Abstract

Gastric cancer is the second most common cancer worldwide and the second most common cause of cancer-related deaths. Despite complete resection of gastric cancer and lymph node dissection, as well as improvements in chemotherapy and radiotherapy, there are still 700 000 gastric cancer-related deaths per year worldwide and more than 80% of patients with advanced gastric cancer die of the disease or recurrent disease within 1 year after diagnosis. None of the treatment modalities we have been applying today can influence the overall survival rates: at present, the overall 5-year relative survival rate for gastric cancer is about 28%. Cellular metaplasia due to chronic inflammation, injury and repair are the most documented processes for neoplasia. It appears that chronic inflammation stimulates tumor development and plays a critical role in initiating, sustaining and advancing tumor growth. It is also evident that not all inflammation is tumorigenic. Additional mutations can be acquired, and this leads to the cancer cell gaining a further growth advantage and acquiring a more malignant phenotype. Intestinalization of gastric units, which is called "intestinal metaplasia"; phenotypic antralization of fundic units, which is called "spasmolytic polypeptide-expressing metaplasia"; and the development directly from the stem/progenitor cell zone are three pathways that have been described for gastric carcinogenesis. Also, an important factor for the development of gastrointestinal cancers is peritumoral stroma. However, the initiating cellular event in gastric metaplasia is still controversial. Understanding gastric carcinogenesis and its precursor lesions has been under intense investigation, and our paper attempts to highlight recent progress in this field of cancer research.

GASTRIC CARCINOMA

Cancer is a major public health problem and at the beginning of the 19th century, gastric cancer was the second most common cancer worldwide[1]. Every year there are 900 000 new cases and 700 000 gastric cancer-related deaths in the world[2]. Although chemotherapy improves life expectancy, and despite seemingly complete resection of gastric cancer (R0) *via* gastrectomy, more than 80% of patients with advanced gastric cancer die of the disease or recurrent disease within 1 year after diagnosis. This situation suggests that standard treatment protocols are ineffective in a considerable number of cases[3]. Thus, the understanding of the mechanism underlying the progression of gastric carcinoma is essential for the management of this disease.

RISK FACTORS

A number of risk factors are known for gastric cancer (Table 1), but study results regarding some factors, especially salt intake, vitamin C, alcohol, occupational exposure to nitrosamines and inorganic dusts, have been inconsistent[4-9].

HISTOLOGY AND PATHOLOGY

The majority of gastric cancer patients have adenocarcinoma (90%); the remaining 10% have lymphoma or gastrointestinal stromal tumor. There are two general types of gastric adenocarcinoma: the intestinal type (50%) and the diffuse type (33%) according to the Lauren classification system[9]. The remaining 17% are mixed or unclassified type[10]. The intestinal type is more common and is more often located in the distal part of the stomach. In contrast, the diffuse type has a poorer prognosis; generally occurs in younger patients; and can occur anywhere in the stomach, but especially in the cardia. The intestinal type is frequently accompanied by liver metastasis, whereas because the diffuse type has an increased propensity for intra- and trans-mural spread, it has been associated with peritoneal dissemination and poorer prognosis[1]. The diffuse type of gastric cancer shows more poorly differentiated cells than the intestinal type[11]. Intestinal-type adenocarcinoma is preceded by metaplastic changes, whereas diffuse-type adenocarcinoma is thought to arise in normal gastric mucosa.

Gastric adenocarcinoma can also be divided into two groups, known as "differentiated" and "undifferentiated", using the Nakamura classification system[12]. Intestinal-type adenocarcinoma is considered to be essentially equivalent to differentiated adenocarcinoma, as is diffuse-type equivalent to the undifferentiated adenocarcinoma. However, some cases of intestinal-type adenocarcinoma also arise from the gastric mucosa without intestinal metaplasia (IM). So based on the type of IM, some authors suggest that gastric cancer phenotypes can be classified into four groups depending on the marker combinations as: complete intestinal type, incomplete intestinal type, gastric type and unclassified type. Gastric-type differentiated adenocarcinomas can be distinguished from other types of differentiated adenocarcinomas on the basis of their increased malignant potential in the incipient phase of invasion and metastasis[13].

The mucous epithelium of the stomach represents a major barrier to the various noxious agents by means of intercellular tight junctions. This epithelium and its components are also vital for complex communications and physiological functions[14]. Histologically, the human gastric mucosa is divided into three regions: cardia, fundus-corpus and antrum-pylorus. Also, a transitional zone separates the stereotypic corpus and antral/pyloric epithelia and has features of each. The epithelium of these regions is composed of millions of glands that are surrounded by supporting stromal cells which are derived from mesenchyme. In the corpus, glands are long and composed of several epithelial cell types, including surface mucous foveolar cells (pit cells), acid-making oxyntic (parietal) cells, mucous neck cells (intermediate progenitor for chief cells), zymogenic (chief) cells, and hormone-secreting endocrine cells. In the antrum, the shorter glands are composed mainly of mucus-secreting cells and endocrine cells that secrete hormones such as gastrin and somatostatin. The stomach mesenchymal compartment surrounding the glands is less studied and little understood[15-18].

The human stomach mucosal tubular glands are further subdivided into foveolus, isthmus, neck and base regions. The gastric glands open into the bottom of the pits, on an average with 4 to 5 glands per pit. Fundic glands are quite straight, whereas antral glands are branched and coiled in their basal ends. Fundic and antral units (combination of a pit and a gland) differ very much in their cell characteristics and turnover rates (the human antral mucosa is known to have a much higher turnover rate). The gastric glands which contain 'surface mucous' cells and "mucous neck" cells (in the foveola), pepsinogen-secreting zymogenic (chief) cells (at the base of the glands), acid-secreting oxyntic (parietal) cells (at the base of the glands), and endocrine cells including the histamine-producing enterochromaffin-like (ECL) cells are located in the fundus; the zymogenic (chief) cells, oxyntic (parietal) cells and ECL cells are also found in the corpus of the stomach. The antral unit contains surface mucous foveolar cells, antral gland cells, endocrine cells (mainly gastrin-producing G-cells, but also EC and somatostatin-producing D cells), and occasional oxyntic cells. In the pylorus, the gastric glands contain many more mucinous cells, no zymogenic cells and few oxyntic cells (Figure 1)[19-23].

In addition, it should be noted that the subepithelial mesenchymal cells and their secreted basement membrane factors compose the lamina propria. This constitutes a structural support while regulating epithelial cell function and epithelial cell networks[24,25].

MOLECULAR TARGETS AND SIGNALING PATHWAYS

Some of the earliest observations in cancer biology as well as recent advances in molecular analyses contribute to our knowledge about the multistep process of gastric carcinogenesis[26-28].

The gastrointestinal tract has rapid epithelial turnover and exposure to injury by infections and dietary toxins. These conditions create very high cancer prevalence. Intestinalization of gastric units, which is called "IM"; phenotypic antralization of fundic units, which is called "spasmolytic polypeptide-expressing metaplasia (SPEM)"; and the development directly from the stem/progenitor cell zone, are three pathways that have been described for gastric carcinogenesis[29-31].

Neoplasia can follow cellular metaplasia due to chronic inflammation, injury and repair[32]. This is the most documented process for gastric cancer[33-35]. An accept-

Table 1 Risk factors for gastric cancer

Genetic factors	Environmental factors	Other factors
Sex	*Helicobacter pylori*	Gastric adenomas
Familial adenomatous polyposis	Epstein-Barr virus	Barrett's esophagus
Hereditary nonpolyposis colorectal cancer (Lynch Ⅱ)	Nitrites	Hamartomas
Genetic diffuse gastric cancer (E-cadherin - CDH1 mutation)	Excess alcohol ingestion	Ménétrier's disease
Genetic polymorphisms for pro- and anti-inflammatory cytokines	High intake of salted, pickled, or smoked foods	Chronic atrophic gastritis
Polymorphisms for cell receptors of innate immune response	Low intake of fiber, fruits and vegetables	Gastric metaplasia
Peutz-Jeghers syndrome	Antioxidant consumption (especially ascorbic acid, carotenoids, folates and tocopherols)	Pernicious anemia
	Tobacco smoking (adenocarcinoma of cardia)	Benign gastric ulcers
		Fundic gland polyps
		Hyperplastic polyps
		Gastric biopsy revealing high-grade dysplasia
		History of subtotal gastrectomy (> 20 yr)

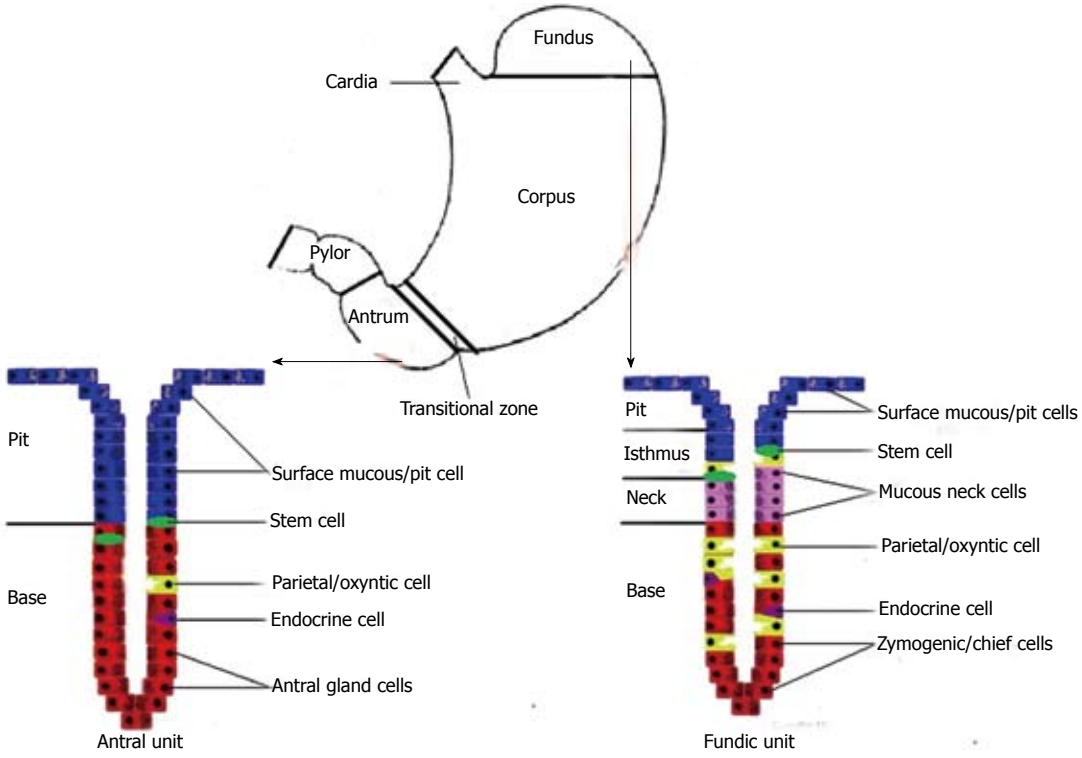

Figure 1 Schematic explanation of fundic and antral units.

able concept is that there are two corner-stones with regard to this process. Firstly, the initial observation of Rudolf Virchow in 1863 about leucocytes in neoplastic tissues and the connection between inflammation and cancer[36]; secondly, about 15 years ago, researchers' evidence about the relationship between stomach cancer and infection by *Helicobacter pylori* (*H. pylori*) (isolated by Drs. Marshall and Warren in 1984[37]. Also, we must note that Epstein-Barr virus has been detected in stomach tissues in approximately 10% of gastric carcinoma cases[38].

Beginning with some of the earliest observations in cancer biology, it appears that chronic inflammation stimulates tumor development and plays a critical role in initiating, sustaining and advancing tumor growth[39,40]. Direct effect of the viral pathogens on neoplastic transformation of epithelial cells has been shown; however, it is also evident that not all inflammation is tumorigenic[41]. It can be suggested that either the tumor alters the immune response by reactive oxygen species and cytokines or chronic inflammation plays a primary role in transforming tissue cells (especially mentioned in "stem cell theory") into tumor cells. In the acute phase of inflammation, the release of endogenous reactive oxygen and nitrogen species (O_2^-, H_2O_2, NO, OH, $ONOO^-$, HOCl) from such innate immune cells as macrophages and leukocytes plays an important role in the elimination of

pathogens[42]. However, when present chronically, this can induce DNA damage in proliferating cells. In addition, it is also possible for other bacteria to colonize the stomach and additionally trigger carcinogenesis by gastric atrophy (result of chronic inflammation) which represents a loss of gastric glands and associated lower acidity of gastric juice[43,44]. Hypoacidity associated with *H. pylori* infection induces gastric mucosal atrophy to advance multistage carcinogenesis in the stomach. Interleukin (IL)-1β, IL-6, IL-8, tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) are elevated in gastric mucosa with *H. pylori* infection. Gastrin is upregulated and acid secretion from parietal cells is inhibited mainly due to pro-inflammatory cytokines IL-1β and TNF-α[45,46]. TNF-α and IL-1β are essential in the initiation of chronic inflammation. Recent works have shown that IL-1β overexpression, in the absence of *Helicobacter* infection, is sufficient to cause gastric cancer and it is one of the essential proinflammatory cytokines modulated during *H. pylori* infection that directs the mucosa toward atrophy, metaplasia, and neoplastic transformation[47-49]. Another important point that should be added is that *H. pylori* has been consistently associated with higher risk of gastric noncardia cancer. The inverse association of *H. pylori* with gastric cardia cancer or esophageal adenocarcinoma has been shown in several studies, especially in Western populations[50]. Furthermore, mast cells in particular play an important role in attracting inflammatory cells by releasing inflammatory mediators. Monocytes differentiate into macrophages, and become activated in response to local chemokine and cytokine interactions[51]. Also, the correlation between tumor-associated macrophage abundance and poor prognosis has been shown[52]. Furthermore, macrophage-deficient mice display reduced progression of tumors to a more malignant phenotype[53]. Recently, direct evidence has also linked IL-6 to inflammation-mediated tumor initiation and proliferation in colon cancer[54]. IL-6 can inhibit dendritic cell maturation and, together with the NF-κB-activating cytokines IL-1 and TNF, can promote tumor progression. Cytokines also affect cell death and cell cycle pathways[55,56]. TNF-α is produced mainly by macrophages. It is also produced by tumor cells. TNF-α is associated with tissue destruction and plays a role in destroying tumor blood supply. However, if it is produced chronically, it can act as a tumor promoter by contributing to tissue remodeling and stromal development[57,58]. Nuclear factor (NF)-κB and STAT3 pathways have emerged as key regulators of the release of these pro-inflammatory cytokines, and important mediators of both tumor proliferation and persistence of chronic inflammation. The activation of these pathways results in further cytokine release[57,59,60].

Activation of the innate immune system is followed by the adaptive immune response. Th1 response and its accompanying mediators (IFN-γ) are not only necessary for *Helicobacter*-induced inflammation but also for the development of atrophy or metaplasia and SPEM; however a Th2 response and its mediators (i.e., IL-4) appear to be protective. The presence of a Th1, rather than a Th2, immune response is also associated with better survival in gastric cancer patients[36].

Although the subsequent pathways are different, chronic inflammation is the first step in both the intestinal and the diffuse type of gastric cancer. While the intestinal type has a sequence of multifocal atrophic gastritis, IM and dysplasia, which advances to carcinoma, the diffuse type tends to be primarily genetic in origin[61,62]. The progress from IM to gastric cancer has a wide range of molecular alterations affecting transcription factors, such as CDX1 and CDX2, telomerases, microsatellite instability, mutations of p53 protein, overexpression of COX-2, cyclin D2, and decreased expression of p27[63]. The next step is gastric dysplasia. During the progression of normal tissue through the metaplasia-dysplasia sequence, there are mutations in genes including *p53*, also loss of heterozygosity of the adenomatous polyposis coli gene, overexpression of the antiapoptotic gene *bcl-2* and a mixture of polyploidy and aneuploidy[63].

Inflammation also plays an important role in the ability of tumor cells to invade and metastasize. The ability of epithelial tumor cells which metastasize to express specific chemokine receptors has been shown[64]. Paracrine secretion of pro-inflammatory cytokines (i.e., IL-1β, IL-6, TNF-α) and certain autocrine cytokine production support this process[65]. During the later stages, additional mutations can be acquired, and this leads to the cancer cell gaining a further growth advantage and acquiring a more malignant phenotype[66,67].

THERAPEUTICS AND OUTCOME

In recent studies investigators have found out that *K-ras* activation resulted in an inflammatory response and enhanced the expression of COX-2 in the glandular stomach. COX2 is upregulated in the gastric epithelium and in the infiltrating inflammatory cells in the stomach during gastritis[68-70]. Furthermore, it has been shown that sulindac, a nonsteroidal anti-inflammatory drug, suppresses the progression of gastric cancer in mice[71]. Hence, a *K-ras* activation-induced inflammatory response may facilitate the formation of IM and promote the progression of gastric cancer.

SPEM is associated more commonly with gastric cancer than IM[72,73]. It can be defined as a corpus lesion. Nevertheless, IM and SPEM often occur together[74,75]. Increase in mucus and loss of mature parietal and chief cells in humans correlates with SPEM (Figure 2)[73]. SPEM is characterized by expression of TFF2 (spasmolytic polypeptide) which is normally a product of mucous neck cells and antral gland cells[72]. SPEM also arises from a second proliferative zone at the bases of metaplastic fundic units, either by transdifferentiation of chief cells or activation of an unknown basal crypt progenitor[76,77]. However, it is not clear whether these cells are related to the gastric progenitor cells[78].

It must be noted that an important factor for the development of gastrointestinal cancers is peritumoral stro-

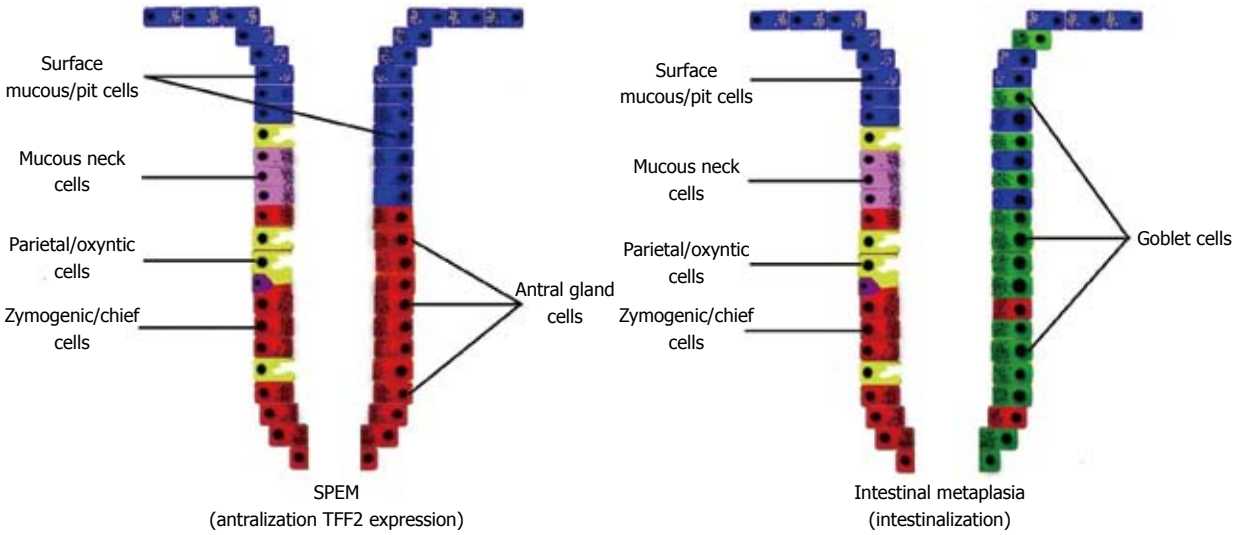

Figure 2 Schematic explanation of spasmolytic polypeptide-expressing metaplasia and intestinal metaplasia. SPEM: Spasmolytic polypeptide-expressing metaplasia; TFF-2: Trefoil family factor 2.

ma. Activated fibroblasts within the stroma can help to create an environment containing vessels and infiltrating inflammatory cells and it is the interaction between these different cell types which is permissive of tumor growth, angiogenesis, and invasion[79-81].

The question that must be answered is: what is the initiating cellular event in gastric metaplasia? The interpretation that the metaplasia is an intermediate step in the development of gastric cancer may be facile, because different types of IM have different degrees of association with malignancy, and early stage gastric cancers can arise in nonintestinalized epithelium[82-84]. Investigators have reported that solid cancers might originate from differentiated cells and they have reported the possible existence of cancer stem cells (CSCs) or tumor initiating cells in solid malignant tumors[85,86]. However, based on the assessment of the differentiation status of tumor cells, they appear to deviate little from their normal progenitors and to show similar differentiation programs. Studies on tissues undergoing continuous cell renewal suggest that cancer cells may originate from a stem cell compartment[87]. The origin of human gastric CSCs has yet to be elucidated, but data obtained from a mouse model of *Helicobacter*-induced gastric cancer have implicated bone marrow-derived cells as a potential candidate. Further studies focusing on the identification and characterization of CSCs in gastric cancer may lead to novel diagnostic and therapeutic tools, dramatically improving the prognosis of gastric cancer patients.

Abstract

The *KRAS* oncogene is mutated in approximately 35%-45% of colorectal cancers, and *KRAS* mutational status testing has been highlighted in recent years. The most frequent mutations in this gene, point substitutions in codons 12 and 13, were validated as negative predictors of response to anti-epidermal growth factor receptor antibodies. Therefore, determining the *KRAS* mutational status of tumor samples has become an essential tool for managing patients with colorectal cancers. Currently, a variety of detection methods have been established to analyze the mutation status in the key regions of the *KRAS* gene; however, several challenges remain related to standardized and uniform testing, including the selection of tumor samples, tumor sample processing and optimal testing methods. Moreover, new testing strategies, in combination with the mutation analysis of *BRAF*, *PIK3CA* and loss of *PTEN* proposed by many researchers and pathologists, should be promoted. In addition, we recommend that microsatellite instability, a prognostic factor, be added to the abovementioned concomitant analysis. This review provides an overview of KRAS biology and the recent advances in *KRAS* mutation testing. This review also addresses other aspects of status testing for determining the appropriate treatment and offers insight into the potential drawbacks of mutational testing.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers worldwide. In the United States, approximately 102 900 cases of colon cancer and 39 670 cases of rectal cancer were diagnosed in 2010, and approximately 51 370 patients died of CRC in the same year, accounting for about 9% of all cancer deaths[1]. With the emergence of two anti-epidermal growth factor receptor (EGFR)-targeted antibodies, cetuximab (Erbitux) and panitumumab (Vectibix), the treatment of metastatic CRC has entered into the era of personalized treatment. Of the two antibodies, one is a human-mouse chimeric IgG1 monoclonal that was approved by the United States Food and Drug Administration (FDA) in 2004 as a second-line treatment of CRC; the other is a human IgG2 k monoclonal antibody that was approved by the FDA as a third-line drug in 2007. However, EGFR, the target of these drugs, which is overexpressed in approximately 80% of colorectal carcinomas, failed to predict a therapeutic response when used clinically[2,3]. Therefore, downstream signaling effectors were sought to help predict the efficacy of anti-EGFR treatment. The *KRAS* gene, which has

been extensively studied for more than three decades, has been demonstrated to be a strong negative predictive biomarker to indicate whether a CRC patient will respond to anti-EGFR treatment. As the target treatment may also be toxic and expensive, *KRAS* mutation status detection has become a crucial diagnostic factor for treating metastatic CRC patients.

KRAS GENE AND ITS ROLE IN EGFR SIGNALING

The *RAS* gene was initially identified as a viral gene homologous to the transforming gene from the Kirsten rat sarcoma virus[4,5]. Mutations in *RAS* are found in approximately 30% of all human cancers, making it one of the most commonly mutated genes in cancer[6]. The KRAS protein, also called p21, is a member of the *Ras* superfamily of proteins, is located on human chromosome 12 and encoded by 189 amino acids, and contains four coding exons and a 5' non-coding exon[7]. KRAS is a membrane-anchored guanosine triphosphate/guanosine diphosphate (GTP/GDP)-binding protein and is widely expressed in most human cells. As a small GTPase (GTP cleaving enzyme), KRAS is involved in intracellular signal transduction and mainly responsible for EGFR-signaling activation. The exchange of the active GTP-bound state and the inactive GDP-bound state is tightly controlled by GTPase-activating proteins (GAPs) and guanine nucleotide exchange factors[8]. Under normal physiological conditions, upstream signals activate wild-type *KRAS* by promoting the exchange of bound GDP for GTP. This process is transient because of GAP-mediated GTP hydrolysis. However, this process becomes altered when the *KRAS* gene is mutated.

Mutant *KRAS* is found in about 35%-45% of CRCs[9-15], and codon 12 and 13 are two hotspots, which account for about 95% of all mutation types, with approximately 80% occurring in codon 12 and 15% in codon 13. Other mutations in codons 61, 146 and 154 occur less frequently in CRC, accounting for 5% of all mutation type[16]. Referring to the Catalogue of Somatic Mutations in Cancer Database, more than 5000 mutations have been found in the *KRAS* gene in CRC samples.

KRAS mutations are almost single nucleotide point mutations as reported, and the most common patterns are G12D, G12A, G12R, G12C, G12S, G12V and G13D. In the codon 12 mutation, p.G12D, pG12V is the most frequent, and in codon 13, the substitution of glycine for aspartate (p.G13D) is the most frequent[17].

These mutations impair the intrinsic GTPase activity of KRAS and prevent GAPs from promoting GTP hydrolysis by KRAS, therefore causing KRAS proteins to accumulate in the GTP-bound, active form. In this manner, mutant *KRAS* results in a constitutively active GTP-bound state and the activation of downstream proproliferative signaling pathways[18,19]. Therefore, *KRAS* mutations play a critical role in human tumorigenesis and are the most prevalent in pancreatic, thyroid, colorectal and lung cancers.

SIGNIFICANCE OF *KRAS* MUTATION TESTING

KRAS as a prognostic factor

It has been suggested that prognostic and predictive factors should be clarified; the former (including traditional clinical markers like lymph node involvement, the histological grade of the tumor, and molecular biomarkers, *etc*.) often refers to the outcome of the natural history of the tumor, while the latter predicts the response to the therapies. Until recently, the prognostic value of *KRAS* mutation was in dispute. Two canonical trials have demonstrated that the *KRAS* mutation may be prognostic of treatment outcomes for patients with CRC. The Kisten Ras in Colorectal Cancer Collaborative Group Study (RASCAL study)[20], with 2721 patient samples collected from 13 different nations, indicated that the presence of a *KRAS* mutation increased the risk of recurrence and death, especially in a guanine (G) to thymine (T) mutation. Moreover, the expanded RASCAL Ⅱ study suggested that the prognostic role of the *KRAS* mutation, limited only to a glycine to valine mutation, was found in 8.6% of all patients and had a statistically significant effect on failure-free survival [P = 0.004, hazard ratio (HR) 1.3] and overall survival (OS) (P = 0.008, HR 1.29)[21]. However, in a translational study of PETACC3[22], a randomized phase Ⅲ trial showed that the *KRAS* mutation status does not have major prognostic value in stages Ⅱ and Ⅲ colon cancer. The difference in results may be largely due to the difference in sample size. The results from other trials are also not consistant[23].

KRAS as a predictive factor

Because *KRAS* is the most frequently mutated factor downstream of the EGFR signaling pathway, it was considered a candidate molecular biomarker for anti-EGFR therapy. In 2006, for the first time, the predictive value of *KRAS* was validated in a study by Lièvre *et al*[24] in which the *KRAS*-mutated patients showed no response to cetuximab and had a poorer OS compared with the wild-type *KRAS* patients. Later, a series of single-arm studies confirmed this result[25-29]. Then, not only cetuximab but also panitumumab were demonstrated to only be effective for wild-type *KRAS* patients[30,31]. These trials demonstrated that the outcomes of patients with wild-type *KRAS* were clearly better than those of the *KRAS*-mutant patients, although these were all retrospective analyses. The publication of two large, multicenter, randomized phase Ⅲ clinical trials unequivocally demonstrated the predictive value of *KRAS* for anti-EGFR therapy (Table 1). In these two trials, panitumumab or cetuximab *vs* best supportive care (BSC) was given to patients with chemorefractory CRC compared with BSC alone. Amado *et al*[10] demonstrated that the response rate of panitumumab was 17% and 0% for the wild-type *KRAS* group and the mutant group, respectively (P < 0.0001). In addition, when combined with chemotherapy [5-fluorouracil, leucovorin and irinotecan (FOLFIRI) or 5-fluorouracil, leucovorin and oxaliplatin], anti-EGFR

Douillard *et al*[14], 2010	Panitumumab + FOLFOX FOLFOX	First-line	III	1096	40	Allele-specific PCR (DxS, United Kingdom)	Significantly improved PFS in patients with WT KRAS tumors
Van Cutsem *et al*[15], 2011	Cetuximab + FOLFIRI, FOLFIRI	First-line	III	1063	37	PCR clamping and HRM (TIB MolBioL, Germany)	Significantly improved OS in patients with WT KRAS tumors

BSC: Best supportive care; WT: Wild type; ORR: Overall response rate; FOLFIRI: 5-fluorouracil, leucovorin and irinotecan; FOLFOX: 5-fluorouracil, leucovorin and oxaliplatin; PFS: Progression-free survival; OS: Overall survival; PCR: Polymerase chain reaction; HRM: High-resolution melting.

antibodies (cetuximab or panitumumab)-treated patients had a better response rate and progression-free survival (PFS) or OS alone in the wild-type *KRAS* group, regardless of the treatment line[11-15]. Recently, better OS (median, 23.5 mo *vs* 20.0 mo; HR 0.796, $P = 0.0093$) was found in the cetuximab plus FOLFIRI-treated wild-type *KRAS* patients compared with the FOLFIRI-treated KRAS-mutated patients[15]. According to a recent meta-analysis of 11 studies conducted between 1966 and 2010[32], the *KRAS* status and the adding of anti-EGFR antibodies to standard chemotherapy were closely related to PFS [95% confidence interval (CI): 57%-90%, $P = 0.005$] and response rate (95% CI: 8.22%, $P < 0.001$).

On the basis of these results, National Comprehensive Cancer Network (NCCN), American Society of Clinical Oncology (ASCO) and European Medicines Evaluation Agency recommended testing for *KRAS* gene mutations in advanced CRC patients. The NCCN added *KRAS* testing to their 2009 clinical practice guidelines for colon and rectal cancers[33,34] and stipulated that only patients with wild-type (normal) *KRAS* genes should receive treatment with cetuximab (Erbitux) or panitumumab (Vectibix). The ASCO, in the same year, proposed a provisional clinical opinion (PCO)[35] demonstrating that testing for *KRAS* mutations should be performed prior to anti-EGFR monoclonal antibody therapy and that patients with KRAS mutations in either codon 12 or 13 should not receive this therapy as part of their treatment. This recommendation is slightly different from the NCCN guideline because the use of anti-EGFR therapy in the *KRAS*-mutated patients may be toxic.

KRAS TESTING STATUS

Frequency of testing

In a recent three cross-sectional survey performed in Europe, Latin America and Asia[36], physicians completed questionnaires on four patients per year. An analysis of 3800 samples per year showed that the *KRAS* testing frequency in metastatic CRC patients increased from 3% in 2008 to 47% in 2009 and 69% in 2010. It appears that the importance of *KRAS* mutation testing has become progressively understood by physicians and oncologists. Because implementation of the testing in the clinical practice has begun, it is essential to identify testing performance, as there are no set criteria for the process of *KRAS* detection, i.e., the selection of tissue specimens, specimen preparation, the timing of testing and the best method.

External quality assessment

A *KRAS* external quality assessment protocol was established in 59 laboratories throughout eight different European countries[37]. In the first assessment round, the results were unsatisfactory. The samples, including unstained sections of 10 invasive CRC with a known *KRAS* mutation status, were tested by each laboratory using their own preferred method for histological evaluation, DNA isolation, and mutation analysis. The test results were centrally validated by one of two reference laboratories. Only 70% of the laboratories correctly identified the *KRAS* mutational status in all samples, and the reports often lacked essential information. In another quality assessment for *KRAS* testing in Italy, five CRC specimens with known *KRAS* mutations were sent to be tested in 59 centers[38]. The limit to pass the assessment was set at 100% true responses. Only two centers failed in both the first round and the second round of testing. In Canada, until recently, there has been no such quality assessment. However, a guideline was developed according to a Canadian consensus conference held in Montreal in April 2010, in which the expert group provided recommenda-

tions on *KRAS* testing in the treatment of CRC[39]. In the United States, there is currently no FDA-approved standardized test. However, the PCO provided recommendations to the *KRAS* testing clinics. In Asia, there has been no external quality assessment system as yet, and it is critical to fulfill this objective.

Mutation status

As reported in 2011, the *KRAS* mutation frequencies in Asia, Europe, Latin American were 24%, 36% and 40%, respectively ($P < 0.0001$)[36]. It is unclear why a lower incidence is observed in Asian patients. In China, *KRAS* mutations were detected in 33.3% (30/90) of the CRC tumor samples using the nucleotide sequence analysis method[40]. These results significantly correlated with the response rate and survival time of cetuximab-treated patients. The difference of mutation status may result from many aspects, such as the tissue, the percent of tumor cells, the extracted DNA quality, the testing methods and the testing target.

Testing target

Currently, in most of the *KRAS* detection methods, only mutations of codon 12 or 13 are certified as informative for selecting non-responders to the anti-EGFR treatment in large clinical trials[15]. Therefore, mutation analysis of these sites is recommended. However, recent research has revealed new findings. Mutations in exons 3 and 4 are also effective in predicting the efficacy of EGFR-antibodies[41,42]. Codon 61 was found to account for 2% of all *KRAS* mutations and, similar to some of the codon 12 mutations, had predictive value[43]. Therefore, codon 61 may be useful in *KRAS* mutation testing. In contrast, not all mutations in codon 13 appear to be informative. In a recent analysis, cetuximab surprisingly worked on patients with chemotherapy-refractory CRC with p.G13D-mutated tumors, and these patients have a longer overall and PFS compared with those with the *KRAS*-mutated tumors[44]. Therefore, efforts are still required to confirm the importance of various mutations of the *KRAS* gene.

Sample selection

The most widely used tissue for *KRAS* testing is formalin-fixed paraffin-embedded (FFPE) tissue blocks[45], which are easy to obtain and convenient to preserve. However, DNA extracted from FFPE is time consuming and may be of poor quality, which can also result in false-positive or false-negative results due to an incomplete tissue fixation or tissue overfixation. Another specimen type is frozen tissue. Studies that compared the mutation detection rates in frozen and FFPE samples from the same tissue have found that the mutation rate in frozen samples is higher than that detected in FFPE samples[46]. The use of frozen tissue is suggested to be the gold standard for analysis, but the associated expense and technical difficulty of using frozen tissue make this method unsuitable for routine testing. In contrast, a high concordance was observed between primary tumors and metastatic locations (91.7%-96.4%)[47-49]. Therefore, the *KRAS* status in a primary site can be used for selecting patients who would benefit from anti-EGFR therapy. However, *KRAS* status can be heterogeneous within a primary tumor, and thus, different parts of such tumors should be examined to accurately predict the *KRAS* status in metastatic lesions.

Beyond the selection of tissue, other choices, such as peripheral blood, have been studied. Yen *et al*[50] detected circulating tumor cells with *KRAS* oncogenes using membrane arrays; *KRAS* mutations were identified in 39.5% (30/76) of peripheral blood samples, which is similar to that in tumors (43.4%). According to a review concerning the validation of *KRAS* mutation testing in CRC blood samples which summarizes the studies that detect *KRAS* status using tissue or plasma/serum[51], a positive *KRAS* mutation in plasma or serum suggests a *KRAS* mutation in the tumor whereas the absence of a *KRAS* mutation in the plasma or serum does not necessarily prove a lack of a similar mutation in the CRC tumor tissue. Further studies are needed in this field.

Methods

A number of methods can be used in *KRAS* mutation testing, with different sensitivity, turnaround time, and cost. In the NCCN guideline or ASCO PCO, no explicit method was assigned. Therefore, the use of assays worldwide is somewhat chaotic. In the Italian quality assessment for *KRAS* testing[38], five CRC specimens were sent to 59 centers, which were asked to use their own preferred method for DNA extraction and mutational analysis. Of these 59 centers, polymerase chain reaction (PCR) sequencing was the predominant method for mutational analysis, as 48 (81.3%) centers used this methodology. Among the remaining centers, 5 centers (8.5%) used pyrosequencing, 3 centers (5.1%) used Real-Time PCR (Therascreen kit), 2 centers (3.4%) used restriction fragment length polymorphism (RFLP) analysis and 1 center (1.7%) used the KRAS strip assay. In the United States, the amplification refractory mutation system was used by most laboratories[52].

The traditional methods used for mutation testing are hybridization and DNA sequencing. These methods are complex and time consuming. The emergence of polymerase chain reaction (PCR) sheds new light on this field. Currently, mutation testing methods are almost exclusively based on this technology, including PCR-based sequencing, high resolution melting analysis (HRMA), amplification refractory mutation system (ARMS), and cleaved amplification polymorphism sequence-tagged sites (PCR-RFLP).

Among these methods, DNA sequencing, also called Sanger sequencing or dideoxy sequencing, is considered the gold standard because this methodology analyzes the DNA sequence nucleotide by nucleotide and can identify all possible mutations in the analyzed *KRAS* gene segment, including base substitutions, insertions and deletions. However, this approach has a low sensitivity of about 20%, and is laborious and time consuming. An alternative approach to this methodology, i.e.,

Table 2 Methods used for *KRAS* mutation testing[45,55,60-62]

Method	Sensitivity (mutant/wild-type) (%)	Turnaround time	Main advantages	Main disadvantages
Sanger sequencing	20–30	Slow (4 d to 2 wk)	Detects all possible mutations, cost-effective	Insensitive, time consuming, open PCR system is easily contaminated
Pyrosequencing	5	Rapid	Detects all possible mutations, sensitive	Open PCR system is easily contaminated
Real-time PCR with HRMA	5	Rapid	Rapid, closed PCR system, detects all possible mutations (heterozygous and homozygous)	Occasionally difficult to distinguish between mutation types
Allele-specific real-time PCR	10	Rapid	Rapid, closed PCR system	Detects only the 7 most common mutations, requires more tissue for analysis compared with other methods
RFLP with sequencing	0.1	Slow (4 d to 2 wk)	Sensitive	Requires confirmation by sequencing, complicated
DxS (ARMS/S)	1	Rapid	Sensitive, time-saving	Expensive, detects specific mutations targeted by the designed primers
COLD-PCR with sequencing	1-2.5	Rapid	Sensitive, cost-effective, detects all possible mutations	-

ARMS: Amplification refractory mutation system; RFLP: Restriction fragment length polymorphism; PCR: Polymerase chain reaction; COLD-PCR: Coamplification at lower denaturation temperature PCR.

pyrosequencing, has a sensitivity proven to be approximately 5%-10% and has commercialized the detection of *KRAS* mutations; corresponding commercial kits, the PyroMark® (Qiagen, Valencia, CA, United States), have been developed[53,54].

Of the non-sequencing methods, ARMS[55], real-time PCR analysis with HRMA[56], RFLP[57] and allele-specific real-time PCR[58], most of which are based on real-time PCR technology, have been well studied in the past three years with Sanger sequencing as the reference, demonstrating the effectiveness and availability of these methods for *KRAS* status testing. A multicenter study[59], which evaluated six different *KRAS* mutation detection methods, including pyrosequencing, HRMA, dideoxy sequencing, and two commercial kits, showed a concordant *KRAS* status in 66/80 (83%) of frozen tissue samples and 71/74 (96%) of paraffin tissues using the five best performing assays. Each of the assays has its advantage and limitations, and as details have been described in previous publications, we have summarized some notable features in Table 2[45,55,60-62]. The HRMA assay, often based on real-time PCR, detects the mutant sequence through measuring changes in the melting of a DNA duplex with the aid of intercalating dyes. This method is fast and sensitive but has been reported to have a false-positive rate of 20%[63]. Therefore, this method requires sequencing confirmation and cannot show the concrete mutation pattern. The allele-specific Real-Time PCR and ARMS can only detect the limited mutation sites of the *KRAS* gene, which makes these methods less feasible in clinical practice. The ARMS-based commercial kit, TheraScreen® (DxS Ltd, Manchester, United Kingdom), however, has been widely used in laboratories[64]. This kit has a real-time PCR-based assay that combines the ARMS with Scorpion probes (seven probes for seven different mutations in *KRAS*), eliminating the need for post-PCR confirmation by direct sequencing, and is thought to be the most sensitive method until recently with a sensitivity of 1%[45].

