic anemia/hypoxia in which iron deficiency is present show decreased lipoprotein lipase and hepatic lipase activities[14-18]. This may be due to decreased synthesis[18], defects in the structure or conversion from precursor to the functional form, or in the activation of these enzymes[14,16]. It may be that iron itself can impact on hepatic uptake pathways. Supporting this idea, Brown *et al*[19] have shown that the binding of low density lipoprotein to its receptors requires a divalent cation. Although speculative, one of the divalent cations may include ferrous-iron. Anaemic rats produced by experimentally induced chronic renal failure show down-regulation of the expression of the VLDL-receptor in a non-erythropoietin dependent manner[20]. Furthermore, the plasma ratio of cholesteryl ester to cholesterol is increased with iron deficiency in rats. This cannot be explained by increased lecithin cholesterol acyl transferase (LCAT) activity, since LCAT is reduced in iron deficiency[21,22].

On the other hand, iron deficiency in rats has been shown to increase hepatic lipogenesis, leading to cellular TG accumulation and steatosis[4,5,23,24]. Given that hepatic uptake pathways are down regulated, the increased lipogenesis could be due to decreased utilization of fatty acids or increased DNL. In iron deficient rats, it is proposed that beta-oxidation of fatty acids is decreased, allowing the fatty acids to be diverted towards TG synthesis[24]. Supporting this, the level of hepatic carnitine, the long chain fatty acid transporter required for β-oxidation of fatty acids is reduced in the iron deficient state. Since this enzyme requires iron as a cofactor, its activity might be expected to decrease with iron deficiency[24,25]. However, others report that beta-oxidation of fatty acids remains unchanged[4], while hepatic DNL increases[4,23]. The increased hepatic lipogenesis seen in iron-deficient rats is supported by genomic studies that show a concurrent decrease in gene expression related to hepatic β-oxidation and an increase in gene expression related to lipogenesis[26]. Therefore, some of the changes in lipid metabo-

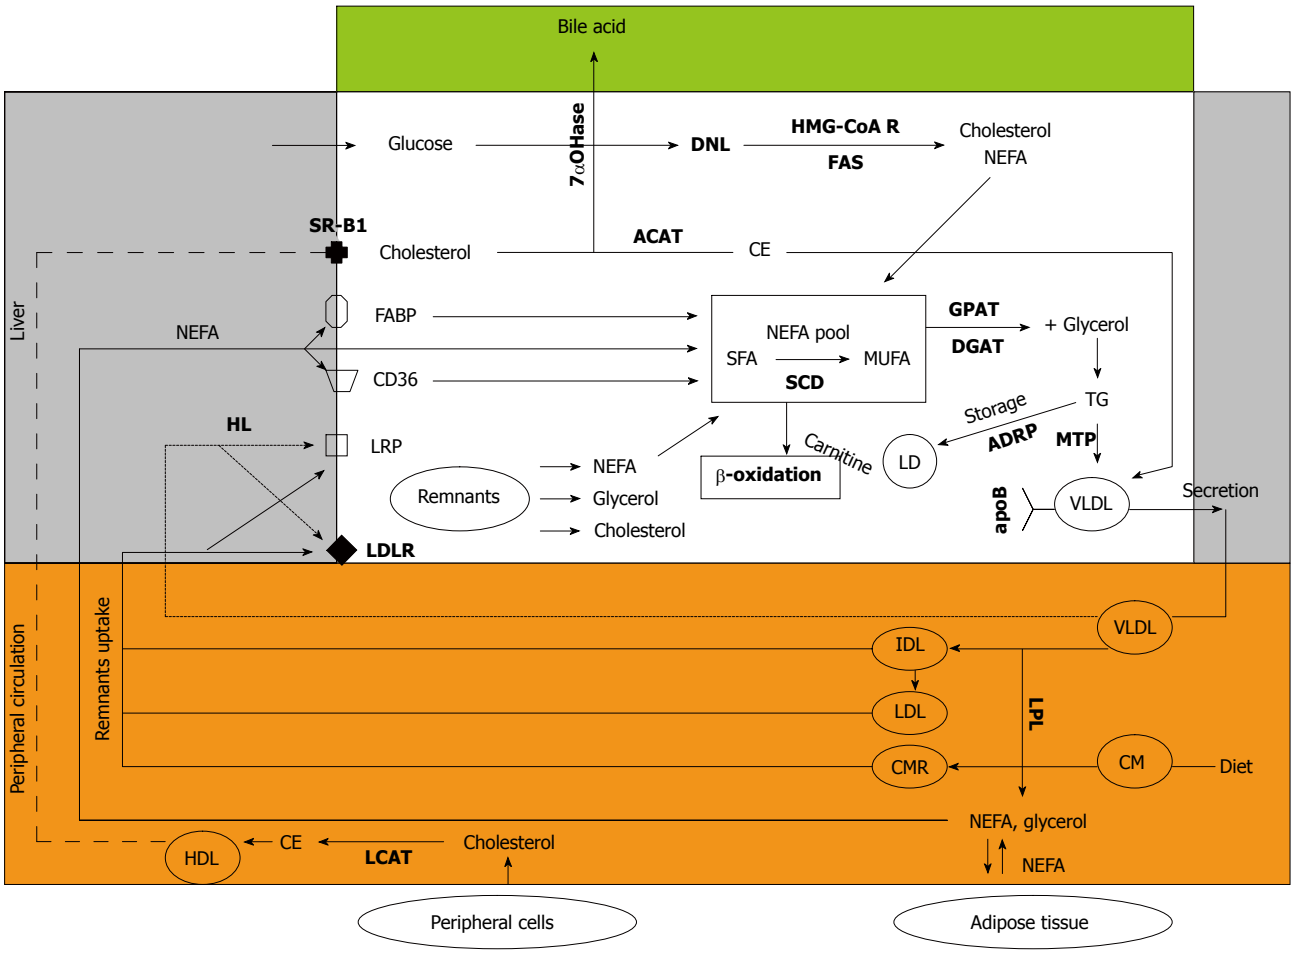

Figure 1 Possible sites (shown in bold) of interactions between iron and lipid metabolism. Iron deficiency can have its effects by generating anaemia/hypoxia while iron overload can interact by generating oxidative stress/lipid peroxidation and cytokine production. The grey area shows the basolateral surface of the hepatocyte bathed in the sinusoidal fluid. The green area is the canalicular surface through which bile is actively secreted into the biliary canaliculi. The orange area shows the lipoproteins and enzymes acting in peripheral circulation. lism appear to be related to effects of iron-deficiency on transcriptional/post-transcriptional mechanisms, as well as to effects on the kinetics/activity of enzymes that depend upon iron as a cofactor.

In contrast to the studies that show an increase in hepatic lipogenesis with iron deficiency, others have reported a decrease in hepatic lipid synthesis. In rats with moderate iron deficiency, glucose-fueled hepatic lipogenesis fell[27] which was attributed to decreased activity of either the rate limiting enzymes [fatty acid synthase (FAS)] or enzymes involved in providing the redox potential for lipogenesis (glucose 6 phosphate dehydrogenase, malic enzyme)[28-30].

In chicks, anemia depresses levels of mitochondrial cytochromes[31-33]. This finding is consistent with that found in yeast in which iron-deficiency down-regulates transcription of certain respiratory cytochromes that require heme as prosthetic groups for activity[34], while the heme degradation enzyme, heme oxygenase, is upregulated[35]. It is proposed that this decrease in the activity of hepatic heme pathways in iron-deficiency preserves the availability of iron for other essential sites/pathways when cellular iron levels are low[36]. Supporting this idea is the observation that when lipid metabolism is affected by iron deficiency in yeast, amino acid homeostasis remains unaltered[36].

Iron deficiency can affect the function of many hepatic enzymes involved in cholesterol metabolism[28]. In a mouse model of iron-deficiency induced by genetic mutation of hephaestin (sla mice), lack of the copper-dependent ferroxidase in the enterocyte results in impaired iron absorption and anaemia[37]. Under these conditions, hepatic cholesterol synthesis is reduced in association with decreased mevalonic acid levels. HMG CoA reductase activity, the rate limiting enzyme in *de novo* cholesterol synthesis, is increased in this model, arguing that this enzyme is not responsible for the decreased cholesterol production[37]. Similarly, acetyl-CoA thiolase and HMG-

CoA synthase involved in cholesterol production are not affected by iron deficiency[37]. All these enzymes act upstream in the production of mevalonic acid, suggesting that this intermediate is shunted to a non-steroidal pathway.

Other studies show that the cholesterol degradation pathway is also affected. One study in dogs shows that iron deficiency can decrease the activity of hepatic 7α hydroxylase, the rate limiting enzyme in the conversion of cholesterol into bile acids[38]. In this study, bile contained cholesterol crystals, suggesting that reduced conversion of cholesterol to bile acids may impair biliary micellar formation and explain the cholesterol precipitates in the bile. However, hepatic lipids were not measured in this study.

Nutritional iron depletion in rats also leads to alterations in the fatty acid composition of hepatic phospholipids, indicating impaired desaturation of saturated and essential fatty acids[29,39,40]. Steroyl CoA desaturase (SCD) is required for the conversion of saturated fatty acids to the unsaturated form and this enzyme is dependent on iron for its activity. Lower activity of SCD in iron deficiency may explain the increased saturated composition of fatty acids in the liver in this condition[29]. The effect of iron on the various steps in lipid metabolism is summarised in Figure 1.

It is likely that some of the reasons for the conflicting observations reported here as a result of iron deficiency can be explained in part by the specifics of the model system, by the means of inducing iron deficiency through phlebotomy or dietary restriction, or by the extent of the iron deficiency. Severe iron deficiency will produce anaemia and hypoxia which are likely to activate additional transcription factors to those stimulated during mild iron deficiency, and in turn, affect the transcription of more genes encoding enzymes/proteins[41]. Analysis of the reports cited in this review for correlations between the extent of iron deficiency and alterations in lipid metabolism was not possible, since the level of iron deficiency was not measured in these studies. It is recommended that future studies exploring effects of iron deficiency need to incorporate measurements of iron into their experimental design.

Another reason for the conflicting observations reported here might be the model systems themselves. Some animal model systems are designed to develop iron-deficiency from birth and others induce iron deficiency in a mature animal[4,23]. There are studies to suggest that metabolic conditions in development can impact on adult metabolism. For example, epidemiological data show that under normal birth weight conditions, there is an inverse correlation between the weight at birth and adult obesity[42,43]. Experimental data show that changing the diets during pregnancy or during the newborn period may permanently change the rate of lipid metabolism[44]. Therefore, it is important to recognize the possibility of fetal programming on hepatic lipid metabolism as an explanation for some of the differences reported.

EFFECTS OF IRON OVERLOAD ON HEPATIC LIPIDS

Iron overload can generate oxidative stress[45,46] and lipid peroxidation, which can modify the fatty acid profile of cellular membranes, leading to their disruption, damage to cell organelles[47-49] and impairment of mitochondrial oxidative metabolism[50,51]. It is suggested that the free radicals that form may cause a change in the ratio of saturated to unsaturated membrane phospholipids, leading to alterations in membrane fluidity[52]. This in turn may affect the activity of the embedded enzymes[53-56]. Enzymes respond to oxidative stress differently by altering their activity[55]. It is also known that the formation of peroxidation products by hepatocytes increases with the proportion of unsaturated fatty acids. Thus, polyunsaturated fatty acids in the presence of iron overload may exert an inhibitory effect on lipogenic genes (e.g., FAS) by generating a peroxidative cytotoxic effect[57] .

Iron overload also has direct effects on hepatic lipid metabolism, although studies report conflicting results based on different experimental models. Specific enzymes in hepatic cholesterol metabolism show variable responses to iron overload. In rats with dietary iron overload, an increase in the activity of acyl-CoA cholesterol acyltransferase (ACAT) coupled with reduced activities of HMG CoA reductase and 7 α-hydroxylase correlates with hypercholesterolemia and unaltered hepatic cholesterol content[55]. Since ACAT increases intrahepatic cholesterol esterification and contributes to VLDL-cholesterol secretion, these findings suggest that the cholesterol synthetic and excretory pathways are not affected while the secretory pathways maybe upregulated in this model system[55,58]. On the other hand, a recent study in mice by Graham *et al*[59], shows that transcripts of seven enzymes, including the rate limiting enzyme HMG CoA reductase, are up-regulated with increasing hepatic iron, suggesting that hepatic iron loading increases liver cholesterol synthesis. Although valuable, genomic analysis does not provide insight into enzyme kinetics and substrate concentration which may also be altered by the level of iron. This may explain some of the differences between these studies as well as different feeding regimes employed. Hepatic iron overload using carbonyl iron in the methionine-choline deficient rat model of NAFLD is associated with decreased hepatic TG and decreased hepatic steatosis; however, an improvement in liver injury is not seen due to increased necroinflammation and a trend towards increased perivenular fibrosis in iron loaded animals[58]. In carbonyl-iron and iron dextran models of iron overload in mice, studies show an upregulation of the mRNA and enzyme activity of SCD. SCD increases the biosynthesis of unsaturated fatty acids at 8 but not 2 mo of feeding[60]. In contrast, feeding ferric citrate for 3 mo has no effect on hepatic fatty acid composition or desaturase activity[40]. These findings suggest that the experimental model used, the level and duration of iron overload, as well as cellular repartition of iron storage in the liver may play a role in

SCD induction[60]. The effect of iron on the various steps in lipid metabolism is summarised in Figure 1.

In vitro studies in HepG2 cells show that iron overload increases intracellular lipid droplet formation by increasing the expression of cluster of differentiation 1d, an unconventional major histocompatibility complex class 1 molecule reported to monitor intracellular and plasma membrane lipid metabolism[61]. Both of these changes are also associated with increased expression of phosphatidylserine in the outer leaflet of the plasma membrane, a feature associated with apoptosis and cell death[62,63]. Hepatosteatosis has also been associated with an increased likelihood of apoptosis[64]. Cell death of mature hepatocytes disproportionate to their ability to regenerate has been referred to as a "third hit" in the pathogenesis of NAFLD/NASH leading to progression of fibrosis[65,66].

Several important factors may contribute to the inconsistencies described here in studies exploring effects of iron overload. These include differences in experimental designs, diets, age, sex, weight and strain of animals; differences in methods for generating iron overload; and also maternal status and its effect on fetal programming, as discussed for models of iron deficiency above.

ROLE OF IRON-OVERLOAD IN NON-ALCOHOLIC STEATOHEPATITIS

NAFLD is now accepted as an hepatic component of the metabolic syndrome[67]. It represents a spectrum of disease ranging from a benign state of non-alcoholic fatty liver to severe fibrosis or cirrhosis. NASH is the intermediate progressive stage between the two conditions. The exact mechanism for this progression is not known but a "two hit theory" is generally accepted. The first hit is considered to be insulin resistance, which leads to excessive accumulation of fat in the liver. The second hit is the generation of oxidative stress by a number of factors, including hepatic iron overload, which lead to cytotoxicity and necroinflammation. A number of clinical and animal studies have shown variable results concerning the effects of iron in NAFLD and NASH. This has lead to controversy about its role in the disease progression (Figure 2).

As already mentioned, excess iron is directly toxic to cells[47-49]. Furthermore, iron accumulation has a proinflammatory and profibrogenic role by activating Kupffer cells to release inflammatory cytokines[68,69] and by activating hepatic stellate cells, which can culminate in the replacement of parenchymal tissue with connective tissue[70]. Bacon *et al*[1], in 1994 first showed abnormal iron parameters (serum ferritin and transferrin saturation) and increased hepatic iron concentration in cases of NASH. Other clinical studies have also shown an increase of hepatic iron deposition in NASH/NAFLD and an increased prevalence of the hemochromatosis gene (*HFE*) mutation[2,3,71-73]. One study showed an association between increased hepatic iron and severity of fibrosis in NASH[2]. In contrast to the work of Bacon and others, however, there are also clinical studies that fail to find an increase in hepatic iron deposition in NASH[74-78] or an increase in HFE mutation[79-81], casting doubt on iron as a causative agent in the progression of the disease.

On the other hand, several clinical studies of NAFLD/NASH show an improvement in liver enzymes and insulin sensitivity with phlebotomies, even in cases without increased levels of iron[82-84]. One case report of a patient with NASH shows complete histologic resolution of steatohepatitis in the liver with phlebotomy-induced iron depletion[85]. However, it must be kept in mind that repeated phlebotomies might predispose to anemia, which could lead to tissue hypoxia and subsequent peripheral vasodilatation. Cardiac output would be expected to increase in response to reduced peripheral resistance, which in turn would increase tissue perfusion and peripheral lipoprotein clearance, reducing the lipid load on the liver. This proposed sequence of events is supported by hemodynamic studies in the anaemic state[86-88] and clearance studies using adrenergic agonists[89,90]. Taken together, an improvement in NAFLD/NASH observed with repeated phlebotomies might be more a physiological response to anaemia/tissue hypoxia rather than a direct effect of reducing iron toxicity. Care must be taken to choose this procedure in cardiac compromised patients.

It is a generally accepted hypothesis that iron overload may play a role in the progression of NAFLD *via* promoting the 2nd hit (Figure 2). However, it is also possible that the steatosis, cytokines and oxidative stress that are integral to NASH pathophysiology secondarily lead to iron overload, which then works in a feed-forward manner to generate more oxidative stress and inflammation, making the environment more favourable for the 3rd hit, injury that overwhelms the capacity of dying hepatocytes to regenerate and increases scar, as proposed by Diehl[65,91]. Supporting the idea, increased hepatic iron deposition is also seen in non-biliary causes of cirrhosis, such as alcoholic liver disease and chronic viral hepatitis as well as NASH[92]. The process of hepatocellular injury may itself result in increased iron uptake from the intestine[93]. The expression of transferrin receptor might be increased in regenerating hepatocytes after liver injury, which could contribute to increased hepatic iron loading[94]. Another mechanism of increased iron accumulation in liver in NAFLD and NASH might be due to changes in levels of ferroportin and the iron regulatory peptide hepcidin[95,96]. Rats developing insulin resistance on a high fat, high energy diet show decreased hepatic mRNA expression of hepcidin[97]. Similarly, mice developing steatosis on a choline deficient diet show a negative correlation of hepcidin and ferroportin (iron export molecule) mRNA with hepatic lipid concentration, suggesting that enhanced dietary intake and reduced hepatic iron efflux may lead to increased hepatic iron content[98]. In patients with NAFLD, there is also reduced expression of ferroportin and the iron-sensing molecule, hemojuvelin, which is associated with an increase of tumor necrosis factor-α, hepatic iron accumulation and increased hepcidin expression[99]. Hepcidin expression and iron regulatory molecules need to be further investigated in the livers of

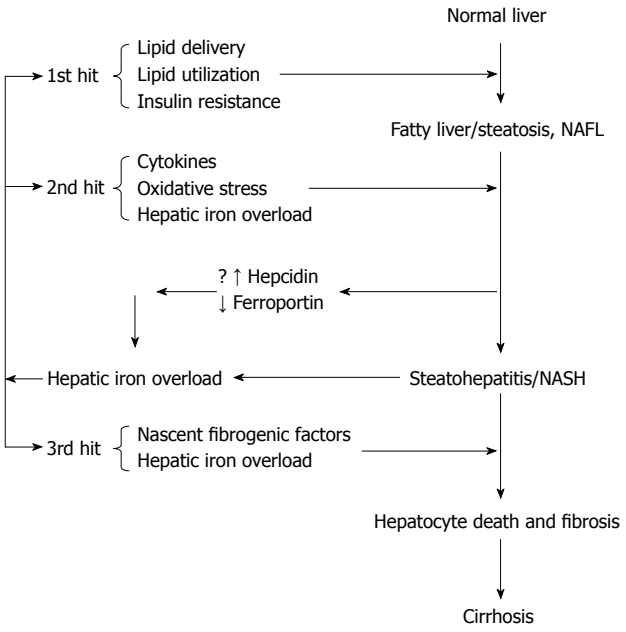

Figure 2 Schematic diagram depicting disease progression in non-alcoholic fatty liver disease modified after Gentile and Pagliassotti[101]. Iron overload is generally hypothesised to play a role in generation of second hit. In non-alcoholic fatty liver (NAFL) disease, iron overload in the liver may promote the development and progression of steatohepatitis, working in a feed-forward manner to promote the "third hit", on-going injury and death of hepatocytes leading to fibrosis and cirrhosis. NASH: Non-alcoholic steatohepatitis.

patients with metabolic syndrome and NAFLD.

It may also be the case that factors inducing localized iron deposition in the microenvironment of the liver are as, or more, important than total hepatic iron or systemic levels of iron. Iron in the microenvironment can promote regional oxidative stress that can lead to changes in microcirculation/capillarization, inflammation and fibrosis in NAFLD. In a rabbit model of steatohepatitis, Otogawa *et al*[100] have shown an increased phagocytosis of erythrocytes by Kupffer cells that is associated with increased hepatic iron deposition, suggesting that iron may accumulate locally as part of heme degradation. This finding is supported by a clinical study of patients with NASH in which aggregations of erythrocytes are seen in inflammed hepatic sinusoids[100].

In the aggregate, the findings reviewed here suggest the hypothesis that hepatic iron overload itself may be a critical event in the progression of NAFLD/NASH by exacerbating the 2nd hit of inflammation or perhaps by providing a critical 3rd hit that can ultimately lead to liver cell loss, failure of hepatocyte replication and eventual cirrhosis. Further studies are required to clearly establish the relationship between NASH/NAFLD, insulin resistance and iron overload.

Abstract

Endoscopic ultrasonography (EUS) has gained wide acceptance as an important, minimally invasive diagnostic tool in gastroenterology, pulmonology, visceral surgery and oncology. This review focuses on data regarding risks and complications of non-interventional diagnostic EUS and EUS-guided fine-needle biopsy (EUS-FNB). Measures to improve the safety of EUS und EUS-FNB will be discussed. Due to the specific mechanical properties of echoendoscopes in EUS, there is a low but noteworthy risk of perforation. To minimize this risk, endoscopists should be familiar with the specific features of their equipment and their patients' specific anatomical situations (e.g., tumor stenosis, diverticula). Most diagnostic EUS complications occur during EUS-FNB. Pain, acute pancreatitis, infection and bleeding are the primary adverse effects, occurring in 1% to 2% of patients. Only a few cases of needle tract seeding and peritoneal dissemination have been reported. The mortality associated with EUS and EUS-FNB is 0.02%. The risks associated with EUS-FNB are affected by endoscopist experience and target lesion. EUS-FNB of cystic lesions is associated with an increased risk of infection and hemorrhage. Peri-interventional antibiotics are recommended to prevent cyst infection. Adequate education and training, as well consideration of contraindications, are essential to minimize the risks of EUS and EUS-FNB. Restricting EUS-FNB only to patients in whom the cytopathological results may be expected to change the course of management is the best way of reducing the number of complications.

INTRODUCTION

Endoscopic ultrasonography (EUS) was first introduced

in 1980, when teams from the Wolfgang von Goethe University in Frankfurt, Germany[1] and the Mayo Clinic in Rochester, United States[2,3] incorporated a rotating mechanical ultrasound scanner or an electronic linear ultrasound array into the tip of side-viewing gastroscopes (Olympus GF-B3; ACMI FX-5), respectively. The clinical use of these early echoendoscopes was limited by the length (80 mm) and diameter (13 mm) of their rigid tips. Due to the devices' limited flexibility, endoscopists often were unable to pass the pyloric channel. Despite these disadvantageous mechanical properties, early reports showed no complications[1,3-5]. The first experience with needle biopsy under direct endosonographic guidance was published in 1992[6]. Over the last three decades, technological improvements have allowed EUS and EUS-guided fine-needle biopsy (EUS-FNB) to become established tools for the diagnosis, staging, and treatment of gastrointestinal diseases and benign and malignant pulmonary disorders[7-12]. In the United States, 60% of gastroenterologists use EUS, and approximately 43% of gastroenterologists and visceral surgeons in four European countries have access to EUS[13,14]. In Germany, EUS systems are used in universities and tertiary referral centers, as well as in 40% of the approximately 2000 hospitals[8]. Data from the prospective EUS registry of the German Society of Ultrasound in Medicine show that EUS-FNB is performed during one out of seven endosonographic examinations. The two basic EUS-FNB techniques are: EUS-guided fine-needle aspiration (EUS-FNA) using hollow-bore 19 Gauge (G) to 25 G needles, and EUS-guided trucut-biopsy (EUS-TCB) using side-notch 19 G core needles[8]. After 30 years of clinical experience with EUS and 20 years' experience with EUS-FNB, reliable data on the incidence of complications and specific risk factors are available and may be used as the background information when obtaining informed consent.

EUS-SPECIFIC RISK FACTORS

Endoscopic ultrasound systems differ from traditional forward-viewing and oblique-viewing endoscopes in the rigidity and stiffness of the scope tip that carries the ultrasound transducer. Moreover, echoendoscopes have a somewhat larger diameter (12.4 mm to 14.6 mm) compared to gastroscopes (9.0 mm to 9.8 mm) and duodenoscopes (11.0 mm to 13.1 mm), and a less flexible bending section[15]. Additionally, most echoendoscopes have a longer non-flexible segment just proximal to the transducer (Figure 1). The mean EUS examination time (20 min in a German multicenter survey[16] or 34 ± 20 min in one US-center with a high case load[17]) is significantly longer than that needed for standard esophagogastroduodenoscopy. With the exception of the electronic radial scanning echoendoscopes of Pentax/Hitachi and Fujinon, all other currently available echoendoscopes are oblique-viewing instruments[15]. Therefore, intubation and advancement of the echoendoscopes, especially through the esophagus, are semi-blind maneuvers. Moreover, in oblique-viewing instruments, the rigid segment containing the transducer extends beyond the optical lens.

EUS-FNA and EUS-TCB differ from forceps biopsies in that the needle penetrates from the non-sterile gastrointestinal tract into sterile extra-intestinal anatomical structures to access the target organ or structure. The target lesions are often near to vascular structures[18] and may themselves have pathological vascularization. For these reasons, it is not possible to apply safety data directly from upper gastrointestinal endoscopy to upper gastrointestinal EUS.

COMPLICATIONS OF NON-INTERVENTIONAL DIAGNOSTIC EUS

Gastrointestinal perforation

Due to its mechanical and optical properties, echoendoscope advancement may perforate the gastrointestinal wall, particularly at: (1) areas of angulation (e.g., hypopharynx, hiatal hernia, tip of the duodenal bulb, and rectosigmoidal junction); (2) in the presence of unexpected anatomical alterations (e.g., esophageal or duodenal diverticula); and (3) in luminal obstruction (e.g., gastrointestinal cancer). Several investigations of EUS staging have documented non-transversable malignant stenosis in 15% to 42% of patients with esophageal cancer[19-25], and in 7% to 23% (mean 12%) of patients with rectal cancer[26].

Esophageal perforation: In a survey of members of the American Endosonography Club published in 2002, 86 members reported 16 cervical esophageal perforations among 43 852 upper gastrointestinal EUS procedures performed using radial echoendoscopes (0.03%)[27]. Almost all of these patients were elderly; seven of the 16 (44%) had a history of difficult intubation during previous endoscopy. Large cervical osteophytes were identified in three cases. In nine of 16 cases (56%), the endoscopist had less than one year of experience in EUS. Two patients required surgery. For 13 patients (81%), the complication was managed successfully with conservative treatment. However, one patient died[27].

Another early multicenter survey including 34 centers from Europe, Japan and the United States[28] reported 13 esophageal perforations in 37 915 radial EUS examinations (0.03%); esophageal perforations accounted for 68% of all complications. Most of these patients (77%) had undergone pre-EUS dilatation of esophageal strictures to allow complete esophageal cancer staging, including celiac lymph-node station. Nine of these patients underwent surgery, four were managed conservatively, and one patient died. Further major complications in this survey were two pharyngeal and one duodenal perforation and two cases of bleeding[28].

Only two studies have investigated the frequency of esophageal perforations prospectively. A single-center study in the United States enrolled all patients who underwent upper gastrointestinal EUS by the same experienced endosonographer over a 7-year period. Cervical esophageal perforations occurred in three of 4844 pa-

[1]Without endoscopic ultrasonography (EUS)-guided fine-needle biopsy or EUS-guided therapeutic interventions. [a]$P < 0.05$ *vs* esophageal perforations.

tients (0.03%). Longitudinal echoendoscopes had been used in all three patients[29]. The second prospective study, performed in a department of surgical endoscopy in Denmark, evaluated EUS complications of 3324 consecutive patients. Esophageal perforation occurred in 5 of 10 patients with complications (0.15% of all EUS examinations; 0.94% of all patients with esophageal cancer). Balloon dilation had been performed prior to EUS in two cases. All five patients recovered fully with conservative (*n* = 4) or surgical treatment (*n* = 1)[30].

From 2004 to 2006, we conducted a survey in German centers performing EUS[31]. Of 67 centers responding to the questionnaire, 32 registered EUS complications prospectively. Esophageal perforation occurred in only eight of 85 084 reported diagnostic EUS procedures (0.009%). None of the perforations were associated with previous dilation of esophageal strictures. Stenosing esophageal cancer was present in five of eight cases[31].

Duodenal perforations: In contrast to the international multicenter survey conducted from 1982 to 1992[28], the German retrospective survey showed that duodenal perforations occurred significantly more often (19 additional cases) compared to esophageal perforations (0.022%)[31]. In 10 of 19 cases (47.4%), duodenal diverticula (*n* = 4), duodenal stenosis (*n* = 3), duodenal ulcer (*n* = 1), duodenal scarring (*n* = 1), or acute pancreatitis (*n* = 1) were reported as potentially contributing factors. Twenty-seven of 28 gastrointestinal perforations were managed surgically, and all the patients survived[31] (Table 1). In a prospective EUS online registry of the German Society of Ultrasound in Medicine, participants reported 10 cases of gastrointestinal perforation in 13 988 diagnostic EUS procedures (0.07%). Again, duodenal perforation was the most common type of perforation, accounting for six out of ten cases[32]. The increasing proportion of duodenal perforations in recent multicenter studies compared to the older surveys may partially reflect changing trends in indications for EUS[7,33].

In a large series of 233 EUS-FNA biopsies in patients with presumed pancreatic cancer, Raut and colleagues reported two cases of duodenal perforation requiring surgical intervention (0.86%)[34]. There was no luminal narrowing of the duodenum in either case[34]. One published case report describes iatrogenic duodenal perforation during EUS, which was managed successfully by endoscopic closure using hemoclips, followed by conservative treatment[35]. In a series of 224 EUS-FNAs, one duodenal perforation accounted for one of five severe complications[36]. A large single-center series of 1034 pancreatic EUS-FNAs found one case of fatal duodenal perforation in a 63-year-old woman with an advanced neuroendocrine tumor of the duodenal wall; the perforation likely resulted from mechanical injury of the duodenal wall by the echoendoscope, rather than from biopsy[37].

A national survey in Israel which investigated mortality associated with diagnostic EUS[38] showed that 13 of 18 reported fatal complications (seven in Israel and six from outside the country) resulted from duodenal tears which led to retroperitoneal perforations. Two of the fatalities were secondary to esophageal perforation. At least four of six cases of duodenal perforation reported from Israel involved patients with duodenal diverticula. Five of

EUS: Endoscopic ultrasonography.

eight fatal complications in Israel occurred during examinations by endoscopists who had performed fewer than 300 EUS procedures[38].

Other gastrointestinal perforations: EUS-related gastric and rectal perforation seems very rare. There is only one case of rectal perforation reported in the prospective German EUS registry[32]. One study of 2490 endorectal ultrasound examinations reported no procedure-related perforations[39]. One case of gastric perforation occurred in each of the German retrospective study[31] and the German prospective registry[32]. In all three cases of rectal or gastric perforations the indication for EUS was staging of a stenosing tumor[31,32]. A few pharyngeal and hypopharyngeal perforations have been reported as well[28,32]. Possible risk factors for EUS-related gastrointestinal perforations are summarized in Table 2.

Aspiration

For appropriate acoustic coupling of the scanner to the gastrointestinal wall, EUS textbooks suggest instillation of water into the gastric lumen for some indications (e.g., gastrointestinal cancer staging, examination of subepithelial tumors). In a Danish prospective study, tracheal suction was needed in 15 of 293 patients (5.1%), and one patient aspirated during the procedure (0.3%). However, the "water-in-stomach" method was only used in nine patients (3.1%)[30]. Only five cases of aspiration pneumonia have been reported following EUS[32,38,41].

Bacteremia

Few data are available concerning the frequency of bacteremia following diagnostic EUS without EUS-FNB. Janssen *et al*[42] investigated the incidence of bacteremia in 100 consecutive patients undergoing longitudinal diagnostic EUS using paired blood cultures: immediately before and again 5 min after EUS. Significant bacteremia (*Streptococcus viridans* and *Propionibacterium* species; *Streptococcus mitis*) occurred in only two patients (2%), both of whom underwent endosonographic staging of esophageal cancer (seven of nine patients with esophageal cancer did not experience bacteremia)[42]. Levy *et al*[43] noted transient bacteremia in one of 52 patients who underwent diagnostic EUS with a radial-scanning echoendoscope (1.9%). None of these three patients with bacteremia following diagnostic non-interventional EUS in the two studies developed symptoms of infection[42,43].

Hematogenous tumor cell dissemination

Hematogenous tumor cell dissemination has been documented in 11 of 45 patients (24%) following transrectal ultrasound (TRUS)-staging of rectal cancer. In 17 other patients (38%), circulating tumor cells were detected in peripheral blood samples before and after TRUS[44]. The clinical and prognostic significance of this observation is presently unclear, although data from the same group suggest that the detection of circulating tumor cells in blood samples of patients with stage Ⅱ colorectal cancer correlates with poor outcome[44]. However, a recent retrospective analysis of metastatic rates of locally advanced esophageal cancer showed no difference between those who required and those who did not require esophageal dilation to complete EUS staging[25]. Prospective data are needed to determine whether passage of an endoscope beyond a stenosing gastrointestinal tumor causes clinically relevant hematogenous tumor cell dissemination.

The influence of age on EUS complications

EUS is reported to be safe in pediatric and elderly populations. No complications were reported in five case series of EUS and EUS-guided procedures performed in a total of 166 children[45-49] plus several case reports. A retrospective analysis of EUS and EUS-FNB in 265 consecutive patients aged 80 years or older showed that diagnostic EUS is feasible and safe in geriatric patients[50]. Another study compared complications of endoscopic retrograde cholangiopancreatography (ERCP) and EUS in elderly (≥ 75 years, n = 184) and non-elderly (< 75 years, n = 816) patient cohorts. The EUS complication rate of 4.8% among elderly patients did not statistically differ from the 3.1% complication rate among non-elderly patients[51].

Results of large single-center and multicenter studies on complications of non-interventional diagnostic endoscopic ultrasonography (EUS), endoscopic ultrasonography-guided fine-needle biopsy (EUS-FNB) [endoscopic ultrasonography-guided fine needle aspiration (EUS-FNA) plus endoscopic ultrasonography-guided trucut biopsy (EUS-TCB)] and endoscopic ultrasonography-guided therapeutic interventions (EUS-I). [1]Without EUS-guided fine-needle biopsies and EUS-guided therapeutic interventions; [2]major complications only; 1 fatality due to pulmonary embolism; [3]EUS-guided trucut-biopsy (19 Gauge); [4]randomized controlled trial.

COMPLICATIONS OF EUS-FNB

Patients who undergo EUS-FNB are approximately ten times more likely to suffer complications or report symptoms following EUS compared to patients undergoing diagnostic non-interventional EUS (Tables 3 and 4)[30-32,36,59,60].

According to a recent systematic review of 51 EUS-FNB trials, the most common complications are post-procedural pain (34%), acute pancreatitis (34%), fever and infectious complications (16%), and bleeding (13%). Perforations and bile leaks are uncommon (3%). The overall complication rate of EUS-FNB in this systematic analysis of 10 941 patients was 0.98% (1.72% in 31 prospective studies). The procedure-related mortality was estimated at 0.02%[61].

Bacteremia and infectious complications

Bacteremia following upper gastrointestinal tract EUS-FNB appears to be rare. Its frequency has been investigated in three prospective studies of 202 patients[42,43,62]. In one study of 100 patients, all blood cultures obtained 30 min and 60 min after the procedure were negative, except in six patients in whom the culture was positive for coagulase-negative *Staphylococcus*, which the investigators regarded as contaminating and non-pathogenic[62]. Among 102 patients studied by Janssen *et al*[42] and Levy *et al*[43], five had bacteremia following EUS-FNB [three with *Streptococcus viridans*, one with *Streptococcus* group F (1), and one with *Gram-negative bacilli*]. No signs or symptoms of infection developed in these five patients. Large case series of EUS-FNB for solid pancreatic mass showed that 0.4% to 1.0% of patients experienced febrile episodes following the procedure[63,64]. In one patient undergoing EUS-FNA of a large pancreatic head mass, pyrexia and abdominal pain emerged followed by extensive acute portal vein thrombosis[65]. In addition to two cases of

fever after lymph node EUS-FNA which resolved with antibiotics[54,66], there have been 12 published reports of serious infectious complications following EUS-FNA or EUS-TCB of mediastinal lymph nodes. In one case, a mediastinal abscess developed after EUS-guided aspiration biopsy of a mediastinal lymph-node metastasis from hepatocellular carcinoma (HCC). The iatrogenic abscess was treated successfully by EUS-guided drainage and subsequent endoscopic closure of the resulting esophagomediastinal fistula[67]. Another mediastinal abscess developed following EUS-FNA of a mediastinal metastasis of malignant teratoma; the lesion required computed tomography (CT)-assisted drainage and subsequent thoracotomy[68]. Infectious mediastinitis has also occurred as a result of transesophageal EUS-FNA of an enlarged necrotic lymph node[69] and of a small benign lymph node in the aortopulmonary window[70]. Another case of mediastinitis after EUS-FNB for mediastinal lymphadenopathy developed as a consequence of perforation due to technical problems with the needle[71]. In one patient, EUS-FNA of a tuberculous subcarinal lymph node led to multiple symptomatic mediastinal-esophageal fistulae, which resolved in the course of tuberculostatic treatment[72]. Only one case has been published describing infectious endocarditis (*Streptococcus salivarius*) secondary to EUS-FNA of a mediastinal lymph node in an oncology patient[73]. Recently, five cases of mediastinal abscess have been reported following EUS-FNA in patients with sarcoidosis; four required surgical treatment[74].

There are six published reports of infection after EUS-FNA or EUS-TCB of subepithelial tumors. In one case, EUS-FNA of an esophageal leiomyoma caused severe intramural infection which resulted in esophagectomy[75]. In another case, fever developed 2 h after EUS-FNA of a large mesenchymal esophageal tumor, presumably due to left lobar pneumonia[41]. In the third case a large duodenal gastrointestinal stromal tumor (GIST) became infected with *Enterobacter cloacae* following EUS-FNA. The resulting abscess resolved following endoscopic transduodenal drainage and antibiotic treatment[76]. In a series of 52 consecutive EUS-TCBs of gastric subepithelial tumors, two cases of severe septic complications (*Streptococcus* sepsis and gastric wall abscess) occurred (3.9%)[77]. In our own series of 46 EUS-guided biopsies of hypoechoic subepithelial gastric tumors using a 19 G aspiration-needle, one extramural abscess and septic infection (*Morganella morganii*) developed in a patient with a large gastric GIST who was receiving 15 mg of prednisolone per day[78]. Despite the high colonization rate of the lower digestive tract lumen with pathogenic bacteria, EUS-FNB of (peri-)rectal and (peri-)colonic solid masses appears relatively safe. Only two cases of infectious complication following transrectal or transcolonic EUS-FNB of solid mass lesions has been published[79,80]. In a prospective risk assessment of bacteremia in 100 patients undergoing EUS-FNB of rectal and perirectal lesions, six patients developed positive blood cultures[81]. However, four of these cases were considered to be contaminants (coagulase-negative *Staphylococcus*, *Moraxella*, *Peptostreptococcus stomatis*). Two patients had true-positive blood cultures (*Bacteroides fragilis* and *Gemella morbillorum*). No immediate or delayed infectious complications occurred in any patient[81]. Five other studies (476 patients) showed no complications in patients who underwent transrectal or transcolonic EUS-FNB of solid masses[82-85].

In contrast, EUS-FNB of cystic lesions appears to carry a significant risk of severe infectious complications. In a large multicenter study of EUS-FNA, two of 18 patients undergoing EUS-FNA for cystic pancreatic lesions without peri-procedural antibiotics developed cyst infection[58]. Despite the large number of EUS-guided diagnostic procedures performed for cystic pancreatic lesions, there have been only four reports of infection after EUS-FNB performed with prophylactic antibiotics[52,86,87]. Of the 909 patients who underwent EUS-FNB of pancreatic cystic lesions included in the systematic review of Wang *et al*[61], 93.7% received prophylactic antibiotics (as recommended by the American Society of Gastrointestinal Endoscopy[88]), and the rate of cyst infection was estimated at 0.55%. However, there is no randomized prospective study supporting the utility of peri-procedural antimicrobial therapy. One recent retrospective study comparing the incidence of infectious complications after 263 EUS-FNBs of cystic pancreatic lesions for 88 cases with and 178 cases without antibiotic prophylaxis showed no significant difference[86]. The authors of one experimental study proposed to implement the combination of systemic antibiotics and local 5% povidone iodine during EUS-FNB of cystic lesions[89].

EUS-FNB of bronchogenic and other mediastinal cysts may cause cyst infection, mediastinitis and severe sepsis. Foregut duplication cysts account for 6% to 15% of primary mediastinal masses[90]. The differentiation between esophageal bronchogenic cysts and subepithelial tumors or paraesophageal masses may be difficult because of the hypoechoic and inhomogeneous mucoid content[91,92]. One study of 19 patients with bronchogenic cysts diagnosed by EUS demonstrated that 13 were anechoic, but the other six were hypoechoic, which suggested, erroneously in these cases, a solid mass lesion. CT or magnetic resonance imaging were diagnostic for a cyst in only four cases[93]. In another study, 9 of 27 benign mediastinal cysts were misdiagnosed as solid masses by CT[94]. Eight cases have been reported of mediastinitis following EUS-FNA or EUS-TCB of mediastinal mass lesions that were hypoechoic on EUS and had high CT attenuation values, but were later shown to be bronchogenic cysts. Because solid lesions were suspected, 5 of these patients did not receive antibiotics[36,92,93,95,96]. In three other cases, severe infection requiring surgical intervention occurred despite pre- and post-interventional intravenous antibiotics[97]. Moreover, one case of asymptomatic contamination of a mediastinal foregut duplication cyst with *Candida albicans* developed following pre-procedural antibiotic prophylaxis[98]. However, no infectious complications were seen among 22 patients who underwent transesophageal EUS-FNA of suspected mediastinal cysts using peri-interventional antibiotic prophylaxis[91].

In one recently published study on the utility of EUS-guided biopsy of extramural pelvic masses, two patients with cystic pelvic masses developed abscesses (7%)[99]. Also EUS-FNA of ascites and pleural fluid carries a risk of infection. Despite levofloxacin prophylaxis, one of 25 patients undergoing transgastric or transduodenal EUS-FNA of suspected malignant ascites developed bacterial peritonitis. Treatment with intravenous antibiotics was successful[100]. In another study, two of 60 patients (3%) developed self-limited fever following EUS-guided paracentesis[101]. Three other studies (47 patients) did not report any complications following EUS-FNA of ascites or peritoneal nodules in ascites in patients who did not receive prophylactic antibiotics[102-104].

Biliary peritonitis and cholangitis

Biliary peritonitis is a severe complication which may develop secondary to penetration or perforation of the common bile duct during EUS-FNB of a pancreatic mass in patients with biliary obstruction[105]. During a study to identify patients with microlithiasis as a cause of idiopathic pancreatitis, EUS-guided gallbladder bile duct aspiration resulted in biliary peritonitis in two of the three patients enrolled; these complications prompted the investigators to discontinue the study[106]. However, a recent systematic review of nine studies (284 patients) showed EUS-FNB of gallbladder masses or bile duct strictures to be safe, with no reported complications[107]. During an international survey of the indications, yield, and safety of EUS-FNB of liver lesions, one death due to septic cholangitis associated with EUS-FNB of a liver metastasis was reported. The patient who died had an occluded biliary stent, with biliary obstruction secondary to pancreatic cancer[108]. Mechanical irritation caused by the tip of the scope or by a water-filled balloon during pancreatic EUS may cause proximal or distal biliary stent migration, possibly followed by cholangitis[109].

Acute pancreatitis

Hyperamylasemia was common following pancreatic EUS-FNB in one recent prospective study, occurring in 11 of 100 patients. However, only two patients developed mild acute pancreatitis[110]. Nine large studies have reported iatrogenic acute pancreatitis following EUS-FNB of pancreatic lesions, with rates ranging from 0.19% to 2.0%[37,41,52,53,60,111-113]. A pooled analysis of 4909 solid pancreatic mass EUS-FNBs from 19 US centers identified 14 cases of iatrogenic post-procedural acute pancreatitis (0.29%)[114]. Among them, 71% were mild, 21% moderate, and 7% severe. One patient with significant co-morbidity died secondary to severe procedure-related pancreatitis. The frequency of acute pancreatitis at individual centers ranged from 0% to 2.35%. Only two centers (413 cases of pancreatic EUS-FNB, two cases of acute pancreatitis) assessed EUS-FNB complications prospectively. Some centers with retrospective complication assessment reported no cases of iatrogenic acute pancreatitis, suggesting that acute pancreatitis may have been underreported for the retrospective cohort. Interestingly, the survey showed that half of patients who developed acute pancreatitis after EUS-FNB had benign disease, suggesting that these patients may carry a higher risk. Another possible risk factor for iatrogenic acute pancreatitis following EUS-FNB is a history of acute recurrent pancreatitis[114]. In a German retrospective survey, eight of nine patients (86%) with reported acute pancreatitis after pancreatic mass EUS-FNB had benign disease[31]. In a large retrospective series of EUS-FNB for pancreatic cystic lesions, acute pancreatitis occurred in six of 603 cases (1%)[52]. A retrospective analysis of pancreatic EUS-FNB detected pancreatitis in three of 114 (2.6%) patients with cystic lesions, but none in the 134 patients with solid lesions[41].

Two studies have investigated the value of EUS-FNA and EUS-TCB in the diagnosis of chronic pancreatitis. Mild acute pancreatitis developed in two of 27 patients (7.4%) following EUS-FNA[115] and in one of 16 patients (6%) following EUS-TCB[116].

Pancreatic leak

This rare complication was reported only recently in two cases following EUS-FNA of pancreatic mass lesions. Both cases resolved after antibiotic treatment, transpapillary duct drainage and percutaneous drainage[117,118].

Hemorrhage

Self-limiting mild intraluminal bleeding due to EUS-FNB has been reported in up to 4% of cases[64] (Figure 2). A prospective study evaluating the risk of extraluminal hemorrhage caused by EUS-FNA found only three cases among 227 patients (1.3%)[119]. Extraluminal bleeding following EUS-FNB can be visualized clearly using EUS. Bleeding appears as an expanding hyperechoic or hypoechoic region adjacent to the sampled lesion[119]. Occasionally, color-coded Doppler may demonstrate blood flow within a "patent needle track" (Figure 3). In a retrospective survey of German EUS centers (13 223 EUS-FNB; Table 3), bleeding was the most common complication of EUS-FNB (0.15% of cases)[31]. Mild and self-limited bleeding was reported in 15 patients, whereas five patients suffered from severe hemorrhages requiring transfusion, and two of those patients required surgical intervention. One patient was treated with low-molecular-weight heparin (LMWH) immediately after the procedure and developed a large mediastinal hematoma and hemothorax; thoracoscopy and transfusion of seven units of packed red cells were required. Another patient required transfusion of four units of packed red cells following EUS-FNB of pancreatic head carcinoma with associated portal hypertension[31]. The prospective German EUS registry also showed that bleeding was the most frequent complication, reported in 1.4% of cases of EUS-FNB. However, 29 of 30 cases were judged to be mild, requiring no endoscopic intervention, surgery, or transfusion[32]. Patients with highly vascularized lesions (e.g., subepithelial mesenchymal tumors, neuroendocrine tumors, and some metastases), as well as those with cystic lesions, may be at greater risk. An Ital-

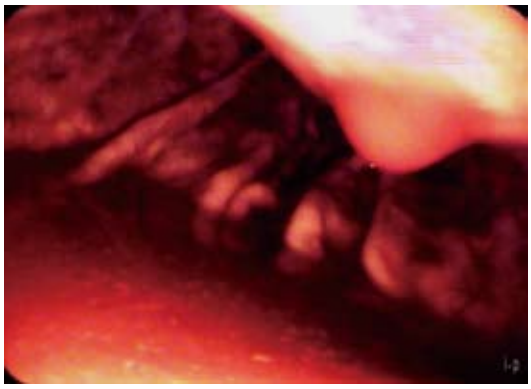

Figure 2 Intraluminal bleeding after endoscopic ultrasonography-guided fine-needle aspiration. Marked intraluminal bleeding occurred following 19 G endoscopic ultrasonography-guided fine-needle aspiration of a large, hypervascularized gastrointestinal stromal tumor in the stomach. Hemorrhage stopped without intervention.

ian multicenter retrospective study of EUS complications showed that three out of seven EUS-FNA complications were intracystic bleeding[59]. Three of 50 patients (6%) in a retrospective study developed acute intracystic hemorrhage following EUS-FNB of pancreatic cystic lesions[120]. Two patients experienced transient abdominal pain, and none of the three patients required blood transfusion. Intracystic bleeding episodes were readily recognized during the investigation as expanding hyperechoic areas surrounding needle puncture sites within the target cysts. Contributing risk factors could not be identified for the bleeding events[120]. In a large Italian single-center experience, bleeding was the most frequent pancreatic EUS-FNA complication (0.96%; n = 1034), with seven of ten cases occurring in cystic lesions[37].

A prospective analysis compared the risk of bleeding after EUS-FNA or EUS-TCB in patients taking non-steroidal anti-inflammatory drugs (NSAIDs), aspirin (ASA) or prophylactic LMWH to those who did not receive those medications[121]. Two of six patients (33.3%) receiving prophylactic LMWH developed extraluminal bleeding, compared to 0 of 26 patients receiving platelet inhibitors, and 7 of 190 patients (3.7%) not receiving those medications. There appears to be no increased bleeding risk during EUS-FNB for patients taking ASA or NSAIDs, but a possible risk for patients receiving prophylactic LMWH[121]. There are no published data regarding the risk of EUS-FNB in patients treated with clopidogrel and other thienopyridines. However, one study of patients undergoing transbronchial lung biopsy showed that clopidogrel, especially when combined with ASA, greatly increased bleeding risk[122].

There have been several case reports of severe bleeding associated with EUS-FNB, including hemosuccus pancreaticus in cystic pancreatic lesions[123], left adrenal gland hemorrhage[124], retroperitoneal bleeding following EUS-FNA of solid and cystic pancreatic lesions[59,125,126], mesenteric bleeding[127], and intramural bleeding following EUS-TCB of subepithelial tumors[78,96,128]. Three fatal cases of extraluminal bleeding have been reported

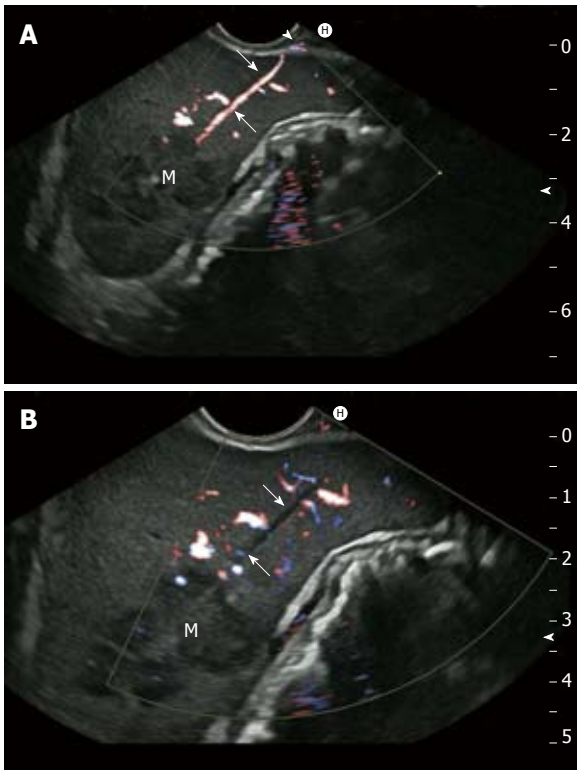

Figure 3 Extraluminal bleeding from needle track following endoscopic ultrasonography-guided fine-needle aspiration. Hemorrhage occurred immediately after endoscopic ultrasonography-guided fine-needle aspiration (22 Gauge) of a splenic metastasis (M) of gastric cancer. A: Note blood flow within needle track (arrows), which extends beyond the splenic capsule (arrowhead); B: Bleeding ceased spontaneously approximately 3 min later (no detectable flow within the needle track; arrows).

following pancreatic mass EUS-FNA. One patient developed uncontrolled bleeding from a pseudoaneurysm and died following EUS-FNB performed using a radial-scanning echoendoscope[129]. Another patient died in the consequence of massive gastrointestinal bleeding 6 h after EUS-FNA of a pancreatic cancer[31]. The third fatal outcome was observed after a 19 G EUS-FNA and intracystic brushing of a cystic pancreatic lesion in a patient receiving anticoagulation therapy. The patient died one month later due to a subacute retroperitoneal bleed related to the EUS-guided procedure and further complications[130].

Abdominal and thoracic pain, pneumothorax and pneumoperitoneum

Several studies have described abdominal pain (following EUS-FNB of pancreatic lesions and abdominal lymph nodes) or thoracic pain (following EUS-FNB of mediastinal lymph nodes and mediastinal mass lesions) without clinical, laboratory, or radiological findings suggestive of any specific complication[30,53,60]. One case of massive pneumoperitoneum due to transduodenal EUS-FNB of a solid pancreatic lesion resolved without any intervention other than antibiotics[131]. In the absence of clinical and radiological evidence of bowel perforation, the authors explained that the pneumoperitoneum resulted from

insufflated air tracking into the peritoneal cavity through the EUS-FNB site. They postulate that some patients with abdominal pain following EUS-FNB have unrecognized pneumoperitoneum[131].

Pneumothorax following EUS-FNB has been reported as one of three complications in a series of 159 EUS-FNBs for transesophageal biopsy of mediastinal masses[132].

Tumor cell seeding

Needle-tract seeding is a rare complication following FNB of intra-abdominal tumors. Based on large retrospective surveys, its frequency is estimated at 0.003% to 0.009%[133]. However, one prospective comparative study reported the incidence of needle-tract implantation of HCC and pancreatic carcinoma after ultrasound-guided percutaneous puncture to be 1.5%[134]. A systematic review and a meta-analysis of percutaneous biopsy of HCC reported tumor seeding frequencies of 2.29%[135] and 2.7%[136], respectively. After percutaneous biopsy of colorectal cancer liver metastases, the risk of needle-track metastases seems even higher, occurring in 10% to 19% of cases[133].

The actual frequency of EUS-FNB-related needle-tract seeding is unknown, but six published case reports have raised concern that the substantial rise of EUS-guided biopsies used to diagnose pancreatic masses and lymphadenopathy may increase the incidence of this complication. In one case, a large gastric wall implantation metastasis with retroperitoneal invasion (50 mm × 30 mm) was diagnosed 16 mo after potentially curative resection of a small (8 mm) T1N0M0 pancreatic tail carcinoma. The tumor had previously been sampled using transgastric EUS-FNA (with five needle passes)[137]. Two similar cases have been reported recently. In both cases, gastric wall metastases occurred at 26 mo and nearly 4 years after transgastric EUS-FNB and pancreatic surgery with curative intent for solid-cystic pancreatic cancer[138,139]. In the fourth case, transgastric EUS-FNB (one needle pass) of a melanoma metastasis to a perigastric lymph node was complicated by a large (30 mm) gastric implantation metastasis along the needle tract. It was detected and resected 6 mo later during surgical resection of lymph node metastasis following neoadjuvant chemotherapy[140]. A recent case report describes needle tract implantation metastasis of the esophageal wall following 19 G EUS-FNA of a large metastatic subcarinal lymph node metastasis of gastric cancer. The esophageal implantation metastasis developed despite perioperative systemic chemotherapy and disappearance of the subcarinal metastatic lymph node; fortunately, it resolved after 2 mo of radiotherapy[141]. The potential risk of peritoneal carcinomatosis due to transgastric EUS-FNA of pancreatic malignancies was highlighted by the case of peritoneal dissemination of an intraductal papillary mucinous neoplasm of the pancreas following EUS-FNA of the tumor[142]. Nevertheless, the risk of peritoneal carcinomatosis appears to be significantly lower with EUS-FNB compared to percutaneous needle biopsy under computed-tomographic or ultrasonographic guidance[143].

Recent data demonstrate vital tumor cell presence within gastrointestinal luminal fluid in 48% of patients with luminal cancers (resulting from tumor cell sloughing), as well as in 10% of patients who underwent EUS-FNB of pancreatic cancer lesions[144]. The importance of this finding with regard to potential tumor cell dissemination by EUS-guided transmural biopsy is speculative at this time. Whereas pancreatic head cancer EUS-FNBs are performed typically through the duodenal wall (which is later resected with the pancreatic head in cases of resectable cancers), pancreatic body and tail tumor EUS-FNBs are performed transgastrically, crossing the peritoneal structures of the Bursa omentalis. Due to the risk of tumor cell seeding along the needle tract, which is proven in principle by the above described case reports, the indication for preoperative EUS-FNB of suspected distal pancreatic cancer is controversial[145-147]. To date, prospective comparative studies of the long-term impact of pre-operative EUS-FNB of suspected pancreatic malignancies are lacking. A recent retrospective study investigated the long-term outcomes of patients undergoing distal pancreatectomy for primary pancreatic neoplasias, comparing patients who received (n = 179) and who did not receive pre-operative EUS-FNB (n = 51)[112]. After a 16-mo median follow-up, no local recurrences were detected within the gastric wall among 91 patients with adenocarcinoma or neuroendocrine tumors who underwent pre-operative EUS-FNB. Median disease-specific survival and recurrence-free survival in patients with pancreatic adenocarcinoma were not statistically worse in 57 patients with pre-operative EUS-FNB as compared with six patients without pre-operative transgastric biopsy. However, partial gastrectomy due to suspected infiltration of the gastric wall by pancreatic adenocarcinoma was performed only in patients with pre-operative EUS-FNB. The study authors expressed concern that surgical pathology showed direct transmural gastric invasion from the pancreatic primary site in six of these seven patients[112].

Postoperative complications

Scarce information exists regarding the potential impact of pre-operative EUS-FNB on complications of subsequent surgery. One study showed no correlation with overall morbidity, specific complications, or technical difficulties during distal pancreatectomy, when analyzed according to specific pancreatic pathology sub-classifications. However, subgroup analysis revealed a higher incidence of postoperative complications in patients with cystic neoplasms who underwent pre-operative EUS-FNB[112].

False-positive results

A false-positive diagnosis obtained from EUS-FNB may result in inappropriate treatment decisions, which could negatively impact the patient's clinical outcome. Therefore, we regard false-positive results as a major EUS-FNB complication in this review. The overwhelming majority of studies report EUS-FNB specificity and positive predictive value for detecting cancer at 100%. A thorough

review of EUS-FNB studies conducted in 2008 identified only ten studies (1750 cases) plus one case study that altogether reported 27 false-positive diagnoses using EUS-FNB[8]. In most of these cases, benign pancreatic diseases (chronic pancreatitis, intrapancreatic splenic heterotopia, mucinous cystic adenoma) were misdiagnosed as ductal adenocarcinoma or neuroendocrine pancreatic tumor[64,66,145,148-154]. However, few studies have correlated EUS-FNB findings with surgical pathology[149,150,155-158]. Therefore, the "true false-positive rate" of EUS-FNB was unknown until a remarkable 2010 study presented a more realistic picture[159]. A cohort of 337 consecutive patients with positive or suspicious EUS-FNB results underwent surgery in the absence of neoadjuvant therapy; there were 19 false-positive cases (5.6%) (based on "positive" cytopathological interpretations) and 25 false-positive cases (7.3%) (based on "positive" plus "suspicious" cytopathological findings), respectively. For pancreatic lesions, the authors reported a 2.2% rate of discordance between preoperative cytological diagnosis and subsequent surgical pathology. In this study, most discordant cases resulted from malignant cell contamination by luminal cancers (primarily esophageal) when performing EUS-FNB of nearby lymph nodes. Retrospectively, only 11 cases were identified as resulting from cytopathological interpretive error[159]. These results are supported by a retrospective cohort study of 367 patients who underwent surgical resection without previous neoadjuvant treatment[160]. This study showed a 1.1% false-positive rate of EUS-FNB for solid pancreatic lesions. When suspicious cytological findings were considered, the false-positive rate was estimated at 3.8%. On review of discordant cases, almost all were caused by pathological misinterpretation in the setting of chronic pancreatitis[160]. Another possible explanation for false-positive diagnosis by EUS-FNB may be inadvertent aspiration of contaminated luminal fluid or traversal of mucosal high-grade dysplasia or malignant infiltration of the gastrointestinal wall[144,161]. Malignant cells are identified within gastrointestinal luminal fluid not only in 48% of cases of luminal cancer, but also in 10% of cases of extraluminal (pancreatic) cancer undergoing EUS-FNB[144].

Safety of pancreaticobiliary tandem procedures and impact of prior biliary stenting on risks associated with EUS-FNB

Due to its high accuracy and lower complication rate compared to ERCP for suspected pancreaticobiliary disease (especially for obstructive jaundice), EUS and EUS-FNB should be performed first when possible. Moreover, biliary stent placement prior to EUS is believed to negatively affect the accuracy of endosonographic staging of pancreatic head malignancies[162]. To perform EUS, EUS-FNB and therapeutic ERCP in one session has advantages with regard to cost, total procedure time and workflow. Several studies have shown that single-session EUS and ERCP does not result in higher complication rates[163-168]. However, ERCP is more widely available than EUS and some cases (e.g., obstructive cholangitis) require biliary decompression more urgently than cytological diagnosis. Therefore, biliary stenting often precedes EUS-FNB. A recent retrospective comparative study showed that pre-EUS stenting of biliary obstructions due to pancreatic cancer did not increase the EUS-FNB complication rate. Moreover, the accuracy of tissue diagnosis was not impaired if ERCP and endoscopic stenting were performed more than one day prior to EUS-FNB[169].

Risk factors for EUS-FNB complications

Due to the relatively low number of complications associated with EUS-FNB, available studies are statistically underpowered to adequately address the question of risk factors. Endosonographer experience seems to be important. Of five nonfatal complications in a large multicenter EUS-FNA study (n = 457), none occurred during the last 12 mo of the study[58]. Similarly, the largest EUS-TCB study (n = 247) showed that all complications were observed among the first 100 patients[56].

There is no evidence that needle size affects complication rate. Only one retrospective multicenter study reported a complication rate of 2% in 540 patients undergoing 22 G EUS-FNA of solid pancreatic masses, versus 0% in 302 patients undergoing 25 G EUS-FNA[113]. Small prospective studies comparing needle sizes reported no complications in any group[170,171]. EUS-FNB using a 19 G needle, when combined with cytobrushing of pancreatic cystic lesions, conveys a significant complication risk associated primarily with cytobrush trauma to the cyst wall. In a prospective controlled study of 37 patients with 39 cystic pancreatic lesions, seven experienced complications (19%): one experienced severe bleeding and one experienced severe pancreatitis[172]. In another study using the same technique (n = 30), three patients experienced complications, including one case of fatal bleeding[130]. This procedure-related morbidity is considerably higher than the 2.2% to 5.2% complication rate reported in several EUS-FNB studies of cystic pancreatic lesions[54,86,87,173]. Nevertheless, the overall EUS-FNB complication rate seems higher for cystic than solid pancreatic masses[54,58,61]. In a systematic review which included 7337 EUS-FNBs of solid pancreatic masses and 909 EUS-FNBs of pancreatic cystic lesions, complications were reported in 60 patients with solid masses (0.82%; only prospective studies: 2.44%) and 25 patients (2.75%; only prospective studies: 5.07%) with pancreatic cystic lesions[61]. Data from the same systematic review confirmed that EUS-FNB is exceptionally safe for mediastinal lesions (n = 1310; complication rate: 0.38%), abdominal masses (n = 381; complication rate: 0.26%) and adrenal gland biopsies (n = 81; complication rate: 0%). EUS-FNB had an associated overall morbidity of 1.03% for pancreatic lesions (n = 8246; only prospective studies: 2.64%), 2.33% for liver lesions (n = 344), 2.07% for perirectal lesions (n = 193), and 3.53% for ascites (n = 85)[61].

Sedation-related complications and safety of propofol-based deep sedation

Safe and effective EUS and EUS-FNB performance re-

quire adequate sedation. Only a few studies report on the frequency of sedation-related complications in EUS and EUS-FNB. In the prospective German EUS registry, oxygen desaturation (SpO2 < 80%) was reported in 0.39% of patients, but most patients (94.4%) did not require intubation or mechanical ventilation[32]. A retrospective single-center study on the safety of nurse-administered propofol sedation for upper gastrointestinal EUS showed that 6 of 806 patients (0.7%) experienced declines in oxygen saturation (SpO2 < 90%), and four patients (0.5%) required assisted positive pressure ventilation[17]. Comparable results have been reported by other authors[174]. Several studies show that EUS with deep sedation using propofol (administered by an anesthesiologist, by a second gastroenterologist, or by a trained nurse) is as safe as conscious sedation using benzodiazepines (midazolam) and pethidine[174-177].

PREVENTION OF EUS-RELATED COMPLICATIONS

Strategies aimed to minimize potential risks of EUS and EUS-FNB include: (1) adequate education and examiner training; (2) familiarity of the endosonographer with the results of previous investigations and of possible therapeutic implications of EUS and EUS-FNB results; (3) appropriate consideration of the patient's clinical condition and of indications and contraindications for EUS and EUS-FNB; (4) careful consideration of a meaningful clinical strategy for investigating and treating each patient; and (5) optimization of prerequisites and conditions for the planned investigation or procedure[40].