Recently, more sensitive methods have been utilized in *KRAS* detection. One method is the PCR-clamp assay, and the other is coamplification at lower denaturation temperature PCR (COLD-PCR). The PCR-clamp assay utilizes mutation-specific hybridization probes and another wild-type-complementary peptide nucleic acid probe to suppress the amplification of the normal sequence and can detect less than 1% of the allele[65,66]. A commercial kit (KRAS LightMix) by TIB MolBiol (Berlin) uses this technology and a melting curve analysis and has been used in multicenter, phase Ⅲ clinical trials in which patients were treated with the anti-EGFR antibody, cetuximab[11,12,15]. COLD-PCR is another selective amplifying system that enriches the "minority alleles" from the mixed DNA sequences based on the lower melting temperature of mutant homoduplexes as compared with wild-type ones. Therefore, in COLD-PCR, the denaturation temperature is set at 80 ℃ whereas the denaturation temperature in conventional PCR is approximately 94 ℃. Using this principle, this technology does not require special equipment or reagents or time-consuming procedures. As a sensitive DNA enrichment method, COLD-PCR is often followed with HRMA or pyrosequencing. Mancini *et al*[67] demonstrated that COLD-PCR combined with HRM can improve the limit of detection of *KRAS* and *BRAF* mutations in CRC, increasing the percentage of mutated CRCs from 40% (47/117) to 48.7% (57/117) compared with traditional PCR and direct sequencing. In another study by Zuo *et al*[68], COLD-PCR combined with pyrosequencing detected all the mutations in 50 samples, including DNA extracted from either fresh or FFPE tissue specimens that were confirmed positive by conventional PCR, and the mutation detection sensitivity was certified as 1.5%.

In addition, COLD-PCR combined with HRMA

assay does not require expensive and time-consuming procedures; thus, in clinical settings, this procedure has the potential to be used to select those patients who are eligible for EGFR-targeted therapies.

Our recommendation

Currently, it is accepted that the DNA fragmentation caused by improper fixation, heterogeneous somatic *KRAS* gene mutations, and the influence of stromal cells can cause false-positive *KRAS* mutation testing results. Fortunately, the technique refinements and sufficient tissue selected can reduce this limitation. It is suggested that at least 300 tumor cells or 30 ng of template DNA are required for *KRAS* status analysis. However, the appropriate method to extend to the clinic is still unclear. Molinari *et al*[69] found that highly sensitive methods could improve the accuracy of predictions of anti-EGFR monoclonal antibody efficacy. Therefore, assay sensitivity when detecting *KRAS* mutations is a key issue for correctly analyzing tumor specimens. However, Carotenuto *et al*[70] demonstrated that in samples with more than 30% tumor cells, the DxS assay and PCR-sequencing, which are the most sensitive and non-sensitive methods, respectively, showed no difference in identifying *KRAS* mutations. Therefore, more effective and sensitive methods are required for inconclusive samples and those with a low number of tumor cells. Upon considering the sensitive detection methods, as previously described, pyrosequencing is a new, robust but expensive technology. The DxS assay (ARMS/S) is now widely used in clinical labs but can only detect the seven common mutations, and it is costly. COLD-PCR, which can enrich the mutant alleles, is considered a simple method that increases *KRAS* testing sensitivity. Therefore, we recommend the use of this assay combined with HRM or sequencing for determining *KRAS* status; although, this approach should be validated by further large sample studies.

CONCOMITANT ANALYSIS WITH OTHER FACTORS

Unfortunately, *KRAS* mutations account for approximately 35% of the nonresponsive patients that receive anti-EGFR treatment[35]. Therefore, using *KRAS* as a predictor of clinical outcomes is not always useful. These results have led researchers back to the molecular mechanisms of cetuximab and panitumumab resistance to find other powerful prognostic markers. *BRAF*, which is another member of EGFR signaling cascade, is located downstream of *KRAS* and is considered the most promising marker for predicting anti-EGFR treatment resistance apart from *KRAS* gene. *BRAF* mutations mainly occur at exon 15 with a frequency of approximately 5% to 10% and the common V600E pattern. It is notable that *BRAF* and *KRAS* mutations are mutually exclusive ($P < 10^{-6}$)[71]. Therefore, *BRAF* mutation analysis is recommended when the *KRAS* gene is the wild type. Di Nicolantonio *et al*[72] found in a retrospective study that none of the *BRAF*-mutated patients responded to cetuximab or panitumumab and that none of the responders carried *BRAF* mutations ($P = 0.029$). In addition, *BRAF*-mutated patients had a significantly shorter PFS ($P = 0.011$) and OS ($P < 0.0001$) compared with wild-type patients. On the basis of these results, the NCCN clinical guidelines in 2010 currently recommend *BRAF* mutational status assessment of metastatic CRC patients with a wild-type *KRAS* to guide the therapeutic use of cetuximab and panitumumab.

Apart from the *KRAS* and *BRAF* gene mutations, other genetic aberrations, such as *PIK3CA* and *PTEN*, were demonstrated to be helpful in predicting the resistance to anti-EGFR treatment[40,73]. In addition, many oncologists and pathologists have proposed that combining the analysis of these factors simultaneously will provide a clearer overall prognostic indication for EGFR inhibitor status. The recent data from a retrospective analysis demonstrated that when the loss of *PTEN* expression and mutations of *KRAS*, *BRAF* and *PIK3CA* are concomitantly ascertained, as many as 70% of the metastatic CRC patients can be identified as unlikely to respond to anti-EGFR therapies[74]. Therefore, CRCs lacking alterations in *KRAS*, *BRAF*, *PTEN* and *PIK3CA*, which may have the highest probability of response to anti-EGFR therapies, are defined as "quadruple negative"[74,75].

In addition, in a retrospective consortium analysis[43], the largest series to date according to our knowledge, the effects of *KRAS*, *BRAF*, *NRAS* and *PIK3CA* mutations on the efficacy of cetuximab plus chemotherapy in chemotherapy-refractory metastatic colorectal was studied. In total, 1022 tumor DNA samples were tested, of which 40.0% (299/747) harbored a *KRAS* mutation, 14.5% had a *PIK3CA* mutation, 4.7% had a *BRAF* mutation, and 2.64% *NRAS* mutation, and carriers of the four mutations had a lower response rate to the cetuximab plus chemotherapy treatment compared with those lacking any of the four mutations. A multivariate analysis also confirmed that if *KRAS* is unmutated, assessing the *BRAF*, *NRAS*, and *PIK3CA* exon 20 mutations provides additional information about patient outcomes. It is notable that while *NRAS* accounts for only 2.64% of these molecular alterations, this mutation is associated with unresponsiveness to panitumumab treatment.

It is obvious that *KRAS* mutational status analysis is insufficient for predicting the efficacy of anti-EGFR therapy, and adding the concomitant analysis of downstream factors can be helpful in selecting the correct patient for this personal treatment. In addition, we suggest that microsatellite inestability (MSI) be added to this concomitant analysis.

Microsatellite instability, defined as small deletions or expansions within short tandem repeats in tumor DNA resulted from the inactivation of the DNA mismatch repair system, has been found in up to 90% of the tumors of the hereditary nonpolyposis CRC and in approximately 20% of sporadic colorectal tumors[76,77]. Using a panel of 5 microsatellites recommended by the National

Cancer Institute, i.e., BAT 25 and BAT 26 (mononucleotide repeats), D2S123, D5S346 and D17S250 (dinucleotide repeats), CRC tumors are classified as MSI-high (MSI-H), MSI-low (MSI-L) and microsatellite stability (MSS), and the MSI-H was thought to indicate a more favorable prognosis[78]. However, with regard to predicting therapy response, the role of MSI is conflicting. Recently, some researchers have combined *KRAS* and MSI in their study[79] and found that both genes are prognostic of CRC. In another study[80], the combined analysis of specific *KRAS* and *BRAF* mutations, and microsatellite instability were used to identify prognostic subgroups of sporadic and hereditary CRC. As the result, 3 distinct prognostic subgroups were observed in univariate (P = 0.006) and multivariable (P = 0.051) analysis: group 1 consisted of patients with *KRAS G12D* or *G12V* or *BRAFV600E* mutations independent of MSI status; they had a poor survival time and suffered more patient deaths. Group 2 included patients with either wild-type *KRAS*/*BRAFV600E* or *KRAS* G13D mutations in the MSS/MSI-L tumors and had a more favorable outcome. Finally, the patients with MSI-H cancers and simultaneous *G13D* mutations were observed to have the worst outcomes. The survival times for groups 1-3 varied significantly (P = 0.006). Therefore, we recommend the concomitant analysis of *KRAS, BRAF, PIK3CA,* and *PTEN* combined with MSI, which can facilitate selecting the appropriate patients for anti-EGFR treatment while also indicating the outcome of CRC patients.

CONCLUSION

KRAS, an important member of the EGFR signaling cascade, can acquire activating mutations in codons 12 and 13 of exon 2 in approximately 35%-45% of the CRC cases, rendering EGFR inhibitors ineffective. Though the prognostic value of *KRAS* is conflicting, it is a promising predictive biomarker of personalized treatment. Numerous clinical trials have clarified the significant benefit of outcomes in patients with wild-type *KRAS* for anti-EGFR therapy, despite the treatment line. Therefore, *KRAS* status testing has been recommended by national organizations, including NCCN, American Society for Clinical Oncology and European Medicines Agency. In recent years, *KRAS* testing is administered with a high frequency; however, standards are desired worldwide, including the selection and processing of the tumor sample and the choice of the appropriate detection method, which may affect the accuracy of the testing results. COLD-PCR is a simple assay that can increase *KRAS* testing sensitivity by enriching the mutant alleles. This technology combined with HRM or sequencing is potentially useful in *KRAS* detection in a clinic practice. In addition, concomitant analysis with other factors, such as BRAF, PIK3CA, PTEN and MSI, is helpful in supporting *KRAS* as predictive and prognostic factors, but further efforts are needed prior to implementation.

Abstract

AIM: To evaluate the effect of double-balloon enteroscopy (DBE) on pancreas histology and levels of pancreatic enzymes.

METHODS: Conventional upper gastrointestinal endoscopy was performed on five control pigs. Oral DBE was performed with an EN-450T5 enteroscope on 20 pigs. Two experimental groups (10 pigs each) were defined according to DBE duration: 90 min for Group 1 and 140 min for Group 2. During oral insertion, the balloons were not inflated in the descending part of the duodenum to avoid the minor duodenal papilla. Serum amylase, lipase and C-reactive protein (CRP) levels were monitored before the procedure and repeated every 30 min until the exploration was finished, as well as 24 h and 7 d after. After the procedure and for a total of 7 d, the pigs were observed twice a day for signs of decreased activity, irritability, vomiting or anorexia. Gross and microscopic examination of the pancreas was performed on day 7.

RESULTS: All animals tolerated DBE without clinical manifestations of acute pancreatitis. Experimental groups had higher levels of enzymes than the control group at 24 h. Throughout the exploration, the amylase levels increased significantly above the baseline 24 h after DBE, although the increase was not statistically significant and did not reach 20% of the baseline. An increase in lipase and CRP was observed at 24 h after the procedure, although by day 7, all enzymatic levels had returned to baseline. No differences between Groups 1 and 2 were found for any enzyme and sampling site during and after the procedure. Similarly, no correlation between insertion depth and enzyme levels was observed. Direct *in situ* and post-removal inspection of the pancreas did not show any evidence of fluid collection, abscesses or hemorrhage. Histological examination of the pancreas from Groups 1 and 2 revealed the existence of focal areas (0.14-0.26 mm^2) of ischemic necrosis in 47.4% of the animals. In the pigs with damaged pancreas, the left lobe (tail) was always affected. However, this only happened in 83.3% of the samples from the right lobe (head) and in 33.3% of the samples from the body of the pancreas. Significant differences were found between the left lobe (tail) and the body for the percentage of affected pancreas. Both the size of the lesions and the percentage of affected pancreas were higher in the left pancreatic lobe (tail). The presence of the lesions was not related to the exploration length.

CONCLUSION: The increase in pancreatic enzymes

after DBE could be related to focal points of pancreatic ischemic necrosis due to mechanical stress.

INTRODUCTION

Double-balloon enteroscopy (DBE) has enabled endoscopic diagnosis and treatment in the small intestine, which had been very difficult for many years[1]. Yamamoto *et al*[2] introduced DBE in 2001 and its usefulness is already recognized in many countries. DBE is considered a well-tolerated and safe endoscopic technique[3-8], but an increase in pancreatic enzymes and potential pancreatitis are recognized as complications directly attributed to the procedure[1,7,9-12].

The mechanism for post-DBE pancreatitis remains unclear. Potential explanations might include: (1) pancreatic duct obstruction by direct oppression of the papilla with the inflated balloon[7,9]; (2) reflux of intestinal fluid into the pancreatic duct owing to an increase in intraduodenal pressure because of mechanical strain[12,13]; or (3) prolonged mechanical injury or ischemia on the pancreas as a result of repeated stretching and shortening of the endoscope and overtube[7,14-16].

Unfortunately, levels of pancreatic enzymes several days after the procedure and evaluation of potential lesions in the pancreas under normal clinical conditions are unknown in humans. Also, to the best of our knowledge, there have been no studies in animal models to clarify the etiology of pancreatic hyperamylasemia and pancreatitis post-DBE. This study was aimed at determining the effects of the DBE technique on the pancreatic enzymes and histology under nonpathological conditions. To assess if the timing of DBE influences the pancreatic enzyme markers, two experimental groups with different DBE duration (90 or 140 min) were established.

MATERIALS AND METHODS

Animals and protocols

Twenty-five Large White pigs (35-40 kg) were used. The day before DBE, animals were fasted, with no liquid restrictions, and given a laxative preparation. Animals were prepared and anesthetized for the endoscopic procedures. Intravenous saline solution was administrated to secure basic hydration during the DBE procedure. After 24 h fasting, each pig was intramuscularly premedicated with diazepam 0.1 mg/kg, ketamine 10 mg/kg and atropine 0.01 mg/kg. General anesthesia was induced with propofol 2 mg/kg intravenously and maintained with sevofluorane 1.8%-2% delivered *via* an endotracheal tube. Animals from the control group (n = 5) underwent conventional upper gastrointestinal (GI) endoscopy. In the remaining 20 pigs DBE was performed with an EN-450T5 enteroscope (Fujinon, Japan) by experienced endoscopists. The exploration depth was estimated according to the methodology established by May *et al*[17].

Two experimental groups (10 pigs each) were defined according to DBE duration: 90 min for Group 1 and 140 min for Group 2. During the oral insertion of the scope and overtube, the balloons were not inflated in the descending part of the duodenum to avoid the major and minor duodenal papilla. Blood samples were taken before the procedure and during the exploration at 20 (control group only) 30, 60, 90 and 140 (Group 2 only) min, and also at 24 h and 7 d after DBE (Groups 1 and 2) and 24 h and 7 d after GI endoscopy (control group) to evaluate the serum concentrations of amylase, lipase and C-reactive protein (CRP). Animals were allowed to feed 24 h after DBE. After the procedure and for a total of 7 d, the pigs were observed twice a day for signs of decreased activity, irritability, vomiting or anorexia. On day 7, all the animals were euthanized with a pentobarbital overdose and the pancreases were removed. Each pancreas was examined *in situ*, palpated, removed from the cadaver and then sectioned to identify gross alterations. The right lobe (head) and left lobe (tail), as well as the body of the pancreas were preserved in 10% buffered formalin, trimmed into 1 cm × 1 cm × 1 cm tissue blocks (18-22 blocks per pancreas) and processed for histopathology after hematoxylin and eosin staining. Histology sections were studied under light microscopy (three fields per block of tissue) and when lesions were observed, the cross-sectional areas were measured with the SigmaScan Pro 5.0 program (Systat Software Inc., San Jose, CA, United States).

Ethical approval

All animals received humane care in compliance with the European Communities Council Directive (86/609/EEC). Protocols were approved by the local government Ethics Committee for Animal Research. The endoscopic equipment used was for research with animals only.

Statistical analysis

Data of enzyme levels were included in a spreadsheet and analyzed with SPSS 17.0 (SPSS, Chicago, IL, United States). Descriptive statistics were obtained and all the

t_0: Samples before the procedure; t_{end}: Samples at the end of the procedure [gastrointestinal endocopy (GI) in control group and double-balloon enteroscopy (DBE) in experimental group]; $t_{24\ h}$: Samples 24 h after the procedure (GI in control group and DBE in experimental group); t_{168h}: Samples 7 d after the procedure (GI in control group and DBE in experimental group). [b]$P < 0.01$ *vs* control group.

variables tested for normality (Kolmogorov-Smirnov test) before being subjected to analysis of variance (ANOVA) (linear model with repeated measures). Within-subject factors were the different timing of blood sampling and the inter-subject factor was the duration of the exploration (90 or 140 min). Tukey and Bonferroni tests were used to ascertain *post hoc* differences. The possible association between the experimental groups and the presence of lesions in the pancreas was checked with the χ^2 test. In addition, the nonparametric Mann-Whitney test was used to ascertain any dependence between the size of the lesions and the portion of the pancreas.

RESULTS

Procedure evaluation

All the animals tolerated the procedure without any clinical manifestations of pancreatitis or distress. During the endoscopic exploration, passing the endoscope and the overtube into the duodenum was not difficult (< 3 min). Remnants of food in stomach did not make DBE more difficult. During the 7 d observation period after the procedure, the activity and dietary intake were normal in all the animals.

Estimations were calculated using the depth of insertion technique described by May *et al*[5]. The average insertion depth in Group 1 was lower than in Group 2: 268 cm (range: 209-336 cm) and 333 cm (range: 230-488 cm), respectively. Nevertheless, due to high data variability, the ANOVA for the insertion depth between the two groups was not significant ($P = 0.181$).

Biochemical evaluation

No statistical differences between sampling states in the control group were found. Experimental Group 1 had higher levels of enzymes than the control group at 24 h (Table 1). These differences were also present between the control group and Group 2.

Enzyme serum levels at the different sampling stages are displayed in Figure 1. To simplify notation, values at 30 and 60 min of the procedure are omitted because they were always similar to time 0.

All the animals had similar basal amylase levels before the procedure (approximately 2000 IU). Throughout the exploration, no significant changes in the amylase levels were noted (Figure 1A). However, the amylase levels increased significantly above the baseline 24 h after DBE, although the increase did not reach 20% of the baseline level. On day 7 after the procedure, the amylase level decreased progressively to the baseline, but it was still significantly higher in Group 1.

Lipase levels showed a variable trend during and after the exploration (Figure 1B). This is well illustrated in Group 1, where there was a significant decrease during the exploration, peak levels at 24 h after the procedure, and the lowest levels 7 d later.

CRP levels were significantly higher 24 h after DBE (more than twice the initial levels) (Figure 1C). However, CRP concentrations then decreased progressively towards the baseline, so no significant differences were found between the initial levels and 7 d after DBE.

No differences between Groups 1 and 2 were found for any enzyme and sampling site during and after the procedure. Similarly, no correlation between insertion depth and enzyme levels was observed (P for Pearson coefficient was always > 0.3).

Histology evaluation

Direct *in situ* and post-removal inspection of the pancreas did not show any evidence of fluid collection, abscesses or hemorrhage (Figure 2).

Light microscopy examination of tissue samples from the control group showed occasional small areas with infiltration and edema. However, the tissue samples from Groups 1 and 2 revealed the existence of limited areas of ischemic necrosis scattered throughout the parenchyma (Figure 3). This was observed in nine of the 19 pigs (47.4%). It should be noted that the histology samples from one pig were not included in the analysis due to bad processing. Some of the necrotic areas showed slight inflammatory cell infiltration around the sites of necrosis, but alterations to the pancreatic duct system were rare. In the nine pigs with damaged pancreas, the left lobe (tail) was always affected. However, this only happened in 83.3% of the samples from the right lobe (head) and in 33.3% of the samples from the body of the pancreas. The average area of lesions (μm^2) related to each portion was: right lobe (head): 198274 ± 23952, body: 136782 ± 24163 and left lobe (tail): 260516 ± 32819. The percentage (%) of affected pancreas in each portion was: right lobe (head): 1.83, body: 0.60 and left lobe (tail): 3.11. Although the overall differences were not statistically significant, the average values for both parameters were higher in the left

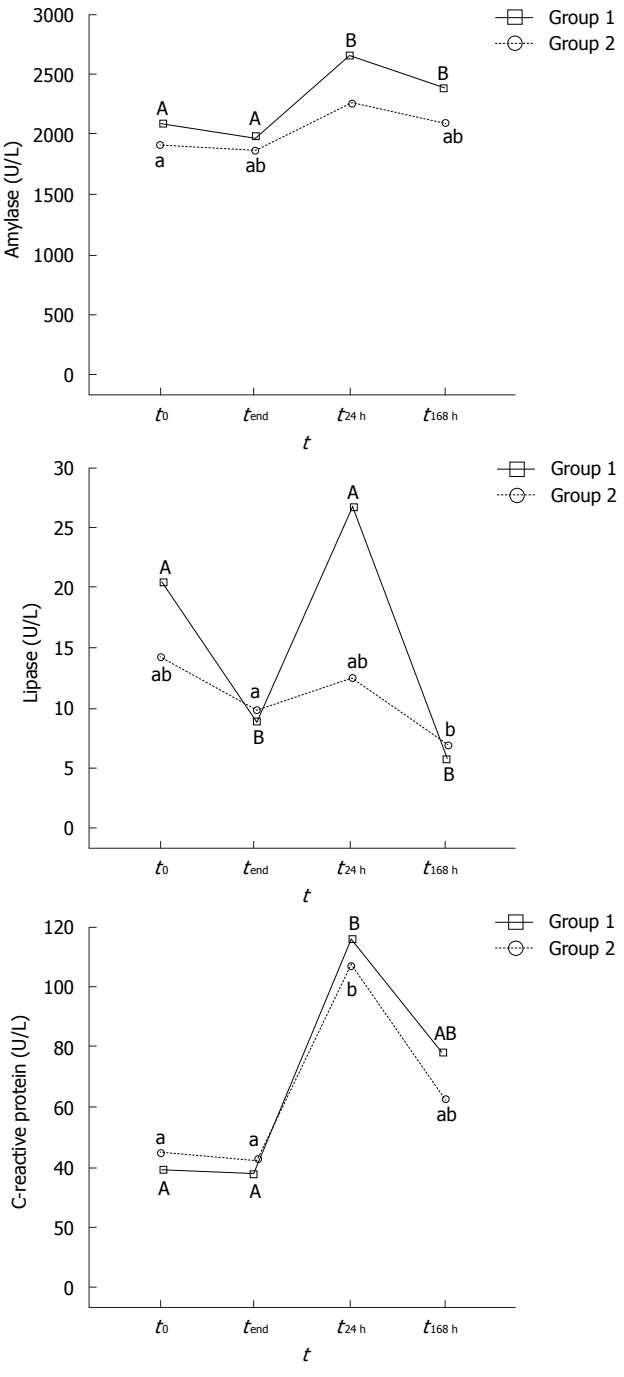

Figure 1 Plots representing the serum levels of amylase (A), lipase (B) and C-reactive protein (C) for Groups 1 and 2 at different sampling intervals. t_0: Samples before the procedure; t_{end}: Samples at the end of the procedure [gastrointestinal endocopy (GI) in control group and double-balloon enteroscopy (DBE) in experimental group]; $t_{24\ h}$: Samples 24 h after the procedure (GI in control group and DBE in experimental group); $t_{168\ h}$: Samples 7 d after the procedure (GI in control group and DBE in experimental group). Within-group differences: sampling stages with no coincident capital (Group 1) or normal case (Group 2) letters were significantly different ($P < 0.05$). No significantly different results between Groups 1 and 2 were found at any sampling stage.

pancreatic lobe (tail). Significant differences were found between the left lobe and the body for the percentage of affected pancreas. Interestingly, the presence of the lesions was not related to the exploration length (90 or 140 min; Pearson χ^2 and Fisher's exact tests > 0.3).

DISCUSSION

A low incidence (0.3%) of acute pancreatitis after diagnostic DBE has been reported in retrospective studies in Europe and Asia[18], and also in the United States[19,20]. However, latent hyperamylasemia without the development of pancreatitis occurs after peroral DBE more frequently than was previously thought[9,10,21].

The physiology and anatomy of the porcine pancreas is similar to that in humans, that is, it is a partially retroperitoneal organ and the pancreatic body wraps the portal vein. The firmness of the pancreatic parenchyma in swine is also similar to the gland in humans[22]. Thus, the porcine model has been used in many types of studies related to the pancreas such as endoscopic approaches to the pancreas[23-25], or experimental obstructive pancreatitis[26]. An *ex vivo* model for training has also been developed on porcine intestine[5,27]. Recently, the swine model has been validated for both DBE training and research, altogether improving the safety conditions of DBE in humans[28].

The characteristics, in terms of duration and insertion depth, of this study have been designed for comparison with DBE in humans. The DBE time length in Group 1 (90 min) and Group 2 (140 min) was selected in accordance with published average values from prospective studies in humans. Thus, Mehdizadeh *et al*[29] referred to a duration of 109.1 ± 44.6 min for the first 10 cases and 92.4 ± 37.6 min for subsequent cases. Similar times were referred to by other authors, namely, 75 min[14], 95 ± 42 min,[7] 115 ± 9 min[21], and 148 min[10,16]. Our results for the average insertion depth in both groups of animals were within the same range as those reported in previous works: 240 ± 100 cm[5], 250 ± 170 cm[30], 220 ± 90 cm[6], 270 ± 100 cm[7], and 351 ± 108 cm[21].

According to the literature, three authors have specifically measured amylase levels in patients before and after oral DBE[9,10,21]. Honda *et al*[9] found that 46% of patients undergoing DBE developed hyperamylasemia. Kopácová *et al*[10] investigated the levels of serum amylase, lipase and CRP both before and after DBE (4 h and 24 h). They found increased levels of amylase and lipase in 51.4% of the patients 24 h after the procedure. However, only 2.8% of them suffered acute pancreatitis. Pata *et al*[21] also checked levels of serum amylase and lipase both before and 4 h and 12 h after DBE. Just 4 h after the procedure, they found 25% of the patients had hyperamylasemia and hyperlipasemia, and 12.5% of the patients had pancreatitis. It is important to pay attention to the fact that the increases in the serum pancreatic amylase described in those three previous studies were twice or even three times higher than normal levels. In contrast, serum levels of amylase and lipase in the present work never reached twice the baseline level, and this could be related to the fact that the balloons were always inflated after the site of the pancreatic duct opening in the duodenum. In support of this, Pata *et al*[21] have described that amylase levels after DBE are negatively correlated to the depth at which the balloons are first inflated. Interestingly, no changes in the levels of serum amylase and lipase have been reported in patients when the first inflation of the balloons was done after reaching the ligament of Treitz[14,31,32]. On the other hand, some authors have described that substantial hyperamylasemia tended to be associated with longer duration of DBE[10,15,21,32]. However, we did not find such a difference, and the enzyme levels of Groups 1 and 2 did not vary significantly at any stage. Similar results have been reported by others authors[9,16].

The mechanical stress to the small intestine, mesentery and pancreas has also been suspected[7,9] to cause increased levels of amylase, lipase and CRP. Thus, a plausible explanation for the increased levels of enzymes[9,12,13] is an effect of the increased intraluminal pressure on the pancreatic ducts allowing intestinal fluid to progress towards the pancreas, and as such, should be kept in mind. However, the histological injuries found in this study are more likely related to an ischemic process in the vascular supply to the pancreas. The continuous pressure of the small intestine and the mesentery during the push and pull maneuvers could compromise the vascular supply to the pancreas, resulting in an increase in the pancreatic enzymes and unspecific inflammatory factors such as CRP. Along these lines, several works have reported pancreatic vascular restriction as a potential mechanism for hyperamylasemia after oral DBE[11,16,33]. On the other hand, the larger and more frequent areas of ischemic necrosis in the left lobe (tail) of the pig pancreas seem to be related to the particular vasculature of this pancreatic portion. In pigs, the left lobe (tail) is supplied by a single artery, which is a branch of the splenic artery. A similar situation is found in humans where the main artery of the tail of the pancreas is the major pancreatic artery. Such anatomical particularity predisposes the left pancreatic lobe to suffer from hypoxia or even ischemia if there is any mechanical restriction to the blood supply through this artery. Although this explanation requires further specific research, it is interesting to highlight that computed tomography has revealed that human pancreatitis is predominantly located in the tail of pancreas[15,34]. Considering the variance of the enzyme levels and that this was a non-survival animal model study, the number of animals could be a limitation of this work.

In conclusion, the inflation of the balloons after the duodenal papilla diminished the iatrogenic effects on the pancreas. However, minor enzymatic alterations and focal lesions in the pancreas remained, which on the other hand, failed to cause any clinical signs of pancreatitis. A vascular component is probably involved in the etiology of DBE-related pancreatic alterations, but this topic needs further research aimed at evaluating the effects of DBE exploration maneuvers on the vascular supply to the pancreas.

COMMENTS

Background

Double-balloon enteroscopy (DBE) has enabled endoscopic diagnosis and treatment in the small intestine, but an increase in pancreatic enzymes and

potential pancreatitis are recognized as complications directly attributed to the procedure.

Research frontiers

Unfortunately, levels of pancreatic enzymes several days after the DBE procedure and evaluation of potential lesions in the pancreas under normal clinical conditions are unknown in humans. In this study, the authors demonstrated that focal ischemic lesions in the pancreatic parenchyma, and minor enzymatic alterations were related with DBE procedure in a porcine model.

Innovations and breakthroughs

Previous reports have highlighted the importance of the amylase levels in patients before and after oral DBE. Increased levels of amylase and lipase in 51.4% of the patients 24 h after the procedure have been reported. However, only 2.8% of them suffered acute pancreatitis. This is believed to be the first study in an animal model aimed at clarifying the etiology of pancreatic hyperamylasemia and pancreatitis after DBE. Furthermore, the study suggested that a vascular component was probably involved in the etiology of pancreatic alterations after DBE.

Applications

By understanding the etiology of post-DBE pancreatic hyperamylasemia, this study demonstrates the need for further research aimed at evaluating the effects of DBE on the vascular supply to the pancreas.

Terminology

DBE is recognized as the gold standard method for total exploration of the small intestine. Based on the already existent push endoscopy, DBE is a form of deep endoscopy that not only allows the exploration but also treatment of the most common digestive disorders of the small intestine, such as obscure gastrointestinal bleeding, tumors, Crohn's disease and polyps. The equipment consists of an endoscope and an overtube; both of them with a latex balloon attached to the tip. The two balloons are inflated and deflated in an alternating sequence so as to allow the endoscope to progress (pushing phase) or fold the explored intestine behind the balloons (pulling phase).

Peer review

This is an important issue because DBE might be associated with an increase of serum pancreatic enzymes or even complicated by acute pancreatitis. The mechanism of post-DBE pancreatitis has not been fully explained yet. That is why such an experimental study is important to understand possible pathogenetic mechanisms.

Abstract

AIM: To investigate whether circulating microRNAs (miRNAs) can serve as molecular markers to predict liver injury resulted from chronic hepatitis B (CHB).

METHODS: The profiles of serum miRNA expression were first generated with serum samples collected from 10 patients with CHB and 10 healthy donors (Ctrls) by microarray analysis. The levels of several miRNAs were further quantitated by real-time reverse transcription polymerase chain reaction with serum samples from another 24 CHB patients and 24 Ctrls. Serum samples of 20 patients with nonalcohlic steatohepatitis (NASH) were also included for comparison. The comparison in the levels of miRNAs between groups (CHB, NASH and Ctrl) was analyzed with Mann-Whitney *U*-test. The correlation between miRNAs and clinical pathoparameters was analyzed using Spearman correlation analysis or canonical correlation analysis. The receiver-operator characteristic (ROC) curves were also generated to determine the specificity and sensitivity of each individual miRNA in distinguishing patients with CHB from Ctrls.

RESULTS: miRNA profile analysis showed that 34 miRNAs were differentially expressed between CHB and Ctrl subjects, in which 12 were up-regulated and 22 down-regulated in CHB subject (fold change > 2.0 and $P < 0.01$). The median levels of miR-122, -572, -575 and -638 were significantly higher ($P < 1.00 \times 10^{-5}$) while miR-744 significantly lower ($P < 1.00 \times 10^{-6}$) in CHB compared with the Ctrl. The levels of miR-122, -572 and -638 were also higher ($P < 1.00 \times 10^{-3}$) while the level of miR-744 lower in CHB ($P < 0.05$) than in NASH, although the difference between them was not as significant as that between CHB and Ctrl. ROC curve analysis revealed that the levels of miR-122, -572, -575, -638 and -744 in serum were sensitive and specific enough to distinguish CHB, NASH and Ctrl. Multivariate analysis further showed that the levels of these miRNAs were correlated with the liver function parameters. Most significantly, it was the scatter plot of principal component with the levels of these miRNAs, but not the parameters of liver function, which clearly distinguished CHB, NASH and Ctrl subjects.

CONCLUSION: Serum levels of miR-122, -572, -575, -638 and -744 are deregulated in patients with CHB or NASH. The levels of these miRNAs may serve as potential biomarkers for liver injury caused by CHB and NASH.

INTRODUCTION

Hepatitis B virus (HBV) infection is one of the major health problems in China[1]. Of the 350 million individuals worldwide infected with the HBV, one-third are from China[2]. HBV infection results in chronic hepatitis B (CHB) and patients with CHB exhibit a high risk of developing liver cirrhosis and hepatocellular carcinoma[3]. Although HBV itself is noncytopathic, host immune response often causes liver damage in patients with HBV infection. Currently, the most commonly used markers of liver injury are the enzymatic activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in blood; however, these markers are devoid of sufficient sensitivity and specificity to diagnose virus-induced liver damages[4,5]. Therefore, assessing the severity of HBV-induced damages and monitoring the progression of CHB are major clinical challenges.

microRNAs (miRNAs) are evolutionarily conserved, and are small (typically ~22 nt in size) regulatory RNA molecules that modulate the levels of specific targets, and are thus actively involved in a wide range of physiologic and pathologic processes[6,7]. Interestingly, miRNAs are very stable in circulation systems, and tissue or organ-specific intracellular miRNAs can often be detected in blood under pathological conditions[8-12]. The elevated levels of these miRNAs in blood are most likely caused by their release into the circulation system in the processes accompanied with cell death, such as cell turnover, cell destruction and pathological injury[13-16]. For example, the levels of miR-1, a muscle and heart-specific miRNA, is elevated in blood during acute myocardial infarction[13]. miR-141, a miRNA highly expressed in prostate cancer cells, is present at a significantly higher level in prostate cancer patients than healthy donors[14]. In addition, the levels of serum miRNAs can also be associated with different physiological conditions. For instance, miRNAs of presumed placental origin were detected at high levels in the plasma of pregnant women[17]. CHB is an infectious illness, and the host immune response to HBV infection is thus expected to cause both hepatocellular damage and viral clearance[18]. In fact, CHB progresses with significant apoptosis and necrosis of hepatocytes[19]. It is of interest to determine whether particular miRNAs are released to blood of CHB patients and can serve as predictor for CHB liver injury.

The goal of this study is to investigate whether the circulating miRNAs can be used as molecular biomarkers to monitor the pathological development of CHB. As liver cells are also damaged along the progression of nonalcoholic steatohepatitis (NASH) and caused by the build-up of fat cell in the liver[20], we included samples of NASH patients in this study. Through the comparison of serum miRNA expression profiles among CHB and NASH patients and healthy donors, we found that the expression of miR-122, -572, -575, -638 and -744 was deregulated in both CHB and NASH patients. The expression of these five miRNAs was significantly correlated with pathological parameters of liver. We, therefore, conclude that these five miRNAs may serve as potential biomarkers for CHB and NASH-induced liver injury.

MATERIALS AND METHODS

Study subjects and clinical parameters

Sera collected from 34 CHB, 20 NASH patients and 34 healthy donors (Ctrls) were included in this study. Samples from 10 CHB patients and 10 Ctrls were subjected to miRNA microarray analysis to obtain serum miRNA profiles. Those miRNAs with altered levels were further measured by quantitative reverse transcription polymerase chain reaction (qRT-PCR) with the samples from the remaining 24 CHB patients and 24 Ctrls. To determine the specificity of miRNA level change, serum samples from 20 NASH patients were also included for qRT-PCR analysis. Serum samples of Ctrls were randomly selected from a collection of 120 individuals who had annual physical examination at Shanghai Shuguang Hospital, Shanghai, China. Samples of CHB and NASH were from patients seeking treatment in Shanghai Shuguang Hospital. The diagnostic criteria for CHB followed the guidelines that defined by the Chinese Society of Hepatology and Chinese Society of Infectious Diseases in 2005[21]. The diagnosis of NASH was based on the guidelines for diagnosis and treatment of nonalcoholic fatty liver diseases that issued by Fatty Liver and Alcoholic Liver Disease Study Group of the Chinese Liver Disease Association in 2006[22]. The clinical parameters of these patients are listed in Table 1. This study was approved by the Institutional Review Board of Shanghai Shuguang Hospital.

Serum sample collection and RNA isolation

All serum samples were derived from freshly-drawn blood and stored at -80 ℃. RNA in serum was isolated using a miRVana PARIS kit (Ambion, Austin, TX, United States) according to the manufacturer's protocol followed by the treatment of RNase-free DNase I (Promega, Madison, WI, United States) to eliminate DNA contamination. The concentration of RNAs extracted from serum ranged from 1.5 to 12 ng/μL.

Table 1 Clinical characteristics of participants in validation

Bile acid were given as medians (range). ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: γ-glutamyltransferase; ALP: Alkaline phosphatase; TBIL: Total bilirubinand; CHB: Chronic hepatitis B; NASH: Nonalcohlic steatohepatitis; Ctrl: Healthy donor; HBsAg: Hepatitis B surface antigen.

Serum miRNA profiling and data analysis

The profiles of serum miRNAs of 10 CHB patients and 10 Ctrls were generated using Agilent Human miRNA microarray V3 (Agilent Technologies Inc, Santa Clara, CA, United States). The microarray chip is comprised of 2371 different probes for a total of 851 human miRNAs. One hundred nanograms of serum RNA was used for each array. The arrays were read using the Agilent microarray scanner and the data were extracted using Feature Extraction V10.7 (Agilent Technologies, CA, United States). All data were transformed to log base 2. The differences between samples were calculated using unsupervised analysis (SAS system, Shanghai Biochip, Shanghai, China). Only the miRNAs with the fold difference > 2.0 and $P < 0.01$ were considered significant.

Validation of internal reference for serum miRNA quantification

There has been no consensus on the reference genes for qRT-PCR analysis of serum miRNAs. However, 6 miRNAs, RNU6B[23], miR-24[14,24], miR-16[15], miR-181a[25], miR-454[26] and miR-638[27], have been reported to be consistently present in human serum. Therefore, these miRNAs were empirically analyzed by qRT-PCR in samples from all patients and Ctrls. The cycle threshold (Ct) values were converted into relative quantities for analysis with geNorm software[28], which selects the optimal number of the most stable genes for normalization. To calculate the expression stability of a given gene (gene stability measure *M*), the program uses an algorithm based on the mean of the pairwise variation of a given reference gene compared to all other control genes. The higher the value of *M* is, the more the expression variability of the corresponding reference gene is. The least stable gene, i.e., the gene with the highest *M* value, was excluded from the subsequent analysis. The remaining genes was recalculated for *M* values and the gene with highest *M* was again excluded until the two most stable genes were left.

Quantification of serum miRNAs

qRT-PCR-based quantification of miRNAs (200 μL of serum from each participant) was performed with Bulge-Loop™ miRNA qPCR Primer Set (Guangzhou Ribobio, Guangzhou, China) and SYBR Green PCR Master Mixture (TOYOBO, LTD, Japan) according to the manufacturer's instructions using a Rotor-Gene 6000 Real-time PCR machine (Corbett Life Science, Sydney, Australia). The specificity of each PCR products was validated by melting curve analysis at the end of PCR cycles. All samples were analyzed in triplicate and the Ct was defined as the number of cycles required for the fluorescent signal to reach the threshold. The levels of miRNAs in serum were calculated using the formula $2^{\Delta Ct}$ where ΔCt = Ct of internal reference -Ct of target miRNA.

Establishment of receiver-operator characteristic curves

Receiver-operator characteristic (ROC) curves were established to evaluate the difference in the levels of serum miRNAs among CHB, NASH and Ctrls. Statistical significance for correlations was calculated using Spearman's non-parametric rank test and the correlation coefficient R generated by Spearman correlation formula.

Statistical analysis

Comparisons between groups were analyzed using Mann-Whitney *U*-test, Pearson χ^2 test, canonical correlation analysis or Spearman correlation analysis wherever appropriate. All tests were two-tailed and $P < 0.05$ was considered statistically significant.

RESULTS

Serum miRNA profiles of CHB patients are distinct from those of Ctrls or NASH patients

To determine whether there was difference in serum miRNA profiles between people with or without CHB, we performed miRNA microarray with RNAs isolated from the sera of 10 CHB patients and 10 Ctrls. Among a total of 851 miRNAs analyzed, 34 of them were differentially expressed between CHB patients and Ctrls (fold change > 2.0 and $P < 0.01$) (Table 2).