We suggest the following measures, which seem appropriate to minimize the risks of EUS and EUS-FNB: (1) participation in supervised training programs in EUS and EUS-guided interventions. EUS and EUS-FNB are complex, technically demanding procedures in which the findings are difficult to interpret and which require advanced endoscopic skills, outstanding experience in diagnostic ultrasonography, and a fundamental understanding of the anatomy of the gastrointestinal tract and surrounding structures. The guidelines for credentialing and granting privileges for endoscopic ultrasound published by the American Society for Gastrointestinal Endoscopy recommend a minimum of 150 supervised EUS investigations, including 75 pancreatobiliary EUS investigations and 50 EUS-FNA procedures, to establish comprehensive competence in all aspects of EUS[178]; (2) specific guidelines for EUS training should be implemented in national gastroenterological societies' training programs[7,179,180]. Curricula of formal training programs should include sessions on complications and contraindications of EUS and EUS-FNB; (3) EUS and EUS-FNB should only be carried out in cooperative and adequately sedated patients. Oxygen saturation, heart rate, blood pressure and (whenever possible and necessary) electrocardiography should be monitored[181-183]; (4) water filling in the upper gastrointestinal tract should be restricted to the minimum amount necessary and the endoscopy unit and team should be prepared to perform nasopharyngeal suction; (5) in EUS examinations of the pancreas, biliary duct, ampulla, and duodenum in patients with biliary stents, the correct position of the stent should be checked prior to examination; (6) in the case of stenosing tumors and for specific anatomical locations (e.g., the tip of the duodenal bulb), care should be taken when maneuvering the echoendoscope. Dilation to achieve echoendoscope passage through malignant strictures should be carried out only in selected cases; (7) EUS and EUS-FNB are contraindicated in all patients and in all conditions in which the risks of the procedure outweigh the expected benefits of its diagnostic information (Table 5)[8,180]. According to recent guidelines, EUS-FNB of solid masses and lymph nodes may be performed in patients taking ASA or NSAIDs, but not in patients receiving: thienopyridines (clopidogrel, prasugrel, ticagrelor), oral anticoagulation, standard heparin treatment, LMWH or fondaparinux in therapeutic doses. EUS-FNB of cystic lesions should be avoided in patients taking any antiplatelet agent (e.g., ASA, thienopyridines). If EUS-guided sampling is indicated in a patient on LWMH, the biopsy should be performed no earlier than 8 h following the last administration of the drug[180,189,190]; (8) whenever possible, color-coded duplexsonography (CCDS) should be used before puncture to avoid vessels and highly vascularized structures in the needle trajectory; (9) before attempting EUS-FNB of large, solid-appearing mediastinal mass lesions, all appropriate methods (e.g., CCDS, contrast-enhanced endosonography (CE-EUS) and real-time elastography) should be used to exclude cystic lesions; (10) transgastric EUS-FNB of pancreatic masses should be restricted to those patients in whom definitive cytopathological diagnosis is likely to alter man-

Table 5 Contraindications to endoscopic ultrasonography and endoscopic ultrasonography-guided fine needle biopsy

Contraindications to EUS and EUS-FNB
Lack of informed consent[1]
Lack of cooperation or insufficient sedation[1]
Results of examination are unlikely to have a significant clinical impact[1]
Anticoagulation treatment or non-substituted coagulopathy (international normalized ratio > 1.5; platelet count < 50 000/mL; heparin administration at therapeutic doses)[2]
Inhibition of platelet aggregation by clopidogrel and other thienopyridines[2]
Failure of ultrasonographic needle control[2]
EUS-FNB of lesions upstream of a bile duct stricture which is insufficiently drained[2]
Cystic mediastinal and pelvic lesions[2,3]
Interposition of vessels[2,4]

[1]Contraindication to endoscopic ultrasonography (EUS) and endoscopic ultrasonography-guided fine needle biopsy (EUS-FNB); [2]contraindication to EUS-FNB; [3]relative contraindication, peri-interventional antibiotic treatment is mandatory; [4]relative contraindication, benefit has to be weighed carefully against risk. Transaortic endoscopic ultrasonography-guided fine needle aspiration of mediastinal lymph nodes and tumors[184,185] of the pericardium and a left atrial mass[186], and of intravascular tumors[187,188] have been reported without any major complications.

Table 6 Morbidity of diagnostic endoscopic ultrasonography compared to other endoscopic procedures (%)

Complications	Total	Bleeding	Perforation
Diagnostic esophagogastroduodenoscopy	0.009-0.2	0.002-0.06	0.0009-0.04
Diagnostic colonoscopy	0.02-0.25	0-0.03	0.005-0.2
Colonoscopy + polypectomy	0.36-9.7	0.26-8.6	0.06-1.1
Diagnostic ERCP	1.38	0	0.11
Therapeutic ERCP	5.0-9.8	0.49-2.0	0.3-0.8
EUS	0.03-0.15	0-0.03	0.03-0.15
EUS-FNB	0.3-6.3	0.15-3.7	0-0.86

Complication risk of non-interventional diagnostic endoscopic ultrasound (EUS) and endoscopic ultrasonography-guided fine-needle biopsy (EUS-FNB): compared to other endoscopic examinations and interventions (pooled data from literature, table adapted from: Jenssen, Mayr, Faiss and Nuernberg[40]). ERCP: Endoscopic ultrasonography-guided trucut biopsy.

agement significantly. In general, there is no indication for EUS-FNB of a pancreatic mass lesion that is typical of adenocarcinoma in patients who have no criteria of non-resectability[8,9,147,180]. Advanced EUS techniques (e.g., CCDS, CE-EUS, real-time elastography) may help to select resectable pancreatic masses that are atypical of ductal pancreatic adenocarcinoma[191-197]; (11) trucut needles should be used with caution in selected cases and indications. Although a prospective randomized study found no significant difference in the complication rates between EUS-TCB and EUS-FNA[57], the use of EUS-TCB is limited by technical drawbacks, especially for pancreatic head lesions[198]. Subepithelial tumors, unexplained gastrointestinal wall thickening, suspected malignant lymphoma, and suspected autoimmune pancreatitis are now emerging as special indications for EUS-TCB[8] or, alternatively, for a new type of aspiration needle that is suited to obtain core particles for histological evaluation[199]; (12) antibiotic prophylaxis should be administered in patients undergoing EUS-FNB of cystic lesions and fluid collections[88,100,180]. Some experts also recommend peri-procedural antibiotic prophylaxis for EUS-FNB of the perirectal space[200] and for EUS-TCB of subepithelial tumors[76]. However, there are no valid data supporting routine use of antibiotics for these indications; and (13) complications should be assessed in a prospective manner, and all complications should be analyzed. Prospective risk assessment is prerequisite to the prevention and analysis of complications. Careful prospective studies show higher EUS-FNB complication rates compared to retrospective studies (2.44% *vs* 0.35%)[61] (Table 4). The American Society for Gastrointestinal Endoscopy recommends that specific quality indicators (e.g., indications, sedation, immediate and delayed complications, procedure success) should be tracked routinely in all patients undergoing EUS[201].

In conclusion, diagnostic EUD is a safe procedure. The EUS complication rate of 0.03% to 0.15% is comparable to that of upper gastrointestinal tract diagnostic endoscopy (Table 6)[40,88,180]. Due to specific mechanical and optical properties of echoendoscopes, the risk of esophageal or duodenal perforation seems somewhat higher compared to esophagogastroduodenoscopy. The major risks of EUS-FNB are pain, acute pancreatitis, infection and hemorrhage[61]. Tumor cell seeding is exceedingly rare. The complication rate of EUS-FNB is 0.3% to 6.3%, which is comparable to that of colonoscopy with polypectomy (Table 6). Very few fatal complications of diagnostic EUS have been reported (overall mortality 0.02%)[31,38,61]. Adherence to guidelines on indications and contraindications, adequate education and training, prospective registration, and careful assessment of all complications are essential preconditions for enhancing safety and efficacy of EUS and EUS-FNB. A constructive process of continuous quality and safety assessment should be implemented in all centers performing endoscopic endosonography.

Abstract

Chronic hepatitis B virus (HBV) infection affects about 350 million individuals worldwide. Management of HBV infection in pregnancy is difficult because of several peculiar and somewhat controversial aspects. The aim of the present review is to provide a tool that may help physicians to correctly manage HBV infection in pregnancy. This review focuses on (1) the effect of pregnancy on HBV infection and of HBV infection on pregnancy; (2) the potential viral transmission from mother to newborn despite at-birth prophylaxis with immunoglobulin and vaccine; (3) possible prevention of mother-to-child transmission through antiviral drugs, the type of antiviral drug to use considering their efficacy and potential teratogenic effect, and the timing of their administration and discontinuation; and (4) the evidence for the use of elective caesarean section *vs* vaginal delivery and the possibility of breastfeeding.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection affects about 350 million individuals worldwide: half of them acquired the infection either perinatally or in early childhood, especially in endemic areas[1,2]. The estimated burden of death associated with HBV infection is 500 000-1.2 million per year. Progression of the disease towards cirrhosis, liver failure or hepatocellular carcinoma occurs in 15%-40% of infected subjects. The risk of chronic infection is inversely proportional to the age at which the infection was acquired[3].

HBV infection in pregnancy has several peculiar aspects among which are the effect of pregnancy on HBV infection, the potential viral transmission from mother to newborn and its possible prevention through antiviral drugs, and the potential teratogenic effect of these drugs. These elements can complicate the management of HBV infection in the setting of pregnancy[4]. The aim of this review was to examine recent studies devoted to the clini-

cal, therapeutic, and prognostic aspects of HBV infection during pregnancy in order to extrapolate and interpret data that can help physicians in the management of HBV infection in this setting.

EFFECT OF HBV INFECTION ON PREGNANCY

In most cases, acute or chronic HBV infection in pregnancy is similar to that in the general adult population: HBV infection does not increase the mortality and it does not yield teratogenic effects. However, a higher incidence of low birth weight and prematurity has been reported during acute infection than in the general population[1], whereas gestational diabetes mellitus, antepartum hemorrhage and preterm delivery are more frequent in chronic maternal HBV infection than in the general population[1]. Acute infection must be differentiated from other acute liver diseases that occur during pregnancy such as intrahepatic cholestasis[1].

Differently, the management of more advanced disease (cirrhosis) may be troublesome. Patients with advanced cirrhosis usually are amenorrheic and infertile due to hypothalamic-pituitary dysfunction, but successful pregnancy may be completed in those with well-compensated disease[5]. In these cases, increased maternal and fetal problems can be expected in about 50% cases, with increased fetal loss[5]. The main risk to the mother is rupture of esophageal varices and consequent bleeding (20%-25%) especially during the second trimester or during labor. Other risks include hepatic decompensation, jaundice, and rupture of splenic aneurysms[5]. In the presence of known esophageal varices, women planning a pregnancy should be considered for endoscopic therapy, shunt surgery, or even liver transplantation before pregnancy. Even if varices are absent before pregnancy, all patients should undergo upper endoscopy for assessment of varices in the second trimester and, if large varices are present, beta blocker therapy must be administered despite occasional fetal effects[5]. Acute variceal bleeding is managed endoscopically, as in the non-pregnant setting, though vasopressin is contraindicated. Ascites and hepatic encephalopathy are treated in the usual way (i.e., use of diuretics, rifaximin, lactulose, *etc.*). Except in patients with known large varices, a vaginal delivery is preferable to avoid abdominal surgery[5].

Pregnancy in a liver transplant recipient represents a unique clinical situation: with the success of liver transplantation, more pregnancies are being reported in liver recipients, and a carefully planned pregnancy in a stable healthy patient, beyond the first 2 years after orthotopic liver transplantation, can have an excellent outcome for fetus, mother, and the graft. However, this is still a high-risk pregnancy with increased fetal prematurity and dysmaturity[5]. In addition, it entails some risk to the allograft from acute cellular rejection or recurrent viral hepatitis[5,6].

EFFECT OF PREGNANCY ON HBV INFECTION

During pregnancy there are several modifications in the maternal immune system, namely, a shift in the Th1-Th2 balance towards a Th2 response, increased amounts of regulatory T cells, *etc.*, that contribute to a depressed immune response against HBV. The aim of these modifications is to prevent the rejection of the fetus who is partially allogenic for the mother's immune system. These modifications result in an increase of HBV DNA and a reduction of aminotransferase levels. After delivery the immune system is restored thereby causing opposite consequences; namely, there is a significant increase in alanine aminotransferase (ALT) and a reduction of HBV DNA in this period[7].

ter Borg *et al*[7] studied the course of the liver disease in 38 HBV-positive pregnancies before, during and after delivery. In 13 pregnancies, antiviral therapy with lamivudine was started during the last trimester of pregnancy due to high viremia to reduce the risk of mother-to-child transmission (see later) and was stopped immediately after delivery. Forty-five per cent of untreated women experienced a flare (defined as a three-fold increase in ALT) within 6 mo after delivery, compared to 62% of women who received lamivudine. No clinical decompensation occurred in these women. However, the authors recommend monitoring closely and, if necessary, administering treatment to women with chronic HBV shortly after delivery.

PERINATAL HBV TRANSMISSION

Perinatal transmission is a common mode of HBV transmission worldwide[1]. HBV infection in newborns is defined as hepatitis B surface antigen (HBsAg) positivity 6 mo after birth. Antibody to hepatitis B e antigen (anti-HBe) and anti-hepatitis B core antigen cross the placental barrier and disappear in nearly all babies before 12 and 24 mo of age, respectively[8]. Therefore, they simply represent the transplacental maternal antibodies and are not indicators of HBV infection status[8].

Without prophylaxis the risk of mother-to-child transmission is very high. It varies with the HBeAg/anti-HBe status of mothers, being 70%-90% for HBeAg-positive mothers, 25% for HBeAg-negative/HBeAb-negative mothers and 12% for HBeAg-negative/anti-HBe-positive mothers[9-12]. Maternal screening programs aimed at identifying HBsAg-positive mothers are part of pregnancy routine examinations in most countries. Once HBsAg-positive mothers are identified, their babies receive passive-active immunoprophylaxis at birth to reduce vertical HBV transmission[3]. Passive immunoprophylaxis consists of the administration of hepatitis B immune globulin (HBIG) whereas active immunoprophylaxis is the administration of hepatitis B vaccine[1,3].

Although this prophylaxis is effective in blocking HBV maternal transmission, a small but not negligible proportion of children (3%-13%) born from HBsAg-positive mothers, especially those carrying HBeAg, become HBsAg carriers despite correct passive-active immunoprophylaxis[1,10,12-14].

The biological explanation for the higher risk of transmission for HBeAg-positive mothers is that, differently from HBsAg, maternal HBeAg could pass through placenta from mother to fetus and induce T-cell tolerance *in utero*[8]. The intra-uterine infection of HBV, whose mechanism remains unclear, is the major cause of unsuccessful immunological blockade. High levels of serum HBV DNA in pregnant women is the main risk factor for the occurrence of HBV intra-uterine infection: it correlates with the cord blood HBV DNA level and HBsAg titer[12,15]. It has also been demonstrated that HBV can infect all kinds of cells in the placenta (decidual, trophoblastic, villous mesenchymal, villous capillary endothelial cells) and that HBV DNA is present in all generations of spermatogenic cells and sperms in HBV-infected males, in follicular fluid and in ovary (cellular transfer)[15,16]. The presence of the virus in the spermatogenic cells can have a role in the transmission of HBV infection to the newborn, as a high homology between the father's and the child's viral sequences in discordant couples has been found[16].

The maternal HBeAg-positive serological status and high viral load are associated positively with intrauterine transmission of HBV, especially through villous capillary endothelial cells. In fact, HBeAg can pass through the placenta *via* partial placental leakage or *via* the "cellular route"[17]. The absence of HBeAg expression is associated with lower levels of viral replication and with a significantly lower risk of intrauterine transmission of HBV[17].

TREATMENT OF HBV DURING PREGNANCY

All decisions about the treatment of HBV in pregnancy must include an analysis of the risks and benefits for the mother and fetus. The major issue regarding the mother is the consequences of the treatment on short- and long-term liver disease outcomes. The major concern for the fetus is the risk of exposure to potentially teratogenic drugs during early embryogenesis[18].

Seven drugs have been approved by the United States Food and Drug Administration (FDA) for the treatment of hepatitis B: PEG-interferon alpha 2a, interferon alpha 2b, lamivudine, adefovir, entecavir, telbivudine and tenofovir[3] (Table 1).

Interferon, contraindicated during pregnancy, can be used in women of childbearing age because it is usually given for a defined period (48-96 wk). The administration of interferon must be accompanied by the recommendation to use contraception during treatment[3,18].

The oral antiviral agents, namely nucleoside or nucleotide analogues that inhibit viral polymerase, are generally used for long periods. However, they also interfere with replication of mitochondrial DNA thereby resulting in potential mitochondrial toxicity; effects of which are poorly known in the developing fetus[18].

Table 1 Pregnancy category of antiviral drugs against hepatitis B virus

Drug	Pregnancy category
Lamivudine	C
Entecavir	C
Telbivudine	B
Adefovir	C
Tenofovir	B
Interferon alpha 2b	C
Pegylated-Interferon alpha 2a	C

The FDA classifies drugs in five categories (A, B, C, D and X) according to their possible teratogenic effects in humans or animal models. The 5 oral nucleos(t)ide analogues for HBV treatment are classified as either a category B or a category C agent. Category C drugs, namely lamivudine, adefovir and entecavir, are those that exert teratogenic or embryocidal effects in animals and for which there are no controlled studies in humans[16]. Lamivudine is highly toxic in rabbits with first trimester exposure; however, because it was the first oral agent approved for the treatment of HBV, extensive clinical experience indicates a general lack of teratogenetic effects in humans[18].

Category B drugs, namely telbivudine and tenofovir, are those that, according to the results of animal studies, carry no teratogenic or embryogenic risk and for which there have been no controlled human studies or for which animal studies may indicate a risk but controlled human studies refute these findings[19]. Tenofovir has both a high power and a high genetic barrier to resistance. Telbivudine has a high power, but a low barrier to resistance[18].

Safety data on HBV antivirals during pregnancy come from two major sources: the Antiretroviral Pregnancy Registry (APR) and the Development of Antiretroviral Therapy Study (DART)[20,21], due to the fact that some analogues are active both against HBV and against human immunodeficiency virus (HIV). The APR, an international, voluntary, prospective registry, has analyzed as of January 2010 a cohort of 11 867 women exposed to antiretroviral therapies, most of whom are HIV-1 monoinfected and only 112 of whom are HBV monoinfected. The results indicate that the rate of birth defects among women exposed to HBV therapy (2.7% of live births) is similar to that in the general population (2.72% rate) as reported by the Centers for Disease Control and Prevention (CDC) birth defect surveillance system. No significant difference was reported in the rate of adverse outcomes if the initial exposure of any HBV drug occurred in the first trimester (2.7%) compared to the second or third trimester (2.5%) of pregnancy. Lamivudine and tenofovir are the two agents with the most *in vivo* experience in the first trimester, and these appear to be

safe. For telbivudine and entecavir, only 5 and 12 pregnancies with exposure in the first trimester are recorded in this registry, with no adverse outcomes reported. The APR has some limitations: short follow-up and recording only defects identified at birth. Therefore, developmental anomalies (e.g., cardiac or neurologic defects) identified at a later date may be omitted[19].

The DART study is a 6-year, multicenter, randomized trial of antiretroviral therapy among adults with symptomatic HIV-1 infection or advanced disease/AIDS in Africa. The rate of congenital anomalies reported in this study is 3% and compares favorably to the 2.72% reported by the CDC birth defect surveillance system[21].

It is difficult to decide what anti-HBV therapy to administer in pregnant women. In addition to parameters usually considered in decision-making about hepatitis B therapy (age, stage of disease, comorbidity, viral load, genotype, power of the agent, genetic barrier to resistance, *etc.*), specific issues in the treatment choice for women of childbearing age include safety of drugs in pregnancy and breastfeeding, and proposed length of therapy[1].

In the case of untreated women who are "planning" a pregnancy, it may be prudent to delay therapy until after the child is born. For example, if the woman is in the immune-tolerant phase of infection (high HBV DNA levels with normal ALT and inactive liver biopsy), treatment can usually be postponed until after delivery. However, should the woman be HBeAg-positive with a high viral load, a 3rd trimester prophylaxis to reduce transmission could be initiated in case of pregnancy (see later)[3].

For pregnant women already in treatment, in the case of significant fibrosis, therapy should be continued to reduce the risk of decompensation of liver disease. This would have a negative impact on the health of the fetus. In this case, it is preferable to switch to an agent that is safe in pregnancy and which has a long *in vivo* experience in this setting[5].

In summary, the choice of the anti-HBV drug to administer in a pregnant woman depends on whether the aim of treatment is to treat an active liver disease for which therapy cannot be delayed, or to prevent transmission of infection to the fetus from high viremia mothers without significant liver disease. A third decision-requiring condition is that of women who become pregnant while on anti-HBV therapy in whom the drug can be continued, stopped or changed into a class B drug.

PREVENTION OF MOTHER-TO-CHILD HBV TRANSMISSION WITH ANTIVIRAL DRUGS

There is no consensus about the therapy choice for pregnant women who are HBsAg-positive and highly viremic in the third trimester to prevent perinatal transmission[18].

In a pilot study published in 2003, eight women with HBV DNA levels greater than 10^9 copies/mL were given 150 mg of lamivudine daily during the last month of gestation: babies received passive and active immunization and only one became infected, compared to 7 of 25 (28%) cases of transmission in a matched historical control population[22].

A randomized, double-blind, placebo-controlled trial conducted with 150 HBsAg-positive highly viremic pregnant women evaluated whether lamivudine administered from the 32nd week of gestation to 4th week post-partum prevented HBV transmission to newborns who received standard prophylaxis with HBIG and vaccination. All but one woman were HBeAg-positive. At 1 year of age, 18% of babies from lamivudine-treated mothers were HBsAg-positive compared to 39% in the placebo-treated arm in intention-to-treat analysis ($P = 0.014$). Based on these results, Xu *et al*[23] recommended treatment in the third trimester for women with high viral loads. However, these data should be interpreted with caution due to a high dropout rate (13% in the lamivudine group and 31% in the placebo group). No safety concerns were noted in the lamivudine-treated mothers and their infants.

A recent meta-analysis of 10 randomized controlled trials for a total of 951 HBV-positive mothers evaluated the efficacy of lamivudine in reducing *in utero* transmission of HBV[24]. The results confirm the safety of lamivudine and its efficacy in preventing HBV intrauterine infection and mother-to-child transmission. However, the limitation of meta-analysis is the different quality of the studies included and the heterogeneity of the cut-off values for high viral load that prompted therapy[24].

A non-randomized, controlled trial that included 190 HBsAg-positive, HBeAg-positive pregnant women with high viremia (> 10^6 copies/mL) evaluated the efficacy and safety of telbivudine *vs* placebo. In both groups, newborns were treated with standard active/passive prophylaxis within 24 h from birth. Telbivudine was given to mothers from 20 to 32 wk before delivery and was continued for 4 wk after delivery in the case of inactive disease and for 28 wk in the case of active chronic hepatitis. At birth, a significant reduction of HBsAg positivity rate was observed in babies born from telbivudine-treated mothers compared to the control group (6.3% *vs* 30.4%). Twenty-eight weeks after birth, the rate of HBsAg or HBV DNA positivity was significantly reduced in babies born from telbivudine-treated mothers compared to placebo-treated ones (2% *vs* 13%). Post-partum ALT flares occurred in 7.5% of telbivudine-treated women and in 18.5% of placebo-treated women. No safety concerns were observed for mothers or children in either group. No cases of severe hepatitis were observed in women who discontinued telbivudine at week 4 post-partum. These data confirm the need of antiviral therapy in HBeAg-positive pregnant women with high viremia (> 10^6 copies/mL) and the efficacy and safety of telbivudine in this setting[14].

Few data are available about the efficacy of tenofovir in pregnant women. Some information regarding toxicity of tenofovir comes from studies on animals, such

as gravid rhesus monkeys, which found a reduction of circulating insulin-like growth factor in newborns and severe growth reduction in approximately 25% of the infant monkeys within 2 mo of maternal treatment[25-27]. However, given its potency and its high barrier to resistance, tenofovir would be expected to be at least equally as effective as lamivudine in reducing perinatal transmission; it is an attractive agent to consider in the third trimester[18].

Regarding the issue of an HBV-infected male spouse who is planning a baby, no data are available in terms of drug safety to the fetus.

MANAGEMENT STRATEGY

A proposed strategy in summarized in Figure 1. Briefly, every woman in the first trimester should be screened for HBV infection. If she is negative, she does not have to be routinely vaccinated during pregnancy, although it is considered safe and should therefore be administered to those with high risk behavior for acquisition. Her child will be vaccinated for hepatitis B together with other routine vaccines. If the pregnant woman is positive in early pregnancy, it is necessary to understand the status of the disease. If she has very active HBV (significantly elevated ALT with a high viral load), or if cirrhosis is suspected, therapy should be initiated regardless of trimester. If the woman has inactive disease (low ALT and low viral load), therapy is not warranted and continued surveillance is suggested because of the risk of a flare of hepatitis B later in pregnancy and for several months postpartum[3,18].

Quantification of HBV DNA is recommended in all infected women at the end of the second trimester (at 26-28 wk of gestation): if the viral load is $>10^6$ copies/mL, antiviral prophylaxis of HBV transmission to newborn can be initiated early in the third trimester (28-30 wk), even though there is no consensus or guidelines on this topic, with consideration to the potential mitochondrial toxicity of all nucleoside/nucleotide analogues. Similarly, there is no consensus regarding discontinuation of the drug and the time of discontinuation. The decision should take into account the pre-pregnancy stage of liver disease because of the potential risk of flare. In the absence of active disease or cirrhosis at baseline, treatment discontinuation 4 wk after delivery is reasonable. If the patient has advanced liver disease we do not recommend discontinuation. It should be stressed that breastfeeding while on treatment for HBV is not recommended (see later)[3,18].

ELECTIVE CAESAREAN SECTION *VS* VAGINAL DELIVERY

A meta-analysis of four randomized trials, involving 789 pregnant women, assessed the efficacy and safety of elective caesarean section (ECS, caesarean section before labor or before ruptured membranes) *vs* vaginal delivery in preventing mother-to-child HBV transmission. It was found that ECS *vs* vaginal delivery significantly reduced the rate of maternal transmission of HBV (ECS: 10.5%; vaginal delivery: 28.0%) (relative risk: 0.41, 95% CI 0.28 to 0.60, $P < 0.000\,001$)[28]. No data regarding maternal morbidity or infant morbidity according to mode of delivery were available. However, the conclusions of the meta-analysis must be viewed with great caution given the high risk of bias in each study included in the analysis. The role of ECS in preventing mother-to-child transmission of HBV is uncertain. Currently, there is no convincing evidence that ECS reduces the rate of mother-to-child transmission of HBV compared with vaginal delivery[28].

BREASTFEEDING BY HBV-INFECTED WOMEN

In 1975, before the availability of neonatal immunization, Beasley *et al*[29] reported a rate of HBV acquisition of 53% in breast-fed and of 60% in formula-fed babies born to HBsAg-positive mothers. With the introduction of immunoprophylaxis, a similar rate of infection in breast-fed and formula-fed infants (0% and 3%) was found[30]. Although the high vertical transmission rates confounded the true rate of acquisition from breastfeeding, the current guidelines state that breastfeeding is not contraindicated in HBV-infected mothers who are not on antiviral therapy and whose infants receive immunoprophylaxis[31]. For mothers on antiviral therapy with lamivudine or tenofovir, breastfeeding is not recommended because few data are available about the safety of antiviral exposure during breastfeeding[18].

CONCLUSION

Testing for HBsAg is recommended for every pregnant woman, regardless of previous testing or vaccination. Identification of HBV-positive pregnant women remains the most effective way to prevent HBV transmission to newborns thanks to a very effective passive/active prophylaxis at birth. However, in the case of women with very high viremia, a non-negligible proportion of newborns can acquire the infection (probably through *in utero* transmission) despite the use of passive/active prophylaxis. For this reason, antiviral treatment in the third trimester can be considered for those women. The choice of antiviral should be restricted to those drugs considered safe in this setting. Decisions regarding the time of eventual discontinuation should consider the stage and activity of liver disease and of infection, taking into account also the risk of post-partum hepatitis flare. Breastfeeding is not contraindicated for HBV patients. However, it is not recommended for women taking antiviral drugs. Finally, there is no clear evidence that ECS reduces the risk of mother-to-child transmission compared to vaginal delivery.

Abstract

AIM: To evaluate the protective properties of novel prostone ClC-2 agonist SPI-8811 in porcine model of gastric acid injury.

METHODS: Porcine gastric mucosa was mounted in Ussing chambers and injured by bathing mucosal tissues in an HCl Ringer's solution (pH = 1.5) with or without SP1-8811 (1 μmol/L), cystic fibrosis transmembrane conductance regulator (CFTR) inhibitor (inhibitor 172, 10 μmol/L, apical) and ClC-2 inhibitor $ZnCl_2$, 300 μmol/L, apical), on the apical surface of tissues. Transepithelial resistance and mucosal-to-serosal ^{3}H-mannitol fluxes were measured over a 90-min period. Tissues were analyzed by morph metric techniques, Immunofluorescence and by western blots.

RESULTS: Compared with control tissues, acid exposure decreased transepithelial electrical resistance (TER) and increased ^{3}H-mannitol flux. Pretreatment of gastric mucosa with SPI-8811 was protective against acid-induced decreases in TER (TER, 50 $\Omega \cdot cm^2$ *vs* 100 $\Omega \cdot cm^2$) and abolished increases in flux (^{3}H-mannitol flux, 0.10 μmol/L·cm^2 *vs* 0.04 μmol/L·cm^2). Evidence of histological damage in the presence of acid was markedly attenuated by SPI-0811. Immunofluorescence and western analysis for occludin revealed enhanced localization to the region of the tight junction (TJ) after treatment with SPI-8811. Pretreatment with the ClC-2 inhibitor $ZnCl_2$, but not the selective CFTR inhibitor 172, attenuated SPI-8811-mediated mucosal protection, suggesting a role for ClC-2. Prostone may serve both protective and reparative roles in injured tissues.

CONCLUSION: ClC-2 agonist SPI-8811 stimulated enhancement of mucosal barrier function by protecting TJ protein occludin in porcine gastric mucosa and thus protected the gastric acid injury in porcine stomach.

INTRODUCTION

It is becoming increasingly evident that many patients suffer from gastric ulcers, particularly in groups of pa-

tients such as those in intensive care facilities[1-4]. This suggests that medications that provide gastro protection have the potential to reduce morbidity associated with gastric ulceration. For decades, agents that suppress acid secretion[5-7] have been widely used for treatment of gastric ulcers[1,7-10]. Gastric ulcer disease and repair is complex, involving inflammation, cell proliferation, formation of granulation tissue, and angiogenesis[3,4,11]. However, gastro protection has also been studied in depth. For example, studies with rebamipide or misoprostol, geranylgeranyl hydrochloride (HSP70) have revealed that these compounds have gastro protective properties as well enhancing ulcer healing[2,7,12]. Nonetheless, our understanding of the mechanisms of gastro protection is incomplete and there is the prospect of novel pharmacological agents, aside from antacids, proton pump inhibitors, and prostanoid activators or analogs, which might protect the stomach[12,13].

The gastric barrier is composed of a single layer of columnar epithelium, mucus, bicarbonate layer, and intraepithelial tight junctions (TJs) residing at the apicalmost region of the paracellular space. The gastric barrier serves as the first line of defense against a hostile luminal environment. The mucus bicarbonate barrier is the only pre epithelial barrier between lumen and the epithelium[14,15]. When it is overwhelmed or breaks down in disease, the next series of protective mechanisms come into play, including intracellular neutralization of acid, rapid epithelial repair, and maintenance and distribution of mucosal blood flow. There are two components of this innate mucosal defense: mechanisms that reduce the ability of pathogens and their toxins to invade the mucosa, and the mechanisms that ensure rapid repair of defects in the epithelial monolayer[3,4,15-17]. The next line of mucosal defense is formed by a continuous layer of surface epithelial cells which secrete mucus and bicarbonate and generate prostaglandins, heat shock proteins, refoil factor peptides, and cathelicidins. Because of the presence of phospholipids on their surfaces, these cells are hydrophobic, repelling acid- and water-soluble damaging agents. Interconnected by TJs, the surface epithelial cells form a "barrier" preventing back diffusion of acid and pepsin. Once the epithelial barrier is disrupted, epithelial repair mechanisms must rapidly re-form a continuous epithelial monolayer in order to prevent entry of protons and bacteria[3,4,14,15,18]. The remarkable phenomenon of epithelial restitution during which epithelium re-seals mucosal defects in the presence of acidic environment has been a subject of several studies.

Acid injury is an important component of gastric ulcer disease, despite more recent findings on the role of *Helicobacter pylori* which also contributes to this troublesome problem. Aside from injuring epithelium directly, acid causes disruption of interepithelial TJ protein complexes thereby increasing epithelial permeability[10,14,16,19]. Models assessing the mechanisms of intestinal injury have demonstrated that the critical event defining disruption of barrier function is the loss of TJ architecture and redistribution of TJ proteins such as occludin from the apical region of the interepithelial space to the cytosol[10,20-22]. In our previous work, we have demonstrated a critical role for Cl^- secretion in restoration of intestinal barrier function in ischemic-injured porcine ileum[21]. This appears to be attributable to activation of the Cl^- channel ClC-2, which is localized to the TJ[21]. More specifically, prior studies have shown that the nonselective secretory agonist prostaglandin E2 triggered rapid recovery of transepithelial electrical resistance (TER) and reduced mucosal-to-serosal fluxes of ^{3}H-mannitol in ischemic-injured intestinal mucus[20,22-24]. Previous studies have shown that activation of ClC-2 by the prostone Lubiprostone[22,25] enhanced recovery of barrier function in ischemic-injured porcine intestine. Cobiprostone (SPI-8811) is an investigational ClC-2 agonist prostone compound under development by Sucampo Pharmaceuticals Inc. (Bethesda, MD). Prostones are derived from fatty acids that are formed naturally within tissues. The present study was performed to evaluate the ability of the novel ClC-2 agonist SPI-8811 to provide gastro protection in acid-injured porcine gastric mucosa.

MATERIALS AND METHODS

Chemicals

$ZnCl_2$, Bumetanide, ^{3}H-mannitol, and cystic fibrosis transmembrane conductance regulator (CFTR) inhibitor 172 were purchased from Sigma-Aldrich (St. Louis, MO). SPI-8811 was provided by Sucampo Pharmaceuticals Inc., Bethesda, MD.

Experimental animals

All studies were approved by the North Carolina State University Institutional Animal Care and Use committee. Yorkshire crossbred pigs of either sex approximately 10-15 kg body weight were housed individually and maintained on a commercial pelleted feed. Pigs were held off feed, but had free access to water, for 12 h before each experiment. Anaesthesia was induced with xylazine (1.5 mg/kg, im) and ketamine (11 mg/kg, im), after which they were euthanized with pentobarbital (20 mg/kg, iv). The entire stomach was clamped proximally and distally with Doyen intestinal forceps.

Ussing chamber studies

After harvesting the entire stomach, it was sharply incised at the lesser curvature and washed in porcine Ringer's (mmol/L: 154 Na^+, 6.3 K^+, 137 Cl^-, 0.3 H_2PO_4, 1.2 Ca^{2+}, 0.7 Mg^{2+}, 24 HCO_3^-, pH 7.4) and maintained in oxygenated (95% O_2/5% CO_2) Ringer's solution. The fundus portion was isolated for Ussing chamber studies. After stripping the mucosa from the seromuscular layer by using blunt scissors, mucosa was mounted in 3.14 cm^2 aperture Ussing chambers. Gastric mucosa from individual pigs was mounted on multiple Ussing chambers and subjected to acid injury and select treatments. Tissues were initially bathed in 10 mL porcine Ringer's on both mucosal and serosal sides. The serosal bathing solution contained 10 mmol/L glucose to maintain tissue viability,

and this was osmotically balanced on the mucosal side with 10 mmol/L mannitol. Indomethacin (5 μmol/L) was added on the serosal and mucosal sides of gastric tissues to prevent prostaglandin production. Bathing solutions were oxygenated and maintained at 37 ℃ by water jacketed reservoirs. The spontaneous potential difference (PD) was measured *via* Ringer's-agar bridges connected to calomel electrodes, and the PD was short-circuited *via* Ag-$AgCl_2$ electrodes using voltage clamps that corrected for fluid resistance to measure short circuit current (Isc). Transepithelial resistance ($\Omega \cdot cm^2$ was calculated from the spontaneous PD and Isc. If the spontaneous PD was between -1.0 mV and +1.0 mV, tissues were current clamped at ± 100 μA for 5 s and the PD was recorded. Isc and PD were recorded at 15 min intervals over a 90 min experimental period.

Experimental treatments

Once tissues were mounted on Ussing chambers, treatments aimed at inhibiting ClC-2 ($ZnCl_2$, 300 μmol/L, apical), CFTR (inhibitor 172, 10 μmol/L, apical), or Na(+)-K(+)-2Cl(-) cotransporter (NKCC1) (bumetanide, 100 μmol/L, basolateral) were added. Alternatively, SPI-8811 was administered to the apical surface of tissues (1 μmol/L) to enhance epithelial Cl^- secretion *via* ClC-2. Following a 30 min equilibration period, HCl (1 mol/L in Ringer's) was added to the mucosal surface of the tissue to induce acid injury. The pH was monitored with a pH meter (Hanna Instruments Inc., Ann Arbor, MI, United States) and maintained the pH at 1.5 by adding 1 mol/L HCl as needed during the experiment.

Mucosal-to-serosal fluxes of ^{3}H-mannitol

To assess mucosal permeability, 0.2 Ci/mL ^{3}H-mannitol was placed on the mucosal side of tissues after experimental treatments. After a 15 min equilibration period, standards were taken from the mucosal side of each chamber and a 30 min flux period was established by taking 0.5 mL samples from the serosal compartments. The presence of ^{3}H was established by measuring emission in a liquid scintillation counter (Rack Beta, Perkin Elmer Life and Analytical Sciences, Boston, MA, United States). Unidirectional mucosal-to-serosal ^{3}H-mannitol fluxes were calculated using a previously established spreadsheet[17].

Histological analyses

Tissue samples were collected at 0, 30 and 90 min during the experimental period and fixed in 10% formalin for histological evaluation. Paraffin embedded samples were sectioned (5 μm) and stained with hematoxylin and eosin and periodic acid-schiff stain (PAS). For each tissue, mucosal epithelial lining and gastric pits (crypts) were identified to assess the damage caused by acid (pH 1.5).

Immunofluorescence labeling of occludin

For this procedure, tissues were embedded in optimal cutting temperature medium, frozen, and sectioned at 5 μm. Tissue sections were blocked with 2% Bovine serum albumin followed by incubation with rabbit anti-occludin polyclonal antibody (1:150, Zymed, San Francisco, CA, United States) overnight at 4 ℃. Sections were washed with PBS and incubated for 45 min with FITC-conjugated anti-rabbit secondary antibody. Sections were mounted in fluorescent mounting medium, and well-orientated gastric pits were examined with a photomicroscope linked to a digital camera.

Gel electrophoresis and Western blotting

Following Ussing chamber experiments, gastric mucosal samples were snap frozen and stored at -70 ℃ prior to performing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Tissue aliquots were thawed at 4 ℃ and added to chilled lysis buffer, including protease inhibitors (0.5 mmol/L Pefabloc, 0.1 mmol/L 4-nitrophenyl phosphate, 0.04 mmol/L glycerophosphate, 0.1 mmol/L Na_3VO_4, 40 μg/mL bestatin, 2 μg/mL aprotinin, 0.54 μg/mL eupeptic, and 0.7 μg/mL pepstatin A) (Sigma-Aldrich Inc., St. Louis, MO, United States) at 4 ℃. This mixture was homogenized on ice and then centrifuged at 4 ℃, and the supernatant was saved. Protein analysis of extract aliquots was performed (BCA Protein Assay Kit, Pierce, Rockford, IL, United States). Tissue extracts (amounts equalized by protein concentration) were mixed with an equal volume of 2 × SDS-PAGE sample buffers and boiled for 4 min. Lysates were loaded on an SDS polyacrylamide gradient gel, and electrophoresis was carried out according to standard protocols. Proteins were transferred to a polyvinylidene fluoride membrane (Immobilon®, Millipore, Billerica, MA, United States) by using an electro blotting minitransfer apparatus. Membranes were blocked at room temperature for 2 h in Tris-buffered saline plus 0.05% tris-buffered saline tween-20 and 5% dry powdered milk, and then incubated overnight in primary antibody at 4 ℃ in rabbit anti-rat ClC-2 (Alpha Diagnostics, San Antonio, TX, United States), rabbit anti-CFTR (Santa Cruz Biotech Inc., CA, United States) or rabbit anti-occludin (Zymed Laboratories Inc., San Francisco, CA, United States). After multiple washings in TBST, membranes were incubated with horseradish peroxidase conjugated secondary antibody, and developed for visualization of protein with luminol enhancer solution (Pierce, Rockford, IL, United States).

For preparation of detergent soluble and detergent insoluble fractions of gastric mucosa, the tissue samples were extracted in lysis buffer (20 mmol/L Tris, 5 mmol/L $MgCl_2$, 0.3 mmol/L EGTA, 210 μg/mL sodium fluoride, 18.5 μg/mL sodium orthovanadate, 30 mmol/L sodium pyrophosphate, and complete mini Protease inhibitor cocktail tablet (Thermo Fisher Scientific, Rockford, IL, United States). Following brief centrifugation to remove debris, Triton X-100 soluble and insoluble fractions were collected by incubation and centrifugation (50 000 *g* for 30 min at 4 ℃) with lysis buffer containing 0.5% Triton X-100 and 0.5% SDS, respectively. The samples were processed through an SDS sample preparation kit (Ther-

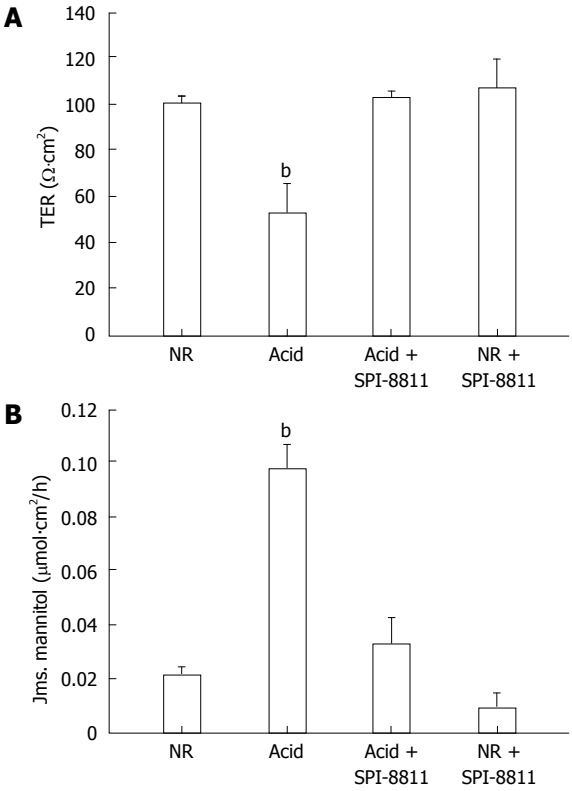

Figure 1 Barrier function of acid injured porcine gastric mucosa to pretreatment of SPI-8811 (1 μmol/L). A: Porcine gastric mucosa mounted on Ussing chambers challenged with mucosal acid (HCl, pH 1.5) over a 90 min period had significantly lower transepithelial electrical resistance (TER) (100 Ω·cm^2 *vs* 50 Ω·cm^2) when compared with control tissues bathed in normal Ringer's (NR). Mucosal application of the ClC-2 agonist SPI-8811 (1 μmol/L) prior to application of acid blocked reductions in TER (TER, 50 Ω·cm^2 *vs* 100 Ω·cm^2) .Values represent means ± SE, n = 8, $^bP < 0.01$ *vs* all other treatment groups; B: As an alternative assessment of gastric mucosal barrier function, mucosal-to-serosal fluxes of ^{3}H-mannitol were examined. In agreement with TER responses, ^{3}H-mannitol flux was significantly elevated by treatment with acid (^{3}H-mannitol flux, 0.02 μmol/L·cm^2 *vs* 0.10 μmol/L·cm^2), and this response was inhibited by SPI-8811. (^{3}H-mannitol flux, 0.10 μmol/L·cm^2 *vs* 0.04 μmol/L·cm^2). Values represent mean ± SE, n = 6, $^bP < 0.01$ *vs* all other treatment groups.

mo Fisher Scientific, Rockford, IL, United States) and a protein assay was performed before proceeding with western blotting.

Statistical analysis

Data were reported as mean ± SE. For Ussing chamber experiments, an experimental number of 6 was used. Data was analyzed by using an analysis of variance and *t*-test using a commercial statistical package (Sigmastat, Systat Software, San Jose, CA, United States). $P < 0.01$ and $P < 0.05$ were considered significant.

RESULTS

Acid injury model

To establish a gastric acid injury model, porcine gastric mucosa was mounted on Ussing chambers. After an equilibration period of 30 min the mucosal side was subjected to normal Ringer's (NR) solutions (pH 7.4) or HCl Ringer's (pH 1.5) for up to 180 min. Acid-bathed tissues had a significant decline in TER by 90 min and a further decline by 180 min (approximately 50% and 150% change in TER following 90 and 180 min of exposure to HCl, respectively, Figure 1A). Histological examination of the gastric mucosa exposed to acid for 90 min revealed injury that was limited to mucosal sloughing and partial damage to the gastric pits, resembling acute peptic ulcer disease. Alternatively, 180 min exposure to acid caused profound sloughing of the mucosal lining with damage extending into the gastric pits. Thus for further studies, gastric mucosa was exposed to HCl (pH 1.5) for 90 min to establish a more clinically relevant level of acid-induced gastric injury (data not shown).

Effects of the ClC-2 agonist SPI-8811 on TER and mucosal-to-serosal ^{3}H-mannitol fluxes in acid-injured porcine gastric mucosa

As previously described, porcine gastric mucosa was mounted on Ussing chambers and the mucosal surface was exposed to acid Ringer's (pH 1.5) for 90 min. Mucosa subjected to acid injury had significantly lower TER values when compared to the gastric mucosa bathed in NR, indicating electrophysiological evidence of disruption of epithelial barrier function. Alternatively, pretreatment of the apical side of gastric mucosa with the ClC-2 agonist SPI-8811 (1 μmol/L) nullified decreases in TER due to acid injury (Figure 1A). Epithelial permeability was assessed by mucosal-to-serosal fluxes of ^{3}H-mannitol in control and acid-injured tissues in the presence or absence of apical SPI-8811. In agreement with TER responses, acid-injured tissues exhibited increases in permeability to ^{3}H-mannitol as compared to control uninjured tissue. Pretreatment of the apical surface of mucosal tissues SPI-8811 ablated changes in permeability noted in untreated acid-injured tissues (Figure 1B).

Histological and Immunofluorescence microscopic findings in acid-injured gastric mucosa

Gastric mucosa from Ussing chambers after 90 min in NR revealed intact gastric pits with intact epithelial lining. Alternatively, when the gastric mucosa was exposed to acid (pH 1.5) over a 90 min period, extensive epithelial sloughing and erosion extending into the glandular region of the gastric mucosa and sub-epithelium was noted. Tissues pretreated with SPI-8811 had far lesser evidence of mucosal injury in response to acid, although the epithelium appeared to have flattened to maintain the barrier and the gastric pits appeared dilated (Figure 2A).

Using PAS staining for mucus we observed that the loss of mucus by acid injury was seen restored by pretreatment of ClC-2 agonist (Figure 2B). In further experiments, we performed Immunofluorescence of occludin to assess the gastric mucosal TJs. As compared to apical immunolocalization of occludin in the control uninjured gastric mucosal lining epithelium, acid-injured tissues revealed loss of occludin immunofluorescence (Figure 2C). In contrast, gastric mucosa pretreated with SPI-8811 and

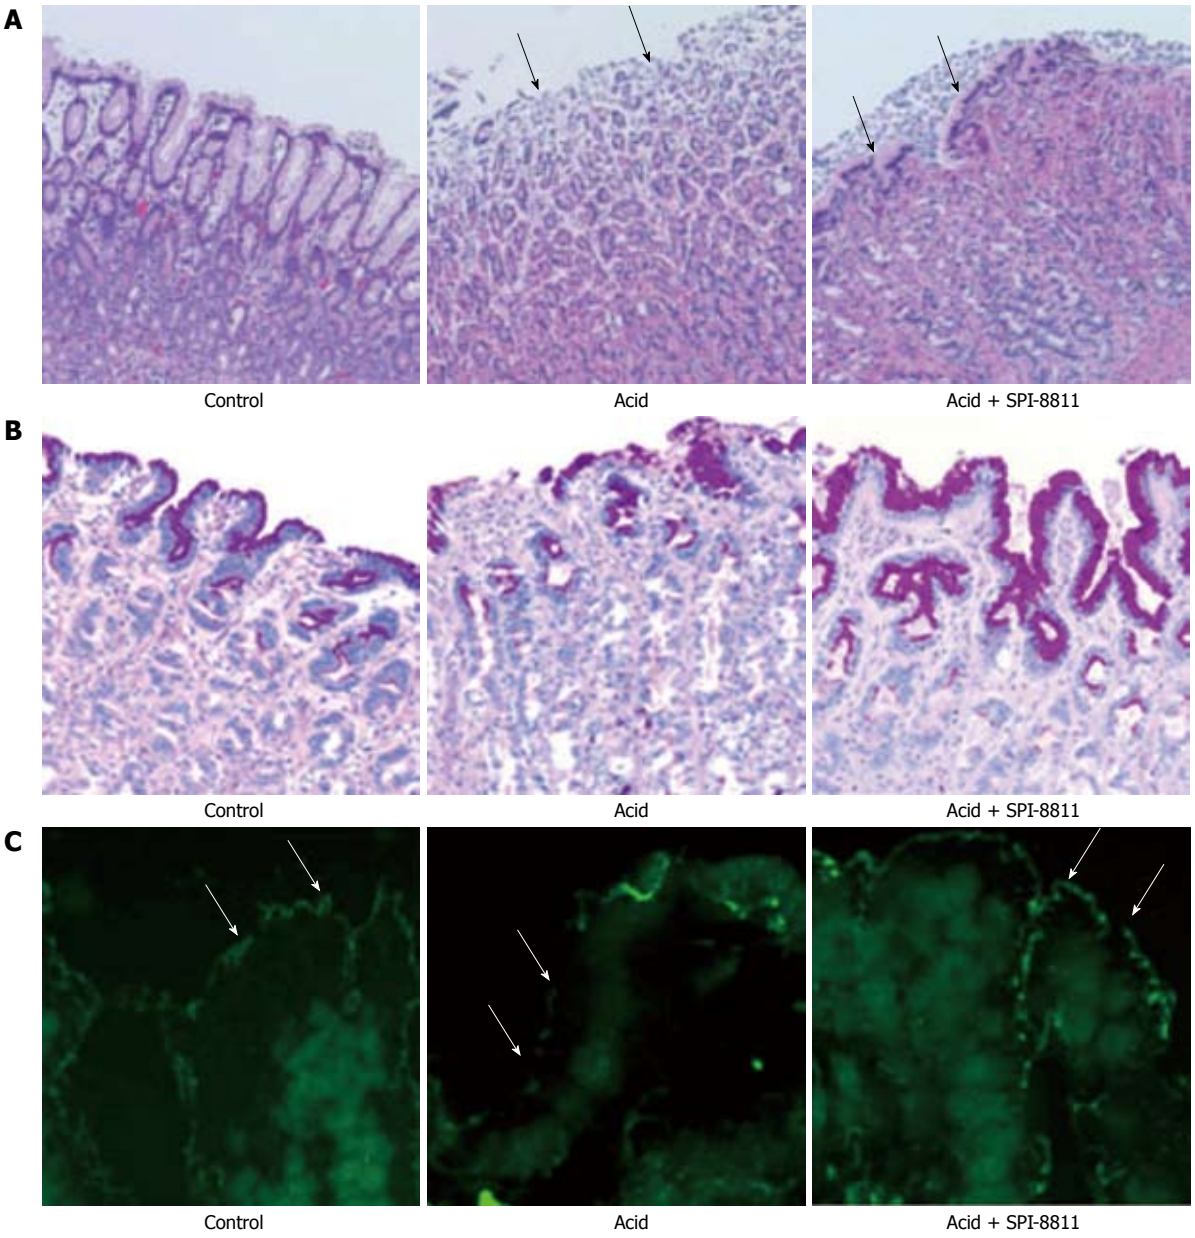

Figure 2 Histological findings in acid-injured gastric mucosal tissues. A: Tissues bathed in normal Ringer's appeared uninjured after 90 min in Ussing chambers, whereas those exposed to acid had substantial evidence of epithelial injury (× 100). Pretreatment with SPI-8811 ameliorated injury evident in acid-injured tissues. Each panel is representative of at least 3 separate animals; B: Periodic acid-schiff stain (PAS) staining findings in control tissues bathed in Ringer's solution for 90 min appeared to have normal expression of surface mucus by PAS-alcian blue staining whereas tissues exposed to acid had distinct loss to surface mucus staining (× 100). However, pretreatment with SPI-8811 prevented the loss of mucus in response to acid and thus preserved the surface mucus; C: Immunofluorescence findings for tight junction protein occludin reveals control tissues bathed in Ringer's solution for 90 min appeared to have normal immunolocalization of the tight junction protein occluding (green fluorescence) whereas tissues exposed to acid had very little visible apical epithelial occludin (× 200). However, pretreatment with SPI-8811 prevented the disorganized appearance of occludin in response to acid. Note the specific localization of occludin in each panel (arrows).

subsequently exposed to acid for 90 min had evidence of localization of occludin to the TJ.

Expression of occludin in gastric mucosal tissues

Since SPI-8811 prevented increases in paracellular permeability in response to acid, based on reduced ^{3}H-mannitol fluxes and apical epithelial localization of occludin, we evaluated expression of occludin. Occludin expression was studied in detergent soluble and detergent insoluble gastric mucosal fractions, using-actin expression as a loading control. Tissues exposed to NR had expression of multiple bands clustered at 65 kD in the detergent insoluble fraction. The finding of several bands for occludin at its expected molecular weight has been attributed to multiple occludin phosphorylation states[26]. The presence of occludin solely in the insoluble fraction was interpreted as an indication of this protein's propensity to localize to the TJ. In contrast to tissues bathed in NR, there was very little expression of occludin in acid-treated tissues, possibly because acid injury was severe enough to cause surface epithelium and interepithelial TJs. On the other hand, occludin expression in the detergent insol-

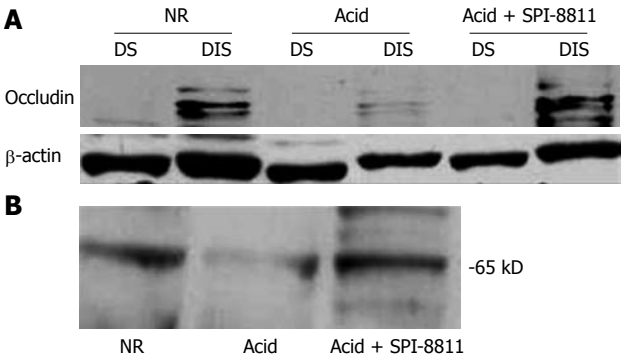

Figure 3 Expression of tight junction proteins in membrane fractions in acid injured porcine gastric mucosa. A: Western analysis revealed expression of occludin in the detergent insoluble in tissues treated with normal Ringer's (NR) alone, with very little discernable occludin in the detergent soluble fraction. On the other hand, treatment with acid (pH of 1.5 for 90 min) markedly reduced the expression of occludin in the detergent insoluble fraction, with a similar lack of occludin expression in the detergent soluble fraction. Pretreatment of tissues with mucosal SPI-8811 resulted in expression of occludin in the different fractions to a very similar extent as control tissues; B: Western analysis revealed expression of whole occludin in either control, acid injured and SPI-8811 pretreated and acid injured porcine gastric mucosa from Ussing chambers. Acid injury markedly reduced expression of whole occludin compared to control while pretreatment with SPI-8811 preserved the loss of occludin from acid injury. DS: Detergent soluble; DIS: Detergent insoluble.

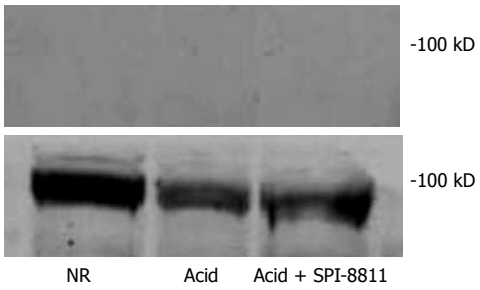

Figure 5 Expression of ClC-2 protein in porcine mucosa. Mucosal homogenates from porcine stomach were studied for expression of ClC-2 by western blotting. Expression of ClC-2 protein at its expected molecular weight (98 kD) was evident in all lanes. However, there appears to be greater expression of tissues bathed in Ringer's solution as compared to those subjected to acid or acid and SPI-8811 (n = 3). NR: Normal Ringer's.

uble fraction of tissues treated with SPI-8811 appeared similar to tissues treated with Ringer's solution alone, suggesting this prostone prevented loss of occludin. Cellular expression of occludin as a whole was also seen markedly reduced compared to control tissue and this loss was prevented with pretreatment with SPI-8811(Figure 3).

Role of Cl channels in SPI-8811-mediated protection of TER and barrier permeability in acid-injured gastric mucosa

To explore the potential role of Cl^- secretion in SPI-8811-associated gastro protection, mucosa was treated with the NKCC1 inhibitor bumetanide (100 μmol/L, basolateral) and SPI-8811 (1 μmol/L, apical), which blocked the ability of SPI-8811 to reduce acid injury (data not shown). In more targeted studies in tissues pretreated with SPI-8811, tissues were pretreated with pharmacological inhibitors of the apical chloride channels ClC-2

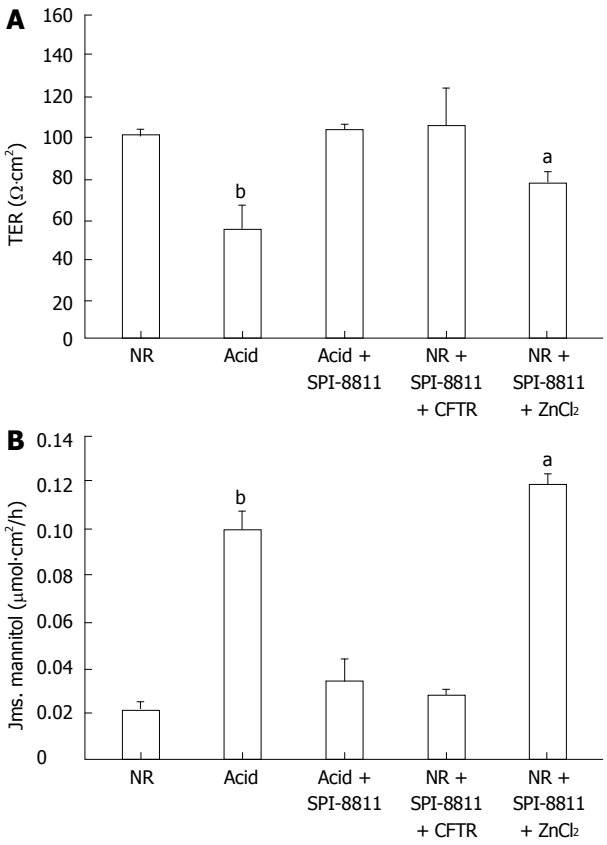

Figure 4 Electrical responses and ^{3}H-mannitol fluxes of acid-injured porcine gastric mucosa. A: Porcine gastric mucosa exposed to acid (pH 1.5 for 90 min) exhibited a significant drop in transepithelial electrical resistance (TER), which was completely blocked by pretreatment with SPI-8811. In attempt to discern which chloride channel was involved in the gastro protective mechanism of SPI-8811, ClC-2 and cystic fibrosis transmembrane conductance regulator (CFTR) were inhibited. Addition of the ClC-2 inhibitor $ZnCl_2$ ameliorated the protective effect of SPI-8811 (TER, 100 Ω·cm^2 *vs* 80 Ω·cm^2) whereas the CFTR inhibitor CFTR inhibitor 172 had no effect (TER, 100 Ω·cm^2 *vs* 100 Ω·cm^2). Values represent mean ± SE, n = 6; $^aP < 0.05$, $^bP < 0.01$ *vs* all treatment groups; B: As an alternate measure of barrier permeability mucosal-to-serosal of ^{3}H-mannitol flux were performed, and reveled a significant increase in mannitol permeability in acid injured tissues ($^bP < 0.01$). Pretreatment with SPI-8811 blocked the increase in ^{3}H-mannitol flux caused by acid injury, whereas blockade of ClC-2 inhibitor $ZnCl_2$ block the protective effect of SPI-8811 (^{3}H-mannitol flux, 0.04 μmol/L·cm^2 *vs* 0.12 μmol/L·cm^2, $^aP < 0.05$) on permeability but CFTR inhibitor had no effect on the level of protective properties of SPI-8811 on permeability (^{3}H-mannitol flux, 0.04 μmol/L·cm^2 *vs* 0.05 μmol/L·cm^2, $^bP < 0.01$). Values represent mean ± SE, n = 6. NR: Normal Ringer's.

and CFTR. Pretreatment of acid-injured mucosa with the ClC-2 inhibitor $ZnCl_2$ (300 μmol/L, apical) abolished the gastro protective properties of SPI-8811 as determined by change in TER and mannitol fluxes. On the other hand, pretreatment with CFTR inhibitor 172 (10 μmol/L, apical) had no effect (Figure 4).

Expression of ClC-2 and CFTR in porcine gastric mucosa

The literature is not clear about the expression of ClC-2 and CFTR in the porcine gastric mucosa, aside from a few studies that describe gastric mucosal changes in CFTR mouse mutants[19]. Therefore, western analyses were performed to study the expression of ClC-2 and

CFTR in porcine gastric mucosa. As shown in Figure 5, ClC-2 was expressed approximate 98 kD in porcine gastric homogenates. ClC-2 expression was observed in porcine gastric mucosa which confirmed the expression of ClC-2 in porcine stomach (Figure 5). Western analyses showed no evidence of CFTR in gastric mucosa, whereas CFTR was clearly present in porcine jejunum as a positive control (data not shown).

DISCUSSION

Prior studies have provided evidence for a critical role of ClC-2 in the recovery of mucosal barrier function in ischemic-injured intestine[20,21,27,28]. For example, Lubiprostone has been shown to interact with ClC-2 channels and enhance repair of the epithelial barrier after acute injury by ischemia[22,25,29,30]. The aim of the present study was to determine if an alternate prostone, SPI-8811, had a protective role against mucosal injury, and we chose to investigate this in the stomach. Acid plays an integral role in gastric mucosal ulceration[1,3,4,8,15,24,31]. Considering the physiological presence of acid to aid digestion in the stomach, mechanisms to provide gastro protection against injury in predisposed patients are critical. To date, this has principally included agents that ameliorate acid secretion. However, according to the results of the present study, prostones appear to provide protection in the face of low levels of pH, which would allow for continued acid secretion for normal digestive processes. Acid causes injury to the gastric mucosa in part by disrupting the TJ protein complexes, thereby increasing epithelial permeability. This in turn allows further injury by permitting permeability to luminal acid, ultimately causing erosion and then ulceration as the mucosa becomes progressively disrupted[3,14,24,32]. Among the established methods to study gastro protection and acute gastric injury are the direct application of acid or ethanol to gastric mucosa[8,31].

The first aim of our study was to produce acute acid injury resembling ulceration in clinical patients in order to study gastro protection. Accordingly, acid Ringer's solution was applied to the mucosal surface as previously described[33]. To mimic peptic ulcer disease, the body of the porcine stomach was used in this study. Optimum gastric injury was achieved (based on TER and histological examination) with a pH of 1.5, over a time period of 90 min. In each of the experiments, SPI-8811 was applied to the gastric mucosa prior to acid injury on the apical surface. Earlier studies have shown that Lubiprostone activates Cl^- secretion by a mechanism associated with recruitment of the TJ occludin in porcine intestine, thereby aiding recovery of barrier function[9,22,34,35]. Gastric mucosa was pretreated with SPI-8811 prior to induction of acid injury and showed evidence of gastro protection as evidenced by blockade of changes in TER and mannitol fluxes in tissues exposed to acid. In addition, histological changes in response to acid were ameliorated by SPI-8811. Because of the important role of TJs in maintenance of barrier function, we also examined the localization of occludin in tissues pretreated with SPI-8811 and exposed to acid. Tissues injured by acid alone appeared to have complete loss of apical epithelial occludin, possibly because of loss of cells due to severe injury, whereas tissues pretreated with SPI-8811 had evidence of apical epithelial occludin similar to that of control tissues. Further studies evaluating detergent soluble and insoluble fractions using western analyses confirmed the loss of occludin in tissues treated with acid. The reason for the loss of occludin, rather than intracellular movement of occludin, is unknown. The simplest explanation would be that the extensive reduction in pH resulted in loss of TJ proteins into the lumen, followed by erosion of epithelium and ultimately ulceration. Tissues pretreated with SPI-8811 evaluated by immunofluorescence were protected from this effect, with localization of occludin to the apical epithelium similar to that of control tissues. Additionally, occludin remained in the detergent insoluble fraction in western analyses under the influence of SPI-8811 indicating localization to the TJs.

The next aim of the study was to investigate the role of Cl^- channels in gastro protection, given that SPI-8811 is a purported Cl^- secretagogue. Because ClC-2 has been shown to be localized to interepithelial TJs in intestinal studies[22], and in gastric mucosa in the parietal cells[29,36] is a target for the prostones, we were particularly interested in this channel. The CFTR served as an alternate possibility. Our data demonstrated that SPI-8811-mediated gastro protection against acid injury was attenuated by the ClC-2 inhibitor $ZnCl_2$ whereas the selective CFTR inhibitor 172 had no effect. Although CFTR is difficult to pharmacologically inhibit, our Western analyses showed a lack of CFTR expression in porcine gastric mucosa as compared to robust expression in jejunal mucosa. In previous studies, investigators have shown that CFTR knockout mice are vulnerable to gastric ulcers due to loss of bicarbonate secretion. The lack of CFTR in porcine gastric mucosa especially in the fundus of stomach might partially explain susceptibility to acid injury in the present studies[32]. Taken together, these studies suggest that activation of ClC-2 by SPI-8811 is integral to the mechanism of gastro protection. Further studies will be required to understand the mechanisms underlying these findings.