In order to validate the serum miRNA profiles generated from microarray, we initially turned our attention to identifying a particular serum miRNA that can be used as an internal control. As the levels of RNU6B, miR-24, -16, -181a, -454 and -638 were previously reported be relatively consistent[14,15,23-26], we measured their levels in 16 serum samples (4 CHB, 4 NASH and 8 Ctrls). We employed GeNorm to calculate the stability values (*M*-values) for these candidate miRNAs and excluded the candidates with the lowest stability (the highest *M* value). The stability value was recalculated until the two most stable miRNAs were predicted. Defining *M*-values below 1.5 as the critical limit, GeNorm data analysis showed that miR-24

[1]MicroRNA (miRNA) cloning studies sometimes identify two about 22 nt sequences miRNAs which originate from the same predicted precursor. When the relative abundancies clearly indicate which is the predominantly expressed miRNA, the mature sequences are assigned names of the form miRNA (the predominant product) and miRNA* (from the opposite arm of the precursor). For example, miR-123 and miR-123* would share a pre-miRNA hairpin, but more miR-123 would be found in the cell. In the past, this distinction was also made with "s" (sense) and "as" (antisense). CHB: Chronic hepatitis B; Ctrl: Healthy donor.

and -181a had the least *M* value (0.656) among these candidate miRNAs, implicating that they were the most stable ones. We thus selected miR-24 as the internal control to standardize differentially presented serum miRNAs in qRT-PCR quantification.

Microarray analysis with 10 CHB and 10 Ctrl samples showed that the median levels of serum miR-122, -572, -575 and -638 were higher while median levels of miR-30c and -744 were lower in CHB patients than those in Ctrls (Table 2). In order to validate these microarray-generated results, RNA was prepared from serum samples of another 24 CHB patients and 24 Ctrls and was subsequently subjected to qRT-PCR to measure the levels of miR-122, -572, -575, -638 and -744. Identical to what we observed with microarray analysis, the levels of miR-122, -572, -575 and -638 were 83.40-, 43.17-, 15.24- and 12.95-fold higher in the sera of CHB patients than those of Ctrls ($P = 1.61 \times 10^{-8}$, $P = 1.20 \times 10^{-6}$, $P = 8.27 \times 10^{-8}$, $P = 2.88 \times 10^{-9}$, respectively) (Figure 1A-D) while the level of miR-744 was 5.11-fold lower in CHB patients than that in Ctrls ($P = 1.04 \times 10^{-7}$) (Figure 1E). The level of miR-30c was a little higher in CHB patients than that in Ctrls although it was not statistically significant (Figure 1F).

To determine how specific these altered serum miRNAs were to CHB, we next examined the levels of these miRNA in serum samples of NASH patients. qRT-PCR showed that the levels of serum miR-122, -638, -575 and -572 were 3.04-, 16.32-, 4.27- and 5.62-fold higher ($P = 6.89 \times 10^{-4}$, $P = 7.50 \times 10^{-5}$, $P = 6.72 \times 10^{-6}$ and $P = 1.14 \times 10^{-7}$, respectively) while the level of miR-744 was 3.75-fold lower in NASH patients than in Ctrls ($P = 2.15 \times 10^{-7}$) (Figure 1A-E). When comparing the levels of these serum miRNAs between CHB and NASH samples, we found that the levels of miR-122, -572 and miR-638 were 27.42-, 2.65- and 3.57-fold higher ($P = 5.83 \times 10^{-7}$, $P = 4.18 \times 10^{-3}$, $P = 8.89 \times 10^{-4}$, respectively) while the level of miR-744 was 1.36-fold lower in CHB patients than in NASH patients ($P = 4.8 \times 10^{-2}$) (Figure 1A-C, E). In contrast, no significant difference was found in the levels of miR-575 and -30c between the serum samples of CHB and NASH patients (Figure 1D and F). These results demonstrated that a subset of miRNAs was differentially present in the sera of CHB patients.

Levels of a subset of serum miRNAs can be used to distinguish CHB patients from NASH patients or Ctrls

To determine whether the levels of serum miRNAs can be used to distinguish patients with CHB from those with NASH or Ctrls, we established ROC curves to analyze the difference in the levels of serum miR-122, -638, -575, -572 and -744 between groups. Comparing CHB subjects with Ctrls, ROC curve areas of miR-122, -638, -575, -572 and -744 were found to be 0.98 (95% CI: 0.88-1.00), 1.00 (95% CI: 0.93-1.00), 0.91 (95% CI: 0.79-0.97), 0.95 (95% CI: 0.85-0.99) and 0.95 (95% CI: 0.84-0.99), respectively. The sensitivity and the specificity of each of these miRNAs were 87.5% and 100%, 100% and 100%, 83.3% and 83.3%, 79.2% and 100%, 91.7% and 95.8%, respectively in the CHB subjects and Ctrls (Figure 2A). These results clearly showed that the levels of serum miR-122, -638, -575, -572 and -744 can distinguish patients with CHB from Ctrls.

We next compared the levels of these serum miRNAs between NASH subjects and Ctrls. ROC curve areas of miR-122, -638, -575, -572 and -744 were 0.80 (95% CI: 0.65-0.91), 0.97 (95% CI: 0.87-0.99), 0.90 (95% CI: 0.77-0.97), 0.85 (95% CI: 0.71-0.94), and 0.96 (95% CI: 0.85-0.99). The sensitivity and the specificity were 95.0% and 62.5%, 95.0% and 95.8%, 90.0% and 79.2%, 100.0% and 66.7%, 100.0% and 95.8%, respectively in NASH subjects and Ctrls (Figure 2B). These results also demonstrated that the levels of these five miRNAs can distinguish patients with NASH from Ctrls. Interestingly, comparison of CHB subjects with NASH subjects implicated that the levels of miR-122, -638, -572 and -744 were use-

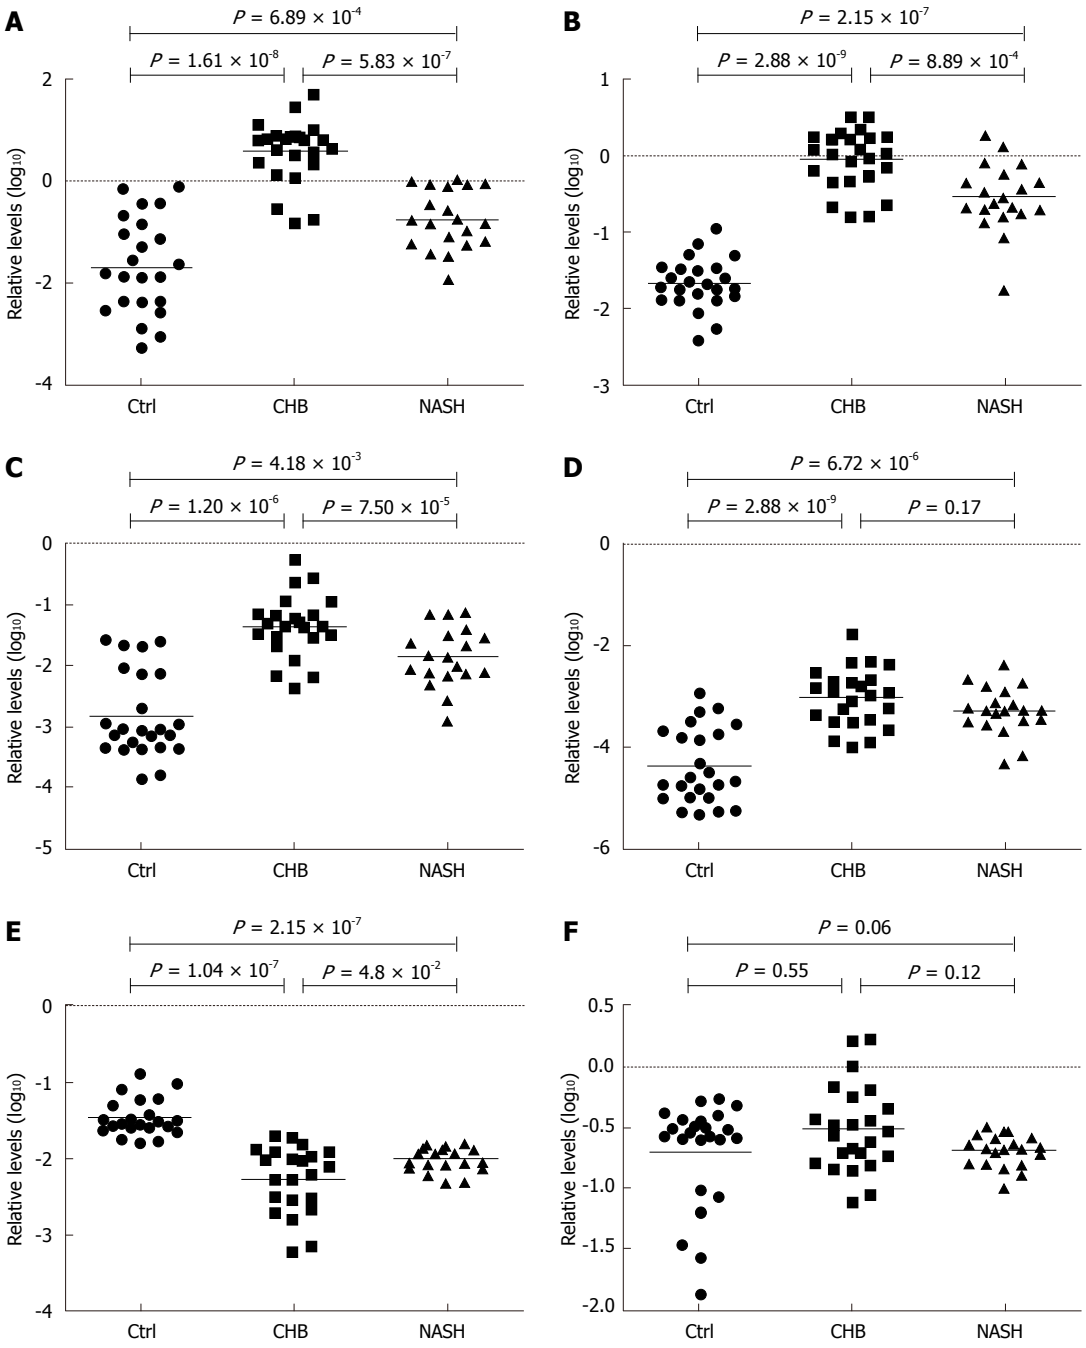

Figure 1 Serum levels of microRNAs in chronic hepatitis B, nonalcohlic steatohepatitis and healthy donors. The levels of serum miR-122 (A), miR-638 (B), miR-572 (C), miR-575 (D), miR-744 (E) and miR-30c (F) in patients with chronic hepatitis B (CHB) (n = 24), with nonalcohlic steatohepatitis (NASH) (n = 20) and healthy donors (Ctrl) (n = 24) were measured by quantitative reverse transcription polymerase chain reaction. The line at each group represents the median value of indicated miRNA. The values are normalized to miR-24 and shown in $\log_{10}$ scale at y-axis. P values on the top are NASH *vs* Ctrl, on the left are CHB *vs* Ctrl and on the right are NASH *vs* Ctrl.

ful markers for discriminating patients with CHB from those with NASH because ROC curve area of miR-122, -638, -572 and -744 were 0.94 (95% CI: 0.83-0.99), 0.79 (95% CI: 0.65-0.90), 0.75 (95% CI: 0.60-0.87) and 0.68 (95% CI: 0.52-0.81) and the sensitivity and the specificity were 87.5% and 100.0%, 83.3% and 70.0%, 75.0% and 75.0%, 50.0% and 85%, respectively, in the two groups (Figure 2C). Together, these results demonstrated that the levels of miR-122, -638, -572 and -744 in serum can be used to distinguish CHB, NASH and Ctrls.

Aberrant levels of serum miR-122, -572, -575, -638 and -744 correlate with the liver pathological parameters

To investigate whether the levels of serum miR-122, -572, -575, -638 and -744 can be used as independent molecular indicators of CHB- or NASH-induced liver injury, we first determined the potential correlation of these five miRNAs in themselves among serum samples from patients with CHB, NASH and Ctrls. Spearman correlation analysis showed that the levels of these five miRNAs in sera were highly correlated among them-

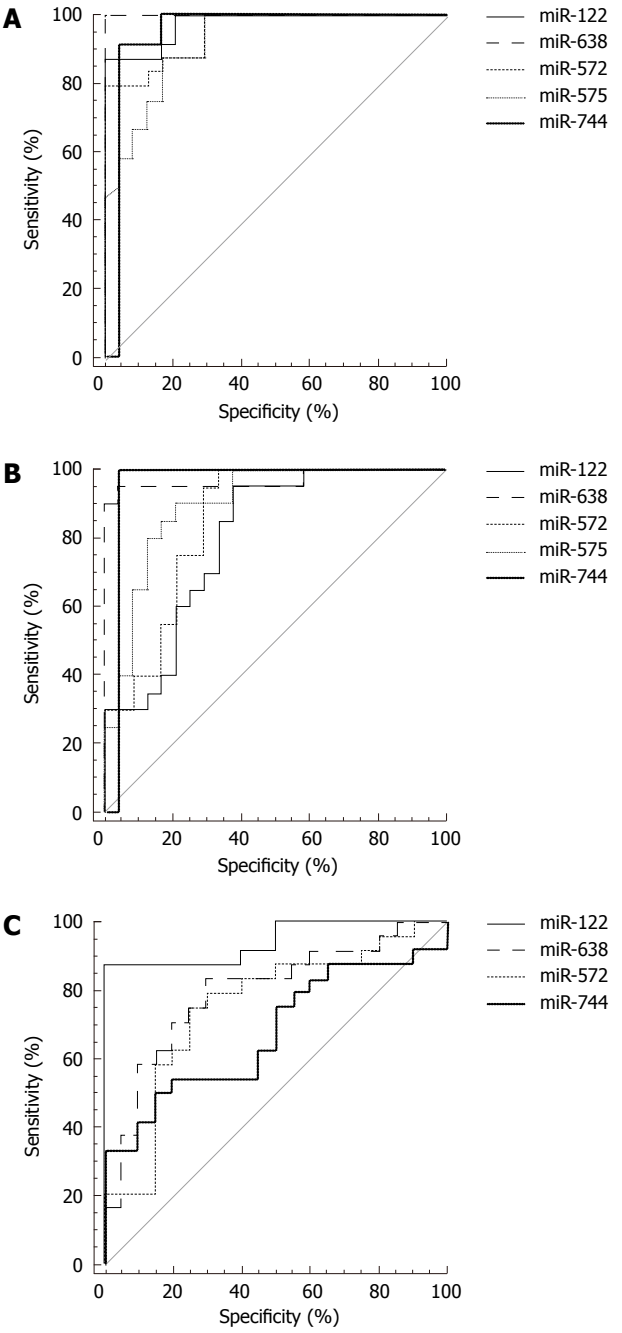

Figure 2 Receiver-operator characteristic curve analyses. Receiver-operator characteristic curves of the miR-122, -638, -572, -575 and -744 were established to discriminate chronic hepatitis B (CHB) from healthy donor (Ctrl) (A), nonalcohlic steatohepatitis (NASH) from Ctrl (B) and CHB from NASH (C).

selves ($r \geqslant 0.57$, $P = 1.00 \times 10^{-4}$; Table 3). We next analyzed the potential correlations between each of these five miRNAs and each of the clinical liver pathological parameters. Spearman correlation analysis showed that correlation only existed between selected miRNAs and selected liver function parameters (Table 3). For example, miR-122 was significantly correlated with both ALT ($r = 0.559$, $P = 1.00 \times 10^{-6}$) and AST ($r = 0.692$, $P = 1.00 \times 10^{-6}$; Table 3). However, none of these miRNAs was correlated with markers of hepatitis viruses including HBsAg, HBeAg and HBV DNA (data not shown).

Table 3 Coefficient of Spearman correlation between microRNA variables and liver function parameter variables (all 68 samples)

Variables	miR-122	miR-638	miR-572	miR-575	miR-744
miR-122	1.000	0.757[b]	0.780[b]	0.614[b]	-0.669[b]
miR-638	0.757[b]	1.000	0.876[b]	0.822[b]	-0.733[b]
miR-572	0.780[b]	0.876[b]	1.000	0.794[b]	-0.639[b]
miR-575	0.614[b]	0.822[b]	0.794[b]	1.000	-0.570[b]
miR-744	-0.669[b]	-0.733[b]	-0.639[b]	-0.570[b]	1.000
ALT	0.559[d]	0.431[d]	0.375[d]	0.299[c]	-0.413[d]
AST	0.692[d]	0.474[d]	0.465[d]	0.324[d]	-0.434[d]
GGT	0.421[d]	0.371[d]	0.280[c]	0.214	-0.355[d]
ALP	0.358[d]	0.312[d]	0.320[d]	0.306[c]	-0.180
TBIL	0.034	0.041	-0.114	-0.074	-0.068
Bile acid	0.068	-0.020	0.008	-0.023	0.090

[b]$P < 0.01$ microRNA (miRNA) *vs* miRNA without superscript b in the same column (2-tailed test); [c]$P < 0.05$ level miRNA *vs* liver function parameter (2-tailed test); [d]$P < 0.01$ level miRNA *vs* liver function parameter (2-tailed test). ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: γ-glutamyltransferase; ALP: Alkaline phosphatase; TBIL: Total bilirubin and bile.

In the subsequent studies, we considered both levels of miRNAs and liver pathological parameters as multiple factors and analyzed their correlation using multivariate analysis (canonical correlation analysis). As shown in Figure 3A, the levels of miR-122, -638, -572, -575 and -744 were apparently correlated with liver functional parameters (ALT, AST, γ-glutamyltransferase, ALP, TBIL and bile acid) ($r = 0.74$, $P < 1.00 \times 10^{-4}$). Moreover, the changes in the levels of these miRNAs were greater than those in the values of ALT or AST in the CHB and NASH subjects (Figure 3B). Most significantly, the scatter plot of principal component with the levels of these miRNAs clearly distinguished CHB, NASH and Ctrl subjects (Figure 3C). In contrast, identical analysis with the values of liver functional parameters was unable to distinguish the three groups of subjects (Figure 3D). These data indicated that the profile of miR-122, -572, -575, -638 and -744 in the serum was a better indicator than those well-established liver functional markers for liver injury caused by CHB or NASH.

DISCUSSION

miRNAs can be released into circulating system through damaged cells and tissues. Circulating miRNAs are very stable in plasma and can be found in lipid or lipoprotein complexes[29], apoptotic bodies[30], microvesicles[31] or exosomes[32]. Recent studies have shown that the levels of circulating miRNAs can alter significantly at different physiological stages and pathological conditions. For example, the level of miR-122 (liver specific), miR-133a (muscle specific), and miR-124 (brain specific) are respectively elevated in blood of patients with liver, muscle, and brain injury[9]. Moreover, the level of miR-141 is significantly higher in patients with prostate cancer than in healthy controls[14]. These observations suggest that circulating miRNAs may represent a new class of

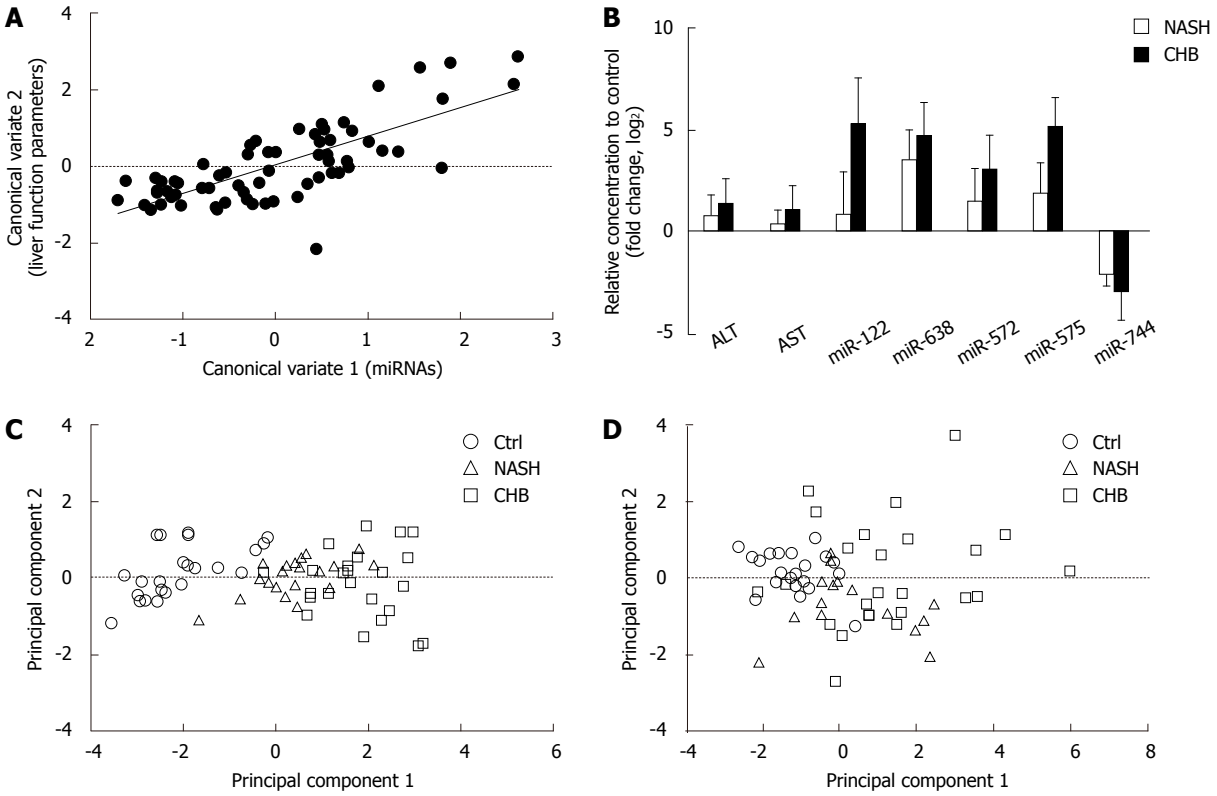

Figure 3 Aberrant levels of serum miR-122, -572, -575, -638 and -744 correlate with the liver pathological parameters. A: Canonical correlation analysis. The correlation between microRNA (miRNA) variables and liver function parameter variables were calculated by canonical correlation analysis. All the data were $\log_{10}$ transformed. Correlation coefficient $r = 0.74$ and $P < 1.00 \times 10^{-4}$. miRNAs: miR-122, -572, -575, -638 and -744; Liver function parameters: Alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ-glutamyltransferase (GGT), alkaline phosphatase (ALP), total bilirubin (TBIL) and bile acid; B: Comparison of serum miRNAs, ALT and AST in chronic hepatitis B (CHB) and nonalcohlic steatohepatitis (NASH). The comparison among the levels of ALT, AST, miR-122, -572, -575, -638 and -744 in serum samples collected from patients with NASH and CHB (indicated on x-axis). The relative change of ALT, AST and miRNA expression levels were expressed ratio in $\log_2$ compared with healthy control (Ctrl) (indicated on y-axis). The values of ALT, AST and miRNA fold change are the average of samples from CHB (n = 24), NASH (n = 20) and Ctrls (n = 24), and the SD is shown as an error bar; C, D: Scatter plot of principal components analysis. All the data were $\log_{10}$ transformed to carry out analysis. Scatter plot of first two principal component of miRNAs variables including miR-122, -572, -575, -638 and -744 (C), and liver function parameters including ALT, AST, GGT, ALP, TBIL and bile acid (D) in CHB (n = 24), NASH (n = 20) and Ctrls (n = 24).

biomarkers for monitoring the progress of certain diseases[8-17]. This possibility is supported by several recent reports which demonstrate the potential of miR-9 as a novel non-invasive molecular marker for traumatic spinal cord injury[10], miR-208a for early detection of acute myocardial infarction[11], miR-146a/223 for sepsis[12], miR571 and miR-652 for liver cirrhosis-induced alcoholic hepatitis or hepatitis C[33] and a plasma miRNA panel (miR-122, miR-192, miR-21, miR-223, miR-26a, miR-27a and miR-801) for HBV-related HCC[34]. In this study, we further validated that the levels of a subset of miRNAs possess the value as novel and sensitive biomarkers for predicting liver diseases.

miR-122 was previously reported as a liver-specific miRNA[35]. In rodents, liver injury induced by alcohol or chemicals leads to the increased level of plasma miR-122 which occurs earlier than the increase in commonly-used marker ALT[9,36]. Moreover, the level of plasma miR-122 exhibits an excellent correlation with the necroinflammatory activity of HBV[23] and HCV infection[37]. In addition to miR-122, the levels of miR-575, -572, -638 and -744 in serum were also altered in patients with CHB or NASH compared with the Ctrls (Figure 1 and Table 2). Importantly, the alteration of these miRNAs correlated well with well-established liver functional parameters (Figure 3 and Table 3). Our study supports a notion that serum miRNA profile may be used to envisage the occurrence of liver injury caused by CHB and NASH.

CHB and NASH have different histological features in necro-inflammation and fibrosis[18-20]. In this study, the median levels of ALT and AST were significantly higher in CHB than in NASH (ALT: 82.6 U/L *vs* 51.7 U/L, $P < 0.05$; AST: 62.6 U/L *vs* 31.55 U/L, $P < 0.05$) (Table 1). Patients with CHB generally exhibited more severe liver damage than those with NASH, thus explaining the detection of higher levels of serum miR-122, -638 and -572, but lower level of miR-744 in CHB than those in NASH (Figure 1). Current laboratory testing with the established liver function parameters do not reliably predict the type and severity of liver injury[4,5]. It is supported by our observation that scatter plot of principal components analysis with liver function parameters was unable to distinguish CHB from NASH (Figure 3D). However, the changes in the levels of these five miRNAs were significantly greater than those in the values of ALT or AST in the CHB and NASH patients (Figure 3B). Scatter

plot of principal components analysis with the levels of serum miRNAs clearly distinguished CHB, NASH and Ctrls (Figure 3C). In hepatitis, hepatocytes die through the mechanisms of both apoptosis (programmed cell death) and necrosis. Hepatocytes presumably synthesize less AST and ALT in the process of apoptosis[38]. In contrast, either apoptosis or necrosis of hepatocytes will release cellular miRNAs directly into the circulating system. This may explain the reason why the sensitivity of serum miRNAs was superior to ALT or AST in diagnosing liver damages. Although investigations with a larger number of samples may be necessary to fully validate our findings, our results do suggest that the alteration of serum miRNA profile may be a more precise molecular biomarker for predicting the seriousness of liver injury.

This study demonstrated that miR-122, -638, -572 and -575 were presented at higher levels while miR-744 was at lower levels in the sera of patients with CHB and NASH. The levels of these miRNAs were not only correlated with liver pathological parameters, but also were more precise indicators for the type and severity of liver diseases than commonly-used markers such as ALT and AST. In conclusion, analyzing the alteration of serum miR-122, -638, -572, -575 and -744 levels may represent a powerful strategy to diagnose liver injury caused by liver inflammation.

We thank Kun Wang for his assistance with statistical analysis.

COMMENTS

Background

microRNAs (miRNAs) are small, non-protein coding transcripts involved in many cellular and physiological mechanisms. Recently, a new class of miRNA called "circulating miRNAs" was found in cell-free body fluids such as serum and urine. Circulating miRNAs have been shown to be very stable, specific, and sensitive biomarkers. In this paper, the authors investigated miRNAs with altered levels in the serum of patients with chronic hepatitis B (CHB).

Research frontiers

Currently, the most commonly used markers of liver injury are the enzymatic activities of alanine aminotransferase and aspartate aminotransferase in blood; however, these markers are devoid of sufficient sensitivity and specificity to diagnose virus-induced liver damages. Therefore, assessing the severity of hepatitis B virus-induced damages and monitoring the progression of CHB are major clinical challenges. Circulating miRNA as a biomarker is a new frontier in diagnostics. The goal of this study was to investigate whether the circulating miRNAs can be used as molecular biomarkers to monitor the pathological development of CHB.

Innovations and breakthroughs

Through comparison of serum miRNA expression profiles among CHB, nonalcohlic steatohepatitis (NASH) patients and healthy donors, the authors found that the expression of miR-122, -572, -575, -638 and -744 was deregulated in both CHB and NASH patients. The authors further showed that the expression of these five miRNAs was significantly correlated with pathological parameters of liver. The authors concluded that these five miRNAs may serve as potential biomarkers for CHB and NASH-caused liver injury.

Applications

The study results suggest that serum levels of miR-122, -572, -575, -638 and -744 are deregulated in patients with CHB or NASH. The levels of these miRNAs may serve as potential biomarkers for liver injury caused by CHB and NASH.

Peer review

The authors compared and analyzed the miRNAs profile of CHB, NASH and healthy control. They found that the level of some miRNAs varied in patients with different clinical diagnosis. For instance, the levels of miR-122, -572, -575, -638 and -744 were significantly correlated with the liver function parameters and they concluded that serum levels of these miRNAs may serve as potential biomarkers for liver injury caused by CHB and NASH. The study is quite interesting and useful for clinical practices, although the results have to be validated by using a larger number of samples.

Abstract

AIM: To study the effect of H_2 gas on liver injury in massive hepatectomy using the Intermittent Pringle maneuver in swine.

METHODS: Male Bama pigs (n = 14) treated with ketamine hydrochloride and Sumianxin Ⅱ as induction drugs followed by inhalation anesthesia with 2% isoflurane, underwent 70% hepatotectomy with loss of bleeding less than 50 mL, and with hepatic pedicle occlusion for 20 min, were divided into two groups: Hydrogen-group (n = 7), the pigs with inhalation of 2% hydrogen by the tracheal intubation during major hepatotectomy; Contrast-group (n = 7), underwent 70% hepatotectomy without inhalation of hydrogen. Hemodynamic changes and plasma concentrations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), hyaluronic acid (HA), tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), and malondialdehyde (MDA) in liver tissue were measured at pre-operation, post-hepatotectomy (PH) 1 h and 3 h. The apoptosis and proliferating cell nuclear antigen (PCNA) expression in liver remnant were evaluated at PH 3 h. Then we compared the two groups by these marks to evaluate the effect of the hydrogen in the liver injury during major hepatotectomy with the Pringle Maneuver in the swine.

RESULTS: There were no significant differences in body weight, blood loss and removal liver weight between the two groups. There was no significant difference in changes of portal vein pressure between two groups at pre-operation, PH 30 min, but in hydrogen gas treated-group it slightly decrease and lower than its in Contrast-group at PH 3 h, although there were no significant difference (P = 0.655). ALT and AST in Hydrogen-group was significantly lower comparing to Contrast-group (P = 0.036, P = 0.011, *vs* P = 0.032, P = 0.013) at PH 1 h and 3 h, although the two groups all increased. The MDA level increased between the two group at PH 1 h and 3 h. In the hydrogen gas treated-group, the MDA level was not significantly significant at pre-operation and significantly low at PH 1 h and 3 h comparing to Contrast-group (P = 0.0005, P = 0.0004). In Hydrogen-group, the HA level was also significantly low to Contrast-group (P = 0.0005, P = 0.0005) although the two groups all increased at PH 1 h and 3 h. The expression of cluster of differentiation molecule 31 molecules Hydrogen-group was low to Contrast-group. However, PCNA index (%) was not statistically significant between the two groups (P = 0.802). Microphotometric evaluation of apoptotic index (AI) in terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling-stained tissue after hepatotectomy for 3h, the AI% level in the hydrogen was significantly low to Contrast-group (P = 0.012). There were no significant difference between Hydrogen-group and Contrast-group at pre-operation (P = 0.653, P = 0.423), but after massive hepatotectomy, the TNF-α and IL-6 levels increase, and its in Hydrogen-group was significantly low compared with Contrast-group (P = 0.022, P = 0.013, *vs* P = 0.016, P = 0.012), respectively. Hydrogen-gas inhalation reduce levels of these markers and relieved morphological liver injury and apoptosis.

CONCLUSION: H_2 gas attenuates markedly ischemia and portal hyperperfusion injury in pigs with massive hepatotectomy, possibly by the reduction of inflammation and oxidative stress, maybe a potential agent for treatment in clinic.

INTRODUCTION

In hepatotectomy, it is often needed to occlude the portal inflow in order to reducing bleeding, causing liver ischemic injury, the Pringle maneuver, interrupts the blood flow to the liver, produces profound hepatic ischemia and intestinal congestion, it has been used clinically during hepatectomy[1-3]. However, ischemia-reperfusion injury (I/R-I) resulting from the Pringle maneuver is one of the pathogenetic factors involved in postoperative liver dysfunction and hepatic failure, especially when the liver is steatotic and cirrhotic[3-5]. The risk of post-operative liver failure (PLF) or "small of size" syndrome (SFSS) is the central problem in the field of liver resection[3,6]. Oxidative stress is regarded as a major contributor to the development of various hepatic disorders including acute hepatic failure, hepatic fibrosis, and hepatic cancer[7-9]. Protective effect of H_2 gas on liver ischemia reperfusion (I/R) injury and toxic liver injury in rodents has been demonstrated. Previously through ameliorating oxidative stress, H_2 becomes an important potential antioxygen spices agent in clinic[10-12]. However, all experiments about H_2 gas focus on small animal[11,13], and lack of the study in big animal which provide a much more clinically relevant means of investigating the pathophysiology of a disease process. Protective effect of H_2 in big animal can provid more treatment options that can be more readily applied in the human setting. In this study, we investigated firstly the effect of H_2 gas on liver remnant injury in major hepatectomy using the Pringle maneuver in swine, and its feasibility in clinic.

MATERIALS AND METHODS

Animals and husbandry

Fourteen pigs male Bama miniature pigs (15-20 kg) were obtained from the Pig and Poultry Production Institute (Guangxi Zhuang Autonomous Region, China). The swine were raised from a closed herd and kept under strict quarantine protocol. The study was approved by the Hospital Clinic Committee on Ethics in Animal Experimentation. All animals in this study were treated humanely and in accordance with institutional and national guide lines for ethical animal.

Surgical technique

An upper midline incision with right or bilateral subcostal extensions (inverse "L" shape or Mercedesb incision) was performed. The subtotal hepatotectomy with loss of bleeding less than 50 mL, and with hepatic pedicle occlusion for 20 min were performed according to the previous introduce[13]. A 16-gauge catheter was inserted into the main portal vein *via* the gastroduodenal vein to measure the portal vein pressure (PVP).

Study group

Hydrogen-group (n = 7) inhaled with 2% and H_2 98% oxygen supplied through trachea cannula, gas inhalation started once trachea cannula accomplished, ontrast-group (n = 7), only inhale oxygen though tracheal tube. In the two groups, the intraoperative PVP and flow were respectively monitored at the proctectomy, 1 h and 3 h after finishing the hepatectomy.

Serum sample analysis

Blood samples were obtained before laparotomy, posthepatectomy 60 min and 180 min. Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), hyaluronic acid (HA), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6) were evaluated. Serum AST, ALT and HA were measured using standard clinical methods for automated analysis (Model 7170; Hitachi Inc, Tokyo, Japan). Plasma TNF-α, IL-6 levels were examined by enzyme-linked immunosorbent assay (ELISA) using a commercial porcine TNF-α/TNFSF2 immunoassay kit (Shanghai Yi Hua Scientifi c, Inc. China). Serum HA levels reflect sinusoidal endothelial damage. HA was measured by a radiometric assay with the Pharmacia HA test (Shanghai Yi Hua Scientific, Inc. China) in prereperfusion and postreperfusion serum samples.

Histological examination

Tissue samples were obtained at 180 min post-hepatotectomy (PH) and were divided into two parts. One was immediately cut into cubes 1 mm and fixed in 2.5% glutaraldehyde in cacodylate buffer (0.1 mol/L sodium cacodylate-HCl buffer, pH 7.4) at 4 ℃, prior to sectioning for transmission electron microscopy. Another was fixed with 10% formalin for 24 h and embedded in paraffin. Three-micrometer-thick sections were stained with he-

matoxylin and eosin and analyzed by the *in situ* terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) method using an apoptosis *in situ* detection kit (Shanghai Yi Hua Scientifi c, Inc. China) according to the manufacturer's instructions[14]. The percentage of TUNEL-positive cells of total cell (apoptosis index, AI) nuclei in 10 high power fields were calculated for the 2 groups then compared. Proliferating cell nuclear antigen (PCNA) is a stable cell cycle nuclear. PCNA protein expression was detected by immunostaining using monoclonal anti-PCN-antibody (Jingmei Biotech Co. Ltd, Shenzhen, China). Data were expressed as the percentage of PCNA-stained hepatocytes per total number of hepatocytes (PCNA index). The mean numbers of PCNA-stained hepatocytes per 10 high power fields were calculated for the 2 groups, divided by the total cell number and then compared.

Malondialdehyde assay in liver tissue

Tissue samples were obtained at pre-hepatotectomy, 60 min, 180 min after hepatectomy for hepatic malondialdehyde (MDA) measurement. Hepatic MDA levels were determined using a agents were purchased from the Nanjing Jiangcheng Bioengineering Institute (Nanjing, China), measured according to the manufacturer's instructions. MDA levels were normalized against protein (pmol/mg).

Serum TNF-α and IL-6 measurement

Serum TNF-α and IL-6 measurement reagents were purchased from the Nanjing Jiangcheng Bioengineering Institute (Nanjing, China). TNF-α and IL-6 ELISA kits (Shanghai Yi Hua Scientifi c Inc., China). TNF-α and IL-6 were measured according to the manufacturer's instructions.

Statistical analysis

Values of parameters are presented as mean ± SD. Statistical significance was determined by Student's *t*-test. Fisher's exact test was used for comparison of adhesions. $P < 0.05$ was considered significant.

RESULTS

Characteristics of the experiment

There were no significant difference between two groups in body weight, removal liver weight, estimated loss of bleeding and operating time (Table 1).

PVP

There was no significant difference in changes of PVP between two groups at pre-operation, PH 30 min (Figure 1). The PVP in hydrogen gas treated-group and moderately increased beyond that measured at laparotomy. The PVP in Contrast-group continue to rise at 3 h of posthepatotectomy, but in hydrogen gas treated-group it slightly decrease and lower than its in Contrast-group, although there no statistical significant differernce ($P = 0.06$).

Hepatocellular injury

The preoperative and serial postoperative measurements of serum ALT and AST, are shown in Figure 2, on which significant differences are noted. There were no significant difference between two groups at pre-operation. After hepatotectomy ALT and AST increased in all of the animals and its in hydrogen gas treated-group was significantly lower comparing to Contrast-group ($P = 0.036$, $P = 0.011$).

Malondialdehyde assay in liver tissue

The serial change of hepatic MDA level in two groups was shown in Figure 3A. Baseline of hepatic MDA between two groups were no significant difference ($P = 0.747$). One hour after massive hepatotectomy, the MDA concentration increased in all the swines. In hydrogen gas treated-group, H_2 gas significantly decreased levels of hepatic MDA, a marker of oxidative stress, the MDA level was significantly low to Contrast-group ($P = 0.0005$, $P = 0.0004$).

Serum HA

The serial change of serum HA level in two groups were showed in Figure 3B. Baseline of HA between two groups were no significant difference ($P = 0.488$). One hour after subtotal hepatotectomy, the HA concentration in serum increased in all the pigs. In Hydrogen-group, the HA level was significantly low to Contrast-group ($P = 0.0051$, $P = 0.0052$).

DISCUSSION

The risk of PLF is the central problem in the field of liver resection[2,3]. This is principally due to the PLF or SFSS, an excessive and destructive portal flow through a remnant liver that is too small, which becomes functionally insufficient[3,4,15], the intraoperative injury including ischemia and inflammatory response is another important pathogenic factors involved in postoperative liver dysfunction and hepatic failure. In studies of extended hepatectomy in dogs, severe damage to the sinusoidal endothelial cells (SECs) of the remnant liver 3 h after the operation was one of the main factors responsible for the high mortality rates[16,17]. Therefore, to reducing the intraoperative injury sometimes is determinant to prevention the PLF or SFSS, when the intraoperative damage is irreversible. It is well known oxidative stress is a major

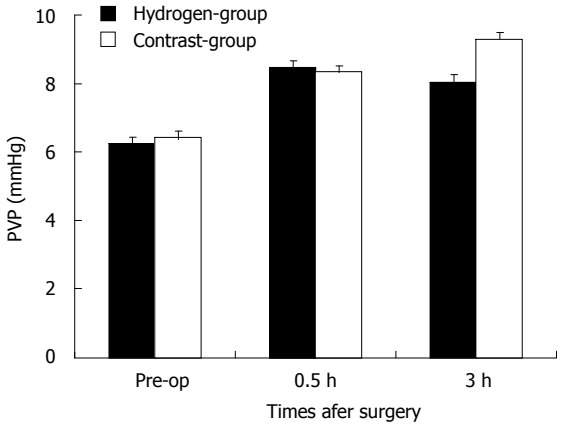

Figure 1 Serial changes of portal vein pressure in two groups. A bar graph shows the mean ± SD of portal vein pressure (PVP) (mmHg) in the two groups. Each group is represented by the mean of 7 swines. There was no significant difference in changes of PVP between two groups at the pre-operation (pre-op), 0.5 h and 3 h.

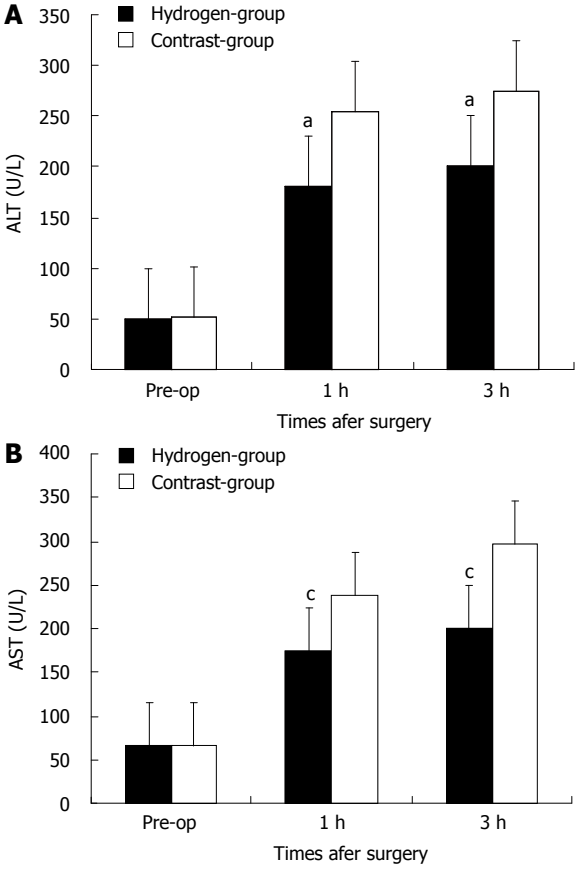

Figure 2 Change of serum alanine aminotransferase level and serum aspartate aminotransferase level in two groups. Each group is represented by the mean of 7 swines. A, B: In hydrogen gas treated-group, the alanine aminotransferase (ALT) (A) and aspartate aminotransferase (AST) (B) levels were significantly lower to Contrast-group. $^{a}P < 0.05$ *vs* ALT level in Contrast-group; $^{c}P < 0.05$ *vs* AST level in Contrast-group. contributor to the development of various hepatic disorders including acute hepatic failure, at present, there are no effective agents to alleviate the oxidative stress during clinically operation. However, molecular H_2, has recently been defined as a novel antioxidant, which selectively quenches detrimental the reactive oxygen species (ROS), while maintaining metabolic oxidation reduction reaction and other less potent ROS[10,11,18], indicating it is promising strategies to alleviate intraoperative injury.

In massive hepatotectomy, the intrahepatic vascular space in the remnant liver experiences a drastic reduction, and this leads to portal congestion and hemodynamic instability[4,5,9], the ischemia attenuate the instability, increases the metabolic burden, mitochondria produce more oxygen radicals. During the hepatic inflow occlusion, the intestinal congestion causing the damage of intestine barrier function and the increase of endotoxin absorbtion or bacterial translocation, however, the function of reticuloendothelial system decrease due to the removing of most of liver masss, which contained a lot of phagocyte[6,9,17]. Each individual Kupffer cell in a small-remnant is exposed to higher amounts of endotoxin than that in a whole liver, and triggers Kupffer cells to release a large quantity of free radicals. Lipid peroxidation, which plays a significant role in oxidative damage[18,19], was measured indirectly by assessing the increases in the levels of a lipid peroxidation product, MDA[19-21]. The MDA level is widely used as an indicator of free radical-mediated lipid peroxidation injury. In the present study, serum levels of MDA in contra-group increased rapidly during hepatotectomy (Figure 3A). The observed increase of liver MDA levels was an indicator of lipid peroxidation, which also verified the oxidative damage in the liver tissue in this animal model. While H_2 inhalation inhibited this increase significantly, inhalation of H_2 gas dramatically decreased MDA levels almost to the normal level.

In the Contrast-group and Hydrogen-group, there were significant endothelial denudation in the medium-sized portal vein branches, sinusoidal dilation, hydropic changes of hepatocytes and hemorrhage into perivenular connective tissue, which extended into the hepatic parenchyma (Figure 4B), and there was no intraparenchymal hemorrhage present in H_2 group (Figure 4A). Transmission electron microscopic photographs of the sinusoid was shown (Figure 4C and D). In the Hydrogen-group, the SECs (arrows) and hepatocytes were well preserved, and the structure of the endothelial lining can also be perceived (Figure 4C), in contrast, the sinusoidal endothelial lining was partially destroyed and detached into the sinusoidal space with enlargement of the Disse's spaces (asterisks). Cluster of differentiation molecule 31 (CD31) immunostaining was notable for destruction of the endothelial lining among animals in Contrast-group (Figure 4F) and, in contrast to mild sinusoidal microarchitecture injury in Hydrogen-group (Figure 4E).

Many studies had demonstrated that the high shear-stress or hyperperfusion, due to small liver remnant could cause the sinusoidal endothelial injury, and hepatocyte injury, swelling degeneration of hepatocytes[22,23]. In Contrast-group, the portal overflow damage the 30% liver remnant underwent 20 min ischemia, causing the endothelial denudation, sinusoidal dilation, hydropic changes of hepatocytes and hemorrhage into perivenular con-

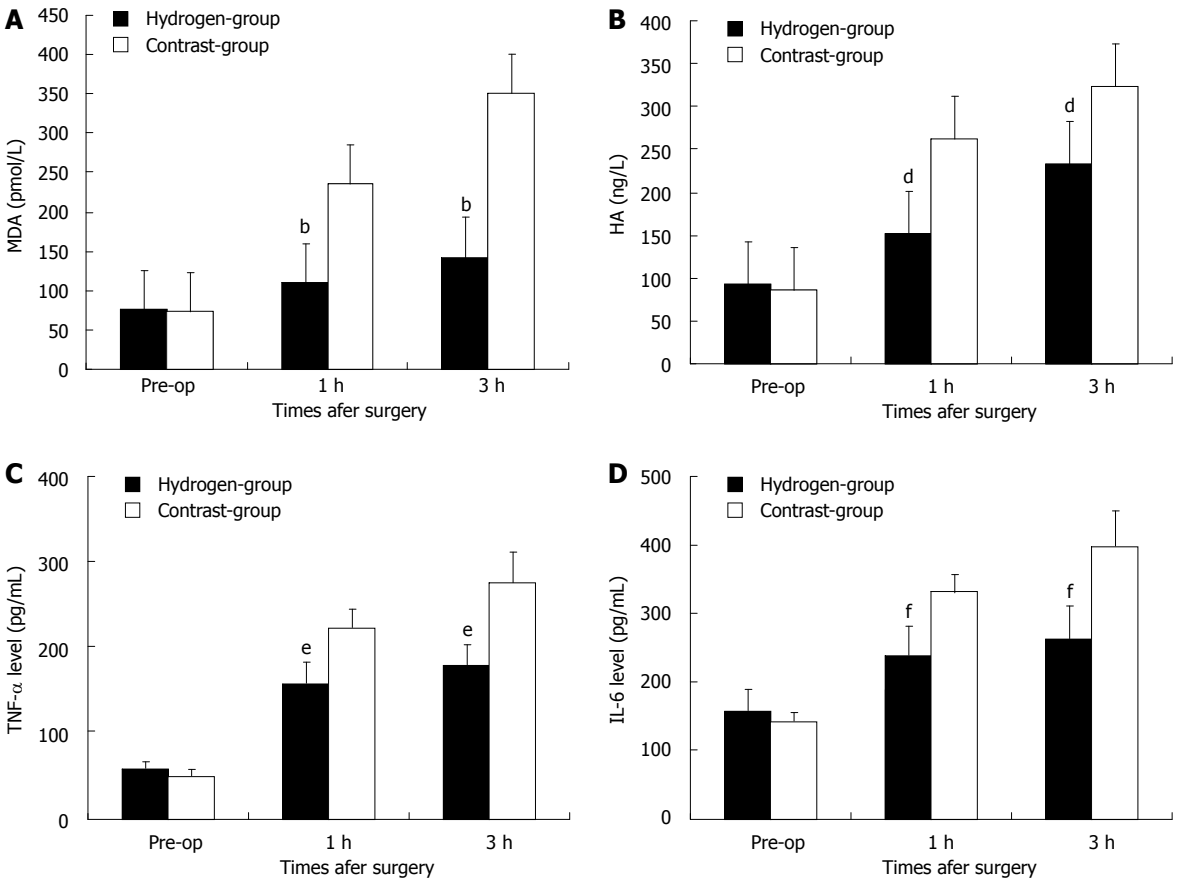

Figure 3 Changes of hepatic malondialdehyde, hyaluronic acid, tumer necrosis factor-α and interleukin-6 levels in two groups. A bar graph shows the mean ± SD of hepatic malondialdehyde (MDA) (A), hyaluronic acid (HA) (B), tumer necrosis factor (TNF)-α (C) and interleukin (IL)-6 (D) level in two groups. Each group is represented by the mean of 7 swines. A, B: In hydrogen gas treated-group, the MDA (A) and HA (B) levels were significantly lower to Contrast-group; C, D: In hydrogen gas treated-group, the TNF-α (C) and IL-6 (D) levels were significantly lower to Contrast-group. Pre-op: Pre-operation. $^{b}P < 0.01$ *vs* MDA level in Contrast-group; $^{d}P < 0.01$ *vs* HA level in Contrast-group; $^{e}P < 0.01$ *vs* TNF-α level in Contrast-group; $^{f}P < 0.01$ *vs* IL-6 level in Contrast-group.

nective tissue, in contrast, the H_2 inhalation alleviated the hyper reperfusion, make the rise in PVP low to Contrast-group, attenuate markedly these injuries (Figure 4A and B). It also identified by the measurement of HA level. HA is synthesized by mesenchymal cells and eliminated in the hepatic sinusoidal endothelium; increased serum HA levels reflect sinusoidal endothelial damage[24,25]. In the present study, an elevation in serum HA level,caused by liver hyperfusion is also significantly low to Contrast-group, indicating the effect of H_2 on hyperfusion injury in the hepatic sinusoidal endothelial (Figure 3B). CD31 immunoglobulin helps maintain endothelial stability by interdigitating with other CD31 molecules at the extracellular border of adjacent cells[26]. The study also showed that hydrogen-inhalation decreased the expression of CD31 molecules (Figure 4E and F), it means the H_2 can reduce the injury of hyperperfusion,and was further demonstrated by the observation of transmission electron microscope examination (Figure 4C and D).

Normal liver has vigorous regenerative potential, portal hyperperfusion is likely to be an important physiologic trigger that stimulates liver regeneration[27,28]. The strength of the regenerative stimulus is proportional to the increase in portal blood flow, as previous shown in experimental animals[29]. The results in the study revealed also there were no significantly difference between the two group at PH 3 h (Figure 5). This means the liver regeneration in the early stage was determined to the portal shear stress, although H_2 decrease free radicals injury. On the other hand, apoptotic cell death is an important contributor to the organ failure common to ALF, even for etiologies thought traditionally to involve mainly hepatocyte necrosis[25,26]. The free radicals may exert a strong cytotoxic effect, and played an important role in inducing apoptosis in the postoperative liver insufficient. The study demonstrated the AI in the hydrogen gas treated-group significantly decrease comparing to the Contrast-group (Figure 6A), this probably attribute to the protection of the H_2 against injury of ROS. Therefore, H_2 play an important role in deceasing the injury of SFSS with decreasing the apoptosis of hepatocyte, without increasing the regeneration.

Even though free radical scavengers have been demonstrated to reduce liver I/R damage[29,30], this is the first observation that the H_2 decreases PVP or hyperperfusion injury in an animal model, which is determinant factor to PLF or SFSS. We observed that H_2 inhalation reduced not only morphological injury, but also serum ALT, AST,

In hydrogen gas treated-group, the AI level was significantly low to Contrast-group ($^aP < 0.05$ *vs* Contrast-group).

IL-1, TNF-α (Figures 2 and 3C, D). We especially investigated the effect of hydrogen on oxidative stress PVP, and injury/regeneration in this liver hypefusion injury model. The use of gas inhalation to treat diseases has become increasingly popular. There are three endogenous gas include nitric oxide, carbon monoxide and H_2 sulfate. The increased production of these gases under stress conditions may reflect the active involvement of these gases in the protective response[31-33]. However, the inherent toxicity of these gases must be investigated for gas inhalation to be considered an effective therapeutic strategy. H_2 is not produced endogenously in mammalian cells since the hydrogenase activity responsible for the formation of H_2 gas has not been identified.

In conclusion, intraoperative H_2 inhalation in massive hepatotectomy was feasible and can protected the liver injury from hyperperfusion, by reduction of inflammation and oxidative stress, liver remnant apoptosis or necrosis, although it didn't increase the regeneration. However, the exact mechanism and signalling pathway involved in the protection role of H_2 in the small liver remnant injury need to be studied in the future. It is required to fully exploit inhalation of H_2 gas as a therapeutic strategy.

COMMENTS

Background

Hydrogen selectively reduce levels of hydroxyl 1 radicals and alleviates acute oxidative stress in many animal models. But most of these study were used in small animal models and lack of the study in big animal which provide a much more clinically relevant means of investigating the pathophysiology of a disease process. In this study, the authors investigated firstly the effect of H_2 gas on small liver remnant injury or "small of size" syndrome (SFSS) after massive hepatectomy, and its feasibility in clinic.

Research frontiers

It is well known oxidative stress is a major contributor to the development of various hepatic disorders including acute hepatic failure, at present, there are no effective agents to alleviate the oxidative stress during clinically operation. However, molecular H_2, has recently been defined as a novel antioxidant, which selectively quenches detrimental the reactive oxygen species (ROS), while maintaining metabolic oxidation reduction reaction and other less potent ROS, indicating it is promising strategies to alleviate intraoperative injury. Oxidative stress is regarded as a major contributor to the development of various hepatic disorders including acute hepatic failure, hepatic fibrosis, and hepatic cancer. Through ameliorating oxidative stress, H_2 becomes an important potential anti-oxygen spices agent in clinic.

Innovations and breakthroughs

Even though free radical scavengers have been demonstrated to reduce liver ischemia reperfusion damage, this is the first observation that the H_2 decreases portal vein pressure or hyperperfusion injury in an animal model, which is determinant factor to post-operative liver failure or SFSS. It was also firstly demonstrated the feasibility of intraoperative inhalation in big animals. As a kind of gas, intraoperative inhalation was convenient and safe.

Applications

The present study demonstrated firstly the protective effect of H_2 gas on liver ischemia-reperfusion injury (I/R-I), toxic liver injury, and portal hyperperfusion injury in swine, that the physiology is similar to human, indicating intraoperative H_2 gas inhalation will be a treatment modality as potential anti-inflammation response agent in clinic .

Peer review

In this study, many biochemical markers mostly investigated in the study of hepatic I/R-I were evaluated and showed that inhaled hydrogen gas attenuated the I/R-I. This study gives a new insight into the pivotal role of hydrogen gas toward the hepatic I/R-I in clinical settings because hydrogen gas was used in swine model.

Abstract

AIM: To introduce and evaluate a new method to repair bile duct defect with a degradable stent and autologous tissues.

METHODS: Eight Ba-Ma mini-pigs were used in this study. Experimental models with common bile duct (CBD) defect (0.5-1.0 cm segment of CBD resected) were established and then CBD was reconstructed by duct to duct anastomosis with a novel degradable stent made of poly [sebacic acid-co-(1,3-propanediol)-co-(1,2-propanediol)]. In addition, a vascularized greater omentum was placed around the stent and both ends of CBD. Cholangiography *via* gall bladder was performed for each pig at postoperative months 1 and 3 to rule out stent translocation and bile duct stricture. Complete blood count was examined pre- and post-operatively to estimate the inflammatory reaction. Liver enzymes and serum bilirubin were examined pre- and post-operatively to evaluate the liver function. Five pigs were sacrificed at month 3 to evaluate the healing of anastomosis. The other three pigs were raised for one year for long-term observation.

RESULTS: All the animals underwent surgery successfully. There was no intraoperative mortality and no bile leakage during the observation period. The white blood cell counts were only slightly increased on day 14 and month 3 postoperatively compared with that before operation, the difference was not statistically significant (P = 0.652). The plasma level of alanine aminotransferase on day 14 and month 3 postoperatively was also not significantly elevated compared with that before operation (P = 0.810). Nevertheless, the plasma level of γ-glutamyl transferase was increased after operation in both groups (P = 0.004), especially 2 wk after operation. The level of serum total bilirubin after operation was not significantly elevated compared with that before operation (P = 0.227), so did the serum direct bilirubin (P = 0.759). By cholangiography *via* gall bladder, we found that the stent maintained its integrity of shape and was still *in situ* at month 1, and it disappeared completely at month 3. No severe CBD dilation and stricture were observed at both months 1 and 3. No pig died during the 3-mo postoperative observation period. No sign of necrosis, bile duct stricture, bile leakage or abdominal abscess was found at reoperation at month 3 postoperatively. Pigs had neither fragments of stent nor stones formed in the CBD. Collagen deposit was observed in the anastomosis by hematoxylin and eosin (HE) and Masson's trichrome stains. No severe cholestasis was observed in liver parenchyma by HE staining. Intestinal obstruction was found in a pig 4 mo after operation, and no bile leakage, bile duct stricture or biliary obstruction were observed in laparotomy. No sign of bile duct stricture or bile leakage was observed in the other two pigs.

CONCLUSION: The novel method for repairing bile

duct defect yielded a good short-term effect without postoperative bile duct stricture. However, the long-term effect should be further studied.

INTRODUCTION

Laparoscopic cholecystectomy (LC) has been the gold standard procedure for benign gall bladder diseases. Unfortunately, the widespread application of LC has led to a concurrent rise in the incidence of major bile duct injuries (BDI) ranging from 0.3% to 0.65%[1-5]. Occurrence of BDI results in difficult reconstruction, even for experienced hepatobiliary surgeons, and a prolonged hospital stay and a high risk of long-term complications. Roux-en-Y hepaticojejunostomy has been the most commonly used approach for biliary reconstruction, especially in cases of duct transection injury[1,6-9]. But its long-term outcome is still far from satisfied due to the high incidence of reflux cholangitis, choledocholithiasis, anastomotic stenosis caused by scar contracture[10-12] and even canceration[13-15]. In recent years, primary duct-to-duct reconstruction has been used in living-donor liver transplantation and has gained good effects[16-18]. It preserves the function of Oddi's sphincter, which provides a barrier to prevent any reflux into the bile duct[13]. However, major drawbacks, including early ischemic necrosis, leakage, and late anastomotic stricture, cannot be overcome so far. In this research, we created a novel method for bile duct defect repair, and proved its feasibility and safety.

MATERIALS AND METHODS

Animals

Eight experimental Ba-Ma mini-pigs of either sex, weighing 15-20 kg, were provided by Shanghai Multi-Bio-Sci-Tech Co., Ltd., China (license No: SCXK 2005-0002). The animals were housed one per cage at the Experimental Animal Center at Zhejiang University. They were allowed to be accustomed to the laboratory environment for more than one week before the start of the experiment. All animals had free access to water and standard food until the day before surgery. The study was approved by the Ethics Committee of Zhejiang University.

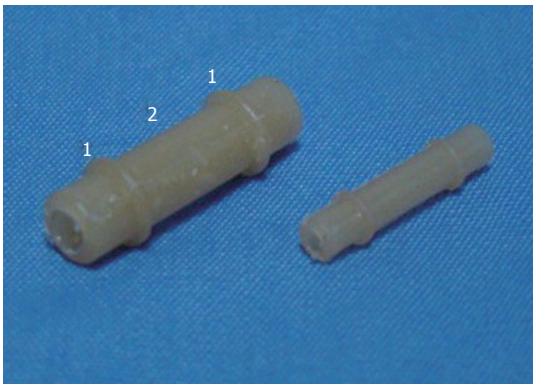

Figure 1 Biodegradable stents of different sizes. 1: Hump rings; 2: Main spindle, 10 mm in length between two hump rings.

Stents

The stent (Figure 1) is made of a novel biodegradable elastomer which is manufactured by the Institute of Polymer Science of Zhejiang University. The elastomer is synthesized with 1,3-propanediol, 1,2-propanediol, and sebacic acid, and then shaped into hollow tube by injecting molding, with a hump ring in both ends. The stent used in the research is 6 mm in external diameter, 1 mm in thickness, and 4 mm in inner diameter. The distance between two hump rings is 10 mm. The stent can completely degrade into carbon dioxide and water in about 3 mo when submerged in fresh human bile *in vitro*. The biocompatible quality of the novel elastomer was approved by the State Food and Drug Administration of China (No. G20090993).

Experimental design

A total of eight Ba-Ma mini-pigs (15-20 kg) were included in this study. The pigs were fasted for 24 h before surgery. Experimental models with common bile duct (CBD) defect (0.5-1.0 cm segment of CBD resected) were established and CBD was reconstructed by duct to duct anastomosis with the novel biodegradable stent. In addition, a vascularized greater omentum was placed around the stent and both ends of CBD. The incidence of jaundice and bile leakage was evaluated. Five pigs were subjected to the examination of complete blood count before operation and on day 14 and month 3 after operation to estimate the inflammatory reaction. Alanine aminotransferase (ALT), γ-glutamyl transferase (γ-GT), serum total bilirubin (TBIL) and direct bilirubin test were also examined pre- and post-operatively to evaluate the liver function. Cholangiography was performed for each pig on months 1 and 3 postoperatively to rule out stent translocation and bile duct stricture. The five pigs were reoperated on to observe anastomosis three months after operation and were sacrificed immediately after that. The

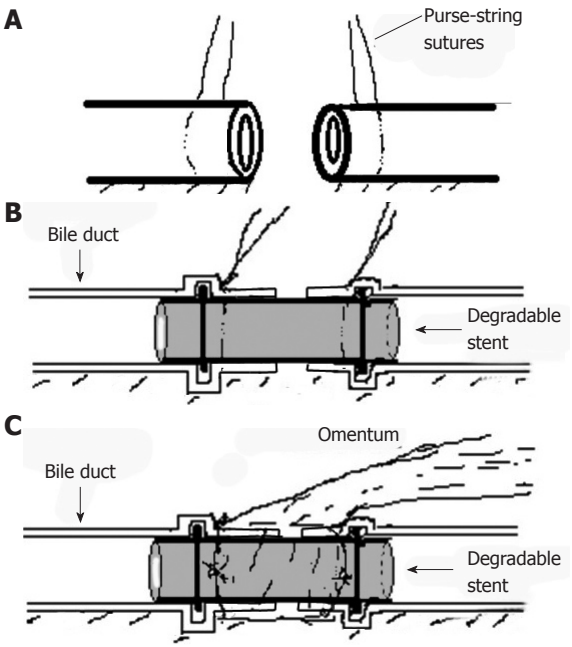

Figure 2 Schematic diagram of repairing bile duct defect with degradable stent and omentum. A: Purse-string sutures with 4-0 Vicryl were made on both ends of bile duct; B: The stent was inserted into both ends of bile duct; C: A vascularized greater omentum was placed around the stent and both ends of common bile duct.

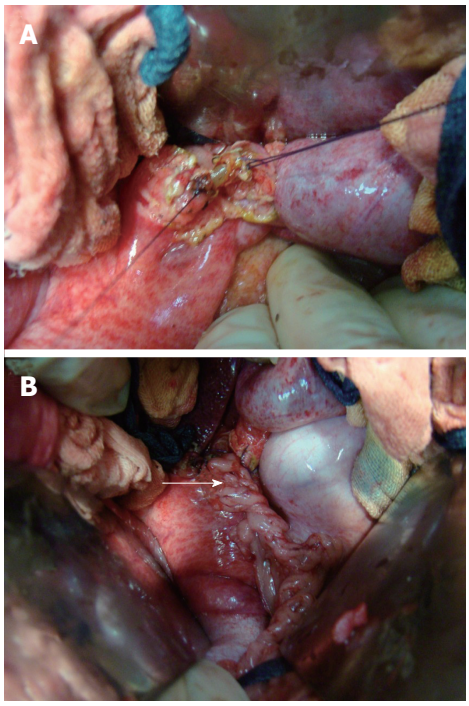

Figure 3 Surgical procedure. A: Stent is placed into common bile duct and two purse-string sutures are tied; B: A layer of large omentum is covered around the stent and two ends of bile duct (arrow).

peritoneal cavity was observed for signs of bile leakage and stricture. The anastomosis was evaluated pathologically, including hematoxylin and eosin (HE) stain and Masson trichrome stain. Liver tissue slides with HE staining were also observed. The other three pigs were raised for one year for long-term observation.

Procedure

Pigs were anesthetized by intramuscular injection of pentobarbital sodium solution (20 mg/mL) with 0.1 mL/kg. Laparotomy was performed *via* a midline incision. Hepatic hilar was dissected firstly to free the CBD. Then a 0.5-1.0 cm segment of CBD under junction of cystic duct was resected. The CBD was reconstructed by duct to duct anastomosis with a stent: purse-string sutures with 4-0 Vicryl (Ethicon, Somerville, NJ, United States) were made on both ends of bile duct (Figure 2A). The stent was inserted into the both ends of bile duct as shown in Figure 2B and 3A. Two ends of bile duct were slightly closed and the purse-string sutures were tied to fix both ends of bile duct on the stent to reconstruct the CBD. A vascularized greater omentum was placed around the stent and both ends of CBD (Figure 2C and 3B).

All pigs were given free access to water, but without food for 24 h postoperatively. They were given half of their normal diet on postoperative day 2. Normal diet was resumed on postoperative day 3.

Statistical analysis

For statistical analysis, the Kruskal-Wallis test was used. $P < 0.05$ was considered statistically significant. Statistical analysis was performed using the SPSS statistical software package (Version 13.0, SPSS Inc, Chicago, IL).

RESULTS

Surgery was successful in all the cases. There was neither intraoperative death nor bile leakage detected during the observation period. The white blood cell counts were only slightly increased on day 14 and month 3 postoperatively compared with that before operation, the difference was not statistically significant. The plasma level of ALT on day 14 and month 3 postoperatively was also not significantly elevated compared with that before operation. Nevertheless, the plasma level of γ-GT was increased after operation in both groups, especially 2 wk after operation. The plasma level of TBIL after operation was not significantly increased compared with that before operation, so did the plasma level of serum direct bilirubin (Table 1).

By cholangiography *via* gall bladder, we found that the stent maintained its integrity of shape and was still *in situ* on month 1, and it disappeared completely on month 3. No severe CBD dilation and stricture were observed both on months 1 and 3 (Figure 4).

No pig died during the 3-mo postoperative observation period. No sign of necrosis, bile duct stricture, bile leakage or abdominal abscess was found when the animals were reoperated on month 3 postoperatively, and none of the pigs had fragment of stents, and stones formed in the CBD (Figure 5).

Histologically, collagen deposit and bile duct glands proliferation were observed in the anastomosis by hema-

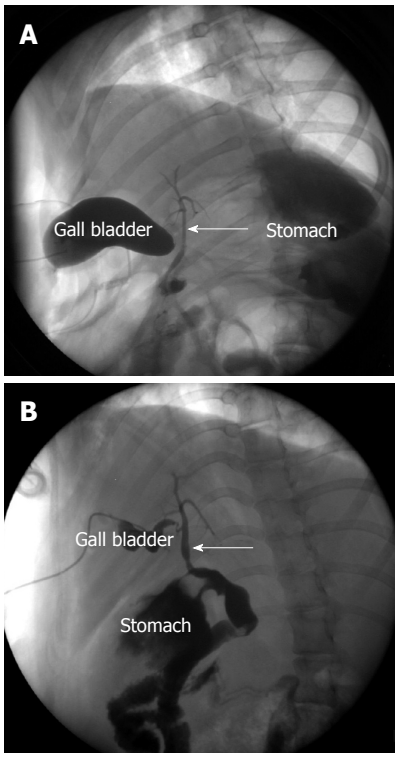

Figure 4 Cholangiography through gall bladder. A: One month after operation, the shape of the stent (arrow) could be visualized in common bile duct; B: Three months after operation, the stent disappeared.

Table 1 Laboratory values

	Before operation	After day 14	Operation month 3	*P* value
WBC	16.62	18.5	18.34	0.652
ALT	51.2	57.2	54.4	0.810
γ-GT	50.2	125.8	72.8	0.004
DBIl	1.1	1.78	1.44	0.227
TBIl	1.76	2.2	2.06	0.759

WBC: White blood cell; ALT: Alanine aminotransferase; γ-GT: γ-glutamic peptidase; DBIl: Direct bilirubin; TBIL: Total bilirubin.

toxylin and eosin and Masson's trichrome stains (Figure 6). No severe cholestasis was found in liver parenchyma by HE staining.

In long-term observation, a pig had intestinal obstruction 4 mo after operation, but no bile leakage, bile duct stricture or biliary obstruction were observed in laparotomy. There was no sign of bile duct stricture or bile leakage in the other two pigs.

DISCUSSION

Bile duct injury is a major complication in biliary surgery such as LC. It can be classified by several classification systems according to the injured site, e.g., Bismuth classification[19] and Strasberg classification[20]. In some cases, bile duct was partially resected and reconstruction with end to end suture was almost impossible for the high incidence of bile leakage and postoperative anastomosis stricture[21,22].

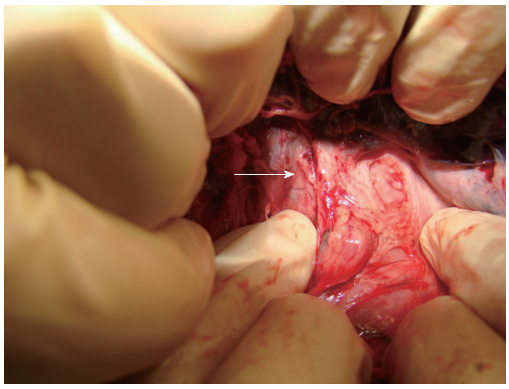

Figure 5 The common bile duct (arrow) three months after operation.

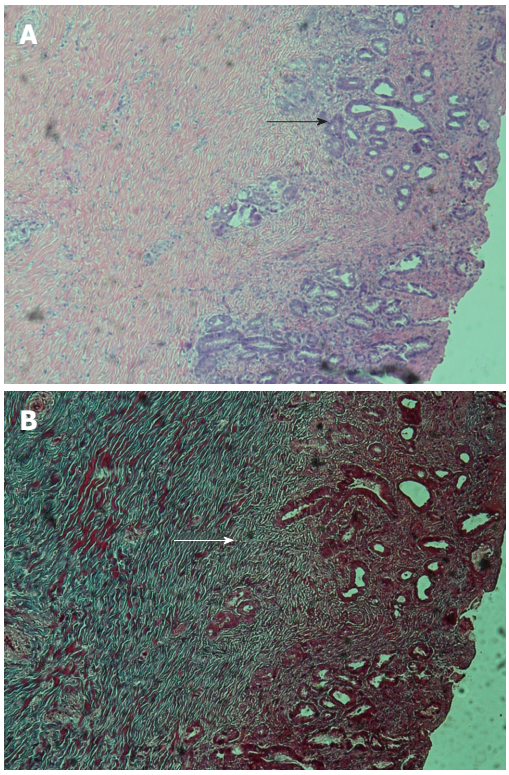

Figure 6 Histology of anastomosis. A: Hematoxylin and eosin stain × 100, black arrow indicates proliferation of bile duct glands; B: Masson's trichrome stain × 100, white arrow indicates deposited collagen fibers.

To keep the biliary continuity and integrality of function is an essential principle for biliary reconstruction. A Roux-en-Y hepaticojejunostomy has been the most commonly used procedure for CBD defect. However, the function of Oddi's sphincter was lost in patients undergoing this procedure, leading to a high incidence of postoperative reflux cholangitis[13,23]. In this research, we aimed to create a new method to repair bile duct defect without sacrificing the function of Oddi's sphincter.

In this procedure, the stent played an important role. The stent was made of degradable material named poly [sebacic acid-co-(1,3-propanediol)-co-(1,2-propanediol)]

(PSPP)[24-26]. Degradable stent had a number of advantages, especially in eliminating the need for stent removal[27,28]. The PSPP belongs to polyester elastomer and possesses a good biocompatibility which is essential for medical applications. The stent connected the two ends of bile duct to maintain the continuity of biliary structure, and it was also used as an inner stent to prevent anastomosis restenoses[22,29,30]. Its degradation time in bile duct is set between 2 and 3 mo, conforming to the healing process of bile duct.

According to the previous reports, the defect of bile duct could be replaced by autologous veins and stents (both silicone stents and biodegradable stents) and they concluded that construction of bile duct appeared to take place by tissue migration[31-34]. Blood supply is important for tissue migration and repair of bile duct defect[35], so vascularized large omentum may be a better autologous tissue compared with veins for temporary repair before bile duct tissue migration was completed. With the assistance of the degradable stent and omentum, we do not need to free much residual bile duct or to mobilize the duodenum to make sure that the anastomosis is tension-free and properly vascularized[36].

Taking into account that bile leakage and bile duct stricture were the two major complications, postoperative cholangiography through gall bladder was repeated to rule out these complications, and liver function was also examined repeatedly to rule out the complication of biliary stricture. The postoperative level of bilirubin and ALT was not significantly elevated compared with that before operation. No obvious bile duct dilatation or stenosis was observed in any pigs by cholangiography. As a result, there was no sign of bile leakage or biliary stricture.

Histologically, collagen deposit and bile duct gland proliferation were observed in the anastomosis three months after operation by HE and Masson's trichrome stains. The neonatal biliary tissue had completely replaced the omentum. Liver parenchyma was also observed by HE stain to rule out cholestasis, and positive result was found. Those results proved that the method is feasible and the biliary tissue can migrate along the surface of stent.

The stent degraded in 3 mo in this research, and the presence of stricture after degradation of the stent is essential to the success of this method, so three pigs were raised for one year to observe its long-term effect. One pig was excluded from long-term observation due to the complication of intestinal obstruction occurring in month 4 after operation and no sign of biliary stricture was found in laparotomy.

This is also a simple method. Only two purse-string sutures are needed without end to end suture and dissection of vein. Vascularized large omentum is easy to mobilize and cover around defect and anastomosis. In addition, two sizes of the stent are available for different situations; the stent would be easily placed into the bile duct if a proper size is selected.

These results suggested that it is a feasible method for repairing bile duct defect, however, the long-term effect (more than one year) should be further observed.

COMMENTS

Background

By the early 1990s, laparoscopic cholecystectomy (LC) had replaced open cholecystectomy as the gold standard procedure for benign gall bladder diseases. Nevertheless, the widespread application of LC has led to a concurrent rise in the incidence of major bile duct injuries. The management of major bile duct injury is a surgical challenge even for experienced hepatobiliary surgeons at tertiary referral centers. Hepaticojejunostomy and duct to duct anastomosis are two commonly used methods for repairing bile duct injury. Despite their advantages, both methods have their critical defects which are difficult to overcome.

Research frontiers

Bile duct injury is a severe complication encountered by almost every hepatobiliary surgeon. The management of major bile duct injury has become a hotspot in clinical studies. With the development of tissue engineering, several researches on biodegradable materials for biliary duct have been conducted.

Innovations and breakthroughs

In this research, the authors created a new method for repairing the bile duct defect with satisfactory effect in a three-month observation period. A novel anastomotic stent and omentum are involved in the new method. By this method, a larger proportion of patients can undergo end-to-end anastomosis and avoid the need for a hepaticojejunostomy. It is also of importance to preserve the function of Oddi's sphincter.

Applications

The study results suggest that repairing bile duct defect by this new method yielded a good short-term effect without postoperative bile duct stricture. It might be applicable in clinical settings in the near future.

Terminology

Elastomer is a class of polymers with a good elasticity. Poly [sebacic acid-co-(1,3-propanediol)-co-(1,2-propanediol)] belongs to polyester elastomer which is considered to have a good biocompatibility.

Peer review

The authors studied the efficacy of the new degradable stent for the bile duct repair in pig experiment. And they concluded that it is a feasible method for repairing bile duct defect. The idea and research of this study are very interesting and applicable for clinical settings in the near future.

Abstract

AIM: To determine the clinical outcome and predictors of survival after transjugular intrahepatic portosystemic stent shunt (TIPS) implantation in cirrhotic patients.

METHODS: Eighty-one patients with liver cirrhosis and consequential portal hypertension had TIPS implantation (bare metal) for either refractory ascites (RA) (*n* = 27) or variceal bleeding (VB) (*n* = 54). Endpoints for the study were: technical success, stent occlusion and stent stenosis, rebleeding, RA and mortality. Clinical records of patients were collected and analysed. Baseline characteristics [e.g., age, sex, CHILD score and the model for end-stage liver disease score (MELD score), underlying disease] were retrieved. The Kaplan-Meier method was employed to calculate survival from the time of TIPS implantation and comparisons were made by log rank test. A multivariate analysis of factors influencing survival was carried out using the Cox proportional hazards regression model. Results were expressed as medians and ranges. Comparisons between groups were performed by using the Mann-Whitney *U*-test and the χ^2 test as appropriate.

RESULTS: No difference could be seen in terms of age, sex, underlying disease or degree of portal pressure gradient (PPG) reduction between the ascites and the bleeding group. The PPG significantly decreased from 23.4 ± 5.3 mmHg (VB) *vs* 22.1 ± 5.5 mmHg (RA) before TIPS to 11.8 ± 4.0 *vs* 11.7 ± 4.2 after TIPS implantation (P = 0.001 within each group). There was a tendency towards more patients with stage CHILD A in the bleeding group compared to the ascites group (24 *vs* 6, P = 0.052). The median survival for the ascites group was 29 mo compared to > 60 mo for the bleeding group (P = 0.009). The number of radiological controls for stent patency was 6.3 for bleeders and 3.8 for ascites patients (P = 0.029). Kaplan-Meier calculation indicated that stent occlusion at first control (P = 0.027), ascites prior to TIPS implantation (P = 0.009), CHILD stage (P = 0.013), MELD score (P = 0.001) and those patients not having undergone liver transplantation (P = 0.024) were significant predictors of survival. In the Cox regression model, stent occlusion (P = 0.022), RA (P = 0.043), CHILD stage (P = 0.015) and MELD score (P = 0.004) turned out to be independent prognostic factors of survival. The anticoagulation management (P = 0.097), the porto-systemic pressure gradient (P

= 0.460) and rebleeding episodes (P = 0.765) had no significant effect on the overall survival.

CONCLUSION: RA, stent occlusion, initial CHILD stage and MELD score are independent predictors of survival in patients with TIPS, speaking for a close follow-up in these circumstances.

INTRODUCTION

Portal hypertension is a common problem in gastroenterology and the treatment of its complications is still a challenging task. Major complications of liver cirrhosis and portal hypertension include variceal bleeding (VB) and refractory ascites (RA)[1]. Despite a wide range of therapeutic modalities, including medical and surgical treatments, there is ongoing debate about the most effective treatment algorithm for the complications of portal hypertension[2-5].

At the end of the 1980's a new nonsurgical procedure was developed to enable decompression of the portal circulation *via* expandable metal stents between hepatic veins and the intrahepatic portal vein system - the transjugular intrahepatic portosystemic shunt (TIPS)[6-8]. Since then, the method has been established and improved systematically, culminating in the actual guidelines of the American Association for the Study of Liver Diseases (AASLD)[9].

Most clinicians agree that TIPS has an excellent hemostatic effect in VB (95%), with low rebleeding rates (< 20%)[10]. When endoscopic hemostasis of esophageal varices fails, TIPS becomes the first-line treatment of choice, with an estimated technical success rate in the range of 93%-100%[11-13]. Due to the circulatory effects on portal hypertension, TIPS is also an interesting approach in cases of RA[14-18] and hepatorenal syndrome[19]. However, following TIPS higher rates of hepatic encephalopathy are observed in patients with cirrhosis and RA[11]. Additionally, TIPS insertion has been reported to be successful in patients with portal vein thrombosis[20,21], Budd-Chiari syndrome[22] and portal cavernoma[23].

The use of bare metal stents has been the gold standard in TIPS procedure[24], but the higher occlusion rate with consecutive bleeding complications has recently led to the development of covered metal stents with significantly lower occlusion rates after TIPS implantation[25-28].

In a retrospective single centre study, we evaluated the efficacy and safety of TIPS in the treatment of portal hypertension using a self-expanding bare metal mesh-wire stent. The major objectives of the present study were to observe stenosis and occlusion rates, occurrence of rebleeding and predictors of survival.

MATERIALS AND METHODS

Patients

This retrospective single center study was conducted at the tertiary referral center of Muenster University Hospital (Department of Medicine B). One hundred and one patients were initially scheduled for TIPS implantation. Eventually 81 patients with complications of portal hypertension were enrolled from 1998 until 2008. Twenty patients were excluded because TIPS insertion was technically not feasible. The indication for TIPS treatment included acute or recurrent VB and RA.

Objectives of the study

Endpoints for the study analysis were: technical success (completed TIPS insertion, lowering of the portosystemic pressure gradient), rates of stent occlusion and stent stenosis, rebleeding, RA and mortality. Clinical records of patients were collected and carefully analysed. Baseline characteristics (e.g., age, sex) were retrieved as shown in Table 1.

Definitions

According to Bureau *et al*[29], the following definitions were used:

Stent dysfunction: > 50% reduction of the lumen of the stent at angiography with an increase of the portosystemic pressure gradient of more than 50% of the initial post-interventional value.

Recurrent VB: Recurrent VB that did not respond to the usual pharmacological and endoscopic therapy[30].

RA: Ascites that did not respond to conservative (low-salt diet) and pharmacological (diuretics) treatment or lack of treatment options because of treatment-induced complications[31].

Transjugular intrahepatic portosystemic stent procedure

All TIPS procedures were conducted in strong collaboration with an interventional radiologist and gastroenterologist at our hospital using standard techniques[32]. Through a transjugular venous approach, the right hepatic vein was catheterized. An intrahepatic branch of the portal vein was punctured. Before dilation of the liver parenchyma

[1]In four patients data acquisition of stent diameter not available. NS: Not significant; NC: Not calculated; LTX: Liver transplantation; TIPS: Transjugular intrahepatic portosystemic stent; PPG: Portal pressure gradient; MELD: Model for end-stage liver disease; PSC: Primary sclerosing cholangitis; PBC: Primary biliary cirrhosis.