There are opposing views regarding the role of ClC-2 in gastric chloride secretion[29,36,37] suggested involvement of ClC-2 in gastric acid secretion while another other group[38], Indicated that ClC-2 chloride secretion plays no role in production of HCl. It is also noteworthy that the apical ClC-2 channel has been suggested to serve as a route for both bicarbonate and Cl^- exit into the lumen[29,39]. This raises the possibility that ClC-2-mediated bicarbonate secretion attenuates acid injury to some extent by raising the pH. However in our studies, constant monitoring and adjustment of pH to a level of 1.5 would nullify this possibility. We also found that SPI-8811 produces a gastro protective effect not only *via* increasing gastric pH, but also by protecting and restoring the gastric mucus level (Figure 2B). The importance of gastro protection *via* mucus protection has been previously shown[7,40,34].

ClC-2 localizes to the TJ in the intestine[21,27,28,41] and this localization facilitates the interactions with TJ proteins and associated regulatory molecules. For example, recent studies have shown that ClC-2 is required for rapid reassembly of TJ proteins after ischemic injury in murine intestine[27]. The rapid process of repair is a hallmark of gastric mucosal barrier function, and may involve rapid restoration of TJs during restitution. Although this study does not completely answer questions as to the mechanism of SPI-8811, it does provide convincing evidence for the ability of SPI-8811 to protect the gastric mucosa against acid, and it does suggest this activity is at least in part attributable to a mechanism related to ClC-2 regulation.

COMMENTS

Background

Important gastric diseases such as peptic ulcer disease are aggravated by acid secretion. Injury caused by acid is characterized by damage to the gastric epithelium lining the gut. Mechanisms are in place to rapidly repair epithelial defects, and prevent epithelial barrier dysfunction and thus protect the gastric mucosa and further acid injury. Currently studies have shown the importance of the interepithelial tight junctions (TJs) in recovery of the epithelial barrier. Studies, particularly in the intestine, have shown particularly in that prostones increase the rate of epithelial recovery *via* re-assembly of TJs.

Research frontiers

The prostone lubiprostone, a new medication on the market indicated for the treatment of chronic constipation and irritable bowel syndrome has its effect on the chloride channel ClC-2. This channel is unusual in that it is located within TJs. These channels are involved in secretion of chloride in the intestine, but until now very little was about the role of ClC-2 in the stomach. Recent studies have shown that ClC-2, when activated by prostones, play an important role in re-assembly of TJs, resulting in increased rate of epithelial repair in the intestine. This study was performed to see if a prostone (cobiprostone, SPI-8811) hastened repair in the gastric mucosa *via* a mechanism involving TJs.

Innovations and breakthroughs

Activation of one of the chloride channels, ClC-2, is an innovative way to induce reassembly of TJs during repair of the epithelial mucosal barrier. Gastric epithelium is continuously exposed to gastric acid and in the case of peptic ulcer disease the gastric acid secretion disrupts the barrier and thus aggravates the condition. In such cases, reducing acid secretion by using various acid secretory antagonists is the most common way to prevent gastric injury. Other alternatives to prevent breakdown of the gastric barrier function are limited. The present data show an innovative breakthrough in the treatment of acid induced gastric epithelium. The authors' findings were consistent with prior studies showing enhanced repair with prostones in the intestine at the level of TJs.

Applications

By understanding the role of prostone activation of ClC-2 in acid injured gastric porcine mucosa, this study might represents a future strategy to therapeutic intervention in patients with non-steroidal anti-inflammatory drugs injury and peptic ulcer disease. Further basic science research followed by clinical trials will be needed to determine the validity of these findings.

Terminology

The term ClC-2 is used to describe a chloride channel in the gut epithelium that is localized to interepithelial TJs. The term prostone refers to a new group of compounds which are distinct from prostaglandins and specifically activate ClC-2.

Peer review

The present study was performed using porcine tissues; it demonstrates that the novel ClC-2 agonist SPI-8811 stimulates recovery of barrier function in acid injured porcine gastric mucosa by preventing loss of the TJ protein occludin. The data were appropriately analyzed and indicate SPI-8811 has an impact on protecting epithelial barrier function by preventing breakdown of TJs and thus prevent further deep injury. Additional molecular studies need to be performed to understand how ClC-2 interacts with prostones to protect the epithelial TJs.

Abstract

AIM: To examine whether the *ob/ob* mouse model of obesity is accompanied by enteric nervous system abnormalities such as altered motility.

METHODS: The study examined the distribution of the P2X$_2$ receptor (P2X$_2$R) in myenteric neurons of female *ob/ob* mice. Specifically, we used immunohistochemistry to analyze the co-expression of the P2X$_2$R with neuronal nitric oxide synthase (nNOS), choline acetyltransferase (ChAT), and calretinin (CalR) in neurons of the small intestine myenteric plexus in *ob/ob* and control female mice. In these sections, we used scanning confocal microscopy to analyze the co-localization of these markers as well as the neuronal density (cm^2) and area profile (μm²) of P2X$_2$R-positive neurons. In addition, enteric neurons were labeled using the nicotinamide adenine dinucleotide (NADH) diaphorase method and analyzed with light microscopy as an alternate means by which to analyze neuronal density and area.

RESULTS: In the present study, we observed a 29.6% increase in the body weight of the *ob/ob* animals (OG) compared to the control group (CG). In addition, the average small intestine area was increased by approximately 29.6% in the OG compared to the CG. Immunoreactivity (IR) for the P2X$_2$R, nNOS, ChAT and CalR was detectable in the myenteric plexus, as well as in the smooth muscle, in both groups. This IR appeared to be mainly cytoplasmic and was also associated with the cell membrane of the myenteric plexus neurons, where it outlined the neuronal cell bodies and their processes. P2X$_2$R-IR was observed to co-localize 100% with that for nNOS, ChAT and CalR in neurons of both groups. In the *ob/ob* group, however, we observed that the neuronal density (neuron/cm^2) of P2X$_2$R-IR cells was increased by 62% compared to CG, while that of NOS-IR and ChAT-IR neurons was reduced by 49% and 57%, respectively, compared to control mice. The neuronal density of CalR-IR neurons was not different between the groups. Morphometric studies further demonstrated that the cell body profile area (μm²) of nNOS-IR, ChAT-IR and CalR-IR neurons was increased by 34%, 20% and 55%, respectively, in the OG compared to controls. Staining for NADH diaphorase activity is widely used to detect alterations in the enteric nervous system; however, our qualitative examination of NADH-diaphorase positive neurons in the myenteric ganglia revealed an overall similarity between the two groups.

CONCLUSION: We demonstrate increases in P2X$_2$R expression and alterations in nNOS, ChAT and CalR IR in ileal myenteric neurons of female *ob/ob* mice compared to wild-type controls.

INTRODUCTION

Obesity is a chronic heterogeneous disorder characterized by abnormal or excessive fat accumulation that presents a risk to health[1]. The leptin-deficient *ob/ob* mouse exhibits both obesity and peripheral diabetic neuropathy, traits characteristic of human patients, and thus represents a valuable animal model of obesity and type 2 diabetes-like pathology[2].

Obesity is associated with an increased risk of type 2 diabetes and is often accompanied by complications of the gastrointestinal tract such as gastroparesis, constipation, diarrhea, and fecal incontinence[1]. Disruptions in the function of the gastrointestinal tract have been associated with alterations in the enteric nervous system[3]. Enteric neurons comprise both the myenteric and submucosal plexuses, which control the motility of the intestine, the transport of fluids from the intestinal mucosa, and local blood flow[3]. The groups of neuronal cell bodies (ganglia) in these plexuses are interconnected by nerve fiber bundles[3]. The myenteric and submucosal plexuses also regulate gastrointestinal secretions important for the digestion of food particles, intestinal lubrication, nutrient uptake, regulation of pH, and the concentration of solutes and elimination of waste products[3]. Studies of chemical coding in neurons of the mouse enteric nervous system have been particularly important to our understanding of the function of enteric neurons[4,5]. Defects in enteric nervous system function have been reported in *ob/ob* mice, including alterations in intestinal motility[6] and in the enteric neurons[7,8]. Down-regulations in intestinal motility have been reported in obese humans[1]. Thus, the mouse is a valuable animal model for the study of obesity-related pathology in the enteric nervous system.

Adenosine 5'-triphosphate (ATP) has been well-established as a neurotransmitter and a ligand of the P2X receptor family, which is made up of seven known receptor subunits (PX_{1-7})[9]. These receptors play an important role in synaptic transmission within the neural pathways that mediate intestinal motility[10]. Previous immunohistochemical studies have documented the distribution of $P2X_2$ receptors ($P2X_2Rs$) in the enteric nervous system of the guinea pig[11-14], rat[15-18] and mouse[19-21]. However, the distribution of $P2X_2R$ expression in the enteric nervous system of obese mice remains unstudied.

It has been reported that the $P2X_2R$ is expressed in inhibitory, cholinergic, and intrinsic afferent neurons in the enteric nervous system[11]. The goal of the current study is to analyze the chemical coding, density, and area profile of neuron immunoreactivity (IR) for the $P2X_2R$, neuronal nitric oxide synthase (nNOS), choline acetyltransferase (ChAT), calretinin (CalR), and positivity for nicotinamide adenine dinucleotide (NADH)-diaphorase activity in the small intestine enteric nervous system of female *ob/ob* and control mice.

MATERIALS AND METHODS

Animals

Two groups of 11-mo-old female mice were compared in these studies. The obese group (OG) consisted of six homozygous (*ob/ob*) C57BL/6J mice, and the control group (CG) was comprised of six wild-type C57BL/6J mice. The animals were bred at the State University of Campinas Breeding Center. The animals were housed at five per cage in an artificially lit room (12 h/12 h, light/dark) and were fed a standard pellet diet (Nuvilab, São Paulo, Brazil) and water *ad libitum*. Animals were euthanized for experiments using a CO_2 chamber. This study was conducted according to current legislation on animal experiments at the Biomedical Science Institute of the University of São Paulo.

Collection of blood for biochemical analysis

Samples of blood were obtained *via* the puncture of the plexus axillary artery of mice previously anesthetized with xylazine (16 mg/kg) and ketamine (120 mg/kg). Following collection, the blood remained at rest for 2 h at room temperature for clot formation, and then was centrifuged at 2500 × *g* for 20 min at 4 ℃ to obtain the serum. The serum supernatant was maintained at -40 ℃ until being analyzed for glucose composition.

Immunohistochemistry

Following CO_2 euthanasia, fresh segments of distal ileum were removed from each animal and placed in phosphate-buffered saline (PBS: 0.15 mol/L NaCl in 0.01 mol/L sodium phosphate buffer, pH 7.2) containing nicardipine (10^{-6} mol/L; Sigma, United States) to inhibit tissue contraction. The dissected segments were sliced open along the mesenteric border and cleaned of their contents using PBS. They were then pinned out tautly, mucosa side down, onto a balsa-wood board and fixed overnight at 4 ℃ in paraformaldehyde in 0.2 mol/L sodium phosphate buffer (pH 7.3). The next day, the segments of ileum tissue were cleared of fixative with three 10-min washes in 100% dimethyl sulfoxide followed by three 10-min washes in PBS. All tissue was stored at 4 ℃ in PBS containing sodium azide (0.1%). The fixed tissue was then dissected and the mucosal, submucosal, and circular layers were removed to obtain whole-mounts of the longitudinal muscle-myenteric plexus. In a second type of preparation, the mucosa and muscularis externa were removed to leave the intact submucosal layer. Whole-mount preparations of the myenteric and submucosa of the ileum were then pre-incubated in blocking buffer, 10% normal horse

Table 1 Characteristics of primary and secondary antibodies

Antigen	Host	Dilution	Code and reference
$P2X_2$ receptor	Rabbit	1:120	AB5244, Chemicon
Nitric oxide synthase	Sheep	1:2000	H205 (Williamson *et al*[31], 1996)
Choline acetyltransferase	Goat	1:50	Chemicon
Calretinin	Goat	1:100	CG1 (Swant)
Secondary antibodies			
Donkey anti-rabbit IgG Alexa 488	Donkey	1:500	Molecular probes
Donkey anti-sheep IgG Alexa 594	Donkey	1:100	Molecular probes

serum in PBS containing 1.5% Triton X-100 for 45 min at room temperature to reduce non-specific antibody binding and to permeabilize the tissue, respectively (Table 1). To localize $P2X_2R$ IR, we used a rabbit antiserum raised against amino acids 457-472 of the rat $P2X_2R$, with a single Cys extension at the N-terminal (AB5244 from Chemicon, Temecula, CA, United States). Tissues were incubated with the antibody at a dilution of 1:120 in blocking buffer for 48 h at 4 ℃. Dual immunohistochemistry was achieved using combinations of antisera (Table 1). Following incubation in primary antisera, the tissue samples received three 10-min washes in PBS and were then incubated in a mixture of secondary antibodies (Table 1). Following three further 10-min washes in PBS, the tissue samples were mounted onto microscope slides in glycerol buffered with 0.5 mol/L sodium carbonate buffer (pH 8.6). Tissues preparations were examined using both Leica and Nikon epifluorescent microscopes. Images were captured using a digital camera coupled to Image-Pro Plus software. Preparations were also analyzed by confocal microscopy using a Zeiss confocal scanning laser system installed on a Zeiss Axioplan 2 microscope. The image dimensions were 512 × 512 pixels, with an optical section thickness of 0.5 μm. Immunoreactive cells were scanned as a series of optical sections, with a center spacing of 0.2 μm, and the images were collected using LSM 5 Image Zeiss processing software, and further processed using Corel Photo Paint and Corel Draw software programs.

Statistical analysis

Antigen colocalization was determined by examining preparations immunolabeled with two fluorescent secondary antibodies. Neurons of interest were identified by immunofluorescence for one antigen; the filter was switched, and labeling for the second antigen was determined. In this way, the proportion of neurons immunoreactive for both antigens was determined. For each antigen pair, the cohort size was 100 neurons. Co-IR for the $P2X_2R$ with that of the other antigens (nNOS, ChAT, or CalR) was assessed. The percentage of double-immunoreactive neurons was calculated and expressed as mean ± SE (n = number of tissue preparations). The number of neurons immunoreactive for the $P2X_2R$, nNOS, CalR, and ChAT, as well as the neuronal profile (area of cell body), were measured by examining the whole-mount preparations under a binocular microscope at 100 × magnification. All neurons present in each cm^2 were counted. The profile areas of 50 nerve cell perikarya from each animal were measured using Image-Pro Plus software. Data were compared by one-way analysis of variance (ANOVA) and Student's t-tests; $P < 0.05$ was considered to be statistically significant.

NADH diaphorase staining

A separate cohort of 12 animals was weighed and euthanized in a CO_2 chamber prior to the opening of the anterior abdominal wall. The distal ileum was removed and washed in Krebs solution. The surface area of the entire small intestine was measured using a planimeter. Each piece of ileum was then ligated with cotton thread at the proximal end and gently distended with Krebs solution introduced with a syringe into the distal end. When the intestine was sufficiently distended, the syringe needle was withdrawn and the ligature was simultaneously tightened. The following steps were then performed to label neurons using the NADH diaphorase histochemical technique[22,23]. Following incubation in Krebs solution at room temperature for 15-30 min, the small intestine was transferred to a permeabilizing agent (0.3% Triton-X 100 in Krebs solution) for 15-90 s and then submitted to three 10-min washes in Krebs solution. The specimens were incubated for 30-45 min at 20 ℃ in 20 mL of incubation medium that contained 0.5 mg/mL of nitro blue tetrazolium (Sigma Chemical Co, St. Louis, MO) in distilled water (25 parts), 0.1 mol/L sodium phosphate buffer, pH 7.3 (25 parts), distilled water (50 parts), and 0.5 mg/mL of the reduced form of β-NADH (Sigma, United States). The reaction was stopped by immersion in 10% buffered formalin solution, in which the tissue samples were fixed for a minimum of 24 h at room temperature. Whole mount preparations were then prepared as follows: the small intestine was opened, the mucosa was removed, and the longitudinal muscle, with the myenteric plexus attached, was lifted at one corner and gently removed from the entire strip. After several washes in distilled water, fragments (2 cm^2) of the proximal, middle, and distal portions of the large intestine were prepared as whole mounts in glycerol on microscope slides and sealed with Entellan (Merck).

Myenteric neurons were identified by the presence of intense formazan reaction product filling the perikaryon, as well as by large, round, and unstained nuclei. The number of neurons and the profile areas of the nerve cell bodies were measured by examining the whole mount preparations under a binocular microscope at a magnification of 400 ×. All labeled neurons in each fragment were counted. The profiles of 100 nerve cell perikarya from each portion were obtained using a semi-automatic morphometry device (Image-Pro Plus Program 3.1)[17,18].

Results are expressed as mean ± SE. Data were compared by ANOVA with Student's t-tests for multiple comparisons, as appropriate. $P < 0.05$ was considered statistically significant.

Table 2 Body weight, small intestine area and glucose levels in female control (n = 4) and *ob/ob* mice (n = 4)

	Control group	Obese group
Body weight (g)	25.62 ± 0.62	65.52 ± 1.08[a]
Small intestine area (cm^2)	26.6 ± 2.8	34.5 ± 3.21[a]
Glucose (mg/dL)	195.75 ± 58.09	322.2 ± 99.2[a]

Student's *t*-tests for multiple comparisons. [a]$P < 0.05$ *vs* control.

RESULTS

In the present study, we found a significant (29.6%, $P < 0.05$) increase in the body weight of the *ob/ob* animals (OG) compared to controls (Table 2). In addition, the average small intestine area was increased by approximately 29.6% in the OG as compared to the CG ($P < 0.05$; Table 2). Plasma glucose measurements revealed levels of 195.75 ± 58 mg/dL in control mice and 322.3 ± 58 mg/dL in the OG mice ($P < 0.05$). Mice with blood glucose levels above 300 mg/dL were considered to be diabetic (Table 2).

Immunolabeling

IR for the $P2X_2R$, nNOS, ChAT and CalR was detectable in the myenteric plexus, as well as in the smooth muscle, in both groups. This IR mainly occurred throughout the cytoplasm and on cell surface and nuclear membranes, and effectively outlined the neuronal cell bodies and their processes in the myenteric plexus (Figure 1). nNOS-IR neurons were detected in both groups. Some nNOS-IR neurons displayed short dendritic processes, characteristic of Dogiel type I morphology. The primary and secondary fiber tracts were also immunoreactive for nNOS (Figure 1). ChAT-IR neuronal cell bodies were abundant in the myenteric ganglia; ChAT-IR was present in the cytoplasm of neurons from both groups. Nearly all of the ChAT-IR neurons displayed Dogiel type I morphology. We also observed a small number of large, smooth-surfaced ChAT-IR cell bodies. In addition, varicose ChAT-IR fibers were observed surrounding the ganglia, and constituted the primary and secondary fiber tracts of the ileum myenteric plexus (Figure 2). IR for CalR was detected in neuronal cell bodies and axonal/dendritic processes in both the control and the OG. Some neurons showed typical Dogiel type I morphology, with short dendritic processes, while others displayed long axonal projections characteristic of Dogiel type Ⅱ morphology (Figure 2).

Statistical analysis

Double immunolabeling for the $P2X_2R$ in combination with anti-nNOS, ChAT, and CalR IR was conducted to identify different chemical classes (chemical coding) of neurons in the myenteric plexus. In the CG, 99.5% ± 0.6% of NOS-IR neurons exhibited $P2X_2R$-IR and, in the OG, the colocalization score was similar (99.1% ± 1.1%). The colocalization of ChAT-IR and CalR-IR with $P2X_2$-IR was 100% in neurons from both the control and the OGs (Table 3). In summary, these analyses did not show any statistically significant differences in the colocalization of $P2X_2R$-IR with that of the other antigens between the two groups (Table 3).

Table 3 Results of the quantitative analysis of double labeling studies of immunoreactivity against the $P2X_2$ receptor, neuronal nitric oxide synthase, choline acetyltransferase, and calretinin in the myenteric plexus of the ileum from control and *ob/ob* female mice (n = 4, mean ± SE) (%)

	Control group	Obese group
$nNOS\text{-}IR^+/P2X_2\text{-}IR^+$	99.5 ± 0.6	99 ± 1.0
$ChAT\text{-}IR^+/P2X_2\text{-}IR^+$	100	100
$CalR\text{-}IR^+/P2X_2\text{-}IR^+$	100	100
$P2X_2\text{-}IR^+/nNOS\text{-}IR^+$	19.5 ± 3.6	19.5 ± 3.6
$P2X_2\text{-}IR^+/ChAT\text{-}IR^+$	23.6 ± 4.2	24.6 ± 4.37
$P2X_2\text{-}IR^+/CalR\text{-}IR^+$	23.7 ± 3.75	21.6 ± 1.20

nNOS: Neuronal nitric oxide synthase; ChAT: Choline acetyltransferase; CalR: Calretinin; IR: Immunoreactivity.

Upon examination of neuronal density in the myenteric plexus, we found an increase of 34.3% in the density of $P2X_2R$-IR neurons in the OG compared to controls ($P < 0.05$). In addition, the density of nNOS-IR and ChAT-IR neurons decreased by 42.6% and 53.4%, respectively, in the OG compared to controls ($P < 0.05$). There were no differences between the groups in the density of CalR-IR neurons (Figure 3). These data suggest that the density of $P2X_2R$-IR neurons increases, while that of nNOS-IR and ChAT-IR neurons decreases, in the OG compared to controls. We then estimated the total number of neuron IR for the $P2X_2R$ and found an increase of 105% in the OG compared to controls, while the total number of nNOS-IR and ChAT-IR neurons was decreased 35% and 47%, respectively, compared to controls ($P < 0.05$). The total number of CalR-IR neurons was not significantly different between the two groups (Figure 3).

We then evaluated the number of $P2X_2R$-IR neurons per myenteric ganglion in both groups. The number of $P2X_2$-IR neurons was 19 ± 1.8 neurons/ganglion in the OG *vs* 18.6 ± 3.9 neurons/ganglion in the CG. In addition, the number of nNOS-IR neurons per ganglion did not significantly differ between the groups, and was 6.6 ± 1.4 neurons/ganglion in the CG, and 5.2 ± 0.7 neurons/ganglion in the OG. The number of ChAT-IR neurons per ganglion also did not differ between the groups (5.9 ± 1.8 for CG, 5.1 ± 1.4 for OG). The number of CalR-IR neurons per ganglion also did not differ between groups (6.5 ± 1.2 for CG, 5.0 ± 0.2 for OG). Therefore, these data show that there were no significant differences between the control and OGs in the numbers of $P2X_2R$-, nNOS-, ChAT- or CalR-IR neurons in the myenteric ganglia (Figure 3).

Neurons with typical Dogiel type I and Ⅱ morphologies were observed in whole mounts immunolabeled for CalR-IR. The density of Dogiel type I neurons in the CG and OG was 6.3 ± 1.4 neurons/cm^2 and 5.7 ± 0.3

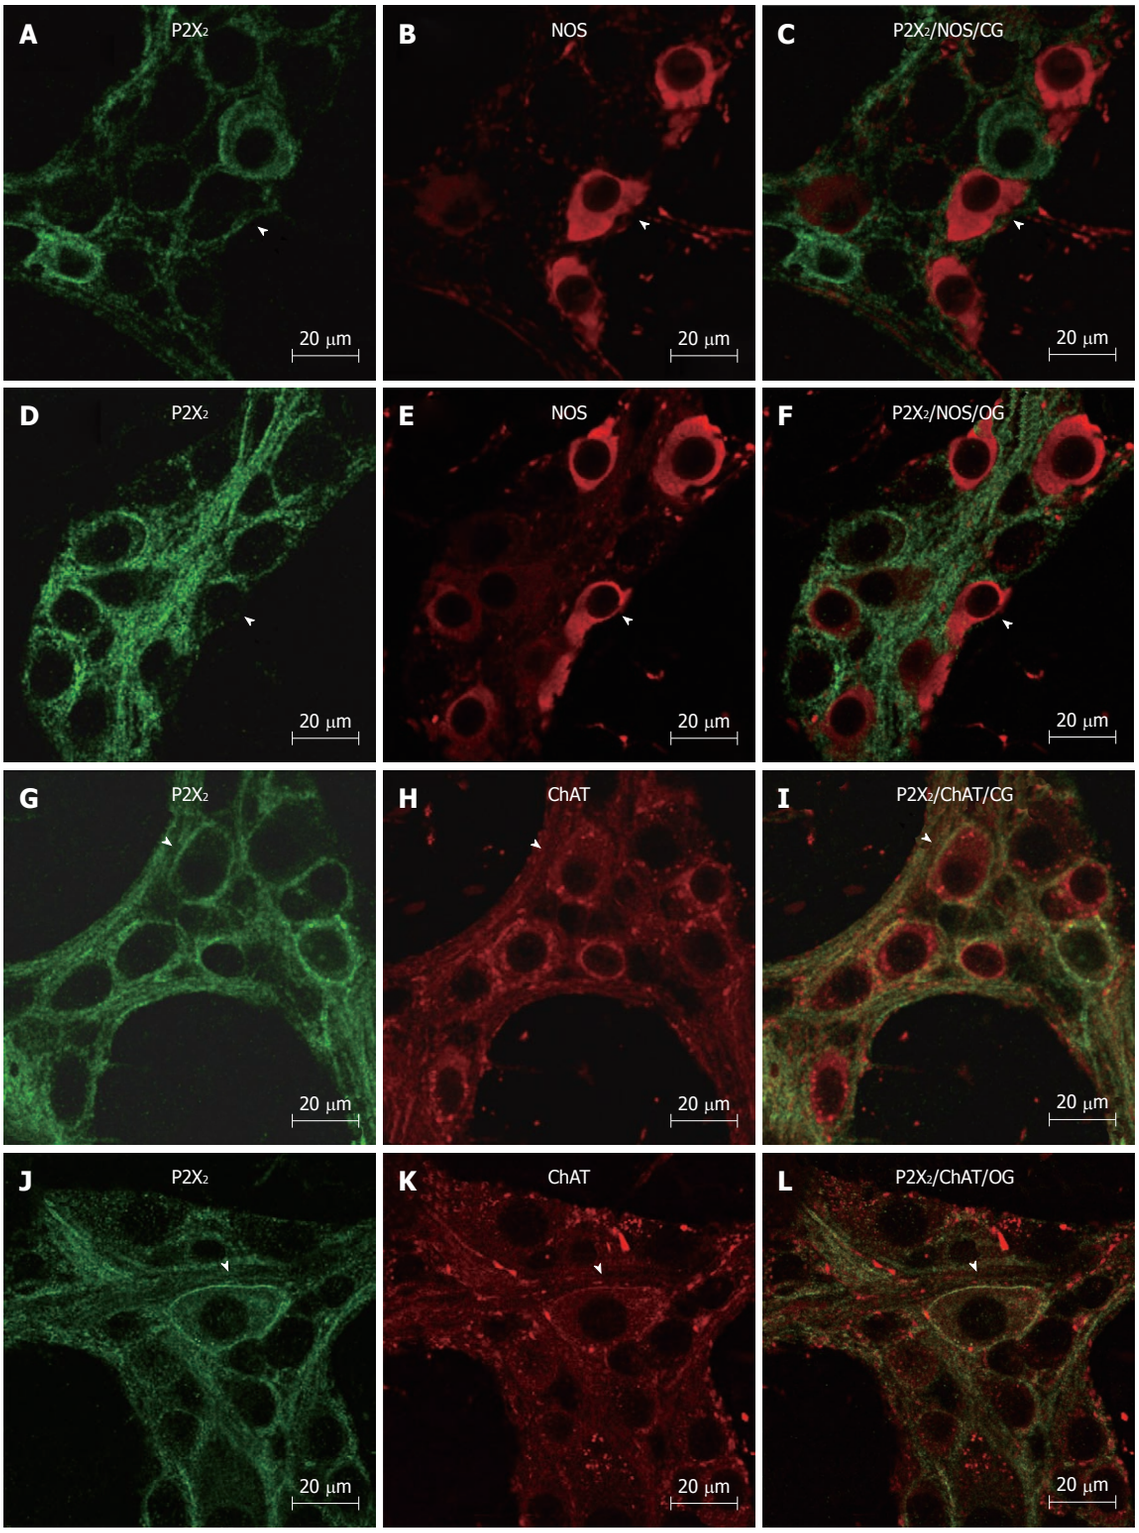

Figure 1 Immunoreactivity for $P2X_2$ receptor (A, D, G, J), nitric oxide synthase (B, E), choline acetyltransferase (H, K; merged images C, F, I, L) was examined in ileum myenteric plexus neurons from the control group (A-C, G-I) and the obese *ob/ob* group (D-F, J-L). Single arrows show double-labeled $P2X_2$ receptor ($P2X_2R$)- and nitric oxide synthase (NOS)-immunoreactivity neurons in the control group (CG) (A-C) and obese group (OG) (D-F) groups. Double-labeling for $P2X_2R$ and choline acetyltransferase (ChAT) in CG neurons (G-I) and OG (J-L) is indicated by arrowheads.

neurons/cm^2, respectively. The density of Dogiel type Ⅱ neurons was 1.3 ± 0.2 neurons/cm^2 in the CG and 1.5 ± 0.2 neurons/cm^2 in the OG. These data show that there were no significant differences in the density of CalR-IR Dogiel type Ⅰ and Ⅱ neurons between the CG and OG (Figure 3).

We then measured the cell body area of neurons in the myenteric plexus from both control and OGs.

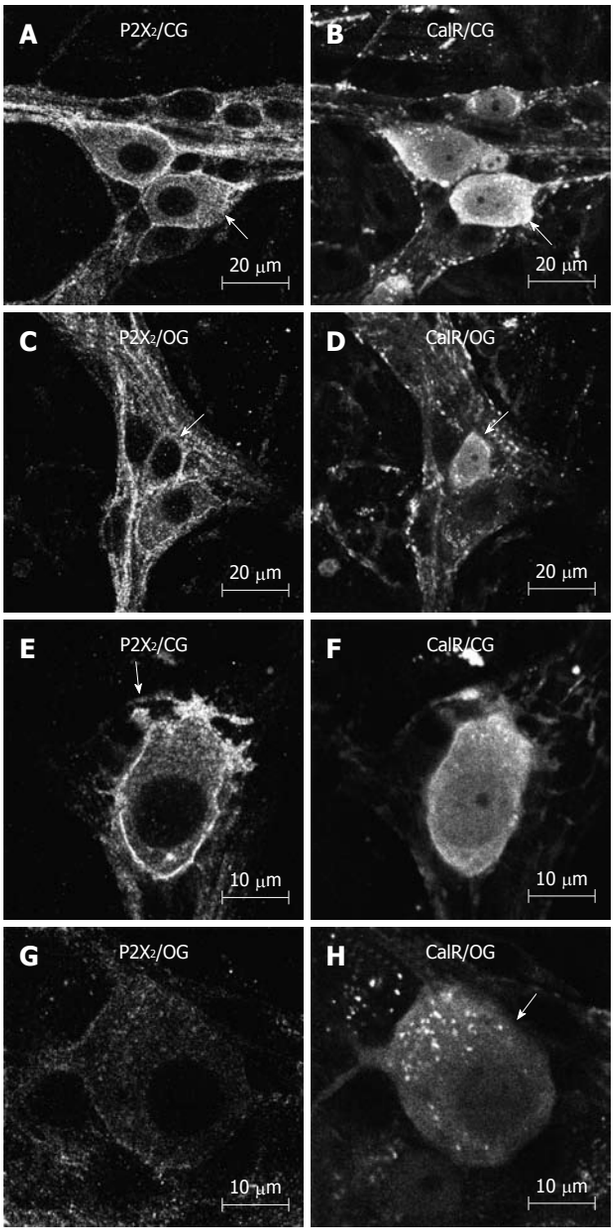

Figure 2 Immunoreactivity for P2X2 receptor (A, C, E, G) and calretinin (B, D, F, H) was examined in the ileum myenteric neurons of the control group (A, B, E, F) and the obese group (C, D, G, H). Single arrows show double labeling for P2X2 receptor and calretinin (CalR) in the neurons of the control group (CG) (A, B) and the obese group (OG) (C, D). E, F: **An example of a Dogiel type Ⅰ neuron with many lamellar and short dendrites; G, H: A neuron with** Dogiel type Ⅱ morphology with a round and smooth cell body and lipofuscin evident in the cytoplasm (arrow).

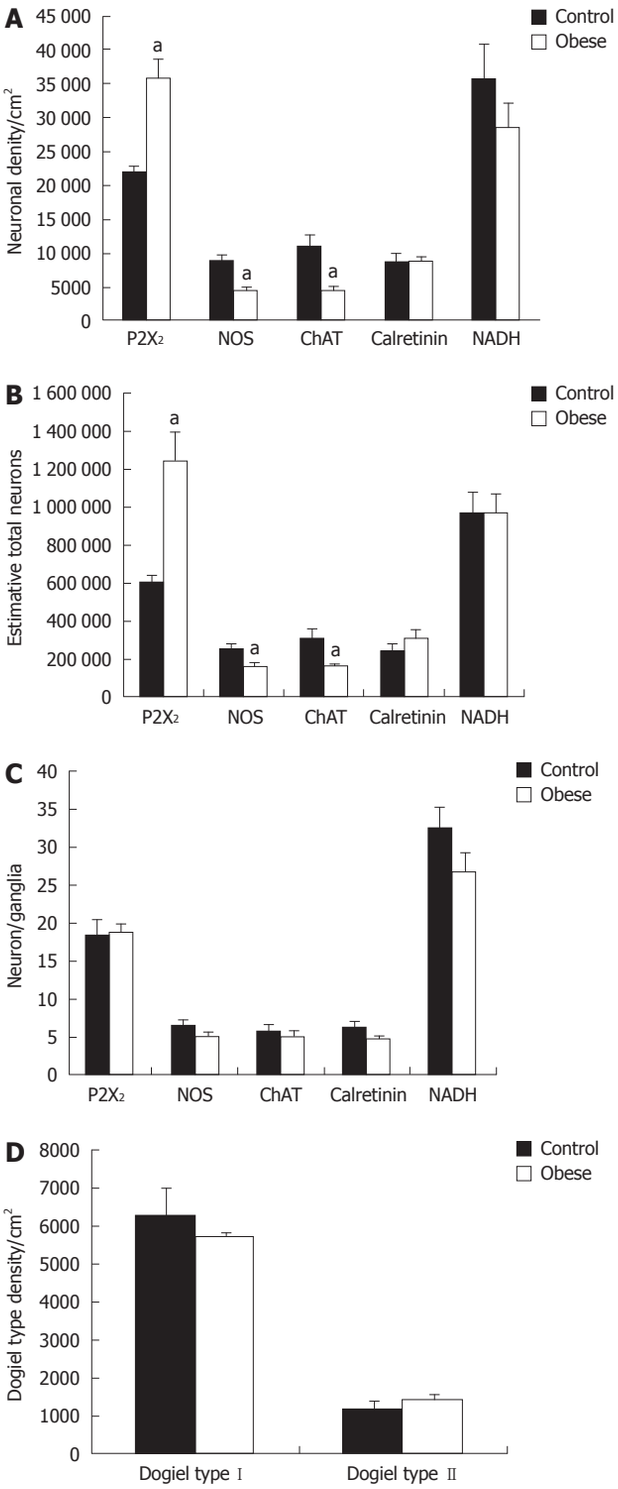

Figure 3 Neuronal density (neurons/cm^2) (A), the estimated total neuron number (B) and neurons per ganglion immunoreactive for P2X2 receptor, nitric oxide synthase, choline acetyltransferase, calretinin, and positive for nicotinamide adenine dinucleotide-diaphorase activity in the ileum myenteric plexus of control and obese mice (C), and densities of Dogiel type Ⅰ and Ⅱ neurons immunoreactive for calretinin (D) in control and obese mice. $^aP < 0.05$ *vs* control, mean ± SE, Student's *t*-test. NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase; NADH: Nicotinamide adenine dinucleotide.

Although there was no change in the size of P2X2R-IR neurons between the groups, we observed a significant increase in the cell body areas of nNOS-IR (34%), ChAT-IR (17%), and CalR-IR neurons (35%) in the OG compared to controls ($P < 0.05$; Figure 4). The size distribution of neurons in the myenteric plexus of CG and OG mice are shown in Figure 5.

NADH-diaphorase analysis

Our qualitative examination of NADH-diaphorase positive neurons in the myenteric ganglia revealed an overall similarity between the two groups. With this method, the formazan reaction product labels the neuronal cy-

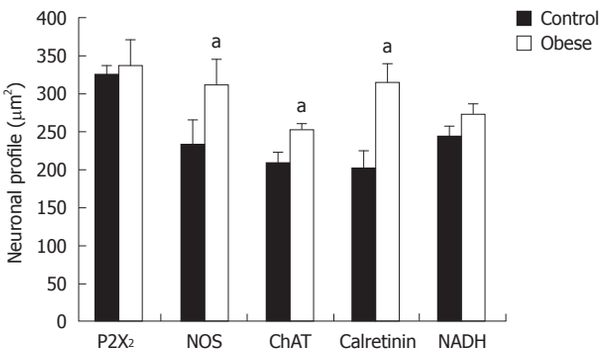

Figure 4 Cell body profile areas (μm²) of neurons immunoreactive for P2X2 receptor, nitric oxide synthase, choline acetyltransferase, calretinin and nicotinamide adenine dinucleotide-diaphorase in the ileum myenteric plexus of control and obese groups. $^{a}P < 0.05$ *vs* control, mean ± SE, Student's *t*-test. NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase; NADH: Nicotinamide adenine dinucleotide.

toplasm with a varying intensity, while neuronal nuclei appear translucent. We did observe that the myenteric neurons appeared to be more widely-spaced (less dense, or grouped) in the myenteric ganglia of the OB group compared to controls (Figure 6).

This histochemical analysis provided some potentially useful general information about the myenteric neuronal population in the mouse ileum. The density of NADH-diaphorase-positive neurons was reduced by about 20% in the OG compared to controls; however, this reduction was not statistically significant (Figure 3). The total surface area of the small intestine in both groups was measured, and the total number of neurons was estimated to be 971 558 ± 205 000 in the CG and 974 042 ± 187 000 in the OG (Figure 3). In addition, an estimate of the number of neurons per myenteric ganglion did not reveal any significant differences between the groups (Figure 3). Cell body area profile measurements of NADH-diaphorase-positive neurons also showed no differences in overall neuronal size between the control and OGs (Figure 4).

DISCUSSION

Gastrointestinal disorders arising from alterations in intestinal motility in obese individuals have been related to alterations in the enteric nervous system[1]. In the current report, we demonstrate changes in the population of enteric neurons of the myenteric plexus in the *ob/ob* mouse that may explain, in part, impairments in intestinal motility suffered by obese individuals[1]. The current study demonstrates, for the first time, the presence of P2X2R IR in the myenteric plexus, and alterations in the chemical identity, or coding, of myenteric neurons in the ileum of obese female *ob/ob* mice compared to controls. Previous studies have revealed the presence of P2X2,3,7 receptor-containing neurons in the enteric nervous systems of various species[11-21]. In the current study, we show that IR for the P2X2R is present in both the cytoplasm and membrane of myenteric plexus neurons in control and obese animals. We confirm that IR for the P2X2R colocalizes with that for nNOS, ChAT and CalR in myenteric neurons. This finding is consistent with previous work demonstrating the presence of P2X2R in inhibitory neurons, as well as in intrinsic excitatory and secretomotor/vasodilator primary afferent neurons in the guinea pig[11] and rat[16-18]. We did not observe any differences in the co-localization of P2X2R with IR for these markers (nNOS, ChAT, CalR) between the control and obese mice, suggesting that the neurochemical coding of these neurons is not altered in the myenteric plexus of obese female *ob/ob* female mice compared to wild-type controls.

The creation of the *ob/ob* mouse on the C57BL/6J background, which followed the cloning and sequencing of the mouse *ob* gene and its human homologue, provides an excellent model for the study of obesity[2]. These mice present with obesity that is accompanied by the manifestation of motor and sensory nerve conduction deficits, small sensory nerve fiber neuropathy, intraepidermal sensory nerve fiber loss, and oxidative nitrosative stress in peripheral nerves, features that are characteristic of human subjects with obesity and diabetes[2]. Previous studies have demonstrated that mice with blood glucose levels above 300 mg/dL are useful as a mouse model of diabetes[2]. In the current study, the obese *ob/ob* mice had average blood glucose levels of 322.3 ± 58 mg/dL, clearly within the diabetic range. Consistent with previous reports, the body weights of the *ob/ob* mice were twice those of the control mice in our study. This increase in body weight was accompanied by a similar increase in the area of the ileum in the obese animals, in accordance with previous findings[6]. Obesity in humans is associated with increased risk of type 2 diabetes and is often accompanied by complications of the gastrointestinal tract. In the current work, we found high levels of glucose, well within the diabetic range, accompanied by alterations in the myenteric neurons in the obese *ob/ob* mice compared to controls, providing a possible explanation for the dysfunctions in intestinal motility that can accompany obesity. In keeping with this idea, animals with type 1 diabetes have been observed to have gastrointestinal complications[2].

We examined nNOS IR as a marker of inhibitory motor neurons, as well as ChAT and CalR-IR to identify excitatory motor neurons and interneurons, respectively. The results we obtained are consistent with the current literature[4]. For example, our morphological analysis showed that nNOS-IR neurons exhibit Dogiel type I morphologies, while CalR-IR neurons exhibit both Dogiel type I and II morphologies. Qu *et al*[4] in 2008 showed that about 15% of all myenteric neurons are Dogiel type II and are immunoreactive for CalR. Our current findings show that 14% of all the CalR-IR neurons in the myenteric plexus were Dogiel type II in the CG, and that a similar percentage (16%) existed in the OG.

ChAT is the synthesizing enzyme for the excitatory neurotransmitter acetylcholine, a transmitter not found in inhibitory motor neurons[3,4]. In the current work, we

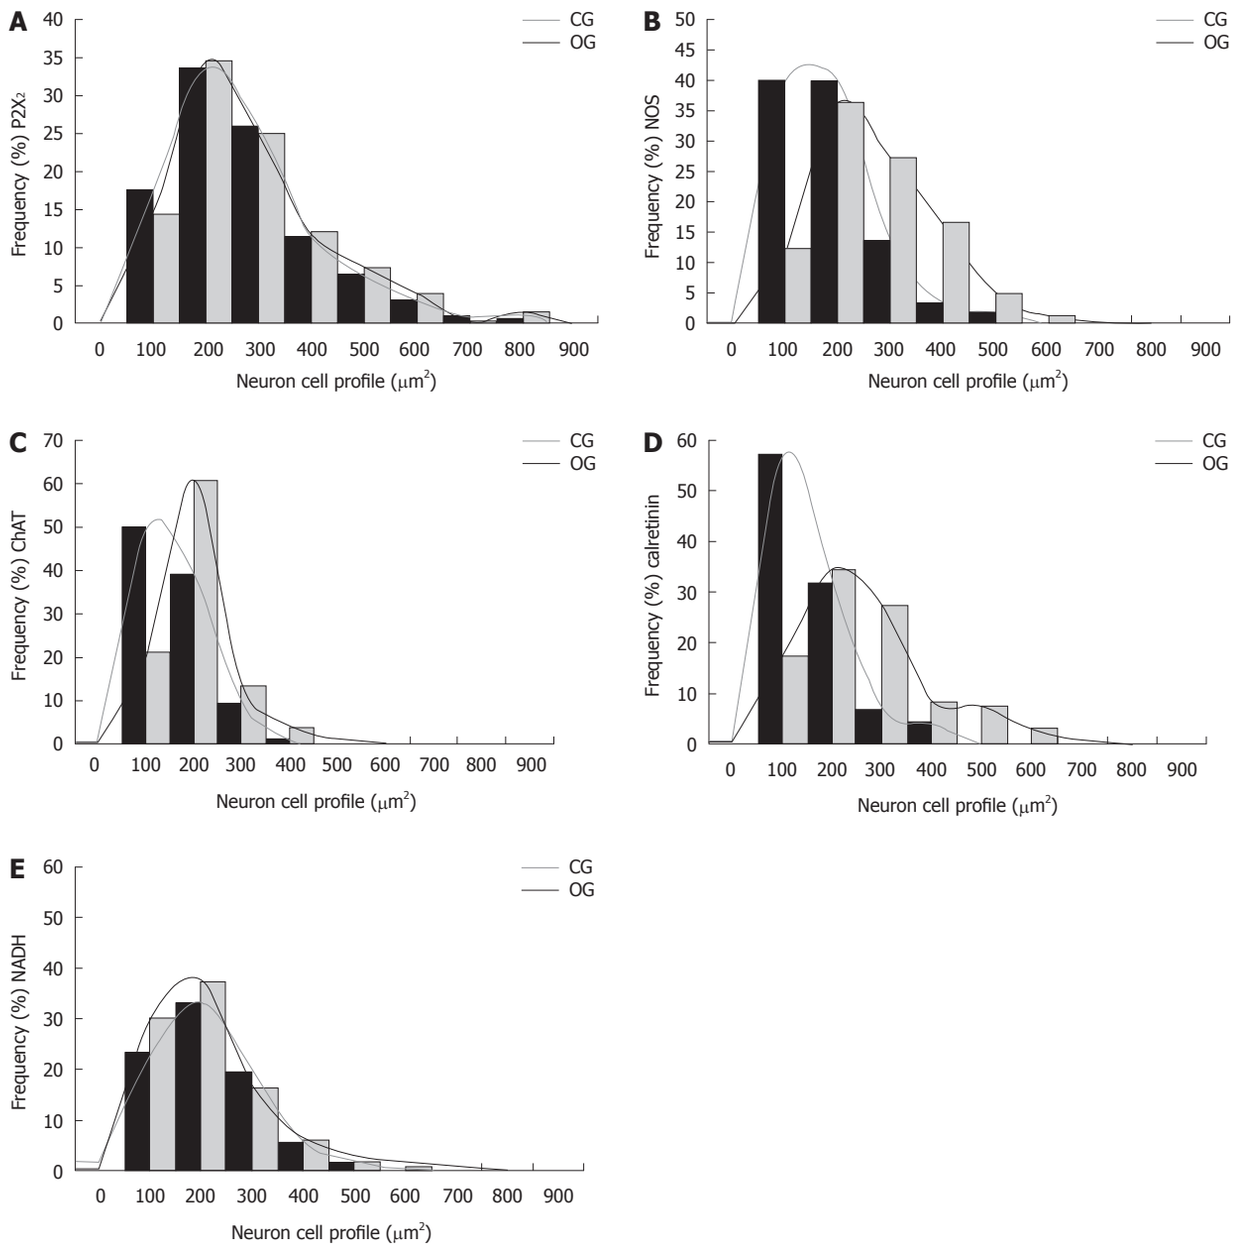

Figure 5 Frequency distribution of neuronal size profiles (μm^2) for neurons immunoreactive for $P2X_2$ receptor (A), nitric oxide synthase (B), choline acetyltransferase (C), calretinin (D), and positive for nicotinamide adenine dinucleotide-diaphorase (E) in the ileum myenteric plexus of control (black bars) and obese (grey bars) groups. NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase; NADH: Nicotinamide adenine dinucleotide; CG: Control group; OG: Obese group.

show that numerous ChAT-IR neurons are present in the myenteric ganglia, as has been described in other species. In addition, we find that all the CalR-IR neurons are also immunoreactive for ChAT, confirming their identity as excitatory cholinergic motor neurons[4].

Changes in neuronal density have been observed in autonomic neurons[24], and various regions of the gastrointestinal tract in rat models of malnutrition and re-feeding[22,23,25] as well as following intestinal ischemia/reperfusion (I/R-i)[18]. In the *ob/ob* group of the current study, the density of nNOS-IR and ChAT-IR neurons was decreased by 42.6% and 53.4% compared to controls; in addition, the total number of nNOS-IR and ChAT-IR neurons was reduced by 35% and 47%, respectively, in the OG compared to controls. No statistically significant difference was found in the density of CalR-IR neurons between the groups. The observed decrease in neuronal density may be explained by the 29% increase in the area of the small intestine that we measured in the obese female mice. However, the estimated overall decrease in the number of neurons in the *ob/ob* intestine implies an actual loss of enteric neurons in these mice. Another enzyme, NADH-diaphorase, has been shown to decrease during malnourishment in neurons of the small and large intestines[22,23]. In the current study, however, we did not observe any alteration in the density of NADH-diaphorase-positive neurons in the OG compared to controls.

In the obese female mouse small intestine, we ob-

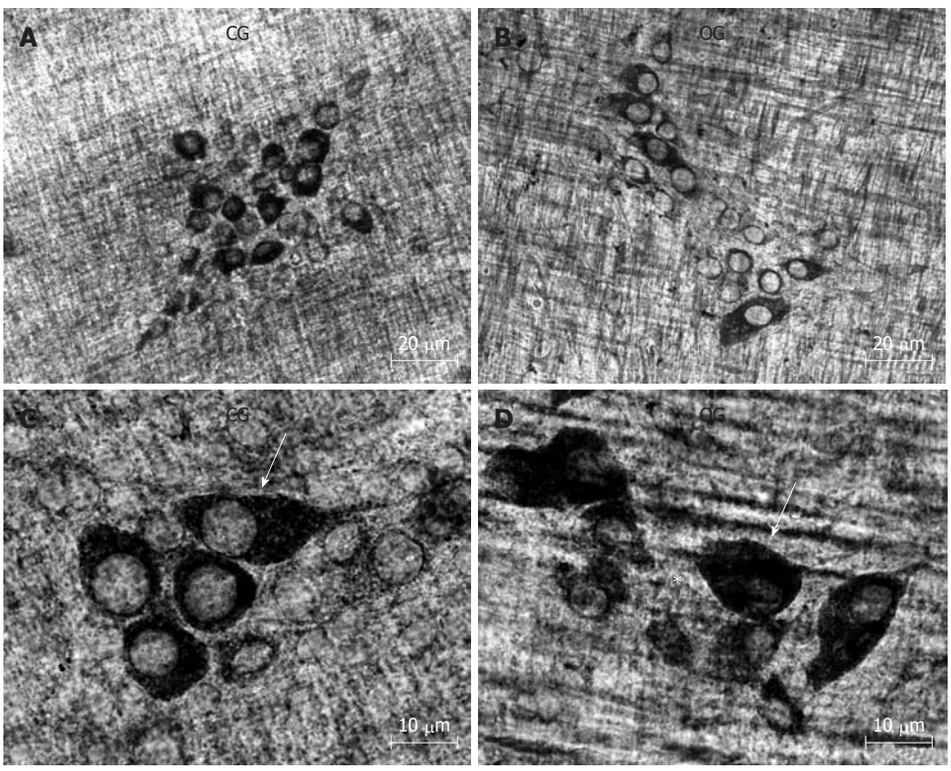

Figure 6 Ileum myenteric neurons labeled for nicotinamide adenine dinucleotide-diaphorase activity in the control group (A, C) and the obese group (C, D), and spaces between the neurons (asterisk) in the obese group group (B, D). Arrows show stained myenteric neurons. CG: **Control group**; **OG**: **Obese group**.

served increases in both the density and estimated number of $P2X_2$R-IR neurons compared to controls. This increase could be due to the presence of $P2X_2$R IR in another type of enteric nervous system cell, one which is not immunoreactive for nNOS, CalR or ChAT; namely, enteric glial cells. The presence of P2X and P2Y receptors has been described in astrocytes and microglia of the central nervous system (CNS)[9] as well as in enteric glial cells[26]. However, the increase of $P2X_2$R IR following undernourishment has been show to occur specifically in enteric neurons[17], making it likely that our observations of increased $P2X_2$R-IR also result from increased neuronal expression.

Changes in the central neuronal expression of $P2X_{1-7}$ purinoceptors frequently occur not only during maturation and neuronal differentiation, but also following various types of acute insults to the CNS. Prolonged stimulation of ATP receptors has been shown to result in changes in the location and density of P2 receptors in the cell membrane[27].

The NADH-diaphorase method is widely used in studies of alterations in the enteric nervous system and other autonomic plexus that relate to undernourishment, re-feeding, and age[22,23,28]. Our current data indicate that the density of NADH-diaphorase positive neurons showed a tendency to decrease in the obese mice compared to controls; however, these differences were not statistically significant.

Previous immunohistochemical and histochemistry studies have shown that under-nutrition[22,23] and I/R-i[18] affect the size profiles of neurons in the gastrointestinal tract. When using NADPH-diaphorase histochemistry to label myenteric neurons, we did not observe differences between the control and OGs, although the range of profile areas using this technique was consistent with that estimated from measurements of nNOS-, ChAT- and CalR-IR. Using an immunohistochemistry technique we were unable to verify exactly which neuronal classes demonstrated alterations in cell size in the obese mouse intestine. We show that cell area was increased for nNOS-, ChAT-, and CalR-IR neurons in the obese mouse, compared to controls. In agreement with these findings, modest (4.4%) increases in the profile area of myenteric neurons have been demonstrated in diabetic rats[29].

Epidemiological studies have suggested that excess body weight may be a major risk factor for colon and breast cancer. In an animal model of colon carcinogenesis, mice fed a high-fat diet exhibited a greater number of colon tumors than lean animals. Their increased abdominal fat was associated with higher concentrations of leptin, insulin, and insulin-like growth factor 1, which possibly mediate tumor growth. These data suggest that the metabolic burden created by excess adiposity accelerates uncontrolled cell growth and survival, thereby increasing the risk of developing breast and colon cancer[30].

Our understanding of the anatomical and molecular consequences of obesity becomes even more complex when we take into account the very complicated nature of the innervation of the gut. We believe that the current

study provides a positive step in our knowledge of the relationship between obesity, diabetes, and gastrointestinal disease. The results of this study suggest that there are significant changes in the intestinal ileum of obese mice, findings that further promote our understanding of obesity and the enteric nervous system.

COMMENTS

Background

Obesity is a chronic heterogeneous disorder characterized by abnormal or excessive fat accumulation that presents a risk to health. Obesity is associated with increased risk of type 2 diabetes and is often accompanied by complications of the gastrointestinal tract, such as gastroparesis, constipation, diarrhea, and fecal incontinence. In addition, defects in enteric nervous system function have been reported in *ob/ob* mice, including alterations in intestinal motility and in the enteric neurons.

Research frontiers

The myenteric plexus is affected in obesity. The chemical coding of enteric neurons, as well as $P2X_2$ receptor ($P2X_2R$) expression, has not been characterized in the *ob/ob* mice.

Innovations and breakthroughs

The present study showed the effects of obesity in *ob/ob* mice on the morphology of the $P2X_2R$-, nitric oxide synthase-, calretinin- and choline acetyltransferase-immunoreactivity (IR) neurons of the myenteric plexus.

Applications

The present study suggests that obesity may change the chemical coding of the $P2X_2R$-IR neurons in the myenteric plexus, as well as that of inhibitory, cholinergic, and intrinsic primary afferent neurons on the enteric nervous system.

Terminology

The enteric nervous system is composed of the myenteric and submucosal plexuses, which control the motility of the intestine. Adenosine 5'-triphosphate is a well-known neurotransmitter and a ligand of the P2X receptor family, which is made up of seven known receptor subunits PX_{1-7}.

Peer review

This study fulfills its purpose and provides good results both qualitatively and quantitatively.

Abstract

AIM: To investigate the roles of the ribonucleotide reductase M2 (RRM2) subunit in colorectal cancer (CRC) and ultraviolet (UV)-induced DNA damage repair.

METHODS: Immunohistochemical staining of tissue microarray was performed to detect the expression of RRM2. Seven CRC cell lines were cultured and three human colon cancer cell lines, i.e., HCT116, SW480 and SW620, were used. Reverse transcription polymerase chain reaction and Western blotting were performed to determine the mRNA and protein expression levels of RRM2, respectively. Cell proliferation assay, cell cycle analysis were performed. Cell apoptosis was evaluated by double staining with fluorescein isothiocyanate-conjugated Annexin Ⅴ and propidium iodide (PI) using Annexin Ⅴ/PI apoptosis kit. The motility and invasion of CRC cells were assessed by the Transwell chamber assay. Cells were irradiated with a 254 nm UV-C lamp to detect the UV sensitivity after RRM2 depletion.

RESULTS: Immunohistochemical staining revealed elevated RRM2 levels in CRC tissues. RRM2 overexpression was positively correlated with invasion depth ($P < 0.05$), poorly differentiated type ($P = 0.0051$), and tumor node metastasis stage ($P = 0.0015$). The expression of RRM2 in HCT116 cells was downregulated after transfection, and HCT116 cell proliferation was obviously suppressed compared to control groups ($P < 0.05$). In the invasion test, the number of cells that passed through the chambers in the RRM2-siRNA group was 81 ± 3, which was lower than that in the negative control (289 ± 7) and blank control groups (301 ± 7.2). These differences were statistically significant ($P < 0.01$). Our data suggest that RRM2 overexpression may be associated with CRC progression. RRM2 silencing by siRNA may inhibit the hyperplasia and invasiveness of CRC cells, suggesting that RRM2 may play an important role in the infiltration and metastasis of CRC, which is a potential therapeutic strategy in CRC. In addition, RRM2 depletion increased UV sensitivity.

CONCLUSION: These findings suggest that RRM2 may be a facilitating factor in colorectal tumorigenesis and UV-induced DNA damage repair.

INTRODUCTION

Colorectal cancer (CRC) is the leading cause of cancer-related death worldwide. In addition, the incidence and mortality rates of CRC are on the rise[1]. CRC develops through a specific series of events, from the transformation of normal colonic epithelium to an adenomatous intermediate, and then ultimately adenocarcinoma[2]; however, the molecular mechanism underlying CRC metastasis is still not fully understood. With evolving insights into the biology of colorectal neoplasia and advances in assay technology, molecular tests are now being developed as accurate, user friendly, safe, and affordable screening tools[3]. For the accurate diagnosis and adequate treatment of CRC, the identification and understanding of the molecules responsible for cancer progression are critical.

Given that all cancer cells rely on changes in metabolism to support their growth and survival, targeting metabolism has the potential to affect cancers arising from many different tissues. Ribonucleotide reductase (RR) is one of these target metabolic enzymes for cancer therapy. RR transforms RNA building blocks to DNA building blocks by catalyzing the substitution of the 2' OH-group of a ribonucleotide with a hydrogen by a mechanism involving protein radicals[4]. In humans, bacteria, and yeast, RR is a highly regulated enzyme in the deoxyribonucleotide synthesis pathway[5]. Human RR is an enzymatic complex that consists of two nonidentical subunits, M1 and M2. M2 has two alternative subunits; namely, ribonucleotide reductase M2 (RRM2), which is involved in DNA replication (the focus of this paper), and p53R2, which is induced by p53 and is involved in supplying dNTPs for mitochondrial DNA replication and repair[6]. In addition, RRM2 is the limiting factor of RR enzymatic complex catalytic activity, which is specifically expressed in the S phase[7,8]. Therefore, RR plays an important role in the regulation of cell proliferation[9-11]. *In vitro* studies have shown that aggressive tumor proliferation results in overamplification of RR[12,13]. In some types of cancer, elevated RRM2 levels correlate with chemoresistance[14], cellular invasiveness[15], and poor patient outcome[16], which suggests that RRM2 may contribute to malignant progression, and thus be a potential therapeutic target. Recent findings have established that p53R2 suppresses the invasiveness of cancer cells, and its expression is associated with a better survival prognosis for CRC patients[17]; however, the function of RRM2 in CRC is unclear. Here, we demonstrate that RRM2 may play an important role in the development of CRC and may contribute to the response to ultraviolet (UV) irradiation.

MATERIALS AND METHODS

Patients, tissue microarray and histological analysis

This study consisted of a tissue microarray (TMA, Shanghai Outdo Biotech, National Engineering Center for Biochip at Shanghai, China) containing 56 CRC tissues and 56 adjacent normal mucosa, which were laparoscopically resected at Shanghai Minimal Invasive Surgery Centre (Shanghai Jiao Tong University School of Medicine) between 2007 and 2009. In addition, another 78 specimens of CRC tissues were laparoscopic resected between 2011 and 2012. None of the patients received preoperative treatment such as radiation or chemotherapy. All research protocols in the present study were approved by the Institutional Review Board. Staging of the tumors was performed according to the tumor node metastasis classification updated by the American Joint Commission on Cancer and the World Health Organization[18]. Pathological diagnoses were verified by two different pathologists. TMA blocks (5 μmol/L) were sectioned. Preparation of sections from paraffin blocks was performed as previously described[19]. Immunohistochemical and immunocytochemical analysis of RRM2 was performed with an anti-RRM2 antibody [R2 (E-16): SC-10846] (1:200, Santa Cruz Biotechnology, Santa Cruz, CA, United States). Relative RRM2 expression and subcellular location were classified into 5 groups based on the intensity of RRM2 staining and its distribution between the cytoplasm and nucleus.

Cell lines and culture conditions

Seven human CRC cell lines were purchased from American Type Culture Collection (Manassas, VA, United States). The CRC cell lines, HCT116 and HT-29, were cultured in McCoy's 5A medium supplemented with 10% fetal bovine serum (FBS), penicillin-streptomycin, L-glutamine, and nonessential amino acids. SW1116, SW620, SW480, LoVo and Colo205 cells were maintained in the same medium, except that McCoy's 5A medium was substituted with RPMI 1640 medium (Sigma Aldrich, St Louis, MO, United States). Cells were maintained at 37 ℃ in a 5% CO_2 incubator, and were grown according to standard protocols.

Quantitative reverse transcription-polymerase chain reaction

Total RNA was extracted with TRIzol (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's instructions. Reverse transcription was performed with oligo dT primers. Real-time polymerase chain reaction (PCR) was carried out in an Applied Biosystems 7500 System with Power SYBR Green PCR Master Mix (2 ×, Applied Biosystems, Warrington, United Kingdom). Relative levels of gene expression were determined with glyceraldehyde 3-phosphate dehydrogenase (GAPDH) as the control.

RNA interference

Transfection of cells with siRNAs targeting RRM2 was

carried out by mixing the siRNAs with diluted Lipofectamine™ 2000 at a final siRNA concentration of 20 nmol/L. The target sequences for siRNAs were as follows: 5'-AAACCCGAGGAGAGAUAUUTT-3', 5'-GGAGCGAUUUAGCCAAGAATT-3' and 5'-GCACUCUAAUGAAGCAAUATT-3'. siRNAs targeting RRM2 and a negative control siRNA (5'-UUCUCCGAACGUGUCACGUTT-3') were purchased from Genepharma (Shanghai, China). Each experiment was performed in triplicate.

Lentiviral shRNA vector

The following sets of oligonucleotides were used to knockdown RRM2 expression; shRRM2-sense: CACCG GAGCGATTTAGCCAAGAAGTCACCACTTCTTGG CTAAATCGCTCC and shRRM2-antisense: AAAAGG AGCGATTTAGCCAAGAAGTGGTGACTTCTTGG CTAAATCGCTCC. Each set of oligonucleotides were annealed and cloned into pGPH1/Neo (Genepharma, Shanghai, China).

Western blot analysis

An anti-RRM2 antibody (0.2 μg/mL) or goat polyclonal anti-GAPDH antibody (Santa Cruz Biotechnology; 0.2 μg/mL) was used as the primary antibody. Seven human CRC cell lines were resuspended in ice-cold NP-40 lysis buffer, and cell extracts from the colorectal mucosa were prepared by scraping mucosal epithelial cells into ice-cold NP-40 lysis buffer (50 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl, 1 mmol/L EGTA, and 1% NP-40) containing protease inhibitors. The isolated protein was quantified by a commercially available modified Bradford assay (Bio-Rad Laboratories, Hercules, CA, United States).

Cell viability assay

Cells were seeded at 2.5×10^3 cells per well in 96-well plates and cultured for 120 h. Cells were counted using the CASY TT Cell Counter (Roche Diagnostics, Indianapolis, United States). Cell viability was determined by adding 10 μL of Cell Counting Kit-8 (Dojindo Molecular Technologies, Kumamoto, Japan) to each well at 37 ℃ in a 5% CO_2 incubator. Each experiment was performed three times. 96-well plates were read using an Epoch Microplate Spectrophotometer (BioTek, Winooski, United States) with Gen5™ Microplate Data Analysis Software included.

Invasion assays

Motility and invasion capabilities *in vitro* were measured in a transwell chamber assay (Becton Dickinson Labware, Bedford, MA, United States). HCT116 cells (2.5×10^5) were seeded in McCoy's' 5A medium without FBS, and then plated on each 8.0 μmol/L pore size membrane insert in 24-well plates. McCoys' 5A medium plus 20% FBS was plated in the bottom wells as chemoattractants. After 24 h, cells on the top side of the inserts were removed with a cotton swab. Cells that had migrated to the underside of the inserts were stained with 0.05% crystal violet for 1 h before rinsing with phosphate buffered saline (PBS) for 20 min. Cells on each insert were counted at a 20 × magnification in 10 random fields of view. The invasion assay was done in the same way except that the 8.0-μmol/L pore size membrane insert was coated with Matrigel that was diluted in McCoys' 5A medium (1:8 dilution). The results were expressed as mean ± SD.

Flow cytometric analysis

HCT116 cells after different treatments were rinsed twice with saline PBS. Cells were dissociated, followed by the addition of 5 μL Annexin V-FITC. Cells were then gently vortexed and incubated for 15 min at 4-8 ℃ in the dark. Propidium iodide (PI, 10 μL) was added to the tube for another 5 min at 4-8 ℃ in the dark. The labeled cells were analyzed using the BD FACS Vantage System (Becton, Dickinson and Company, Franklin Lakes, NJ, United States) in accordance with the manufacturer's protocol. Gating was implemented on the basis of the staining profiles of the negative control.

UV irradiation

Cells were irradiated with a 254 nm UV-C lamp (UVP Inc., Upland, CA), and doses were measured with a UVX radiometer (Upland).

Statistical analysis

All continuous values were expressed as mean ± SD and all experiments were repeated three times. The results were subjected to a nonparametric Mann-Whitney *U* test. A paired Student's test was also used to analyze the intragroup differences. All statistical analyses were done using Stat View 5.0 for Windows (SAS Institute Inc., Cary, NC, United States). Fisher's exact test and Cochram-Artimage test were applied to analyze the relationship between RRM2 immunoreactivity and clinicopathological features. Student's *t*-test was also used to test differences in cell viability assays. A P value less than 0.05 was considered statistically significant.