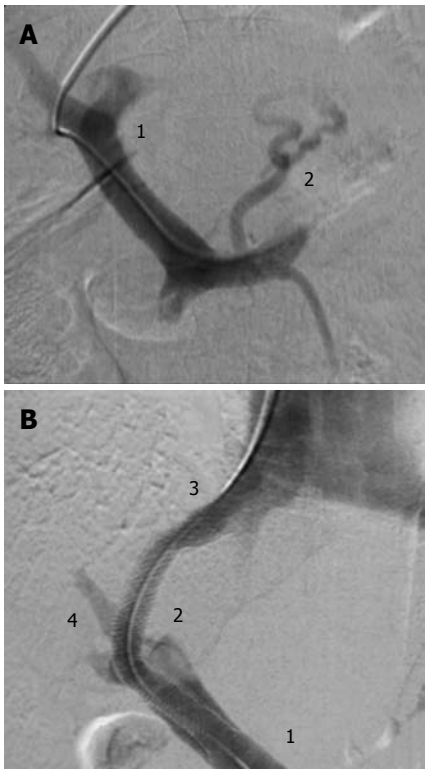

Figure 1 Fluoroscopic images showing transjugular intrahepatic portosystemic shunt placement procedure. A: Portogram after catheterisation of the portal vein, showing perfusion of the portal vein system (1) and oesophageal varices (2); B: Portogram after transjugular intrahepatic portosystemic stent placement. Contrast can be seen in the portal vein (1), through the shunt (2) flowing into the hepatic vein and inferior vena cava (3). Decompression of the portosystemic pressure can be seen in reduced contrast in the portal branch (4). The varices can no longer be identified in the fluoroscopic image.

both the portal pressure and the blood pressure of the right atrium were measured. Then the optimal stent length was defined using a special catheter with opaque markers. After the deployment of the bare metal stent the pressures of the portal vein and the right atrium were measured again. Pressures were measured using an Exadyn transducer set (Braun, Melsungen, Germany). The portal pressure gradient (PPG) resulted as the difference of the portal pressure minus the right atrium pressure (Figure 1). Postinterventional Doppler ultrasonography was carried out the day after TIPS insertion assessing stent patency. As presented by Sahagun *et al*[33] in 1997 shunt stenosis of bare metal stents can effectively be treated by interventional techniques to maintain patency. Stent stenosis due to endothelial growth usually occurs after 3 mo. It was therefore the policy of our institution to reevaluate each patient regularly with Doppler ultrasonography every 3 mo. Interventional angiography was performed every 12 mo or earlier when there was sonographic evidence of stenosis (fall of the initial increase of the portal blood velocity after stenting by > 50% according to Biecker *et al*[34]) or clinical features of recurrent portal hypertension (e.g., hepatic encephalopathy, worsening ascites, presence of high-risk varices at endoscopy or re-bleeding). A TIPS reintervention was performed, when a restenosis or occlusion was affirmed during the angiographic follow-up examination.

Model for end-stage liver disease score

To judge the clinical status of each cirrhotic patient, the model for end-stage liver disease score (MELD score) was calculated based on creatinine, bilirubin and clotting time.

The MELD score for each patient was computed according to the modified method of Wiesner *et al*[35]. This approach differs from the method originally published method by Malinchoc *et al*[36] in two ways: firstly, to avoid negative scores, laboratory serum creatinine levels that were less than 1 mg/dL were rounded off to 1. Preliminary studies in cohorts of non-transplantation candidates have implied that inclusion of the liver disease diagnosis variable does not increase the predictive value of the MELD score; secondly, as previously described by Wiesner *et al*[37,38], 6.43 points as a constant for liver disease aetiology was added to each patient's score to make the results comparable to the originally published studies. The following MELD equation was applied to calculate the severity score: 3.78 [Ln serum bilirubin (mg/dL)] + 11.20 (Ln international normalized ratio) + 9.57 [Ln serum creatinine (mg/dL)] + 6.43.

Table 2 Median survival times depending on various parameters

Parameter	Survival (mo)	95% CI (mo)	Tests	*P* value
Stent open	> 60	NC	Stent occluded *vs* open	0.027
Stent occluded at first control	50	36.6-63.4		
Ascites prior to TIPS	29	1.36-56.64	Ascites *vs* bleeding	0.009
Bleeding prior to TIPS	> 60	NC		
LTX after TIPS	> 60	NC	LTX *vs* no LTX	0.024
Stent diameter < 12 mm or ⩾ 12 mm	> 60	NC	Stent diameter < 12 mm *vs* ⩾ 12 mm	0.486
Anticoagulation	50	14.8–85.2	Anticoag *vs* no anticoag	0.060
No anticoagulation	> 60	NC		
PPG < 12 mmHg or ⩾ 12 mmHg after TIPS	> 60	NC	PPG < 12 mmHg *vs* ⩾ 12 mmHg	0.507
Age (yr)				
⩾ 65	51	33.4-68.6	Age < 65 yr *vs* ⩾ 65 yr	0.053
< 65	> 60	NC		
CHILD score				
A	48.9	40.6-57.2	CHILD A *vs* B	0.013
B	40.0	32.7-47.4		
C	15.0	1.4-28.6		
MELD score				
⩽ 10	52.2	46.3-58.0	MELD score ⩽ 10 *vs* > 10	0.001
> 10	35.3	26.9-43.6		

LTX: Liver transplantation; TIPS: Transjugular intrahepatic portosystemic stent; PPG: Portal pressure gradient; MELD: Model for end-stage liver disease; 95% CI: 95% confidence interval; NC: Not calculable.

Statistical analysis

Data were analyzed using SPSS 17.0 (Chicago, IL, United States). Results are expressed as medians and ranges. Comparisons between groups were performed by using the Mann-Whitney *U*-test and the χ^2 test as appropriate. $P < 0.05$ was considered statistically significant.

For screening of risk factors, univariate analysis was performed. The Kaplan-Meier method was employed to calculate survival from the time of TIPS implantation and comparisons were made by log rank test. A multivariate analysis of factors influencing survival was carried out using the Cox proportional hazards regression model.

RESULTS

Patient characteristics

In the study period (1998-2008), a total of 81 patients were admitted to the study with a mean age of 62.2 ± 10.5 years (range: 38-84 years). According to the indication for TIPS implantation, the patient cohort was subdivided into two groups: VB (group A) and RA (group B). The baseline characteristics of the study population are given in Table 1.

The aetiology of cirrhosis was related to chronic viral hepatitis B or C, alcohol abuse, autoimmune hepatitis and primary sclerosing cholangitis/primary biliary cirrhosis. The mean age in the VB and the RA group showed no statistical difference (61.7 years *vs* 63.3 years, $P = 0.497$). Likewise, the male/female ratio in both groups was comparable, with a slight trend to male patients. The severity of liver disease was calculated according to the CHILD scoring system[39]. Overall, 37% of patients with CHILD A, 57% with B and 6% with CHILD C were enrolled in this study. The MELD score in the RA group was significantly higher compared to the VB group (13.7 ± 5.2 *vs* 9.4 ± 4.9, $P = 0.001$).

TIPS shunt function and patient survival

The PPG significantly decreased from 23.4 ± 5.3 mmHg (VB) *vs* 22.1 ± 5.5 mmHg (RA) before TIPS to 11.8 ± 4.0 mmHg *vs* 11.7 ± 4.2 mmHg after TIPS implantation ($P = 0.001$ within each group). On the other hand, gradient reduction in the VB group did not statistically differ from that in the RA group. Referring to stent diameters there were no relevant differences between both groups. Anticoagulation therapy with enoxaparin at weight-calculated dose was applied for 12 wk after TIPS implantation in 50% of the patients. Thirty-one out of 54 patients in the bleeding group received subcutaneous anticoagulation therapy after TIPS, while only 9 out of 27 patients with RA were anticoagulated post-procedurally ($P = 0.042$). Neither the stent occlusion rate nor the rebleeding rate depended on the anticoagulation state ($P = 0.7$ and $P = 0.47$, respectively). In our patient cohort, the median patency rate of the TIPS shunt was 10 mo. The median survival time was > 60 mo in the VB group *vs* 29 mo in the RA group, showing a significant difference ($P = 0.009$). The number of radiological controls for stent patency was 6.3 ± 4.8 (VB) *vs* 3.8 ± 3.1 (RA) ($P = 0.029$). The mean time interval until the first radiological control was 9.3 ± 10.6 mo (VB) *vs* 4.5 ± 5.6 mo (RA) ($P = 0.133$).

Kaplan-Meier calculation indicated that the stent function (open *vs* occluded) at first control was a significant predictor of survival ($P = 0.027$) (Table 2 and Figure 2B). Furthermore, the median survival time was longer in patients with TIPS due to VB compared to that in patients with RA ($P = 0.009$) (Table 2 and Figure 2A). Seven patients in the VB group and one patient in the RA group underwent liver transplantation. As expected, in univariate analysis survival rates were significantly higher after liver transplantation ($P = 0.024$). The PPG after TIPS had no significant influence on median survival times in both groups (Table 2). Mortality was not significantly increased in patients aged > 65 years (Table

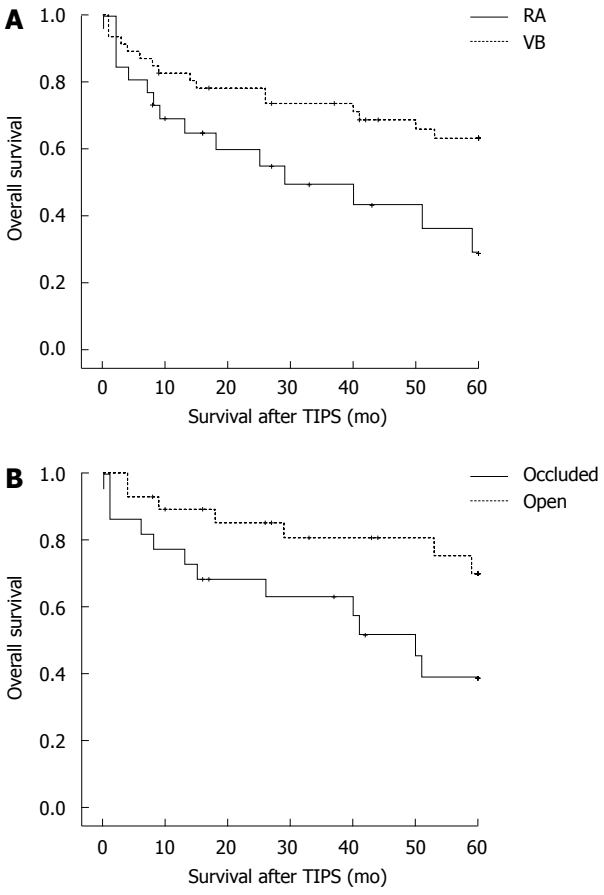

Figure 2 Kaplan-Meier survival analysis of patients after transjugular intrahepatic portosystemic shunt placement. A: In patients with initial ascites as indication for transjugular intrahepatic portosystemic stent (TIPS), survival is significantly shorter than that in patients with variceal bleeding [refractory ascites (RA) *vs* variceal bleeding (VB), log rank test $P = 0.009$]; B: In patients with occluded stent at first fluorographic control, survival is significantly shorter than that in patients with open stent (occluded *vs* open, log rank test $P = 0.027$).

2). For those patients having a MELD score greater than 10, the median survival was significantly shorter than for those with a MELD score less than or equal to 10 (35.3 mo *vs* 52.2 mo, $P = 0.001$).

In the Cox regression model, only stent occlusion at first control ($P = 0.022$), ascites prior to TIPS ($P = 0.043$), CHILD stage ($P = 0.015$) and MELD score ($P = 0.004$) were independent prognostic factors of survival. In contrast, anticoagulation management ($P = 0.097$), the porto-systemic pressure gradient ($P = 0.460$) and rebleeding episodes ($P = 0.765$) had no significant effect on the overall survival.

We further performed a subgroup analysis using the Kaplan-Meier method in terms of survival of the two groups considering the independent risk factors by Cox regression model analysis such as age, stent patency at first control, CHILD and MELD scores.

When survival was analyzed based on MELD scores (Figure 3A and B) we found that patients with VB had a statistically improved survival over those with RA (MELD score < 10 *vs* $\geqslant 10$, log rank $P = 0.001$).

Stratification by CHILD stages B and C or age > 65 years demonstrated that patients in the VB group had a significantly improved long-term survival compared with those in the RA group (log rank test $P = 0.021$ each) (Figure 3C and D).

Due to limited patient numbers the overall survival in patients with stent occlusion at first control did not differ significantly in both groups (Figure 3E, log rank test $P = 0.289$).

DISCUSSION

Since its introduction in the 1980s, the TIPS procedure has played a major role in the management of portal hypertension[9,24,40-43]. In the present study, shunt insertion was completed successfully in 81 patients (80% of patients scheduled). The baseline characteristics show the heterogeneous patient population at our hospital, the distribution of underlying diseases is typical for western countries[44,45] (Table 1).

Until recently, bare metal stents were the treatment of choice for establishing the TIPS tract. In contrast to the actual AASLD guidelines[9], in the United States[46] about 20% of all TIPS procedures still use uncovered TIPS stents.

Even though covered TIPS stents require fewer reinterventions, after a 12-mo-follow-up, the total procedure-related expenses were higher with covered TIPS stents due to their higher initial cost[43]. Further, a study by Bureau *et al*[25] in 2007 could not detect any survival benefit of covered *vs* uncovered stents. For these reasons we used non-coated TIPS stents during the study period of 1998 until 2008. Since this study was initiated at our institution, polytetrafluoroethylene-covered stents are now widely used, with the recent literature showing a significant improvement of primary patency up to 90% within 12 mo of application[25,28,47].

In agreement with Membreno *et al*[48], we show that in patients with TIPS due to VB, the overall long-term survival is significantly better than that in patients with TIPS due to RA (> 60 mo *vs* 29 mo, $P = 0.009$) (Figure 2A).

In the VB and RA groups of our study, the degree of reduction of the PPG following TIPS implantation was almost identical and there was no significant correlation with stent diameters. According to the literature, an adequate decompression of portosystemic hypertension can be achieved by 50% reduction of the initial pressure[49]. Other series describe a 20% reduction as sufficient and the PPG should be decreased and maintained under 12 mmHg[50]. In our study, the PPG was lowered post-procedurally at a recommended threshold of approximately 12 mmHg[24] (VB 11.8 ± 4.0 mmHg *vs* RA 11.7 ± 4.2 mmHg). Biecker *et al*[34] demonstrated in their study with 118 cirrhotic patients, that the initial decrease in the PPG after TIPS is a predictor of the rebleeding risk, but not of survival. Our study was not able, however, to confirm these findings.

In our patient cohort, the Cox multivariate regression analysis identified stent occlusion at first control as an

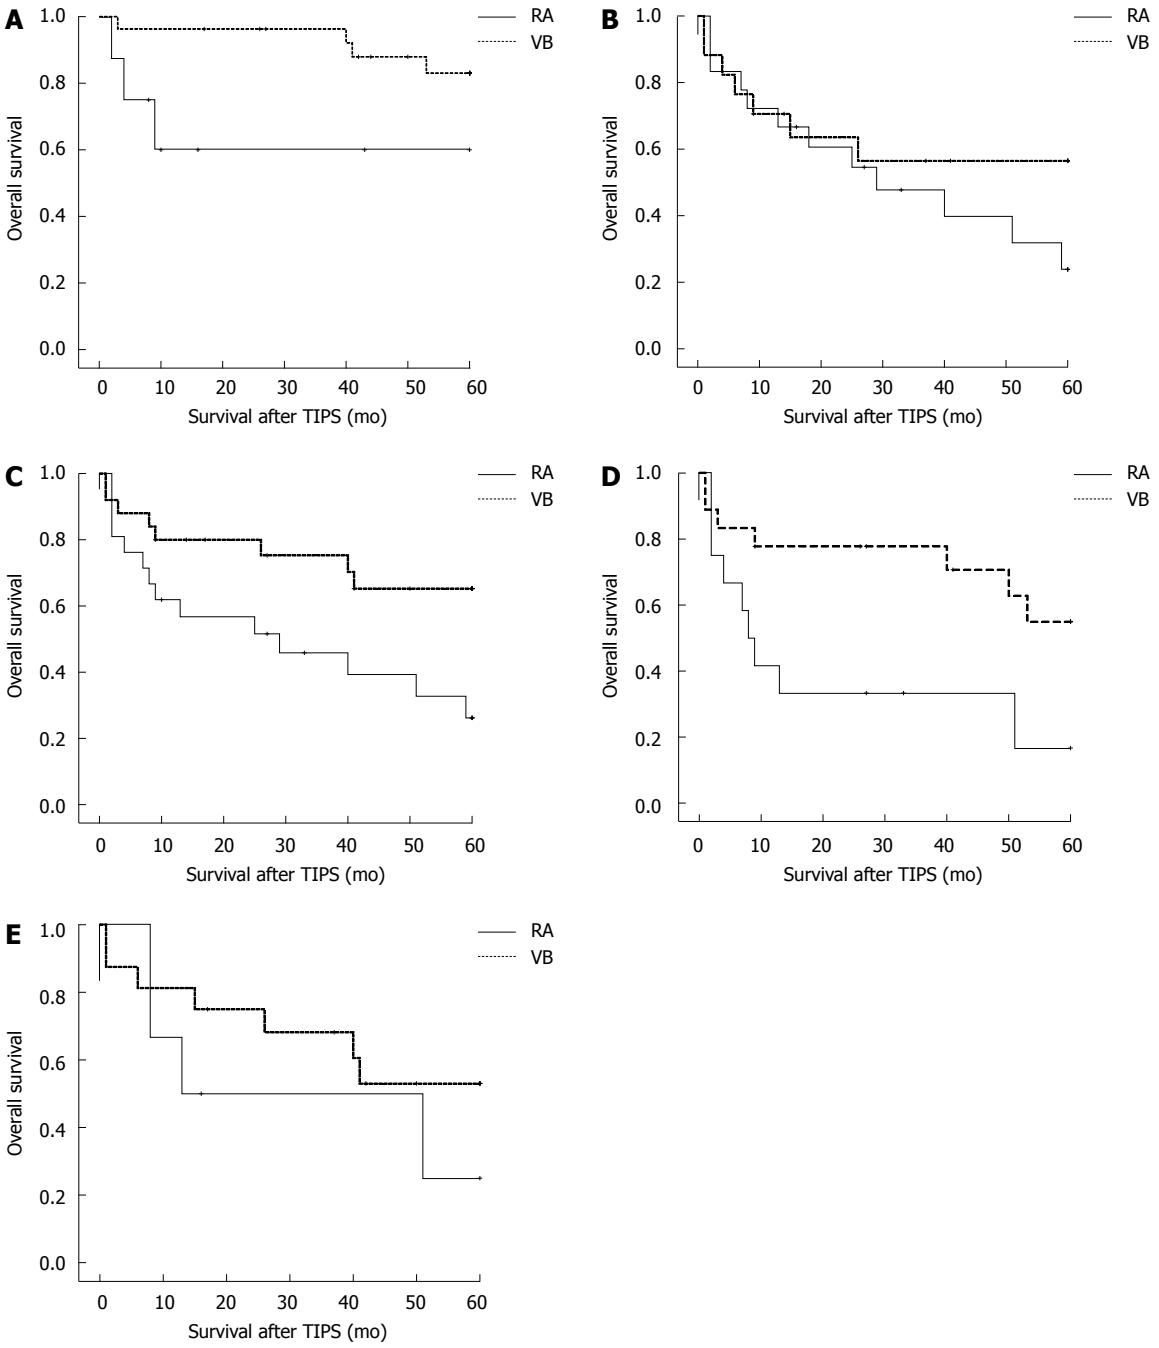

Figure 3 Kaplan-Meier survival analysis of patients after transjugular intrahepatic portosystemic shunt placement. A: Subgroup analysis with patients having a model for end-stage liver disease score (MELD) < 10: Significant difference in overall survival relating to indication [refractory ascites (RA) *vs* variceal bleeding (VB) group, log rank test $P = 0.031$]; B: Subgroup analysis with patients having a MELD score > 10: No significant difference in overall survival relating to indication (RA *vs* VB group, log rank test $P = 0.274$); C: Subgroup analysis with patients with CHILD B or C cirrhosis: Significant difference in overall survival relating to indication (RA *vs* VB group, log rank test $P = 0.021$); D: Subgroup analysis with patients age > 65 years: Significant difference in overall survival relating to indication (RA *vs* VB group, log rank test $P = 0.021$); E: Subgroup analysis with stent occlusion at first control: No significant difference in overall survival relating to indication (RA *vs* VB group, log rank test $P = 0.289$).

independent predictor of survival regardless of the indication for TIPS (Figure 2B and Figure 3E). Therefore, regular monitoring of the TIPS patients is highly recommended to provide early intervention when stenosis occurs[51]. In our institution, after successful TIPS insertion the first controls are conducted within 3 mo. Based on the results of the first interventional control (angiography), the following examinations are scheduled. Routinely colour Doppler ultrasound is used as a non-invasive device for monitoring the TIPS function.

Unsurprisingly, CHILD stage was an independent prognostic factor of survival ($P = 0.015$), probably due to the fact that the CHILD scoring system is a validated tool for assessing prognosis[39,52]. When survival was analyzed based on CHILD B or C, we found that patients with VB had a statistically improved survival over those

with RA (Figure 3C). Similar findings could be observed for patients being older than 65 years or having a MELD score < 10 leading to a significant overall survival relating to the indication for TIPS as displayed in Figure 3A, B and D.

These observations are consistent with those by Membreno *et al*[48]. The retrospective design and the use of uncovered stents as well as the relatively small sample size may introduce a certain bias. Nevertheless, our retrospective study emphasises several clinical aspects of portal hypertension in liver cirrhosis to be considered in conjunction with TIPS treatment.

In conclusion, TIPS is an established and safe nonsurgical method to decompress portal hypertension and to avoid its sequelae. RA prior to TIPS and stent occlusion at first control are independent predictors of survival in patients with bare metal TIPS shunts. This observation militates in favour of close follow-ups for patients with TIPS due to RA.

COMMENTS

Background

Liver cirrhosis is a common problem in gastroenterology. Various medical and interventional treatment options have been developed to manage the complications of portal hypertension. Minimal invasive placement of a transjugular intrahepatic portosystemic shunt (TIPS) is now widely used to lower the portosystemic pressure gradient.

Research frontiers

The authors undertook a retrospective study to work out the clinical outcome and predictors of survival after TIPS insertion with bare metal stents.

Innovations and breakthroughs

Refractory ascites (RA), stent occlusion at first control, initial CHILD stage and model for end-stage liver disease score were identified as independent predictors of survival in cirrhotic patients after TIPS implantation.

Applications

By understanding, which risk factors can influence survival in cirrhotic patients scheduled for TIPS insertion, the authors contribute to a better knowledge of this common clinical scenario. This may lead to a better risk stratification for the indication of TIPS insertion.

Terminology

The TIPS procedure decompresses the portosystemic pressure by establishing a "short cut" between the portal vein and the caval venous system.

Peer review

This is a retrospective study with the major objective to observe the role of stenosis and occlusion rates of uncovered stents on the survival of cirrhotic patients with TIPS inserted for variceal bleeding or RA.

Abstract

AIM: To evaluate the effectiveness of infliximab as a second-line therapy in Crohn's disease patients after adalimumab failure.

METHODS: A historical cohort study in a community-based gastroenterology practice evaluated Crohn's disease patients treated with infliximab (induction plus maintenance) after adalimumab failure. Patients were identified using a large Spanish database (ENEIDA).

RESULTS: We included 15 Crohn's disease patients who received infliximab after adalimumab failure. Five patients discontinued adalimumab due to loss of response, 3 due to adverse events and 7 due to partial response. After infliximab therapy was started, all patients who had interrupted adalimumab due to loss of efficacy regained response. All patients who discontinued adalimumab due to adverse events responded to infliximab and maintained this response; one of these patients had an uneventful course on infliximab, but 2 developed adverse events. None of the 7 patients who interrupted adalimumab due to partial response reached remission with infliximab.

CONCLUSION: Switching from adalimumab to infliximab may be useful in patients who develop adverse effects or loss of response, however, the benefit of infliximab in primary nonresponders was not established.

INTRODUCTION

Crohn's disease (CD) is a chronic, relapsing, transmural inflammation of the gastrointestinal tract that affects mainly young patients, and results in a considerably decreased quality of life[1]. There is no medical or surgical cure for CD, and the goal of the existing therapeutic modalities is to induce and maintain remission[2]. Since tumor necrosis factor (TNF)-α has a pivotal role in the pathogenesis of CD[3], the introduction of antibodies against TNF-α has created new perspectives for the management of this disease[4,5].

Infliximab is a murine, chimeric, monoclonal immunoglobulin G1 antibody against TNF-α which was approved for CD treatment ten years ago. Infliximab is effective in inducing and maintaining remission in patients with moderate to severe CD and in patients who have failed conventional non-biologic therapy[6]. However, one-third of these patients do not respond to induction therapy. In addition, a subset of patients who initially respond to infliximab will discontinue therapy due to loss of response or intolerance[7,8].

Adalimumab is a recombinant fully human immunoglobulin G1 monoclonal antibody against TNF-α. Randomized controlled trials have demonstrated the efficacy of adalimumab for induction and maintenance of remission in patients naïve to anti-TNF therapy[9-11]. There are also several studies providing data on the efficacy of adalimumab after infliximab failure[12-16]. The CHARM trial[9] evaluated adalimumab as a maintenance therapy in patients after infliximab failure as part of a subgroup analysis. The GAIN study[16], a randomized placebo-controlled trial, demonstrated that adalimumab therapy is effective in inducing remission in patients with active CD who initially responded to infliximab, but then lost response or became intolerant to the drug.

Since adalimumab was approved in 2007 for use in CD, it can be prescribed as a first-line therapy, and similar to infliximab, one-third of patients do not respond to this drug and a proportion of patients can lose efficacy or become intolerant over time[12,17,18]. In clinical practice, patients who do not respond to infliximab, who lose response, or become intolerant may be prescribed adalimumab in an attempt to regain response, but to the best of our knowledge, there are no published data on the effectiveness of infliximab after adalimumab failure. Therefore, the aim of this study was to evaluate the effectiveness and safety of infliximab after adalimumab failure in CD patients.

MATERIALS AND METHODS

Study subjects

Patients who received infliximab for CD after adalimumab failure at a community-based gastroenterology practice were evaluated in a historical cohort study. They were identified using a large Spanish database (ENEIDA), promoted by the Spanish Working Group in Crohn's and Colitis (GETECCU), including patients with inflammatory bowel disease. The database prospectively records the use, effectiveness and adverse events of immunomodulators and anti-TNF therapy. The database at the time of the study included 10752 patients, of whom 5467 had CD. Patients were excluded from the study if adalimumab or infliximab was initiated for treatment of a disease other than CD.

Data collection

Data collected included: sex, age, smoking status, age at diagnosis, location of disease, disease behavior (inflammatory, stenosing or fistulizing), perianal disease, concurrent use of immunomodulators, indication of anti-TNF therapy, data regarding adalimumab therapy (start date for adalimumab therapy, initial response, loss of response, date of loss of response, dose escalation of adalimumab after loss of response, response to escalated dose, loss of response to escalated dose, date of loss of response to escalated dose, adverse events with standard and with escalated treatment), reasons for discontinuation of adalimumab therapy, data regarding infliximab therapy (start date for infliximab therapy, initial response, loss of response, date of loss of response, dose escalation of infliximab after loss of response, response to escalated dose, loss of response to escalated dose, date of loss of response to escalated dose, adverse events with standard and with escalated treatment) and reasons for discontinuation of infliximab treatment. Individual charts were reviewed to obtain all data.

Definitions

Dose escalation: Dose escalation of adalimumab was defined as a decrease in the interval of administration from every-other-week to every-week. In the case of infliximab, dose escalation was defined either as an increase in infliximab dose, e.g., from 5 to 10 mg/kg, or a decrease in infliximab infusion interval, e.g., from every 8-wk to every 4-wk, or both a dose increase and an interval decrease.

Evaluation of response: For luminal disease, response to adalimumab and infliximab was evaluated using the Harvey-Bradshaw index (HBI)[19] four weeks after the first dose. Partial response was defined as a decrease in the HBI of more than 3 points. Remission was defined as a HBI below or equal to 4 without steroids. In perianal CD, complete response was defined as closure of all fistulas and partial response as a 50% or more reduction in the number of draining fistulas.

Loss of efficacy: Loss of efficacy was defined as impairment in patient's symptoms coupled with endoscopic, radiographic, and/or serologic (elevated C-reactive protein) evidence of inflammation that made the physician escalate the dose of treatment or change to other drug.

Disease behavior and location: Disease behavior was categorized based on the Montreal classification as: (1) inflammatory or CD without fistulizing or stricturing complications; (2) stricturing disease was defined as the presence of clinical symptoms of partial or complete obstruction with fixed narrowing and/or narrowing with proximal dilatation; and (3) fistulizing, which included the presence of enteric fistulas, intraabdominal abscesses, or bowel perforation. The location of disease was established by identifying macroscopic evidence of CD in any part of the gastrointestinal tract. Possible categories of disease location included the ileum, colon, ileum and colon, upper gastrointestinal tract, and perianal/perineal area.

Concomitant immunomodulators: Concomitant immunosuppressive treatment was considered if a patient had been on immunomodulators for at least the first 6 mo after starting the anti-TNF therapy.

Smoking history: Smoking was defined as the consumption of at least 1 cigarette daily for a period of at least 3 mo prior to study entry.

Statistical analysis

mean ± SD was calculated for continuous variables. Percentages and 95% confidence intervals were provided for categorical variables.

RESULTS

We included 15 CD patients who received infliximab after adalimumab failure. The main characteristics of the study population are summarized in Table 1. Mean time from diagnosis to adalimumab treatment was 69 mo and the median time of adalimumab treatment was 5 mo (range: 2-19 mo). Four patients had stricturing CD. Two of these patients discontinued treatment with adalimumab due to partial response, one patient had an initial partial response but lost this response, and the other patient was in remission but experienced adverse events which led to the interruption of adalimumab. The two patients who had a partial response achieved a partial response after switching to infliximab and the patient who lost the partial response achieved a partial response with infliximab. The patient who had adverse events tolerated infliximab without secondary effects. Four patients received immunosuppressants concomitantly with adalimumab and seven patients were on immunosuppressants previously and maintained this therapy when they started adalimumab.

Adalimumab discontinuation due to loss of efficacy

Five patients discontinued adalimumab due to loss of efficacy. Three were women, 3 had CD of the ileum, 4 showed inflammatory behavior and one perianal disease. Two of these patients had extraintestinal manifestations and 2 were on concomitant immunomodulators (azathioprine).

Median time to loss of efficacy of adalimumab was 6.2 mo (range: 3-9 mo). After loss of efficacy, the dose of adalimumab was escalated in 3 of these patients, but only 1 responded to this treatment strategy (Table 2).

All patients who discontinued adalimumab due to loss of efficacy regained response after switching to infliximab (3 reached remission and 2 had a partial response) (Table 2).

Adalimumab discontinuation due to lack of response

Seven patients discontinued adalimumab due to partial response. Four were women, 5 had CD of the ileocolic region, 6 showed inflammatory behavior and 2 perianal disease. The dose of adalimumab was escalated in 3 of these patients with the aim of reaching remission, but without improvement in response (Table 2).

None of the 7 patients who interrupted adalimumab due to partial response reached remission with infliximab: 5 (71%) maintained partial response and 2 (29%) lost partial response (Table 2).

Adalimumab discontinuation due to adverse events

Three patients discontinued adalimumab due to adverse events: 1 had facial edema, 1 an injection site reaction and 1 had dizziness. All of these patients were female, 2 had CD of the ileum, 2 showed stricturing behavior, 1 perianal disease and 2 were on concomitant immunomodulators (azathioprine). Two of these patients were in remission and 1 had a partial response at the time of adalimumab discontinuation due to adverse events. All patients maintained the response they had with adalimumab after switching to infliximab (patients in remission maintained

remission with infliximab and the single patient with partial response had a partial response to infliximab). One of these patients received infliximab uneventfully, 1 had a delayed hypersensitivity reaction controlled by premedication with steroids before infliximab infusion, and the third patient interrupted infliximab due to facial edema (the same adverse event that forced the discontinuation of adalimumab).

DISCUSSION

The treatment of CD has evolved over the past decade with the introduction of anti-TNF agents. However, some patients do not respond or show suboptimal response to these drugs. Furthermore, patients who respond initially may lose efficacy over time or develop adverse events, which sometimes forces them to discontinue treatment. In these different scenarios, switching from one anti-TNF-α to another could represent an option for CD patients who fail the first anti-TNF drug.

The findings of the present observational study suggest that the probability of achieving clinical response after switching from adalimumab to infliximab may be higher in patients who discontinue adalimumab due to loss of efficacy or adverse events; as compared to those switching due to primary failure with adalimumab. In fact, patients who did not reach remission with adalimumab had no response to infliximab, whereas a relatively high proportion of patients showed a satisfactory response after discontinuing adalimumab due to loss of response or adverse events.

These observations seem to be in agreement with some of the published reports focusing on the effectiveness of adalimumab after infliximab failure[11,12,16,17]. In this respect, we have evidence that after loss of efficacy or intolerance to infliximab, adalimumab can be effective. However, to the best of our knowledge, this is the first study evaluating the effectiveness of infliximab after adalimumab failure.

Both infliximab and adalimumab are monoclonal antibodies and can be recognized by the human immune system as foreign antigens which respond by creating their own antibodies to different sites on the molecule[7,20,21]. In the case of infliximab, the development of antibodies to infliximab and, as a consequence, low trough concentration of the drug, have been implicated as predisposing factors for infliximab treatment failure[21-24]. The presence of antibodies to infliximab has been associated with the development of hypersensitivity reactions (infusional or delayed), while low trough concentration of infliximab has shown a high correlation with loss of response to treatment[7,21,24,25].

Although fully human, adalimumab is not devoid of immunogenicity. Antibodies to adalimumab have been reported in 2.6%-38% of patients treated for CD and rheumatoid arthritis[11,26,27]. In patients with rheumatoid arthritis, antibodies to adalimumab have been associated with low adalimumab trough serum concentration and decreased clinical response[26]. Karmiris *et al*[20] in a recently published study on CD patients treated with adalimumab after infliximab failure, found that 9% of patients developed antibodies to adalimumab, and that patients who developed antibodies to adalimumab frequently had low trough serum concentrations. They also reported that adalimumab trough serum concentration was lower throughout the follow-up period in patients who had to discontinue treatment due to loss of efficacy[20]. These findings suggest that the role of immunogenicity in the loss of response and in the development of adverse events following adalimumab treatment may be similar to that previously described with infliximab.

There is a lack of data on the development of adverse events with an anti-TNF drug in the subgroup of patients that had discontinued other anti-TNF drugs due to this reason, as the published studies provide this information globally irrespective of the type of failure (loss of efficacy or adverse events)[7,11,16]. The occurrence of immunoallergic reactions has been related to the for-

mation of antibodies against the anti-TNF drug and, in this respect, Karmiris *et al*[20] found that the presence of antibodies to infliximab before initiation of adalimumab therapy was not associated with a higher incidence of antibodies against adalimumab. There are no data on the development of antibodies to infliximab in patients with previous antibodies to adalimumab, but we would expect that they were not increased based on the findings of the previously mentioned study[20]. In our study, among the 3 patients who discontinued adalimumab due to adverse events, 2 had adverse events with infliximab and 1 of them had to interrupt infliximab due to the same adverse event which had developed with adalimumab. Considering that antibodies to one anti-TNF drug do not seem to be increased in patients with antibodies to other anti-TNF drug, our findings could be explained by the existence of cross reactions between antibodies to adalimumab and infliximab molecules, but this hypothesis has not been proved.

Finally, we found no benefit after switching from adalimumab to infliximab in patients who discontinued treatment due to partial response to adalimumab. The lack of efficacy of the anti-TNF agent in these patients could be due to particular disease characteristics in which TNF-α does not play a pivotal role[23]. In the adjunctive catheter-directed thrombolysis trial performed in rheumatoid arthritis patients, the authors found that an incomplete response to anti-TNF therapy in the population included in the study was not related to an insufficient concentration of the drug or to the presence of antibodies against it, concluding that other pro-inflammatory molecules different from TNF-α could play a main role in these patients.

One limitation of our study is the small sample size. Although our results are original, since there are no published data on the efficacy and safety of infliximab after adalimumab failure in CD patients, studies with a larger sample size are needed to establish the benefit of switching to another anti-TNF agent after one anti-TNF agent has failed.

In conclusion, the results of the present study suggest that CD patients may be successfully treated with infliximab after adalimumab failure, specifically those withdrawing for loss of efficacy or adverse events. Conversely, in patients discontinuing adalimumab due to lack of response, the efficacy of infliximab was not established and other drugs with different targets might offer a greater chance of therapeutic success.

COMMENTS

Background

There is no medical or surgical cure for Crohn's disease (CD), and the goal of the existing therapeutic modalities is to induce and maintain remission. Infliximab and adalimumab are monoclonal antibodies against tumor necrosis factor (TNF-α). However, one third of patients can lose response or become intolerant to these drugs.

Research frontiers

Studies are being performed in order to identify which are the factors responsible of the loss of efficacy or intolerance to anti-TNF drugs.

Innovations and breakthroughs

In clinical practice, patients who do not respond to infliximab, who lose response or become intolerant may be prescribed adalimumab in an attempt to regain response. Data regarding the outcome of patients who received infliximab after adalimumab failure are scarce. This study assesses the effectiveness of infliximab after adalimumab failure in CD patients.

Applications

The results of the present study suggest that CD patients may be successfully treated with infliximab after adalimumab failure, specifically those withdrawing due to loss of efficacy or adverse events. Conversely, in patients discontinuing adalimumab due to lack of response, the efficacy of infliximab has not been established and other drugs with different targets might offer a greater chance of therapeutic success.

Peer review

This is a good study in which the authors valuated the effectiveness of infliximab as a second-line therapy in CD patients after adalimumab failure. The result is interesting and suggested that CD patients may be successfully treated with infliximab after adalimumab failure.

Abstract

AIM: To assess if software assisted-contrast-enhanced ultrasonography (CEUS) provides reproducible perfusion parameters of hepatic parenchyma in patients affected by chronic liver disease.

METHODS: Forty patients with chronic viral liver disease, with (n = 20) or without (n = 20) cirrhosis, and 10 healthy subjects underwent CEUS and video recordings of each examination were then analysed with Esaote's Qontrast software. CEUS dedicated software Qontrast was used to determine peak (the maximum signal intensity), time to peak (TTP), region of blood value (RBV) proportional to the area under the time-intensity curve, mean transit time (MTT) measured in seconds and region of blood flow (RBF).

RESULTS: Qontrast-assisted CEUS parameters displayed high inter-observer reproducibility (κ coefficients of 0.87 for MTT and 0.90 TTP). When the region of interest included a main hepatic vein, Qontrast-calculated TTP was significantly shorter in cirrhotic patients (*vs* non-cirrhotics and healthy subjects) (71.0 ± 11.3 s *vs* 82.4 ± 15.6 s, 86.3 ± 20.3 s, $P < 0.05$). MTTs in the patients with liver cirrhosis were significantly shorter than those of controls (111.9 ± 22.0 s *vs* 139.4 ± 39.8 s, $P < 0.05$), but there was no significant difference between the cirrhotic and non-cirrhotic groups (111.9 ± 22.0 s *vs* 110.3 ± 14.6 s). Peak enhancement in the patients with liver cirrhosis was also higher than that observed in controls (23.9 ± 5.9 *vs* 18.9 ± 7.1, P = 0.05). There were no significant intergroup differences in the RBVs and RBFs.

CONCLUSION: Qontrast-assisted CEUS revealed reproducible differences in liver perfusion parameters during the development of hepatic fibrogenesis.

INTRODUCTION

Changes in hepatic perfusion are a key feature of cirrhosis[1]. Capillarization of the sinusoids with loss of

endothelial fenestration and increased tone of activated hepatic stellate cells (HSCs) increase the mechanical resistance to portal blood flow and augment hepatic vascular tone, leading to portal hypertension[2]. Alterations involving the microvascular bed of the liver are already evident during the precirrhotic stages of hepatic fibrogenesis. The ongoing liver damage induces the overexpression of angiogenic growth factors (such as vascular endothelial growth factor or platelet-derived growth factor)[3], which promote the persistence of inflammatory changes and fibrogenic tissue repair, facilitating the development of shunts between branches of the portal vein, the hepatic veins, and the hepatic artery within the newly formed fibrotic septa[2,4].

Computed tomography (CT) and magnetic resonance imaging (MRI) have both been used for quantitative and qualitative assessment of parenchymal perfusion in cirrhotic livers. CT studies revealed increased hepatic arterial flow and decreased mean transit times (MTT), as compared with values observed in control subjects[5]. In contrast, MRI with low molecular weight contrast material revealed increases in the MTT[6]. Use of these methods in clinical practice is limited, however, by the intensive post-processing required to obtain perfusion data, high costs, and the lack of standardized examination protocols[7].

B-mode ultrasonography with Doppler study of hepatic vessels is often the first-line imaging study for the work-up of patients with diffuse liver disease. The Doppler technique is used mainly to measure flow in macroscopic vessels and is not strictly related to the microcirculation of the liver[8]. Contrast-enhanced ultrasonography (CEUS) is performed after intravenous administration of a suspension of gas-filled microbubbles, which remain entirely within the intravascular space and thus act as a blood pool tracer. CEUS studies of perfusion in the liver parenchyma have focused mainly on the measurement of contrast-medium transit times (from the portal vein to the hepatic veins), which have proved to be significantly shorter in patients with cirrhosis (compared with non-cirrhotic patients with chronic liver disease)[9-11]. CEUS has also documented increased regional perfusion of the hepatic parenchyma in cirrhotic patients (compared with healthy subjects), and this increase displayed correlation with the degree of liver failure[12].

A major shortcoming of CEUS is its user-dependency. Qontrast™ (Esaote S.p.a., Florence, Italy) is a post-processing computational tool, which can be used with CEUS to obtain objective, quantitative parameters of microvascular damage in various organs, including the liver.

We examined patients with chronic liver disease using CEUS with Qontrast analysis of hepatic parenchymal perfusion. The aims of this study were to assess the reliability and reproducibility of software assisted-CEUS studies of hepatic parenchymal perfusion and to evaluate if the analysis of the parameters obtained could help to understand vascular changes developing during liver fibrogenesis.

MATERIALS AND METHODS

The study protocol, which conformed to the guidelines outlined in the 1975 Declaration of Helsinki, was pre-approved by the institutional ethics committee. Written informed consent was obtained from all participants.

Study populations

Participants were enrolled between March 2007 and December 2010. They included 10 control patients with no liver disease (as documented by self-reported history and blood chemistry data obtained during screening) and 40 patients consecutively seen by our staff for chronic viral liver disease. At the time of enrollment, all of these patients had been positive for hepatitis B surface antigen and/or anti-hepatitis C virus antibodies for at least 6 mo.

All participants underwent complete physical examinations, laboratory tests, and standard B-mode abdominal ultrasonography. Candidates were excluded if they presented any of the following: (1) sonographic evidence of focal liver lesions; (2) history of alcohol consumption of $\geqslant$ 20 g/d; and (3) current use of medication known to affect the intra- or extra-hepatic circulation.

The patients with chronic liver disease included 20 patients in whom the absence of cirrhosis had been confirmed by liver biopsy (non-cirrhotic group) and 20 others (cirrhotic group) with cirrhosis diagnosed by liver biopsy or on the basis of commonly accepted clinical criteria. The latter included a history of chronic liver disease together with portal hypertension manifested by two or more of the following: (1) endoscopic evidence of esophageal or gastric varices and/or portal hypertensive gastropathy; (2) hypersplenism (reflected by a white blood cell count of $< 3500/mm^3$ and/or a platelet count of $< 100\,000\ /mm^3$); (3) sonographic evidence of ascites; and (4) a hepatic venous pressure gradient (HVPG) of $\geqslant$ 12 mmHg[13,14]. The severity of the cirrhosis was rated with the Child-Pugh[15] and model for end-stage liver disease (MELD)[16] systems.

The liver biopsies used for patient classification had all been performed under sonographic guidance 1-3 mo prior to enrollment (mean: 1.8 mo; median: 1 mo). For the purposes of this study, all slides were independently reviewed by a single experienced liver pathologist, who was blinded to the patient's clinical data and the results of his/her hepatic ultrasound examination. This examiner rated the presence of inflammation and fibrosis in each case with the Metavir scoring system[17].

Ultrasound and CEUS analysis

All sonographic examinations were carried out by an experienced radiologist using a 3.5-MHz convex array transducer and a General Electric Logiq 9 scanner (Milwaukee, WI, United States) equipped with software for contrast imaging and color and power Doppler. Patients were examined after a fast of 6 h. After a standard B-mode scan, the second phase of the examination started, during which we evaluated perfusion within the hepatic parenchyma using a sonographic contrast agent composed of sulfur hexafluoride-filled microbubbles (Sonovue®, Bracco Spa, Milan, Italy). The probe was placed over the middle hepatic vein (at least 3 cm from the confluence)

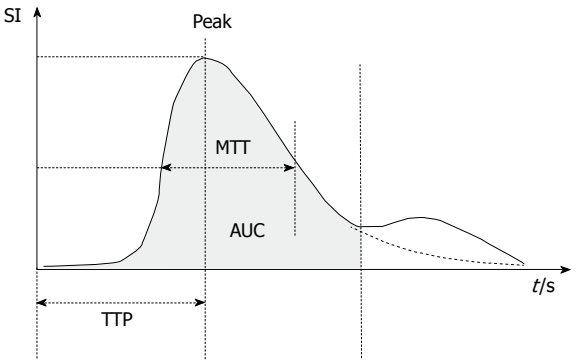

Figure 1 Main parameters extrapolated by Qontrast analysis of the time-intensity curve obtained by liver perfusion with an ultrasound contrast agent. SI: Signal intensity; TTP: Time to peak; MTT: Mean transit time; AUC: Area under the curve.

and surrounding tissue, where heartbeat artifacts were negligible. If an acceptable signal could not be obtained from this vein due to abdominal gas, the scan was made over the left or right hepatic vein. Tissue enhancement of these areas was recorded in a digital video format from 20 s before (baseline signal) to 130 s after the injection of a 2.5 mL bolus of Sonovue. Sonovue was injected manually into the antecubital vein at the rate of 1 mL/s, and the line was flushed with a 2.5-mL bolus of normal saline delivered at the same rate. Patients were instructed to breath gently during the procedure to minimize movement-related artifacts. Vital signs were monitored for 1 h after the examination, and patients were interviewed by phone 48 h after discharge to identify any adverse effects.

Video recordings were then analysed with the Qontrast software, which performs a full-map parametric analysis of perfusion within a selected set of frames in a specific region of interest (ROI). The loop of images is automatically processed after the tissue region and perfusion period have been defined; translational movements of the selected area can also be corrected. The area is then automatically aligned over all frames, and perfusion is analysed for points that continuously identify the moving tissue. Signal brightness is analysed separately at each point, and the optimal fitting curve is evaluated for each point.

In each patient, we evaluated two different ROIs. The first was a 25 cm^2 area of parenchyma that included one of the main hepatic veins and surrounding tissue; the second was a smaller area (5 cm^2) that included no major vessels. For each ROI, time-enhancement intensity curves were plotted with the Qontrast software, and the following parameters were generated (Figure 1): peak signal intensity (in dB) reached during the transit of the Sonovue bolus; time to peak (TTP) intensity, measured in seconds; regional blood volume (RBV), which is proportional to the area under the time-intensity curve; MTT (measured in seconds); and regional blood flow (RBF), which is the ratio of the RBV to MTT.

Intraobserver and interobserver agreement

We evaluated interobserver and intraobserver variation in measurements of the MTT and TTP during CEUS. For the former assessment, two observers (one experienced physician the other one in training) independently and blindly reviewed the video recording of each examination. For the latter analysis, each video was re-examined by one of the observers (still blind) 2-3 mo after the original review. Concordant measurements were those that differed by no more than ± 1 s.

Table 1 Clinical and biochemical characteristics of the three study groups (mean ± SD)

Group characteristics	Controls *n* = 10	Patients with chronic liver disease	
		Non-cirrhotic *n* = 20	Cirrhotic *n* = 20
Age (yr)	48.5 ± 14.4	48.9 ± 12.4	57.7 ± 11.4

Statistical analysis

Data were expressed as group mean ± SD. Differences between the three groups (cirrhotic patients, non-cirrhotic patients, and controls) were evaluated with the Kruskall-Wallis test. A post-hoc *t* test was then used to evaluate differences between each group of participants. Differences in the proportion of male or female patients were assessed with the χ^2 test. Kappa statistics were used to assess interobserver and intraobserver agreement in the calculation of the Qontrast parameters[18,19].

McGraw-Hill Primer Statistical Software (2nd edition, 1986) and MedCalc Statistical Software (version 11.6, 2011, Mariakerke, Belgium) were used for all analyses. Statistical significance was defined as $P < 0.05$.

RESULTS

The characteristics of the control group and the patients with chronic liver disease are shown in Table 1. Most of the patients with cirrhosis [diagnosed by liver biopsy (*n* =

Table 2 Contrast-enhanced ultrasonography parameters calculated with Qontrast software in the three study groups (mean ± SD)

Perfusion parameter	Controls		Non-cirrhotic patients		Cirrhotic patients

4) or on the basis of clinical criteria ($n = 16$)] were Child-Pugh class A ($n = 11$), but classes B and C were also represented (5 and 4 patients, respectively). The mean MELD score for the cirrhotic subgroup was 10.3 ± 3.9. Eleven of these patients had ascites, 2 had signs of hepatic encephalopathy, esophageal varices were found in 11, and HVPG more than 12 mmHg was evident in 3 patients. There were no significant age differences between the three groups, but males were significantly more common in the subgroups with chronic liver disease.

Ultrasound and CEUS studies were successfully completed for all participants, and no adverse effects were observed during or after the procedure (as documented by phone interviews with patients).

Qontrast analysis of contrast-enhanced ultrasound of liver parenchyma

The perfusion parameters generated by Qontrast analysis of the two ROIs examined is shown in Table 2: the first containing a hepatic vein and surrounding tissue, the second containing parenchyma alone, with no major vessels. In both cases, the MTTs in the patients with liver diseases were significantly shorter than those of controls, but there was no significant difference between the cirrhotic and non-cirrhotic groups. Analysis of the ROIs containing a hepatic vein (middle in 46 cases, right in 3, left in 1) revealed that TTPs in cirrhotic patients were significantly shorter than those of controls and of non-cirrhotic patients ($P < 0.05$). Similar findings emerged when we analyzed data obtained for the smaller ROIs although the differences in this case were not statistically significant. Peak enhancement in the patients with liver disease was also higher than that observed in controls, but again, this difference was significant only when the area analyzed included a main hepatic vein ($P < 0.05$). There were no significant intergroup differences in the RBVs, regardless of which ROI was considered. As for the RBF, the values observed in the chronic liver disease groups were appreciably (but not significantly) increased over those of controls, probably as a result of the shorter MTTs in these patients. This difference was also seen when the hepatic vein was not included in the ROI.

Observer agreement

Intraobserver agreement was calculated for MTT and TTP. Full agreement was considered when the two different analyses differed no more than ± 1 s. According to this finding, the agreement in reviewing Qontrast analysis for MTT and TTP by the same examiner was considered almost perfect: κ coefficient for MTT of 0.84 [95% confident interval (CI): 0.796-0.902] and for TTP of 0.92 (95% CI: 0.892-0.946). More interesting, the interobserver agreement for MTT and TTP by two examiners was found also to be almost perfect: κ coefficients for MTT of 0.87 (95% CI: 0.826-0.916) and for TTP of 0.90 (95% CI: 0.867-0.935).

DISCUSSION

CEUS represents the natural continuation of standard B mode ultrasound and Doppler studies, which are widely used for the diagnosis and follow-up of chronic liver disease. Compared with CT and MRI, ultrasound offers important advantages in terms of availability, safety, repeatability, and costs. We found CEUS of liver parenchyma to be safe and effective since we obtained a good quality digital video from each examination without any adverse effect observed. One of its main shortcomings is that it is highly operator dependent. We found Qontrast-assisted CEUS analysis of parenchymal perfusion to be highly reproducible. Intraobserver agreement was excellent (κ coefficient of 0.92) and, more interesting, interobserver agreement was almost perfect (κ coefficient: 0.90). Post-processing analysis of digitally recorded CEUS findings may thus be useful for standardizing this approach and improving its reproducibility.

When analysis was restricted to ROIs containing no major vessels, the time-intensity curves in the healthy control group were generally flat with a late enhancement peak (86.8 ± 24.9 s) and long MTT (range: 91.4-192.1 s),

findings that probably reflect an extensive vascular bed characterized by slow, continuous flow (Figure 2). By contrast, in patients with liver disease peak enhancement was higher and tended to occur earlier, and this pattern was more evident as the severity of the liver disease increased. From a quantitative point of view, this trend was reflected by MTTs in cirrhotic patients that were significantly shorter than those of the patients without liver disease. The steeper curve is an expression of faster, more concentrated flow of a volume of blood similar to that found in a healthy liver (the total hepatic blood volume is no different from that observed in the control group, as demonstrated by the RBVs). This picture (i.e., shorter MTTs associated with the same RBV) is fully compatible with sinusoid capillarization and increased activated HSC tone, which occur during the progression of chronic liver disease and can lead to high-velocity blood flow through the liver. When one of the major hepatic veins was included in the ROI, the TTP also decreased significantly across the three groups (controls > non-cirrhotics > cirrhotics). This picture could reflect the development of intrahepatic shunts that permit portal veins and branches of hepatic artery to cross cirrhotic areas, leading directly or indirectly into the central venous compartment[20].

Qontrast analysis indeed revealed more substantial differences between our patient subgroups when one of the hepatic veins was included in the ROI. The significant TTP shortening observed under these conditions is probably related in large part to the increasing presence of intra-hepatic shunts between branches of portal and/or hepatic artery and the hepatic veins. This is also the basis of the shortened hepatic vein arrival times documented in our cirrhotic patients (and those of other studies)[10,11,20] and also in patients with malignant liver disease[21].

The main limitation of our study is the small number of patients examined. Definitive conclusions on value of Qontrast analysis of CEUS data in diagnosing cirrhosis will have to be based on studies in much larger populations. In any case, use of this software does appear to increase the reproducibility of CEUS findings, and this could be useful for standardizing CEUS protocols and enhancing the comparability of findings obtained by different groups (that is for example a major weakness of Doppler examinations[22]).

Our initial experience with Qontrast-assisted CEUS studies of liver perfusion revealed clear differences between cirrhotic and non-cirrhotic patients with chronic liver disease and may serve as an incentive for further investigations. The reproducibility of Qontrast-assisted CEUS (although some training and experience are essential for optimal results) and its broad availability make it suitable for repeat examinations. Liver perfusion by CEUS could thus represent a valuable "non fibrotic-non invasive" tool to evaluate liver disease severity and to monitor the progression of chronic liver diseases.

COMMENTS

Background

Changes in hepatic perfusion are a key feature that parallels the process of liver fibrogenesis developing during chronic liver diseases. These changes could be used to evaluate liver disease severity during the clinical follow up of chronic liver diseases.

Research frontiers

Evaluation of liver disease severity by studies of perfusion in the liver parenchyma has been mainly performed by computer tomography or magnetic resonance imaging. These methods in clinical practice are limited, however, by the intensive post-processing required to obtain perfusion data, high costs, and the lack of standardized examination protocols. Contrast enhanced ultrasonography (CEUS) could represent the best way to assess liver perfusion due to its wide availability, low cost and safety of ultrasound.

Innovations and breakthroughs

Previous studies performed by CEUS to assess liver disease severity have been mainly focused on the measurement of contrast-medium transit times (mainly from the portal vein to the hepatic veins). A major shortcoming of CEUS is its user-dependency. In this study the authors performed a software-assisted CEUS: Qontrast™ (Esaote S.p.a., Florence, Italy) is a post-processing computational tool, which can be used with CEUS to obtain objective, quantitative parameters of microvascular damage in the liver. The authors demonstrated that software assisted CEUS studies of liver perfusion revealed clear differences between cirrhotic and non-cirrhotic patients with chronic liver disease. The reproducibility of Qontrast-assisted CEUS is quite high and could be useful for standardizing CEUS protocols and enhancing the comparability of findings obtained by different groups.

Applications

The authors' initial experience with Qontrast-assisted CEUS studies of liver perfusion may serve as an incentive for further investigations. It is believed that liver perfusion by CEUS could represent a valuable "non fibrotic-non invasive" tool to evaluate liver disease severity and to monitor the progression of chronic liver diseases.

Terminology

Liver perfusion: Alterations involving the microvascular bed of the liver are already evident during the pre-cirrhotic stages of hepatic fibrogenesis. Main features are capillarization of the sinusoids with loss of endothelial fenestration and increased tone of activated hepatic stellate cells leading to the increase of the mechanical resistance to portal blood flow and augment hepatic vascular tone. The development of shunts between branches of the portal vein, the hepatic veins, and the hepatic artery within the newly formed fibrotic septa are also a key event; CEUS: Performed after intravenous administration of a suspension of gas-filled microbubbles, which remain entirely within the intravascular space and thus act as a blood pool tracer. CEUS studies of perfusion can be applied to the liver to evaluate the times and the intensity of enhancement of liver parenchyma occurring after the contrast injection (i.e., the time-intensity curve of enhancement).

Peer review

This is a good pivotal study in which the authors found time to peak contrast enhancement was significantly shorter in cirrhotic patients and contrast transit time was significantly shorter in the patients with liver diseases than those of controls. These results indicate that this new non-invasive method of analyzing hepatic vein transit time is useful for the prediction of liver disease progression.

Abstract

AIM: To investigate if high-definition (HD) colonoscope with i-Scan gave a higher detection rate of mucosal lesions *vs* standard white-light instruments.

METHODS: Data were collected from the computerized database of the endoscopy unit of our tertiary referral center. We retrospectively analyzed 1101 consecutive colonoscopies that were performed over 1 year with standard white-light (n = 849) or HD+ with i-Scan (n = 252) instruments by four endoscopists, in an outpatient setting. Colonoscopy records included patients' main details and family history for colorectal cancer, indication for colonoscopy (screening, diagnostic or surveillance), type of instrument used (standard white-light or HD+ plus i-Scan), name of endoscopist and bowel preparation. Records for each procedure included whether the cecum was reached or not and the reason for failure, complications during or immediately after the procedure, and number, size, location and characteristics of the lesions. Polyps or protruding lesions were defined as sessile or pedunculated, and nonprotruding lesions were defined according to Paris classification. For each lesion, histological diagnosis was recorded.

RESULTS: Eight hundred and forty-nine colonoscopies were carried with the standard white-light video colonoscope and 252 with the HD+ plus i-Scan video colonoscope. The four endoscopists did 264, 300, 276 and 261 procedures, respectively; 21.6%, 24.0%, 21.7% and 24.1% of them with the HD+ plus i-Scan technique. There were no significant differences between the four endoscopists in either the number of procedures done or the proportions of each imaging technique used. Both techniques detected one or more mucosal lesions in 522/1101 procedures (47.4%). The overall number of lesions recognized was 1266; 645 in the right colon and 621 in the left. A significantly higher number of colonoscopies recognized lesions in the HD+ plus i-Scan mode (171/252 = 67.9%) than with the standard white-light technique (408/849 = 48.1%) (P < 0.0001). HD+ with i-Scan colonoscopies identified more lesions than standard white-light imaging (459/252 and 807/849, P < 0.0001), in the right or left colon (mean ± SD, 1.62 ± 1.36 *vs* 1.33 ± 0.73, P < 0.003 and 1.55 ± 0.98 *vs* 1.17 ± 0.93, P = 0.033), more lesions < 10 mm (P < 0.0001) or nonprotruding (P < 0.022), and flat polyps (P = 0.04). The cumulative mean number of lesions per procedure detected by the four endoscopists was significantly higher with HD+ with i-Scan than with standard white-light imaging (1.82 ± 2.89 *vs* 0.95 ± 1.35, P < 0.0001).

CONCLUSION: HD imaging with i-Scan during the withdrawal phase of colonoscopy significantly increased the detection of colonic mucosal lesions, particularly small and nonprotruding polyps.

INTRODUCTION

Screening colonoscopy is widely considered the gold standard for detection of colonic neoplasia and adenomatous lesions[1]; however, there are several reports of failure to detect small and flat neoplastic lesions[1-10], meaning that in these cases, colonoscopy does not provide adequate protection against colorectal cancer. This inadequacy results in up to 6% of new or missed cancer 3 years after colonoscopy[11,12]. In a recent study, colonoscopy in the preceding 10 years was associated with an overall 77% lower risk for colorectal cancer and approximately 50% lower risk for right-sided cancer[13].

Major factors affecting this polyp miss rate are the presence of blind segments in the colon, poor colon cleaning, and the fact that standard white light may be unable to recognize some small or flat lesions, which are particularly frequent in the right colon. The operator's experience and a longer withdrawal time, permitting closer observation, can only partly overcome these limitations. Even experienced endoscopists may miss up to 6% of adenomas larger than 1 cm and 30% of all adenomas[2,14,15].

Endoscopes have now been designed to improve mucosal visualization, with a wide angle of view and high-resolution, high-definition imaging. Despite these technical improvements, however, there is still debate about the value of high-definition colonoscopy in clinical practice. Out of 11 studies published so far evaluating the capacity of high-definition imaging to improve the lesion detection rate during colonoscopy, five have concluded that it gave no significant advantage over standard white-light colonoscopy[16-26]. A recent meta-analysis evaluating five studies involving 4422 patients and comparing high-definition *vs* standard white-light colonoscopy showed that there were marginal differences between the two imaging technologies for detection of colonic polyps and no advantages of high-definition in the detection of high-risk adenomas[27]. The introduction of instantaneous non-white-light imaging that mimics chromoendoscopy (Narrow-band, Olympus Ltd. and FICE, Fujinon Ltd.) makes it possible to enhance contrast and potentially to improve the detection of mucosal lesions; these filter techniques significantly raised the polyp detection rate in all but three of 13 studies to date[16,28-39]. However, two meta-analyses gave conflicting results[38,40].

A newly developed post-processing filter technology, the i-Scan (Pentax Ltd., Tokyo, Japan), combined and integrated into a high-definition processor (EPKi) that generates images above the high-definition television standard (HD+ resolution), highlights the mucosal surface and architecture by surface enhancement (SE), contrast enhancement (CE), and tone enhancement (TE) modes. So far, in all reports but one, retrospective, it permitted significantly better recognition and characterization of the mucosal lesions during colonoscopy[41-45]. In one recent study, narrow-band imaging and i-Scan significantly improved the polyp detection rate and showed similar efficacy[46].

However, most of the studies using these new post-processing filter techniques are based on prospective, controlled clinical trials in a limited number of patients, in which endoscopists are likely to do the colonoscopy more diligently than in routine practice, with adequate bowel preparation, so it is not clear whether the better polyp detection rates reported can be maintained in routine practice.

The aim of the present study was therefore to determine whether the routine use of colonoscopes equipped with high-definition combined with i-Scan technology (HD+ plus i-Scan) gave a higher rate of detection of overall mucosal lesions, particularly of flat adenomas, than standard white-light video colonoscopes, in a consecutive series of patients undergoing screening, diagnostic or surveillance colonoscopy by different endoscopists with similar expertise, in an outpatient clinical practice setting.

MATERIALS AND METHODS

Data for the study were collected from the computerized database of the endoscopy unit of our tertiary referral center. Colonoscopy records included patients' main details and family history for colorectal cancer, indication for colonoscopy (screening, diagnostic or surveillance), type of instrument used (standard white-light or HD+ plus i-Scan), name of endoscopist, and bowel preparation, defined on the basis of a modified Ottawa scale[47].

Records for each procedure included whether the cecum was reached or not and the reason for failure (inadequate cleaning, strictures, and pain during the procedure), complications during or immediately after the procedure, and number, location and characteristics of the lesions. Polyps or protruding lesions were defined as sessile (Ⅰs) or pedunculated (Ⅰp), and nonprotruding lesions as elevated (Ⅱa), flat (Ⅱb), and depressed (Ⅱc), according to Paris classification[48]. For each lesion, histological diagnosis was recorded. Size and location of the lesions were classified as follows: 0-5 mm, 6-10 mm, 11-15 mm, 16-20 mm, 21-30 mm, > 30 mm; right and left colon. Withdrawal time was recorded for all screening colonoscopies, being

these procedures the object of other studies. Images of each lesion were stored in the database. For each patient, pO_2, heart rate, and blood pressure were measured and recorded before, during and at the end of the procedure.

Data collection

Over a 1-year period, all consecutive screening, diagnostic and surveillance colonoscopies in outpatients done by four expert endoscopists, each of whom had done 200-400 colonoscopies/year for at least 15 years and at least 50 procedures with HD+ plus i-Scan definition equipped instruments were evaluated. The four endoscopists used the two endoscopy techniques in a random fashion, depending of the availability of the instruments. Colonoscopies in subjects younger than 18 years, with genetic-associated colon cancer risk conditions, acute gastrointestinal bleeding, or inflammatory bowel disease were excluded. Procedures with insufficient bowel cleansing, patients in whom residual stool could not be removed by endoluminal washing and suctioning, and patients in whom the cecum was not reached were also excluded.

All patients gave informed consent for the procedures, diagnostic or therapeutic, and for data management for scientific purposes. The retrospective, observational study was approved by the institutional ethics committee.

Examination technique

The bowel was prepared in all cases with polyethylene glycol: 4 L SELG (Promefarm S.r.l, Milan, Italy) or 3 L Moviprep (Norgine GmbH, Marburg, Germany), divided into two parts, were taken the day before the procedure. All patients received conscious sedation with midazolam (Ipnovel, Roche SPA, Basel, Switzerland) and fentanyl (Fentanest, Pfizer, New York, United States) or deep sedation with propofol (Diprivan, AstraZeneca, Zug, Switzerland); 20 mg Butylscopolamin (Buscopan, Boehringer Ingelheim Pharma GmbH, Ingelheim, Germany) were administered if necessary, unless contraindicated.

Standard white-light video colonoscopy was carried out with Pentax colonoscopes EC-3870FZK, EC 3885F, EC 3885L (Pentax Ltd., Tokyo, Japan) and an EPM 3500 or EPK 1000 processor. The colon was inspected during withdrawal of the instrument and lesions were identified and characterized with light imaging only. Magnification was not possible with these endoscopes.

HD+ plus i-Scan video colonoscopy was carried out with Pentax colonoscopes EC-3890FI and EC 3870FZK, using the EPKi processor. The i-Scan technology is a digital contrast method using a light filter that uses different software algorithms with real-time image mapping embedded in the EPKi processor. It enhances mucosal imaging by activating three distinct functions-one for SE mode, the second for CE mode, and the third for TE mode. For SE and CE, there are three enhancement levels (low, medium and high); TE mode can be specifically tailored for the esophagus, stomach, or colon. SE mode enhances the structure through recognition of the edges; compared to normal images, SE images do not differ in brightness and differ little in color, but allow easier recognition of minute glandular structures, which makes it simpler to check changes on the basis of structural differences. With CE mode, areas with lower luminance intensity than surrounding pixels are identified on the basis of pixel-wise luminance intensity data. Processing images with CE does not change the image brightness but enhances minute irregularities and depressed areas of the mucosal surface with a slight bluish-white stain. With TE mode, the RGB components of an ordinary endoscope image are broken down into their parts, and each one is then converted independently along the tone curve, followed by resynthesis of the three components to yield a reconstructed image[43].

The three modes are arranged in series, so two or more can be applied at one time. The modes of enhancement and their levels can be switched on a real-time basis, permitting efficient endoscopic observation.

In all cases, colonoscopy was done using the SE (low) + CE (low) modes; the TE mode for the colon was routinely activated during withdrawal of the instrument once the cecum had been reached, so the whole retrieval phase of the procedure was done using the i-Scan technique with TE mode set for the colon.

Statistical analysis

Data were analyzed using SPSS version 17.0 software (Chicago, IL, United States). Continuous data were described by mean and standard deviation or compared with the Mann-Whitney test. Statistical differences in categorical variables were analyzed using two-sided Fisher's exact tests or χ^2 tests, as appropriate. All differences were considered significant at two-sided P value < 0.05.

RESULTS

A total of 1101 colonoscopy records with images obtained by the four endoscopists were eligible for the study: 849 with the standard white-light video colonoscope and 252 with the HD+ plus i-Scan video colonoscope. The four endoscopists did 264, 300, 276 and 261 procedures, respectively; 21.6%, 24.0%, 21.7% and 24.1% of them with the HD+ plus i-Scan technique. The number of colonoscopies carried out for screening, diagnosis, and surveillance with standard white-light and HD+ plus i-Scan technology by the four endoscopists are reported in Table 1. There were no significant differences between the four endoscopists in either the number of procedures done or the proportions of each imaging technique used.

Both techniques detected one or more mucosal lesions in 522/1101 procedures (47.4%). The overall number of lesions recognized was 1266: 645 in the right colon and 621 in the left. A significantly higher number of colonoscopies recognized lesions in the HD+ plus i-Scan mode (171/252 = 67.9%) than with the standard white-light technique (408/849 = 48.1%) ($P < 0.0001$). The number of mucosal lesions recognized by the two imaging tech-

niques and the mean numbers detected by each procedure were significantly higher for HD+ plus i-Scan than with standard white light, for screening, diagnostic, and surveillance colonoscopies (Table 2). In both the right and left colon, HD+ plus i-Scan colonscopy recognized a larger mean number of lesions than standard white light (mean ± SD 1.62 ± 1.36 *vs* 1.33 ± 0.73, $P < 0.003$ and 1.55 ± 0.98 *vs* 1.17 ± 0.93, $P = 0.033$).

Overall, 154 nonprotruding lesions were identified and removed: 70 with the HD+ plus i-Scan mode (27.8%) and 84 with the standard white-light technique (9.9%). The HD+ plus i-Scan mode recognized a significantly higher number of nonprotruding lesions than the standard white-light technique ($P = 0.04$) (Figures 1 and 2).

The overall number and size of the lesions, protruding or nonprotruding, found with HD+ plus i-Scan and standard white light are shown in Table 3. The HD+ plus i-Scan technique identified a significantly larger number of lesions smaller than 10 mm, either protruding or nonprotruding, than standard white light ($P < 0.0001$); the difference was not significant for lesions measuring 11-20 mm, 21-30 mm, and > 30 mm. Colonoscopies performed with HD+ with i-Scan technique also identified a significantly larger number of overall lesions and nonprotruding lesions smaller than 10 mm than did standard white light ($P < 0.0001$ and $P < 0.022$, respectively), while the difference was not different for larger lesions, either protruding or nonprotruding. The differences were not significant considering screening, diagnostic, and surveillance colonoscopies.

Among the 154 nonprotruding lesions, histological report was available for 133 lesions, because in 21 cases, resected specimens were missed during colonoscopy (Table 4). Adenoma detection rate was significantly higher with HD+ plus i-Scan mode than with standard white light only for lesions smaller than 10 mm (32/35 *vs* 19/27, $P = 0.05$), while the difference was not significant for larger adenomas.

The number of procedures managed by the four endoscopists and the distribution of HD+ plus i-Scan and standard white-light colonoscopies, with the mean numbers of lesions found by each one. The lesion detection rates were very similar for all four. The cumulative mean number of lesions per procedure detected with the two techniques was significantly higher with the HD+ plus i-Scan than with standard white-light imaging (mean ± SD, 1.82 ± 2.89 *vs* 0.95 ± 1.35, $P < 0.0001$). In fact, each of the four endoscopists identified twice as many lesions with the HD+ plus i-Scan as with standard white-light imaging.

The overall withdrawal time, reported only for screening colonoscopies, did not significantly differ between procedures performed with the HD+ plus i-Scan and standard white light (8.4 ± 1.2 min *vs* 8.3 ± 1.4 min, respectively) (Table 5).

DISCUSSION

To date, only one study has evaluated the impact of the routine use of i-Scan with TE mode and HD+ imaging in the detection of mucosal lesion during the withdrawal phase of colonoscopy, compared to standard white-light imaging, in a large series of patients in clinical practice[45]. The study was retrospective and did not improve adenoma detection rate in a population with mixed risk for colorectal cancer.

In our retrospective study, with the HD+ plus i-Scan imaging routinely activated during the withdrawal phase of colonoscopy, once the cecum had been reached, a significantly larger number of examinations identified some mucosal lesion and adenomas, either protruding or flat, and there were also significant improvements in the overall detection rate of lesions and the mean number of lesions recognized for each colonoscopy, compared with standard white-light imaging. The rate was most markedly higher for lesions not bigger than 10 mm and nonprotruding ones. Although the rates of detection of

HD: High-definition.

lesions larger than 10 mm did not differ with the two imaging techniques, protruding and nonprotruding lesions smaller than 10 mm were recognized significantly more frequently using the HD+ plus i-Scan technology. In particular, HD+ plus i-Scan technology identified flat polyps smaller than 10 mm three times more than the white-light technique.

The cumulative mean number of lesions per colonoscopy recognized by the four colonoscopists was significantly higher with HD+ plus i-Scan than with standard white-light imaging, while the withdrawal time, when recorded, did not differ between the two techniques.

Only two studies published so far have assessed the combined use of HD+ plus i-Scan for colonoscopy; they have reported similar results in favor of this technique but they were obtained in a prospective trial setting and in a smaller number of selected patients[42,44].

Identifying more polyps by colonoscopy in clinical practice, including small (< 10 mm) and flat ones, may have an important impact for colorectal cancer prevention. The polyp miss rate is probably the main factor accounting for a persistent risk of colorectal cancer reported in 10%-24% of cases after screening colonoscopy[49].

A systematic review of six tandem colonoscopy studies using standard white-light imaging showed an overall polyp miss rate of 22%. The rate rose with smaller lesions, ranging from 2.1% for lesions bigger than 10 mm, to 13% for those between 5 and 10 mm, and up to 26% for those smaller than 5 mm[8]. A prospective multicenter study of back-to-back colonoscopies with white-light imaging reported 9% and 27% miss rates for adenomas > 5 mm and < 5 mm, respectively, and 11% for advanced adenomas[9]. This means that small and flat mucosal lesions, mostly in the right colon, are the ones that may frequently be missed during colonoscopy.

A limited number of studies have compared the efficacy of HD+ colonoscopy with standard white-light colonoscopy, and the findings are far from clear: four of the nine studies concluded that high-definition imaging gave no benefit compared to standard resolution[17,18,21,24]. The addition of electronic filters, such NBI and FICE, to the high-definition imaging did improve the polyp detection rate for small/flat lesions but some results were still disappointing for this end-point[16,30].

Even though there is a general belief that detecting and removing small lesions (1-5 mm) in the colon may not have any significant clinical impact, a number of studies have found that small lesions, mainly flat ones, may have unfavorable histology. One reported that small depressed colorectal lesions had up to a 40% chance of submucosal invasion[49]; two found that 3.9% and 16% of adenomas between 6 and 10 mm had high-grade dysplasia[50,51], and 0.5% of adenomas measuring 6-9 mm were actually cancer[51]. These data might explain the reported occurrence of colorectal cancer after negative screening colonoscopy and support the need for detecting and removing all protruding lesions of the colon, regardless of the size, and selecting the most appropriate techniques to ensure maximum recognition of lesions at colonoscopy.

HD+ plus i-Scan can also differentiate diminutive adenomas and hyperplastic polyps[52], and a recent study using a Markov simulation model suggested that a resect and discard strategy for very small polyps might improve the cost-effectiveness of colorectal cancer screening[53].

A potential limitation of the present study was its retrospective nature. However, data used for analysis, in-

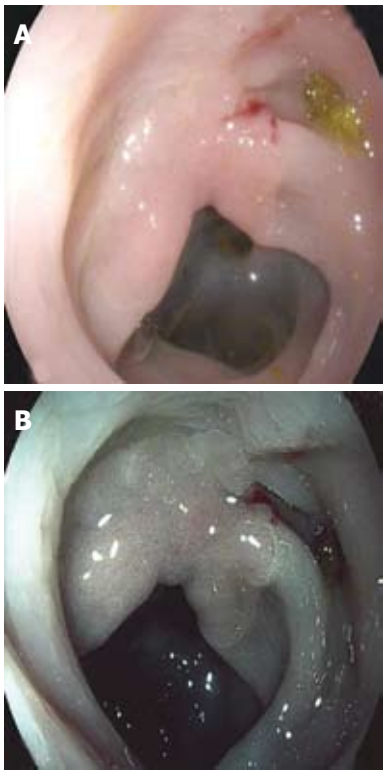

Figure 1 Flat lesion Ⅱb + Ⅱa on left colon examined by high-definition-white light and visualized with i-Scan. A: Flat lesion Ⅱb + Ⅱa of 25 mm × 25 mm on left colon examined by high-definition white light; B: Same lesion visualized with i-Scan.

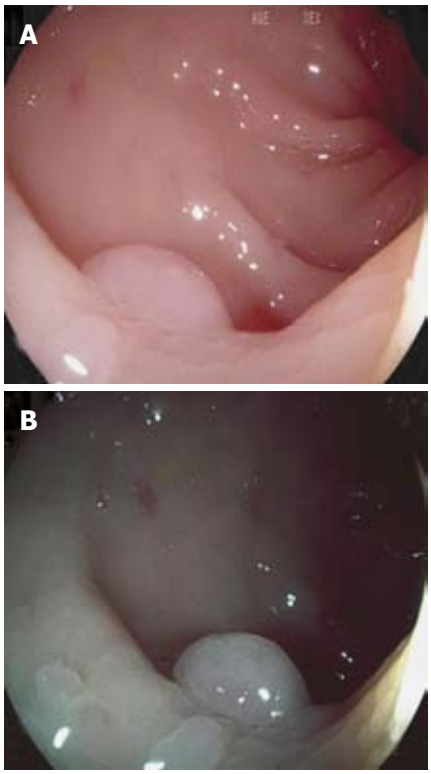

Figure 2 Flat lesion 0-Ⅱa visualized with high-definition white light and surface enhancement and visualized with i-Scan and digital chromoendoscopy. A: Flat lesion 0-Ⅱa visualized with high-definition white light and surface enhancement; B: Same lesion visualized with i-Scan and digital chromoendoscopy.

cluding the adequacy of bowel preparation, were detailed and were collected prospectively for each procedure and stored in a database. Only procedures that included all the data required for the study were considered. As with all nonrandomized trials, potential confounding variables cannot be entirely excluded; however, we examined a large number of colonoscopies and statistical analysis found highly significant differences. Although colonoscopies carried out for different purposes (screening, diagnostic and surveillance) may represent different settings, the differences reported from overall results were also confirmed in the three settings. On the other hand, the retrospective design has the advantage of providing information on the true yield of HD+ plus i-Scan imaging for detecting polyps during colonoscopy in current clinical practice. Prospective trials evaluating new imaging systems could allow the endoscopist to be more attentive during the procedures outside routine practice and very likely give greater accuracy for polyp detection, especially for flat and small lesions, but the good results are not necessarily directly transferable into routine clinical practice.

The lack of documentation of withdrawal time for all colonoscopies is another potential limitation of a retrospective study, compared with prospective ones, because withdrawal time plays an important role in adenoma detection, although here too data are conflicting. In this retrospective evaluation, we were able to assess reliably the withdrawal times only for screening colonoscopies without therapeutic interventions: withdrawal time was comparable by using the two imaging techniques. Besides the imaging technology, probably the endoscopist's technique and experience is perhaps more important than other factors, including withdrawal time, in detecting polyps by colonoscopy[54-56]. The endoscopists in this study were experts, with many colonoscopies behind them and on their current schedules, and adequate experience with HD+ plus i-Scan imaging in the year leading up to the study. In addition, we compared the numbers of colonic lesions recognized by the same endoscopist using the two techniques, thus applying similar expertise and technique, in a similar clinical setting, and found that the four endoscopists using HD+ plus i-Scan imaging detected cumulatively more lesions. Only one other study comparing the diagnostic yield for colonic polyps using standard white-light and HD+ colonoscopy followed a retrospective design, with an adequate number of unselected patients undergoing colonoscopy in routine practice. The findings confirmed the greater accuracy for detecting polyps of HD imaging compared with white light (42.2% *vs* 37.8%)[20]. In our hands, 67.8% and 27.8% of colonoscopies with HD+ plus i-Scan recognized some mucosal lesions and flat small polyps (< 10 mm), respectively, compared to 48.1% and 9.9% for standard white-light imaging. HD+ plus i-Scan thus gave an approximately 30% higher diagnostic yield for mucosal lesions of the colon and increased by three times the diagnostic accuracy for flat polyps smaller than 10 mm.

In conclusion, this retrospective study on a large se-

ries of consecutive outpatients undergoing colonoscopy in different settings by four expert endoscopists showed that the routine addition of i-Scan to HD imaging during the entire withdrawal phase of colonoscopy, once the cecum had been reached, significantly increased the diagnostic yield for detection of mucosal lesions of the colon, particularly small and nonprotruding ones, without affecting the withdrawal time. In colon cancer screening, the routine use of HD+ plus i-Scan can recognize more mucosal lesions without the need to prolong the withdrawal time to allow for closer inspection, as suggested in other studies, and could probably enable less-skilled endoscopists to achieve performances comparable to those of experienced ones in detecting colonic polyps.

COMMENTS

Background

Screening colonoscopy is widely considered the gold standard for detection of colonic neoplasia and adenomatous lesions, however, there are several reports of failure to detect small and flat neoplastic lesions, meaning that in these cases, colonoscopy does not provide adequate protection against colorectal cancer. Besides the operator's experience, withdrawal time, quality of colon cleansing, presence of blind segments in the colon, and quality of imaging provided by endoscopes play an important role in lesion detection. Standard white-light imaging may be unable to recognize some small or flat lesions, which are particularly frequent in the right colon, and it may affect the polyp miss rate during routine colonoscopy. High-definition (HD) imaging and filter technologies have been applied to colonoscopies to improve detection of lesions, but results are conflicting.