RESULTS

Overexpression of RRM2 in CRC tissues and clinicopathologic significance of RRM2 expression in CRC patients

To examine RRM2 protein expression in normal mucosa and CRC tissues, we performed hRRM2 immunohistochemistry on the TMA. The normal human colon exhibits occasional $RRM2^+$ cells located at the base of the crypt (six cases). In comparison, 38 of 56 tumor samples exhibited a substantial increase in overall RRM2 expression and in the number of $RRM2^+$ cells. In the majority of these tumors, RRM2 was present in the cytoplasm (Figure 1). We set the cutoff point of RRM2 overexpression as 10%, because this is obviously higher than the positivity in normal colorectal mucosa, and because it was easy to determine positive or negative expression with this simple cutoff value. Among the 56 CRC tissues included in the TMA, RRM2 overexpression (⩾ 10% cancer cells stained) was observed in 38 cases (67.9%). The

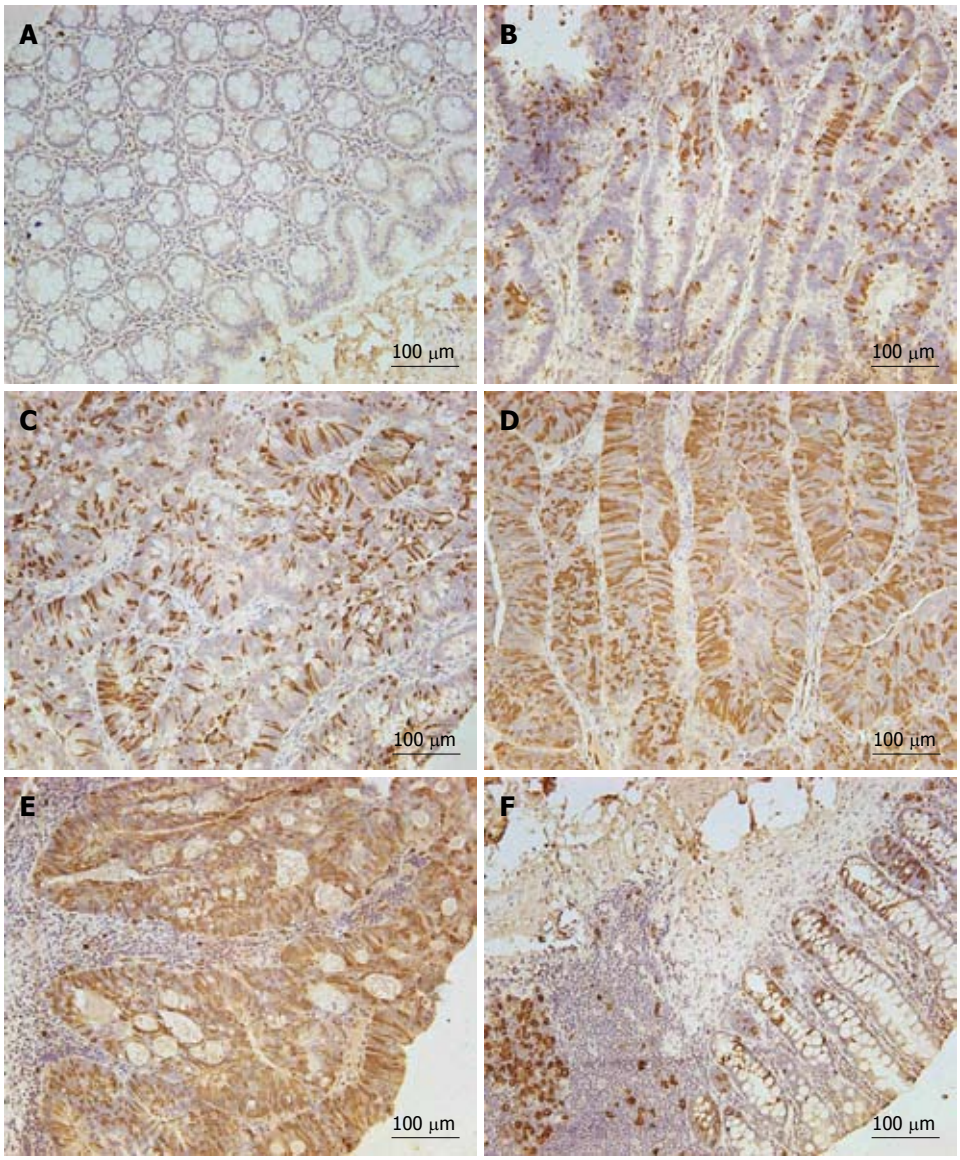

Figure 1 Immunohistochemical analysis of ribonucleotide reductase M2 expression in surgical specimens of tumor tissues or adjacent normal mucosa from patients with colon cancer. A: Normal colorectal mucosa without ribonucleotide reductase M2 (RRM2) expression. This case was considered RRM2-negative; B: Lower RRM2 expression in colorectal cancer (CRC); C-E: High RRM2 expression in CRC; F: Lymph node metastasis of CRC with RRM2 overexpression (original magnification × 20).

relationship between RRM2 expression and clinicopathologic characteristics in CRC patients is summarized in Table 1. RRM2 overexpression was significantly positively correlated with invasion depth ($P = 0.0015$) and differentiation ($P = 0.0051$), although the frequency of RRM2 overexpression was lower in T4 tumors (20%) compared to T3 tumors (75%). However, no significant differences were observed with respect to gender, age, tumor size, or lymph node metastasis. To further elucidate the clinicopathologic significance of RRM2 overexpression in CRC, especially the correlation with invasion depth and poor differentiation, we examined RRM2 expression in another 78 CRC tissues. The results are summarized in Table 2 and RRM2 immunostaining was categorized further as score 0-3[20]. These data are in accordance with previous studies showing correlation between RRM2 overexpression, invasion depth ($P < 0.0001$) and differentiation ($P < 0.0001$).

Suppression of RRM2 inhibits CRC cell growth and invasion

We next sought to determine whether RRM2 overexpression is functionally important for the *in vitro* proliferation of colonic cancer cell lines. RRM2 had the highest expression levels in HCT116 cells (Figure 2A and B). Then, HCT116 cells were transfected with three different siRNA sequences or a scrambled siRNA control. Quantitative PCR analysis of the HCT116 cell line demonstrated that the expression of RRM2 mRNA was reduced by three siRNA oligos segments to varying degrees (Figure 2C). We used the most efficient one to down-regulate RRM2 and evaluated cell growth; efficient knockdown of RRM2 protein levels after transfection was observed (Fig-

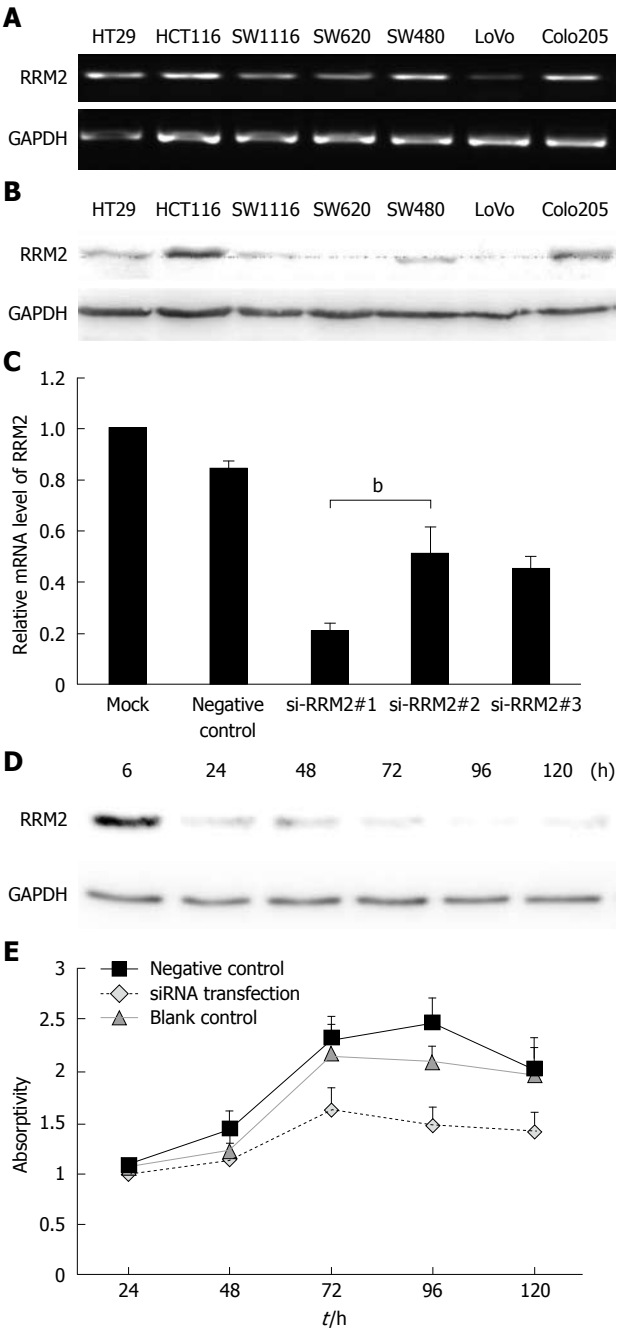

Figure 2 Expression of ribonucleotide reductase M2 in colorectal carcinoma cell lines and effect of ribonucleotide reductase M2 depletion on cell proliferation. A: Ribonucleotide reductase M2 (RRM2) expression in seven colorectal cancer (CRC) cell lines (PCR analysis); B: Expression of RRM2 protein in seven CRC cell lines (Western blotting); C: 48 h after siRNA transfection, relative mRNA level of HCT116 was determined (mock: lipofectamine only, negative control: lipofectamine + control siRNA), $^{b}P < 0.01$ si-RRM2#1 *vs* si-RRM2#2; D: HCT116 cells were transfected with si-RRM2#1 and cultured for 120 h. Cells were lysed and RRM2 protein levels were detected by Western blotting. Glyceraldehyde 3-phosphate dehydrogenase expression was used to control equal protein loading; E: At 24-120 h after siRNA transfection, the viability of HCT116 cells was determined by the CCK-8 assay. Analysis of cell growth in the presence or absence of RRM2 siRNAs revealed that blocking RRM2 protein synthesis significantly inhibited HCT116 cell growth. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

ure 2D). Analysis of cell growth in the presence or absence of the RRM2 siRNAs revealed that blocking RRM2 protein synthesis significantly inhibited CRC cell growth (Figure 2E). We used Annexin V/PI staining to identify the dead cells and then stratified them into categories of necrosis, early apoptosis, and both later apoptosis and necrosis. In each flow cytometry graph, later apoptotic or necrotic cells are shown in the upper-right quadrant. The total death rate 48 h after siRNA treatment showed a 2-3 fold increase. Flow cytometric analysis showed evidence of apoptosis when RRM2 functions were abrogated (Figure 3A and B). In the invasion assay, the number of cells that crossed through the chambers in the RRM2-siRNA group was 81 ± 3, which was lower than that in the negative control (289 ± 7) and empty control groups (301 ± 7.2). These differences were statistically significant ($P < 0.01$) (Figure 3C and D).

Inhibition of hRRM2 by expression of antisense hRRM2 results in increased UV sensitivity of CRC cells

Four human CRC cell lines with low RRM2 expression, namely, SW1116 (p53 mutant-type), SW620 (mutated p53), HT29 (mutated p53), SW480 (p53 mutant-type), and LoVo (p53 wild-type), all proved to be more sensitive to UV irradiation in colony formation assays than HCT116 cells (p53 wild-type). HCT116 cells transfected with shRRM2 revealed significant RRM2 depletion, and its colony-forming ability under UV radiation was suppressed. At a dosage of 10 J/m^2, the colony-forming ability of the HCT116 cells transfected with RRM2 antisense was inhibited by 93.13%, whereas wild-type HCT116 cells maintained 51.28% viability, and SW620 cells (RRM2-/-) maintained 32.40% viability (Figure 4A and B). In addition, the cell cycle distribution of the CRC cells did not significantly change at the various time points in the UV (–) panel. After a sublethal dose of UV radiation, an increased number of cells in the S-phase could be seen at 24-36 h (Figure 4C). Cellular morphology was observed by light microscopy. HCT116 cells with high levels of RRM2 expression, and SW480 cells, which do not express RRM2, were cultured under normal conditions or exposed to UV radiation for 48 h. Under these conditions, SW480 cells showed UV hypersensitivity, whereas the UV sensitivity of HCT116 cells with suppressed RRM2 levels increased and cells went through necrosis. Thus, endogenous RRM2 functions to suppress hypersensitivity to UV radiation. Figure 5A gives a visual depiction of the morphological changes that occurred.

DISCUSSION

The importance of altered metabolism in the context of tumorigenesis has received renewed attention as metabolic changes entwined with the molecular hallmarks of cancer have been elucidated. Previous studies have shown that alterations in RR levels may significantly influence the biological properties of cells, including tumor promotion and tumor progression, suggesting that RR may be implicated in tumorigenesis. Thus, we were interested in determining the effect of RRM2 on tumor cell growth. The discovery of p53R2, an analog of RRM2 in mammalian cells, provided an interesting link between RR and cancer because it is a downstream target for the p53 tumor suppressor. Previous studies have shown that p53R2 is negatively related to tumor invasion and lymph node involvement. In addition, investigations have revealed that p53R2 correlates with a better survival of CRC with advanced grade Ⅲ and grade Ⅳ tumors, rather than earlier grade Ⅰ and grade Ⅱ tumors[18]. The genes for p53R2 and RRM2 are located on separate chromosomes.

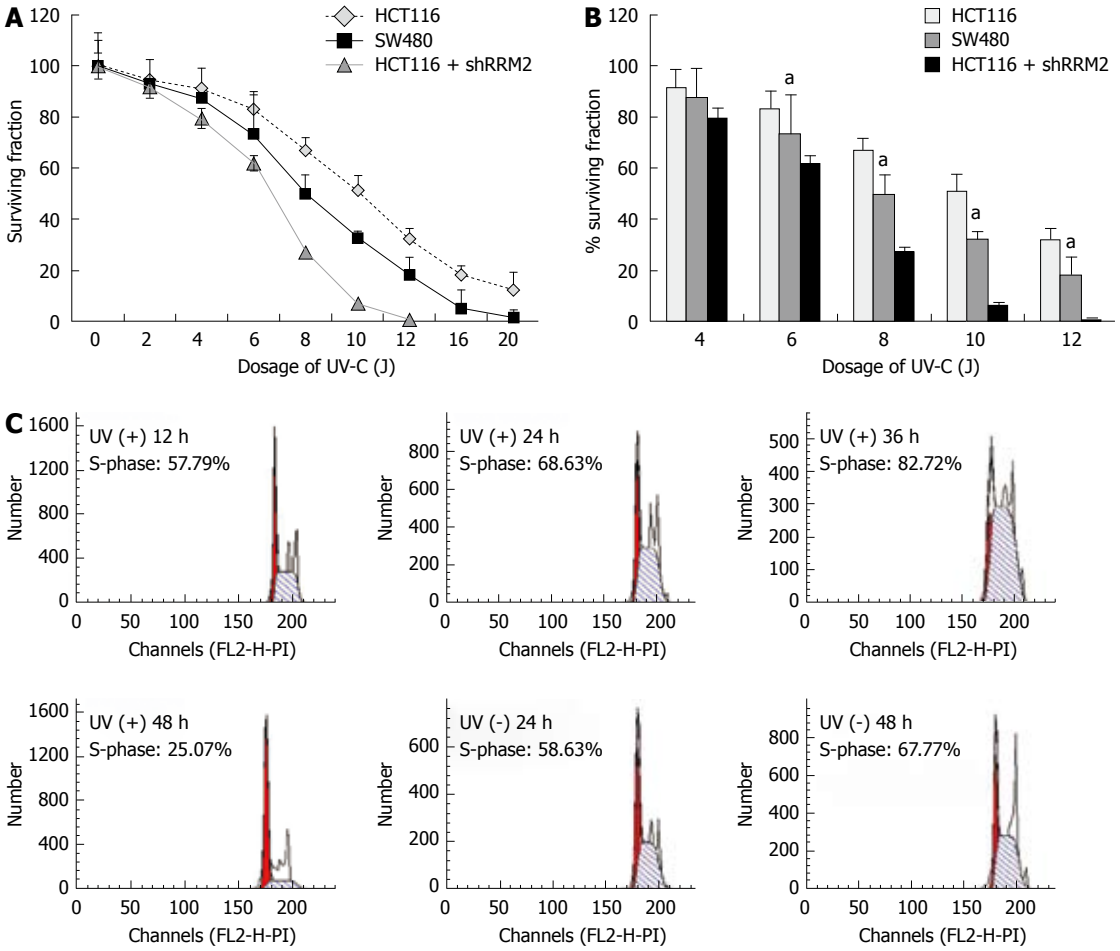

Figure 4 Inhibition of ribonucleotide reductase M2 by expression of antisense hRRM2 results in increased ultraviolet sensitivity of colorectal cancer cells. A: Ribonucleotide reductase M2 (RRM2)-/- tumors and RRM2-depleted cells are hypersensitive to ultraviolet (UV)-C. SW620 cells, HCT116 cells (WT), and HCT116 cells (RRM2-/-) were irradiated with increasing doses of UV-C and assayed for colony formation; B: Bar graph showing the quantification of the surviving fraction following 4-12 J irradiation. HCT116 cells transfected with shRRM2 revealed significant RRM2 depletion, and its colony-forming ability under UV radiation was suppressed, $^{a}P < 0.05$ *vs* HCT116 group; C: Effects of colorectal cancer cell cycle irradiated with UV-C. After UV irradiation, an S-phase increase could be seen, starting from 12 h with a continued significant increase at 24 and 36 h.

p53R2 is 80%-90% identical to RRM2, but lacks its 33 amino-terminal residues, including a KEN box required for degradation during mitosis. p53R2 can substitute for RRM2 and form a highly active RR, which is believed to be active in DNA repair after DNA damage[4]. However, the current knowledge about RRM2 function in human CRCs is still preliminary[20,21]. Therefore, determining if RRM2 is essential for CRC progression may provide promising therapeutic opportunities.

Our findings showed that RRM2 expression is substantially upregulated in CRC using microarray analysis and RT-PCR. Moreover, RRM2 overexpression was significantly associated with invasion depth and differentiation, and clinical tissue specimens also showed that the expression levels of RRM2 may be associated with tumor stage (Figure 5B). These data suggest that RRM2 overexpression could be associated with CRC progression. Several previous reports demonstrated the frequent overexpression of the RRM2 protein and its possible role in other cancers[20-23]. Recent observations showed that top 400 gene lists is produced by microarrays for each of the 13 cancer types and RRM2 appeared in nine lists of significantly altered genes in cancers[23], the results point to the value of RRM2 in normal to cancer transformation. RRM2 is upregulated in esophageal/gastric cancers and melanomas compared to pancreatic cancer[24]. Other groups have also suggested that RRM2 may be a novel diagnostic marker and potential therapeutic target in bladder and gastric cancers. Furthermore, the studies suggested that RRM2 overexpression is associated with the male sex, the presence of muscularis propria invasion, the presence of Epstein-Barr virus, and expression of survivin, but not with age, histology, tumor size, lymph node metastasis, or expression of the phosphatase and tensin homolog, the phosphorylated signal transducer, and p53. Suppression of RRM2 synthesis inhibited the growth of gastric cancer cell lines *in vitro*[20]. In addition, RRM2 is one of the putative tumor markers that is strongly expressed in the very early stages of premalignancy and preneoplasia of breast carcinomas[25], and hepatocellular carcinoma cells are highly dependent on these genes for proliferation[26]. Analyses also revealed that hRRM2 positively correlates with poor tumor differentiation of non-small cell lung cancer[27]. It may be that

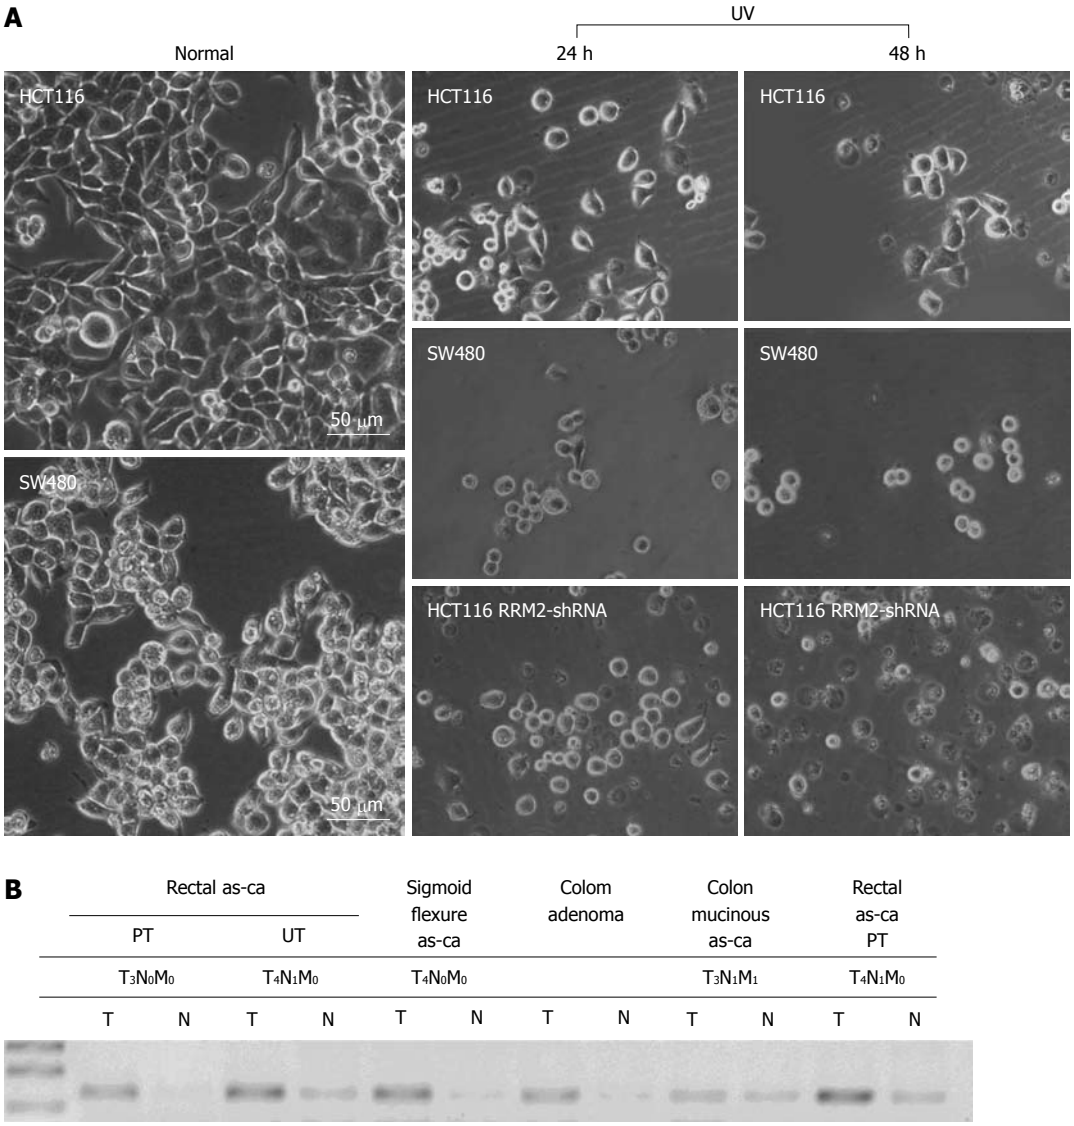

Figure 5 Light-microscopic photograph of cellular morphology. A: After 48 h of culture in normal conditions or exposed to ultraviolet (UV), HCT116 cells [high expression level of ribonucleotide reductase M2 (RRM2)] and SW480 cells (low expression level of RRM2) were photographed (20 × magnification). With UV-C irradiating, SW480 cells formed spheroids and HCT116 cells still adhered to each other and attached; B: Expression of RRM2 mRNA in clinical tissue specimens. Polymerase chain reaction analyses of 25 colorectal cancer patients (we show 6 patients) showed the expression levels of RRM2. PT: Protrude type; UT: Ulcerative type; as-ca: Adenocarcinoma.

the altered expression of metabolic enzymes or changes in the regulation of metabolic pathways also occur downstream of many oncogenes and tumor suppressor genes, and cancers with specific genetic lesions are dependent upon some of these metabolic changes. As was previously shown, RRM2 is upregulated in several cancers, and abrogating its expression reduces the proliferation of cancer cells, and triggered the development of RRM2-targeted siRNA-containing nanoparticles.

We also demonstrated that siRNA-mediated suppression of RRM2 synthesis inhibited the growth of the CRC cell lines investigated. In addition, abrogating its expression induced cell apoptosis. Therefore, it is likely that RRM2 overexpression is essential for the survival of CRC cells. Our finding is consistent with recent observations demonstrating that cells with altered RRM2 expression exhibit significantly reduced subcutaneous tumor latency and increased tumor growth rates in syngeneic mice, and show markedly elevated metastatic potential in lung metastasis assays[28]. Their studies demonstrate that RRM2 can participate in other critical cellular functions in addition to ribonucleotide reduction. For example, RRM2 overexpression may increase pancreatic cancer cell invasion in an NF-κB-dependent manner, and RNA interference mediated silencing of RRM2 expression attenuated cell invasion and matrix metallopeptidase 9 activity[16]. Another laboratory also reported that RRM2 overexpression plays an important role in tumor invasiveness[29,30]. Our results are consistent with these previous reports, and suggest that targeting RRM2 has the potential for the treatment of CRC.

RRM2 is known to be involved in chemoresistance. The suppression of RRM2 can sensitize colon cancer cells to chemotherapeutic agents and significantly inhibit

the proliferation of melanoma cell lines with different oncogenic mutations with synergistic enhancement in combination with temozolomide[31]. The relationship between RRM2 expression and chemotherapeutic effects in clinical settings has also been investigated. For instance, GTI-2040, an antisense oligonucleotide targeting RRM2, has been tested for the treatment of advanced metastatic solid tumors in clinical settings[32]. Radiation is also a key component of carcinoma therapy. Unfortunately, it results in significant side effect in some patients. Thus, agents that radiosensitize CRC cells would be very useful. Here we show that RRM2 depletion decreased the surviving fraction of tumor cells in response to radiation and increased the sensitizer enhancement ratios. Recent observations suggest that targeting polo-like kinase 1 (PLK1) with small molecule inhibitors, in combination with radiation therapy, is a novel strategy in the treatment of some cancers[33]. In addition, it has been hypothesized that there are some links between RRM2 and PLK1, because PLK1 was one of the most drastically downregulated genes following RRM2 silencing[34]. Our data suggest RRM2 depletion increased UV sensitivity and make an argument for further exploring the role of RRM2 inhibition in CRC. It will be important to elucidate in detail the specific mechanisms by which RRM2 mediates tumor cell radiosensitivity.

In conclusion, we performed both functional and correlative studies on RRM2 in CRCs and provide strong evidence that RRM2 overexpression may be associated with CRC progression; thus suppressing its function may be a potential therapeutic strategy in CRC.

COMMENTS

Background

Previous studies have shown that alterations in ribonucleotide reductase (RR) levels may significantly influence the biological properties of cells, including tumor promotion and tumor progression, suggesting that RR may be implicated in tumorigenesis. Thus, the authors were interested in determining the effect of ribonucleotide reductase M2 (RRM2) on colorectal cancer (CRC) cells.

Research frontiers

Recently, metabolic genes have received increasing and specific attention due to their potential role in carcinogenesis. Overexpression of RRM2 has been revealed in breast cancer, renal cell carcinoma, prostate cancer and gastric cancer to elevated cellular proliferation and invasiveness.

Innovations and breakthroughs

Few studies have described the correlation between RRM2 and the development of CRC. And the possible mechanism by which RRM2 mediates CRC progression is unclear. It is well established that in some types of cancer, elevated RRM2 levels correlate with chemoresistance, but whether it may contribute to the response to ultraviolet (UV) irradiation is unclear. The results of this study suggest that RRM2 may be a facilitating factor in colorectal tumorigenesis and UV-induced DNA damage repair.

Applications

The data suggests that RRM2 subunit overexpression is associated with the CRC progression. RRM2 silencing may inhibit the hyperplasia and invasiveness of CRC cells. RRM2 may play an important role in the infiltration and metastasis of CRC and that suppression of its function could be a potential therapeutic strategy in CRC.

Terminology

RR is an essential enzyme required for the *de novo* conversion of ribonucleoside diphosphates to deoxyribonucleoside diphosphates, and it plays an important role in DNA synthesis and repair. RR consists of two subunits, RRM1 and RRM2/p53R2.

Peer review

This is an interesting study investigating the importance of the hRRM2 in CRC and UV-induced DNA damage repair.

Abstract

AIM: To study and provide data on the evolution of medical procedures and outcomes of patients suffering from perforated midgut diverticulitis.

METHODS: Three data sources were used: the Medline and Google search engines were searched for case reports on one or more patients treated for perforated midgut diverticulitis (Meckel's diverticulitis excluded) that were published after 1995. The inclusion criterion was sufficient individual patient data in the article. Both indexed and non-indexed journals were used. Patients treated for perforated midgut diverticulitis at Vestfold Hospital were included in this group. Data on symptoms, laboratory and radiology results, treatment modalities, surgical access, procedures, complications and outcomes were collected. The Norwegian patient registry was searched to find patients operated upon for midgut diverticulitis from 1999 to 2007. The data collected were age, sex, mode of access, surgical procedure performed and number of patients per year. Historical controls were retrieved from an article published in 1995 containing pertinent individual patient data. Statistical analysis was done with SPSS software.

RESULTS: Group Ⅰ: 106 patients (48 men) were found. Mean age was 72.2 ± 13.1 years (mean ± SD). Age or sex had no impact on outcomes (P = 0.057 and P = 0.771, respectively). Preoperative assessment was plain radiography in 53.3% or computed tomography (CT) in 76.1%. Correct diagnosis was made in 77.1% with CT, 5.6% without (P = 0.001). Duration of symptoms before hospitalization was 3.6 d (range: 1-35 d), but longer duration was not associated with poor outcome (P = 0.748). Eighty-six point eight percent of patients underwent surgery, 92.4% of these through open access where 90.1% had bowel resection. Complications occurred in 19.2% of patients and 16.3% underwent reoperation. Distance from perforation to Treitz ligament was 41.7 ± 28.1 cm. At surgery, no peritonitis was found in 29.7% of patients, local peritonitis in 47.5%, and diffuse peritonitis in 22.8%. Peritonitis grade correlated with the reoperation rate (r = 0.43). Conservatively treated patients had similar hospital length of stay as operated patients (10.6 ± 8.3 d *vs* 10.7 ± 7.9 d, respectively). Age correlated with hospital stay (r = 0.46). No difference in outcomes for operated or nonoperated patients was found (P = 0.814). Group Ⅱ: 113 patients (57 men). Mean age 67.6 ± 16.4 years (range: 21-96 years). Mean age for men was 61.3 ± 16.2 years, and 74.7 ± 12.5 years for women (P = 0.001). Number of procedures per year was 11.2 ± 0.9, and bowel resection was performed in 82.3% of patients. Group Ⅲ: 47 patients (21 men). Patient age was 65.4 ± 14.4 years. Mean age for men was 61.5 ± 17.3 years and 65.3 ± 14.4 years for women. Duration of symptoms before hospitalization was 6.9 d (range: 1-180 d). No patients had a preoperative diagnosis, 97.9% of patients underwent surgery, and 78.3% had multiple diverticula. Bowel resection was performed in 67.4% of patients, and suture closure in 32.6%. Mortality was 23.4%. There was no difference in length of history or its impact on survival between Groups Ⅰ and Ⅲ (P = 0.241 and P = 0.198, respectively). Resection was more often performed in Group Ⅰ (P = 0.01). Mortality was higher in Group Ⅲ (P = 0.002).

CONCLUSION: In cases with contained perforation, conservative treatment gives satisfactory results, laparosco-

py with lavage and drainage can be attempted and continued with a conservative course.

INTRODUCTION

Perforated midgut diverticulitis is an uncommon, acquired condition that is only sporadically observed and treated in surgical departments[1]. This could be the reason for the confusion that still exists when clinical manifestations, diagnosis and treatment options are concerned. The evidence at hand does not seem to be satisfactory to provide the answers needed. Furthermore, there are no data on the use of minimally invasive procedures in the treatment of perforated midgut diverticulitis. A previously published review by Chendrasekhar *et al*[2] in 1995 provided individual patient data for all case reports previously published. This article was chosen to be the landmark for this study because of its extensive data, firm grasp of the problem up to 1995, prior to important developments in diagnostics and treatment.

The aim of this study is to provide new data on the evolution of medical procedures and outcomes in patients with perforated midgut diverticulitis based on individual patient data derived from published case reports, original data and the Norwegian patient registry.

MATERIALS AND METHODS

The data obtained in this study came from three different sources: (Group Ⅰ) review of published case reports in the literature after 1995 combined with original data; (Group Ⅱ) data from the Norwegian patient registry; and (Group Ⅲ) case reports from the literature prior to 1995 as historical controls[2].

Case reports and original data (Group Ⅰ)

Search strategy: Two independent researchers with a medical degree performed the search. The Medline database (http://www.ncbi.nlm.nih.gov/PubMed/) was searched for articles published after 1995. An effort to incorporate all available articles not included in Medline was made through the use of the Google search engine (http://www.google.com/). The following key search strategy was used: ("perforated" or "perforation") and [("jejunum" or "jejunal") or ("intestine, small") or ("intestine" and "small") or ("small intestine") or ("small" and "bowel") or ("small bowel")] and ("diverticulum" or "diverticulitis") for medline databases; and ("perforated" or "perforation") and [("jejunum" or "jejunal") or ("intestine" and "small") or ("small intestine" or "intestine") and ("bowel" or "small bowel")] and ("diverticulum" or "diverticulitis") not sigmoid for Google. References did not have to have abstracts. There were no restrictions by language or publication type. English, French, Spanish, Portuguese, Italian, German and the Scandinavian and Slavic languages were translated by the authors, while help was acquired for translations of Turkish and Korean. All references matching the search were identified and screened for retrieval. Duplicate references were removed by a manual search. The retrieved references were scanned by the authors independently.

Selection: The inclusion criterion was original articles or case reports with any study design including at least one patient undergoing any kind of treatment for perforated midgut diverticulitis (Meckel's diverticulitis excluded), containing pertinent individual patient data. Perforated midgut diverticulitis was defined either as histopathologically confirmed in the surgical specimen (operated patients) or where clear radiological evidence was provided in conservatively treated patients. This evidence was usually computed tomography (CT)-based (localized inflammation or thickened wall of the midgut with/without air bubbles, pseudotumor or abscess in the midgut mesentery), or confirmed with a small bowel series, and in some cases, through radiography with contrast medium after abscess drainage. The population selected were 18 years or older.

Data abstraction: Individual data for each patient included the following: age; sex; surgical procedure (if operated); access (laparoscopic/open/combined); number of diverticula (single/multiple); distance from the ligament of Treitz; diverticula in other segments of the gut (jejunum/ileum/colon); length of symptoms prior to hospitalization; fever; peripheral blood leucocytes and C-reactive protein (CRP) at admission; method of diagnosis; hospital stay; complications (general and surgical); reoperation; and outcome. Details of the intervention included any type of treatment (conservative or surgical). Surgical procedure was classified as resection, suture closure or exploration, laparoscopic or open. Other complications of midgut diverticulitis (bleeding, bacterial overgrowth) were not studied.

Vestfold hospital patient data: Patients treated at Vestfold hospital for perforated midgut diverticulitis from March 2008 to December 2010 were included in this series. All patients had an abdominal CT scan at hospitalization. Indication for surgery was made through the evaluation of abdominal tenderness, rebound tenderness, bowel sounds, blood work-up and CT scan. Antibiotics

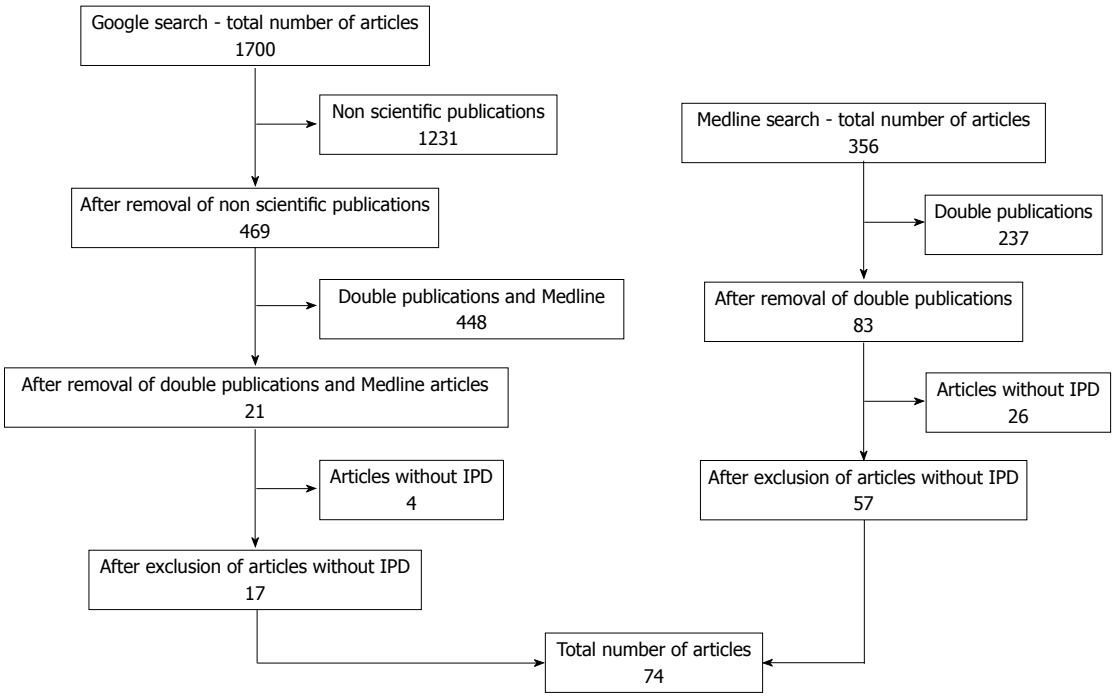

Figure 1 Schematic of the search strategy. IPD: individual patient data.

were administered. Patients who were operated upon had laparoscopy that confirmed the diagnosis, and thereafter a precisely placed minilaparotomy 4-5 cm in length, through which a limited small bowel resection and end-to-end hand-sewn anastomosis was performed. Further investigations (gastroscopy, colonoscopy and small bowel series) were done several weeks after the patient was discharged from the hospital.

Norwegian patient registry (Group Ⅱ)

A comprehensive search of the Norwegian patient registry was performed. The time limit was from 1999 (introduction of the ICD-10 coding system in Norway) to 2007. The search criteria: K57.0 (midgut diverticulitis with perforation or abscess), K57.4 (small and large bowel diverticulitis with perforation or abscess), K57.8 (bowel diverticulitis, unspecified with perforation or abscess), Q43.0 (Meckel's diverticulum) excluded, crossed with JFB00 (small bowel resection), JFB01 (laparoscopic small bowel resection), JFA70 (enterorrhaphy), JFA71 (laparoscopic enterorrhaphy). Patients under the age of 18 years were excluded. The data requested were age, sex, mode of access, surgical procedure performed, and number of patients per year.

Historical controls (Group Ⅲ)

The data on historical controls was retrieved from Chendrasekhar *et al*[2]. Patients under the age of 18 years, and patients that did not have data on age were deleted and the remaining data were copied into the statistical software and used for further analysis.

Statistical analysis

Analysis was done using SPSS statistical software (Chicago, IL, United States). Distribution of data was checked with the Shapiro-Wilks test. Nonparametric values were compared using the χ^2 test and the Mann-Whitney test, while parametric values were compared using Student's *t* test. Correlations were tested with Spearman's test. The *P* values given were two sided, $P < 0.05$ was considered as the limit of significance.

RESULTS

Case reports and patients treated in Vestfold Hospital (Group Ⅰ)

The search strategy (Figure 1) provided 356 articles from the Medline database, and 1700 documents were retrieved through the Google search engine. After manual removal of duplicate references, 104 articles were retrieved. Thirty of these did not contain pertinent patient data and were, therefore, excluded. The end result was 74 articles with 103 case reports containing detailed and pertinent individual patient data mostly retrieved through Medline[3-59], while 22.9% of these came from Google alone[60-76]. The individual patient data collected from the three patients treated for perforated midgut diverticulitis at Vestfold Hospital were added to this group, making a total of 106 patients (48 men and 58 women). The mean age of the group was 72.2 ± 13.1 years, and the age distribution was not normal ($P = 0.001$). The mean age for men was 73.7 ± 12.2 years and the mean age for women was 71.1 ± 13.8 years, with non-normal distribution for both sexes, $P = 0.005$ and $P = 0.001$, respectively. Sex distribution according to age was not significantly different in this group ($P = 0.296$). Patient age or sex did not have an impact on outcome ($P = 0.057$ and $P = 0.771$, respectively).

Preoperative assessment was described as plain radi-

Table 1 Overview of complications in Group Ⅰ (case reports)

Complications	Frequency	Present
General[1]	5	4.7
Surgical[2]	8	7.5
Both	3	2.9
None	59	55.7
Not available	31	29.2
Total	106	100

[1]Acute myocardial infarction, pulmonary embolism, pneumonia, deep vein thrombosis, urinary tract infection and stroke; [2]wound infection/dehiscence, anastomotic leakage, small bowel obstruction, intra-abdominal abscess and incisional hernia.

ography in 49 patients (53.3%) or CT in 70 (76.1%) in a total of 92 (86.8%) patients. Case reports did not include preoperative assessment in 14 (13.2%) patients. Where CT was performed, the correct preoperative diagnosis was made in 54 (77.1%) patients, while the probability of detecting perforated midgut diverticulitis without CT was 5.6% (two patients), both patients were previously known to have midgut diverticulosis. The difference in diagnosis with/without CT was statistically significant ($P = 0.001$).

Data on the duration of symptoms prior to hospitalization were present for 88 (83.0%) patients. The mean duration of symptoms prior to hospitalization was 3.6 d (range: 1-35 d). A longer duration of symptoms did not result in a poor outcome ($P = 0.748$). Data on fever were listed in 49 (46.2%) patients. Patients most often presented with moderate fever 23 (46.9%), while no fever or high fever was present in 26.5% each. Leukocyte and CRP levels were 13.8 ± 3.6 × 10^9/L and 155.4 ± 100.6 mg/L, respectively. Ninety-two (86.8%) patients underwent surgery, and 14 (13.2%) received conservative treatment. The surgical procedure most often performed was small bowel resection (83, 90.1%), followed by suture closure (5, 5.5%). Two patients (2.2%) underwent complex procedures that included multiple resections and 2 (2.2%) underwent surgical exploration with drainage. Access was through open surgery in 85 (92.4%) patients, while laparoscopic access was chosen in 5 (5.5%) and converted in 3 (60%). Two procedures (2.2%) were completed through laparoscopy. Data on postoperative complications were accessible in 73 patients. Complications occurred in 19.2% (Table 1). Fifteen (16.3%) patients underwent reoperation.

The operative report contained data on the distance of the perforated diverticulum to the ligament of Treitz in 29 patients, setting the mean distance to 41.7 ± 28.1 cm (range: 4-110 cm). Data on peritonitis was missing in five (4.7%) patients. There was no peritonitis or abscess in 30 (29.7%) patients, local peritonitis was present in 48 (47.5%), and 23 (22.8%) had diffuse peritonitis. Two (2.0%) patients had a mesenteric abscess. A reasonable correlation between the grade of peritonitis and reoperation rate was noted ($r = 0.43$, Spearman's test).

Seventeen (16.8%) patients had a solitary midgut diverticulum. Multiple jejunal diverticula were noted in 84 (83.2%) patients, while no data were provided for 5 (4.7%).

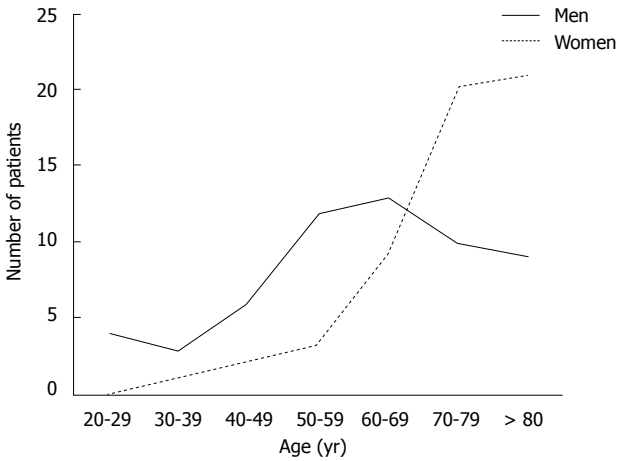

Figure 2 Correlation between sex and age for patients in the Norwegian patient registry.

Data on location and number of diverticula throughout the digestive tube were listed for 46 (43.4%) patients. Concomitant ileal diverticulosis was found in 18 (39.1%), while 31 (67.4%) had colon diverticulosis. In all, 21 (45.6%) patients had diverticulosis throughout the intestinal tract.

Mean hospital stay was 10.7 ± 7.9 d. Conservatively treated patients did not have a longer hospital stay than operated patients (10.6 ± 8.3 d *vs* 10.7 ± 7.9 d, respectively). Reoperated patients had a longer hospital stay 13.6 ± 8.4 d. There was a reasonable correlation between patient age and length of hospital stay ($r = 0.46$). Overall mortality was 5.7%. There was no statistically significant difference in outcomes for operated or nonoperated patients ($P = 0.814$).

Norwegian patient registry (Group Ⅱ)

The analysis of the Norwegian patient registry provided data on 113 patients, 57 men and 56 women. Patient mean age was 67.6 ± 16.4 years (range: 21-96 years). The age distribution within this group was not normal ($P = 0.04$). Mean age for men was 61.3 ± 16.2 years, while that for women was 74.7 ± 12.5 years, with non-normal distribution for both sexes, $P = 0.027$ and $P = 0.013$, respectively. The difference in age between the sexes was highly significant ($P = 0.001$) (Figure 2). The mean frequency of surgical procedures per year was 11.2 ± 0.9. The procedures most often performed were small bowel resection in 93 (82.3%) patients and enterorrhaphy in 17 (15%). Equivalent procedures performed through laparoscopic access were performed in 2 (1.8 %) and 1 (0.9 %) patients, respectively.

Historical controls (Group Ⅲ)

After the exclusion of patients under the age of 18 years, the group consisted of 47 patients (21 men and 26 women). Patient mean age was 65.4 ± 14.4 years. The age distribution within this group was normal ($P = 0.18$). Mean age for men was 61.5 ± 17.3 years, while that for women was 65.3 ± 14.4 years, with normal distribution for both sexes, $P = 0.29$ and $P = 0.76$, respectively.

Duration of symptoms prior to hospitalization was 6.9 d (range: 1-180 d). No patients had a preoperative diagnosis. Only one (2.1%) patient was treated conservatively, while the remaining 46 (97.9%) underwent surgery. Peroperative data were available for 24 (51.1%) patients, and cited as perforation in all, without grade of peritonitis. Twenty-three (48.9%) patients had data on number of diverticula, 18 (78.3%) had multiple and 5 (21.7%) had solitary diverticula. Small bowel resection was performed in 31 (67.4%) patients and suture closure in 15 (32.6%). Mortality in this group was 23.4%.

Comparison between patient groups

When length of history was concerned there was no difference between Groups I and Ⅲ (P = 0.241). Furthermore, there was no impact of length of history on survival between Groups I and Ⅲ (P = 0.198). No significant difference was detected in outcomes of conservative and surgical treatment (P = 0.23). However, there was a significant difference noted for type of surgical procedure, in favor of resection in Group Ⅰ compared to Group Ⅲ (P = 0.01), as well as the number of diverticula (P = 0.001). Mortality was significantly higher in Group Ⅲ compared to Group Ⅰ (P = 0.002).

DISCUSSION

One of the objective difficulties that a researcher encounters when investigating rare conditions is the absence of evidence and data. Data from the Norwegian patient registry show that a trial on a national level would prove to be difficult, including at most 10 patients per year. In these circumstances, one chooses the next best solution, reanalysis of small case series or case reports that contain sufficient individual patient data. A tendency to not publish case reports or small case series in indexed journals is noted, making this task even more demanding, hence, the contribution of the Google search engine in locating almost 20% of these case reports. We are well aware of the shortcomings of such a study; however, the use of abductive, probabilistic reasoning[77] allows for some valuable conclusions to be drawn.

The main finding of the present study is a transition in treatment, diagnosis and outcomes of patients suffering from perforated midgut diverticulitis. There seems to be a shift towards conservative treatment when properly diagnosed, a much higher percentage of accurate diagnosis, and small bowel resection is usually performed with lower mortality rates. This implies that elderly patients suffering from acute abdominal symptoms with elevated infection parameters should undergo a CT scan. Hence, the surgeon should have a high level of suspicion that the patient is suffering from perforated midgut diverticulitis after the initial CT scan is performed. Moreover, it seems that a substantial number of patients that could have been treated conservatively underwent surgery, because the majority of operated patients suffered from contained perforation. Surgical treatment should be avoided not only because of the burden of age and comorbidity in this patient group, but rather to avoid the risk of extensive resection in patients with multiple diverticula[1,2,78]. The fact that laparoscopy was so seldom used is even more surprising, because laparoscopic exploration and evaluation do not represent advanced minimally invasive surgical procedures.

The present study provides an opportunity to recommend the intensive use of laparoscopic exploration and evaluation in the emergency surgical setting. Nowadays, it seems that laparoscopic exploration provides at least as useful evaluation of abdominal pathology as open surgery does. Apart from the obvious benefits, laparoscopic exploration allows us to abandon the abdomen after lavage and drainage, and continue a conservative course[79]. A heavy proximal (within 1 m from the Treitz ligament) midgut mesentery with fibrin deposits is typical for the condition, and if generalized peritonitis is not present, our results seem to show that a conservative approach is feasible. The rationale is the fact that length of history prior to surgery does not seem to affect treatment outcome; there was no increase in mortality or morbidity between the groups. Even length of hospital stay was equal between patients operated upon and those conservatively treated. On the other hand, generalized peritonitis had a significant correlation with length of hospitalization and mortality, and should be treated surgically. The affected loop can be exteriorized through a mini-laparotomy after laparoscopic mobilization, and limited resection performed. Suture closure does not seem to have a place in the treatment of perforated midgut diverticulitis.

Such an approach would minimize the frequency of midgut resections in this high-risk population, while allowing the correct choice of patients for conservative treatment. A similar approach has recently had an impact on the treatment of sigmoid diverticulitis. Laparoscopic lavage and drainage have been advocated for generalized peritonitis due to perforated sigmoid diverticulitis. In this study, only 8% of patients underwent conversion and surgical resection, while the vast majority were handled conservatively after lavage and drainage[79].

It seems that correct diagnosis, together with the recognition of the immunological and physiological advantages of minimally invasive surgery, modern antibiotics and critical care could contribute to even better outcomes.

In summary, technological developments have led to better diagnosis of patients with perforated midgut diverticulitis. However, these have as yet not been applied in the operating room, where open surgery is still dominant over laparoscopy. When properly diagnosed, a transition in treatment is noticed towards conservative treatment. Only generalized peritonitis seems to have a significant correlation with length of hospitalization and mortality, and should be treated surgically. In these patients, laparoscopy and small bowel resection should be performed.

COMMENTS

Background

Perforated midgut diverticulitis is an uncommon, acquired condition that is only

sporadically observed and treated in surgical departments. Most of the literature consists of case reports, and this could be the reason for the confusion that still exists when clinical manifestations, diagnosis and treatment options are concerned. In addition, developments in surgery, radiology and other branches of medicine have occurred since the last review that has changed both surgical and conservative treatment.

Research frontiers

As demonstrated in the results this is a condition occurring in the elderly, and therefore has its challenges in choice of conservative treatment over surgical in the individual patient. Minimally invasive surgery would seem to have a place in this setting as well as the development of innovative surgical techniques to tackle this specific setting.

Innovations and breakthroughs

A transition to conservative treatment due to a correct preoperative diagnosis is apparent. Laparotomy continues to be dominant and the use of minimally access surgery is negligible. Small bowel resection is most often performed; suture closure is abandoned.

Applications

All elderly patients presenting with fever, infection and abdominal pain should have a computed tomography (CT) scan at admission. Surgery should be considered only in cases with generalized peritonitis. Conservative treatment should have a main role in treatment. Innovative minimally invasive procedures are required.

Terminology

Midgut is a segment of bowel that extends from the apex of the duodenal loop to the last third of the transverse colon. The midgut is supplied with blood by the superior mesenteric artery and innervated by the vagus nerve.

Peer review

The paper described a transition in diagnosis, treatment (a shift toward conservative treatment when properly diagnosed with CT), and outcomes (lower mortality rates) of patients suffering from perforated midgut diverticulitis. This topic will be of interest to WJG readers.

Abstract

AIM: To determine the prevalence and significance of primary biliary cirrhosis (PBC)-specific autoantibodies in first-degree relatives (FDRs) of Greek PBC patients.

METHODS: The presence of antimitochondrial antibodies (AMA) and PBC-specific antinuclear antibodies (ANA) were determined using indirect immunofluorescence assays, dot-blot assays, and molecularly based enzyme-linked immunosorbent assays in 101 asymptomatic for liver-related symptoms FDRs of 44 PBC patients. In order to specify our results, the same investigation was performed in 40 healthy controls and in a disease control group consisting of 40 asymptomatic for liver-related symptoms FDRs of patients with other autoimmune liver diseases namely, autoimmune hepatitis-1 or primary sclerosing cholangitis (AIH-1/PSC).

RESULTS: AMA positivity was observed in 19 (only 4 with abnormal liver function tests) FDRs of PBC patients and none of the healthy controls. The prevalence of AMA was significantly higher in FDRs of PBC patients than in AIH-1/PSC FDRs and healthy controls [18.8%, 95% confidence interval (CI): 12%-28.1% *vs* 2.5%, 95% CI: 0.1%-14.7%, $P = 0.01$; 18.8%, 95% CI: 12%-28.1% *vs* 0%, 95% CI: 0%-10.9%, $P = 0.003$, respectively]. PBC-specific ANA positivity was observed in only one FDR from a PSC patient. Multivariate analysis showed that having a proband with PBC independently associated with AMA positivity (odds ratio: 11.24, 95% CI: 1.27-25.34, $P = 0.03$) whereas among the investigated comorbidities and risk factors, a positive past history for urinary tract infections (UTI) was also independently associated with AMA detection in FDRs of PBC patients (odds ratio: 3.92, 95% CI: 1.25-12.35, $P = 0.02$).

CONCLUSION: In FDRs of Greek PBC patients, AMA prevalence is significantly increased and independently associated with past UTI. PBC-specific ANA were not detected in anyone of PBC FDRs.

INTRODUCTION

Primary biliary cirrhosis (PBC) is an autoimmune cholestatic liver disease of unknown cause which predominantly affects women and is characterized by immune-mediated destruction of the intrahepatic bile ducts, gradually leading to fibrosis, cirrhosis, and eventually, liver failure[1].

The disease is now diagnosed earlier than it was in the past as attested by the fact that more than 60% of PBC patients are asymptomatic at diagnosis as opposed to fewer than 40% a decade ago[2]. Early detection of PBC seems important, since patients with PBC, albeit asymptomatic, have reduced overall survival compared to controls[3], whereas timely treatment with ursodeoxycholic acid before the development of late-stage disease may normalize life expectancy[4,5].

The pathogenesis of PBC remains elusive, although it is generally considered to involve a combination of genetic and environmental factors[6]. The observed differences in PBC prevalence between populations living in different geographical regions but sharing similar genetic backgrounds support that environmental factors play a pivotal role in disease etiology[7,8]. Epidemiologic evidence suggests several non-genetic risk factors to be associated with PBC, including a history of urinary tract infections (UTI), past smoking and use of hormone replacement therapy[9]. Additionally, experimental data have proposed xenobiotics and several infectious agents, such as *Escherichia coli* and *Novosphingobium aromaticivorans* as initiating factors in the development of PBC[10].

Conversely, genetic factors also play an important role in conferring susceptibility to PBC, as indicated by the high concordance rate among monozygotic twins and the increased prevalence of PBC and other autoimmune disorders in patients' families[11,12]. During the past 15 years, several studies have reported familial PBC prevalence to range between 1.3% and 9%[13-18]. In addition to clustering of PBC and other autoimmune diseases in the families of PBC patients, the presence of antimitochondrial antibodies (AMA) aggregates in first-degree relatives (FDRs) of afflicted individuals as well, with AMA prevalence ranging between 1% and 13.1%[16,19-23]. Circulating AMA against the 2-oxo-acid dehydrogonase components of inner mitochondrial multi-enzyme complexes are considered the serological hallmark of PBC[1,24]. The main antigenic targets of AMA include the E2 subunits of the pyruvate dehydrogonase complex (PDC-E2), the branched-chain 2-oxo-acid dehydrogonase complex (BCOADC-E2), the oxoglutarate dehydrogenase complex (OGDC-E2), and the E1a subunit and the E3 binding protein of PDC[24]. AMA are present in 90%-95% of patients and are often detectable years before clinical signs appear[1,24]. Indeed, AMA detection in otherwise asymptomatic individuals with normal liver function tests may be associated with PBC-compatible histology in 40% of cases and eventual progression to clinically apparent disease[25,26].

In addition to AMA, previous studies have shown that antinuclear antibodies (ANA) giving a multiple nuclear dot (MND) or a rim-lime/membranous (RL/M) pattern by indirect immunofluorescence (IIF) are found in up to 65% of PBC patients if IgG isotype specific antibodies are investigated[27-29]. These antibodies seem to be disease specific (ANA-PBC specific) and have prognostic significance[27-29]. However, to the best of our knowledge these antibodies have not yet been investigated in asymptomatic for liver-related symptoms FDRs of PBC patients.

Accordingly, the aim of the present study was to determine the prevalence of AMA and ANA-PBC specific antibodies in asymptomatic for liver-related symptoms FDRs of Greek patients with PBC in comparison with asymptomatic FDRs from patients with other autoimmune liver diseases (disease control group) and healthy controls. To the best of our knowledge a combination of sensitive diagnostic techniques was used for the first time in order to improve the overall performance. In addition, we investigated the association of these antibodies with known comorbidities and reported risk factors for PBC as similar data on these issues is scarce in FDRs of PBC patients.

MATERIALS AND METHODS

Study population

From a cohort of 140 well-defined Greek PBC patients, 44 gave informed consent to participate in the study. Upon consent, patients were asked to provide information about their FDRs, i.e. parents, siblings and children. Subsequently, FDRs were contacted and were asked to participate in the study by attending an interview, physical examination and donation of blood. Accordingly, 101 FDRs of these 44 PBC patients were finally investigated. The diagnosis of PBC was based on the criteria published in our previous reports[30-33]. In brief, PBC patients met the following criteria: (1) positivity for AMA (positive titre $\geqslant$ 1/40) either by IIF on in-house fresh rodent tissue substrates confirmed by Western blot using in-house mitochondrial subtraction of rat livers, or by enhanced performance M2 enzyme-linked immunosorbent assay [M2 EP (MIT3) ELISA, QUANTA LiteR, INOVA Diagnostics, San Diego, CA], which was shown to have higher sensitivity compared to the conventional anti-M2[33]; (2) elevated cholestatic enzymes for more than 6 mo; and (3) histologic lesions consistent with PBC.

The disease control group consisted of 40 FDRs of Greek patients with well-defined autoimmune hepatitis-type 1 (AIH-1) or primary sclerosing cholangitis (PSC)

who were recruited through an identical process after an informed consent[34]. Their corresponding probands were 11 AIH-1 patients and 7 PSC patients.

All FDRs from the PBC patients and disease control patients underwent medical history and physical examination by a single investigator. The medical history was based on the US National Health and Nutrition Examination Survey questionnaire (NHANES 1999-2000)[35] with special attention to the environmental, familial and medical factors previously reported to associate with PBC[9]. Therefore, the questionnaire included data regarding demographics, smoking and alcohol consumption and past history of the FDRs. In particular, a past history of autoimmune diseases and other comorbidities reported to have increased prevalence in patients with PBC like Sjogren's syndrome, Hashimoto's thyroiditis, *etc*. was recorded in detail. From each subject serum samples were obtained and stored at -80 ℃, until assayed. Finally, a healthy control group consisted of 40 age and sex matched blood donors were also investigated. The study protocol was approved by the Ethical Committee of the Larissa Medical School, University of Thessaly, Larissa, Greece.

Detection of autoantibodies

IIF-Rodent tissues: AMA were detected by IIF on an in-house rat multiorgan substrate panel that included kidney, liver, and stomach using standard protocols[36-38]. The initial screening dilution was 1/40, and positive samples were further diluted in order to determine the maximum titer. Anti-total human Ig-fluorescein isothiocyanate conjugate was used (IgG, A, M, κ and λ; Dako Ltd.; High Wycombe, Bucks, United Kingdom) according to our laboratory practice[24,31,36]. AMA titers > 1/40 were considered positive.

IIF-HEp-2cells: A commercially available IIF assay was used for the semi-quantitative determination of ANA (NOVA Lite HEp-2, INOVA Diagnostics, San Diego, CA, positive titer > 1/40).

Dot blot assay: In order to confirm AMA-reactivity and to detect other liver-related autoantibodies, all sera were further examined using a commercial line (dot) blot assay (Euroline Liver Profile, Euroimmun AG, Lübeck, Germany), according to manufacturer's instructions. The Euroline Profile assay consists of membrane strips coated with thin parallel lines of purified, biochemically characterized antigens, allowing the detection of AMA, antibodies against liver kidney microsomes type 1, antibodies against liver cytosol type 1, and antibodies against soluble liver antigen/liver-pancreas antigen.

M2 ELISA: IgG-isotype specific AMA detection was also performed with an enhanced performance M2 ELISA, which utilizes a recombinant antigen (MIT3) containing the three immunodominant mitochondrial antigenic epitopes, namely PDC-E2, BCOADC-E2 and OGDC-E2 (INOVA Diagnostics, San Diego, CA), as we have described previously[33].

Utilizing all methods for the detection of AMA we have calculated the cumulative AMA reactivity of the study population, in which serum samples were considered positive if they fulfilled one of the following criteria: (1) they were AMA positive by IIF on rat multiorgan substrate at a dilution > 1/40 accompanied by AMA reactivity either in the dot blot assay or the enhanced MIT3-based ELISA; and (2) they were AMA positive on M2 MIT3-based ELISA irrespective of the AMA titer obtained by the IIF assay.

Anti-sp100 and anti-gp210 ELISAs: Semi-quantitative detection of anti-sp100 and anti-gp210 antibodies of the IgG class was performed with commercially available specific ELISAs according to the manufacturer's instructions (QUANTA Lite sp100 and gp210, INOVA Diagnostics, San Diego, CA). Serum samples were tested in duplicate and considered positive for PBC-specific ANA only when fulfilled the following criteria: MND or RL/M reactivity by IIF on Hep2 cells accompanied by positivity against anti-sp100 or anti-gp210, respectively, by using the molecularly based assays mentioned above (ELISAs)[24].

Statistical analysis

Data normality was analyzed using the Kolmogorov-Smirnov test. Continuous, normally distributed variables are presented as mean ± SD, and non-normally distributed variables as median (interquartile range). Categorical and ordinal data are presented as frequencies and/or percentages. Student's *t*-test, Mann-Whitney *U*-test, Kruskal-Wallis test, χ^2 test, Fischer's exact test and binary logistic regression analysis were also used, where applicable. *P* values of < 0.05 were considered statistically significant.

RESULTS

Demographic characteristics

The baseline demographic characteristics of the study population are summarized in Table 1. In total, the FDRs group consisted of 141 participants (61% children, 24.1% siblings and 14.9% parents).

Since a significant percentage of the FDRs group consisted of descendants of patients with autoimmune liver diseases, the mean age in the proband group was higher than the FDRs group. However, this difference was statistically significant only in PBC probands compared to PBC FDRs (58.8 ± 11.8 *vs* 40.8 ± 17.9, $P < 0.01$). Moreover, there were no statistically significant differences in age between the PBC FDRs, the AIH-1 FDRs and the PSC FDRs group.

Clinical disorders in FDRs

The prevalence of clinical disorders reported by FDRs of patients with autoimmune liver diseases is shown in Table 2. There were no statistically significant differences

Table 1 Demographic characteristics of the study population

	Total	Male	Female	Age (yr)
PBC probands	44	4 (9.1)	40 (90.9)	58.8 ± 11.8
PBC FDRs	101	45 (44.6)	56 (55.4)	40.8 ± 17.9

Autoantibody prevalence in FDRs

According to the above-mentioned criteria, AMA were detected in 20 FDRs of patients with autoimmune liver diseases (14.2%, 95% CI: 9.1%-21.3%) and none of the healthy controls (0%, 95% CI: 0%-10.9%, $P = 0.008$). The prevalence of AMA was also significantly higher in FDRs of patients with PBC compared to FDRs of patients with AIH-1 or PSC (18.8%, 95% CI: 12%-28.1% *vs* 2.5%, 95% CI: 0.1%-14.7%, $P = 0.01$; Table 3). PBC-FDRs had significantly increased AMA prevalence compared to healthy controls (18.8%, 95% CI: 12%-28.1% *vs* 0%, 95% CI: 0%-10.9%, $P = 0.003$).

ANA reactivity on Hep-2 cells is presented in Table 3. Specifically, antibodies giving RL/M pattern of ANA were observed in 7.9% (95% CI: 3.7%-15.5%) of PBC-FDRs. RL/M pattern of ANA was also observed in one PSC-FDR and in none of the controls; however, this difference did not approach significance. MND pattern of ANA tended to be detected in more AIH-1/PSC-FDRs (12.5%, 95% CI: 4.7%-27.6%) and PBC-FDRs (8.9%, 95% CI: 4.4%-16.7%) compared to none of healthy controls ($P = 0.05$ and $P = 0.06$, respectively). According to the predefined criteria of the study, PBC-specific ANA positivity was only observed in one FDR of a PSC patient.

Data are shown as n (%) or mean ± SD. UTI: Urinary tract infections; AMA: Antimitochondrial antibodies; PBC: Primary biliary cirrhosis; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; γ-GT: Gamma-glutamyl transpeptidase; ALP: Alkaline aminophosphatase; NS: Not significant.

FDR characteristics associated with AMA positivity

Demographic and clinical characteristics according to the presence of AMA are presented in Table 4. AMA-positive FDRs were predominantly female (60%). Age, level of education, smoking habits, body mass index, and daily alcohol consumption were not significantly associated with AMA-positivity. However, a medical history of UTI was significantly more frequently reported in AMA-positive FDRs, compared to AMA-negative FDRs, whereas a trend towards a higher number of UTI recurrences in AMA-positive FDRs was observed (Table 4). Binary logistic regression revealed having a proband with PBC or a positive history for UTI were both independently associated with AMA positivity (odds ratio: 11.24, 95% CI: 1.27-25.34, P = 0.03 and odds ratio: 3.92, 95% CI: 1.25-12.35, P = 0.02, respectively).