Research frontiers

Endoscopes have now been designed to improve mucosal visualization, with a wide angle of view, filter-aided techniques that can enhance characterization of mucosal morphology and surface architecture, and high-resolution/high-definition imaging that can improve endoscopic recognition of mucosal lesions. In this study, the authors demonstrated that the routine use of HD+ plus i-Scan recognized more mucosal lesions without the need to prolong the withdrawal time to allow closer inspection.

Innovations and breakthroughs

Recent studies have analyzed the capacity of high-definition imaging to improve the lesion detection rate during colonoscopy with conflicting results. The value of high-definition colonoscopy in clinical practice is still debated. In this study, the authors showed that the routine addition of i-Scan to HD+ imaging during the entire withdrawal phase of the colonoscopy significantly increased the diagnostic yield for detection of mucosal lesions of the colon, particularly small and nonprotruding ones, without affecting the withdrawal time, and could probably enable less-skilled endoscopists to achieve performances comparable to those of experienced ones in detecting mucosal lesions.

Applications

This study may encourage the utilization of advanced imaging technologies to reduce polyp miss rate and improve colonoscopy performance in the prevention of colorectal cancer.

Terminology

The i-Scan technology is a digital contrast method employing a light filter that uses different software algorithms with real-time image mapping embedded in the Pentax EPKi processor. i-Scan enhances mucosal imaging by activating three distinct functions: one for surface enhancement (SE), the second for contrast enhancement (CE), and the third for tone enhancement (TE), allowing a better recognition and characterization of the mucosal lesions during colonoscopy. SE mode enhances the structure through recognition of the edges, compared to normal images, and allows easier recognition of minute glandular structures which makes it simpler to identify changes on the basis of structural differences. CE mode enhances minute irregularities and depressed areas of the mucosal surface with a slight bluish-white stain. In TE mode, the RGB components of an ordinary endoscope image are broken down into their parts, and each one is then converted independently along the tone curve, followed by resynthesis of the three components to yield a reconstructed image.

Peer review

The authors examined the role of HD+ i-Scan *vs* white-light colonoscopy on polyp detection rates. The research is a significant addition to the literature on the use of contrast technology in improving the quality of colonoscopy in detecting polyps. The results of the study will encourage those regularly involved in performing colonoscopy to consider a lower threshold in utilizing these techniques to improve polyp detection rates. The research novelty is in the fact that the study was conducted in a real clinical practice environment and could be considered to have greater clinical applicability.

Abstract

AIM: To determine the factors affecting mortality in patients who developed graft-versus-host disease (GvHD) after liver transplantation (LT).

METHODS: We performed a review of studies of GvHD following LT published in the English literature and accessed the PubMed, Medline, EBSCO, EMBASE, and Google Scholar databases. Using relevant search phrases, 88 articles were identified. Of these, 61 articles containing most of the study parameters were considered eligible for the study. Risk factors were first examined using a univariate Kaplan-Meier model, and variables with a significant association ($P < 0.05$) were then subjected to multivariate analyses using a Cox proportional-hazards model.

RESULTS: The 61 articles reported 87 patients, 58 male and 29 female, mean age, 40.4 ± 15.5 years (range: 8 mo to 74 years), who met the inclusion criteria for the present study. Deaths occurred in 59 (67.8%) patients, whereas 28 (32.2%) survived after a mean follow-up period of 280.8 ± 316.2 d (range: 27-2285 d). Among the most frequent symptoms were rash (94.2%), fever (66.6%), diarrhea (54%), and pancytopenia (54%). The average time period between LT and first symptom onset was 60.6 ± 190.1 d (range: 2-1865 d). The Kaplan-Meier analysis revealed that pancytopenia (42.8% *vs* 59.3%, $P = 0.03$), diarrhea (39.2% *vs* 61.0%, $P = 0.04$), age difference between the recipient and the donor (14.6 ± 3.1 years *vs* 22.6 ± 2.7 years, $P < 0.0001$), and time from first symptom occurrence to diagnosis or treatment (13.3 ± 2.6 mo *vs* 15.0 ± 2.3 mo, $P < 0.0001$) were significant factors affecting mortality, whereas age, sex, presence of rash and fever, use of immunosuppressive agents, acute rejection before GvHD, etiological causes, time of onset, and donor type were not associated with mortality risk. The Cox proportional-hazards model, determined that an age difference between the recipient and donor was an independent risk factor ($P = 0.03$; hazard ratio, 7.395, 95% confidence interval, 1.2-46.7).

CONCLUSION: This study showed that an age difference between the recipient and donor is an independent risk factor for mortality in patients who develop GvHD after LT.

INTRODUCTION

Graft-versus-host disease (GvHD) results from the reac-

tion of donor immunocompetent cells against tissues of an immunosuppressed host[1-5]. GvHD is a well-known complication in patients who undergo allogeneic bone-marrow transplantation. However, few reports of GvHD after solid-organ transplantation include liver transplantation (LT)[6-9]. The reported incidence of this complication varies from 0.1% to 2%, with a mortality rate of > 75%; GvHD usually occurs between the second and sixth week after LT[5,10,11]. The clinical manifestations of GvHD following LT include fever, rash, diarrhea, and hematocytopenia, but the basic function of the transplanted liver is not affected[2,9,12,13]. The diagnosis of GvHD following LT can be difficult, as many of the clinical signs can be caused by drug reactions or viral infections including cytomegalovirus (CMV)[9]. Although a sizable number of modalities have been used to manage this disease, the most effective combination has not been determined.

MATERIALS AND METHODS

The primary purpose of this study was to examine the existing literature on GvHD following LT. Thus, we conducted a thorough literature search regarding GvHD developing after LT using the PubMed, Medline, EBSCO, EMBASE, and Google Scholar databases from November 2011 to March 1988, when Burdick *et al*[14] presented the first study on GvHD following LT. The keywords we used for the search were "graft-versus-host disease," "graft-versus-host disease after liver transplantation," "graft-versus-host disease following liver transplantation," and "graft-versus-host disease and solid-organ transplantation." The reference lists of all articles introduced as reviews were checked to attain a wider search range. The search identified 88 article titles. More detailed information was requested through contact with the corresponding authors and/or the related journal editors for studies in which insufficient data were provided or in which full texts could not be accessed. Twenty-seven full-text articles were excluded from the study because the authors could not be reached, a case presentation was duplicated, or only a literature review was provided that did not include sufficient information for comparison with other studies. A total of 61 articles containing most of the parameters mentioned below were considered eligible for the study. One of the two cases presented by Schuchmann *et al*[15] was excluded because it was presented in another study. The study by Knox *et al*[16] was excluded because only pulmonary GvHD developed following LT. In the 61 studies for which full texts could be accessed, the following data were evaluated: age, sex, donor age, age difference between the recipient and the donor, blood group compatibility (identical or not), donor type (living/cadaveric), use of primary immunosuppressive medications (tacrolimus, cyclosporine, or azathiopurine), primary hepatic disease, time of onset (postoperative day), first manifestations (rash, fever, pancytopenia, thrombocytopenia, leukopenia, and diarrhea), time interval elapsed between the first manifestation and the diagnosis and/or treatment (d), re-transplantation, mortality, and follow-up. The aim of this literature search was to identify factors affecting the occurrence of mortality in post-transplantation GvHD. Thus, the patients were divided into a mortality group (n = 59) and a survival group (n = 28). Accordingly, symptoms such as fever, rash, and diarrhea were collected under the title of "first symptoms" after ruling out other possible causes. Similarly, pancytopenia, thrombocytopenia, or leukopenia that developed before the confirmation of the GvHD diagnosis were all collected under the title of "pancytopenia." Symptoms or hematological disorders developing after commencement of treatment were left out of the former classifications. The time period between development of the first symptom associated with the disease and the transplantation was termed "time of onset."

Statistical analysis

SPSS version 13.0 (SPSS, Inc., Chicago, IL, United States) was used for the statistical analysis. Data are presented as mean ± SD for continuous variables and as frequencies for categorical variables. The statistical significance of differences between groups was examined using Pearson's χ^2 test for categorical variables and the Student t-test for continuous variables. Risk factors for outcomes were first examined using a univariate Kaplan-Meier model, and variables with a significant association ($P < 0.05$) were then subjected to multivariate analyses using a Cox proportional-hazards model. All statistical tests were two-sided with a significance level of 0.05.

RESULTS

We retrospectively evaluated 61 studies that included 87 patients, 58 male and 29 female, with age range of 8 mo to 74 years (mean, 40.4 ± 15.5 years). There were 59 (67.8%) deaths, while 28 (32.2%) survived at a mean follow-up of 280.8 ± 316.2 d (range: 27-2285 d). In the Kaplan-Meier model, parameters such as pancytopenia (P = 0.03), diarrhea (P = 0.04), age difference between the recipient and the donor ($P < 0.0001$), and the time elapsed between development of the first symptoms and the diagnosis or treatment ($P < 0.0001$) were significant risk factors for mortality. The results of multivariate Cox proportional-hazards model analysis revealed that age difference was an independent and strong risk factor (P = 0.03; hazard ratio, 7.395, 95% confidence interval, 1.2-46.7). Kaplan-Meier mortality curves for patients with and without diarrhea and pancytopenia are presented in Figure 1. Demographic and statistical data for the mortality and survival groups is provided in Tables 1 and 2. The distribution of both groups by time since the first description of GvHD after LT is depicted in Figure 2. We noted that mortality rates peaked in some years and that cases in the survival group pursued a more stable course compared with those in the mortality group.

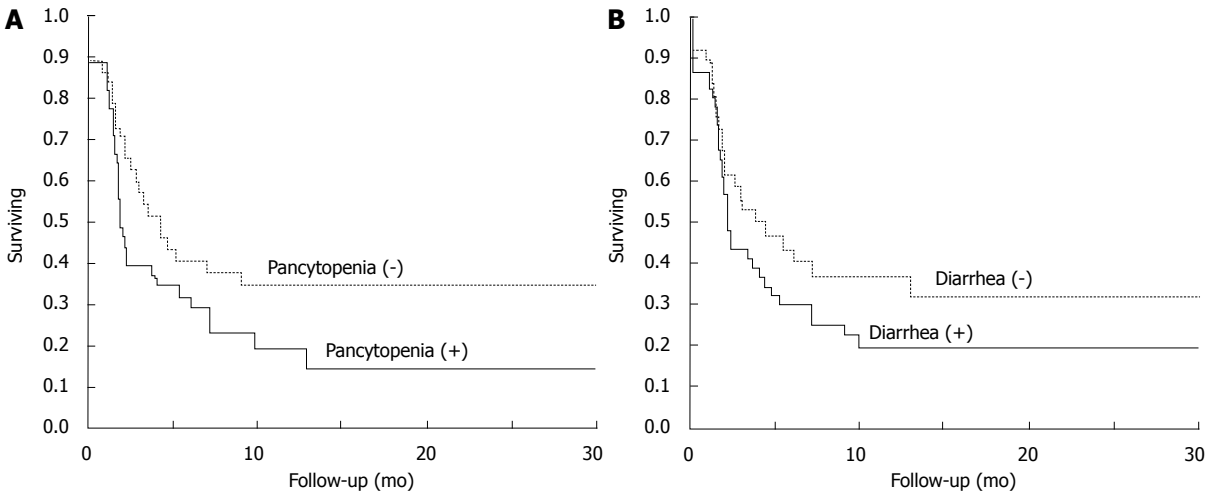

Figure 1 Kaplan-Meier survival curves for patients with and without pancytopenia and diarrhea. A: Pancytopenia; B: Diarrhea.

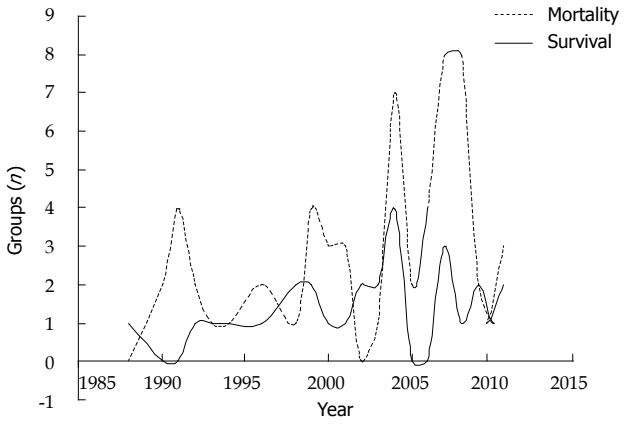

Figure 2 Distribution of survival and mortality groups by time of first description of graft-versus-host disease after liver transplantation.

DISCUSSION

Description, pathogenesis, and incidence of GvHD after liver transplantation

GvHD was first described by Billingham in 1966 as a reaction of the donor's immunocompetent cells against the recipient's cellular antigens[17,18]. The development of GvHD implies the fulfillment of three prerequisites: (1) a source of immunocompetent lymphocytes; (2) histocompatible antigenic differences between donor and host; and (3) inability of the host to reject donor lymphocytes[10,19-21]. This reaction occurs in as many as 80% of patients after bone-marrow transplantation. It has also been infrequently reported after transfusion of blood products or after solid-organ transplantation, such as pancreas-spleen, heart-lung, and liver[6,14,17,22,23]. The development of GvHD after solid-organ transplantation was first defined in 1984 by Starzl *et al*[24] in a patient undergoing a combined pancreas and splenic transplantation operation. GvHD developing after LT was first defined by Burdick *et al*[14] in 1988.

Although the exact mechanisms are still unclear, the three basic prerequisites mentioned above are also applicable to GvHD after LT. An estimated 10^9-10^{10} donor lymphocytes remain in the portal tracts and the parenchyma of a donor liver graft after flushing with cold preservative solution[18,21,25-27]. These T-cells are detectable in the peripheral blood and organs of patients during the first weeks after LT[18,20,25,26,28]. The donor lymphocytes colonize the recipient, recognize the host tissue antigens as foreign, and react against the host tissue. In other words, if the "balance of power" between the donor and recipient immune systems favors the donor, donor lymphocytes may be activated, leading to GvHD.

Although the exact incidence of GvHD following LT remains to be determined, various studies have cited rates of 0.1%-2%[27,29-32]. Yuksekkaya *et al*[11] reported that the incidence of GvHD was as high as 22.2% in patients whose donors were mismatched on at least one human leukocyte antigen (HLA) A and B antigens[11,33]. In our examination of 15 articles, we found that GvHD was evident in only 62 (0.06%) of 9492 patients undergoing LT, which was similar to frequencies reported previously[32-36].

Classification of GvHD after liver transplantation

GvHD has been reported after solid-organ transplantation with humoral and cellular presentations. The humoral type, also known as graft-versus-host hemolysis, is characterized by hemolysis and fever and occurs in patients transplanted with ABO-incompatible or nonidentical grafts. The cellular type of GvHD occurs when immunocompetent donor lymphocytes originating from the transplanted liver undergo activation and clonal expansion, allowing them to mount a destructive cellular immune response against recipient tissues. The response is directed against the major histocompatibility complex and often results in severe multisystem disease with a high mortality rate[19,37-40].

GvHD responses can be classified as acute or chronic, depending on the timing and character of alloimmune activity[11,41,42]. Acute GvHD comprises all manifestations that occur during the first 100 d after transplantation, and chronic GvHD includes all manifestations that oc-

cur after 100 d[11,42-44]. However, multiple findings suggest that this may no longer be a suitably useful distinction. Acute GvHD lesions may be found after 100 d, whereas chronic GvHD lesions sometimes appear before 100 d. Acute GvHD histological findings can be found in biopsies performed after day 100, and lichenoid findings can be found in biopsies performed before day 100[42,44]. The number of days after transplant is an insufficient criterion to distinguish acute from chronic GvHD. Good clinical and pathological descriptions are needed. Chronic GvHD can occur as a progression of acute GvHD, as a recurrence following a disease-free interval, or without a history of acute GvHD. Each of these forms accounts for approximately one-third of cases.

Risk factors for development of GvHD

The causes of GvHD following organ transplantation have not been clarified, but several risk factors have been implicated, including close HLA matching between the recipient and donor[18,27,45], blood transfusion prior to transplantation[11], immunosupressive treatment before transplantation[11,27], glucose intolerance[35], rejection before GvHD[4], autoimmune hepatitis[35], alcoholic liver disease[35], hepatocellular carcinoma (HCC)[27,35], re-transplantation[27], a large age discrepancy between donor (younger) and recipient (older)[25], recipient age > 65 years[18,27,45,46], and multiorgan transplantation[5,21,33,35,40]. Only two studies offered an evidence-based risk analysis with regard to the development of GvHD after LT. In a study by Smith *et al*[33], risk factors included recipient age ≥ 65 years, recipient-donor age difference ≥ 40 years, and close matching of the HLA types of the donor to those of the recipient. Chan *et al*[35] documented glucose intolerance, autoimmune hepatitis, alcoholic liver disease, HCC, and various combinations of these but not such parameters as age, sex, ischemia duration, HLA mismatch, or age dif-

Table 2 Distribution of patients according to underlying liver disease

Etiology	Surviving (*n* = 28)	Dead (*n* = 59)	Total (*n* = 87)

ferences as risk factors. Chan *et al*[35] argued that most of the risk factors they identified permitted patients to lapse into an immunosuppressive state, suggesting an inclination toward development of the disease before the LT operation. Our literature search showed that the most frequently encountered liver diseases in affected patients were HCC (23%) and alcoholic liver disease (20.7%). The suggestions by Chan *et al*[35] support our findings, but we lack confirming evidence.

Clinical presentation of GvHD

The clinical presentation of GvHD following LT includes skin rash, fever, diarrhea and hematocytopenia[5,47]. Characteristically, the transplanted liver is not a target of GvHD after LT because both graft liver and immunocompetent cells responsible for GvHD are of donor origin[25,28,30]. The most frequently appearing symptoms in our search were rash (94.2%), fever (66.6%), diarrhea (54%), and pancytopenia (54%). Among these symptoms, pancytopenia (P = 0.03) and diarrhea (P = 0.04) were confirmed by univariate analysis to be risk factors affecting mortality. These results indicate that intestinal and bone-marrow involvement may give rise to severe complications.

The clinical symptoms of GvHD usually become apparent between 1 and 8 wk after LT, often after an initial uneventful recovery from surgery and discharge from the hospital[40,48]. Our literature review revealed that the first symptoms appear 60.6 ± 190.1 d (range: 2-1865 d) after the LT operation. Although the time interval was shorter in the non-surviving group, it was not among the risk factors for death (P = 0.4). Despite this result, we believe that the mortality in cases complicated with GvHD within the first month is much higher.

Diagnosis of GvHD

A diagnosis of GvHD after LT is based on the presence of clinical manifestations, a demonstration of chimerism, and histopathological evidence[29,42,47,49]. As the clinical presentation of GvHD is inconsistent, a high degree of suspicion is necessary to pursue a diagnosis. Any or all clinical symptoms mentioned above may be seen during the initial presentation of GvHD. A skin biopsy showing epidermal dyskeratosis with epithelial cell necrosis is highly suggestive but not pathognomonic for GvHD[29,39,40,48]. Chimerism can be established by various methods that examine the presence of donor cells in the recipient's peripheral blood or various tissues[41,50]. These methods include serological HLA typing of peripheral blood, restriction fragment length polymorphism[28,29,51-53], and fluorescent *in situ* hybridization (FISH), which have been used to demonstrate chimerism in recipients with suspected GvHD after LT[28,34,48]. Chimerism at the tissue level has been shown by polymerase chain reaction, short tandem repeat analysis, and FISH techniques in the skin and bone marrow of patients with GvHD after LT[46,48,52,54,55]. Peripheral blood chimerism appears transiently in the majority of patients during the early postoperative period after LT, particularly in the first week, and rapidly declines by the third to fourth week post-transplant[39,45]. For this reason, chimerism may not be evident in the peripheral blood of patients with late-onset GvHD[32,56].

Differential diagnosis and clinical significance

The differential diagnosis of GvHD after LT is frequently delayed because early symptoms are often non-specific. The differential diagnosis consists of (1) drug-induced skin reactions, including toxic epidermal necrolysis and mycophenolate mofetil toxicity; (2) viral exanthemas; (3) infectious enteritis, including CMV infection and *Clostridium difficile* colitis, and (4) organ rejection[13,41,57-59]. Many of the clinical signs of GvHD may also be seen with CMV infection. The presence of CMV in a patient with GvHD may complicate the appropriate diagnosis and delay treatment. A significant association between acute GvHD and CMV after transplant has been documented and may be related to pancytopenia resulting from bone-marrow depletion by attacking donor lymphocytes[9,11,34,39].

A rapid differential diagnosis and early implementation of treatment for GvHD following LT are two factors that affect survival. In contrast, studies showing that early treatment was not effective in the ultimate outcome have also been published[18,40]. Taylor *et al*[40] based their opinions on a literature search. They reported that early implementation of treatment did not produce a statistically significant difference in mortality. We found that the time interval between the appearance of first symptoms

and definitive diagnosis and/or treatment, which ranged from 1 to 65 d, was a statistically significant predictor of death ($P < 0.0001$).

Treatment of GvHD after liver transplantation

The evidence base for selecting the most appropriate therapy for established GvHD after LT is very limited; thus, treatment is largely empirical, although the extensive literature on managing acute GvHD after stem cell transplantation provides guidance[21,25,27,40]. A number of treatment modalities have been proposed based on the known pathophysiological mechanism of GvHD. However, as most of the treatment modalities are implemented in combinations, the optimal combination has not yet been identified. Moreover, some patients respond well to a decrease in the intensity of immunosuppressive treatment[38,55], or to replacement with another immunosuppressive agent[38,39,60,61], but good outcomes have also been reported using incremental doses of immunosuppressive drugs[52,57,58,62]. On the other hand, the literature has also reported the development of acute rejection in patients whose immunosuppressive drug dosage was decreased or the relevant medication was ceased; hence, switching to another medication may seem more reasonable than changing the dosage of the main immunosuppressive agent[31]. Each patient should be evaluated individually.

Among the most frequently administered treatment modalities for GvHD after LT mentioned in the literature are corticosteroid treatment[9,25,46,56], decrease/cessation/increase in or replacement of the immunosuppressive medication[22,26,52,55,62], and the use of antibodies directly targeting T lymphocytes, monoclonal antibodies targeting various receptors on the surfaces of lymphocytes, intravenous immunoglobulin[31,42,58,63,64] as an immune support, and antimicrobial treatments appropriate to suppress the infection[10,18].

Most of the experience regarding corticosteroid use in treating GvHD is based on the practices of hematopoietic stem cell transplantation[4]. The lympholytic and immunosuppressive effects of steroids, in addition to their potent anti-inflammatory characteristics, have provided justification for their widespread administration[4]. In our literature search, steroid treatment was instituted in 61 of 87 patients in whom GvHD developed after LT, whereas other treatment modalities were preferred in 21, and the remaining 5 patients were monitored for symptoms[19,38,65]. Death occurred in 43 patients on steroid treatment. Immunosuppressive treatment was re-administered upon development of acute rejection in two patients in whom the main immunosuppressive treatment was replaced by steroid treatment. Etanercept (Enbrel) therapy was commenced in one patient due to a failed response to steroid treatment, and a reduction in cyclosporine, and this approach yielded a successful outcome[45]. Most of the patients who experienced complications or a suboptimal response to treatment were administered various monoclonal antibodies or antagonist agents to T-lymphocytes[65-69]. The most commonly used drugs were the following: daclizumab (Zenapax)[21,29,32,68] and basiliximab (Simulect)[4,5,11,28,41], which bind to the CD25 subunit of interleukin (IL)-2 receptors on the surface of T-lymphocytes; muromonab (OKT3)[7,23,47,53], which binds to CD3 receptors on the surface of T-lymphocytes; alemtuzumab (Campath-1H)[50], which binds to CD52 receptors on the surface of mature lymphocytes; infliximab (Remicade)[30,32], which was developed against tumor necrosis factor-alpha; denileukin diftitox (Ontak)[39], which was developed by conjugation with diphtheria toxin for use against the IL-2 receptors on the surface of T-lymphocytes; and rituximab (Mabthera)[5], which binds to CD20 receptors on the surface of B lymphocytes. In addition to these agents, anti-thymocyte globulin (ATG)[26,28,66,67,69], effective directly on T-lymphocytes, and anti-lymphocyte globulin (ALG)[6,19,22] were also frequently utilized during treatment. In our literature analysis, we found that ATG, basiliximab, muromonab, ALG, daclizumab, infliximab, alemtuzumab, and rituximab and denileukin diftitox were administered in 25, 11, 7, 5, 4, 2, 1, 1, and 1 of the patients, respectively. Of these 57 patients, 13 were placed on monoclonal antibodies and/or T-lymphocyte antagonists as a first treatment modality, whereas steroids, immunosuppressive agents, and various combinations thereof were administered in 44 patients. Mortality rates did not differ among treatment conditions but were quite high in all treatment modalities, indicating that the most appropriate treatment modality has yet to be developed.

Prognosis of GvHD after liver transplantation

The prognosis for GvHD that develops after LT is rather poor, and mortality rates mentioned in the literature range from 75% to 91.6%[9,27,28,32,58]. The mortality rate observed in our literature analysis (67.8%) was lower than that reported in studies cited above. Nearly all patients died of multiple organ dysfunction syndrome, sepsis, or gastrointestinal bleeding despite significant antimicrobial and hematologic support. The only study evaluating mortality in GvHD after LT was a literature search conducted by Taylor *et al*[40] that included 51 cases. According to that study, rash and fever were identified as risk factors for mortality. We obtained different results (Table 1), which suggest that bone marrow (pancytopenia) and intestinal (diarrhea) involvement had a severe effect on mortality. However, the retrospective nature of this study, exclusion of some studies due to inadequate data, failure to obtain sufficient data regarding an HLA match, and the absence of a standardized treatment protocol were limiting factors. Such high rates of mortality despite any type of aggressive treatment revive the issue of protective precautions prior to LT.

Prevention of GvHD after liver transplantation

Preventing GvHD among patients undergoing LT is an important issue. Depletion of T-lymphocytes from the liver before transplantation would eliminate the risk of GvHD. This could be achieved, at least in principal, by

treating the cadaveric donor with ALG or by modifying the donor liver *ex vivo* by irradiation or perfusion with lytic monoclonal antibodies directed against a lymphocyte cell-surface protein[7,8]. However, whether these approaches can be justified is debatable, given the low incidence of GvHD after LT[40,47]. The donor's immunoactive cells can be removed by sufficient perfusion of the graft by carefully removing perihepatic lymph nodes or through graft radiation[31]. Based on our LT experience, perfusion of grafts from living or cadaveric donors with University of Wisconsin (Viaspan) or histidine-tryptophan-ketoglutarate (Custodiol) solution, followed by lactated Ringer's solution at 4 ℃, has proved a fairy efficacious method to remove donor-related lymphocytes from graft material. Some authors believe that transfusion-associated GvHD can be prevented by irradiating blood products and avoiding the use of related donors. Therefore, limiting the application of blood products and using washed red blood cells, white blood cell-free plasma, or platelets could contribute to the prevention of GvHD[31]. We prefer to irradiate erythrocyte suspensions routinely before transfusion in patients who have undergone LT.

In conclusion, although GvHD is a rare complication of LT and the mortality rate remains very high, clinical features represent an important tool for early diagnosis. The prognosis remains poor and further research is needed to clarify the pathogenesis of GvHD and to provide new therapeutic agents for treating this condition effectively.

COMMENTS

Background

Graft-versus-host disease (GvHD) occurs when the donor's immunocompetent cells react against the recipient's cellular antigens. GvHD is a well-known complication in patients who undergo bone-marrow transplantation. However, few reports have described GvHD after liver or other solid organ transplantation. The prognosis for GvHD after liver transplantation (LT) is rather poor, and mortality rates mentioned in the literature range from 75% to 91.6%. Therefore, it is important to determine the factors that affect the prognosis of the disease.

Research frontiers

The authors performed an extensive literature review regarding the development of GvHD after LT that included articles in the PubMed, Medline, EBSCO, EMBASE, and Google Scholar databases published between November 2011 and March 1988.

Innovations and breakthroughs

This study is the most extensive literature review examining factors affecting mortality in patients who develop GvHD after LT.

Applications

Univariate analyses showed that pancytopenia, diarrhea, an age difference between the recipient and donor, and time from first symptom occurrence to diagnosis or treatment were significant risk factors for mortality, and multivariate analysis demonstrated that an age difference between the recipient and donor was an independent risk factor for mortality.

Terminology

GvHD can be divided into acute and chronic forms depending on the timing and character of alloimmune activity. The acute form comprises all manifestations that occur during the first 100 d after transplantation, and the chronic form includes all manifestations that occur after 100 d. GvHD can also be divided into humoral and cellular forms. The humoral form is characterized by hemolysis and fever and occurs in patients transplanted with ABO-incompatible or non-identical grafts. The cellular form occurs when immunocompetent donor lymphocytes originating from the transplanted liver undergo activation and clonal expansion, allowing them to mount a destructive cellular immune response against recipient tissues.

Peer review

This is a good descriptive study in which authors determine the factors affecting mortality in patients who developed GvHD after LT. The results are interesting and showed that an age difference between the recipient and donor is an independent risk factor for mortality in patients who develop GvHD after LT.

Abstract

AIM: To introduce the combination method of radiochemoembolization for the treatment of selected hepatic metastases.

METHODS: Twenty patients with biopsy proven hepatic metastases were selected from those who underwent transarterial radiochemoembolization, a novel combination protocol, between January 2009 and July 2010. Patients had different sources of liver metastasis. The treatment included transarterial administration of three chemotherapeutic drugs (mitomycin, doxorubicin and cisplatin), followed by embolization with large (50-150 μm) radioisotope particles of chromic 32P. Multiphasic computer tomography or computer tomography studies, with and without contrast medium injections, were performed for all patients for a short-term period before and after the treatment sessions. The short-term effectiveness of this procedure was evaluated by modified response evaluation criteria in solid tumors (mRECIST), which also takes necrosis into account. The subjective percentage of necrosis was also assessed. The response evaluation methods were based on the changes in size, number, and the enhancement patterns of the lesions between the pre- and post-treatment imaging studies.

RESULTS: Patients had liver metastasis from colorectal carcinomas, breast cancer, lung cancer and carcinoid tumors. The response rate based on the mRECIST criteria was 5% for complete response, 60% for partial response, 10% for stable disease, and 25% for progressive disease. Regarding the subjective necrosis percentage, 5% of patients had complete response, 50% had partial response, 25% had stable disease, and 20% had progressive disease. Based on traditional RECIST criteria, 3 patients (15%) had partial response, 13 patients (65%) had stable disease, and 4 patients (20%) had disease progression. In most patients, colorectal carcinoma was the source of metastasis (13 patients). Based on the mRECIST criteria, 8 out of these 13 patients had partial responses, while one remained stable, and 5 showed progressive disease. We also had 5 cases of breast cancer metastasis which mostly remained stable (4 cases), with only one partial response after the procedure. Six patients had bilobar involvement; three of them received two courses of radiochemoembolization. The follow up imaging study of these patients was performed after the second session. In the studied patients there was no evidence of extrahepatic occurrence, including pulmonary radioactive deposition, which was proven by Bremsstrahlung scintigraphy performed after the treatment sessions. For the short-term follow-ups for the 2 mo after the therapy, no treatment related death was reported. The mostly common side effect was post-embolization

syndrome, presented as vomiting, abdominal pain, and fever. Nineteen (95%) patients experienced this syndrome in different severities. Two patient had ascites (with pleural effusion in one patient) not related to hepatic failure. Moreover, no cases of acute liver failure, hepatic infarction, hepatic abscess, biliary necrosis, tumor rupture, surgical cholecystitis, or non-targeted gut embolization were reported. Systemic toxicities such as alopecia, marrow suppression, renal toxicity, or cardiac failure did not occur in our study group.

CONCLUSION: Radiochemoembolization is safe and effective for selected hepatic metastases in a short-term follow-up. Further studies are required to show the long-term effects and possible complications of this approach.

INTRODUCTION

Although complete surgical resection of the hepatic portion affected by metastasis is usually the best treatment option, most patients with hepatic metastasis are not amenable to resection or have some contraindications to the surgery[1]. As alternatives to standard systemic chemotherapy, some recent palliative therapies have been developed for unresectable hepatic metastases, which include transarterial administration of chemotherapeutic drugs or radiopharmaceuticals, selective tumor vessel embolization and percutaneous tumor ablation with ethanol injection, cryotherapy, radiofrequency, or the use of microwaves[1,2].

Transcatheter arterial chemoembolization (TACE) is a dual minimally invasive therapeutic approach combining transarterial administration of chemotherapeutic drugs and hepatic artery embolization[3]. Although there are many advantages of this combination, it does produce marked tumoral ischemia at the time of drug administration which potentiates the effect of cytotoxic agents and augments tumoral cell apoptosis[4,5].

Radioembolization, on the other hand, is a technique that preferentially targets hepatic lesions by infusing the hepatic arteries that supply the tumor with radioactive microspheres[6]. Traversing the hepatic vascular plexus, these microspheres embed within the tumor arterioles, where they deliver high-energy low-penetrating radiation doses to the tumoral cells, while the normal hepatic tissue is relatively preserved[6,7]. As can be determined from the method's name, radioembolization has also microembolic effects and leads to subsequent vessel occlusion[8].

Regarding the effectiveness of radioembolization and chemoembolization for hepatic malignant neoplasms[2,9], we assumed that the local combination of the two methods (i.e., radiochemoembolization) would be more effective. It has been shown that radioembolization in combination with systemic chemotherapy is an effective first-line therapy for liver metastases[10]. The most commonly used agent for radioembolization of hepatic tumors is Yttrium-90 (^{90}Y) in the form of ^{90}Y microspheres[9], which has a half-life of 64 h[11]. In this study, however, a phosphorus-32 containing particle was adopted as the radiopharmaceutical. In the process of phosphorus-32 (^{32}P) decay, the molecule emits relatively high energy beta particles[12]. Although there are reports of safe clinical ^{32}P application for hepatic tumors[12-16], larger particles were used in the current study to reduce systemic toxicities even more by decreasing hepatic-to-systemic shunt. In addition, the higher half-life of ^{32}P (14.3 d[17]) would provide a longer irradiation time in order to achieve chemo-radiation effects.

The primary purpose of this study is to introduce the radiochemoembolization method for the treatment of hepatic metastases. Short-term effectiveness of this treatment based on imaging criteria was also assessed. As World Health Organization (WHO) criteria and response evaluation criteria in solid tumors (RECIST) guidelines are based solely on the degree of tumor shrinkage for assessing tumor response, we used other criteria like modified RECIST (mRECIST), which includes the degree of necrosis to show the effectiveness of the therapy[18]. Finally, *via* a brief review of the literature concerning ^{32}P application and TACE, possible limitations, concerns, and complications that may be encountered with radiochemoembolization were addressed.

MATERIALS AND METHODS

This was a single institution clinical study approved by the ethics committee of our imaging center. A written consent form was obtained from all patients and they were all informed about the novelty of the method. This paper reports the results of 20 patients who underwent radiochemoembolization between January 2009 and July 2010. The inclusion criteria included: biopsy proven hepatic metastatic lesion/lesions from any source; contraindication to ablative therapies and resection; an eastern cooperative oncology group performance status score of 0 to 2[19]; and the patient needed to be at least 18 years of age. Although more than 20 patients met these criteria and received radiochemoembolization, another inclusion criterion was added to only report the results of patients

who had available contrast-enhanced computer tomography (CT) or magnetic resonance imaging (MRI) 1 to 2 mo previous and after the treatment session. Only 20 patients such patients were qualified. Exclusion criteria were: bleeding diathesis that could not be controlled; significant extra-hepatic involvement, generally more than 50% of the whole tumoral bulk outside the liver; imminent threat to the patient's life caused by the disease; greater than 75% involvement of the hepatic parenchyma; severe hepatic dysfunction; and an active uncontrolled infection.

Patients fasted overnight and received a prophylactic antibiotic (ceftriaxone, 1 g) and antiemetics (granisetron, 3 mg; dexamethasone, 8 mg). During the procedure, fentanyl or pethidine were infused to alleviate the pain caused by embolization. All procedures were performed in the angiography room under aseptic conditions. Intravenous hydration was started 1 h before the procedure.

In this study, ^{32}P-containing particles were used (Nuclear Science and Technology Institute, Iran) with $Cr^{32}PO4$ as the active component. These particles had a grain size of 50-150 μm, significantly larger than previously used colloidal ^{32}P particles also based on $Cr^{32}PO4$[13,14,20]. The physical half-life period of ^{32}P is 14.28 d, with an average penetration distance of 3-4 mm in soft tissues (maximum 8 mm)[13]. Ranging from 0.185 to 0.444 GBq, the dose of injected solution was calculated based on liver volume (not tumor burden) which was estimated with CT or MRI. The prepared ^{32}P solution was dissolved in 1-3 mL of radiographic contrast. The chemotherapeutic mixture consisted of 50 to 100 mg of cisplatin, 50 mg of doxorubicin, and 8-10 mg of mitomycin-C dissolved in 10 mL of radiographic contrast and 10 mL of normal Saline.

Using the Seldinger technique, a catheter was introduced through the femoral artery and selective catheterization of the hepatic artery was performed. A 3-F hydrophilic microcatheter (Cook, United States) used with a 0.014 or 0.021 guide wire was suffice to catheterize the desired artery. This standard catheter allows rapid injection of viscous radiochemoembolic emulsions and is unlikely to clog with particles. A digital subtraction angiography was performed to confirm that there was no hepatic arteriovenous fistula or duodenogastric reflux. For patients who had bilobar involvement, the treatment mixture was infused in both lobes simultaneously or separately in two sessions (3-4 wk apart) depending on the patient's liver function test and number of metastases. Only in one case (case 4) was coil embolization of gastroduodenal artery was performed before radiochemoembolization.

After placing the catheter in a suitable location, the chemotherapeutic mixture was infused and continuously monitored *via* fluoroscopy to avoid reflux into the untargeted arterial bed. Following this step, again under fluoroscopic surveillance, chromic ^{32}P solution was infused for vessel occlusion. If reflux happened, the infusion would be paused until the arterial flow resumed and then restarted at a lower speed.

After the procedure, intravenous hydration, antibiotics, and antiemetic therapies were continued for 24 h and analgesics were supplied for control of pain as needed. All the patients were discharged on the day after the procedure. Oral antibiotics were continued for 5 d, as well as oral antiemetics and analgesics if needed. Twenty-four to 72 h after radiochemoembolization of hepatic tumors, bremsstrahlung scintigraphy was performed in all patients to document ^{32}P particles that accumulated in tumoral locations of the liver, and also to ensure that there were no extrahepatic radioactive deposits.

For evaluating the short-term effectiveness of radiochemoembolization by means of imaging studies, two scans, whether CT or magnetic resonance (MR), were performed 1 to 2 mo before and after the treatment session. CT examinations were performed using a multidetector scanner (Sensation 64, Siemens, Germany), with 5-mm sections (120 kV, 250 mAs). Triphasic liver imaging (including unenhanced, arterial and portal venous phase images) was acquired. Contrast-enhanced scans were performed after approximately 30 s in the arterial phase and after 70 s in the venous phase from the injection of the contrast agent iohexol (Omnipaque 350, Amersham Health; 125 mL at a rate of 3-5 mL/s). MR studies were performed using a 1.5 Tesla machine (Magnetom Symphony, Siemens, Germany). The protocol consisted of axial and coronal thin-section T2-weighted HASTE, axial unenhanced spoiled-T1-weighted gradient echo with fat suppression, and dynamic axial fat-suppressed contrast-enhanced spoiled-T1-weighted gradient-echo sequences for the arterial and venous phases (45, 60 and 90 s) and also the delayed phase (2-5 min) after contrast infusion. The contrast agent was gadopentetate dimeglumine (Magnevist, Berlex Pharmaceuticals, 20 mL), followed by 20 mL of saline flush.

Evaluation of tumor response to therapy was based on mRECIST criteria and subjective percentage of necrosis. Firstly, up to two hepatic target lesions were selected in pre-treatment imaging studies. Said lesions must (1) be capable of being accurately measured in at least one dimension as 1 cm or more; (2) be suitable for repeat measurement; and (3) have intratumoral enhancement after contrast injection. If more than two lesions could met these criteria, the one with larger enhancing portions would be selected. All other hepatic lesions were only recorded and not measured at the baseline; their presence or absence would be noted in the follow-up exams. A viable tumor was defined as a portion of the target lesion which had an uptake of the contrast agent in any phase of the contrast enhanced studies. For the mRECIST criteria, the change in the longest diameter of viable tumors was considered for the evaluation of the response to treatment. On the other hand, necrosis was a portion of the target lesions which remained without contrast enhancement. Based on these necrotic portions, a subjective percentage of necrosis was attributed to each target lesion. Every individual patient had a sum of longest viable tumor diameters and necrosis percentages of target lesions. According to the changes in these amounts, responses were categorized into complete response, partial response, stable disease and progressive disease (Table 1).