Clinical and laboratory manifestations of PBC in AMA-positive FDRs

Of the 20 FDRs, who were determined positive for AMA reactivity, 5 (25%) presented with abnormal liver enzymes and their characteristics are shown in Table 5. Male FDRs with AMA were asymptomatic either for liver- or extrahepatic-related symptoms whereas one female suffered from Sicca syndrome and two from Hashimoto thyroiditis. Physical examination was unremarkable in all 5 subjects. To date, none of these subjects have agreed to undergo liver biopsy.

Table 5 Characteristics of antimitochondrial antibodies-positive relatives with abnormal liver enzymes

	Age (yr)	Proband disease	Relationship to the proband	AST/ ALT (U/L)	ALP/ γ-GT (U/L)	Symptoms
Patient A	44	PBC	Son	37/45	102/122	No
Patient B	47	PBC	Brother	23/18	65/104	No
Patient C	40	PBC	Son	37/90	67/154	No
Patient D	24	PBC	Daughter	60/165	136/61	Sicca + Hashimoto's thyroiditis
Patient E	52	PSC	Sister	53/103	91/94	Hashimoto's thyroiditis

AST: Aspartate aminotransferase (upper limit: 35 U/L); ALT: Alanine aminotransferase (upper limit: 40 U/L); γ-GT: Gamma-glutamyl transpeptidase (upper limit: 37 U/L); ALP: Alkaline aminophosphatase (upper limit: 104 U/L); PBC: Primary biliary cirrhosis; PSC: Primary sclerosing cholangitis.

DISCUSSION

The data reported herein demonstrate that FDRs of patients with PBC have increased prevalence of AMA compared to healthy controls, whereas the presence of PBC-specific ANA was similar among all groups. During the seventies, two studies investigating the autoantibody prevalence in relatives of patients with PBC reported AMA detection in approximately 7.5% of the screened subjects[19,20]. In a subsequent study, Caldwell *et al*[21] reported a somewhat lower prevalence of 4.9% in 41 FDRs of 27 PBC probands. Using IIF, Floreani *et al*[16] observed AMA positivity in 6.1% of 115 relatives of unspecified relationship to 30 PBC probands. Conversely, in a 2004 study from Brazil, AMA prevalence in FDRs was estimated to be as low as 1%[22]. Taken together, these studies illustrate that AMA prevalence in PBC FDRs varies significantly according to the method used for AMA detection and their prevalence in the general population from which the study population is derived. Indeed, several studies from Europe have reported AMA prevalence in the general population to range between 0.5% and 0.9%, while in studies from China and Japan it was lower (range: 0.16% to 0.64%), demonstrating again slight variances according to methodology used and the origin of the populations studied[39-42].

In the most comprehensive study concerning AMA prevalence in FDRs of PBC patients conducted in Minnesota, an area with one of the highest reported PBC prevalence[43], Lazaridis *et al*[23] found AMA positivity in 13.1% of the FDRs and 1% of healthy controls. AMA prevalence in FDRs of PBC patients in our study was found to be slightly higher (18.8%) compared to that recorded in all the abovementioned reports[16,19-23]. In particular, taking into account that first, the proportion of female FDRs

in the study of Lazaridis *et al*[23] was higher (64%-68.5%) compared to the present study, and second, that their population consisted predominantly of older FDRs, the actual difference in AMA prevalence in FDRs of Greek and US patients with PBC might be even higher.

One possible explanation for the higher AMA prevalence in FDRs of Greek PBC patients compared to the previous reports[16,19-23] is that we used a combination of diagnostic techniques for AMA detection which may improve the overall sensitivity. Indeed, to the best of our knowledge this is the first study to utilize a combination of IIF, MIT3-based ELISA and dot-blot for the detection of AMA in FDRs of PBC patients. It is well known that almost 90% of AMA-positive PBC sera react to PDC-E2, while approximately 10% of them react only to BCOADC-E2 and/or OGDC-E2 indicating that, as we have previously demonstrated, testing for AMA by the first generation commercial M2-ELISAs (using only the PDC-E2 as the primary substrate) or using only IIF would result in low sensitivity of AMA testing[33]. The latter has been shown recently by our group since up to 12.6% of AMA-negative PBC patients by IIF were MIT3-ELISA positive whereas 4.8% of MIT-3 negative PBC sera were AMA positive by IIF[33].

An alternative explanation for the relatively high rates of AMA positivity in FDRs of Greek PBC patients observed in our study could be attributed to the background of the study population. Although no published data on PBC prevalence exist for Greece, subjects of Greek descent have been shown to carry the highest prevalence of PBC in an Australian study[7]. Of course, the participation of a relatively low number of patients' families (44 families out of 140 patients) may have led to selection bias, which theoretically could influence our analysis.

Of interest, AMA prevalence was significantly higher in FDRs reporting a past history of UTI with a trend towards a higher number of UTI recurrences in AMA-positive FDRs. This finding was stable even after multivariate analysis suggesting UTI as an independent factor for AMA detection among FDRs of PBC patients. Epidemiological data have suggested past history of UTI as a risk factor for PBC development[9] whereas patients with recurrent UTI have an increased incidence of AMA seropositivity[44]. Recurrent UTI have been suggested to increase the exposure to microbial antigens like *Escherichia coli* which may then induce the development of PBC in genetically susceptible individuals through molecular mimicry mechanisms[45].

The second major finding of this study is that FDRs of Greek patients with PBC do not have increased prevalence of PBC-specific ANA. Using HEp2 cells as substrate, ANA in PBC patients are heterogeneous[24,46]; however, ANA presenting with the MND or rim-like membranous (RLM) pattern by IIF have proven to be clinically significant for PBC[24,46]. The molecular targets of ANA with the MND pattern in PBC are mainly the nuclear body protein sp100 and less often the promyelocytic leukemia protein, small ubiquitin-related modifiers and more recently SP140 antigen, whereas the molecular targets of the RLM pattern are structural components of the nuclear envelope primarily gp210, nucleoporin p62 and lamin B receptor[24,46-48]. A possible limitation of our study is that we have determined reactivities only against the two most common molecular targets of PBC-specific ANA, namely anti-gp210 and anti-sp100, which are highly specific for PBC and have been found in up to 65% of PBC patients if IgG-isotype specific antibodies (IgG1, 2, 3 and 4) are investigated[24,27-29,46,49].

According to the available evidence, there are significant differences between AMA- and ANA-reactivity in patients with PBC, since AMA may appear several years before the clinical or histological signs of disease, whereas PBC-specific ANA are more frequently found in those patients with advanced disease[24,27,28,46,50]. Moreover, the detection of PBC-specific ANA seems to confer prognostic information, because when ANAs become detectable during the course of disease, a higher rate of disease progression could be expected[24,46,49,51,52]. Therefore, the lack of PBC-specific ANA in AMA-positive FDRs might suggest a pre-clinical stage of the disease. Furthermore, the detection of PBC-specific ANA in FDRs who exhibit AMA-positivity may indicate further diagnostic evaluation. According to a cohort study by Invernizzi *et al*[52], antibodies against the nuclear pore complex (anti-NPCs), may aid prognostic evaluation in patients presenting at early PBC stages, i.e., those with normal total bilirubin levels at presentation. Actually, the contribution of anti-NPC detection in a prognostic model incorporating the Mayo score and the histological stage was greater in early PBC cases.

In conclusion, using a combination of tests for AMA detection, we have provided evidence that AMA prevalence in asymptomatic for liver-related symptoms FDRs of Greek patients with PBC is significantly increased compared to FDRs of Greek patients with other autoimmune liver diseases and healthy controls. This prevalence is in fact the highest reported to date among FDRs of PBC patients and it is significantly associated with past history of UTI. Further large-scale multicentre prospective studies with the use of combination techniques for AMA detection are needed in order to precisely define the AMA prevalence in FDRs from PBC patients and assess whether these subjects will develop the clinical and biochemical spectrum of PBC in the future. We are currently undertaking such follow-up in our AMA positive FDRs from PBC patients. PBC-specific ANA are not detected in FDRs of PBC patients. Nevertheless, in our opinion the sequential determination of the latter antibodies as a marker of progression from a pre-clinical to an early clinical stage should be further evaluated.

COMMENTS

Background

Primary biliary cirrhosis (PBC) is an autoimmune liver disease characterized usually by an insidious or even silent onset with long asymptomatic course which can eventually lead to cirrhosis and liver failure. The laboratory hallmark of the disease is the detection of antimitochondrial antibodies (AMA). Early diagnosis is crucial for timely treatment and improvement of the quality of life and

survival. Among several factors, genetic predisposition is important in conferring susceptibility to PBC. Indeed, during the past 15-20 years, several studies have reported familial clustering of PBC whereas the presence of AMA seems to aggregate in first-degree relatives (FDRs) of afflicted individuals as well, with AMA prevalence among FDRs ranging between 1% and 13.1%.

Research frontiers

The research hotspot is to estimate the prevalence and associations of AMA along with PBC-specific ANA with known risk factors of PBC development in asymptomatic FDRs of Greek patients with PBC. This could be very important in an attempt to identify new asymptomatic PBC cases and potentially alter the disease course by the prompt initiation of the indicated therapy.

Innovations and breakthroughs

In the present study, the authors estimated the prevalence and significance of AMA in FDRs of PBC patients using for the first time a combination set of sensitive diagnostic techniques (indirect immunofluorescence, dot-blot assays, and molecularly based enzyme-linked immunosorbent assays) in order to improve the overall performance of AMA detection. In addition, they assessed for the first time, the significance of PBC-specific ANA in the same population since these autoantibodies are known prognostic factors for PBC outcome and progression.

Applications

Based on their results the authors believe that further large-scale multicentre prospective studies with the use of combination techniques for AMA detection (not only indirect immunofluorescence) are needed in order to precisely define the AMA prevalence in FDRs of PBC patients and assess whether these subjects will develop the clinical and biochemical spectrum of PBC or not in the future.

Terminology

PBC is an autoimmune cholestatic liver disease of unknown etiology with clustering in families of PBC patients whereas AMA detection is higher in FDRs of PBC patients compared to healthy population. The use of combination tests for AMA detection in FDRs of PBC patients seems to be the design of choice in order to identify asymptomatic individuals who potentially will develop the disease since the present study showed the highest incidence of AMA in FDRs of PBC ever reported using this methodology. This is of particular importance especially among those with a past history of urinary tract infection.

Peer review

This study described the prevalence and significance of AMA and PBC-specific ANA in FDRs of Greek PBC patients. The authors concluded that AMA prevalence in this group of subjects is significantly increased compared to healthy and FDRs of patients with other autoimmune liver diseases like autoimmune hepatitis-1 or primary sclerosing cholangitis. In addition, AMA detection in FDRs of PBC patients was independently associated with past history of urinary tract infections. To the contrary, PBC-specific ANA were not detected in PBC FDRs. Therefore, the study provides significant data, which is of great importance, as it includes original and useful data for these otherwise healthy subjects (FDRs of PBC patients).

Abstract

AIM: To investigate the effects of titanium dioxide (TiO_2) nanoparticles ($NPTiO_2$) and microparticles ($MPTiO_2$) on the inflammatory response in the small intestine of mice.

METHODS: Bl 57/6 male mice received distilled water suspensions containing TiO_2 (100 mg/kg body weight) as $NPTiO_2$ (66 nm), or $MPTiO_2$ (260 nm) by gavage for 10 d, once a day; the control group received only distilled water. At the end of the treatment the duodenum, jejunum and ileum were extracted for assessment of cytokines, inflammatory cells and titanium content. The cytokines interleukin (IL)-1b, IL-4, IL-6, IL-8, IL-10, IL-12, IL-13, IL-17, IL-23, tumor necrosis factor-α (TNF-α), intracellular interferon-γ (IFN-γ) and transforming growth factor-β (TGF-β) were evaluated by enzyme-linked immunosorbent assay in segments of jejunum and ileum (mucosa and underlying muscular tissue). $CD4^+$ and $CD8^+$ T cells, natural killer cells, and dendritic cells were evaluated in duodenum, jejunum and ileum samples fixed in 10% formalin by immunohistochemistry. The titanium content was determined by inductively coupled plasma atomic emission spectrometry.

RESULTS: We found increased levels of T $CD4^+$ cells (cells/mm^2) in duodenum: NP 1240 ± 139.4, MP 1070 ± 154.7 *vs* 458 ± 50.39 ($P < 0.01$); jejunum: NP 908.4 ± 130.3, MP 813.8 ± 103.8 *vs* 526.6 ± 61.43 ($P < 0.05$); and ileum: NP 818.60 ± 123.0, MP 640.1 ± 32.75 *vs* 466.9 ± 22.4 ($P < 0.05$). In comparison to the control group, the groups receiving TiO_2 showed a statistically significant increase in the levels of the inflammatory cytokines IL-12, IL-4, IL-23, TNF-α, IFN-γ and TGF-β. The cytokine production was more pronounced in the ileum (mean ± SE): IL-12: NP 33.98 ± 11.76, MP 74.11 ± 25.65 *vs* 19.06 ± 3.92 ($P < 0.05$); IL-4: NP 17.36 ± 9.96, MP 22.94 ± 7.47 *vs* 2.19 ± 0.65 ($P < 0.05$); IL-23: NP 157.20 ± 75.80, MP 134.50 ± 38.31 *vs* 22.34 ± 5.81 ($P < 0.05$); TNFα: NP 3.71 ± 1.33, MP 5.44 ± 1.67 *vs* 0.99

± 019 ($P < 0.05$); IFNγ: NP 15.85 ± 9.99, MP 34.08 ± 11.44 *vs* 2.81 ± 0.69 ($P < 0.05$); and TGF-β: NP 780.70 ± 318.50, MP 1409.00 ± 502.20 *vs* 205.50 ± 63.93 ($P < 0.05$).

CONCLUSION: Our findings indicate that TiO_2 particles induce a Th1-mediated inflammatory response in the small bowel in mice.

INTRODUCTION

We are exposed daily through inhalation, ingestion or contact to many environmental and engineered particles. The gastrointestinal tract is continuously exposed to particles in the diet, such as titanium dioxide (TiO_2), which is an insoluble white powder that is used as an anti-caking and whitening agent in many commercial products, including paint, cosmetics, plastics, paper, pharmaceuticals, and food colorants[1]. The ingestion of exogenous particles is substantial, as demonstrated by Lomer *et al*[2], who reported that about 40 mg of exogenous particles are ingested per person per day in the United Kingdom. Besides the amount of exogenous particles that are ingested, nanoparticulates can be inhaled and trapped on the mucus of the respiratory tract and then swallowed, thus reaching the gastrointestinal tract[3]. Clearance studies in animals involving radiolabeled nanoparticles (NP) showed that 30%-50% of inhaled NP are translocated to the gastrointestinal tract[4].

TiO_2 can be found as microparticles (MP) (diameter of 0.1 to 1.0 μm) and NP (diameter less than 100 nm). The increasing utilization of nanomaterials in industrial as well as consumer products has increased the possibility of human exposure but their influence on human health remains uncertain. Although studies reporting TiO_2 toxicity are still limited, some suggest that smaller particles produce a greater inflammatory response in comparison with the larger fine-sized particles of similar chemistry at the same mass concentrations[5-7].

Many studies have revealed that exposure to TiO_2 can cause adverse effects such as the generation of reactive oxygen species[8-10], inflammatory responses[5,6,11-13], tumors[14], cytotoxicity[15] and apoptosis[16]. *In vivo* studies showed that NP can be accumulated in many organs such as the liver, kidney, spleen, lung, heart and brain[17,18], thus generating a number of adverse effects. Previous investigations have found that TiO_2 accumulates in the intestine in rats[19] and fish[20] and migrates to other organs. Accumulation of TiO_2 inside the intestinal cells, especially in lymphoid-rich areas (Peyer's patch), might lead to damaging outcomes such as inflammation and could be involved in the pathogenesis of inflammatory bowel disease[21,22]. However, little is known about the influence of either micro- or NP on the gut, which is potentially exposed to particles in the diet, such as TiO_2. To date, most of the studies regarding the adverse effects of TiO_2 particles on human health have involved the pulmonary tract. No available *in vivo* work has evaluated the impacts of TiO_2 particles in terms of their inflammatory potential within the gastrointestinal tract.

Therefore, the present study was designed to investigate the effects of TiO_2 as MP and as NP on the inflammatory response in the small intestine of mice. We aimed to evaluate cytokine production and inflammatory cell proliferation in the small intestine of mice after oral exposure to TiO_2.

MATERIALS AND METHODS

Particles

Uncoated anatase TiO_2 microparticles ($MPTiO_2$) (260 nm) that are commercially available for use in food, pharmaceuticals, and cosmetics were obtained from Evonik Degussa (Kronos® 1171). Uncoated TiO_2 nanoparticles ($NPTiO_2$) (mean diameter of 66 nm), consisting mostly of anatase, were synthesized by Professor de Azevedo WM from the Department of Fundamental Chemistry of the Federal University of Pernambuco (Recife, Brazil) at pH = 2.0, followed by centrifugation. Particle size was determined by dynamic light scattering Nanotrac® (Microtrac Inc., United States) by Professor Toma SH from the Laboratory of Supramolecular Chemistry and Nanotechnology of the Chemistry Institute of the University of São Paulo (São Paulo, Brazil). Particle phase was characterized using an X-ray diffractometer Rigaku Miniflex® (Rigaku Corporation, Japan) under monochromatic radiation, Cu Kα (1.541 Å, 30 kV, 15 mA, 0.02°, 2° to 61° range), also by Professor Toma SH.

Animals and treatment

Bl 57/6 male mice (20 to 25 g) were obtained from the Center of Bioterism of the School of Medicine, University of São Paulo (São Paulo, Brazil). Animals were housed in cages in a ventilated room in a 12-h light/dark cycle. Food and water were available ad libitum. They were acclimated to this environment for 1 wk before treatment. All animal experimental procedures were in

compliance with the School of Medicine, University of São Paulo Ethics Committee. Mice were randomly divided into three groups of 12 animals, and received either distilled water suspensions containing TiO_2 (100 mg/kg body weight) as MP, or as NP, or distilled water as a control. The suspension was given by gavage for 10 d, once a day. TiO_2 particles were suspended in 500 μL of distilled water. The suspension was mixed and sonicated immediately before being administered to animals to minimize particle aggregation. At the end of the treatment the animals were weighed and killed in a CO_2 chamber, and had their duodenum, jejunum and ileum extracted for assessment of cytokines, inflammatory cells and titanium content.

Assessment of cytokines

Segments of jejunum and ileum - mucosa and underlying muscular tissue - were extracted from animals, stored at -80 ℃ and subsequently homogenized with Tris-buffer (10 mmol)-ethylenediamine tetraacetic acid (1 mmol)-Triton (1%) containing protease, aprotinin, chymostatin and leupeptin inhibitors (1 μg/mL of solution) and phenylmethylsulfonyl fluoride (1 μL/mL of solution). After homogenization, the sample was centrifuged at 14 000 *g* for 10 min at 4 ℃ and the supernatant was stored at -80 ℃ until the cytokines were analyzed using an enzyme-linked immunosorbent assay (ELISA). Interleukin-1β (IL-1β) IL-4, IL-6, IL-8 (Keratinocyte Chemoattractant), IL-10, IL-12, IL-13, IL-17, IL-23, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ) and transforming growth factor-β (TGF-β) were evaluated using ELISA kits (IL-1β, IL-4, IL-6, IL-12, IL-13, IL-17, IL-23, TNF-α, IFN-γ, and TGF-β from eBioscience; and IL-10 and IL-8 from R and D systems) according to the manufacturer's recommendations.

Quantification of inflammatory cells

Duodenum, jejunum and ileum samples were fixed in 10% formalin and were embedded in paraffin. Five-mm thick sections were cut for evaluation of $CD4^+$ and $CD8^+$ T cells, natural killer cells (CD57), and dendritic cells (S100+) by immunohistochemistry using specific antibodies: anti-CD4 [Dako M0834 (OPD4 clone)], anti-CD8 [Dako® M7103 (clone C8/144B)], anti-S100+ [Dako® M7103 (clone C8/144B)], and anti-CD57 [Dako® M7103 (clone C8/144B)]. For cell quantification, the observers randomly selected ten areas and counted positive cells under the 40 × objective.

Histopathological evaluation of small intestine

Duodenum, jejunum and ileum samples were fixed in 10% formalin and embedded in paraffin. Five-mm thick sections were cut, placed onto glass slides and then stained with HE. The slides were examined by optical microscopy (E800, Nikon, United States) by Professor Dagli MLZ from the Department of Pathology of the School of Veterinary Medicine, University of São Paulo (São Paulo, Brazil).

Titanium content analysis

The titanium content in intestinal samples from each group was analyzed with the purpose of verifying the efficacy of the treatment, and to make sure that the animals of the control group did not contain titanium (Ti) in their tissues. To determine the presence of Ti in the small intestine of the animals receiving TiO_2 particles, the experiment was repeated including two animals in each group. At the end of the treatment, the small intestine was extracted for analysis of the titanium content by inductively coupled plasma atomic emission spectrometry (ICP-AES). The small intestine was removed in its entirety (from the pylorus to the ileocecal valve), preserving the mucosa and muscle tissue, stored at -80 ℃ and taken to the Basic Analysis Laboratory of the Analytical Center, Chemistry Institute, University of São Paulo (São Paulo, Brazil) where it was homogenized and processed by the local team following their standard protocol.

Statistical analysis

Data for each parameter evaluated are shown as the mean ± SE. Data were analyzed assuming a gamma distribution (identity link) and using generalized linear models. Pairwise comparisons and Fisher's least significant difference post-hoc test were applied to evaluate the differences between the groups. $P < 0.05$ was considered significant. Commercially available software was used for analysis (PASW Statistics Version 18, United States).

RESULTS

Titanium content

The titanium content in the small intestine from each group was determined by ICP-AES. The control group showed no detectable levels of titanium in the intestine. The titanium content (mg/kg of tissue) in the intestine was (animal 1/animal 2): 1.43/11.68 in the NP group, and 0.39/0.22 in the MP group.

Cytokine concentration in jejunum and ileum

In comparison to the control group, $MPTiO_2$ and $NPTiO_2$ generated a statistically significant increase in inflammatory cytokines. The group receiving $MPTiO_2$ showed an enhanced concentration of IFN-γ and IL-23 in the jejunum, and IL-12, TNF-α, IFN-γ, IL-4, IL-23, and TGF-β in the ileum (Figure 1). The group receiving $NPTiO_2$ showed increased TNF-α, IFN-γ, IL-4, IL-23, and TGF-β, but only in the ileum. There was no significant difference between the groups receiving $MPTiO_2$ and $NPTiO_2$, as both showed statistically similar levels of cytokine production. A more important cytokine production was found in the ileum compared to the jejunum.

Inflammatory cell infiltration in small intestine

We found a statistically significant increase in T $CD4^+$ cells in the duodenum, jejunum and ileum of mice treated with $MPTiO_2$ and $NPTiO_2$, compared to the control group. There was no significant difference between the

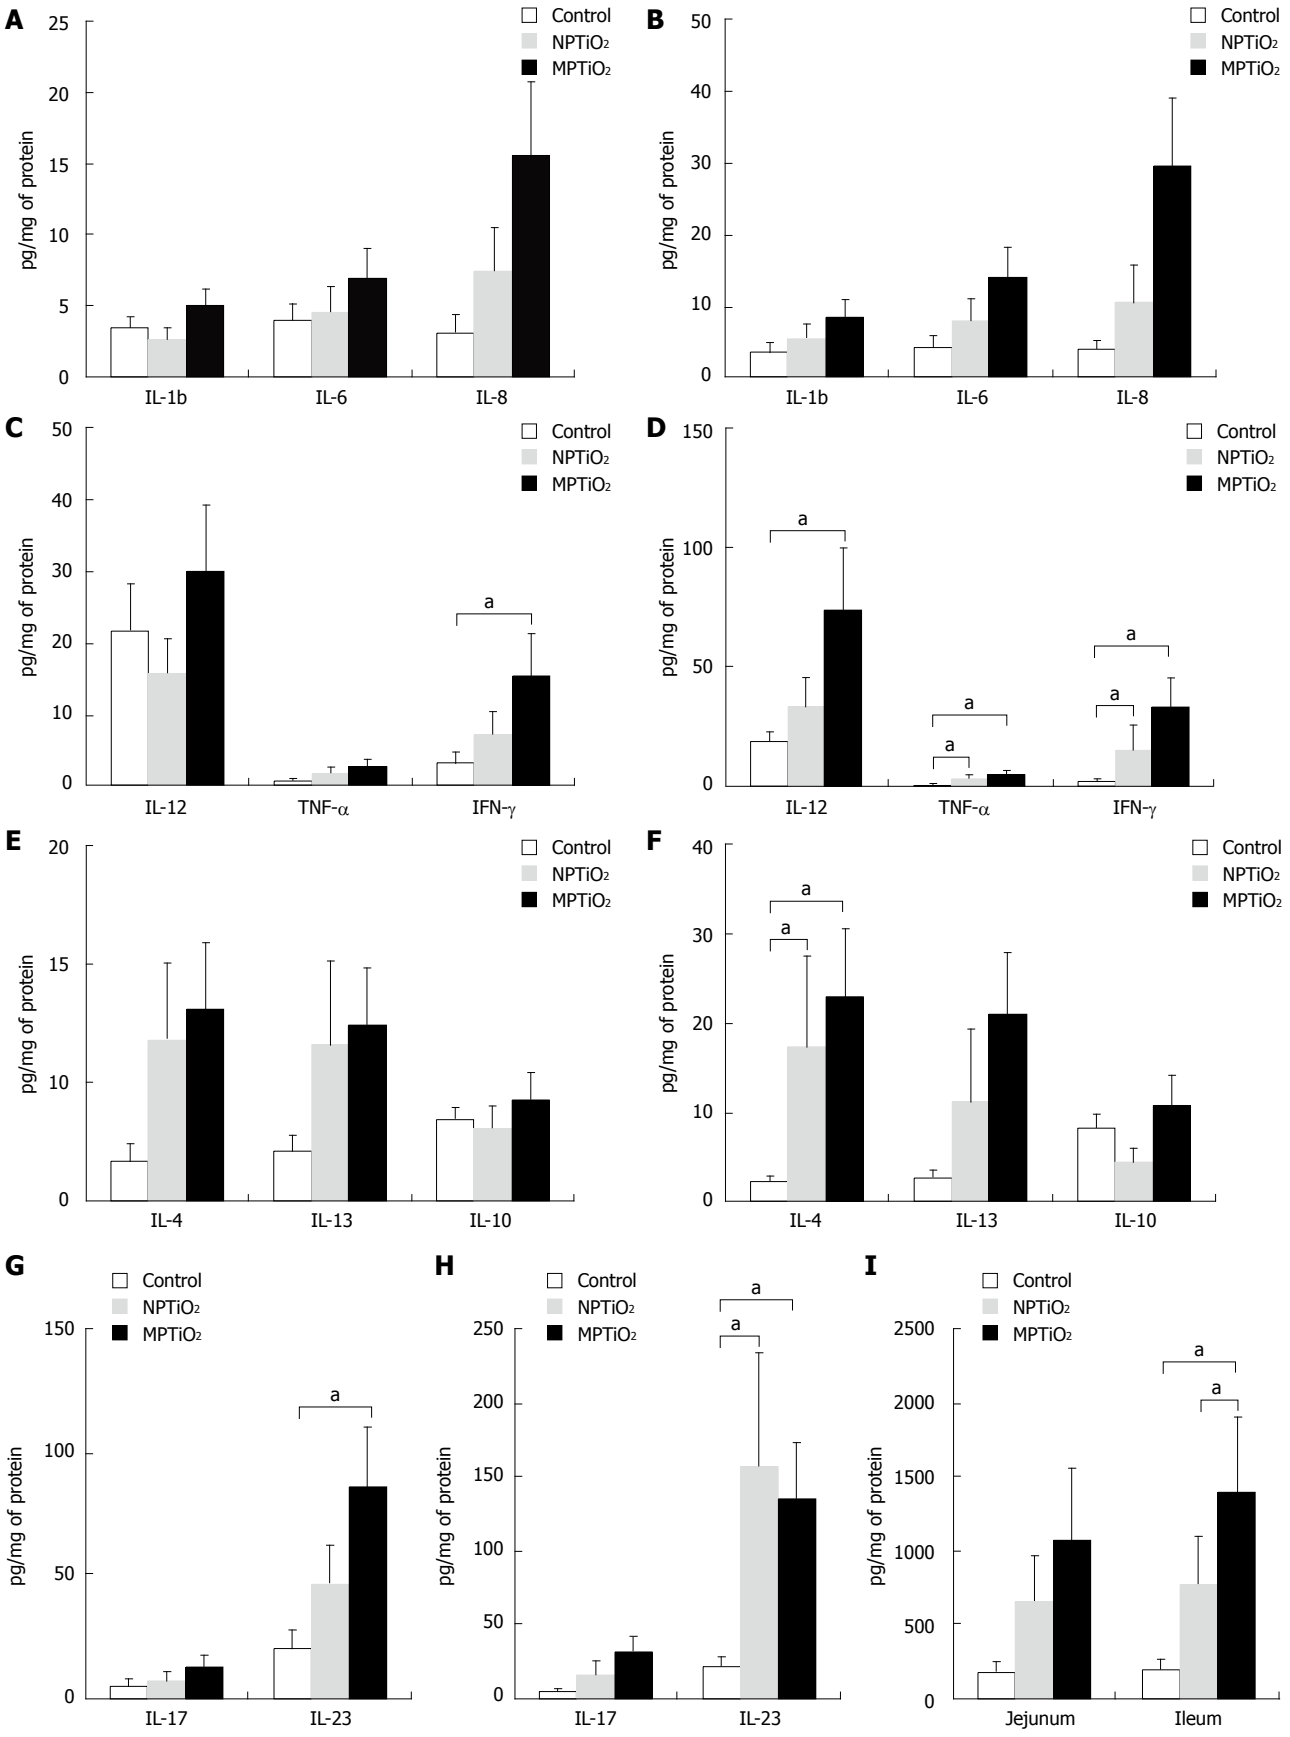

Figure 1 Mean and SE of cytokine concentration in the small intestine of mice according to treatment groups. A: Pro-inflammatory cytokines in the jejunum; B: Pro-inflammatory cytokines in the ileum; C: T-helper (Th) 1 type cytokines in the jejunum; D: Th1 type cytokines in the ileum; E: Th2 type cytokines in the jejunum; F: Th2 type cytokines in the ileum; G: Th17 type cytokines in the jejunum; H: Th17 type cytokines in the ileum; I: Transforming growth factor-β in the jejunum and ileum. $^aP < 0.05$ for pairwise comparison test. $NPTiO_2$: Titanium dioxide nanoparticles; $MPTiO_2$: Titanium dioxide microparticles; IL: Interleukin; IFN: Intracellular interferon.

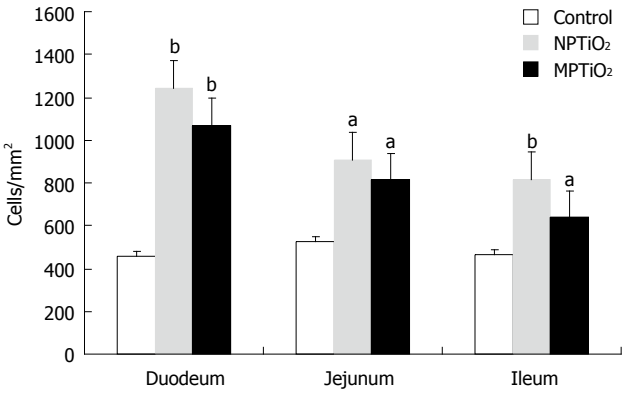

Figure 2 T CD4$^+$ cells quantified by immunohistochemistry in the duodenum, jejunum and ileum of mice, according to treatment group. Mean and SE of $^aP < 0.05$, $^bP < 0.01$ *vs* control group for pairwise comparison test. $NPTiO_2$: Titanium dioxide nanoparticles; $MPTiO_2$: Titanium dioxide microparticles.

$MPTiO_2$ and $NPTiO_2$ groups. The results are illustrated as the mean and SE in Figure 2. Mice treated with $MPTiO_2$ or $NPTiO_2$ showed no increase in T CD8$^+$, natural killers, or dendritic cells in the small intestine (data not shown).

Histopathological evaluation of the small intestine

No major histological changes were found in small intestine samples of experimental animals, except for hypertrophy and hyperplasia of the mucosal epithelium of mice receiving TiO_2 particles, which were not seen in the control group. These findings were observed in all three regions of the small intestine (duodenum, jejunum and ileum) of mice treated with $NPTiO_2$, while animals treated with $MPTiO_2$ showed these effects only in the ileum.

DISCUSSION

Inflammatory response

To date, there have been few data regarding the inflammatory potential of TiO_2 particles in the intestine. Here, we sought to evaluate inflammatory responses induced by TiO_2 in the small intestine in mice. We found that TiO_2 as micro- and nano-sized particles produced a pro-inflammatory response in the small intestine by generating increased inflammatory cytokine production and T CD4$^+$ cell proliferation. The generation of pro-inflammatory cytokines and T CD4$^+$ cells induced by $NPTiO_2$ was also described by Schanen *et al*[23] in an *in vivo* immune construct study.

The main cytokines enhanced in our study were IL-12, IFN-γ, TNF-α, IL-4, IL-23 and TGF-β. IL-12, TNF-α and IFN-γ are Th1-type cytokines, whereas IL-23 and TGF-β are both involved in the Th17 pathway. In murine models, TGF-β together with IL-6 promotes differentiation of naïve T cells to Th17 cells[24]. Here we found no significant increase in IL-6 or IL-17, which is produced by Th17 cells. Taken together, these data suggest that TiO_2 particles provoked a pro-inflammatory response mainly through the Th1-mediated pathway in the small bowel in mice. Other authors found a Th-2 mediated immune response in the lungs, induced by nano-sized TiO_2 exposure in mice[13,25]. However, inflammatory responses differ depending on the organ, and thus the immune response caused by exposure to TiO_2 may diverge between the respiratory tract and the gut.

Cytokine production was more pronounced in the ileum. These findings might be related to differences concerning particle uptake throughout the gut. It is known that the ileum presents the greatest concentration of M cells (Peyer's patch) in the intestine, which are believed to represent the main pathway of particle uptake across the gastrointestinal tract[26,27]. Li *et al*[28] observed greater absorption of lipid NP in the ileum and colon of rats when compared to other segments of the intestine, reinforcing the importance of M cells as a pathway of particle uptake. Given that the ileum represents the major site of particle uptake, we would expect to find a more substantial inflammatory response in this area.

We also evaluated histopathological changes in the small intestine of mice after exposure to TiO_2. We observed hypertrophy and hyperplasia of the mucosal epithelium in both groups receiving TiO_2 particles. These findings were also described by other authors in TiO_2-related studies. Alveolar epithelium hypertrophy was observed in the lungs of rats exposed to nano-sized TiO_2[29]. Mice, rats and hamsters showed histopathological changes consistent with alveolar epithelial cell hypertrophy and hyperplasia after long-term inhalation of fine TiO_2[30].

Taken together our data provide evidence that micro- and nano-sized TiO_2 particles induce a pro-inflammatory response in the small intestine in mice, after a short period of oral exposure.

The titanium content of the small intestine samples was determined by ICP-AES at the end of the experiments to guarantee the efficacy of the treatment with TiO_2 and to ensure that the control group had no detectable levels of titanium in their tissues. Our results demonstrated that TiO_2 particles were absorbed by the small intestine in mice after a short period of oral exposure, as the animals that received TiO_2 particles had titanium in their tissues at the end of the experiment. The control group showed no detectable levels of titanium in any sample. We found greater amounts of titanium in the small intestine of the animals receiving $NPTiO_2$ in comparison to those receiving $MPTiO_2$. These findings indicate that smaller particles may be absorbed to a greater extent than larger ones in the gut.

Nanoparticles vs microparticles

Previous investigations of TiO_2 particles found that TiO_2 as nano-sized particles is more toxic than similarly composed, but larger sized particles[5-7,11,29,31]. Thus, we aimed to compare the effects of micro- and nano-sized TiO_2 on the small intestine. However, we found no statistically significant difference in cytokine secretion or T CD4$^+$ cell proliferation between the groups who received $MPTiO_2$

and NPTiO_2. Other authors have already reported the lack of significant differences in the pulmonary effects in rats exposed to TiO_2 particles of different sizes[14,32-35].

In conclusion, We demonstrated that over a short period TiO_2 as micro- and nano-particles induced a Th1-mediated inflammatory response in the small intestine of mice, especially in the ileum. These findings provide evidence of the inflammatory potential of TiO_2 particles in the gastrointestinal tract. Since we are exposed to TiO_2 particles on a daily basis, as well as to many other engineered particles, these data should be taken into consideration when evaluating the safety of biomaterials.

COMMENTS

Background

Titanium dioxide (TiO_2) is a white pigment that is widely found as nano- and micro-sized particles added to commercial products such as food, drugs, cosmetics, *etc*. Many studies involving the respiratory tract warn of adverse effects resulting from exposure to TiO_2. Although the gastrointestinal tract is exposed to TiO_2 particles on a daily basis there is little information regarding their adverse effects on the intestine. Adverse effects resulting from exposure to TiO_2, such as cytotoxicity, generations of reactive oxygen species, tumors, inflammation, allergic reactions, lung emphysema, among others, have been reported in studies involving the respiratory tract. Although the lung is the most widely studied organ as far as exposure to particles such as TiO_2 is concerned, the gastrointestinal tract is considerably more exposed to environmental particles.

Research frontiers

The present study shows that nano- and micro-sized particles may lead to an inflammatory process in the bowel. As a result, small particles of TiO_2, which are present in the diet, may be involved in the development of inflammatory bowel disease.

Innovations and breakthroughs

Most researches related to TiO_2 particles studied their effects on the respiratory tract or were performed *in vitro*. This study was conducted *in vivo* to investigate the effects of TiO_2 as micro- and nanoparticles on the inflammatory response in the intestine of mice. To do so, mice received high doses of TiO_2 by gavage for 10 d and subsequently the small intestine was extracted for assessment of cytokines, infiltration of inflammatory cells and morphological alterations of tissue. Authors found the highest concentration of cytokines [interleukin (IL)-12, IL-4, IL-23, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ) and transforming growth factor-β (TGF-β) and of $CD4^+$ T cell in the intestine of animals that received TiO_2, suggesting the pro-inflammatory effect of these particles on the small intestine of mice.

Applications

Based on their results, authors can infer that TiO_2 elicited a pro-inflammatory response in the small intestine of mice, which seems to be predominantly a T-helper 1-type response and more pronounced in the ileum. These data are *in vivo* evidence of the inflammatory potential of TiO_2 particles on the gastrointestinal tract. Their findings emphasize the need to investigate the adverse effects of TiO_2 particles on health since they are exposed to products containing this substance on a daily basis.

Terminology

Microparticles are particles whose size ranges from 0.1 and 100 μm; Nanoparticles are particles smaller than 100 nm. Nanoscale materials are developed to display some specific features based on their size, shape, surface, *etc*. TiO_2 is a white powder that is used as an anti-caking and whitening agent in many commercial products, including paint, cosmetics, plastics, paper, pharmaceuticals and food colorants

Peer review

This study reports on the mice intestinal inflammatory responses to TiO_2 nano- and micro-particles administration. The presented results show that daily administration of 100 mg/kg of TiO_2 nano- as well as micro-particles elicited substantial inflammatory responses in the intestinal tissue and jejunum, as evidenced by the increase in IL-12, TNF-α, IFN-γ, IL-4, IL-23 and TGF-β. These effects were observed with both types of particles. Considering the increasing use of various form of titanium in the food industry and pharmaceuticals and implants, this adds an important evidence to a growing list of potential adverse effects of Ti on human health.

Abstract

AIM: To delineate indications and limitations for "extended" radical cholecystectomy for gallbladder cancer: a procedure which was instituted in our department in 1982.

METHODS: Of 145 patients who underwent a radical resection for gallbladder cancer from 1982 through 2006, 52 (36%) had an extended radical cholecystectomy, which involved *en bloc* resection of the gallbladder, gallbladder fossa, extrahepatic bile duct, and the regional lymph nodes (first- and second-echelon node groups). A retrospective analysis of the 52 patients was conducted including at least 5 years of follow up. Residual tumor status was judged as no residual tumor (R0) or microscopic/macroscopic residual tumor (R1-2). Pathological findings were documented according to the American Joint Committee on Cancer Cancer Staging Manual (7th edition).

RESULTS: The primary tumor was classified as pathological T1 (pT1) in 3 patients, pT2 in 36, pT3 in 12, and pT4 in 1. Twenty-three patients had lymph node metastases; 11 had a single positive node, 4 had two positive nodes, and 8 had three or more positive nodes. None of the three patients with pT1 tumors had nodal disease, whereas 23 of 49 (47%) with pT2 or more advanced tumors had nodal disease. One patient died during the hospital stay for definitive resection, giving an in-hospital mortality rate of 2%. Overall survival (OS) after extended radical cholecystectomy was 65% at 5 years and 53% at 10 years in all 52 patients. OS differed according to the pT classification ($P < 0.001$) and the nodal status ($P = 0.010$). All of 3 patients with pT1 tumors and most (29 of 36) patients with pT2 tumors survived for more than 5 years. Of 12 patients with pT3 tumors, 8 who had an R1-2 resection, distant metastasis, or extensive extrahepatic organ involvement died soon after resection. Of the remaining four pT3 patients who had localized hepatic spread through the gallbladder fossa and underwent an R0 resection, 2 survived for more than 5 years and another survived for 4 years and 2 mo. The only patient with pT4 tumor died of disease soon after resection. Among 23 node-positive patients, 11 survived for more than 5 years, and of these, 10 had a modest degree of nodal disease (one or two positive nodes).

CONCLUSION: Extended radical cholecystectomy is indicated for pT2 tumors and some pT3 tumors with localized hepatic invasion, provided that the regional nodal disease is limited to a modest degree (up to two positive nodes). Extensive pT3 disease, pT4 disease, or marked nodal disease appears to be beyond the scope of this radical procedure.

INTRODUCTION

The history of radical surgery for gallbladder cancer started with cholecystectomy combined with wedge resection of the gallbladder fossa (without regional lymphadenectomy) in the early 20th century[1,2]. However, outcomes after this procedure were disappointing even in tumors limited to the wall of the gallbladder, probably due to the lack of regional lymphadenectomy[1,2]. In 1954, Glenn *et al*[3] first proposed a radical resection procedure with intended regional lymphadenectomy (portal lymph node dissection), designated as "radical cholecystectomy" (Glenn operation), for localized gallbladder cancer. Pack *et al*[4] in 1955 and Fahim *et al*[5] in 1962 advocated radical resection consisting of hepatectomy and portal lymph node dissection, and this strategy remains the one recommended by the National Comprehensive Cancer Network (NCCN) for pathological T1b (pT1b) or more advanced gallbladder cancer[6]. Outcomes after such radical resections, however, remain unsatisfactory, particularly for node-positive patients[7-10].

In Japan, an aggressive attitude toward gallbladder cancer emerged and gradually grew among specialized hepatobiliary surgeons in the 1970s and 1980s[11]. In this context, "extended" radical cholecystectomy (designated as the modified Glenn operation) was instituted in 1982 in our department (Figure 1)[11-13], as a modification of the radical cholecystectomy described by Glenn *et al*[3,14]. The procedure involves *en bloc* resection of the gallbladder, gallbladder fossa, extrahepatic bile duct, and the regional lymph nodes as defined previously[11,15]. Although this procedure has been widely used for gallbladder cancer among Japanese surgeons[11,16-18], indications and limitations remain to be established.

This study aimed to delineate indications and limitations for the extended radical cholecystectomy procedure for gallbladder cancer by retrospectively analyzing the long-term outcomes of 52 patients who underwent this procedure in the study department. The study goal was to definitively establish the role of this particular procedure in surgical management strategies for gallbladder cancer.

MATERIALS AND METHODS

Patient population

From May 1982 through December 2006, 145 consecutive patients underwent a variety of radical resection procedures for gallbladder cancer (including cancer arising in the cystic duct[19]) in the study department (Table 1). A radical resection was defined as an *en bloc* resection of both the primary tumor and the regional lymph nodes. This study period was selected in order to evaluate long-term outcomes after resection; the follow-up period was at least 5 years in all the patients. Of these, 52 (36%) who underwent an extended radical cholecystectomy (modified Glenn operation; Figure 1) were selected as our study cohort. They comprised 39 women and 13 men ranging in age from 43 to 84 years (median, 66.5 years).

Among the 52 patients, 34 underwent the extended radical cholecystectomy as an initial radical resection and 18 underwent this procedure as a radical second resection after a prior simple cholecystectomy for presumed benign disease. Although early (pT1) tumors do not warrant radical resection[20], three patients with pT1 tumor underwent the extended radical cholecystectomy because pT2 or more advanced disease was not ruled out before resection.

Scope of "extended" radical cholecystectomy

Extended radical cholecystectomy involves a cholecystectomy, wedge resection of the gallbladder fossa with a rim of non-neoplastic liver tissue (approximately 2 cm in thickness or more), resection of the suprapancreatic segment of the extrahepatic bile duct (bile duct resection), and regional lymph node dissection in an *en bloc* fashion (Figure 1). The main differences between this procedure and the original radical cholecystectomy described by Glenn *et al*[3,14] comprise the extent of regional lymphadenectomy and the presence or absence of bile duct resection.

The regional lymph nodes of the gallbladder include the cystic duct, pericholedochal, posterior superior (posterosuperior) pancreaticoduodenal, retroportal, right celiac, and hepatic artery node groups[11,15]. The cystic duct and pericholedochal node groups have been regarded as the first-echelon nodes of the gallbladder, whereas the other node groups as the second-echelon nodes[11,15]. Extended radical cholecystectomy harvests both the first- and second-echelon nodes *en bloc* (Figure 1).

We perform a bile duct resection to facilitate the regional lymphadenectomy, to remove pericholedochal lymphatic vessels and nodes simultaneously, to remove the possible presence of ductal (periductal) involvement[21], and to avoid the occurrence of ischemic biliary stricture after aggressive periductal nodal dissection[22].

The extent of hepatectomy appears to be similar between the extended procedure and the original described by Glenn *et al*[3,14]. With regard to resection of the gallbladder fossa for invasive tumors, we emphasize the need for complete excision of the cystic plate to avoid violating the subserosal tumor plane (Figure 2).

[1]Designated as "extended" radical cholecystectomy (modified Glenn operation) since 1982[11]; [2]cholecystectomy with full-thickness dissection: cholecystectomy combined with removal of the cystic plate. C: Cholecystectomy; WR: Wedge resection of the gallbladder fossa; BD: Resection of the extrahepatic bile duct; N: Regional lymphadenectomy; H: Major hepatectomy defined as removal of two sections or more; PD: Whipple or pylorus-preserving pancreaticoduodenectomy.

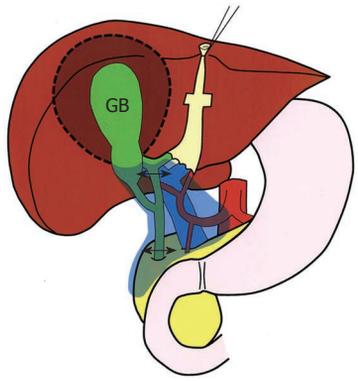

Figure 1 "Extended" radical cholecystectomy for gallbladder cancer. The dashed line indicates the scope of wedge resection of the gallbladder fossa (about 2 cm in thickness or more). The double-headed arrows indicate lines of division of the extrahepatic bile duct. The pale blue area indicates the extent of regional lymph node dissection, which achieves *en bloc* harvesting of both the first-echelon nodes (cystic duct and pericholedochal node groups) and the second-echelon nodes (posterosuperior pancreaticoduodenal, retroportal, right celiac, and hepatic artery node groups)[11,15]. GB: Gallbladder.

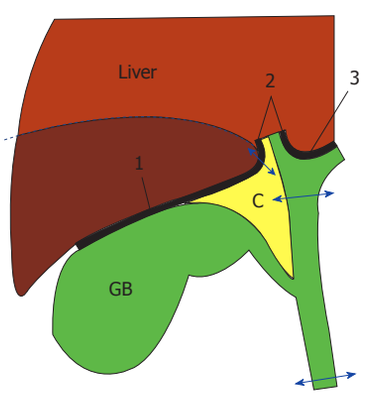

Figure 2 Wedge resection of the gallbladder fossa in "extended" radical cholecystectomy. The dashed line indicates the line of hepatic parenchymal division. The short double-headed arrow indicates the line of division of the cystic plate. The long double-headed arrows indicate lines of division of the extrahepatic bile duct. At the end of parenchymal division, the cystic plate is identified as a fibrous plate connecting with the right portal pedicle, and then divided at its base. Arabic numerals indicate the plate system of the liver (1: Cystic plate; 2: The dense fibrous sheath encircling the right portal pedicle; 3: Hilar plate). GB: Gallbladder; C: The triangle of Calot.

Among the 52 patients who underwent an extended radical cholecystectomy, 19 with suspected (or confirmed) regional nodal disease also underwent a dissection of the paraaortic lymph nodes (cephalad to the origin of the inferior mesenteric artery). Paraaortic nodal disease was classified as N2 disease according to the American Joint Committee on Cancer (AJCC) Cancer Staging Manual (7th edition)[19].

Pathological examination

Immediately after resection, the surgeon(s) retrieved lymph nodes from the node-bearing adipose tissues of the fresh surgical specimen. A total of 871 regional lymph nodes (excluding paraaortic nodes) were retrieved from the 52 patients (median 16, range 6 to 36 per patient). Resected specimens together with the retrieved lymph nodes were submitted for histological examination. Residual tumor status was judged as no residual tumor (R0) or microscopic/macroscopic residual tumor (R1-2). All pathological findings were documented according to the AJCC Cancer Staging Manual (7th edition)[19].

Patient follow-up

Adjuvant chemotherapy was administered to 23 patients at the discretion of the individual surgeon. No patients received adjuvant radiotherapy. Patients discharged to home were followed regularly in outpatient clinics every 1-6 mo for at least 5 years, with a median follow-up period of 188 mo (range: 82-351 mo).

Prognostic factors after extended radical cholecystectomy

To determine prognostic factors after extended radical cholecystectomy, the following 15 conventional variables were tested univariately and multivariately in 52 patients who underwent the procedure (Table 2): age, gender, gallstone (absent *vs* present), timing of radical resection (initial resection *vs* second resection), adjuvant chemotherapy (absent *vs* present), size of the primary tumor (≤ 60 mm *vs* > 60 mm), pT classification, pathological regional lymph nodes (pN) classification, pathological distant metastasis (pM) classification, histological type, histological grade, lymphatic vessel invasion, venous invasion, perineural invasion, and residual tumor status.

Statistical analysis

Medical records and survival data were obtained for all 52 patients. Overall survival (OS) was defined as the interval between the date of definitive resection and the date of last follow up or death from any cause. The Kaplan-Meier method was used to estimate cumulative OS rates, and the log rank test was used to evaluate differences between groups. The Cox proportional hazards regression model using a step-backward fitting procedure was applied to

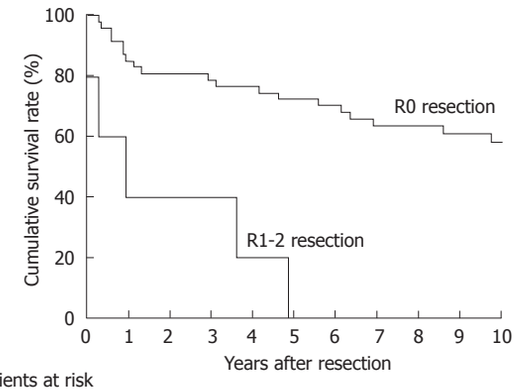
identify independent prognostic factors. In this model, a step-wise selection was used for variable selection with entry and removal limits of $P < 0.05$ and $P > 0.10$, respectively.

The IBM SPSS Statistics 19 software (IBM Japan, Tokyo, Japan) was used for all statistical evaluations. All tests were two-tailed, and $P < 0.05$ was taken to indicate statistical significance.

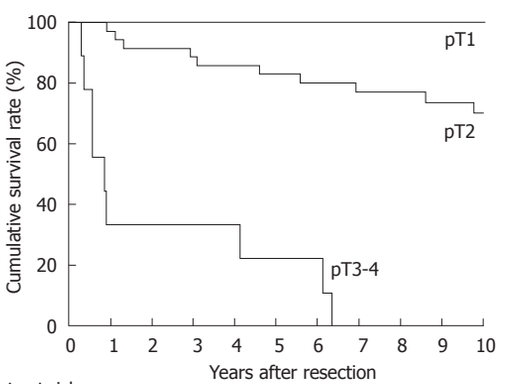


RESULTS

The pT was classified as pT1 in 3 patients, pT2 in 36, pT3 in 12, and pT4 in 1. Twenty-three patients had lymph node metastases, with the number of positive nodes per patient ranging from 1 to 41 (median, 2); 11 patients had a single positive node, 4 had two positive nodes, and 8 had three or more positive nodes. None of the three patients with pT1 tumors had nodal disease, whereas 23 of 49 (47%) with pT2 or more advanced tumors had nodal disease. One patient who underwent a radical second resection died during the hospital stay for definitive resection, giving an in-hospital mortality rate of 2%.

Long-term outcomes after extended radical cholecystectomy

Of the 52 patients who underwent an extended radical cholecystectomy, 34 survived for more than 5 years and 18 died within 5 years. OS following extended radical cholecystectomy was 65% at 5 years and 53% at 10 years (median survival time, not reached) across the study cohort. OS was significantly worse in the 5 patients undergoing a noncurative (R1-2) resection than in the 47 patients undergoing a potentially curative (R0) resection ($P < 0.001$; Figure 3); the R1-2-resected patients died of recurrence within 5 years. This result indicated that R0 resection is a prerequisite for long-term survival after extended radical cholecystectomy.



We then focused on the subgroup of 47 patients who had undergone an R0 resection for subsequent survival analyses. OS after R0 resection differed according to the pT classification ($P < 0.001$; Figure 4) and nodal status ($P = 0.010$; Figure 5). At the time of last follow-up, 11 patients with node-positive disease had survived for more than 5 years, suggesting that regional lymphadenectomy could achieve an acceptable rate of long-term survival for node-positive patients given an R0 resection (Figure 5).

No. of patients at risk

R0 resection	47	40	38	37	36	34	33	29	25	24	21
R1-2 resection	5	2	2	2	1	0	0	0	0	0	0

Figure 3 Kaplan-Meier overall survival estimates stratified for residual tumor status (R) across the study cohort (52 patients). The median overall survival (OS) was not reached with a 5-year OS rate of 72% in patients undergoing an R0 resection, whereas it was 11 mo with a 5-year OS rate of 0% in patients undergoing an R1-2 resection ($P < 0.001$).

No. of patients at risk

pT1	3	3	3	3	3	3	3	3	2	2	2
pT2	35	34	32	31	30	29	28	26	23	22	19
pT3-4	9	3	3	3	3	2	2	0	0	0	0

Figure 4 Kaplan-Meier overall survival estimates stratified for pathological T classification in 47 patients who underwent an no residual tumor resection. The median overall survival (OS) was not reached with a 5-year OS rate of 100% in patients with pathological T1 (pT1) disease. The median OS was not reached with a 5-year OS rate of 83% in pT2 patients, whereas it was 10 mo with a 5-year OS rate of 22% in pT3-4 patients. OS differed significantly among the groups ($P < 0.001$).

Five-year survival according to pT classification

All patients with pT1 tumor and most (29 of 36) patients with pT2 tumor survived for more than 5 years, while most (10 of 12) patients with pT3 tumor and the only patient with pT4 tumor died within 5 years (Table 3).

Of the 12 patients with pT3 tumors, 3 had an R1-2 resection, 2 had distant metastasis (pM1) in the liver, 2 had extensive extrahepatic organ involvement, and 1 had both an R1-2 resection and pM1 in the liver. All of these patients died within 5 years. Of the remaining four pT3 patients who had localized hepatic spread through the gallbladder fossa and underwent an R0 resection, 2 survived for more than 5 years, 1 survived for 4 years and 2 mo, and another succumbed to the cancer 4 mo after resection. Taken together, the above observations indicated that extended radical cholecystectomy was effective for most T1-2 lesions and some pT3 lesions with localized hepatic spread.

Table 3 Five-year survival according to the extent of tumor spread

Extent of tumor spread[1]	No. of 5-yr survivors (n = 34)	No. of non-5-yr survivors (n = 18)
pT1 (n = 3)		
pT1a pN0 pM0 (Stage Ⅰ)	2	0
pT1b pN0 pM0 (Stage Ⅰ)	1	0
pT2 (n = 36)		
pT2 pN0 pM0 (Stage Ⅱ)	20	1

Table 4 Eleven 5-year survivors who underwent "extended" radical cholecystectomy for node-positive gallbladder cancer

Patient No.	Age (yr)	Sex	pT	Lymph node status	
				Location of positive nodes	No. of positive nodes
1	58	M	2	Hepatic artery	1
2	67	F	2	Cystic duct	1
3	68	F	2	Cystic duct	1
4	77	M	3	Cystic duct	1
5	75	F	3	Pericholedochal	1
6	62	F	2	Cystic duct	1
7	63	F	2	Cystic duct and posterosuperior pancreaticoduodenal	2
8	60	F	2	Cystic duct	2
9	67	F	2	Retroportal	2
10	55	F	2	Cystic duct and hepatic artery	2
11	57	F	2	Paraaortic	9[1]

[1]Isolated paraaortic nodal metastases. pT: Pathological T classification; M: Male; F: Female.

Five-year survival according to lymph node status

Among the eleven 5-year survivors with node-positive disease (Table 4), the number of positive lymph nodes was limited to one or two in 10 patients (patient No. 11 underwent an aggressive paraaortic lymphadenectomy for a total of nine positive paraaortic nodes), suggesting that extended radical cholecystectomy was effective in patients with up to a modest degree of regional nodal disease (up to two positive nodes).

No. of patients at risk

Without nodal disease	27	25	25	25	25	23	23	21	17	16	15
With nodal disease	20	15	13	12	11	11	10	8	8	8	6

Figure 5 Kaplan-Meier overall survival estimates stratified for nodal status in 47 patients who underwent an no residual tumor resection. The median overall survival (OS) was not reached with a 5-year OS rate of 85% in patients without nodal disease, whereas it was 67 mo with a 5-year OS rate of 55% in patients with nodal disease (P = 0.010).

Prognostic factors after extended radical cholecystectomy

Among the 15 conventional variables, age, pT classification, pN classification, pM classification, histological type, histological grade, lymphatic vessel invasion, venous invasion, perineural invasion, and residual tumor status were identified as significant prognostic factors on univariate analyses (Table 2). Timing of radical resection (initial resection *vs* second resection) did not affect OS rates after resection (P = 0.404).

The 10 univariately significant variables were then entered into multivariate analyses, with pT classification, pM classification, and histological type identified as independently significant variables (Table 2).

DISCUSSION

A standardized resection procedure has not been established for gallbladder cancer due to the diverse modes of spread possible with this disease[5,23]. Thus, the scope of radical resection when treating gallbladder cancer should be tailored based on the extent of spread in individual patients. Here, we analyzed 52 patients undergoing extended radical cholecystectomy and found it to be effective for pT1-2 tumors and some pT3 tumors with localized hepatic invasion, provided that the regional nodal disease was absent or only present to a modest degree (one or two positive lymph nodes).

In 1954, Glenn *et al*[3] first proposed a radical surgical procedure, designated as "radical cholecystectomy", where the gallbladder fossa and the node-bearing tissues within the hepatoduodenal ligament (portal lymph node dissection) were excised *en bloc* at the time of cholecystectomy. Extended radical cholecystectomy in our department (Figure 1) differs from the original Glenn and Hays procedure in the extent of lymphadenectomy and the presence or absence of bile duct resection. The extent of lymphadenectomy in the former procedure includes both the first- and the second-echelon node groups[11,15], but that in the original procedure was more limited[3,6,14]. The difference in the extent of lymphadenectomy may explain, in part, the acceptable rate of long-term survival (55%) achieved in our node-positive patients (Figure 5). Bile duct resection provides better local control by removing the possible presence of ductal (periductal) spread[21] as well as better clearance of nodal disease (especially periductal nodal disease). Thus, we believe that extended radical cholecystectomy confers oncological advantages over the original radical procedure.

The main modes of hepatic spread from resectable gallbladder cancer involve both direct invasion and portal tract invasion (lesions within the portal tracts of adjacent liver), the latter of which features intrahepatic lymphatic invasion[5,23-25]. We previously reported that the portal tract invasion is seen only in the vicinity (within about 1 cm) of the advancing margin of direct liver invasion[24,25]. Thus, a hepatectomy margin of approximately 2 cm or more in our extended radical cholecystectomy appears to be sufficient. The fact that local recurrence in hepatectomy margins did not occur in any of our patients (data not shown) also supports the validity of our 2 cm hepatectomy margin. When performing a wedge hepatectomy for invasive tumor, the entire cystic plate should be resected (Figure 2) because incomplete excision of the cystic plate violates the subserosal plane of the gallbladder and thus may leave behind tumor cells in this plane. Also, complete excision of the cystic plate facilitates removal of the adipose tissue within the triangle of Calot, which usually contains cystic duct node(s).

The current study showed that most patients with pT2 gallbladder cancer who underwent an extended radical cholecystectomy survived for more than 5 years (Figure 4), suggesting that pT2 tumors are the best candidates for this procedure. Regarding pT3-4 tumors, we cannot draw a definitive conclusion due to the small number of patients analyzed in this study. However, the fact that three of the four pT3 patients with localized invasion of the liver through the gallbladder fossa survived for more than 4 years suggests that such pT3 patients may benefit from extended radical cholecystectomy, provided that they have no distant metastases and undergo an R0 resection. Our results also suggest that a considerable proportion of node-positive patients may benefit from this procedure (Figure 5). By analyzing 5-year survivors with nodal disease (Table 4), we realized that this procedure might clear only a modest degree of nodal disease (one or two positive nodes in our cohort). Taken together, the above observations indicate that the extended radical cholecystectomy undertaken in our department provides survival benefit for most patients with pT2 tumors and some patients with pT3 tumors with localized hepatic invasion, provided that the nodal disease is limited to a modest degree and an R0 resection is feasible.

In 2007, Yokomizo *et al*[26] argued that hepatectomy and/or bile duct resection could be withheld in radical surgery for pT2 gallbladder cancer provided that negative resection margins are achieved. The current NCCN guidelines[6] recommend hepatectomy and lymphadenectomy

for pT1b or greater tumors, whereas bile duct resection is suggested as optional. We previously reported that a considerable proportion (40%) of pT2 patients could survive for more than 5 years after cholecystectomy alone if the resection margins are negative[12]. The above observations indicate that bile duct resection, hepatectomy, and even lymphadenectomy could be omitted for some pT2 patients. Indeed, some of our pT2 patients with advanced age or comorbid disease(s) had a less aggressive resection by omitting bile duct resection and/or hepatectomy (Table 1). However, considering the excellent outcomes after extended radical cholecystectomy for pT2 tumors (Figure 4), we now usually recommend application of the extended radical cholecystectomy to robust patients with pT2 gallbladder cancer.

The authors' policy on radical surgery for gallbladder cancer is to select a resection procedure for each patient based on the extent of tumor spread in the patient. Although extended radical cholecystectomy has been considered the standard procedure for fairly localized tumors in our department, only one-third (52 of 145) of our patients underwent this procedure (Table 1). The current study implies that extensive pT3 disease, pT4 disease, or marked nodal disease is beyond the scope of extended radical cholecystectomy. Such tumors may require more extensive resections (major hepatectomy, pancreaticoduodenectomy, *etc*.) for clearance of the locoregional disease[11]. Adequate selection of a resection procedure in individual patients is mandatory to improve survival for gallbladder cancer.

The main limitations of the current study include the retrospective nature of the analysis and the small number of patients spanning a long period of time. We believe, however, that these limitations did not greatly affect the results of the study as the differences between the groups were too marked to have resulted from bias. In addition, the role of extended radical cholecystectomy in surgical management strategy for gallbladder cancer is now more clearly defined than previously[11,12,16]. Our results thus provide useful information for selecting an adequate resectional procedure for individual patients with gallbladder cancer.

In conclusion, extended radical cholecystectomy is indicated for gallbladder cancer patients with pT2 tumors and for some with pT3 tumors with localized hepatic invasion, provided that the regional nodal disease is limited to a modest degree (up to two positive nodes). Extensive pT3 disease, pT4 disease, or marked nodal disease appears to be beyond the scope of this procedure and thus may require more extensive resection. This study confirms that extended radical cholecystectomy plays a key role in the surgical management of invasive gallbladder cancer if the spread is moderate.

COMMENTS

Background

In 1954, Glenn and Hays first proposed "radical cholecystectomy", which has been used worldwide for localized gallbladder cancer. "Extended" radical cholecystectomy (designated as the modified Glenn operation) was instituted in the study department in 1982. Although the authors' procedure has been widely used among Japanese surgeons, indications for this particular procedure have not yet been established.

Research frontiers

As a standardized resection procedure has not been defined for gallbladder cancer, the scope of radical resection should be tailored based on the extent of spread in individual patients. However, adequate selection of a resection procedure in individual patients remains yet to be established.

Innovations and breakthroughs

The current study clearly defines the role of extended radical cholecystectomy in surgical management strategy for gallbladder cancer. Briefly, **extended radical cholecystectomy is indicated for pathological T2 (pT2) tumors and for some pT3 tumors with localized hepatic invasion, provided that the nodal disease is limited to a modest degree (up to two positive nodes). Extensive pT3 disease, pT4 disease, or marked nodal disease appears to be beyond the scope of this procedure and thus may require more extensive resection.**

Applications

The current study provides practical information for selecting an adequate resectional procedure for individual patients with gallbladder cancer.

Terminology

Radical cholecystectomy (Glenn operation): *en bloc* excision of the gallbladder, gallbladder fossa, and the node-bearing tissues within the hepatoduodenal ligament; **"Extended" radical cholecystectomy (modified Glenn operation):** *en bloc* excision of the gallbladder, gallbladder fossa, extrahepatic bile duct, and the regional lymph nodes (first- and second-echelon node groups).

Peer review

Overall, this paper is well written, concise and informative. "Extended" radical cholecystectomy involves more extensive regional lymphadenectomy compared with the "original" radical cholecystectomy proposed by Glenn and Hays. This has led to achievement of good long-term survival in node-positive patients.

Abstract

AIM: To assess the prognostic significance of nuclear factor-κB (NF-κB) and its target genes in gastric cancer.

METHODS: The tumor tissues of 115 patients with gastric cancer were immunohistochemically evaluated using monoclonal antibodies against NF-κB RelA. Preoperative serum levels of vascular endothelial growth factor (VEGF), interleukin-6 (IL-6) were assessed *via* enzyme-linked immuno-sorbent assay. C-reactive protein (CRP) and serum amyloid A (SAA) were measured *via* immunotrubidimetry.

RESULTS: Positive rate of NF-κB RelA was 42.6%. NF-κB RelA expression in tumor tissues was also related to serum levels of IL-6 (P = 0.044) and CRP (P = 0.010). IL-6, SAA, CRP were related to depth of invasion, VEGF and SAA were correlated with lymph node metastasis. IL-6, VEGF, SAA and CRP were related to the stage. Univariate analysis demonstrated that immunostaining of NF-κB RelA, levels of IL-6, VEGF, SAA were significantly related with both disease free survival and overall survival (OS). Multivariate analysis verified that NF-κB RelA [hazard ratio (HR): 3.40, P = 0.024] and SAA (HR: 3.39, P = 0.045) were independently associated with OS.

CONCLUSION: Increased expression of NF-κB RelA and high levels of serum SAA were associated with poor OS in gastric cancer patients.

Kwon HC, Kim SH, Oh SY, Lee S, Lee JH, Jang JS, Kim MC, Kim KH, Kim SJ, Kim SG, Kim HJ. Clinicopathologic significance of expression of nuclear factor-κB RelA and its target gene products in gastric cancer patients. *World J Gastroenterol* 2012; 18(34): 4744-4750 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i34/4744.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i34.4744

INTRODUCTION

Gastric cancer continues to pose a significant health prob-

lem, despite its declining incidence in the West. It is the 4th most common cancer worldwide, accounting for 8.6% of all new cancer diagnoses in 2002[1]. In South Korea, gastric cancer is the most common carcinoma in men, and the third-most common cancer type in women[2]. Surgery is the only potentially curative treatment for localized gastric cancer. However, the majority of patients will relapse after definitive surgery, and the 5-year overall survival (OS) rates of this condition remain lower than 30% to 40% in Western countries[1]. These high levels of gastric cancer mortality can be attributed to the high incidence of serosal invasion, direct invasion into the adjacent organs, peritoneal seeding, lymph node metastasis, and distant metastasis of gastric cancer. The assessment of biological prognostic factors is of great clinical importance in gastric cancer. The widely used tumor node metastasis (TNM) staging exhibits high prognostic power, but cannot predict outcomes perfectly for particular individuals. The outcome of cancer patients may be affected by variability in tumor biology. Thus, tumors with similar clinical or pathologic characteristics frequently evidence different clinical outcomes. Gaining insight into the underlying molecular mechanisms of initiation and progression of gastric cancer will be a necessary step in definitively identifying groups of patients with poor prognoses. The transcription factor nuclear factor-κB (NF-κB) is a heterodimeric complex of the Rel-family proteins. The most common dimer is the RelA (p65)/p50 heterodimer, i.e., NF-κB[3]. NF-κB is sequestered in the cytoplasms in an inactive form *via* interaction with the inhibitor of nuclear factor-κB proteins (IκBs). A variety of stimuli, including cytokines and infectious agents, induce the phosphorylation, ubiquitination, and degradation of IκBs, and also allow the nuclear translocation of NF-κB[4]. Once in the nucleus, NF-κB binds to DNA at its response elements and activates the expression of genes. Recent studies using anti-RelA immunostaining have shown that NF-κB is constitutively activated in gastric cancer[5-7], Additionally, there is some evidence to suggest that NF-κB levels are higher in gastric cancer cells than in normal adjacent epithelial cells, and that NF-κB activation in gastric cancer is associated with lymphatic invasion, advanced stage, and poor clinical outcomes[5,7]. However, other investigators have reported conflicting data with regard to the relationship of NF-κB protein with patient survival[6].

The active NF-κB transcription factor promotes the expression of more than 150 target genes[8]. The majority of proteins encoded for by NF-κB target genes participate in host immune responses, whereas others appear to be involved in the proliferation, invasion, angiogenesis, and metastasis of cancer cells. NF-κB promotes the production of cytokines that function as growth factors for transformed enterocytes[9]. One of these growth factors was subsequently identified as interleukin-6 (IL-6), which is encoded for by a NF-κB target gene. IL-6 acts on a broad range of tissues and cell lines, and induces cell growth and differentiation, the production and expression of other cytokines, and acute-phase protein synthesis. IL-6 also promotes growth arrest[10], and promotes angiogenesis *via* the induction of vascular endothelial growth factor (VEGF) expression[11]. A previous study reported that the preoperative serum level of IL-6 was associated with lymph node metastasis, depth of invasion, advanced stage, and poor survival in gastric cancer patients[12].

C-reactive protein (CRP) and serum amyloid A (SAA) are nonspecific, acute-phase, hepatic proteins secreted in response to cytokines, including IL-1, IL-6, and tumor necrosis factor-α[13]. CRP is a representative marker for inflammatory conditions, and carries out a crucial anti-infection function in the immune system. In many cancers, chronic inflammation has reportedly been involved with malignant change, and the risks of colorectal cancer appear to be increased when pre-diagnostic CRP levels are high[14]. Cancer invasion begins with inflammation around cancer cells. Thus, serum CRP levels have generally been shown to be higher in cases of invasive cancer than in cases of non-invasive cancer[12].

An increasing body of *in vitro* evidence supports the involvement of SAA in carcinogenesis and neoplastic diseases[15]. An accumulating body of evidence has been collected to suggest that SAA might be included in a group of biomarkers for the detection of a pattern of physiological events that reflects the growth of malignancy and host response. There have also been some reports indicating that the SAA-induced upregulation of matrix metalloproteinase 9 was mediated *via* formyl peptide receptor like-1 and was achieved at the transcriptional level *via* NF-κB[16], and also that preoperative SAA was useful in predicting the survival of gastric cancer patients[17].

The expression of several angiogenic factors is also known to be regulated by NF-κB. Macrophages as well as tumor cells have been shown to generate VEGF under the control of NF-κB activation[18]. VEGF is the most important pro-angiogenic growth factor, and its stimulation under hypoxic conditions carries out critical functions in promoting the survival of malignant cells, in local tumor growth and invasion, and in the development of metastases[19]. We demonstrated that VEGF expression was correlated with the depth of invasion and NF-κB expression in stage Ⅲ colorectal cancer patients[20].

The objective of the current investigation was to evaluate the prognostic significance of NF-κB RelA and its target gene products in gastric cancer patients.

MATERIALS AND METHODS

Patients

From March 2005 to July 2006, a total of 115 patients with histologically-confirmed gastric carcinomas at the Dong-A University Hospital were enrolled in this study. After operation, the disease status of patients was evaluated *via* gastroendoscopy and abdominal computed tomography (CT). During the first 2 years, we checked CT and endoscopy at 6-mo intervals, and afterwards CT and endoscopy were conducted every 12 mo. We also carried out abdomen CT when we observed abdominal distension, acute abdominal pain, severe diarrhea and

chest X-ray abnormalities suggestive of lung metastasis. Endoscopy was conducted in cases in which patients complained of unexplained abdominal discomfort and dyspepsia. On average, in the stage Ⅲ and Ⅳ patients, the first evaluation was conducted within 3 mo after operation. All patients provided informed consent, and the hospital review board approved the study.

Construction of tissue microarray

Two cores of 2-millimeters in diameter of formalin-fixed, paraffin-embedded tissue blocks were obtained from each gastric cancer patient's sample and arranged in new recipient paraffin blocks using an UNITMA apparatus (UNITMA, Seoul, South Korea) after careful histological assessment. All cases except for one endoscopic biopsy sample and the normal control tissue, were embedded in 6-tissue microarray blocks. Tissue microarray blocks were serially cut into 4 μm sections and stained for routine hematoxylin and eosin staining and immunohistochemistry.

Immunohistochemistry

All immunohistochemistry processes were automatically performed using a Ventana autostainer (Benchmark; Ventana Medical Systems, Tuscon, Arizona, United States). For antigen retrieval, retrieval solution (Ventana) was automatically poured onto the sections, and heated for 60 min at 100 ℃. Endogenous peroxide activity was blocked *via* immersion in 3% hydrogen peroxide for 4 min. With diluted primary antibody for NF-κB p65 (rabbit monoclonal antibody, 1:250, Epitomics, CA, United States), the tissue sections were incubated for 32 min at 36 ℃. Immunoperoxidase staining was carried out using a DAB system (iView DAB detection kit, Ventana) and the sections were counterstained lightly with hematoxylin.

Interpretation of immunohistochemical staining

The percentage and intensity of the immunoreactive tumor cells in each core was recorded and the final values of the positive tumor cells were evaluated as the mean of the immunoreactivity in three cores. The presence of tumor tissue in at least two interpretable cores was required for the inclusion of a case in the statistical analysis. All of the slides were evaluated independently by an experienced pathologist (Kim SJ) who was blinded to all of the clinicopathologic data. Immunostaining for NF-κB RelA was regarded as positive when tumor cells evidenced granular cytoplasmic immunostaining of the lesion, with a minimal background. The percentage scoring of the immunoreactive tumor cells was as follows: 0 (0%), 1 (1%-10%), 2 (11%-50%) and 3 (> 50%). The staining intensity was visually scored and stratified as follows: 0 (negative), 1 (weak, if it was a blush), and 2 (strong, if it was obviously positive at × 20 magnification). A final score was obtained for each case by multiplying the percentage by the intensity score. Therefore, tumors with multiplied scores exceeding 4 (i.e., tumors with a strong intensity of > 10% of the tumor cells) were regarded as positively immunoreactive to NF-κB RelA; all other scores were considered negative.

Assay of serum IL-6, VEGF, SAA and CRP

Peripheral venous blood samples were obtained within 7 d prior to gastrectomy, collected in plain tubes, permitted to clot, and centrifuged for 10 min at 3000 r/min at 4 ℃ within one hour of collection to obtain the serum. The sera were aliquoted and stored at -80 ℃ until being assayed. The VEGF and IL-6 levels from the sera of patients and the standard solutions supplied were measured using a commercial system (Quantikine hVEGF, hIL-6 Immunoassay, R and D Systems, United States) in accordance with the manufacturer's instructions. All serum samples were measured by an investigator who was blinded to the clinical data. The blood samples for CRP analysis were collected in serum separation tubes, and the serum CRP levels were measured *via* immunoturbidimetry (Denka Seiken Co. Ltd., Japan). SAA protein was measured *via* latex agglutination turbidoimmunometric assays (Eiken Chemical Co., Japan).

Statistical analysis

The associations between NF-κB RelA expression and the relevant clinicopathological parameters were assessed *via* an χ^2-test or Fisher's exact test. Serum levels of VEGF, IL-6 and CRP were expressed as mean values. The Mann-Whitney *U*-test was used to evaluate the relationship between protein concentration and clinicopathological features. Disease-free survival (DFS) was defined as the length of time from surgery to initial recurrence of disease. OS was defined as the length of time from surgery to death. The Kaplan-Meier method was utilized to construct curves for DFS and OS. Data on patients who died without any evidence of disease recurrence were censored at the time of death for DFS calculations. The log-rank test was employed to compare distributions. In order to identify the independent factors that were significantly related to patient prognosis, we utilized Cox's proportional hazard analysis *via* a stepwise procedure. All tests were two-sided, and $P < 0.05$ was considered statistically significant. Analyses were conducted using SPSS version 18.0 (SPSS, Chicago, IL, United States).

RESULTS

Patient characteristics

The mean age of the patients was 59 years (range: 24-75 years), and the study population included 47 (40.92%) females and 68 (59.1%) males. Thirty-six of the patients (31.3%) underwent radical total gastrectomy, 75 (65.2%) underwent radical subtotal gastrectomy, and four patients (3.5%) did not have operation due to distant metastasis. The majority of the tumors were located in the middle or lower stomach (72.1%), and were moderate to poorly differentiated carcinomas (75.7%). Thirty-four of the patients (30.6%) had pathological T3 (pT3) or pT4 tumors, 69 (63.2%) had lymph node metastases, and 26 patients (23.4%) had a positive lymph node ratio of ⩾ 0.2. The postoperative stages of the patients were Ⅰ, Ⅱ, Ⅲ and Ⅳ in 43 (37.4%), 23 (20.0%), 31 (27.0%) and 18 (15.7%)

patients, respectively. With regard to the Lauren classifications, 46 (40.0%) patients were of the intestinal type, 43 (37.4%) of the diffuse type, and 15 (13.0%) of the mixed type. Sixteen patients (14.4%) had well, 28 (25.2%) had moderate, and 56 (50.5%) had poorly differentiated adenocarcinoma. Fifty-five patients (47.8%) received oral 5-fluorouracil, and 46 patients (40.0%) received cisplatin-based adjuvant chemotherapy after gastrectomy.

Correlations between the NF-κB RelA expression, target gene expression and clinicopathological parameters

A representative tumor specimen evidencing increased NF-κB RelA expression in the cytoplasm is shown in Figure 1. NF-κB RelA expression was found to be significantly correlated with several findings (Table 1). NF-κB RelA expression was more common in cases of more than 5 cm ($P = 0.045$), deeper invasion ($P = 0.012$), lymph node metastases ($P < 0.001$), advanced stage ($P < 0.001$), positive lymphovascular invasion ($P = 0.012$), and increased Carbohydrate antigen 19-9 ($P < 0.001$). However, no significant correlations were noted between Nf-κB a RelA nd other parameters. We noted that VEGF, SAA levels were significantly correlated with tumor size ($P = 0.022$, $P < 0.001$, respectively). IL-6, SAA and CRP levels were related to the depth of invasion ($P = 0.007$, $P < 0.001$, $P = 0.015$, respectively). We also noted significant differences in serum VEGF and SAA levels between patients with lymph node metastasis and those without lymph node metastasis ($P < 0.001$, respectively). The mean levels of IL-6, VEGF, SAA and CRP were increased proportionally with the cancer stage ($P = 0.031$, $P < 0.001$, $P < 0.001$, $P < 0.001$, respectively). Additionally, NF-κB RelA expression was correlated positively with IL-6 ($P = 0.044$), and CRP ($P = 0.010$) levels (Table 2).

NF-κB RelA expression, target gene expressions and clinical outcomes

The median follow-up duration of the patients was 66.6 mo (range: 9.3-88.8 mo). Univariate analysis of clinicopathologic parameters and DFS and OS are provided in Table 3. Tumor size, location, lymphovascular invasion, stage, and positive lymph node ratio were significantly associated with both 5-year DFS and OS. Positive correlations were detected between immunostaining of NF-κB RelA, levels of IL-6, VEGF, SAA, and DFS and OS. CRP levels were not correlated with 5-year DFS or OS. The OS curves of SAA and NF-κB RelA are provided in Figure 2. In order to determine the independent prognostic values of these markers, we employed a multivariate Cox proportional hazard analysis to control for other prognostic factors (Table 4). Accordingly, stage was identified as an independent prognostic factor of both DFS [hazard ratio (HR): 7.83, 95% confidence interval (CI) = 2.44-25.18, $P = 0.001$], and OS (HR: 6.15, 95% CI = 1.97-19.22, $P = 0.002$). Positive lymph node ratio was also identified as a significant predictor of both DFS (HR: 1.68, 95% CI = 1.01-2.79, $P = 0.043$), and OS (HR: 2.46, 95% CI = 1.01-5.94, $P = 0.047$), after controlling for other clinicopathologic parameters. The expressions of NK-κB and

nohistochemistry using the same anti-RelA (p65) antibody[5,7]. The present study confirms constitutively active NF-κB RelA in gastric carcinoma, which is consistent with the findings of previous studies[5,7]. The expression rate of NF-κB RelA in gastric carcinoma is higher than that observed in normal adjacent epithelial cells, and NF-κB RelA expression was observed primarily in gastric carcinoma cytoplasm with an expression rate of 42.6%; this is somewhat higher than in other studies[5,7]. We showed that NF-κB RelA expression was correlated with tumor size, depth of invasion, lymph node metastasis, lymphovascular invasion and advanced stage. Furthermore, positive NF-κB RelA staining was associated with both DFS and OS, and NF-κB RelA was identified as an independent prognostic factor in multivariate analysis (HR: 3.40, 95% CI = 1.17-9.87, $P = 0.024$).

Sasaki *et al*[5] also reported that NF-κB activation was correlated with tumor size and lymphatic invasion. However, Lee *et al*[6] previously demonstrated that NF-κB activation was not correlated with poor patient prognosis, but rather was significantly associated with better prognosis of early stage gastric carcinoma patients. The absence of clear-cut criteria in the evaluation of NF-κB immunoexpression may be the major reason for the conflicts among the previously published data regarding the prognostic impact of this molecule in gastric cancer.

The activation of NF-κB regulates a variety of genes involved in the proliferation, invasion, angiogenesis, and metastasis of cancer cells[8]. In this study, NF-κB RelA expression was correlated positively with IL-6 and CRP levels. According to some studies attempting to evaluate the clinical significance of IL-6 in gastric cancer patients, IL-6 levels were higher in malignancies than in non-malignancies, increased with increasing tumor size and depth, and were associated with poor clinical outcomes[12,21]. We found significant correlations between elevated IL-6 levels and several conditions: large tumor size, deeper invasion depth, advanced stage, and poor DFS and OS.

Findings from studies of gastrointestinal cancer patients have demonstrated that those subjects with elevated serum CRP concentrations tended toward poorer prognoses than those whose CRP levels were not increases[14,22]. CRP was related to the depth of tumor invasion, tumor differentiation, and TNM stage. However, we found no significant associations between CRP and DFS or OS.

SAA is the most sensitive plasma protein indicative of inflammatory activity[23]. SAA is superior to CRP for the detection of inflammation associated with severe burns, viral infections, kidney transplantation, Crohn's disease, and ulcerative colitis[23]. In this study, SAA was related to tumor size, depth of invasion, lymph node metastasis, clinical stage, and cancer recurrence. Similar results have been reported in other studies[17]. Those studies showed that gastric cancer patients had higher SAA levels than did patients with gastric ulcers and healthy individuals, and that SAA concentrations were correlated with prognosis[17]. SAA was related significantly to DFS and OS, and was determined to be an independent prognostic factor for OS in multivariate analysis (HR: 3.39, 95% CI = 1.02-11.23, $P = 0.045$).

Tumor VEGF expression was identified as a significant marker for tumor recurrence or reduced survival independent of conventional clinicopathological variables in gastric cancer[24,25]. However, the prognostic value of VEGF expression in gastric cancer remains unclear, and some studies have indicated that tumor VEGF expression may constitute an independent prognostic factor in DFS[24,25], whereas others have reported no such association[26]. In our study, VEGF expression was significantly correlated with tumor size, lymph node invasion and staging; however, our findings do not appear to confirm a significant association between VEGF expression and unfavorable prognosis in multivariate analysis.

Univariate analysis demonstrated that the immunostaining of NF-κB RelA and levels of IL-6, VEGF and SAA were all significantly related with both DFS and OS. Multivariate analysis results verified that NF-κB RelA and SAA were independently associated with OS. Although changes in the expression levels of several cytokines have been frequently reported, their proposed role in the pathogenesis and progression of gastric cancer remains controversial. The results of such studies may be confounded by several factors, including small patient sample size and variable therapeutic protocols which may potentially have affected patient outcomes. Well-designed large scale studies will be necessary to confirm our data.

COMMENTS

Background

The active nuclear factor-κB (NF-κB) transcription factor promotes the expression of target genes. The majority of proteins encoded for by NF-κB target genes participate in host immune responses, proliferation, invasion, angiogenesis, and metastasis of cancer cells.

Research frontiers

The objective of the current investigation was to clarify the prognostic significance of NF-κB RelA and its target gene products in gastric cancer patients.

Innovations and breakthroughs

In the present study, NF-κB RelA expression in tumor tissues was related to increased serum levels of interleukin (IL)-6 (P = 0.044) and C reactive protein (CRP) (P = 0.010). Levels of serum IL-6, vascular endothelial growth factor (VEGF), serum amyloid A (SAA) and CRP were related to the stage. Univariate analysis demonstrated that immunostaining of NF-κB RelA, levels of IL-6, VEGF, SAA were significantly related with both disease free survival and overall survival (OS). Multivariate analysis verified that NF-κB RelA and SAA were independently associated with OS.

Applications

Increased expression of NF-κB RelA and high levels of serum SAA were associated with poor OS in gastric cancer patients.

Peer review

The authors of this manuscript examined potential prognostic value of NF-κB RelA expression in gastric cancer patients and reported an inverse relationship between RelA expression and patient survival. In addition to RelA, the contribution of several inflammatory mediators/cytokines to the patient prognosis was also investigated. The study was well-designed and the data are convincing.

Abstract

AIM: To investigate whether expressing biliary phenotype predicted poor outcome after the surgical treatment in primary liver cancers.

METHODS: Out of 204 patients that underwent liver resection due to hepatocellular carcinoma (HCC), liver specimens of 70 patients with HCC were evaluated for biliary components by cytokeratin (CK) 19 immunostain ($CK19^-$ HCC and $CK19^+$ HCC). CK19 positivity was defined as membranous and/or cytoplasmic expression in $\geqslant$ 5% of tumor cells with moderate or strong intensity. Patients with other primary liver cancers, such as combined HCC and cholangiocarcinoma (cHCC-CC), intrahepatic cholangiocarcinoma (ICC) who received curative liver resection, were also included in the study. Clinical characteristics of $CK19^-$ HCC and $CK19^+$ HCC patients, including survival outcome after curative liver resection, were compared with that of cHCC-CC and ICC patients.

RESULTS: The overall survival (OS) rate of $CK19^-$ HCC (n = 49) after the curative surgical treatment was 90.7%, and 80.4% at 1 and 5 years after the resection. OS rate of $CK19^+$ HCC (n = 21) was 74.3%, 28.9% and OS rate of cHCC-CC (n = 22) was 66.7%, 32.2% at 1 and 5 years after the surgery. For ICC (n = 19), 1 and 5-year-OS rate was 50.2% and 14.3% after the curative resection. The OS rates of $CK19^+$ HCC and cHCC-CC were significantly lower than that of $CK19^-$ HCC, but higher than the OS rate of ICC (P = 0.000). There was no statistically significant difference in OS rate between $CK19^+$ HCC and cHCC-CC. The disease free survival (DFS) rate of $CK19^-$ HCC was 72.0% and 54.5% at 1 and 3 years after the surgical treatment. DFS rate of $CK19^+$ HCC was 53.3%, 34.3% and DFS rate of cHCC-CC was 51.5%, 39.2% at 1 and 3 years after the resection. For ICC, 1 and 3-year-DFS rate was 28.0% and 14.0% after the curative resection. DFS rate of $CK19^-$ HCC was significantly higher than that of ICC (P = 0.017), but marginally higher than DFS rate of either $CK19^+$ HCC or cHCC-CC (P = 0.097, P = 0.089, respectively). Predictors of outcome after the surgery of primary liver cancer were pathology of the resected mass, existence of microvascular invasion and accompanying satellite nodule.

CONCLUSION: Primary liver cancers with biliary components tended to show poorer surgical outcome. This suggested that immuno-phenotype of liver cancers was as important as their morphological classification.

INTRODUCTION

Proposed treatment strategy for solid tumor is usually guided by tumor stage. In case of hepatocellular carcinoma (HCC), Barcelona Clinic Liver Cancer (BCLC) staging system, that has come to be widely accepted in clinical practice[1], carefully allocates HCC patients according to tumor stage and liver function as well as physical status. Despite the careful selection of candidates for each treatment option, HCC patients with similar BCLC grade that underwent the same mode of treatments may show very different outcome. It has been suggested that HCC heterogeneity in the molecular and morphological features may be related to the treatment outcome[2,3]. Recently, efforts have been made to classify HCC histopathologically, encompassing subpopulations of HCC according to their distinct molecular features[4].

While the World Health Organization (WHO) still classifies primary liver cancer into HCC, intrahepatic cholangiocarcinoma (ICC), and combined hepatocellular and cholangiocarcinoma (cHCC-CC)[5], there has been a report on HCCs whose cells of some proportion displayed cholangiolar differentiation and which showed highly aggressive behavior[6]. The authors claimed that this type of HCC with biliary differentiation must be different from cHCC-CC since it displayed typical HCC morphological features, and referred it as dual-phenotype HCC. On the other hands, according to the WHO classification, cHCC-CC is characterized by having unequivocal, intimately mixed elements of both HCC and ICC components within a single nodule[5], and it is also reported to show much worse prognosis than HCC[7-11].

Meanwhile, it has recently been proposed that HCC with biliary differentiation should be categorized as HCC with stem/progenitor cell immunophenotype whereas cHCC-CC should be included as mixed hepatobiliary carcinoma, classical type[4].

Since both HCC with biliary differentiation and cHCC-CC appeared to be the primary liver cancer displaying biliary phenotype, we hypothesized that the outcome of curative resection in primary liver cancer would be grave as the cancer expressed biliary phenotype rather than hepatic phenotype. In order to test this hypothesis, we compared the surgical outcome of classical HCC without biliary differentiation, with that of HCC with biliary differentiation, defined as having cytokeratin (CK) 19 positive cells, along with cHCC-CC and ICC.

MATERIALS AND METHODS

Case selection and histopathologic analysis

Liver specimens, surgically resected between January 2000 and August 2010 at Inha University Hospital (Incheon, South Korea) were reviewed and selected from pathologic files. Out of 204 patients who underwent liver resection due to HCC, 70 patients were assessed for CK19 positivity. These patients had well preserved liver function, evaluated by Child-Pugh scoring system. None of the selected cases experienced preoperative cancer treatment including transarterial chemoembolization (TACE). HCC was diagnosed under hematoxylin and eosin (HE) stain according to the morphologic criteria as defined by the WHO. Edmondson and Steiner Grading System (E-S, I-IV) was used to evaluate the degree of differentiation[5]. The primary antibody for CK19 (monoclonal, DAKO, Glostrup, Denmark, 1:50) was applied in order to detect CK19 positivity in HCC. CK19 positivity was defined as membranous and/or cytoplasmic expression in $\geqslant$ 5% of tumor cells with moderate or strong intensity.

Twenty-two cases of cHCC-CC were analyzed. Combined HCC-CC was diagnosed when there were evidences of both HCC and CC differentiation demonstrated within the same nodule[12]. Nineteen cases of ICC were included as the control.

Medical records of the selected patients were reviewed for etiology of underlying liver disease and laboratory data for liver function and tumor markers. The patients were regularly followed up. Liver function tests, acrylic fixed prosthesis measurements were done every 2-3 mo. Dynamic CT was regularly performed with the interval no longer than 6 mo. All patients were followed until the time of death or for at least 12 mo. Recurrence was defined as the appearance of a new lesion with the radiologic features of HCC. Early recurrence was defined as any recurrence within 12 mo after the initial hepatectomy.

Histopathologic analysis was also performed for tumor size, differentiation, presence of multiple tumors, microvascular and major vessel invasion, lymph node metastasis and existence of background liver cirrhosis.

Statistical analysis

Statistical analysis was performed using SPSS software version 12.0 (SPSS, Chicago, IL). Clinicopathologic characteristics among different liver cancers were compared using χ^2 test. Overall survival (OS) was calculated using Kaplan-Meier method, and differences in survival rate were compared using Log-rank test. Univariate analysis for factors affecting prognosis of primary liver cancer after curative resection was evaluated using Log-rank test. All variables that appeared to be associated with the prognosis were put under multivariate analysis using Cox proportional hazards model. Statistical significance and marginal significance were assumed when $P < 0.05$ and $P < 0.01$, respectively.

RESULTS

Pathological evaluation

Diagnosis of HCC was made under HE stain in all 70 cases. Forty-nine HCC patients had CK19 immunostain

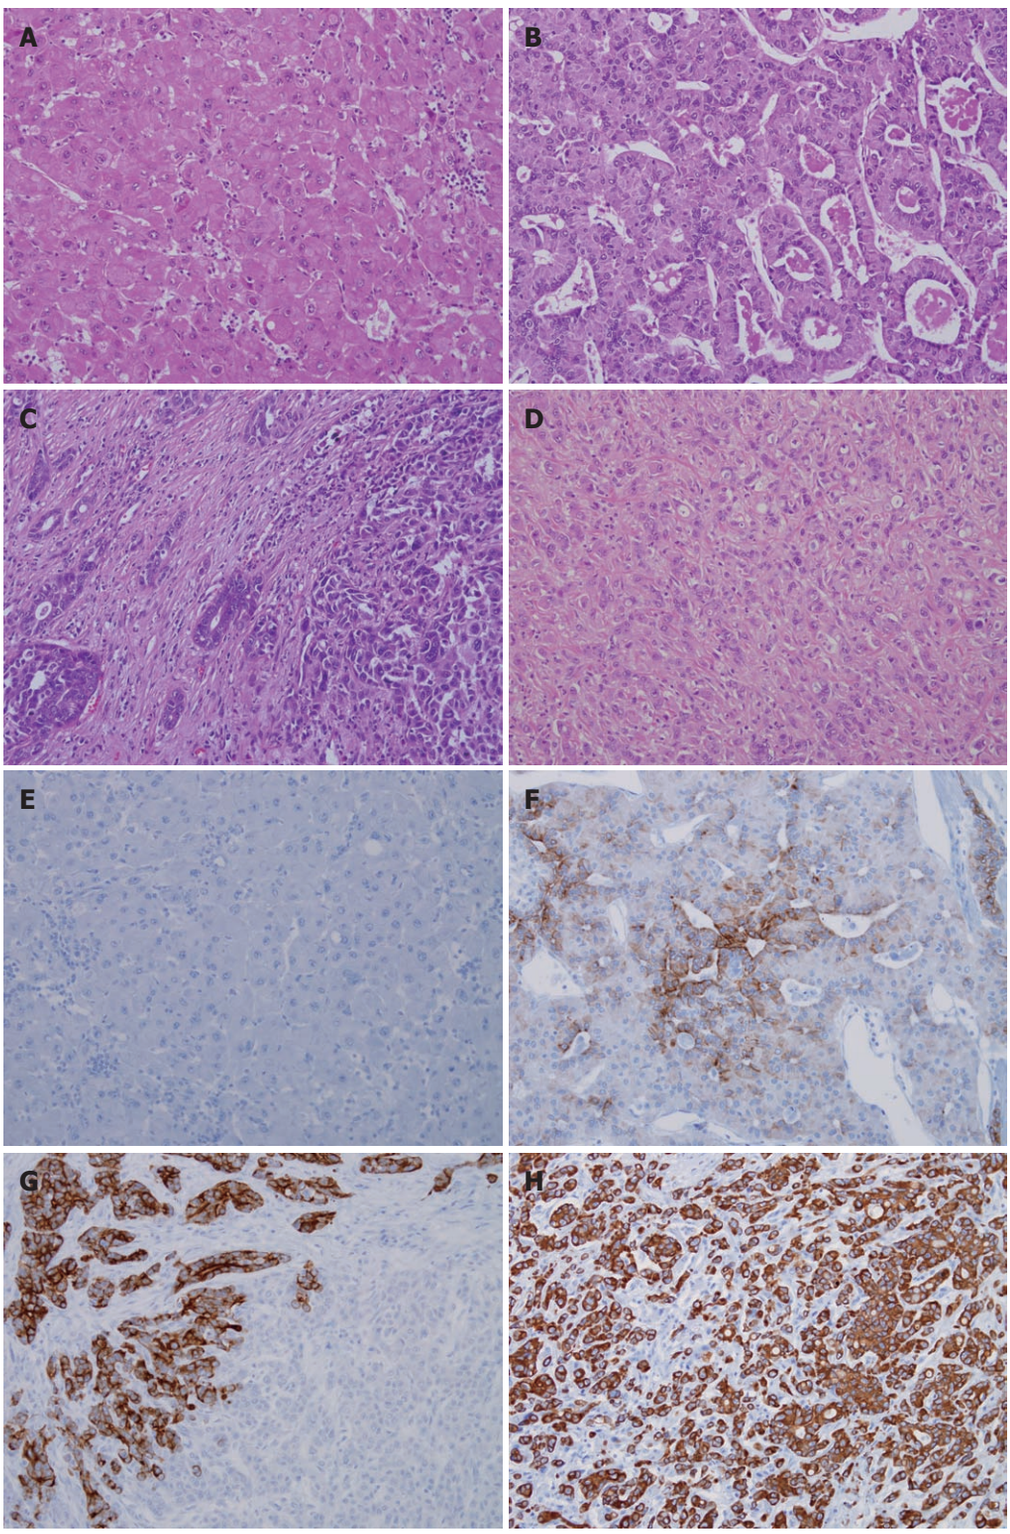

Figure 1 Pathological features of primary liver cancer. A-D: Hematoxylin and eosin (HE) stain for cytokeratin 19 negative hepatocellular carcinoma (CK19$^-$ HCC) (A), cytokeratin 19 positive hepatocellular carcinoma (CK19$^+$ HCC) (B), combined hepatocellular carcinoma and cholangiocarcinoma (cHCC-CC) and intrahepatic cholangiocarcinoma (ICC); E-H: Immunohistochemical stain results of CK19 stain for CK19$^-$ HCC (E), CK19$^+$ HCC (F), cHCC-CC (G) and ICC (H). All in original magnification × 200.

negative (CK19$^-$ HCC), and identified as HCC without biliary differentiation (Figure 1). Another 21 cases out of 70 HCC cases showed CK19 positivity (CK19$^+$ HCC) and classified as HCC with biliary differentiation (Figure 1).

Clinical features

All the patients underwent curative liver resection of primary liver cancer. There were no statistically significant differences in clinical findings of CK19$^-$ HCC (n = 49),

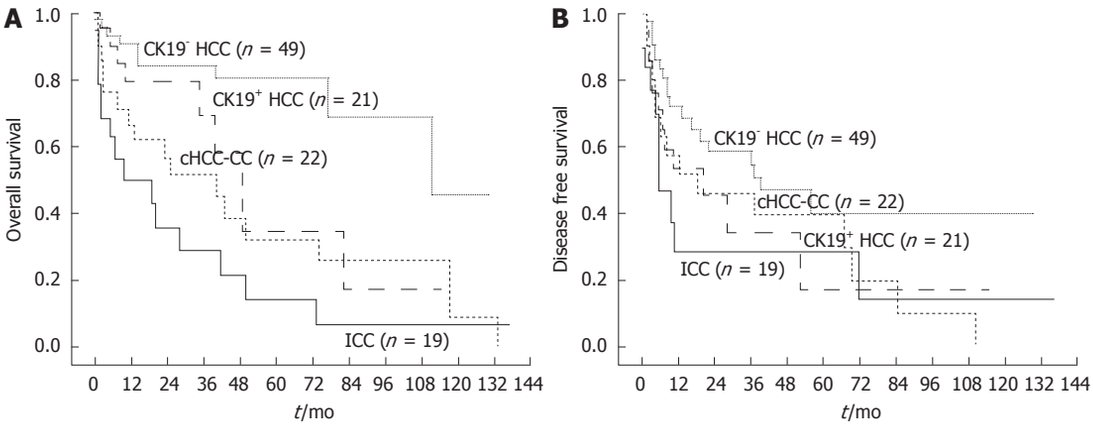

Figure 2 Clinical outcome after the curative liver resection of primary liver cancers. A: Overall survival (OS) rates of different groups of primary liver cancer after the curative resection. The OS rates of cytokeratin 19 positive hepatocellular carcinoma (CK19$^+$ HCC) and combined hepatocellular carcinoma and cholangiocarcinoma (cHCC-CC) were significantly lower than that of cytokeratin 19 negative hepatocellular carcinoma (CK19$^-$ HCC), but higher than the OS rate of intrahepatic cholangiocarcinoma (ICC) ($P < 0.05$). There was no statistically significant difference in OS rate between CK19$^+$ HCC and cHCC-CC ($P = 0.245$); B: Disease free survival (DFS) rate. The DFS rate of CK19$^-$ HCC was significantly higher than that of ICC ($P = 0.017$), but marginally higher than DFS rate of either CK19$^+$ HCC or cHCC-CC ($P = 0.097$, 0.089, respectively).

CK19$^+$ HCC (n = 21), cHCC-CC (n = 22) and ICC (n = 21) except in gender composition, etiologies of liver disease, and proportion of patients having liver cirrhosis (Table 1). In cases of CK19$^-$ and CK19$^+$ HCC, as well as cHCC-CC, male gender was the predominant population, whereas in ICC, there was no gender predisposition (Table 1). There was significantly lower number of patients with liver cirrhosis in the ICC group.

Comparison of clinical prognosis

The OS rate of CK19$^-$ HCC after the curative surgical treatment was 90.7% and 80.4% at 1 and 5 years after the resection, respectively. OS rate of CK19$^+$ HCC was 74.3%, 28.9%, and OS rate of cHCC-CC was 66.7%, 32.2% at 1 and 5 years after the surgery. In cases of ICC, 1 and 5-year-OS rate was 50.2% and 14.3% respectively after the curative resection. The OS rates of CK19$^+$ HCC and cHCC-CC were significantly lower than that of CK19$^-$ HCC, but higher than the OS rate of ICC (P = 0.000) (Figure 2A). There was no statistically significant difference in OS rate between CK19$^+$ HCC and cHCC-CC (Figure 2A).

The disease free survival (DFS) rate of CK19$^-$ HCC was 72.0% and 54.5% at 1 and 3 years after the surgical treatment. DFS rate of CK19$^+$ HCC was 53.3%, 34.3%, and DFS rate of cHCC-CC was 51.5%, 39.2% at 1 and 3 years after the resection. In cases of ICC, 1 and 3-year-DFS rate was 28.0% and 14.0% respectively after the curative resection. The DFS rate of CK19$^-$ HCC was significantly higher than that of ICC (P = 0.017), but marginally higher than DFS rate of either CK19$^+$ HCC or cHCC-CC (P = 0.097, P = 0.089, respectively) (Figure 2B). However there was no statistically significant difference in DFS rate among CK19$^+$ HCC, cHCC-CC and ICC (Figure 2B). The percentage of patients that received treatment for the recurred cancer was much smaller in cases of ICC whereas the majority of HCC regardless of CK19 expression, and cHCC-CC patients underwent TACE for the recurred mass (Table 1).

Prognostic factors for primary liver cancer after the curative resection

In cases of resectable primary liver cancer in functionally well preserved liver, surgical resection is usually recommended regardless of its pathologic diagnosis. Univariate analysis of prognostic factors after the curative resection in primary liver cancer was performed. The tested factors included pathologic diagnosis of the liver mass, age at the operation, gender, existence of liver cirrhosis, tumor size, tumor number, coexisting satellite nodule, existence of micro and macro vascular invasion, as well as lymph node and distant metastasis. Pathologic diagnosis of the resected mass, tumor size, accompanying satellite nodule, existence of microvascular, macrovascular and lymph node invasion were possible prognostic factors forecasting survival after the curative surgery (Table 2). On multivariate pathologic diagnosis of the resected mass, existence of microvascular invasion and accompanying satellite nodule affected the prognosis of primary liver cancer after the surgical resection (Table 2).

DISCUSSION

This study suggested that the outcome of the surgical treatment in the primary liver cancer would be worse as the resected tumor expressed more components with biliary phenotypes.

Although current WHO classification of primary liver cancer is still guided by the morphologic features of the tumor[13], new classification emphasizing morpho-phenotypic categories with patho-genetic implications is rapidly emerging[4]. Demand for the new type of primary liver cancer classification came from heterogeneous treatment outcome within the liver mass that had similar morphological features. Several studies supported that there would be subpopulation of HCCs, expressing bili-

ary phenotype as being CK19 positive, and that this subpopulation would demonstrate aggressive behavior[6,14-17]. Our study also showed that morphologically similar HCC might exhibit very different outcome after the curative treatment if their malignant cells contain components of biliary phenotype detected by CK19 immunochemical study.

Out of 70 patients who had CK19 immunochemical study, 21 patients had CK19 positive. These 70 patients underwent immunochemical study due to atypical pathologic features that made diagnosis ambiguous without immunochemical evaluation. Therefore, the proportion of CK19⁺ HCC was relatively higher than that of other studies[6,14]. Even though HCC patients in this study had resectable liver mass, they had higher Edmonson grade in more than 60% regardless of CK19 immunostain result. It is very likely that HCC with ambiguous morphology under HE stain might have poorer differentiation and thus might demonstrate less favorable surgical outcome. However, it appeared that CK19⁻ HCC had more favorable outcome compared with that of CK19⁺ HCC independent of Edmonson grade.

It is beyond the scope of this study addressing the origin of this biliary component in HCC. However, since CK19 is known as a stem cell marker, it can be contemplated that CK19 positive phenotype reflected an origin from a progenitor cell. Studies suggesting primary liver cancer of progenitor cell origin used CK19 as one of liver stem cell markers[18-22]. Moreover, one recent study reported that CK19 was well correlated with tumor aggressiveness, compared to other stemness-related markers[20,23]. In addition CK19 being a stem cell marker, a re-

CK19$^-$ HCC: Cytokeratin 19 negative hepatocellular carcinoma; CK19$^+$ HCC: Cytokeratin 19 positive hepatocellular carcinoma; cHCC-CC: Combined hepatocellular carcinoma and cholangiocarcinoma; ICC: Intrahepatic cholangiocarcinoma; 95% CI: 95% confidence interval.

port suggested that expression of CK19 was related with epidermal growth factor thereby increasing the growth abilities of HCC[24-26].

Most of the studies on CK19 in liver cancer performed immunohistochemical analysis in order to evaluate its expression[15-19]. Some studies that assessed *CK19* gene expression along with its protein expression demonstrated that protein expression well correlated gene expression[20,27].

Meanwhile, origin of cancer cells in cHCC-CC also needs to be verified. By definition, cHCC-CC has areas of typical HCC and areas of typical cholangiocarcinoma. It was reported that cholangiocarcinoma components in cHCC-CC were usually positive for CK19, and careful examination usually revealed intermediate morphology at the interface between HCC and cholangiocarcinoma areas[4].

Clinically, studies consistently reported that prognosis of cHCC-CC worse than that of HCC in general[7,8,21]. In this study, when CK19$^+$ HCC was compared with cHCC-CC, we found their clinical features somewhat similar, as both cell types demonstrated unfavorable prognosis than CK19$^-$ HCC. Regarding OS, both CK19$^+$ HCC and cHCC-CC showed lower OS rates than CK19$^-$ HCC, and higher rates than ICC. However, when we compared DFS rates, although CK19$^-$ HCC still showed higher DFS rate than any other types of primary liver cancer, there were no significant differences in DFS rates of CK19$^+$ HCC, cHCC-CC and ICC. This discrepancy in OS and DFS rates might be resulted from not having effective means of treating recurrent ICC when HCC and cHCC-CC could partly be controlled by the non-surgical method such as TACE.

Recently suggested histopathological classification of primary liver cancer put CK19$^+$ HCC as cancer of hepatocellular phenotype with stem/progenitor cell immunophenotype, whereas cHCC-CC as cancer of mixed hepatobiliary carcinoma, classical type. According to this proposed classification, these two subpopulations of liver cancer resided between the spectrum of HCC and ICC, where CK19$^+$ HCC closer to HCC and cHCC-CC being closer to cholangiocarcinoma[4]. In accordance with this classification, our study showed that clinical outcome of CK19$^+$ HCC and cHCC-CC after the curative liver resection was also placed between that of HCC and ICC where HCC side showing good prognosis and ICC side displaying poor prognosis. It seemed that primary liver cancer that possessed more components with biliary phenotype resulted in poor prognosis after the curative surgical treatment. However, since our study was limited by relatively small number of patients, especially in CK19$^+$ HCC and cHCC-CC group, another study over larger number of patients should be able to verify this suggestion.

COMMENTS

Background

Hepatocellular carcinoma (HCC) of similar clinical stage may produce heterogeneous treatment outcome, and immuno-phenotypical information of HCC might facilitate more appropriate stratification of the tumor.

Research frontiers

Efforts have been made to classify HCC histopathologically according to their distinct molecular features. Several studies suggested that there would be subpopulation of HCCs, expressing biliary phenotype as being cytokeratin (CK) 19 positive, and that this subpopulation would demonstrate aggressive behavior.

Innovations and breakthroughs

New classification emphasizing morpho-phenotypic categories with pathogenetic implications is rapidly emerging. This histopathological classification of primary liver cancer put cytokeratin 19 positive hepatocellular carcinoma (CK19$^+$ HCC) as cancer of hepatocellular phenotype with stem/progenitor cell immunophenotype, whereas combined hepatocellular and cholangiocarcinoma (cHCC-CC) as cancer of mixed hepatobiliary carcinoma, classical type. According to this proposed classification, these two subpopulations of liver cancer resided between the spectrum of HCC and intrahepatic cholangiocarcinoma, where CK19$^+$ HCC closer to HCC and cHCC-CC being closer to cholangiocarcinoma.

Applications

Primary liver cancer that possessed more components with biliary phenotype, detected by CK19 immunochemical study, might predict poor outcome after the curative surgical treatment. Therefore, alternative treatments or more vigorous adjuvant therapy after the surgical treatment could be recommended in such cases.

Terminology

Studies on primary liver cancer of progenitor cell origin used CK19 as one of liver stem cell markers along with other markers such as cluster of differentiation 133, c-kit and epithelial cell adhesion molecule. Among many stemness-related markers, a recent study reported that CK19 was well correlated with tumor aggressiveness.

Peer review

The authors examined three different types of primary liver cancers for its biliary phenotype and gave a vital conclusion that primary liver cancer that showed more of biliary components resulted in poor prognosis after the surgery. This work provides useful information on immuno-phenotype of primary liver cancers might be as important as their morphological classification with interesting results.

Abstract

AIM: To investigate the contribution of fucosyltransferase 2 (FUT2) variants to the genetic susceptibility and clinical heterogeneity of ulcerative colitis (UC) between Han and Uyghur patients in Xinjiang, China.

METHODS: A total of 102 UC patients (53 Han patients including 22 men and 31 women, and 49 Uyghur patients including 25 men and 24 women; aged 48 ± 16 years) and 310 age- and sex-matched healthy controls were enrolled from January 2010 to May 2011 in Xinjiang People's Hospital of China. UC was diagnosed based on the clinical, endoscopic and histological findings following Lennard-Jones criteria. Blood samples were collected and genomic DNA was extracted by the routine laboratory methods. Polymerase chain reaction-sequence-based typing method was used to identify FUT2 variants rs281377, rs1047781, rs601338 and rs602662. Genotypic and allelic frequencies were documented and compared between the UC patients and the healthy controls. Genotypic frequencies were also compared between Han and Uyghur patients. Potential association of genetic variation and UC between Han and Uyghur patients was examined.

RESULTS: rs281377 was found significantly associated with UC in the Han population as compared with the controls (P = 0.011) while rs281377 was not associated with UC in the Uyghur population (P = 0.06). TT homozygous rs281377 frequencies were higher in the UC groups than in the controls (88.7% *vs* 68.7% and 55.1% *vs* 50.3%). rs1047781 was specifically associated with UC in the Uyghur population (P = 0.001), but not associated with UC in the Han population (P = 0.13). TT homozygous rs1047781 frequencies were lower in the UC groups than in the controls (9.5% *vs* 11.8% and 4.0% *vs* 6.7%). rs601338 was statistically related to UC in both populations (Han, P = 0.025; Uyghur, P = 8.33 × 10^{-5}). AA homozygous rs601338 frequencies were lower in the UC groups than in the controls (0% *vs* 1.8% and 12.2% *vs* 13.4%). No association was found between rs602662 and UC in both Han and the Uyghur populations. Allelic analysis showed that rs281377 allele was significantly associated with UC in the Han population as compared with the controls [P = 0.001, odd ratio (OR) = 0.26], however, it was not associated with UC in the Uyghur population (P = 0.603, OR = 1.14), and rs1047781 allele was associated with UC in the Uyghur population (P = 0.001, OR = 0.029) while it was not associated with UC in the Han population (P = 0.074, OR = 0.62). Moreover, rs601338 was associated with UC in both Han (P = 0.005, OR = 0.1) and Uyghur populations (P = 0.002, OR = 0.43). Meta analysis showed that rs1047781 and rs601338 conferred risk of UC as compared with the controls [P = 0.005, OR = 0.47; P = 0.0003, OR = 0.35; 95% confidence interval (CI) = 0.31-0.72 and 0.21-0.58], but rs281377 and rs602662 showed no statistically significant differences between

patients with UC and controls (P = 0.10, OR = 0.71; P = 0.68, OR = 0.09; 95% CI = 0.47-1.07 and 0.56-1.47).

CONCLUSION: Functionally relevant *FUT2* gene variants are associated with UC, suggesting that they play a potential role in the pathogenesis of UC and may contribute to the clinical heterogeneity of UC between Han and Uyghur patients.

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease are often characterized as chronic inflammatory bowel diseases (IBD). Clinical features in both disorders include abdominal pain, diarrhea, weight loss and increased risk of developing colorectal cancer[1]. The etiology of UC is thought to be multifactorial, such as genetic, environmental, immune, and gut barrier factors[2]. Genetic factors involved in the regulation of the immune system are considered to play a significant role in the pathogenesis of IBD[3,4]. Much progress has been achieved in recent years regarding the genetic etiology of IBD. Studies have found that disease distribution and phenotypic appearance differ significantly between ethnic groups and even within populations. Apart from varying environmental factors that affect susceptible individuals, genetic heterogeneity between different populations itself plays an important role in IBD[5]. We previously compared the clinical characteristics of UC between the Han and Uyghur populations residing in the Xinjiang Uyghur Autonomous Region of China. We found differences between the Uyghur and Han populations living in the same region, where Uygur population had a higher prevalence of UC, a younger age of onset, an increased prevalence of the chronic persistence and acute outbreak type, more moderate and severe forms, a higher complication rate, and an increased frequency of positive anti-neutrophilic cytoplasmic antibodies[6,7]. However, the genetic heterogeneity related to UC between these two ethnic groups need to be investigated.

Secretor/non-secretor phenotypes [determined by the fucosyltransferase 2 (*FUT2*) gene] are associated with some metabolic and infectious diseases, and ABO glycosyltransferase activity has been shown to be involved in the pancreatic cancer risk[8]. Genetic variation in FUT2 has been implicated in susceptibility to *Helicobacter pylori*[9], Norovirus (Norwalk virus)[10,11], progression of human immunodeficiency virus[12], recurrent urinary tract infections[13], the development of vaginal candidiasis[14], gram-negative sepsis in infants[15] and cholera[16]. Carriers of non-secretor variants have higher plasma vitamin B12 levels than carriers of the secretor genotypes[17]. In addition to the genetic associations mentioned above, non-secretion of ABO blood group antigens into body fluids has been shown to be associated with rheumatic fever[18] and Crohn's disease, but not associated with UC[19].

Earlier studies have shown differences in the intestinal microbiota between the UC patients and healthy subjects[20] and alterations in the microbiota of IBD patients are related to changes in the FUT2 genotype[21]. The *FUT2* gene codes for an α (1,2)-fucosyltransferase and regulates the expression of ABH antigens in body secretions and the intestinal mucosa[22]. The *FUT2* gene is located on chromosome 19q13.3.4 (chromosome 19: 49, 199, 228-49, 209, 207) and consists of two exons. The cDNA is 3.1 kb long and encodes a polypeptide of 332 amino acid residues. The gene determines the secretion status of the ABO antigens with secretors having at least one functional FUT2 allele (Se), whereas non-secretors are homozygous for nonfunctional FUT2 allele[23]. rs601338 nonsense mutation (Trp143stop) in the *FUT2* gene of non-secretors has been reported in Caucasians (Europeans and Iranians) and Africans[24] and was found in approximately 1% of Chinese[25]. The frequency of non-secretors among east Asians is similar to Europeans and Africans, but east Asians are homozygous for a different weak-activity allele resulting from a rs1047781 missense mutation (Ile129phe)[26]. In Portuguese, two FUT2 polymorphisms, rs602662 and T839C, are associated with decreased or absent FUT2 enzyme activity[27]. rs281377 synonymous mutation (Asn-Asn) in the *FUT2* gene of secretors is found all over the world with a higher frequency than the wild type allele (Se)[28]. Four variants (rs281377, rs1047781, rs601338 and rs602662) in the *FUT2* genes have been identified in healthy Uyghur donors[29]. The rs1047781 was found in 54.7% of the Han populations with the most common alleles being rs281377, and rs281377 and rs1047781 were found in 94% of Chinese population[25]. rs281377 was reported in 71.2% and rs1047781 in 22.0% among the Uyghur populations[29]. In this study, we examined whether polymorphism of the *FUT2* gene differed between the Han and Uyghur patients with UC.

MATERIALS AND METHODS

Patients and controls

A total of 102 consecutive patients with UC (53 Han and 49 Uyghur, 47 men and 55 women, aged 18-78 years) and 310 age- and sex-matched healthy controls (161 Han and 149 Uyghur, 137 men and 173 women, aged 18-75 years) were enrolled from January 2010 to May 2011 in the De-

partment of Gastroenterology and the Physical Examination Center, Xinjiang People's Hospital of China. UC was diagnosed based on the clinical, endoscopic and histological findings following the Lennard-Jones criteria[30]. The extent of the disease was assessed by colonoscopy at the initial diagnosis and during follow-up. Extensive colitis was defined as lesions located beyond the splenic flexure. Distal colitis was defined as lesions limited to the region distal to the spleen flexure[31,32]. The study protocol was approved by the Ethics Committee of Xinjiang People's Hospital. Selected patients with UC and healthy controls are Chinese Han and Uyghur from Urumqi, Xinjiang, China. Informed consent was obtained from all the subjects.

Extraction of DNA

Genomic DNA was purified using a QIAamp DNA Blood Midikit (Qiagen, Germany). Purified genomic DNA from blood donors was stored frozen in micro-titre plates (10 ng/μL in TE buffer) until analyzed.

Polymerase chain reaction and sequencing primers

Primers for the polymerase chain reaction (PCR) amplification and sequencing were designed using conventional standard criteria. Primer specificity was checked with published nucleotide sequences using Basic Local Alignment Search Tool and analyzed for the risk of primer-dimer formation and secondary structures using Oligo 6.0 Software. The following pair of primers was used for the FUT2 (forward, 5'-AGCGCCCCGGGCCTCCATCTCC-3'; reverse, 5'-GGAACCATGTGTGCTTCTCATGCCCG-3'). The same forward and reverse primers were used for sequencing.

PCR and PCR product purification

Water of 17.3 μL, 0.5 μL 20 μmol/L forward primer, 0.5 μL 20 μmol/L reverse primer, 2.5 μL PCR buffer, 1 μL dNTPs, 2 μL $MgCl_2$ and 0.2 μL TaqGold (Applied Biosystems, Branchburg, New Jersey, United States) were added to 1 μL DNA (≥ 50 ng). Amplification conditions for the FUT2 PCR were: one cycle of 5 min at 95 ℃ followed by 10 cycles of 20 s at 95 ℃ and 40 s at 78 ℃ and 23 cycles of 10 s at 95 ℃, 10 s at 62 ℃ and 2 min at 72 ℃, and finally one cycle of 5 min at 72 ℃ and 4 ℃. The PCR was performed by a GeneAmp PCR system 9700 from the Applied Biosystems. PCR products were purified using the SAP-Exon method.

PCR product sequence

Twelve μL water, 1 μL 10 μmol/L forward primer, 2 μL BigDye sequencing buffer, 4 μL Bigdye (BigDye® Terminator v3.1Cycle Sequencing Kit) were added to 1 μL PCR product (≥ 50 ng). Cycle sequencing conditions for the FUT2 were: one cycle of 1 min at 96 ℃ followed by 25 cycles of 10 s at 96 ℃, 5 s at 50 ℃ and 4 min at 60 ℃ and 4 ℃. The PCR was performed by a GeneAmp PCR system 9700 from Applied Biosystems. DNA sequencing was performed using an automated sequencer (ABI 3730XL, Applied Biosystems). Chromas software version 2.0 was used to analyze the raw sequence data. The FUT2 genotyping method was established in accordance with the polymorphism (Figure 1). The frequencies of the genotypes were calculated by direct counting.

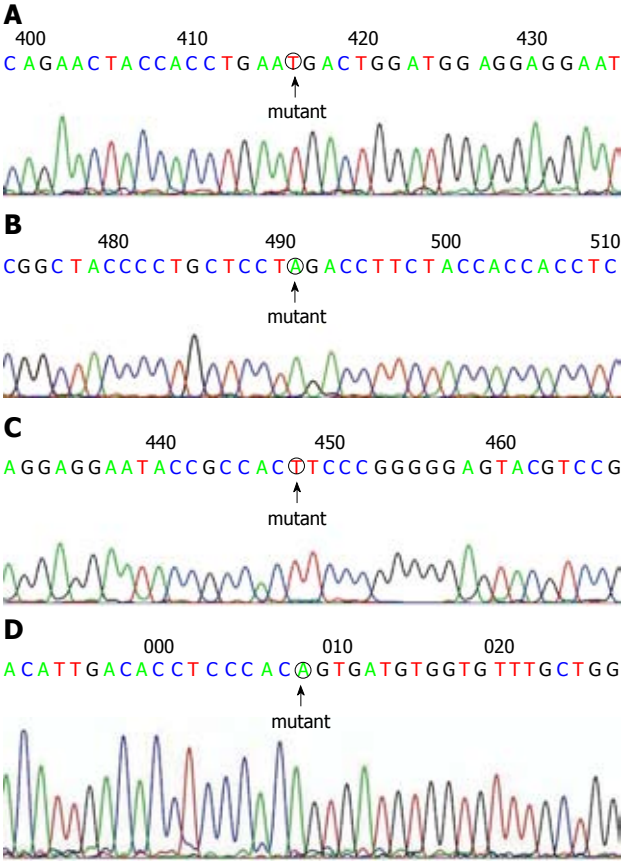

Figure 1 DNA sequence. A: Fucosyltransferase 2 (*FUT2*)-rs281377TT in a Han patient; B: FUT2- rs601338AA in a Uyghur patient; C: FUT2-rs1047781TT in a Han patient; D: FUT2-rs602662AA in a Uyghur patient.

Statistical analysis

Hardy-Weinberg disequilibrium was assessed with χ^2 test and clinical records including age were analyzed with *t* test. Allelic and genotypic association analyses were performed using the Pearson's 2 × 2 or 2 × 3 table χ^2 test. Odd ratio (OR) and 95% confidential interval (95% CI) were also calculated by Pearson's 2 × 2 χ^2 test. To adjust for the multiple tests performed and obtain an empirical null distribution of the association test *P* values (*P* empirical), we conducted 10 000 permutations in the case-control samples. Tests for the heterogeneity of effect size between Han and Uyghur populations were carried out using Cochrane's *Q* test, and $P < 0.05$ indicated that heterogeneity existed. When heterogeneity was found, random-effects model was applied using Cochran-Mantel-Hansel test to calculate the overall genetic effect of single nucleotide polymorphisms by combining the data from Han and Uyghur populations; otherwise, fixed-effects model was applied. The above analyses were performed using PLINK v.1.07 (http://pngu.mgh.harvard.edu/purcell/plink/).

Table 1 Clinical characteristics of the study subjects

Items	Han population	Uyghur population	Total
UC patients	53	49	102
Gender (male/female)	22/31	25/24	47/55
Age of onset (yr)	52 ± 15	46 ± 15	48 ± 16
Extensive colitis	20 (0.38)	30 (0.61)	50 (0.49)
Distal colitis	33 (0.62)	19 (0.39)	52 (0.51)
Mild and moderate	47 (0.89)	40 (0.82)	87 (0.85)
Severe	6 (0.11)	9 (0.18)	15 (0.15)
Healthy controls	161	149	310
Gender (male/female)	67/94	70/79	137/173
Age of onset (yr)	48 ± 15	49 ± 13	47 ± 14

Data are shown as mean ± SD or *n* (%). UC: Ulcerative colitis.

RESULTS

Clinical characteristics of UC patients

DNA was obtained from 102 consecutive UC patients and 310 healthy individuals who were well matched by sex and age. The main clinical characteristics of the UC patients are summarized in Table 1. UC patients included 47 women and 55 men with 53 Han and 49 Uyghur, and their average age at onset was 48 ± 16 years. Among the 310 healthy controls, there were 161 Han and 149 Uyghur including 137 men and 173 women, and their average age was 47 ± 14 years. There were no significant differences in sex ratio and the average age between the UC patients and healthy controls ($P = 0.74$ and $P = 0.801$).

Comparison of FUT2 genotype and allelic variants between UC patients and healthy controls

The genotype frequencies of the *FUT2* gene variants of the UC patients and the healthy controls are presented in Table 2. rs281377 was only associated with UC in Han population ($P = 0.011$), while rs1047781 was associated specifically with UC in Uyghur population ($P = 0.001$). rs601338 was statistically related to UC in both Han and Uyghur populations (Han, $P = 0.025$; Uyghur, $P = 8.33 \times 10^{-5}$). rs602662 was not associated with UC in both Han and Uyghur populations. TT homozygote of rs281377 was compared between the two ethnic UC groups and controls. Its frequencies were higher in the UC groups than in the controls (88.7% *vs* 68.7% and 55.1% *vs* 50.3%, respectively). TT homozygous rs1047781 frequencies (9.5% *vs* 11.8% and 4.0% *vs* 6.7%) and AA homozygous rs601338 frequencies (0% *vs* 1.8% and 12.2% *vs* 13.4%) were both lower than in the controls.

In allelic analysis as shown in Table 3 and Figure 2, rs281377 was found associated with UC only in the Han population ($P = 0.001$, OR = 0.26). rs1047781 was associated specifically with UC in Uyghur population ($P = 0.001$, OR = 0.29), whereas rs601338 was associated with UC in both Han and Uyghur populations (Han, $P = 0.005$, OR = 0.10; Uyghur, $P = 0.002$, OR = 0.43) and rs602662 was not associated with UC in both Han and Uyghur populations (Han, $P = 0.985$; Uyghur, $P = 0.652$, Figure 1).

The comparison between Han and Uyghur UC patients and controls revealed that genotype and allele rs281377 and rs601338 in the Han population were significantly associated with UC while in the Uyghur population, rs1047781 and rs601338 were significantly associated with UC.

Meta-analysis showed that rs1047781 and rs601338 conferred risk of UC as compared with the controls, ($P = 0.005$, OR = 0.47; $P = 0.0003$, OR = 0.35; 95% CI = 0.31-0.72 and 0.21-0.58) while rs281377 and rs602662 were not significantly different statistically between patients with UC and controls ($P = 0.100$, OR = 0.71; $P = 0.680$, OR = 0.90; 95% CI = 0.47-1.07 and 0.56-1.47).

DISCUSSION

UC is thought to fundamentally represent an altered interaction between the intestinal microbiota and the intestinal immune system[33]. The intestinal microbiota interacts with luminal enterocytes *via* host cell surface molecules, including oligosaccharides synthesized by glycosyltransferases[34]. Previous studies have shown that the allele polymorphism with a synonymous mutation rs281377, including the nonsense mutation rs601338, and missense mutation rs1047781 and rs602662, is almost inactive and is responsible for some instances of non-secretor statu[27]. Non-secretor phenotypes in the population occurring as the absence of particular carbohydrate molecules in the mucosa may have conferred protection against some pathogens. It is demonstrated that Fut2-null mice do not express fucosyl glycolipid FGA1 in the colon, whereas normal mice do[35]. Commensal bacteria and probiotics may exert their protective effects *via* preventing adherence, or even displacing pathogenic bacteria[36], which is consistent with the notion that FUT2 and non-secretor may affect the status of the gastrointestinal microbiota. Furthermore, changes in the microflora of IBD patients have been documented.

Our study indicated that the genetic polymorphisms of the *FUT2* gene were correlated with UC, and the associations differed between Han and Uyghur people in China. We analyzed four variants of *FUT2* gene, the frequency of three variants of the *FUT2* genotype (*rs281377*, *rs1047781* and *rs601338*) showed significant associations with UC ($P < 0.05$), however, the associations differed between the two ethnic groups. In the Han population, genotype and allele of rs281377 and rs601338 were significantly associated with UC whereas in the Uyghur population, genotype rs1047781 and rs601338 were associated with UC.

We also compared the TT homozygote of rs281377 between the two ethnic UC groups and controls. Its frequencies were higher in the UC groups than in the controls (88.7% *vs* 68.7 and 55.1% *vs* 50.3%, respectively). TT homozygous rs1047781 (9.5% *vs* 11.8 and 4.0% *vs* 6.7%) and AA homozygous rs601338 frequencies (0% *vs* 1.8% and 12.2% *vs* 13.4%) were both lower than in the controls.

A limitation of the present study was the relatively

Table 2 Genotypic association of four single nucleotide polymorphisms with ulcerative colitis in Han and Uyghur populations *n* (%)

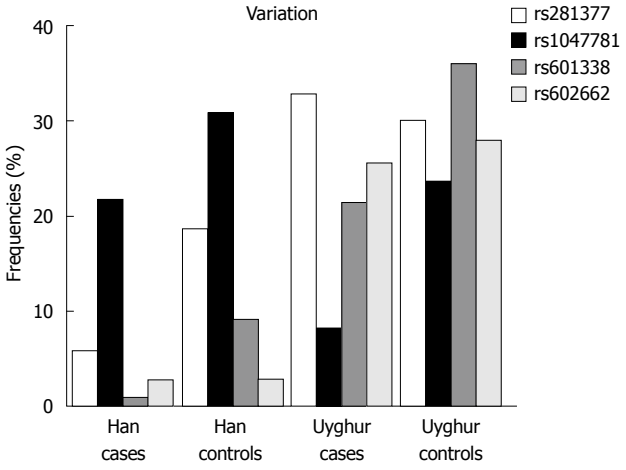

Figure 2 Allelic analysis of fucosyltransferase 2 variants and ulcerative colitis in Han and Uyghur populations.

small number of patients included. In the subgroup analysis, population stratification may lower the sufficient number of correlation analysis and weaken the significance of our results. In order to overcome these inadequacies and confirm our results, further research on a larger number of participants will be needed in the future.

In conclusion, our study found that the functional FUT2 variants might not only play a role in the pathogenesis of UC, but also contribute to the different clinical manifestations of UC between Han and Uyghur patients in north-west China. The effects of the different genotypes on the intestinal microbiota of normal controls and patients with UC are still unknown and likely represent a potentially productive area for future research in the quest to better understand the pathogenesis and treatment of UC.

ACKNOWLEDGMENTS

The authors thank Professor David Graham for his assistance with English revision, and Professor Fan Wang for his technical assistance.

COMMENTS

Background

Earlier studies have shown differences in the intestinal microbiota between the ulcerative colitis (UC) patients and healthy subjects, and alterations in the microbiota of inflammatory bowel diseases (IBD) patients are related to changes in the fucosyltransferase 2 (*FUT2*) genotype. In this study, the authors examined whether polymorphism of the *FUT2* gene differed between the Han and Uyghur patients with UC.

Research frontiers

FUT2 and non-secretor may affect the status of the gastrointestinal microbiota. Studies have found that disease distribution and phenotypic appearance differ significantly between ethnic groups and even within populations. The associations of the genetic heterogeneity of UC between two ethnic groups, Chinese Han and Uyghur, were investigated.

Innovations and breakthroughs

This study found that the functional FUT2 variants might not only play a role in the pathogenesis of UC, but also contribute to the different clinical manifestations of UC between Han and Uyghur patients in North-West China.

Applications

The effects of the different genotypes on the intestinal microbiota of normal controls and patients with UC are still unknown and likely represent a potentially productive area for future research in the quest to better understand the pathogenesis and treatment of UC.

Terminology

UC is a form of IBD. It is a refractory, chronic, and nonspecific disease which usually occurs in the rectum and the entire colon; FUT2 encodes the α (1,2) fucosyltransferase that determines blood group secretor status, and synthesizes the H-type 1 antigen in saliva and mucosa.

Peer review

The author investigated the contribution of FUT2 variants to the genetic susceptibility and clinical heterogeneity of UC between Han and Uyghur patients. This manuscript contains potentially interesting findings.

Abstract

AIM: To evaluate the efficacy and safety of emergency transcatheter arterial embolization (ETAE) for patients with acute massive duodenal ulcer hemorrhage.

METHODS: Twenty-nine consecutive patients with acute massive bleeding of duodenal ulcer were admitted to our hospital from 2006 to 2011. Superselective angiography of the celiac and gastroduodenal arteries was performed to find out the bleeding sites before ETAE, then, embolotherapy was done with gelatin sponge particles or microstrips *via* a 5 French angiographic catheter or 3 French microcatheter. After ETAE, further superior mesenteric arteriography was undertaken in case collateral circulation supplied areas of the duodenal ulcer. Technical and clinical success rates were analyzed. Changes in the mucous membrane were observed using endoscopy following ETAE.

RESULTS: Angiography showed active bleeding with extravasation of contrast medium in seven cases with a 24% positive rate of celiac artery bleeding, and in 19 cases with a 65.5% rate of gastroduodenal artery bleeding. There were no angiographic signs of bleeding in three patients who underwent endoscopy prior to ETAE. Twenty-six patients achieved immediate hemostasis and technical success rate reached 90%. No hemostasis was observed in 27 patients within 30 d after ETAE and clinical success rate was 93%. Recurrent hemorrhage occurred in two patients who drank a lot of wine who were treated by a second embolotherapy in the same way. Five patients underwent transient ischem with light abdominal pain under xiphoid, spontaneous restoration without special treatment. No mucous necrosis happened to 29 cases for ischem of gastroduodenal arteries embolized.

CONCLUSION: ETAE is an effective and safe measure to control acute massive bleeding of duodenal ulcer.

Emergency transcatheter arterial embolization for patients with acute massive duodenal ulcer hemorrhage. *World J Gastroenterol* 2012; 18(34): 4765-4770 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i34/4765.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i34.4765

INTRODUCTION

Acute massive hemorrhage of duodenal ulcer is a common emergency. Emergency endoscopic hemostasis for duodenal ulcer is regarded as the first-choice therapy and considered to be the gold standard treatment[1-3]. However, endoscopic therapy does not successfully control bleeding or rebleeding in 8%-25% of patients[4-6]. Surgical treatment is a second choice after failure of endoscopic hemostatic therapy, and improves efficacy in these patients, but there is no decrease in mortality rate[7]. Most patients, especially, treated by endoscopy but rebleeding occurred, are physically weak, the indications of life are not stable, thus it is difficult to receive a second endoscopic or surgical treatment. Transcatheter arterial embolization has been performed for at least two to three decades and has been shown to be effective at controlling hemorrhage and decreasing mortality[7,8-12]. With the development of interventional radiology, emergency transcatheter arterial embolization (ETAE) has also been used for treatment of massive bleeding of duodenal ulcer because it is minimally invasive, repeatable, effective and safe for patients with advanced age, weakness and unstable blood pressure[3,13,14].

MATERIALS AND METHODS

Materials

We collected and retrospectively analyzed data from 29 consecutive patients with acute massive bleeding of duodenal ulcer, and a transfusion requirement of at $\geqslant$ 4 units of packed red blood cells per 24 h[3,15-17], who were admitted to our hospital from January 2006 to August 2011. There were 18 male and 11 female patients, aged 16-67 years, with an average age of 36 years. All cases were diagnosed by endoscopy, and 10 patients received endoscopy, before receiving angiography and artery embolization, which clearly indicated the existence of duodenal ulcer. Electrocoagulation was carried for treatment, including three patients who suffered from rebleeding after surgery, and then ETAE was conducted. Nineteen patients presented with massive bleeding or hemodynamic instability (hypotension with systolic pressure < 100 mmHg or clinical shock secondary to blood loss) that did not respond to conservative treatment combined with volume replacement and proton pump inhibitors. They were sent directly from the emergency room for interventional radiological angiographic diagnosis and ETAE. Three to five days after treatment, endoscopic diagnosis clearly indicated the presence of duodenal ulcer once again. Six to eleven units of blood were transfused before treatment and 2-4 units were transfused after ETAE, which aimed to correct severe anemia, instead of correcting blood volume and restoring blood pressure.

Operating methods and procedures of ETAE

Under digital subtraction angiography, we used the improved Seldinger technique to puncture the right or left femoral artery, inserted a 6 F arterial catheter sheath (Japan Terumo), for elderly patients with significant tortuosity of the femoral artery, and used a 6 F anti-bending catheter sheath to open the tortuous blood vessels, to facilitate the superselective intubation of the catheter. We used a 5 F Rosch or Yasiro radiography catheter to conduct celiac artery angiography, and a 0.035-inch ultrasmooth black guide wire, to superselect the radiography catheter for gastroduodenal artery angiography. For patients with significant tortuous vessels, w used a coaxial catheter technique to superselect the 3F SP microcatheter (Japan Terumo), under the support of the radiography catheter, for angiography of the gastroduodenal artery or its branches. For branch arteries with clear bleeding or for the bleeding branch arteries that the microcatheter could reach, we used the microcatheter technique. Microcatheters were used for embolization of 17 patients, 14 of whom underwent embolization of bleeding the branch arteries, and three of whom underwent embolization of duodenal arteries; 5 F catheters were used for 12 patients. After the bleeding sites were identified, the catheter or microcatheter was placed in the proximal end of the bleeding artery, and then gelatin sponge particles or sponge strips were injected *via* the catheter or microcatheter. The specifications of the sponge particles were: 1 mm × 1 mm × 1 mm; the specification of the sponge strips were 5 mm × 1 mm × 1 mm. Under continuous fluoroscopy, we used contrast agent to inject the embolic agent, stop injecting the sponge particles or the sponge strips once the contrast agent in corresponding bleeding artery or bleeding gastroduodenal artery slow flow or the contrast agent is held up. Superior mesenteric artery angiography should be carried out after gastroduodenal artery embolization, to prevent the establishment of collateral arterial blood supply of the branches from the superior mesenteric artery: the pancreaticoduodenal anterior inferior arcuate artery and pancreaticoduodenal posterior inferior arcuate artery. If collateral blood supply is found by radiography, there is a possibility of rebleeding, and arterial embolization must be carried out using a microcatheter. Conservative treatment is recommended after embolization: to give drugs for inhibition of gastric acid secretion and gastric mucosal protective agents and hemostasis, and inject fluid to correct hypovolemia. For patients who did not have preoperative endoscopy, 3-5 d after bleeding stopped, when they had stable blood pressure and partial recovery from weakness, we carried out endoscopy and *Helicobacter pylori* (*H. pylori*)-related examination. Patients who were *H. pylori*-positive were treated with oral antibacterial medication. Before 2008, follow-up was by outpatient visit and letter, and after that time, follow-up was by outpatient visit and telephone interview for 3-6 mo.

Evaluation of efficacy and safety

The bleeding artery after ETAE is occluded by angiography, or contrast agent extravasation disappears, and the blood pressure is stable; no further bleeding occurs within 30 d after ETAE, and the occult blood test of fecal within the 3-6 mo follow-up period is negative. The

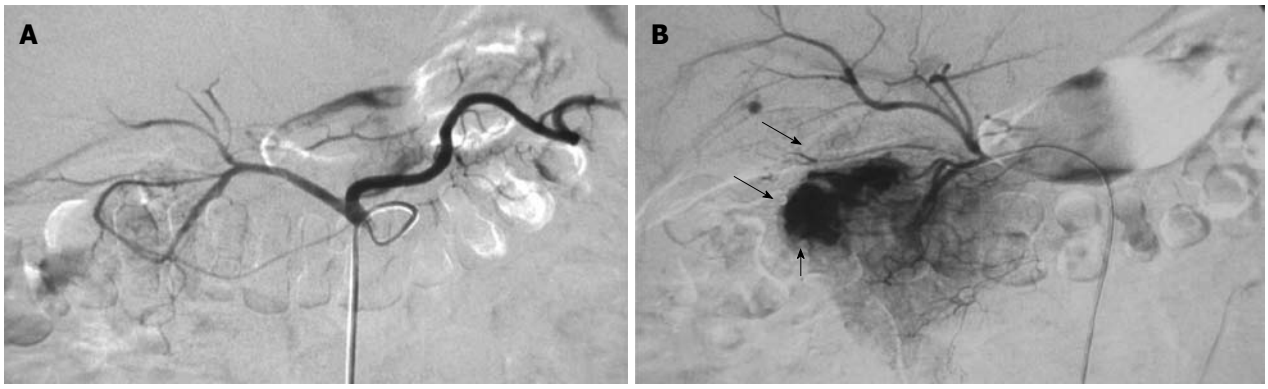

Figure 1 Impact of catheter position on the signs of bleeding. A: When the catheter tip was in the celiac artery, radiography failed to show signs of bleeding in the gastroduodenal artery; B: When the catheter super-select to the beginning site of the gastroduodenal artery for angiography, and the exo-contrast agent and smearing of the duodenal mucosa (arrows) are shown.

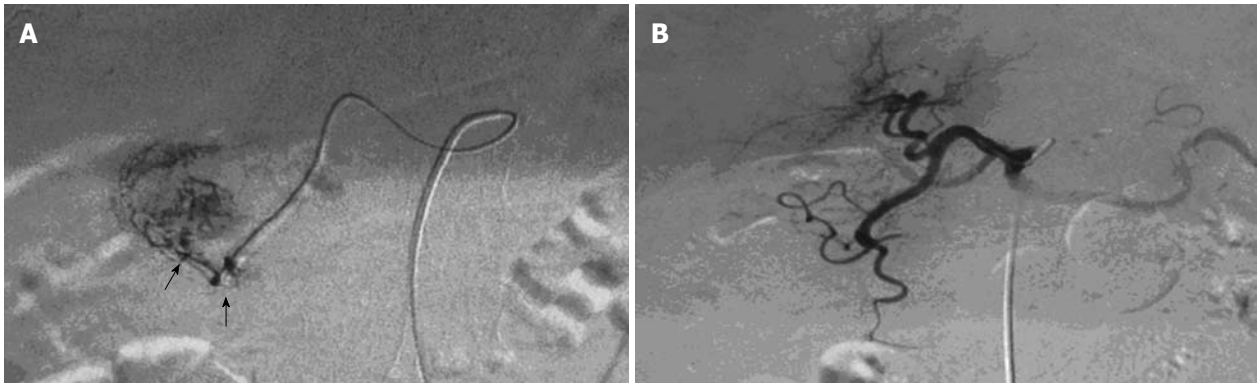

Figure 2 Angiographic changes before and after embolization of the gastroduodenal branch by microcatheter. A: Micro-catheter super-select to the gastroduodenal artery branch for angiography, and the exo-contrast agent is shown (indicated by the arrows); B: After embolization by micro-catheter, angiography showed that the bleeding had stopped; the distal end of the bleeding artery was kept open, to avoid widespread ischemia of normal tissue.

serious complications of ETAE are duodenal infarction or ischemic necrosis perforation, which are indicated by persistent upper abdominal (xiphoid) pain, peritoneal irritation, or muscle guarding sign.

Note for vascular grading: the 1st-grade-artery is abdominal aortic artery, the 2nd-grade-artery is celiac artery, the 3rd-grade-artery is gastroduodenal artery, and the 4th-grade-artery is branch arteries of gastroduodenal artery (the grading of blood vessels is defined by the authors, pending further discussion).

RESULTS

Among the 29 patients, there were three cases with multiple organ failure and seven elderly patients. Angiography with a celiac artery catheter (opening of the 2nd grade vessel) found bleeding in seven cases, with a positive rate of 24%; gastroduodenal arteriography (opening of the 3rd grade vessel) found signs of bleeding in 19 patients, with a positive rate of 66%; and there were three cases with no significant bleeding, with a negative proportion of 10%. Manifestations of hemorrhage were as follows: angiography of most celiac aorta hemorrhage was shown as the contrast agent gathering in small areas or with no imaging; angiography of gastroduodenal artery bleeding was shown as the contrast agent gathering into a lake-like area, with a large amount smearing the duodenal wall (Figures 1 and 2). There were 26 cases of immediate hemostasis after ETAE, with a technical success rate of 90%. The three cases that showed no significant escape of contrast agent on angiography were not included in the calculation of the technical success rate. Twenty-nine patients had stable blood pressure after ETAE. Four patients had a hemoglobin concentration of 4.5-5.0 g/L due to a large amount of bleeding before ETAE, and to correct anemia, 2-4 units of red blood cell suspension were infused. The amount of red blood cell suspension infused was significantly lower compared to 4-11 units before ETAE. The clinical success rate was 93% (27/29), and there were only two cases of rebleeding due to ulcers caused by heavy drinking. Angiography was carried out again and treated with the same procedure for embolization. After 3-6 mo follow-up, there was only one case of recurrence, and ETAE treatment was conducted once again. The first angiography of all the 3 cases of rebleeding showed positive bleeding.

Five patients had showed transient upper abdominal pain due to acute ischemia after ETAE, and the symptoms relieved spontaneously without treatment. There was no occurrence of persistent upper abdominal pain,

muscle guarding and other peritoneal irritation caused by severe gastroduodenal artery infarction, ischemia, or perforation.

Nineteen patients received endoscopy after ETAE. Seven of the 10 patients who had received endoscopy before ETAE received endoscopy again after treatment. Endoscopy showed that the normal duodenal mucosa in the embolization area showed pale change, and there was no case of necrosis. We distinguished complicated mucosal defects from previous duodenal ulcer by histological representations under endoscopic examination, which showed that complicated mucosal defects were not only around the areas near the duodenal ulcer but also far removed from them, distributed along the embolized artery.

Twenty-eight cases of duodenal ulcer were certainly related to *H. pylori* infection, and only in one case could the cause of duodenal ulcer not be identified. All patients who were *H. pylori*-positive took oral antibacterial medication during follow-up.

DISCUSSION

Efficacy of medical conservative therapy for upper gastrointestinal hemorrhage caused by duodenal ulcer is poor. Endoscopy and endoscopic hemostasis is the recognized method for first-line treatment[1-3,18,19]. The incidence of rebleeding after initial endoscopic treatment is about 14.1%, and in 15%-25% of cases, the bleeding cannot be controlled endoscopically or rebleeding requires alternative treatment[20,21], and surgery has become such an alternative[22,23]. However, for elderly patients with other associated diseases[24], and patients after surgery, rebleeding is a poor prognostic factor for massive hemorrhage of duodenal ulcer, with mortality of 44%-60%[3]. In recent years, interventional radiology has played an increasingly important role in the emergency treatment of the disease. Angiography cannot only quickly and clearly identify the bleeding site, but ETAE has become an effective alternative treatment for patients with recurrence after endoscopic and surgical treatment[12,25]. It has even been reported that ETAE can be the preferred treatment for emergency gastrointestinal hemorrhage[7,26,27].

The efficacy of interventional treatment is largely influenced by the treatment devices and methods. From the mid-1980s to mid-1990s, the diameter of the catheter used ranged between 5 and 6 F, and the texture of the catheter was coarse. Therefore, it was difficult to carry out super-selective catheterization, which meant that most patients with gastroduodenal bleeding due to arterial rupture used transcatheter perfusion of vasopressin to shrink arterial lesions, to stop the bleeding. However, local perfusion of drugs still achieved a good technical success rate. Miller *et al*[28] have reported that there were 267 patients who received perfusion therapy between 1979 and 1984; the success rate was 70%-80%, but the rebleeding rate was still nearly 20%, and for perfusion patients with difficulty in hemostasis, the rebleeding rate was up to 40%. The reason was that some elderly patients had hypertension, coronary atherosclerosis, or myocardial infarction and other underlying diseases, even partial use of vasopressin, its usage amount and continuous drug use time were still limited. In addition, the rich collateral circulation still provide much more blood supply for the bleeding duodenal intestinal. In recent years, with improvements of the technical skills of catheter, guide wire and other devices and the extensive use of coax system of micro-catheter (2.4-2.6 French size)[29], and arterial intubation by super-selection to the 3rd-grade or more above and the embolization have been skillfully used in most units, which has ensured the accuracy and effectiveness of ETAE, and has ensured blood supply of normal tissues. From our ETAE results of 29 patients, the success rate and clinical success rate were 90% and 93%, respectively. The results basically agreed with the technical success rate of 95% and clinical success rate of 52%-95% reported previously for ETAE treatment of upper gastrointestinal hemorrhage[29,30]. Earlier reports have shown that only two of seven cases of embolization had rebleeding, and four of six patients with conservative treatment had rebleeding. Toyoda *et al*[31] have reported control of bleeding after endoscopic treatment of 11 patients with duodenal ulcer. The bleeding was stopped in 10 patients treated with ETAE, with an efficacy of 91%. The remaining patient had atherosclerosis and embolization could only be applied to the proximal gastroduodenal artery, and as the embolization of the distal artery has established collateral circulation which led to rebleeding.

The patients with hemorrhage of gastroduodenal ulcer who had been clearly diagnosed by endoscopy and treated showed intermittent bleeding, while angiography could not clearly indicate the signs of bleeding, and there were three such patients in this group. Are such patients treated with ETAE? Although they were not included in calculating the technical success rate of ETAE, we believe that stopping bleeding or negative performance in angiography is only an illusion, which is related to low blood volume, vasoconstrictor drugs, or short-term thrombosis caused by hemostatic agents. If not handled, once the blood pressure is corrected, the contracted blood vessel expands again, or thrombolysis occurs, and rebleeding occurs. Under such circumstances, ETAE should still be applied[13], and the three patients treated by ETAE achieved clinical success.

For patients with multiple organ failure, although there were only two cases in this group of patients, randomized controlled studies could not be carried out. ETAE treatment effectively controlled massive bleeding caused by arterial rupture, and both of the two cases achieved technical and clinical success. There were another seven elderly patients, and only one had rebleeding after ETAE treatment, due to arteriosclerosis and tortuous vessels. Only the proximal gastroduodenal artery was embolized, and the branch of the superior mesenteric artery - pancreatic collateral arteries was open. Hemostasis was achieved after super-selective embolization of the collateral branch of the superior mesenteric artery. At the same time, the patient's situation reminded us that angiography

of the superior mesenteric artery can be used as a routine procedure before ETAE, by which rebleeding caused by collateral circulation of the duodenum can be avoided. In general, second endoscopic treatment, subsequent reoperation and unfavorable prognosis do not adversely affect the effective implementation of ETAE; on the contrary, ETAE can be repeatedly used for partial treatment of rebleeding due to its minimally invasive nature. It can be rapidly implemented because there is no need for preoperative preparation, and it can effectively control bleeding because it is a real-procedure and it accurately shows the bleeding site.

From the results of this group of patients, we can conclude that the treatment of duodenal massive bleeding using ETAE is safe, without severe ischemic complications such as duodenal infarction[32,33]. After ETAE treatment, some patients showed short-term duodenal ischemic symptoms, xiphoid pain or secret anguish, but these were relieved spontaneously without treatment. We initially selected, without experience, small particles as embolic agents, with a diameter of 300-500 μm. This resulted in mucosal defects far removed from the immediate area of the duodenal ulcer, which were distributed extensively along the embolized artery. For a few patients, endoscopy after ETAE showed that there were mild ischemic changes in the duodenal mucosa, manifested as the normal mucosa surrounding the ulcers was pale, but there were no ulceration and necrosis of normal mucosa after arterial embolization. Literature reported 28 patients with gastroduodenal distal artery embolized, and 7 cases had duodenal stenosis caused by ischemia, and for the 29 cases with arterial proximal embolized, only two cases showed the aforementioned pathological changes. The reason is related to mixed use of various embolic agents, including liquid embolic agents, at the same as ETAE treatment. There were 32 cases reported in another group, ETAE caused two cases of duodenal necrosis and one of new ulcer formation[34]. This was related to the use of gelatin sponge powder. Both liquid embolic agents and gelatin sponge powder can cause damage to the submucosal microvascular network, which can lead to loss of the compensatory blood supply of the mucosa.

We used large gelatin particles or strips of gelatin sponge for embolization of the proximal gastroduodenal artery. even the embolization of small bleeding artery is also under the premise that the bleeding targeting is a very clear, to implement the micro-catheter superselective ETAE, that is on the two levels of the diameter of embolic agent and embolization range, to ensure the submucosal microvascular network is not damaged, thus the complications reported in the literature did not occur. In terms of safety, we do not agree with the approach proposed by Lee *et al*[35] in choosing the type of embolic agents. They have used the liquid embolic agent N-butyl-2-cyanoacrylate to embolize 16 patients, and two patients showed a large area of thrombosis and multiple gastric ulcers. Therefore, choosing embolic agents of the right size and superselective catheterization and controlling the embolization range can guarantee ETAE safety.

In conclusion, ETAE is an effective, safe and fast emergency procedure for the treatment of massive bleeding of duodenal ulcer, which is especially suitable for frail elderly patients or those with multiorgan dysfunction with bleeding duodenal ulcer.

COMMENTS

Background

Acute massive hemorrhage of duodenal ulcer is a life-threatening condition. Emergency endoscopic hemostasis for duodenal ulcer is regarded as first-line therapy and considered to be the gold standard treatment. Surgery is usually considered for secondary intervention after failure of endoscopic hemostasis, or rebleeding. Transcatheter endovascular embolization is an alternative method of surgical treatment for stopping bleeding.

Research frontiers

Emergency transcatheter arterial embolization (ETAE) is an alternative to hemostasis after failure of endoscopic treatment. In the area of hemostasis for massive bleeding of duodenal ulcer, the research hotspot is to evaluate the efficacy and success rate of ETAE, and whether it becomes a first-line therapy.

Innovations and breakthroughs

Transcatheter arterial embolization has become a mature and effective method of hemostasis for arterial bleeding, but it is still controversial whether it can become the first choice for massive gastrointestinal hemorrhage. It has been successful in treating peptic ulcer bleeding. The innovations of this study were that the authors adopted the supra-selected arterial angiography to increase the positive rate of diagnosis and identify sites of ulcer bleeding. They also used it as the first-line treatment for some particular patients, such as older patients, the extra-weakness and the unstable-pressure with acute massive ulcer hemorrhage.

Applications

The results suggest that ETAE *via* supraselection angiography is an effective and safe therapy and could be an alternative, even first-choice therapy, for endoscopic hemostasis in some patients with acute massive hemorrhage of duodenal ulcer.

Terminology

Transcatheter arterial embolization: In peptic ulcer, trauma and other injury to the arterial system results in arterial rupture and massive hemorrhage, a catheter is inserted into the target artery, and contrast agent is injected to locate the ruptured vessel. Other agents can then be injected *via* the catheter to block the artery.

Peer review

This was a case series of 29 patients who received ETAE for acute massive hemorrhage of duodenal ulcer. The success rate of hemostasis was 90%. Recurrent hemorrhage occurred in two patients. Severe complications were not found. In conclusion, transcatheter arterial embolization is an effective and safe procedure to control acute massive bleeding of duodenal ulcer. It has some minor problems.

Abstract

AIM: To evaluate the diagnosis of different differentiated gastric intraepithelial neoplasia (IN) by magnification endoscopy combined with narrow-band imaging (ME-NBI) and confocal laser endomicroscopy (CLE).

METHODS: Eligible patients with suspected gastric IN lesions previously diagnosed by endoscopy in secondary hospitals and scheduled for further diagnosis and treatment were recruited for this study. Excluded from the study were patients who had liver cirrhosis, impaired renal function, acute gastrointestinal (GI) bleeding, coagulopathy, esophageal varices, jaundice, and GI post-surgery. Also excluded were those who were pregnant, breastfeeding, were younger than 18 years old, or were unable to provide informed consent. All patients had all mucus and bile cleared from their stomachs. They then received upper GI endoscopy. When a mucosal lesion is found during observation with white-light imaging, the lesion is visualized using maximal magnification, employing gradual movement of the tip of the endoscope to bring the image into focus. Saved images are analyzed. Confocal images were evaluated by two endoscopists (Huang J and Li MY), who were familiar with CLE, blinded to the related information about the lesions, and asked to classify each lesion as either a low grade dysplasia (LGD) or high grade dysplasia (HGD) according to given criteria. The results were compared with the final histopathologic diagnosis. ME-NBI images were evaluated by two endoscopists (Lu ZS and Ling-Hu EQ) who were familiar with NBI, blinded to the related information about the lesions and CLE images, and were asked to classify each lesion as a LGD or HGD according to the "microvascular pattern and surface pattern" classification system. The results were compared with the final histopathologic diagnosis.

RESULTS: The study included 32 pathology-proven low grade gastric IN and 26 pathology-proven high grade gastric IN that were detected with any of the modalities. CLE and ME-NBI enabled clear visualization of the vascular microsurface patterns and microvascular structures of the gastric mucosa. The accuracy of the CLE and the ME-NBI diagnosis was 88% (95% CI: 78%-98%) and 81% (95% CI: 69%-93%), respectively. The kappa coefficient of agreement between the histopathology and the *in vivo* CLE imaging was 0.755; between the histopathology and the *in vivo* CLE imaging was 0.615. McNemar's test (binomial distribution used) indicated that the agreement was significant ($P < 0.05$). When patients were diagnosed by ME-NBI with CLE, the overall accuracy of the diagnosis was 86.21% (95% CI: 73%-96%), and the kappa coefficient of agreement was 0.713, according to McNemar's test ($P < 0.05$).

CONCLUSION: Higher diagnostic accuracy, sensitivity

and specificity of CLE over ME-NBI indicate the feasibility of these two techniques for the efficacious diagnostic classification of gastric IN.

INTRODUCTION

Gastric cancer is one of the most common malignant diseases of the gastrointestinal (GI) tract. Substantial interest has arisen in recent years in the diagnosis and management of early gastric cancer because of the high cure rate achieved with treatment of these lesions. Diagnosis and localization of early gastric cancer is problematic because of the lack of any endoscopic characteristics, even with multiple random biopsies.

In recent years, endoscopic image quality has improved as the devices have advanced technologically, including chromoendoscopy, high resolution and magnification endoscopy[1]. Additionally, magnification endoscopy combined with narrow-band imaging (ME-NBI) has been used to achieve endoscopic pathology in gastric disease.

Although these techniques improve the visualization and detection of mucosal lesions, a biopsy of the targeted lesion must still be performed for a formal histological diagnosis of cellular and architectural atypia. However, there are several disadvantages that may be associated with biopsies or endoscopic resection, including bleeding and perforation. Non-representative biopsies may miss relevant portions of tissue, leading to an underestimation of the diagnosis. Random biopsy sampling or endoscopic resection for non-neoplastic lesions can also be time-consuming. It would be ideal if a definite diagnosis could be made during endoscopy without the need for a biopsy.

Recent technological advances in miniaturization have allowed for a confocal scanning microscope to be integrated into a conventional flexible endoscope, or into trans-endoscopic probes, a technique now known as confocal endomicroscopy (CEM) or confocal laser endomicroscopy (CLE)[2-4]. This newly-developed technology has enabled endoscopists to collect real-time *in vivo* histological images, or "virtual biopsies", of the GI mucosa during endoscopy, and has stimulated significant interest in the application of this technique in clinical gastroenterology.

MATERIALS AND METHODS

Patients

Patients with suspected gastric intraepithelial neoplasia (IN) lesions previously diagnosed by endoscopy in secondary hospitals and scheduled for further diagnosis and treatment were recruited for this study from September 2008 to July 2009 at the General Hospital of the People's Liberation Army, Beijing, China.

Excluded from the study were patients who had liver cirrhosis, impaired renal function, acute GI bleeding, coagulopathy, esophageal varices, jaundice, and GI post-surgery. Also excluded were those who were pregnant, breastfeeding, were younger than 18 years old, were unable to provide informed consent, or had a known allergy to fluorescein sodium. The General Hospital of the People's Liberation Army's clinical research ethics committee approved the protocol, and written informed consent was obtained from all participants.

NBI and magnified endoscopy system

The magnifying video endoscope used in this study was a GIF-H260Z (Olympus Medical Systems Co, Tokyo, Japan).

The videoendoscope is mounted on the charge coupled device (CCD) positioned on the tip of the endoscope as the imaging sensing device, with a xenon lamp used as the light source. The system is based on a black and white CCD, in which color separation is achieved through the use of a red-green-blue (RGB) rotary filter wheel equipped within the light source unit. The RGB filter consists of three broadband optical filters and covers all wavelengths of the visible spectrum, ranging from approximately 400 to 800 nm.

The NBI system uses two narrow band illuminations of 415 nm and 540 nm by NBI filter. Under NBI observation, the broadband white light derived from the xenon lamp splits into two bands (wavelength of 415 nm and 540 nm) and illuminates the surface of the mucosa. In the RGB sequential system, the NBI filter is placed on the light path in front of the RGB rotary filters. When observing with the NBI filter, the light illumination passes only B and G filters to obtain 415 nm and 540 nm images. Then, 415 nm is allocated to B and G channels so that blood vessels on the mucosal surface are reproduced in a brownish color, and 540 nm is allocated to the R channel so that the vessels in the deeper layer can be indicated in a greenish-blue color.

CLE system

All procedures were performed using a confocal laser endomicroscope (EC-3870K; OptiScan, Notting Hill, Australia and Pentax Corp., Tokyo, Japan)[5].

The confocal microscope integrated into the conventional endoscope collects images at a scan rate of 1.6 frames per second (1024 × 512 pixels) or 0.8 frames per second (1024 × 1024 pixels) with an adjustable scanning depth ranging from 0 to 250 μm, a field of view of 475 μm × 475 μm, a lateral resolution of 0.7 μm, and an axial resolution of 7 μm.

NBI and magnified endoscopic procedure

It is important to clear all mucus and bile from the stomach before upper GI endoscopy. Patients were given the following mixture 30 min before the endoscopic procedure: 100 mL of water with 10 000 units of pronase (Kaken Pharmaceutical, Tokyo, Japan), 1 g of sodium bicarbonate, and 10 mL of dimethylpolysiloxane (20 mg/mL, Horii Pharmaceutical Ind., Osaka, Japan).

A soft black hood (MB-162 for GIF-Q240Z, or MB-46 for GIFH260Z and GIF-Q160Z; Olympus, Tokyo) is essential for optimal magnification endoscopy. Prior to the NBI examination, the hood is mounted on the tip of the endoscope to enable the endoscopist to consistently fix the mucosa at a distance of approximately 2 mm so that maximal magnification of the endoscopic image can be obtained.

Before detailed inspection, adherent mucus is removed by water flushing. After the endoscope was inserted, the entire stomach was initially observed with conventional white light to exclude obvious lesions. At least 35 photographs were taken from the entire stomach, even if there were no obvious lesions.

Once a mucosal lesion is found during observation with white-light imaging, it is then visualized using maximal magnification, employing gradual movement of the tip of the endoscope to bring the image into focus, with the distally attached soft black hood being used to stabilize the tip of the endoscope onto the tissue. Instead of pressing the tip of the hood, gentle suction should be applied, without causing mucosal injury, and the lesion is then observed by magnification endoscopy with NBI. The images were saved to a specific folder for later analysis.

CLE procedure

After observation *via* ME-NBI, fluorescent contrasts should be used for CEM[6] (such as intravenously delivered fluorescein or topically administered acriflavine) and deployed through a spraying catheter.

Intravenously delivered fluorescein distributes throughout the extracellular matrix of the surface epithelium and lamina propria, but does not stain cell nuclei. Topically administered acriflavine stains cell nuclei of the surface epithelium, but does not penetrate to deeper layers of the GI mucosa. Acriflavine is a mutagenic dye and a potential human carcinogen, which limits its clinical utility.

Fluorescein is usually administered within 5 min of imaging; however, the dose and timing of contrast administration have not been standardized. After the contrast administration, the tip of the confocal endomicroscope or miniprobe is positioned in gentle contact with the area of interest to obtain high-resolution confocal images. Accumulated images can be saved for post-procedural analysis.

Histologic assessment

The resected specimens were fixed in 4% methanal, embedded in paraffin, sectioned into 4 mm thick samples, and stained with hematoxylin-eosin for routine histopathologic examination. Slides were coded and examined blindly by two pathologists (Wang YL and Wei LX), who were blinded to the endomicroscopic result, with diagnoses being confirmed by both individuals. The histological diagnostic criteria were based on the WHO classification. Early gastric cancer is defined as a malignant tumor limited to the mucosa or submucosa irrespective of the presence of lymph node metastases[7,8]. This includes the two types of low-grade neoplasia/dysplasia (LGD) and high-grade neoplasia/dysplasia (HGD), which are categorized according to the modified Vienna classification[9]. Early gastric cancer is further classified into two major groups: differentiated early gastric cancer which has tubular or papillary structures resembling the metaplastic intestinal epithelium; and undifferentiated early gastric cancer, which includes poorly differentiated carcinoma, and is characterized by discretely proliferating tumor cells with sparse or no tubular formation[10]. In the images of magnification endoscopy with NBI, an irregular microvascular pattern (MVP) and/or an irregular microsurface pattern (MSP), together with a clear demarcation line, are the hallmarks of early gastric cancer.

Evaluation of confocal images

All the confocal laser endoscopy images were stored in a specific folder, with the quality of each image being scored as good (no moving artifacts, gastric pit structure and vessel can be identified clearly), average (artifacts present but gastric pit and vascular architecture can be recognized), and poor (artifacts do not allow judgment of the image). The images were evaluated by two endoscopists (Huang J and Li MY) who were familiar with CLE, blinded to the related information about the lesions, and asked to classify each lesion as either a LGD or HGD according to the aforementioned criteria. The results were compared with the final histopathologic diagnosis.

Evaluation of ME-NBI images

All the NBI magnified images were stored in a specific folder. The images were evaluated by two endoscopists (Lu ZS and Ling-Hu EQ) who were familiar with NBI, blinded to the related information about the lesions and CLE images, and asked to classify each lesion as either a LGD or HGD according to the "microvascular pattern (V) and surface pattern (S)" classification system[11]. The results were compared with the final histopathologic diagnosis.

Statistical analysis

The statistical analysis was performed using the statistical software package SPSS 13.0 (SPSS, Chicago, IL, United States). The accuracy, sensitivity and specificity of the

CLE and ME-NBI diagnosis were respectively calculated in comparison with the histopathologic diagnosis.

RESULTS

Study population

A total of 59 patients participated in this study. The mean (± SD) age of the participants was 63.1 years, and the study population consisted of 44 male and 15 female patients.

In CLE, the 36 patients with low grade gastric intraepithelial neoplasia (LIN) included 9 women (25%) and 27 men (85%), with an average age of 60 years (range: 35-85 years). The 23 patients with high grade gastric intraepithelial neoplasia (HIN) showed significant male predominance as well, with 17 men (74%) and 6 women (23%). The average age was 68 years (range: 45-84 years).

A total of 1912 CLE images obtained from 62 lesions were used for analysis. The mean duration of the CLE procedure for each patient was 19 min (range: 11-30 min). After CLE, all patients developed a slight yellow coloration of the skin and urine, which disappeared in all cases within 24 h. No severe side-effects were noted.

In ME-NBI, the 45 patients with LIN included 12 women (27%) and 33 men (73%), with an average age of 63 years (range: 40-84 years). The 14 patients with HIN showed significant male predominance as well, with 11 men (79%) and 3 women (21%). The average age was 65 years (range: 36-85 years). The endoscopic and pathologic features of all the lesions are summarized below.

A total of 688 ME-NBI images obtained from 62 lesions were used for analysis. The mean duration of the ME-NBI procedure for each patient was 17 min (range: 10-25 min).

CLE characteristics

Gastric fundus: Superficial lamella gastric pits are round. Few pits compose one unit. The edge crack is the line type. Net-like subepithelial capillary network patterns surround the gastric pits (Figure 1A).

Gastric body: The gastric pits are round. Honeycomb-like subepithelial capillary network patterns surround the gastric pits (Figure 1B).

Gastric antrum: The gastric pits are line type. Coil-shaped subepithelial capillary network patterns surround the gastric pits (Figure 1C).

Gastric IN

LIN showed that, for the different sizes of gastric pits, all capillary networks are thickening and circuitous (Figure 2A); HIN showed an abnormal arrangement of gastric pits. The thickening capillary network and the increasing branch present a mass shape (Figure 2B).

ME-NBI characteristics

Gastric fundus: S: The individual morphology of the crypt epithelium shows a uniformly round/oval structure. Few structures are composed of one unit separated from the others. The width and length of the crypt epithelium are constant. The arrangement and distribution are regular and symmetrical; V: The mucosal capillaries have a uniform shape that can be closed-loop (polygonal). They have a consistent size and their arrangement and distribution are regular and symmetrical. Superficial lamella gastric pits are round (Figure 3A).

Gastric body: S: The individual morphology of the crypt epithelium shows a uniformly round structure. The width and length of the crypt epithelium are constant. The arrangement and distribution are regular and symmetrical; V: The mucosal capillaries have a uniform shape that can be closed-loop (polygonal). They have a consistent size and their arrangement and distribution are regular and symmetrical (Figure 3B).

Gastric antrum: S: The individual morphology of the crypt epithelium shows a uniformly round/linear structure. The width and length of the crypt epithelium are constant. The arrangement and distribution are regular and symmetrical; V: The mucosal capillaries have a uniform shape that can be open-loop. They have a consistent size and their arrangement and distribution are regular and symmetrical (Figure 3C).

LIN presented irregular surface and MVPs with a clear demarcation line (Figure 4A). HIN presented irregular surface and MVPs with a demarcation line. Few areas showed as flat (mean absent MSP) with an obscured demarcation line (Figure 4B).

Irregular surface pattern: The individual morphology of the crypt epithelium shows an irregular tubular/linear/curved/papillary/villous structure. The width and length of the crypt epithelium varies. Arrangement and distribution are irregular and asymmetric.

Irregular MVP: The vessels differ in shape, being closed-loop (polygonal), open-loop, tortuous, branched, bizarrely-shaped, and with or without a network. The size of the vessels also varies and their arrangement and distribution are irregular and asymmetrical.

Comparative data in CLE imaging and histopathology

Among 58 patients with gastric IN, 22 lesions with HIN and 29 lesions with LIN were diagnosed by CLE. The results are summarized in Table 1. The sensitivity and specificity of CLE for predicting low grade gastric IN were 90.63% and 84.62%, respectively. The overall accuracy of the CLE diagnosis was 88% (95% CI: 78%-98%), and the kappa coefficient of agreement between the histopathology and the *in vivo* CLE imaging was 0.755. McNemar's test (binomial distribution used) indicated good agreement between the final histopathology and the CLE imaging ($P < 0.05$).

Comparative data in ME-NBI imaging and histopathology

Among 58 patients of gastric IN, 20 lesions with HIN and 27 lesions with LIN were diagnosed by ME-NBI.

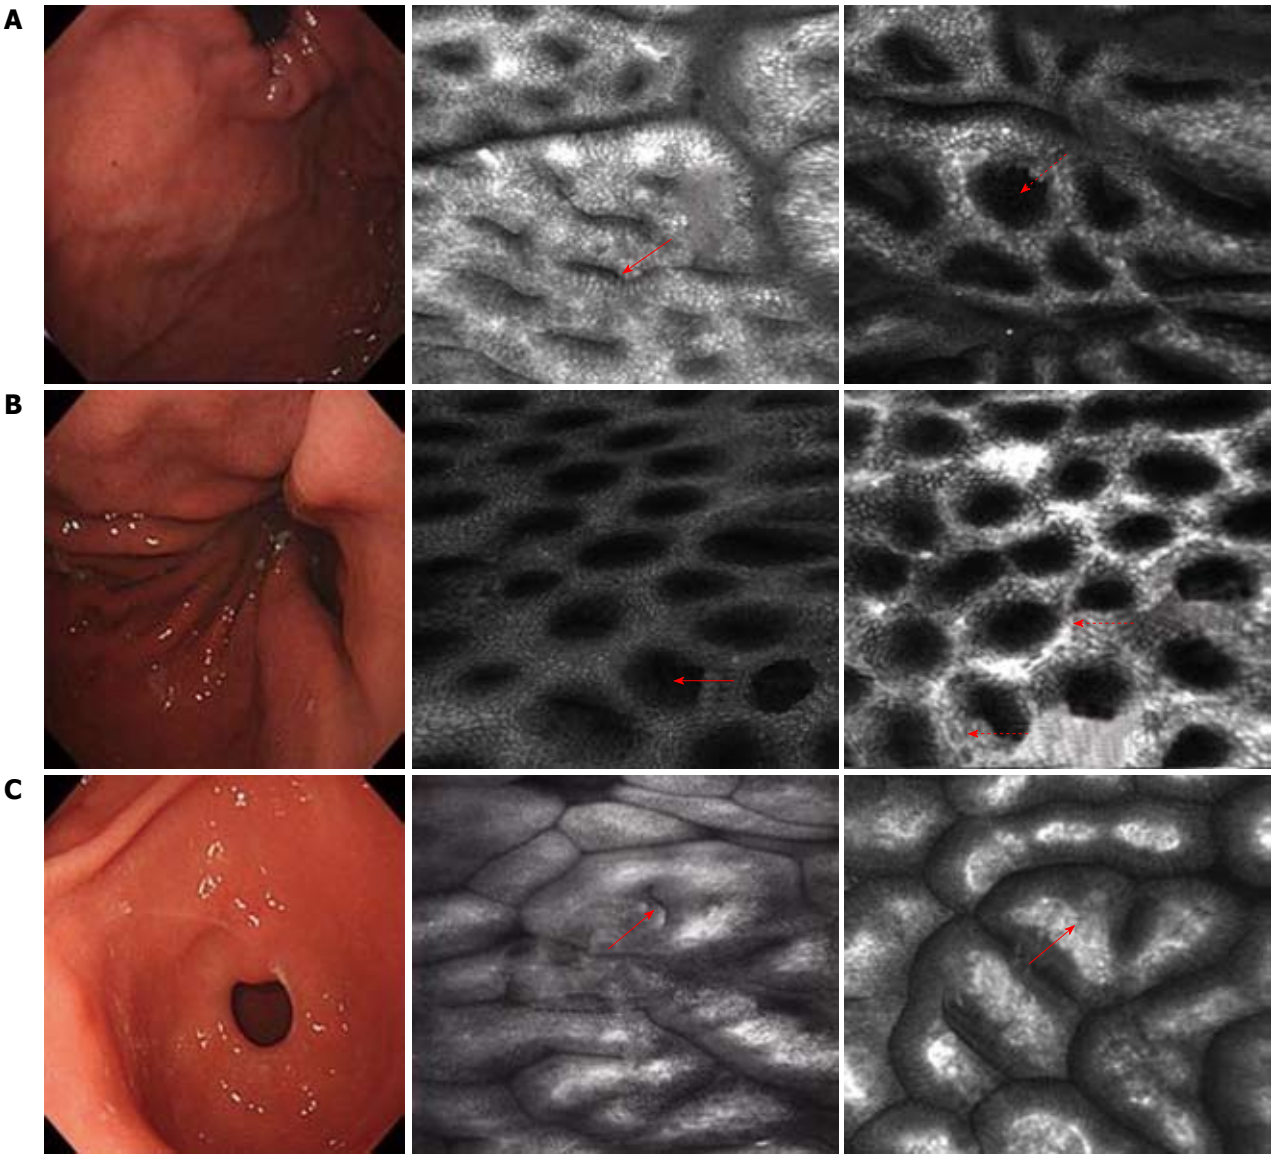

Figure 1 Routine endoscopy and confocal laser endomicroscopy images. A: Gastric fundus: Superficial lamella gastric pits are round (solid arrow). Few pits compose one unit. The edge crack is the line type. Net-like subepithelial capillary network patterns surround the gastric pits (dash arrow); B: Gastric body: The gastric pits are round (solid arrow). Honeycomb-like subepithelial capillary network patterns surround the gastric pits (dash arrows); C: Gastric antrum: The gastric pits are the line type (solid arrow). Coil-shaped subepithelial capillary network patterns surround the gastric pits (dash arrow).

The results are summarized in Table 1. The sensitivity and specificity of ME-NBI for predicting low grade gastric IN were 84.38% and 76.92% respectively. The overall accuracy of the ME-NBI diagnosis was 81% (95% CI: 69%-93%), and the kappa coefficient of agreement between the histopathology and the *in vivo* CLE imaging was 0.615. McNemar's test (using binomial distribution) indicated good agreement between the final histopathology and the CLE imaging ($P < 0.05$).

Comparative data in CLE + ME-NBI imaging and histopathology

Among 58 patients of gastric IN, 18 lesions with HIN and 32 lesions with LIN were diagnosed by ME-NBI with CLE. The results are summarized in Table 1. The sensitivity and specificity for predicting low grade gastric IN were 100% and 69.23% respectively. The overall accuracy of the ME-NBI diagnosis was 86.21% (95%CI: 73%-96%), and the kappa coefficient of agreement between the histopathology and the *in vivo* CLE imaging was 0.713. McNemar's test (using binomial distribution) indicated good agreement between final histopathology and CLE imaging ($P < 0.05$).

DISCUSSION

Endoscopy plays an important role in the early detection of GI tract neoplasms., It has been difficult to assess pre-malignant and early neoplastic lesions precisely using conventional white light or dye-based image enhanced endoscopy. NBI is an innovative optical technology that can increase the contrast of the precise morphological changes in the mucosal surface and clearly visualize microvascular structures. It dramatically improves the detec-

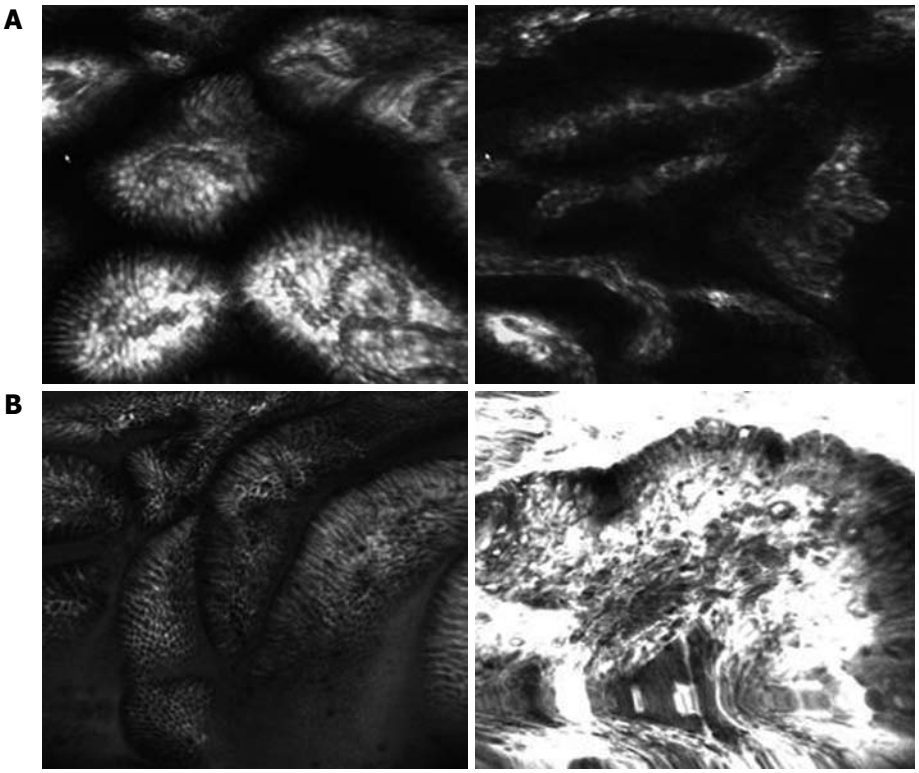

Figure 2 Confocal laser endomicroscopy images of low and high grade gastric intraepithelial neoplasia. A: Low grade gastric intraepithelial neoplasias show that in the different sizes of gastric pits, any capillary network are thickening and circuitous; B: High grade gastric intraepithelial neoplasias show the abnormal arrangement of gastric pits. The thickening capillary network and the increasing branch present a mass shape.

tion of pre-malignant and early neoplastic lesions, particularly in combination with magnification endoscopy. These features allow the better targeting of biopsies, and improved and more appropriate treatment, thereby contributing to optimal quality of life and patient survival. ME-NBI has allowed brand new possibilities for the endoscopic diagnosis of GI tract diseases.

Mucosal morphology includes microvascular architecture, and changes in the course of malignant transformation. There have been many studies on the vasculature in cancerous mucosa using magnification endoscopes or NBI. Sano *et al*[12] first reported the clinical utility of NBI in the GI tract in 2001. Nakayoshi *et al*[1] classified the MVP of superficial gastric cancers based on their magnifying NBI images into three groups: (1) fine network pattern; (2) corkscrew pattern; and (3) unclassified pattern. They also compared the endoscopic pattern with the histological findings. Fine network and corkscrew patterns are useful for identifying differentiated adenocarcinoma and undifferentiated adenocarcinoma, respectively. At the same time, they imply that magnifying NBI is also useful for identifying the lateral extension of superficial gastric cancer. In their reports, they studied the microvascular networks of 165 patients with depressed-type early gastric cancer lesions using a magnification endoscope with NBI and demonstrated that 66.1% of differentiated adenocarcinoma possessed fine networks, while 85.7% of undifferentiated adenocarcinoma had a corkscrew network[13]. In 2004, the clinical value of ME-NBI in the diagnosis and treatment of gastric neoplasia was been reported by Sumiyama's group. They came to the conclusion that it is important for the accurate assessment of the safety margin to ensure complete resection by endoscopic submucosal dissection or *en bloc* endoscopic mucosal resection for neoplastic lesions. In 2005, Yao *et al*[14,15] reported MVP is important for diagnosing early gastric carcinoma, as it provides 98.7% accuracy[16,17]. Then they implied the morphology of the white opaque substance (WOS) could be an alternative new optical sign for dis-

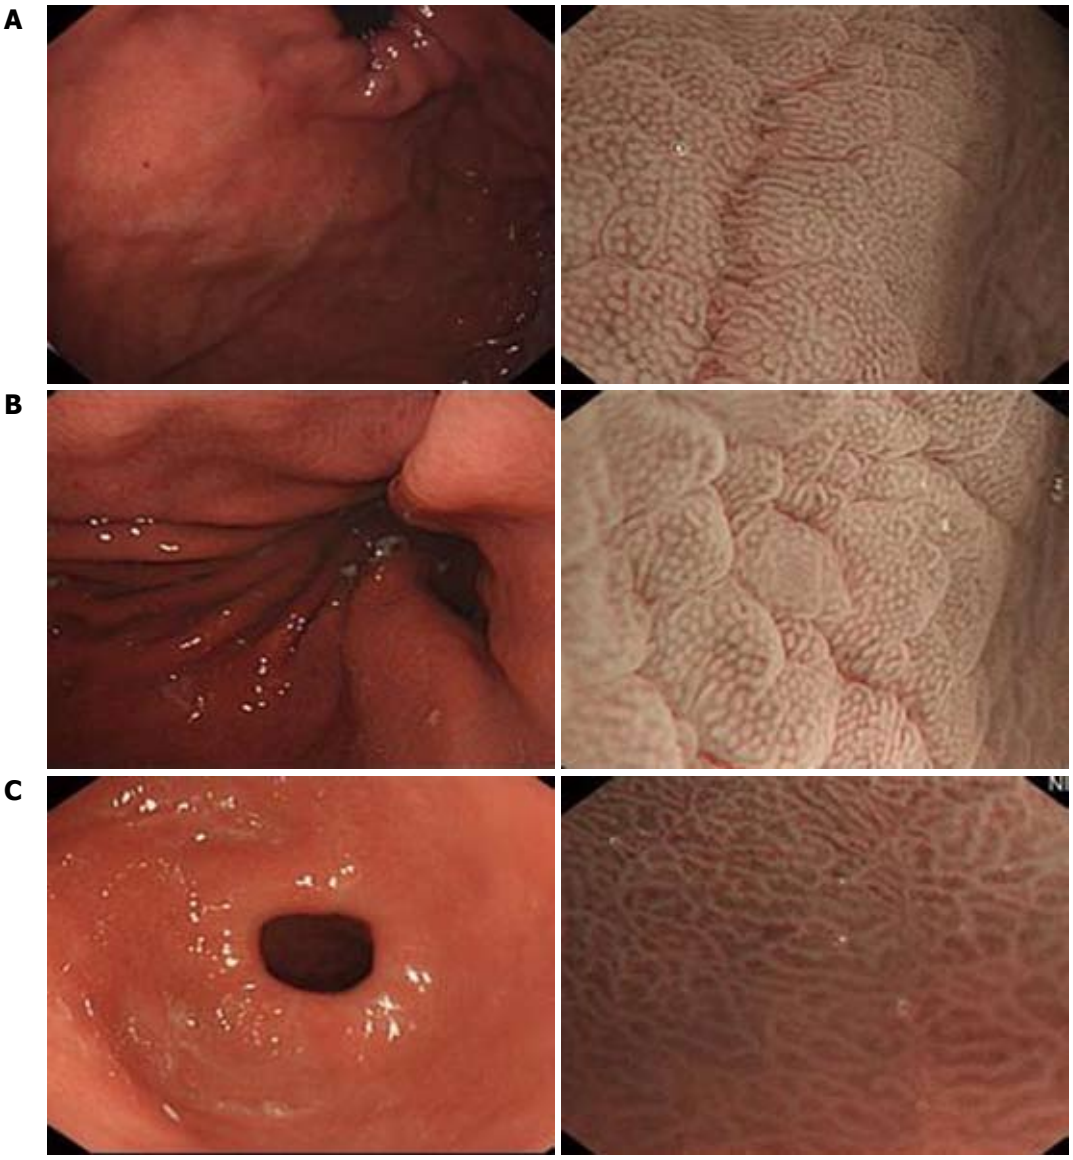

Figure 3 Routine endoscopy and intraepithelial neoplasia by narrow-band imaging images. A: Gastric fundus; B: Gastric body; C: Gastric antrum.

criminating adenoma from carcinoma.

In our studies, we found the WOS was one of the phenotypes in NBI magnification images, but not the main discrimination. However, the MSP and microvascular structures differ between LIN and HIN. LIN showed an irregular MSP and MVP with a clear demarcation line. The individual morphology of the crypt epithelium showed the different shapes (tubular, linear, curved or papillary). The vessels differ in shape (closed-loop, open-loop, tortuous or branched). Both the MSP and MVP have the irregular arrangement and variation in width and length. In contrast with LIN, HIN showed as flat because of a few areas without a network. The accuracy, sensitivity and specificity of ME-NBI for predicting low grade gastric IN were 81.03%, 84.38% and 76.92%, respectively.

Gastric mucosa IN is acknowledged as precancerous, with early diagnosis and prevention being important. To date, the final diagnosis still depends on histopathology. CLE has been developed which is an integration of a confocal laser microscope in the distal tip of a conventional videoendoscope. The components enable confocal microscopy in addition to standard videoendoscopy, and the new device can provide real-time, high magnification, cross-sectional images of the GI epithelium during routine endoscopy without the need for biopsy. Thusly, histopathology has been termed optical biopsy. This endoscopic tool allows for the observation of images magnified up to 1000-fold, which enables the visualization of mucosal microvascular architecture in units as small as the capillaries in the mucosal layer. Compared with other new optic techniques, the greatest advantage of CLE is that it can enables surface and subsurface imaging of living cells in the mucosa during ongoing endoscopy.

The first publication about an integrated confocal fluorescence microscope into the distal tip of a conventional colonoscope (Pentax EC 3830FK, Tokyo, Japan) was made by Kiesslich *et al*[18] in 2004, showing that *in vivo*

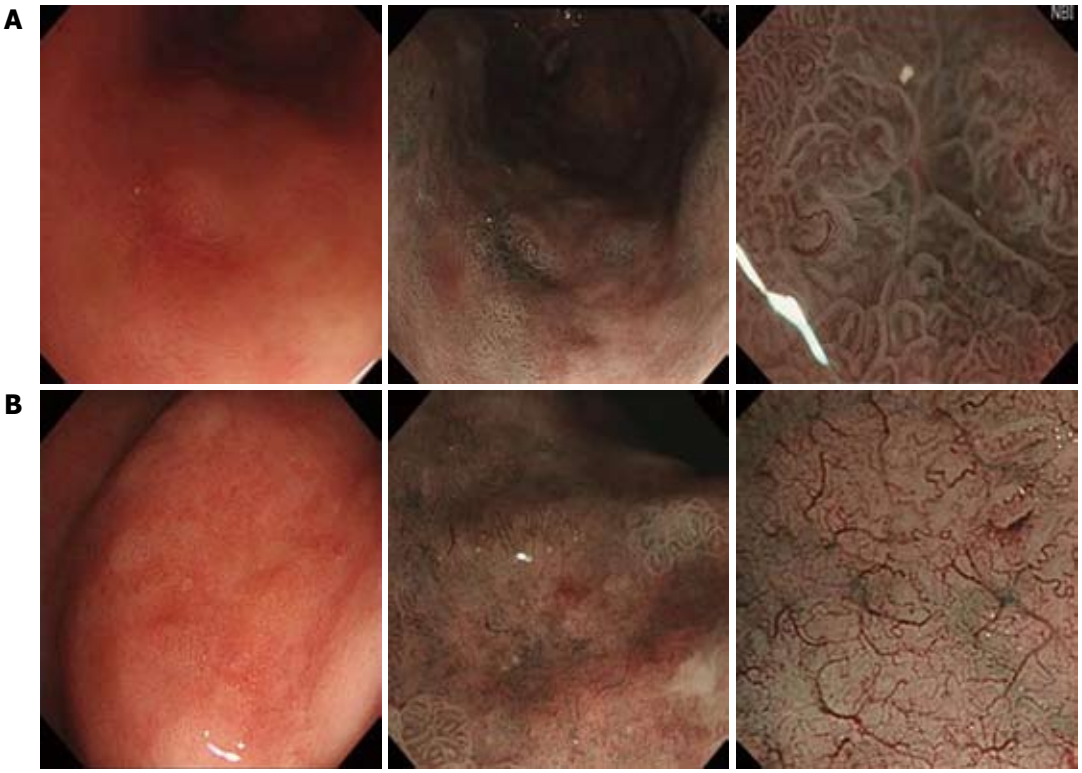

Figure 4 Routine endoscopy and narrow-band imaging images of low and high grade gastric intraepithelial neoplasia. A: Low grade intraepithelial neoplasias present an irregular surface and microvascular pattern with a clear demarcation line; B: High grade gastric intraepithelial neoplasias present the irregular surface pattern and microvascular pattern with a demarcation line. Few areas show as flat (absent microsurface pattern) with an obscured demarcation line.

microscopy at a subcellular resolution (0.7 μm) simultaneously displayed to white light endoscopy was possible and achieved high accuracy. This permitted immediate diagnosis of colorectal INs using fluorescein or acriflavine as contrast agents. Nuclear changes can best be observed using acriflavine as a topical contrast agent, as shown by Kakeji *et al*[19].

The endoscopic detection of early gastric cancer is challenging. Endomicroscopy allows immediate microscopic analysis of the gastric mucosa during ongoing endoscopy. Fluorescein-guided endomicroscopy is particularly good at demonstrating blood vessel architecture, which can be used to differentiate between non-neoplastic and neoplastic lesions. Kitabatake *et al*[20] showed the differences of mucosal vasculature according to the grade of tumor differentiation using CLE. The accuracy for the diagnosis of gastric cancer was above 90%. Liu *et al*[9] reported that comparison of regular and altered gastric mucosa facilitates the interpretation of the confocal images. Changes in tissue and microscopic blood vessel architecture, as well as changes in cell morphology, are valuable endomicroscopic criteria in defining neoplasias. Zhang *et al*[21] investigated the pattern and *in vivo* architecture of gastritis and gastric cancer on 132 consecutive patients. They classified gastric pit-pattern cellular architecture into seven types: normal mucosa with fundic glands mainly showed type A (round pits); corporal mucosa with histologic gastritis showed type B (non-continuous short rod-like); normal mucosa with pyloric glands mainly showed type C (continuous short rod-like); antral mucosa with histologic gastritis showed type D (elongated and tortuous branch-like); type E showed in intestinal metaplasia mucosa (the Goblet cells could be easily identified); and the corresponding values of the type G pattern (corkscrew-like and irregular in quality) for predicting gastric cancer were 90.0% and 99.4%.

Our study showed that the pit pattern and capillary network in the gastric mucosal layer was made visible using the confocal endomicroscope. In normal gastric antrum mucosa, the gastric pits are line type and the capillary network patterns showed a coil-shaped subepithelial capillary network pattern which surrounded the gastric pits. In the gastric body mucosa, the gastric pits are round and the capillary network patterns are characterized by a honeycomb-like network which was situated along or between the mucosal ridges. However, in the gastric fundus mucosa, the findings were incompatible with previous studies on gastric pit pattern and vascular network[21]; the superficial lamella gastric pits are round. Few pits compose one unit. The edge crack is the line type. Net-like subepithelial capillary network patterns surround the gastric pits.

When we studied gastric IN, we classified the mucosa into two types and observed the differences between them. LIN showed the different sizes and abnormal arrangement of gastric pits. The capillary network was thickening and circuitous. However, in the confocal images of HIN, the gastric pits presented strange shape. Some of them were unrecognized. A black tumor substance substituted the gastric patterns in some areas. The

thickening capillary network and the increasing branch present a mass shape. The accuracy, sensitivity and specificity of the CLE for predicting the low grade gastric IN were 87.93%, 90.63% and 84.62%, respectively. These findings do not conflict with the previous studies of Kitabatake *et al*[20].

The confocal images of normal gastric mucosa are similar to the NBI magnification images, but the MSP and MVP are more clearly visible by CLE than magnification endoscopy. The recent study of the diagnosis of the differentiation of gastric IN by the technique of CLE combined with ME-NBI has been lacking. Our study showed the accuracy, sensitivity and specificity of CLE combined with ME-NBI for predicting the low grade gastric IN were 86.21%, 100% and 69.23%, respectively. From the results, we know that the diagnostic accuracy and specificity for the differentiation of gastric IN by CLE are 87.93% and 84.62%, which is higher than the alternatives. CLE is the best technique for the diagnosis of the differentiation of gastric IN. However, the diagnostic sensitivity by CLE combined with ME-NBI is 100. This shows the consistency of the technique of CLE and NBI-ME for the diagnostic differentiation of gastric IN.

There are some limitations to CLE, in particular, the limited infiltration depth of the blue laser light. The depth of scanning is approximately 250 μm. Therefore the vessels in the submucosa were not visible by endomicroscopy. In addition, the collecting vein in gastric body mucosa was visible by magnifying NBI, but can not be discerned in confocal images. This is because CLE covers only a very small area while a collecting vein can be seen in about every 60 gastric pits. In conclusion, the CEM system provides precise and clear images of the microvascular architecture of gastric mucosa. There are distinct characteristics distinguishing normal and malignant superficial microvascular networks in the mucosal layer. Our findings suggest that changes in the MCV may indicate early endoscopically detectable signs of cancer, which might facilitate on-site diagnoses and enable better management.

When we analyzed the confocal images, we excluded some poor images. The main reason for this was the moving artifacts caused by GI motility, breath and heartbeats. In addition, excessive mucus often influenced laser scanning depth, which produced images without a clear microsurface or microvascular architecture. In clinical practice, both good and average images could be used for clinical analysis. The findings indicate that the images of normal mucosa were better than those of the cancerous mucosa. The reason for this is that the cancerous mucosa is not always flat. The confocal images of cancer were easily distinguishable from normal mucosa in our study.

We know the importance in using a contrast agent when performing CLE[19,22]. Fluorescein is inexpensive and non-mutagenic, and has been used in ophthalmology for decades. The subtle architecture of microvascular caliber vessel walls and even blood cells could be identified. The capillaries were much brighter than epithelial cells because of the flow of fluorescein in the vessels[20]. Nuclear changes can best be observed using acriflavine as a topical contrast agent. In our study, fluorescein was used as contrast agent, so that observation covered not only the surface structure, but also the deeper layer which displays the architecture of microvessels. However, we did not use the contrast agent acriflavine, so the nuclear changes could not be observed and analyzed in the confocal images.

We could not assess interobserver agreement about the mucosal patterns seen in magnification NBI and CLE in this study. Future studies could determine whether our results can be reproduced by using two blinded observers. Our study needs further longitudinal investigation. The other limitation of this study was the small number of cases. Further prospective blinded studies with a sufficient number of patients are therefore important.

In conclusion, these endoscopic techniques of magnifying endoscopy with NBI and CLE that can provide valuable information regarding normal gastric mucosa and should be used for evaluating the grade of gastric IN.

COMMENTS

Background

Diagnosis and localization of early gastric cancer is problematic because of the lack of any endoscopic characteristics, even with multiple random biopsies. In recent years, endoscopic image quality has improved. Magnifying endoscopy combined with narrow-band imaging (ME-NBI) has been used to achieve endoscopic pathology in gastric disease. Confocal laser endomicroscopy (CLE) is a newly-developed technology that has enabled endoscopists to collect real-time *in vivo* histological images or "virtual biopsies" of the gastrointestinal (GI) mucosa during endoscopy, and has stimulated significant interest in the application of this technique in clinical gastroenterology. The following attempts to concisely and accurately summarize the related background of the article and to enable the readers to gain some basic knowledge relevant to the article, thus helping them better understand its significance.

Research frontiers

Any prognosis of GI cancer is closely related to the stage of the disease at diagnosis. Endoscopic submucosal dissection (ESD) and *en bloc* endoscopic mucosal resection (EMR) have been performed as curative treatments for many early-stage GI lesions in recent years. However, before engaging in endoscopic therapy, an accurate diagnosis is a precondition affecting the complete cure of the underlying malignancy or carcinoma *in situ*. For the past few years, many new types of endoscopic techniques, including ME-NBI and CLE, have emerged in many countries since these methods provide a strong indication of early lesions and are very useful in determining treatment options before ESD or EMR.

Innovations and breakthroughs

This study showed that the pit pattern and capillary network in the gastric mucosal layer was made visible using the confocal endomicroscopy. In normal gastric antrum mucosa, the gastric pits are of the line type and the capillary network patterns showed a coil-shaped subepithelial capillary network pattern which surrounded the gastric pits. In the gastric body mucosa, the gastric pits are round and the capillary network patterns are characterized by a honeycomb-like network which was situated along or between the mucosal ridges.

Applications

The diagnostic accuracy and specificity for the differentiation of gastric IN by CLE are 87.93% and 84.62%, which is higher than the alternatives. CLE is the best technique for the diagnosis of the differentiation of gastric intraepithelial neoplasia (IN). However, the diagnostic sensitivity of CLE combined with ME-NBI is 100%, which showed the consistency of CLE and NBI-ME for the diagnostic differentiation of gastric IN.

Terminology

Gastric carcinoma is the second commonest cause of cancer deaths worldwide. Early detection and diagnosis of gastric cancer in the stomach is important for improving patient prognosis. CLE is a novel endoscopic modality that allows subsurface analysis of the gastric mucosa during ongoing endoscopy. ME-NBI is more accurate in the diagnosis of gastric cancer when the diagnostic triad of the disappearance of fine mucosal structure, microvascular dilation, and heterogeneity is used. Several studies have reported that this technique is of value in the diagnosis of premalignant lesions in the GI tract. Patients underwent an examination with CLE and magnifying NBI. Obtained image resolution was evaluated, and the morphology, pit patterns and blood capillary forms of lesions were analyzed. The results indicate the feasibility of these two techniques for the efficacious diagnostic classification of gastric INs.

Peer review

For the study of gastric INs, the authors classified the mucosa into two types and observed the differences between them. Low grade gastric intraepithelial neoplasia (LIN) showed different sizes and an abnormal arrange of gastric pits. In the confocal images of high grade gastric intraepithelial neoplasias (HIN), the gastric pits presented strange shapes. The results showed that white opaque substance is one of the phenotypes in NBI magnification images, but not the main discrimination. The microsurface pattern and microvascular structures differ between LIN and HIN. LIN showed the irregular microsurface and microvascular pattern with a clear demarcation line. The study also showed that the pit pattern and capillary network in the gastric mucosal layer was made visible using a confocal endomicroscope. The method for CLE, ME-NBI is clearly stated.

Abstract

AIM: To investigate the effect of hyperthermia on hypoxia-induced epithelial-mesenchymal transition (EMT) in HepG2 hepatocellular carcinoma (HCC) cells, and its mechanism.

METHODS: Cells were treated with hyperthermia at 43 ℃ for 0.5 h, followed by incubation under hypoxic or normoxic conditions for 72 h. Cell morphology was observed. Expressions of E-cadherin and vimentin were determined by immunofluorescence assay or Western blot. The protein and mRNA expressions of Snail were also determined by Western blot and reverse transcription-polymerase chain reaction. Cell migratory capacity was evaluated.

RESULTS: Hypoxia induced EMT in HepG2 cells, which was evidenced by morphological, molecular and functional changes, including the formation of a spindle shape and the loss of cell contact. The expression of E-cadherin was decreased but the expression of vimentin was increased; also, the migratory capability was increased by 2.2 ± 0.20-fold as compared with normoxia. However, those effects were inhibited by hyperthermia pretreatment. Furthermore, protein synthesis and mRNA expression of Snail in the cells were enhanced by hypoxia as compared with normoxia, and also significantly inhibited by hyperthermia pretreatment.

CONCLUSION: Hyperthermia may inhibit hypoxia-induced EMT in HepG2 HCC cells, and the mechanism may involve inhibition of induced expression of Snail.

Hyperthermia inhibits hypoxia-induced epithelial-mesenchymal transition in HepG2 hepatocellular carcinoma cells. *World J Gastroenterol* 2012; 18(34): 4781-4786 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i34/4781.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i34.4781

INTRODUCTION

Hepatocellular carcinoma (HCC) is a major health problem worldwide, and ranks third in the leading causes of cancer mortality[1]. There are approximately 560 000 new cases diagnosed each year, and around 550 000 deaths occur mostly in developing countries[2]. However, the choices for its treatment, especially for advanced HCC, is limited, and the prognosis is poor.

Hyperthermia is a physical treatment with fewer side effects than chemotherapy and radiotherapy. Numerous phase Ⅱ/Ⅲ studies have shown that hyperthermia is feasible and effective especially if combined with chemotherapy or radiotherapy in a variety of solid tumors (e.g., melanoma, breast cancer, HCC)[3-5]. It is reported that local hyperthermia can inhibit metastasis in an animal model[6]; however, the exact mechanisms remain unclear. Epithelial-mesenchymal transition (EMT) is a key step during cancer invasion and metastasis[7], and has been associated with cancer stem cells and resistance to chemotherapy and radiotherapy[8-10]. In the present study, we investigated the effect of hyperthermia on hypoxia-induced EMT in HepG2 HCC cells, and its underlying mechanism.

MATERIALS AND METHODS

Cell line culture

The human HCC cell line HepG2 (Wuhan University Cell Center) was cultured in RPMI1640 medium supplemented with 10% fetal bovine serum, 100 U/mL streptomycin, and 100 U/mL penicillin in a humidified 5% CO_2 atmosphere at 37 ℃.

Cell hyperthermia and hypoxia treatment

Water-bath warming was performed and the temperature was controlled at 43 ℃. The cell culture bottles were packaged and put into the water at 43 ℃ for 0.5 h. Then the culture bottles were returned to the cell-incubator immediately and incubated at 37 ℃ for 24 h. Thereafter, the cells were incubated under hypoxic (1% O_2, 5% CO_2, 37 ℃) or normoxic (21% O_2, 5% CO_2, 37 ℃) conditions for 72 h.

Immunofluorescence detection of E-cadherin

After hyperthermia, cells were plated on sterile coverslips. After 24 h, the cells were treated with hypoxia as mentioned above. Then, the cells were fixed in 4% formaldehyde, permeabilized with 0.2% Triton X-100, and blocked with 10% goat serum for 60 min at room temperature. Thereafter, cells were incubated with antibodies specific for goat E-cadherin (SC-31020, diluted 1:50) at 4 ℃ overnight. After washes with phosphate-buffered saline (PBS) 3 times, the cells were incubated with Alexa Fluor® 488 mouse anti-goat IgG (H+L) (A11078, diluted 1:200) for 60 min at room temperature. The expression of E-cadherin was detected under the fluorescence microscope.

Western blot analysis

Protein lysates were prepared using total protein extraction kit (ProMab, SJ-200501), and stored at -20 ℃ until assay. The protein concentrations were determined with the Bradford method. The equivalent aliquots of protein were separated by 10% sodium dodecylsulfate polyacrylamide gel electrophoresis, then transferred onto a nitrocellulose filter. The filters were blocked with 5% nonfat dry milk in PBS for 2 h at 37 ℃. After washing with PBST (PBS with Tween 20), they were incubated at 4 ℃ overnight with goat E-cadherin (SANTA, SC-31020, diluted 1:400), mouse vimentin (ProMab, 20301, diluted 1:1000), mouse Snail (CST, 3895, diluted 1:500) or mouse beta-actin (ProMab, 20270, diluted 1:1000) antibodies. Following 4-time PBST washing, the filters were incubated with secondary antibody of horseradish peroxidase-conjugated rabbit anti-goat IgG (diluted 1:4000, for E-cadherin) or goat anti-mouse IgG (diluted 1:5000, for vimentin, Snail and β-actin) for 1 h at room temperature. The immunoreactive proteins were detected using an enhanced chemiluminescent detection system.

Reverse transcription-polymerase chain reaction analysis

Total RNA was isolated using TRIzol reagent (Invitrogen) as suggested by the supplier. One micrograms of total RNA were reverse-transcribed. The sequences for forward and reverse primers were 5'-TCAACTGCAAATACTGCAAC-3' and 5'-CTTGACATCTGAGTGGGTCT-3' (Snail), and 5'-ACCACAGTCCATGCCATCAC-3' and 5'-TCCACCACCCTGTTGCTGTA-3' (glyceraldehyde-3-phosphate dehydrogenase, GAPDH). The sizes of their amplified fragments were 242 and 450 bps, respectively. Amplification was performed with 40 cycles with initial incubation at 95 ℃ for 5 min and final extension at 72 ℃ for 5 min. Each cycle consisted of denaturation for 30 s at 94 ℃, annealing for 30 s at 54 ℃ and extension for 30 s at 72 ℃. Following PCR, 10 μL samples of amplified products were resolved by electrophoresis in 1% agarose gel, then stained with ethidium bromide. The levels of Snail expression were semiquantitatively evaluated using a Kodak ultraviolet imaging system and an image analysis system (Vilber Lourmat, France), and normalized to GAPDH.

Cell migration assay

Cell migration was assessed using 6.5-mm Costar Transwell chambers with 8 μm pores (Corning). Cells were trypsinized and resuspended in serum-free medium containing 0.5% bovine serum albumin. Cells (5×10^4) were plated in the upper chamber in the above serum-free medium, and 1 mL serum-containing standard medium was placed in the lower chamber as a chemoattractant. The system was incubated in 1.0% or 21% O_2 for 24 h. After incubation, the nonmigrating cells were removed from the upper surface of the Transwell membrane by a cotton swab, and the membrane was fixed with 95% ethanol for 15-20 min before staining with hematoxylin and eosin. Cells that migrated through the membrane to the lower surface were counted under light microscopy.

Statistical analysis

Data were pooled from at least three independent experiments, and presented as mean ± SD unless otherwise indicated. Differences between groups were analyzed using one-way analysis of variance. All the statistical analyses were performed with SPSS13.0. $P < 0.05$ was considered statistically significant.

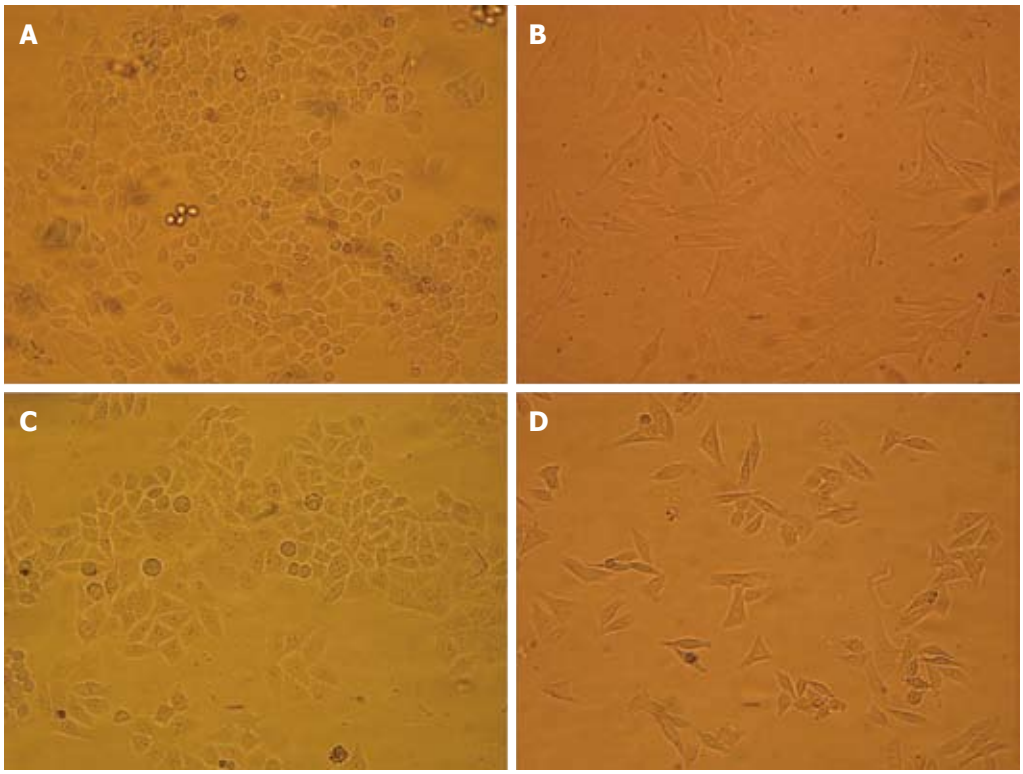

Figure 1 Morphologic changes after hyperthermia or hypoxia treatment in HepG2 cells. A: Cells were cutured in 21% O_2 for 72 h; B: Cells were cultured in 1.0% O_2 for 72 h; C: Cells were treated with hyperthermia at 43 ℃ for 0.5 h, followed by treatment with normoxia; D: Cells were treated with hyperthermia at 43 ℃ for 0.5 h, followed by treatment with hypoxia.

RESULTS

Effects of hyperthermia and hypoxia on cell morphology

Folding and corrugation of the cell membrane, and a number of vacuoles in the cytoplasm were observed after hyperthermia at 43 ℃ for 0.5 h. The cells cultured in 1.0% O_2 for 72 h showed a spindle shape and lost cell contact. However, these features were partially inhibited by pretreatment with hyperthermia (Figure 1).

Effects of hyperthermia and hypoxia on expressions of E-cadherin and vimentin

Expressions of E-cadherin were determined by immunofluorescence assay and Western blot. As shown in Figure 2, E-cadherin immunofluorescence staining intensity was significantly decreased in cells after incubation in 1.0% O_2 for 72 h as compared with cells cultured in normoxic conditions. However, hyperthermia pretreatment significantly blunted the above effects caused by hypoxia. As compared with untreated cells, hyperthermia alone moderately increased the immunofluorescence intensity of E-cadherin staining.

Consistent with the results obtained in immunofluorescence assays, Western blot analysis also showed that, under hypoxia, the expression of E-cadherin was significantly reduced, but the expression of vimentin was substantially increased when compared with normoxia. These effects were blunted after hyperthermia pretreatment (Figure 3). Hyperthermia alone also moderately increased the expression of E-cadherin but decreased the expression of vimentin compared with untreated cells.

Effects of hyperthermia and hypoxia on the protein and mRNA expressions of Snail

The protein and mRNA expressions of Snail were determined by Western blot and reverse transcription-polymerase chain reaction analysis, respectively. Similar to the expression of vimentin, the protein expression of Snail was significantly increased under hypoxia as compared with normoxia, and hyperthermia pretreatment inhibited the effect induced by hypoxia (Figure 4A). Hyperthermia alone moderately decreased the protein expression of Snail compared with untreated cells.

Consistent with protein expression, Snail mRNA expression was induced under hypoxia, but its induction was inhibited by hyperthermia pretreatment (Figure 4B). Hyperthermia alone also moderately decreased the mRNA expression of Snail compared with untreated cells.

Effects of hyperthermia and hypoxia on cell migration

Transwell chamber assays were performed to investigate the migratory capability of HepG2 cells treated with hyperthermia and hypoxia. Under hypoxia, cell migration was increased by 2.2 ± 0.20-fold as compared with normoxia ($P < 0.01$), which was attenuated to 1.4 ± 0.25-fold by hyperthermia pretreatment (Figure 5). Hyperthermia alone moderately decreased the cell migration compared with untreated cells.

The bar graphs show the relative expression levels of indicated proteins after normalization to β-actin. $^{a}P < 0.05$ *vs* untreated cells; $^{c}P < 0.05$ *vs* hypoxia-treated cells.

DISCUSSION

Hypoxia is a common hallmark of solid cancers, including liver cancer, and is associated with treatment failure and poor prognosis[11,12]. Previous studies have shown that it can induce both chemo- and radio-resistance, and also promotes cell migration, invasion and metastasis[11-13]. EMT, originally identified as a process vital for morphogenesis during embryonic development, is now recognized as a key step during cancer invasion and metastasis[7], and has been associated with cancer stem cells and resistance to chemotherapy and radiotherapy[8-10]. EMT is characterized by the loss of epithelial cell markers such as adherens protein E-cadherin, the acquisition of mesenchymal markers such as vimentin and fibronectin, and an increase in cell motility[9]. Several studies have shown that hypoxic conditions can induce EMT in cancer cells, the mechanisms of which may involve reactive oxygen species generated during hypoxia, hypoxia-inducible factor-1α and phosphoinositide-3-kinase/Akt signaling[14-16]. Consistent with other studies, the present study showed that hypoxia induced morphological (spindle shape and loss of cell contact), molecular (decreased E-cadherin but increased vimentin expressions) and functional (increased cell migration) changes in HepG2 HCC cells, all of which are in line with EMT.

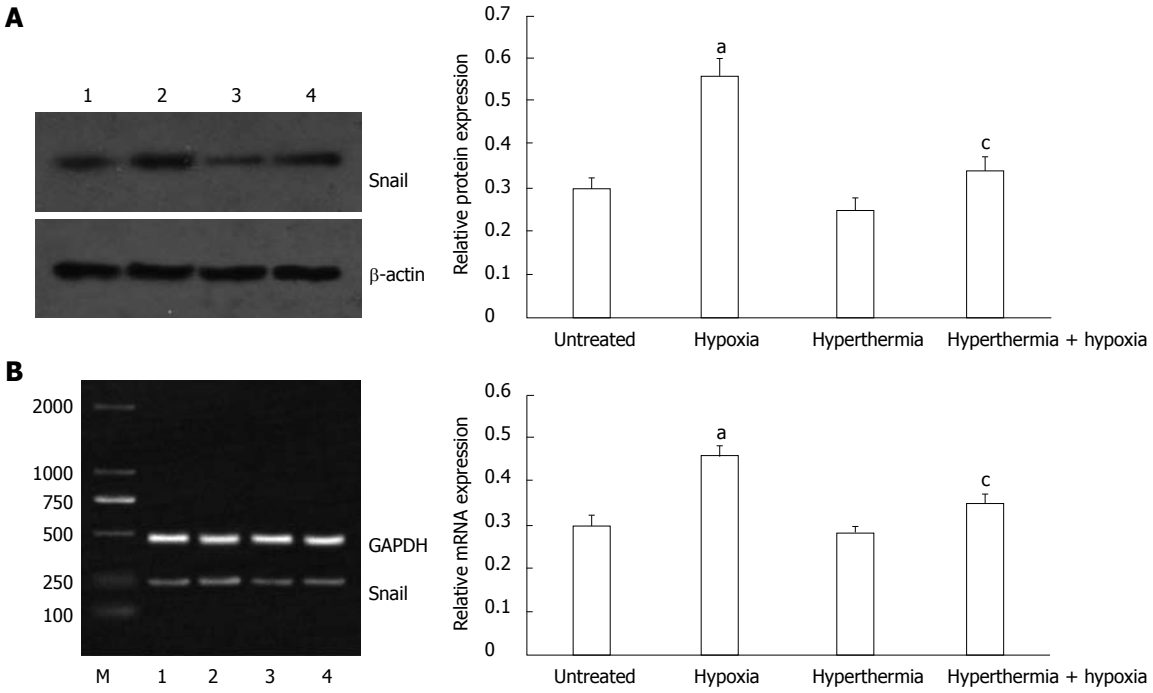

Figure 4 Western blot and reverse transcription-polymerase chain reaction analysis of Snail expression in HepG2 cells. A: Western blot: Lanes 1, 2, 3 and 4 represent untreated cells, hypoxia-treated cells, hyperthermia-treated cells and hyperthermia + hypoxia-treated cells, respectively. The bar graphs show the relative expression levels of Snail after normalization to β-actin; B: Reverse transcription-polymerase chain reaction: The representation of the lanes was the same as in (A); the bar graphs show the relative expression levels of Snail normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH). $^{a}P < 0.05$ *vs* untreated cells; $^{c}P < 0.05$ *vs* hypoxia-treated cells.

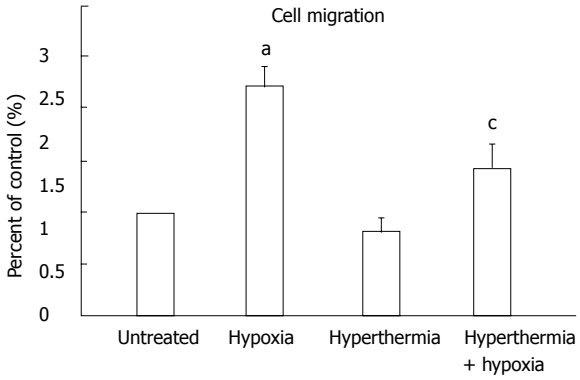

Figure 5 Migration assay of HepG2 cells treated with hyperthermia or hypoxia. Quantification of the cell migration results from three experiments: each bar (hypoxia-, hyperthermia-, hyperthermia + hypoxia-treated cells) represents the relative levels observed in untreated cells (control). $^{a}P < 0.05$ *vs* untreated cells; $^{c}P < 0.05$ *vs* hypoxia-treated cells.

In recent years, hyperthermia has emerged as an effective approach for cancers, with fewer side effects than chemotherapy and radiotherapy. Clinical studies have shown that hyperthermia, usually classified as local, regional and whole body, is a tolerable and clinical practical adjunctive therapy for the patients with advanced malignant tumors[3-5]. Previous reports have demonstrated that local hyperthermia can inhibit tumor metastasis in animal model[6]. Furthermore, the expressions of some genes associated with metastasis such as vascular endothelial growth factor, membrane type 1-matrix metalloproteinase, were shown to be suppressed by heating[17-19]. In the present study, we found that hyperthermia can inhibit hypoxia-induced EMT, as hyperthermia before hypoxia exposure significantly blunted the inhibition of E-cadherin, the induction of vimentin expressions, and the increase of cell migration triggered by hypoxia in HepG2 HCC cells. These findings suggested that hyperthermia may alter the metastatic potential of cancer cells and inhibit tumor metastasis.

A number of transcription factors have been found to play an important role in EMT, including zinc finger homologs (e.g., Snail), basic helix-loop-helix transcription factors (e.g., Twist) and ZEB family members (ZEB1, ZEB2/SIP1)[9]. Snail has been found to be expressed in numerous human tumors, including gastric and hepatic carcinoma[20-22], and has been described as a direct repressor of E-cadherin both *in vitro* and *in vivo* through binding to E-box elements in the E-cadherin promoter, repressing its expression and producing changes in cell phenotype consistent with EMT[23,24]. Our experiments showed that hypoxia induced mRNA and protein expressions of Snail in HepG2 HCC cells, which may be involved in the mechanism of hypoxia-induced EMT. However, the induction of Snail expressions by hypoxia was inhibited by hyperthermia pretreatment. Therefore, the mechanism by which hyperthermia inhibits hypoxia-induced EMT may involve the reduction in Snail expression.

Taken together, the present study demonstrated that hyperthermia inhibits hypoxia-induced EMT in HepG2 HCC cells, and the mechanism may be associated with the reduction of mRNA and protein expressions of Snail. This study provides further evidence that hyperthermia can inhibit tumor metastasis.

COMMENTS

Background

Epithelial-mesenchymal transition (EMT) has been recognized as a key step during cancer invasion and metastasis, and may be induced by environmental stresses such as hypoxia, reactive oxygen species, and growth factors such as transforming growth factor β1. Hypoxia is a common phenomenon in solid tumors, and hypoxic conditions are known to induce EMT in cancer cells. Hyperthermia is a potent approach for cancers with fewer side effects compared with chemotherapy and radiotherapy. Recent reports have shown that local hyperthermia can inhibit tumor metastasis in an animal model, and the mechanisms are associated with vascular endothelial growth factor, membrane type 1-matrix metalloproteinase. However, the effect of hyperthermia on EMT of cancer cells is unknown.

Research frontiers

EMT plays an essential role in tumor progression and metastasis, and has been associated with cancer stem cells and resistance to chemotherapy and radiotherapy. To reverse EMT or to target EMT related pathways is a promising novel approach to overcome the chemoresistance and radioresistance for cancer treatment, and to help prevent tumor metastasis.

Innovations and breakthroughs

Hyperthermia can inhibit EMT induction in cancer cells, suggesting that hyperthermia may alter the properties of metastatic potential of cancer cells and inhibit tumor metastasis. Furthermore, the mechanism of inhibition is associated with inhibition of expression of the transcription factor Snail.

Applications

The results of the study provide a novel theoretical basis for hyperthermia in the treatment of malignant tumors, especially combined with chemotherapy or radiotherapy.

Terminology

EMT is a physiological and pathological process in which epithelial cells acquire the motile and invasive characteristics of mesenchymal cells. EMT is characterized by the loss of epithelial cell markers such as E-cadherin, the acquisition of mesenchymal markers such as vimentin and fibronectin, and an increase of cell motility. EMT has been recognized as a key step during embryonic morphogenesis, heart development, chronic degenerative fibrosis, and cancer metastasis.

Peer review

The paper described the effect of hyperthermia on EMT in HepG2 hepatocellular carcinoma cells, and its associated mechanism. The authors concluded that hyperthermia may inhibit EMT induction in cancer cells and the mechanism is associated with inhibition of expression of the transcription factor Snail. The results are interesting, but the mechanism needs to be further studied, especially employing Snail knockdown technique.

Abstract

A 46-year-old female patient with terminal ileum Crohn's disease and ankylosing spondylitis presented with recurrent angioedema and urticaria. Investigations ruled out hereditary angioedema, and environmental or food allergen triggers. She was diagnosed with chronic idiopathic urticaria with angioedema, and was treated with a trial of intravenous immunoglobulin immunotherapy, danazol, prednisone and hydroxyzine. Due to ongoing bowel and arthritic complaints, she was started on infliximab infusions and within 2 treatments, she had complete resolution of the angioedema and urticaria, as well as of the bowel and arthritic symptoms. Unfortunately she developed allergic reactions to the infliximab and was switched to another anti-tumor necrosis factor (TNF)-α agent, adalimumab. Since then, she has had no further angioedema or urticaria, and her Crohn's disease has been quiescent. This is the first known case report of chronic idiopathic urticaria with angioedema coexistent with Crohn's disease that was successfully treated with anti-TNF-α agents.

INTRODUCTION

Studies have shown that there is a strong autoimmune involvement in the pathophysiology of urticaria and angioedema. There are increases in pro-inflammatory cytokines, such as interleukin (IL)-1 β, IL-12p70, tumor necrosis factor (TNF)-α, IL-6, IL-10 and IL-17, in chronic idiopathic urticaria. Crohn's disease also has autoimmune involvement, and there is evidence for an altered cytokine milieu leading to mucosal inflammation. Recent studies have shown that T-cell production of certain cytokines play a strong role. One common thread in the pathophysiology of chronic idiopathic urticaria and Crohn's disease is the derangement in cytokine levels, in particular, IL-17 and TNF-α. The IL-17 cytokines are T-cell derived cytokines that stimulate various cells to secrete cytokines and chemokines, and therefore play an important role in many autoimmune diseases. It has been shown that IL-17A positive cells are increased in the inflamed mucosa of inflammatory bowel disease (IBD) patients, and IL-17F mRNA expression is elevated in the mucosa of Crohn's disease patients. Infliximab and adalimumab are anti-TNF-α agents that block the inflammatory cascade. Given the similarity in cytokine derangements found in

chronic idiopathic urticaria and in Crohn's disease, medications that target these cytokines, such as anti-TNF-α agents should be effective in both conditions.

This case brings to attention the common pathophysiology between autoimmune diseases, and the need for further research looking into the changes in the cytokine milieu as potential targets for treatment.

CASE REPORT

A 46-year-old female with terminal ileum Crohn's disease and ankylosing spondylitis presented to our Gastroenterology clinic with recurrent angioedema and urticaria. Her Crohn's disease was diagnosed in 1993 when she began having abdominal pain and diarrhea. A small bowel follow through revealed terminal ileum involvement, and she was started on Pentasa at that time. She remained well on Pentasa and for unclear reasons discontinued the medication in 2001. She was diagnosed with ankylosing spondylitis in 2004 just prior to presentation. On examination, she had angioedema and urticaria involving the tongue, lips, eyes, face, feet, hands and genital areas (Figure 1). Laboratory investigations revealed white blood cell 1.0 (normal, range: 4.0×10^9 - 11.0×10^9/L), neutrophils 10.0 (normal, range: 2.0×10^9 - 7.50×10^9/L), erythrocyte sedimentation rate 68 (normal, range: 0-20 mm/h). She was restarted on an aminosalicylate, Pentasa, for treatment of active Crohn's disease with the concern that the angioedema may be related to the activity of the Crohn's disease. A subsequent colonoscopy revealed aphthous ulceration in the terminal ileum. Biopsies of the ileocecal valve and terminal ileum showed mild acute on chronic inflammation with no granulomas and no dysplasia.

After restarting the Pentasa, her urticaria and angioedema subsided for 3 mo. Unfortunately her symptoms then recurred. The episodes became more frequent, and she required Prednisone and Atarax to control her symptoms. An allergist performed skin testing which revealed environmental allergies but no significant food allergies. Further investigations revealed an elevated IgM (3.02, range: 0.2-2.2), elevated IgE (1120) without eosinophilia, normal C3 (1.19), and normal C4. There was a question of hereditary angioedema, however she had normal C1 esterase inhibitor levels (313). Based on these results, she was diagnosed with chronic idiopathic recurrent urticaria with angioedema.

She was treated with a trial of intravenous immunoglobulin immunotherapy, but developed aseptic meningitis, and was instead treated with repeated courses of prednisone. A trial of Danazol did not alleviate her symptoms and she continued to be dependent on Prednisone and Atarax.

In 2007, because of her ongoing bowel, arthritis, and urticaria/angioedema symptoms, she was started on intravenous infliximab infusions (5 mg/kg) and within two treatments (weeks 0 and 2); she improved with resolution of the angioedema and urticaria, as well as of the bowel and arthritic symptoms. Unfortunately, while receiving her thirteenth infusion, she developed allergic reactions to the Infliximab. She was switched to another anti-TNF-α agent, adalimumab (160 mg subcut week 0, 80 mg week 2, 40 mg week 4 then 40 mg 2 wk). We have continued to follow her and since then, she has had no further angioedema or urticaria, and her Crohn's disease has been quiescent. This is the first known case report of chronic idiopathic urticaria with angioedema coexistent with Crohn's disease that was successfully treated with anti-TNF-α agents.

DISCUSSION

Urticaria refers to swelling of the superficial skin layer, and can be acute or chronic (present for at least 6 wk). When no external cause can be found for chronic urticaria, the patient is referred to as having "chronic idiopathic urticaria"[1]. Urticaria can occur alone (approximately 40% of patients), or in combination with angioedema (approximately 50% of patients)[1]. Angioedema refers to non-pruritic, non-pitting areas of swelling or cutaneous and mucosal tissues, affecting the deep dermal and subcutaneous/submucosal skin layers[1,2]. Angioedema can be further categorized into hereditary, acquired, associated with allergic reactions, and idiopathic. Degranulation and histamine release by mast cells and basophils leads to the erythema and edema typical of urticaria and angioedema.

Studies have shown that there is a strong autoimmune involvement in the pathophysiology of urticaria and angioedema. These conditions have been associated with other autoimmune diseases such as autoimmune thyroid disease and celiac disease[1,2]. Chronic urticaria and angioedema have been attributed to reactions to food, drugs, environmental antigens, and *Helicobacter pylori* infection, but the etiology for a majority of patients remains unknown. However, even for these "idiopathic" chronic urticaria patients, it is believed that the underlying mechanism is an autoimmune phenomenon[1,3,4].

Up to 30%-50% of patients with chronic urticaria have autoantibodies to the α-chain of the high affinity receptor for IgE (FceRIa); it is thought that these autoantibodies cross-link the IgE receptors, therefore activating the infiltrating basophils and skin mast cells, leading to histamine release[1,3,4].

In addition, other circulating mediators may play a role in activation and histamine release studies have shown increases in pro-inflammatory cytokines, such as IL-1β, IL-12p70, TNF-α, IL-6, IL-10 and IL-17, in chronic idiopathic urticaria[5,6].

Crohn's disease is also a disease with autoimmune involvement, and there is evidence for an altered cytokine milieu leading to mucosal inflammation. Although the exact mechanism of Crohn's disease has not been determined, recent studies have shown that T-cell production of certain cytokines play a strong role in the pathophysiology of Crohn's disease[7-11].

A thorough literature review has revealed very few

Figure 1 Angioedema and urticaria of the face and abdomen. A: Face; B: Abdomen.

case reports of urticaria or angioedema associated with IBDs. These include cases of Hereditary angioedema associated with Crohn's disease[12,13], angioedema of the small intestine masquerading as Crohn's disease[14,15], and a single case of chronic urticaria without angioedema in a patient who was subsequently diagnosed with Crohn's disease[16]. There has also been a case report of chronic urticaria and ulcerative colitis[17].

One possible common thread in the pathophysiology of chronic idiopathic urticaria and Crohn's disease is the derangement in cytokine levels, in particular, IL-17 and TNF-α. The IL-17 cytokines are T-cell derived cytokines that stimulate various cells to secrete cytokines and chemokines, and therefore play an important role in many autoimmune diseases[7], The Th17 CD4+ T cells produce a distinct set of cytokines (IL-17A, IL-17F, IL-6, IL-22 and IL-26) which enhance immune and host defenses. IL-17A plays a role in the expansion and recruitment of innate immune cells (neutrophils), and interacts with toll-like receptor ligands, IL-1 β, and TNF-α to enhance inflammatory reactions. IL-17F induces the secretion of other inflammatory cytokines such as IL6, IL-8 and LIF. It has been shown that Il-17A positive cells are increased in the inflamed mucosa of IBD patients[9], and IL-17F mRNA expression is elevated in the mucosa of Crohn's disease patients[8].

Infliximab and adalimumab are anti-TNF-α agents that block the inflammatory cascade. Both of these agents have been found to be effective in the treatment of Crohn's disease[18,19]. Given the similarity in cytokine derangements found in chronic idiopathic urticaria and in Crohn's disease, anti-inflammatory medications that target these cytokines should be effective in both conditions. Anti-TNF-α agents are still experimental for the treatment of urticaria, and have been tried in patients with various forms of urticaria, with a few case reports that have indicated successful treatment[20].

In summary, this is the first known case report of chronic idiopathic urticaria with angioedema coexistent with Crohn's disease that was successfully treated with anti-TNF-α agent. We hypothesize that the derangement in cytokines, especially IL-17 and TNF-α, may be the reason the anti-TNF-α agents were successful, and that there may be a common pathophysiology between autoimmune diseases. Patients with IBD and concurrent angioedema or urticaria could have their cytokine levels checked and compared to see if there is any trend. These levels could be checked before and after treatment with biologics to confirm the biologic effect on the cytokine milieu in these two diseases. This case brings to attention the need for further research looking into the changes in the cytokine milieu as potential targets for treatment.

Abstract

In patients with inflammatory bowel diseases (IBD) the prevalence of thrombosis is 6.2%, the average incidence of thromboembolism (TE) is 3.6 times higher compared to normal population. The TE is a common extraintestinal complication of IBD, squarely associated with the IBD activity. The application of anticoagulant and thrombolytic therapy in severe IBD is an unresolved issue. Herein we report the first case in literature of an active IBD patient with an upper limb acute arterial occlusion and successful catheter-directed thrombolysis (CDT). A 46-year-old male patient is reported who had Crohn's disease for 10 years. His right hand suddenly became cold and painful. Angiography proved acute occlusion of the brachial and radial artery. Vascular surgery intervention was not applicable. Endoscopy showed extended, severe inflammation of the colon. Despite the severe endoscopic findings, frequent bloody stools and moderate anaemia, CDT with recombinant tissue plasminogen activator was performed. The control angiography proved improvement, the radial artery pulse appeared. No bleeding complication was observed. This case supports that CDT-after careful estimation of the bleeding risk-can be effective and safe in patients with severe or life-threatening TE and active IBD.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) the two main forms of inflammatory bowel diseases (IBD) are systemic disorders often associated with extraintestinal

manifestations, complications, and other immune mediated disorders. These chronic inflammatory conditions are characterized by a hypercoagulable state and prothrombotic condition, and accompanied by abnormalities in coagulation. Thromboembolism (TE) is a significant cause of morbidity and mortality in patients with IBD. Recent data suggest that TE is a disease-specific extraintestinal manifestation of IBD, which is developed as the result of multiple interactions between acquired and genetic risk factors. The incidence of systemic thromboembolic events in IBD patients ranges from 1%-7.7%[1], patients having a 3-4-fold overall increase risk for venous TE compared to control population[2].

The application of anticoagulant and thrombolytic therapy in severe IBD is an unresolved issue. Generally the management of TE in IBD patients not differs from treatment in non-IBD patients, although there are currently no clear guidelines for the management of IBD-related TE[3].

CASE REPORT

A 46-year-old male with a past medical history of 10 years' CD, was presented with symptoms of relapse of IBD: weight loss, lower abdominal pain, bloody diarrhoea and arthralgia (CD activity index: 345). He was treated with high dose prednisone due to severe activity of IBD one year before this event. Actually he was on a treatment with azathioprine (2.5 mg/bwkg) and mesalazine (3 g/d), on a stable dose during the last 1 year. He also complained about an acute onset of pain and coldness of his right hand. The physical examination revealed to an acute arterial occlusion of the right hand. No provoking factor could have been detected. The colour-Doppler imaging and the angiography proved the acute occlusion of the right brachial and radial artery (Figure 1A and B). Vascular surgery intervention was not applicable. The laboratory findings showed anaemia (haemoglobin was 85 g/L) and thrombocytosis (platelet count was 409 g/L normal 150-400 g/L), the D-dimer test was positive (1.0 normal < 0.5 Feu/μL). Liver and kidney panels were normal. An acutely performed endoscopy showed extended, severe inflammation of the colon with deep ulcers and signs of chronic activity involving the sigmoid colon. Considering the severity of the occlusion and the risk of a potential limb-loss catheter-directed thrombolysis (CDT) was suggested, despite the severe endoscopic findings, frequent bloody stools and moderate anaemia. After 24 h from onset of symptoms of arterial occlusion endovascular arterial intervention was performed: 5 mg bolus of radial artery pulse appeared (rt-PA) (Actilyse injection, Boehringer Ingelheim International) was injected into the thrombus, followed by a continuous rt-PA infusion through the catheter in a dose of 0.1 mg/bwkg per hour. The treatment was carried on for 9 h and proceeded with enoxaparin (60 mg QD, subcutaneously). The pain and coldness quickly decreased, the radial pulse became palpable. The control angiography proved the improvement (Figure 1C and D). Despite the high risk of bleed no bleeding complication was observed. Echocardiography found no source of an embolus. Low-molecular-weight heparin (LMWH) prophylaxis was applied for 3 mo (enoxaparin, 60 mg OD, subcutaneously). No congenital thrombophilia was proved (antithrombin-Ⅲ: 120% normal: 80-120; protein C: 132% normal: 70-130; protein S: 93% normal: 60-140; activated protein C resistance: 2.51 normal: > 2; FVLeiden: wild type; Factor Ⅱ 20210A: wild type; Factor Ⅷ: 188% normal: 60-150). Neither lupus anticoagulant nor antiphospholipid autoantibody was detectable. The level of homocystein was also normal. The relapse of the CD was treated with anti-tumor necrosis factor-α (anti-TNF-α) antibody (infliximab). One year after the biological treatment and continuous LMWH prophylaxis the patient is in remission of IBD and has a complete recovery of the right upper limb arterial circulation.

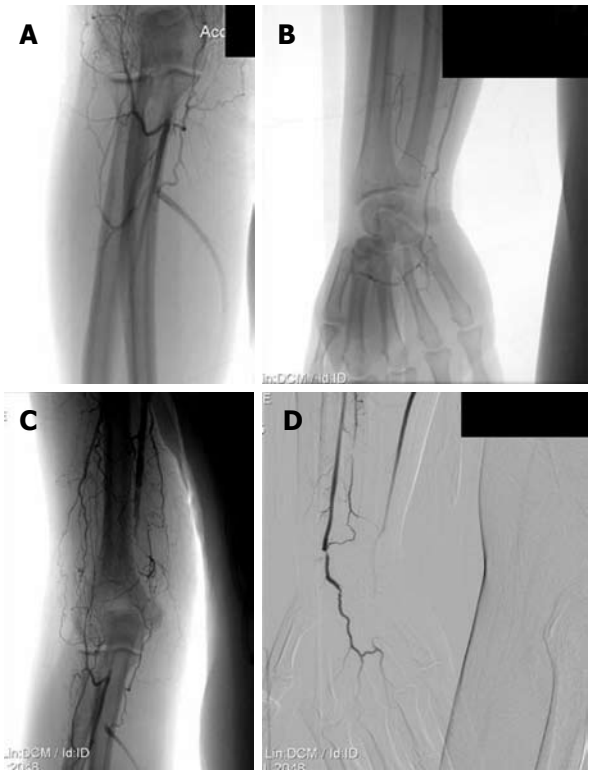

Figure 1 Angiographic pictures. A: Occlusion of the right brachial; B: Occlusion of the radial artery; C and D: Angiographic control after local thrombolytic treatment.

DISCUSSION

We report a case of a peripheral arterial TE of the right upper limb in a 46-year-old patient with acute relapse of CD. In the background no provoking factors could have been detected. Thrombophilia evaluation was normal and a source of an embolus was undetectable either. The background of the hypercoagulability that is present in IBD is the altered platelet/endothel cell function and interaction, the elevated level of coagulation factors and the decreased activity of fibrinolysis. In patients with IBD the prevalence of thrombosis is 6.2%, the average

incidence of TE is 3.6 times higher compared to normal population[1]. TE events occur mainly in the venous circulation[1,4], but can also develop in the arterial circulation[5]. Deep vein thrombosis and pulmonary embolism are the most common types of TE, but thromboses are also reported in unusual sites such as cerebral, innominate, retinal, hepatic and mesenteric veins[2,6]. Arterial thromboembolic complications occur less frequently[7] and the majority of cases seem to occur post surgery[8]. Patients with IBD have a markedly increased risk of acute mesenteric ischemia. IBD patients are more likely to have cardiac arterial thromboembolic disease, regardless of diagnosis or sex[9]. CD has an increased risk for cerebral arterial thromboembolic disease with some differences regarding the sex[10]. While the risk of gastrointestinal bleeding has to be considered in each case, most patients tolerate anticoagulants at full dose. Thrombolytic therapy is generally preserved for massive, life-threatening thrombosis. So far, only 17 cases of local thrombolytic treatment in IBD patient have been reported[11,12]. Until now there has been no case reported about upper limb arterial occlusion and CDT in IBD. In conclusion, moderate-severe active CD has to be considered as a risk factor for systemic TE[13]. Practice guidelines strongly recommend the use of thrombosis-prophylaxis in active IBD[3]. Arterial thrombosis is a rare, but severe complication of IBD. Considering the severity of the occlusion, in cases of life-threatening TE CDT could be an effective and safe intervention.

Abstract

We report a case of acute fulminant amoebic colitis that resulted in the development of a perianal ulcer in a 29-year-old Japanese homosexual man with acquired immunodeficiency syndrome (AIDS). The patient was admitted to our hospital with a persistent perianal abscess that was refractory to antibiotic therapy administered at another hospital. On admission, we observed a giant ulcer in the perianal region. At first, cytomegalovirus colitis was suspected by blood investigations. Ganciclovir therapy was initiated; however, the patient developed necrosis of the skin around the anus during therapy. We only performed end-sigmoidostomy and necrotomy to avoid excessive surgical invasion. Histopathological examination of the surgical specimen revealed the presence of trophozoite amoebae, indicating a final diagnosis of acute fulminant amoebic colitis. The patient's postoperative course was favorable, and proctectomy of the residual rectum was performed 11 mo later. Amoebic colitis is one of the most severe complications affecting patients with AIDS. Particularly, acute fulminant amoebic colitis may result in a poor prognosis; therefore, staged surgical therapy as a less invasive procedure should be considered as one of the treatment options for these patients.

INTRODUCTION

Amoebiasis is a parasitic infection caused by the protozoan *Entamoeba histolytica*, which principally affects the colon and liver. A majority of infected patients remain asymptomatic; however, the development of acute fulminant amoebic colitis is often fatal, with a very high mortality rate of 70%-100%[1,2] because of serious complications like colonic perforation[3,4] and necrotizing colitis[5]. On the other hand, the formation of a perianal ulcer due to acute fulminant amoebic colitis is very rare[6]. We describe the case of a 29-year-old homosexual man with acquired immunodeficiency syndrome (AIDS), who developed a perianal ulcer as a result of acute fulminant amoebic colitis.

CASE REPORT

A 29-year-old Japanese homosexual man was admitted to our hospital with a complaint of spiking pyrexia and anal pain with a perianal abscess, which was refractory to an-

Figure 1 A giant ulcer covered with necrotic tissue is identified in the perianal region.

tibiotics therapy administered at another hospital. On admission, we observed a giant ulcer in the perianal region (Figure 1). A diagnosis of AIDS was made on the basis of serum human immunodeficiency virus (HIV) antigen positivity and an increased HIV viral load (90 000 RNA copies/mL); his condition was further complicated by *pneumocystis carinii* infection. Moreover, cytomegalovirus (CMV) colitis was suspected from the occurrence of severe bloody diarrhea and the presence of serum antigenemia. Ganciclovir therapy was initiated without performing a colonoscopy because of patient refusal. However, he developed infected necrosis of the skin around the anus and over the perianal ulcer during therapy. Laboratory investigations revealed the following: white blood cell count, 7500/mm^3; hemoglobin, 9.7 g/dL; platelets, 545 000/mm^3; and serum C-reactive protein, 13.1 mg/dL. Abdominal computed tomography (CT) revealed an abscess formed due to necrosis and extending from the perianal region to the lower rectum (Figure 2). We therefore ruled out chances of anus preservation and performed only end-sigmoidostomy and necrotomy of the skin tissue from around the anus to the lower rectum. This was done to avoid excessive surgical invasion because of a significant decrease in the CD4-positive lymphocyte count (52 cells/mm^3). Macroscopic findings of the resected colon revealed multiple deep ulcerations covered with yellow necrotic plaques (Figure 3). Histopathological examination of the surgical specimen revealed trophozoite amoebae that had ingested red blood cells in the resected colon and necrotic tissue, leading to in a final diagnosis of acute fulminant amoebic colitis (Figure 4). Furthermore, the serological test for *Entamoeba histolytica* was also positive. Typical cytomegalic intranuclear inclusion bodies were not observed in the endothelial cells of the resected specimen. Soon after receiving the pathological diagnosis of amoebiasis, metronidazole therapy was initiated. The patient's postoperative course was uneventful because of intensive care. Antiretroviral therapy was also prescribed. The HIV viral load gradually decreased to below the detection limit of the HIV-RNA assay, and the CD4-positive lymphocyte count increased to 112 cells/mm^3. On the basis of these findings, proctectomy of the residual rectum was performed 11 mo later.

DISCUSSION

Amoebiasis, which is caused by the protozoan *Entamoeba histolytica* (*E. histolytica*), is the second most frequent parasitosis worldwide, particularly in tropical and subtropical areas[7]. Recently, the risk of amoebiasis has also increased in developed countries, particularly among travelers returning from endemic areas and homosexual men, including those with HIV infection[8,9]. Interestingly, 13.4%-20.4% Japanese homosexual men test positive for amoebic antibodies[10]. However, acute fulminant amoebic colitis is uncommon, and Adams *et al*[11] reported that acute fulminant colitis developed in only 3% of 3013 patients with amoebic colitis in South Africa. The outcome of this condition is very poor, with a high mortality rate of 70%-100%[1,2] because of serious complications like colonic perforation[3,4], necrotizing colitis[5], and toxic megacolon[12]. Perianal ulcers caused by acute fulminant amoebic colitis, such as that observed in the present case, are very rare and occur in only 0.04% patients[11]. Especially in homosexual men, the pathogen can easily invade the anal epithelium, thus resulting in the formation of a perianal ulcer.

Amoebic colitis can be diagnosed by the identification of *E. histolytica* in the stool or in colonic tissue removed by colonoscopy. Testing for serum antibodies against *E. histolytica* is also useful, with a high sensitivity of 85%[13]. In the present case, we could not perform colonoscopic examination because the patient did not consent to this procedure. He was initially treated by ganciclovir therapy after CMV colitis was suspected because of the occurrence of severe bloody diarrhea and the presence of serum antigenemia; however, he responded poorly to this treatment. Because the final diagnosis of amoebic colitis was only made after surgery, metronidazole therapy, which is the standard treatment for amoebic colitis, was delayed. It is very difficult to distinguish these two diseases by nonspecific clinical manifestations, such as diarrhea, abdominal pain, and gastrointestinal bleeding; moreover, a few cases of mixed infection with *E. histolytica* and CMV have been previously reported[14-16]. However, it should be considered that amoebic colitis is one of the causes of perianal ulcers in homosexual men. The primary treatment of amoebic colitis is metronidazole; nevertheless, surgical treatment is necessary in cases of perforative peritonitis[1,2], necrotizing colitis[5], and toxic megacolon[12] despite high mortality and poor prognosis. In the present case, the perianal ulcer may have developed as a result of acute fulminant amoebic proctitis, which may be attributed to homosexuality. Several reports have advocated less invasive surgical procedures, such as diverting colostomy or ileostomy and simple closure of the perforation, because of the high mortality rate following bowel resection surgery[17,18]. On the other hand, resection to resolve the septic focus and stoma creation should be considered one of the treatment options, depending on the general status of the patient[19]. We performed only end-sigmoidostomy and necrotomy of the skin tissue from around the anus

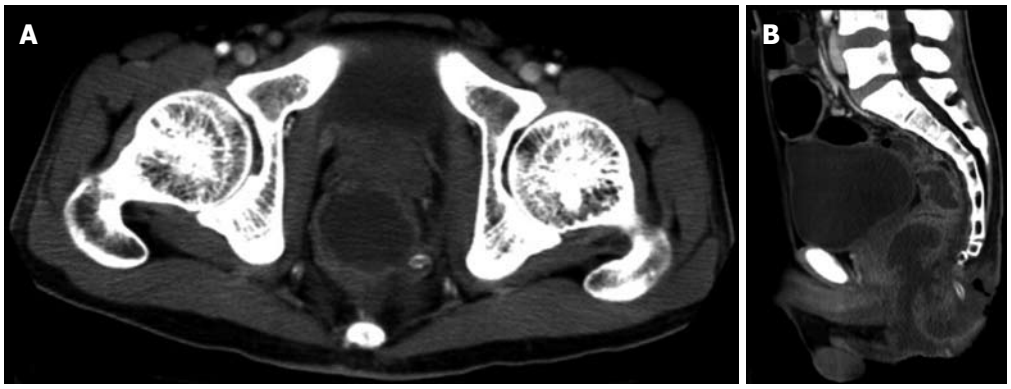

Figure 2 Abdominal computed tomography revealing an abscess formation of the perianal region. A: The axial view shows an abscess of the perianal region due to necrosis; B: The sagittal view shows an abscess formation extending from the perianal region to the lower rectum.

Figure 3 Macroscopic findings of the resected colon following end-sigmoidostomy show numerous deep ulcerations covered with yellow necrotic plaques.

to the lower rectum to avoid excessive surgical invasion because of a significant decrease in the CD4-positive lymphocyte count due to AIDS. Proctectomy of the residual rectum was performed after the recovery of his immunocompetence 11 mo later. The patient's postoperative course following staged surgical treatment was favorable, and he has survived for 2 years since the first surgery.

Because of the rarity of this disease, the effectiveness of invasive surgical procedures for the treatment of acute fulminant amoebic colitis needs further investigation.

In summary, we described an extremely rare case of acute fulminant amoebic colitis that resulted in the development of a perianal ulcer in a homosexual man with AIDS. He was successfully treated by staged surgical treatment. Amoebiasis is the second most frequent parasitosis worldwide, but almost all of these infections are asymptomatic. However, acute fulminant amoebic colitis has a poor prognosis in immunocompromised patients, particularly those with AIDS. Early diagnosis, opportune surgical procedures, and intensive care for sepsis appear to decrease mortality. Therefore, amoebic colitis must be kept in mind when perianal ulcers manifest in immunocompromised patients; moreover, minimally invasive, staged surgical treatment should be considered in these patients.

Abstract

We report a rare case of a small-bowel lymphangioma causing massive gastrointestinal (GI) bleeding that we successfully diagnosed and treated using double-balloon enteroscopy (DBE). An 81-year-old woman suffering from repeated GI bleeding of unknown origin underwent a capsule endoscopy at a previous hospital. She was suspected of having bleeding from the jejunum, and was referred to our department for diagnosis and treatment. An oral DBE revealed a 20 mm × 10 mm, regularly surfaced, white to yellowish, elongated, pedunculated jejunal polyp with small erosions at 10 cm distal to the ligament of Treiz. Since no other source of bleeding was identified by endoscopy in the deep jejunum, an endoscopic polypectomy (EP) was performed for this lesion. A subsequent histopathological examination of the resected polyp showed clusters of lymphatic vessels with marked cystic dilatation in the submucosa and the deep layer of the lamina propria mucosae. These characteristics are consistent with the typical features of small-bowel lymphangioma with erosions. Although clipping hemostasis was performed during EP, re-bleeding occurred. Finally, a complete hemostasis was achieved by performing an additional argon plasma coagulation.

INTRODUCTION

A small-bowel lymphangiomas is a rare benign tumor of the lymphatic system but has been previously reported as

a cause of significant gastrointestinal (GI) bleeding[1]. Recently, double-balloon enteroscopy (DBE) has been used for the diagnosis and treatment of obscure GI bleeding. We here report a rare case of a pedunculated polyp-shaped small-bowel lymphangioma causing massive GI bleeding that we successfully treated using DBE. In this patient, DBE therapy was performed using a combination of endoscopic polypectomy (EP), hemoclipping, and argon plasma coagulation (APC). This is a particularly unusual and interesting case as it has not only revealed a further rare form of small-bowel lymphangioma but also that DBE is an effective procedure for not only the diagnosis but also the treatment of this disorder. We conclude from our findings in this case that future differential diagnoses of GI bleeding of unknown origin should include small-bowel lymphangioma even though it is a rare condition.

CASE REPORT

An 81-year-old woman was treated for chronic heart failure and myeloid dysplasia (MDS). Since MDS was the underlying disease in this patient, her Hb levels were low at approximately 9.0 g/dL and in February 2011 decreased to 5.0 g/dL. Although upper GI endoscopy, lower GI endoscopy, and computed tomography procedures were performed, no source of bleeding could be identified. Subsequently, she had frequent episodes of melena and received a total of 20 transfusions of packed red cells (2800 mL), and underwent capsule endoscopy using a PillCam SB (Given Imaging, Ltd., Israel). This testing raised suspicions that the source of her bleeding was from the jejunum. She was subsequently referred to our hospital for further diagnosis and treatment.

Since the lesion in this patient was located in the jejunum, antegrade DBE (Fujinon EN-450T5/W, Fujinon Corp., Saitama, Japan) was performed under intravenous propofol anesthesia. As a result, a collection of blood was observed at 10 cm distal to the ligament of Treitz, and a 20 mm × 10 mm white to yellowish, elongated, pedunculated jejunal polyp with erosions was identified (Figure 1). The DBE was advanced as far as possible to examine the distal jejunum and ileum, but no other source of bleeding was evident. After the placement of two hemoclips at the polyp base, EP was performed (Figure 2). The total time taken to perform the examinations and treatment, including the examination of the distal jejunum and the EP procedure, was 90 min. Surgery was completed without complications. Subsequent histopathological examination of the resected polyp revealed clusters of lymphatic vessels with marked cystic dilatation in the submucosa and in the deep layer of the lamina propria mucosae (Figure 3). These findings were consistent with the typical features of small-bowel lymphangioma with erosions. Following treatment, re-bleeding occurred twice at one and two months post-surgery. An antegrade DBE revealed that this occurred from the polypectomy site on both occasions. Hemoclipping and APC, after a submucosal saline injection to prevent perforation, were performed to achieve hemostasis at each instance of bleeding (Figure 4). No subsequent progression of anemia or recurrence of melena was observed in the patient.

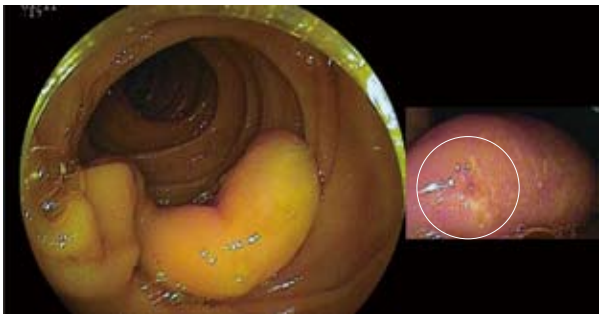

Figure 1 A 20 mm × 10 mm, white to yellowish, elongated, pedunculated jejunal polyp with erosions was detected in the patient following a double balloon enteroscopy.

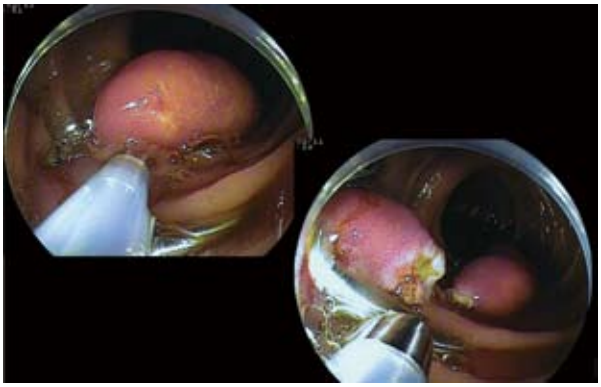

Figure 2 An endoscopic polypectomy was performed after the placement of two hemoclips at the polyp base.

DISCUSSION

Small-bowel lymphangiomas are commonly asymptomatic, but sometimes present with symptoms such as GI bleeding, abdominal pain, intussusception, and protein-losing gastroenteropathy[1,2]. Only 15 cases, including our current patient, of small-bowel lymphangioma with GI bleeding have been reported since 1967[1,3-9]. Of these, five individuals including our present case were diagnosed using DBE from 2007 onward[4-6]. The form of small-bowel lymphangioma revealed in the four previous cases was either a circumferential polyp with adjacent intestinal wall thickening or a flat or sessile polyp. The pedunculated polyp identified in our present case is therefore an extremely rare finding for a small-bowel lymphangioma.

Two reported patients, including the current case, have been treated endoscopically using DBE. Li *et al*[5] reported the treatment of a flat, hemorrhagic lesion by APC after a submucosal epinephrine injection to stop an occurrence of bleeding, thereby achieving complete hemostasis. However, as our present patient had a pedunculated polypoid lesion, EP was first performed by additional hemoclipping. However, re-bleeding occurred in our case, and hemostasis was finally achieved by APC. In

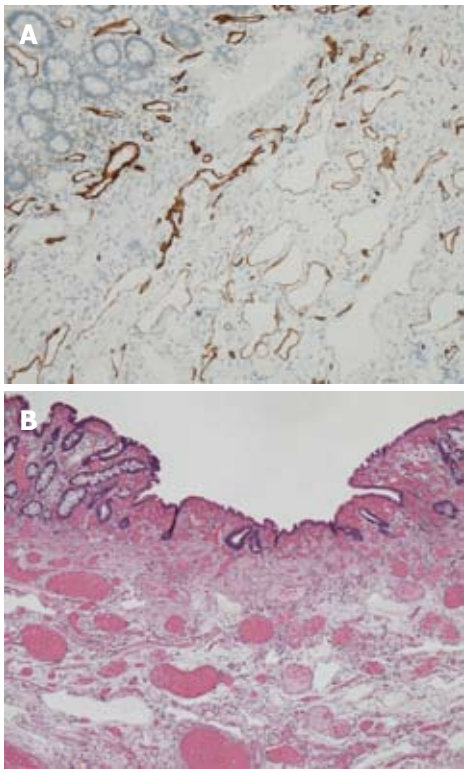

Figure 3 Histological view of the tumor revealing clusters of lymphatic vessels with a marked cystic dilatation in the submucosa and deep layer of the lamina propria mucosae. A: Staining was performed with D2-40; B: Staining was performed with hematoxylin and eosin. These characteristics are consistent with the typical features of small-bowel lymphangioma with erosions.

terms of the cause of this re-bleeding, we speculate that a residual lymphangioma was present at the polypectomy site. Another previous case report has described a giant pedunculated angiolipofibroma of the distal duodenum for which EP was performed using an endoloop[10]. In this case, re-bleeding did not occur, but it was not certain from this that complete *en bloc* resection could be achieved by EP using an endoloop in cases of small-bowel lymphangioma.

We conclude from our present analysis that in cases of small-bowel lymphangioma causing GI bleeding, DBE therapy with a combination of EP, hemoclipping, and APC, would likely be beneficial approaches to treatment.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

We acknowledge our sincere thanks to our reviewers. Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of our World Series Journals. Both the editors of the journals and authors of the manuscripts submitted to the journals are grateful to the following reviewers for reviewing the articles (either published or rejected) over the past period of time.

Salvatore Auricchio, MD, PhD, Professor, Scientific Director of European Laboratory for the Investigation of Food-Induced Diseases, University Federico II, Via S. Pansini 5, I-80131 Naples, Italy

Roberto Bergamaschi, MD, PhD, FRCS, FASCRS, FACS, Professor, Chief, Division of Colon and Rectal Surgery, State University of New York, Stony Brook, NY 11794-8191, United States

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/1007-9327office/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of Gastroenterology

A peer-reviewed, online, open-access journal of gastroenterology and hepatology

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1352 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 64 countries, including Albania (1), Argentina (8), Australia (33), Austria (15), Belgium (14), Brazil (13), Brunei Darussalam (1), Bulgaria (2), Canada (21), Chile (3), China (82), Colombia (1), Croatia (2), Cuba (1), Czech (6), Denmark (9), Ecuador (1), Egypt (4), Estonia (2), Finland (8), France (29), Germany (87), Greece (22), Hungary (11), India (32), Indonesia (2), Iran (10), Ireland (6), Israel (13), Italy (124), Japan (140), Jordan (2), Kuwait (1), Lebanon (4), Lithuania (2), Malaysia (1), Mexico (11), Morocco (1), Moldova (1), Netherlands (32), New Zealand (2), Norway (13), Pakistan (2), Poland (11), Portugal (6), Romania (4), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (11), Slovenia (1), South Africa (3), South Korea (46), Spain (43), Sri Lanka (1), Sweden (17), Switzerland (12), Thailand (1), Trinidad and Tobago (1), Turkey (30), United Arab Emirates (2), United Kingdom (95), United States (285), and Uruguay (1).

Abstract

Biliary cysts (BC) are rare dilatations of different parts of a biliary tract. They account for approximately 1% of all benign biliary diseases. BC occur the most frequently in Asian and female populations. They are an important problem for pediatricians, gastroenterologists, radiologists and surgeons. Clinical presentation and management depend on the BC type. Cholangiocarcinoma is the most serious and dangerous BC complication. The other complications associated with BC involve cholelithiasis and hepatolithiasis, cholangitis, acute and chronic pancreatitis, portal hypertension, liver fibrosis and secondary liver cirrhosis and spontaneous cyst perforation. Different BC classifications have been described in the literature. Todani classification dividing BC into five types is the most useful in clinical practice. The early diagnosis and proper treatment are very important, because BC are associated with a risk of carcinogenesis. A malignancy risk increases with the age. Radiological investigations (ultrasonography, computed tomography, endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography) play an important role in BC diagnostics. Currently, prenatal diagnosis using ultrasonography is possible. It allows to differentiate biliary disorders in fetals and to perform the early surgical treatment that improves results. In most patients, total cyst excision with Roux-Y hepaticojejunostomy is the treatment of choice. Surgical treatment of BC is associated with high success rate and low morbidity and mortality. The early treatment is associated with a lower number of complications. Patients following BC surgery require permanent and careful postoperative observation using laboratory and imaging investigations because of possibility of biliary anastomosis stricture and biliary cancer in tissue remnant.

INTRODUCTION

Biliary cysts (BC) are rare dilatations of different parts of a biliary tract. They account for approximately 1% of all benign biliary diseases. BC occur the most commonly in Asian populations and in females (with a female:male ratio of 3-4:1). Incidence of this pathology in Asian populations is 1:1000 and it is lower in western countries (1:100 000 to 1:150 000)[1-6]. They are usually a surgical problem of infancy or childhood; however in approximately 20% of cases they are recognized in adults[2]. The early diagnosis and proper treatment are very important, because BC are associated with a risk of carcinogenesis. According to the literature, biliary tract malignancy occurs in 2.5%-28% of patients with BC[3,4]. The risk of biliary cancer increases with the age. It is the lowest in the childhood in the first decade (< 1%)[6]. In the third decade the cancer

risk is > 10%[7,8]. According to the literature, cholangiocarcinoma is reported the most frequently at the age of 32 years in patients with BC (about 20 years earlier than in general population)[7]. There are reports of cholangiocarcinoma developing in adult many years after radical BC resection in infant[9]. Cholangiocarcinoma is the most serious and dangerous BC complication. The other complications associated with BC involve cholelithiasis and hepatolithiasis, cholangitis, acute and chronic pancreatitis, portal hypertension, liver fibrosis and secondary liver cirrhosis and spontaneous cyst perforation[8-12]. Nicholl *et al*[9] noted a higher number of complications in adults compared to children. Therefore, BC constitute an important problem for pediatricians, gastroenterologists, radiologists and surgeons. The role of pediatricians and gastroenterologists is a proper early diagnosis. Radiological investigations play an important role in BC diagnostics. Currently, the prenatal BC diagnosis using ultrasonography (USG) is possible[6,13,14].

Surgery is the treatment of BC. The goal of surgical treatment is to remove a cyst and to reconstruct the proper bile flow to the alimentary tract. In order to achieve this goal, different techniques are used. Roux-Y hepaticojejunostomy is the method of choice in most patients with BC[5-22].

ETIOLOGY AND PATHOGENESIS OF BC