Table 1 Assessment of target lesion response

mRECIST		RECIST		Subjective percentage of necrosis	
CR	Disappearance of any intratumoral enhancement in all target lesions	CR	Disappearance of all target lesions	CR	Disappearance of any intratumoral enhancement in all target lesions
PR	At least a 30% decrease in the sum of diameters of viable target lesions	PR	At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum of the diameters of target lesions	PR	At least a 30% increase in the sum of target lesion necrosis percentages
SD	Any cases that do not qualify for either partial response or progressive disease	SD	Any cases that do not qualify for either partial response or progressive disease	SD	Any cases that do not qualify for either partial response or progressive disease
PD	An increase of at least 20% in the sum of the diameters of viable target lesions or new lesion appearance	PD	An increase of at least 20% in the sum of the diameters of target lesions or new lesion appearance	PD	A decrease of at least 20% in the sum of target lesion necrosis percentages or new lesion appearance

mRECIST: Modified response evaluation criteria in solid tumors; CR: Complete response; PR: Partial response; SD: Stable disease; PD: Progressive disease.

[1]For patients with new lesions in the follow-up scan, the measurements were not performed and the patient was marked as progressive disease (PD); CR: Complete response; PR: Partial response; SD: Stable disease; U: Unilobar; B: Bilobar; F: Female; M: Male; BRE: Breast cancer; CRC: Colorectal carcinoma; CAR: Carcinoid tumor; LUN: Lung cancer; mRECIST: Modified response evaluation criteria in solid tumors.

RESULTS

Patients had different sources of liver metastasis, but most were from colorectal cancer. None of our patients had a history of surgery for hepatic metastases. The demographic, clinical, radiological and response data of the studied patients are shown in Table 2.

The mean and median of the baseline total viable diameters (i.e., the sum of the maximum diameters of the viable portions of target lesions in each patient) were 84.85 mm and 61 mm (range: 25-245 mm), respectively. The response rate, based on mRECIST criteria, was 5% for complete response (Figure 1A and B), 60% for partial response (Figure 1C and D), 10% for stable disease, and 25% for progressive disease (Figure 1E and F).

The baseline sum of the estimated percentage of necrosis in target lesions was calculated for each patient, and had a mean and median of 29.5% and 17.5%, respectively (range: 0% to 155%). Regarding the necrosis percentage, 5% of patients had complete response, 50% had partial response, 25% had stable disease and 20% had progression. Based on traditional RECIST criteria 3 patients (15%) had partial response, 13 patients (65%) had stable disease, and 4 patients (20%) had disease progression.

In most patients, colorectal carcinoma was the source of metastasis (13 patients). Based on mRECIST, 8 out of these 13 patients had partial responses while one remained stable and 5 showed progressive disease. We also had 5 cases of metastasis from breast cancer, which mostly remained stable (4 cases) with only case of one partial response after the procedure.

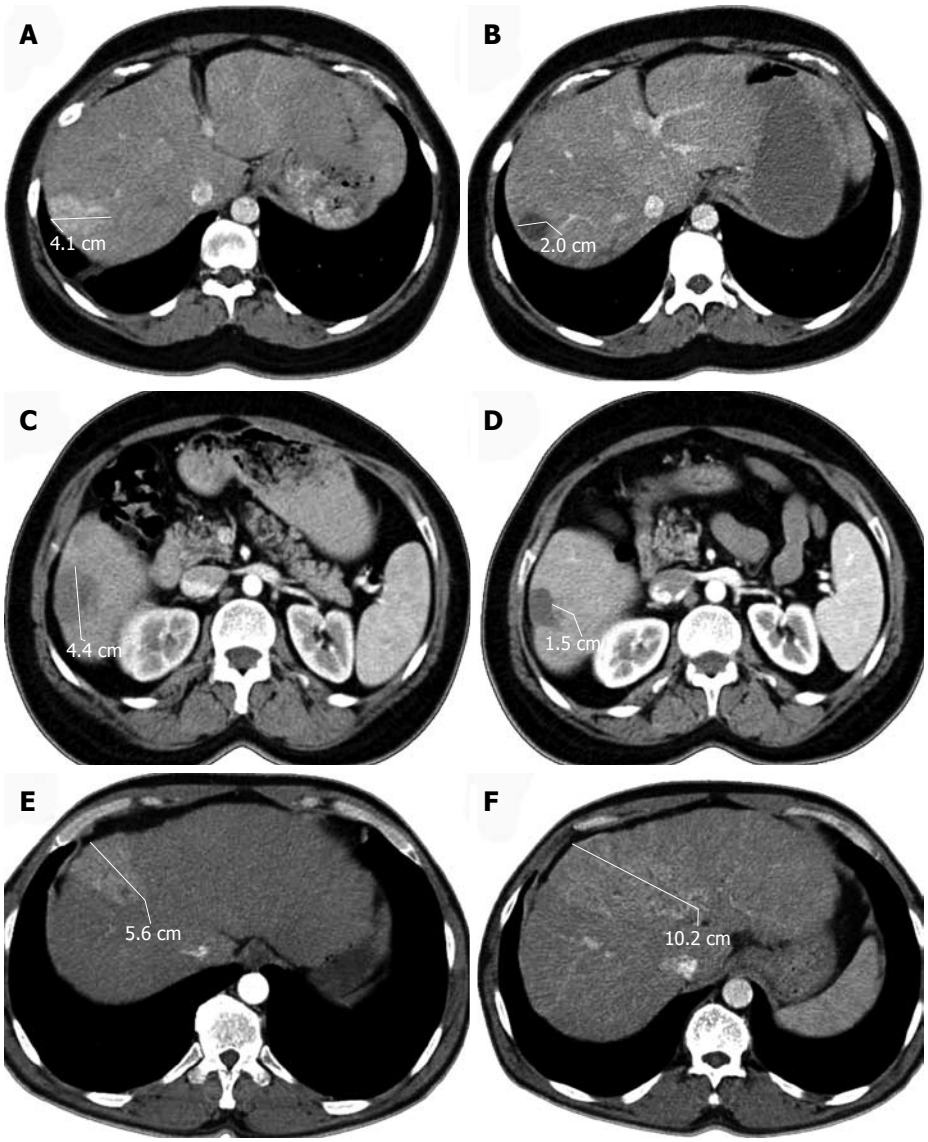

Figure 1 Radiochemoembolization images. A, B: Pre- (A) and post- (B) radiochemoembolization images in a 27 year-old female with a metastatic carcinoid tumor. There is no evidence of enhancing of the viable tumor after treatment. Based on modified response evaluation criteria in solid tumors (mRECIST) criteria, the response is complete, but regarding RECIST criteria we have a partial response; C, D: Pre- (C) and post- (D) radiochemoembolization images in a 41 year-old female with a metastatic carcinoid tumor. Based on modified response evaluation criteria in solid tumors criteria the response is partial; E, F: Pre- (E) and post- (F) radiochemoembolization images in a 55 year-old male with a metastatic colorectal carcinoma. Based on modified response evaluation criteria in solid tumors criteria the response is progressive.

Six patients had bilobar involvement, with three of them receiving two courses of radiochemoembolization. The follow-up imaging study of these patients was performed after the second session. In the studied patients there was no evidence of extrahepatic occurrence (such as pulmonary radioactive deposition), which was proven by Bremsstrahlung scintigraphy performed after the treatment.

For short-term follow-ups for the 2 mo after the therapy, no treatment-related death was reported. The most common side effect was post-embolization syndrome, presented as vomiting, abdominal pain and fever. Nineteen (95%) patients experienced this syndrome in different severities. Two patient had ascites (with pleural effusion for one patient) not related to hepatic failure. Moreover, no cases of acute liver failure, hepatic infarction, hepatic abscess, biliary necrosis, tumor rupture, surgical cholecystitis, or non-targeted gut embolization were reported[2]. Systemic toxicities, such as alopecia, marrow suppression, renal toxicity, or cardiac failure did not occur in our study group.

DISCUSSION

Liver metastases are one of the most difficult therapeutic challenges in oncological management, and are not usually amenable to resection. Many studies have been performed to find more effective palliative options for non-operable metastatic tumors. Although systemic chemotherapy still has a role[10,21], there are attempts at focusing treatment on hepatic tumors[22]. The present study introduced a novel combination of two effective treatment

options, TACE and radioembolization, for metastatic hepatic lesions.

In the current study, large-molecule chromic phosphate containing ^{32}P particles were used. Colloidal ^{32}P, another chromic phosphate-containing agent, has been previously used for radiosynovectomy *via* intrasynovial injection[23], treatment of stage I and II ovarian carcinoma *via* intraperitoneal instillation[24,25], and for regional radiotherapy of some tumors *via* direct intratumoral injection[13,20]. The usual forms of colloidal ^{32}P particles are small, approximately 1 μm[14,26], and might leak into systemic circulation, causing irradiation to undesired parts of body and toxicity. For intrasynovial and intraperitoneal application, as the risk of leakage is low, the colloidal ^{32}P solution is safely used[23]. For direct intratumoral injection on the other hand, the retention of colloidal ^{32}P radioactivity at the site of a solid tumor requires the co-administration of macroaggregated albumin[27]. However, the risk of leakage from the injection site is still present due to intratumoral interstitial pressure[14].

There was only one report of intravascular injection of ^{32}P colloid in our literature review. Kim *et al*[28] administered colloidal ^{32}P *via* the portal vein to prevent growth of occult metastases in the liver. They concluded that the mentioned approach would be expected to prevent liver metastases of completely resected colorectal cancers. Other studies on radioactive phosphorus use phosphorus-32 glass microspheres (^{32}P-GMS) with grain sizes of 46-76 μm to reduce systemic toxicity[13]. Although transarterial administration of this compound has been used safely for hepatic primary or metastatic tumors[13,15,16], the main use for a radioactive pharmaceutical for this purpose is a ^{90}Y microsphere with a particle size of 20-35 μm[9]. There has also been an early report of ^{90}Y systemic leakage[29].

In terms of systemic toxicity, the used compound did not have a higher risk than ^{32}P-GMS or ^{90}Y microspheres. We can, however, raise an advantage for ^{32}P over ^{90}Y regarding our purpose. The half life of this radioactive element (14.28 d) provides a significantly longer period of irradiation than ^{90}Y with its half-life of 64 h[11,13]. Considering the 2 half-lives, there was almost 28 d of radiation for the optimal chemoradiation effect in the presence of chemotherapy drugs.

Another consideration is our chemotherapeutic mixture. Although there is no consensus on the best chemotherapeutic agent for TACE, doxorubicin is the most commonly used drug for the purpose[30]. The most commonly combined drug regimen for TACE, including cisplatin, doxorubicin, and mitomycin C[2,30] was used in this study. In combination with radiotherapy, however, we needed to find some supports and check if there were previous contraindications in the literature. Cisplatin is similar to other platinum-based agents that act as a radiosensitizer[31]. There was one clinical trial combining hepatic radioembolization with ^{90}Y and a systemic chemotherapy regimen containing the platinum-based agent, oxaliplatin[32]. Concerning doxorubicin, which is also a potent radiosensitizer[33], we found no previous usage for hepatic malignancies in combination with radiotherapy, although its co-administration has been used in other body parts[34-36]. Another study on nude mice for medullary thyroid cancer showed the combination of radioimmunotherapy and doxorubicin chemotherapy had synergistic therapeutic efficacy, which may be due to the radiosensitizing effect of doxorubicin[37]. Like doxorubicin, mitomycin C has also had concurrent administration with radiotherapy in several studies[38-40]. Therefore, there is no proven contraindication to applying radiotherapy along with this chemotherapeutic regimen. Moreover, it is expected that in the case of cisplatin and doxorubicin, which are radiosensitizers, the effect of therapy would be more effective than just the addition of TACE and radioembolization effects.

The mRECIST criteria were originally designed for hepatocellular carcinoma (HCC) and are based on the changes in the viable portion of hepatic lesions. Older methods of image-based response evaluation of solid tumors only assess the change in anatomic size of target lesions[18]. Measurements were either by the bilinear product approach (WHO criteria) or by single linear summation (RECIST criteria)[41]. As acknowledged before, relying solely on the changes in tumor size can be misleading[42]. Modified RECIST and a subjective percentage of necrosis criteria take tumor necrosis induced by treatment into account[18].

Studies which used ^{90}Y radioembolization for metastatic hepatic lesions from mixed sources generally relied on WHO and RECIST criteria to assess the treatment response (Table 3). Expanding the response rate to cases with complete or partial response, there were reports of 13% to 42.8% responsiveness with regard to WHO and RECIST criteria. Only Peynircioğlu *et al*[43] reported that all of their patients had at least a partial response in target lesions. Considering necrosis in combination with anatomic size, Miller *et al*[7] showed an increase in response rate from 19% to 50%. The studies on metastatic hepatic lesions using a chemotherapy regimen of doxorubicin, cisplatin, and mitomycin-c for TACE are summarized in Table 4. Only papers which reported an imaging-based response rate were included. WHO and RECIST criteria showed a response rate that differed from 8% to 60% in these studies. A paper by Artinyan *et al*[44] on mixed-source hepatic metastases showed a response rate of 14.8%.

Firusian *et al*[20] reported 5 cases of hepatic metastasis for which direct intratumoral colloidal ^{32}P injection led to three complete and two partial responses. No toxicity was encountered in these 5 patients and there were no alterations in hepatic function. In a study by Gao *et al*[13] on 60 patients with refractory solid tumors, including 25 cases of HCC and 5 cases of hepatic metastatic carcinoma, they administered ^{32}P-GMS *via* the hepatic artery for thirty-two cases. Among all 60 patients, 31 cases achieved complete response (51.7%), 25 cases partial response (41.7%) and 4 cases no effect. Most patients had post-procedural nausea and vomiting. There were also reports of discomfort or pain in the right upper abdominal quad-

Table 3 Studies on Yttrium-90 radioembolization for metastatic hepatic lesions from mixed sources

Study	Procedure	Agent	Absorbed dose or mean activity delivered[1]	Number of patients	Response criteria	Response measured at (months post treatment)	Response rate	Complications
Blanchard *et al*[49], 1989	Radioembolization	^{90}Y plastic microspheres	NA	15	WHO	NA	Partial response in 5 (33.3%), minimal response in 2 (13.3%)	Gastritis or gastric ulceration in 6 (in three this was proven to be due to unintended infusion of microspheres into the gastric circulation)
Andrews *et al*[50], 1994	Radioembolization	^{90}Y glass microspheres	150 Gy	24	WHO	2	Partial response in 5 (20.8%), minimal response in 4 (16.7%), stable disease in 7 (29.2%), progressive disease in 8 (33.3%)	Mild gastrointestinal symptoms in 4 (unrelated to treatment)
Miller *et al*[7], 2007	Radioembolization	^{90}Y glass microspheres	100-120 Gy	42	WHO	2.3[2]	Complete/partial response in 8 (19%), stable disease in 22 (52%), progressive disease in 23	Radiation cholecystitis in 10, liver edema in 18
					RECIST	3.9[2]	Complete/partial response in 10 (24%), stable disease in 21 (50%), progressive disease in 23	
					Necrosis	1[2]	Complete/partial response in 19 (45%)	
					Combined	1.1[2]	Complete/partial response in 21 (50%), stable disease in 11 (26%)	
Sato *et al*[8], 2008	Radioembolization	^{90}Y glass microspheres	112.8 Gy/ 1.83 GBq	137	WHO	1-3	Complete response (2.1%), partial response (40.7%)	Fatigue (56%), vague abdominal pain (26%), nausea (23%)
Lim *et al*[51], 2005	Radioembolization	^{90}Y resin microspheres	NA	46	RECIST	2	Partial response in 12 (27%), stable disease in 12 (27%), progressive disease in 19 (44%)	Between 2 and 8 wk of lethargy, anorexia, nausea and right upper quadrant pain in most patients, severe gastric/duodenal ulceration in 4 (8%), portal hypertension in 1, radiation hepatitis in 1
Yu *et al*[52], 2006	Radioembolization	^{90}Y resin microspheres	42 Gy	49	RECIST	NA	Response rate of 29%	Fatigue in 18 (37%), vague abdominal pain in 10 (20%), nausea/vomiting in 10 (20%), ascites and/or leg edema in 3 (6%)
Szyszko *et al*[53], 2007	Radioembolization	^{90}Y resin microspheres	1.9 GBq	21	RECIST	1-2	Partial response in 2 (13%), stable disease in 9 (60%), progressive disease in 4 (27%)	NA
Stuart *et al*[54], 2008	Radioembolization	^{90}Y resin microspheres	NA	30	RECIST	NA	Partial response or stable disease in 14 (47%)	Gastrointestinal ulceration in 1 (3%)
Kennedy *et al*[55], 2009	Radioembolization	^{90}Y resin microspheres	1.1 ± 0.6 GBq	502[3]	RECIST	3	Complete response in 23 (4.5%), partial response in 48 (9.5%), stable disease in 386 (76.8%), progressive disease in 45 (9%)	Fatigue and upper abdominal pain (29%), gastritis and overt gastric ulceration (2%), severe liver disease (4%)
Peynircioğlu *et al*[43], 2010	Radioembolization	90Y resin microspheres	1.24 GBq	10	RECIST	1-2	All patients had at least partial response of the target lesions	Post-procedural mild to moderate fatigue in all patients for 7 d, with mild to moderate fever and abdominal pain in some patients
Omed *et al*[56], 2010	Radioembolization	^{90}Y resin microspheres	NA	11	RECIST	NA	Partial response (20%), stable disease (50%), progressive disease (30%)	No major complications, 82% of patients experienced side-effects, mainly nausea, vomiting and abdominal pain
Cianni *et al*[57], 2010	Radioembolization	^{90}Y resin microspheres	1.64 Gbq	110	RECIST	2	Complete/partial response in 45, stable disease in 42, progressive disease in 23	Hepatic failure in 1, gastritis in 6, cholecystitis in 2

[1]The absorbed dose in Gy and/or the mean delivered activity in Gbq are provided with respect to their availability; [2]median; [3]the total number of patients in the study was 680, but the response evaluation criteria in solid tumor (RECIST) criteria were only available for 502 patients. ^{92}Y: Yttrium-90; WHO: World Health Organization; NA: Not available.

rant within 1 wk after treatment[13].

There are significant differences between lesion outcomes rated by the mRECIST and RECIST criteria in our series. In agreement with many other reports, in short-term follow-up the degree of necrosis is a major factor for response evaluation and a criteria lacking this factor may

Table 4 Studies on chemoembolization for metastatic hepatic lesions with cisplatin, doxorubicin and mitomycin

Study	Primary diagnosis	Procedure	Chemotherapeutic agents	Embolic material	Number of patients	Response criteria	Response measured at months treatment	Response rate	Complications
Diaco *et al*[58], 1995	Carcinoid tumor	Chemoembolization	Cisplatin, doxorubicin, mitomycin	NA	10	WHO	NA	Partial response (60%), stable disease (30%)	NA

Tellez *et al*[60], 1998	Colorectal carcinoma	Chemoembolization	Cisplatin, doxorubicin, mitomycin	Angiostat (a bovine collagen material)	27	Designed by authors[2]	NA	Radiological response in 17 of 27 patients (63%)	Fever in 83%, RUQ pain in 100%, nausea/vomiting in 83%, gastritis in 17%, lethargy in 60%
Buijs *et al*[45], 2007	Breast cancer	Chemoembolization	Doxorubicin (50 mg), cisplatin (100 mg), and mitomycin (10 mg) in a 1:1 mixture with iodized oil	300- to 500-μm embolic microspheres	14[3]	RECIST	1-2	No complete response, partial response in 7 lesions (26%)[6]	NA
Ruutiainen *et al*[61], 2007	Neuroendocrine tumor	Chemoembolization	Cisplatin, doxorubicin, mitomycin in a mixture with iodized oil	150- to 250-μm granular polyvinyl alcohol particles	44	RECIST	1	88% partial response/stable disease	High incidence of postembolization syndrome, severe pain in 3 sessions, severe nausea in 1 session, severe vomiting in 1 session, severe GGT/ALP elevation in 4 sessions, severe AST elevation in 1 session, severe ALT elevation in 1 session, severe infection in 1 session
Artinyan *et al*[44], 2008	Mixed	Chemoembolization	Doxorubicin (50 mg), mitomycin (10 mg), and cisplatin (150 mg)	Polyvinyl alcohol microspheres (300-700 μm)	61[4]	RECIST	At least 1	Partial response in 9 (14.8%), progressive disease in 3 (4.9%)	Bleeding in 2 patients (2%), renal failure in 6 patients (5%), hepatic failure in 7 patients (6%), infection in 3 patients (3%), mortality in 30 d in 7 patients (6%)
Buijs *et al*[48], 2008	Ocular melanoma	Chemoembolization	Doxorubicin (50 mg), cisplatin (100 mg), and mitomycin (10 mg) in a 1:1 mixture with iodized oil	300- to 500-μm embolic microspheres	6[5]	RECIST	1-2	No complete response, partial response in 8 lesions[6]	NA
Albert *et al*[62], 2011	Colorectal carcinoma	Chemoembolization	Cisplatin, doxorubicin, mitomycin in a mixture with ethiodized oil	Polyvinyl alcohol	95[6]	RECIST	NA	Partial response in 9 (14.8%), stable disease in 49 (80.3%), progressive disease in 3 (4.9%)	NA

[1]There were 15 patients at first, however one died before the follow up imaging and one patient's follow-up was out of state. Three patients only received hepatic artery embolization; [2]at least 75% decrease in the density of lesions consistent with necrosis or 25% decrease in the size of the lesions without the development of concomitant lesions; [3]twenty-seven lesions; [4]the total number of patients was 119, but for 61 patients the response evaluation criteria in solid tumors (RECIST) criteria were available; [5]twenty-one lesions, reporting by patient, all patients were considered non-responders to transcatheter arterial chemoembolization because the total tumor burden did not decrease by 30% in any given patient; [6]ninety-five of 141 treatment cycles were evaluable for response. The response rate is calculated per treatment cycle. NA: Not available; RUQ: Right upper quadrant; WHO: World Health Organization; GGT/ALP: Gamma-glutamyl transpeptidase/alkaline phosphatase; AST/ALT: Aspartate aminotransferase/alanine aminotransferase.

underestimate the effectiveness of the therapy[7,42,45-48]. There were differences in the results of mRECIST and necrosis percentage criteria for 3 patients. In these cases the change was in the anatomical size of lesions without a significant change in necrosis percentage. This finding shows that, in addition to its inherent flaw of being subjective, necrosis percentage cannot always reveal the real response. It seems that criteria that gather both anatomic sizes and the degree of necrosis (e.g., mRECIST) are more accurate. In 2 patients with newly appeared lesions (cases 12 and 13) after the treatment, these new lesions were in the lobe other than the one that underwent radiochemoembolization. These lesions could be new metastatic lesions or previously non-visible metastatic

foci in the non-treated lobe. For that reason, assessing the response by patient and not by lobe might have shown lower response rates in this study.

Our patients, like in most other studies on radioembolization and TACE, generally had constitutional and mild gastrointestinal symptoms after treatment sessions. There was no severe toxicity in the short-term follow-up of our series. Various degrees and severities of complications have been previously encountered after TACE and radioembolization procedures (Tables 3 and 4).

One limitation of the current study is the lack of control groups which only receive either TACE or radioembolization. Therefore, statistical comparison between the methods is impossible. However, many studies in this field perform new treatment strategies without a sample group and compare their result with the literature (Tables 3 and 4). Other weaknesses of this study were the short-term follow-up period and the mixed sources of hepatic metastases. The metastatic foci from different sources may have different responses to the administrated therapy. Longer than 2 mo period imaging results, long-term survival rates, time to progression (i.e., the post procedural elapsed time after which imaging studies show progressive disease), and also response rates in larger series of patients with single source of metastasis remain to be reported on the forthcoming steps after completion of regular long-term imaging evaluations and follow-ups.

In conclusion, this study introduces a new treatment approach for hepatic metastatic lesions on a rational basis. This was a combination of TACE and radioembolization which have been used individually for such lesions. It also shows that in short-term follow-ups this method is safe and effective, with a response rate of 65% with regards to the mRECIST criteria. Further studies are required to show the long-term effects and possible complications of this approach.

COMMENTS

Background

Liver metastases are a therapeutic challenge in oncological management. Surgery is frequently impossible due to disease extent and systemic chemotherapy usually fails. Transcatheter arterial chemoembolization and radioembolization are two separately used locoregional palliative therapies for metastatic hepatic lesions.

Research frontiers

Designing new treatments for patients with multiple or unresectable liver metastases is an interesting field of oncology. Transcatheter arterial administration of therapies is rapidly developing with the aid of diverse chemotherapeutic drugs and radiopharmaceuticals. Application of microsphere and particle technology is an evolving area of interventional oncology.

Innovations and breakthroughs

This study presents a novel image-guided combination of transcatheter arterial chemoembolization and radioembolization for advanced hepatic metastases, referred to as radiochemoembolization, which substantially intensifies local treatment effect. The authors used chromic phosphorus-32 molecules embedded in large particles with greater local effects and less systemic toxicities.

Applications

By showing the short-term effectiveness of the new combination method, the study opens the way for further research studies to assess the effects and complications of radiochemoembolization more thoroughly. After the release of results from the ongoing and upcoming studies by the authors and other scientists, an adjusted form of radiochemoembolization might play an important role in the treatment of hepatic metastases.

Terminology

Radiochemoembolization is a newly designed combination of radioembolization and transcatheter arterial chemoembolization, which are minimally invasive therapeutic approaches for administrating radioactive microspheres and chemotherapeutic drugs transarterially.

Peer review

This paper presents the short-term effectiveness of radiochemoembolization for selected hepatic metastases. This is the first report in which the novel combination of two commonly used effective options of treatment is described.

Abstract

AIM: To investigate the value of adenosine deaminase (ADA) for early detection of tuberculous peritonitis (TBP) among cirrhotic patients.

METHODS: We retrospectively analyzed 22 patients with TBP from July 1990 to June 2010. Twenty-five cirrhotic patients with uninfected ascites were prospectively enrolled as the cirrhosis control group from July 2010 to June 2011. An additional group of 217 patients whose ascites ADA levels were checked in various clinical conditions were reviewed from July 2008 to June 2010 as the validation group.

RESULTS: The mean ascites ADA value of cirrhotic patients with TBP (cirrhotic TBP group, n = 8) was not significantly different from that of non-cirrhotic patients (non-cirrhotic TBP group, n = 14; 58.1 ± 18.8 U/L *vs* 70.6 ± 29.8 U/L, P = 0.29), but the mean ascites ADA value of the cirrhotic TBP group was significantly higher than that of the cirrhosis control group (58.1 ± 18.8 U/L *vs* 7.0 ± 3.7 U/L, P < 0.001). ADA values were correlated with total protein values (r = 0.909, P < 0.001). Using 27 U/L as the cut-off value of ADA, the sensitivity and specificity were 100% and 93.3%, respectively, for detecting TBP in the validation group.

CONCLUSION: Even with lower ADA activity in ascites among cirrhotic patients, ADA values were significantly elevated during TBP, indicating that ADA can still be a valuable diagnostic tool.

INTRODUCTION

Tuberculous peritonitis (TBP) is one of the most frequent extra-pulmonary locations of tuberculosis, and the mortality rate may exceed 50% without prompt treatment[1,2]. The gold standard for diagnosing TBP is culture

of *Mycobacterium* in ascites fluid or peritoneal biopsy, but the cultures are time-consuming and have low positivity rates, with a mean sensitivity of 43%-83% depending on the quality of samples cultured and methods utilized[3,4]. In addition, caseous granulomas of peritoneal biopsies obtained by either laparoscopy or laparotomy are alternative methods for rapid primitive diagnosis, but the procedures are invasive and may increase rates of morbidity and mortality[4-6]. The high mortality rate in untreated patients warrants a quick and noninvasive test for diagnosing TBP[1,3,7], and adenosine deaminase (ADA) in ascites is an available test that has been proposed to be useful for rapid diagnosis[1,4,6,8,9]. By analyzing ADA level in ascites, the sensitivity and specificity for diagnosing TBP have been reported to be as high as 100% and 97%, respectively[2,8,10-12].

The risk of TBP is increased in patients with underlying liver cirrhosis[4,13], and the percentage of underlying cirrhosis among patients with TBP could be as high as 50% in the United States[14]. However, concerns regarding the sensitivity of ascites ADA in detecting TBP have been raised among patients with underlying liver cirrhosis[3,15], and the low sensitivity is thought to be caused by the concomitant immunocompromised status and dilutional phenomenon in advanced liver disease[3]. In addition, cirrhotic patients always have a low protein level in ascites, and the correlation between total protein and ADA activity has been discussed in previous studies[3,10,15]. However, the laboratory analysis of ascites might be confounded by heterogenous clinical conditions in the control groups, and previous studies show conflicting results for cirrhotic patients with TBP[4]. Therefore, in the present study, we employed a prospectively-enrolled cirrhosis control group in order to investigate the laboratory changes in ascites and the clinical utility of measuring ADA activity in cirrhotic patients with TBP.

MATERIALS AND METHODS

Retrospective tuberculous peritonitis cohort

All patients diagnosed with TBP at Taichung Veterans General Hospital, a tertiary referral center in central Taiwan, from July 1990 to June 2010 were retrospectively analyzed and formed the TBP group. The patients' medical records were reviewed and demographic, laboratory, microbiological, histological and laparoscopic features were collected. A definite diagnosis of TBP was based on one or more of the following: (1) positive TB cultures of ascites or peritoneal biopsy; (2) characteristic finding of caseous granulomas on histology of peritoneal biopsy; and (3) clinical judgment of TBP by a physician based on ascites data followed by a good response to anti-tuberculous treatment. A good response to therapy was defined as complete resolution or clinical improvement during the follow-up period. Exclusion criteria included (1) ascites ADA data unavailable; (2) ascites ADA analyzed after anti-tuberculous treatment; and (3) patients with concomitant end-stage renal disease under continuous ambulatory peritoneal dialysis, whose ascites might be diluted by dialysate. In addition, for further analysis of the role of liver cirrhosis, patients were evaluated to determine whether or not they had concurrent liver cirrhosis. Liver cirrhosis was defined as typical morphologic change such as blunted edge of liver, irregular liver surface and highly coarse liver parenchyma[16], with or without evidence of portal hypertension, such as previous history of ascites before TBP, splenomegaly or esophageal/gastric varices recognized by imaging techniques or endoscopy.

Prospective control cohort of cirrhosis

Patients with liver cirrhosis and uninfected ascites were prospectively enrolled as the cirrhosis control group from July 2010 to June 2011, and medical history, etiology of cirrhosis, and Child-Pugh's classification, as well as imaging features were recorded. Patients with primary or metastatic liver malignancy, peritoneal carcinomatosis, congestive heart failure, spontaneous bacterial peritonitis, nephritic syndrome, renal failure under dialysis, or evidence of peritonitis were excluded. Ascites was obtained and analyzed with regard to parameters including ADA, albumin, total protein, lactate dehydrogenase, glucose, cell counts, cytology, ordinary and anaerobic culture, acid-fast stain, bacteria and tuberculosis cultures.

Validation cohort

Patients whose ascites ADA levels were detected by a clinical need for differential diagnosis from July 2008 to June 2010 comprised the validation group and their medical records were retrospectively reviewed. The patients in the cirrhosis control group were not included in the validation cohort. Further analysis of subgroups according to etiology of ascites was performed.

Method of adenosine deaminase determination

ADA activity was determined using a method similar to that described by Slaats *et al*[17] with an autoanalyzer (Hitachi 7170, Japan) and ADA-N kit (Denka Seiken Co. Ltd, Japan). The kinetic method estimated ADA activity by coupling the liberated NH_3 to oxoglutarate with glutamate dehydrogenase, which leads to a decrease in the reduced form of nicotinamide adenine dinucleotide phosphate absorbance at 340 nm[3,17]. The ratio of decreased absorbance reflects the activity of ADA.

χ^2 test and Fisher's exact test. Diagnostic utility of ADA for TBP was evaluated at various cutoff values by the sensitivity and specificity. These were assessed based on comparisons of relative operating characteristic curves. Spearman's linear regression was used to evaluate the correlation between total protein of ascites and serum. $P < 0.05$ was considered to be statistically significant.

RESULTS

A computerized database search identified 29 consecutive patients who were diagnosed with TBP from July 1988 to June 2010 and who met the inclusion criteria. Seven patients (6 patients without ADA data and 1 patient under continuous ambulatory peritoneal dialysis) were excluded according to the exclusion criteria of this study, and none had concurrent liver cirrhosis. A total of 22 patients with TBP were included in the final analysis and formed the TBP group, which was further divided into two subgroups: (1) cirrhotic TBP group: concomitant cirrhosis was diagnosed in 8 of 22 patients; and (2) non-cirrhotic TBP group: no evidence of cirrhosis among the other 14 of 22 patients. The demographic and ascites data of the two TBP subgroups were compared (Table 1), and there were no significant differences in ascites ADA, white blood cell (WBC) count and lymphocyte count between the two subgroups. However, the mean total protein concentration of ascites in the non-cirrhotic TBP group was significantly greater than that in the cirrhotic TBP group ($P < 0.05$).

The demographic and ascites data of the cirrhotic TBP group and the cirrhosis control group were compared (Table 2), and there were no significant differences in demographic data between the two groups. However, the mean values of ADA, total protein, WBC counts and lymphocyte counts in ascites of the cirrhotic TBP group were significantly higher than those of the cirrhosis control group ($P < 0.05$).

The distribution of ascites ADA values among the patient groups were compared (Figure 1), and the values of ascites ADA in the cirrhosis control group were markedly different from those of the other two groups with no overlapping area. Using 27 U/L as a cut-off value of ADA in ascites (the lowest value in the TBP group), no patient in the cirrhosis control group was found to have an ascites ADA concentration higher than this value.

The validation group included 217 patients, and subgroup analysis was performed according to the different etiologies of ascites (Figure 2). Using 27 U/L as a cut-off value of ascites ADA in the validation group, the sensitivity in detecting TBP was 100% and specificity was 93.3%. There were fifteen (6.9%) patients (one hepatocellular carcinoma, four malignancy other than hepatoma, five intra-abdominal infection, three nephrogenic ascites, one cardiogenic ascites and one hepatocellular carcinoma mixed with spontaneous bacterial peritonitis) who had ascites ADA levels higher than 27 U/L but did not have TBP.

Spearman's correlation analysis revealed that ascites ADA levels of all patients were strongly correlated with ascites total protein amounts ($r = 0.909$, $P < 0.001$) (Figure 3).

DISCUSSION

The utility of ascites ADA in the differential diagnosis of TBP for patients with underlying liver cirrhosis remains controversial due to conflicting results in previous studies. This is the first study to investigate cirrhotic patients with TBP involving a prospectively-enrolled cirrhosis control group, which was included to avoid the potential confounding effects of heterogeneous clinical conditions. In this study, even though lower levels of ascites ADA were found in the cirrhotic TBP group, their mean ascites ADA value was not significantly different from that of the non-cirrhotic TBP group. Moreover, ascites ADA values of cirrhotic patients with TBP were notably higher than those of the cirrhosis control group, and every pa-

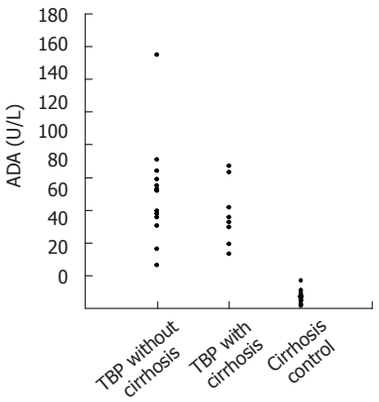

Figure 1 Adenosine deaminase distribution in the study groups. ADA: Adenosine deaminase; TBP: Tuberculous peritonitis.

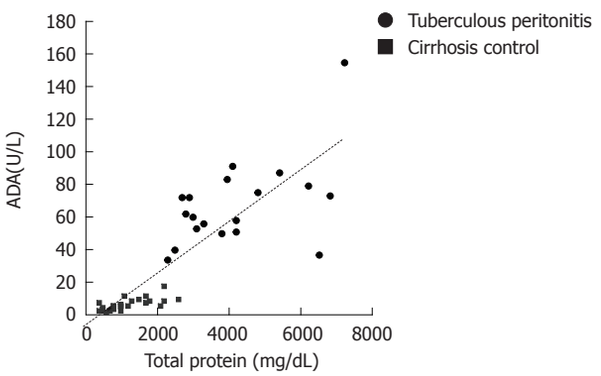

Figure 3 Correlation between adenosine deaminase and total protein in ascites among patients with tuberculous peritonitis. ADA: Adenosine deaminase.

tient in the cirrhosis control group had an ascites ADA level lower than the lowest value in the TBP group (27 U/L). Therefore, these data provide convincing evidence that ascites ADA may be significantly raised in TBP patients with underlying cirrhosis, and thus TBP should be considered in the differential diagnosis.

Previous studies showed high sensitivity and specificity in detecting TBP by checking ADA activity in ascites, based on ADA cut-off values of 36-40 IU/L[2,10,11,18]. However, Hillebrand *et al*[3] used only 7 IU/L as the cut-off value of ADA, and they found the sensitivity of ADA was only 30% in the setting of cirrhosis. There was considerable overlap in the ADA activity between TBP and sterile ascites among cirrhotic patients. Furthermore, Hillebrand *et al*[3] postulated that lower sensitivity and cut-off value might be caused by the higher proportion of cirrhosis (59%) in their patients with TBP. In contrast, Burgess *et al*[4] reported a sensitivity of 94% and a specificity of 92% for cirrhotic patients with TBP using a cut-off value for ADA of 30U/L. In the current study, there was no overlapping phenomenon in the ADA activity between TBP and sterile ascites among cirrhotic patients, and the sensitivity and specificity in detecting TBP were also high (100% and 93.3%, respectively) in the validation group using a cut-off value for ADA of 27 U/L. In

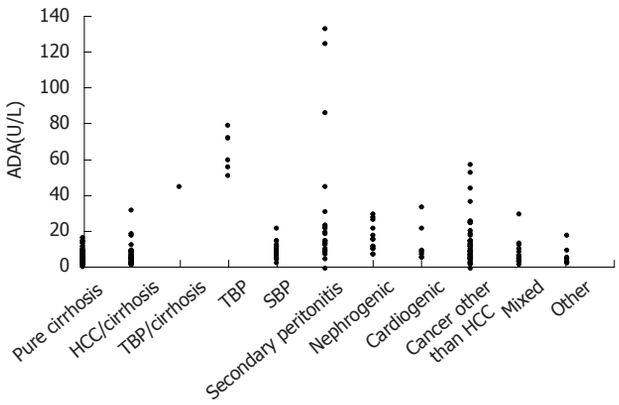

Figure 2 Adenosine deaminase distribution for various ascites etiologies in the validation group. ADA: Adenosine deaminase; TBP: Tuberculous peritonitis; SBP: Spontaneous bacterial peritonitis; HCC: Hepatocellular carcinoma.

addition, Hillebrand *et al*[3] determined ADA activity by detecting the decrease in adenosine concentration under the action of ADA, but this method was different from the measurement techniques applied in most previous studies. The methods employed by Slaats *et al*[17] or Giusti *et al*[19] have been extensively described in the literature[2,4,9,18], and involve determination of ADA activity by changes of NH_3 or NADH, respectively, after interacting ADA with adenosine. The different techniques used might affect the sensitivity and specificity of the ADA test, so the correlation of ADA values obtained from different methods need further investigation.

As shown in our validation group and in previous studies[2-4], false positive findings of ascites ADA are still possible. Peritoneal carcinomatosis and secondary bacterial peritonitis are the two most likely etiologies after TBP. ADA plays an important role in regulating the level of adenosine, and its primary function in humans is development and maintenance of the immune system[20,21]. ADA is involved in proliferation and differentiation of T lymphocytes, and diseases such as malignant conditions, collagen vascular diseases and some microorganism infections that are associated with lymphocytosis may increase ADA levels[22]. Therefore, for patients with elevated ascites ADA, further differential diagnosis by ascites cytological examination or radiological imaging studies should be performed, and laparoscopic visualization and biopsy may be considered for equivocal cases. Furthermore, due to the high negative predictive value (100%) found in this study, invasive procedures such as laparoscopic peritoneum biopsy or laparotomy, which are relatively high risk in cirrhosis patients, may be unnecessary and should be avoided when ascites ADA activity is low. In addition, the mean time to develop positive tuberculosis culture from ascites was 36.4 ± 18.2 d in our study, but the mean time in previous studies on ascites ADA was only 3.0 ± 0.5 d. Testing for ADA in ascites has high sensitivity and specificity, and may therefore be useful as a rapid test for diagnosis. Although TB polymerase chain reaction (PCR) has been used as a rapid diagnostic tool for pulmonary TB, PCR cannot be suggested for diagnosing TBP due to its

low sensitivity rate[9,23]. In endemic area of tuberculosis, DNA from dead TB bacilli may also give a false-positive result[9]. In addition, testing for ADA may also be currently more widely available than other valuable clinical tests such as interferon-gamma[24].

In this study, ADA activity was found to be strongly correlated with total protein in ascites in the TBP and control groups, and this finding was compatible with the simultaneously elevated total protein and ADA found in cirrhotic patients suffering from TBP. It is interesting to note that Fernandez-Rodriguez *et al*[15] found ADA was correlated with total protein in ascites among patients with TBP ($r = 0.842$), but the correlation was non-significant when the control group was included in the analysis. This inconsistent finding might be explained by heterogeneous etiologies and complex clinical conditions in the control group. Elevated total protein in the body fluid has been one of the diagnostic markers for inflammatory exudate[25], and it is also an important finding in ascites of TBP[5,15]. ADA is related to activation and differentiation of mononuclear leukocytes, and it is secreted during immune responses[3,21,26]. Lymphocytes are the predominant cells in ascites of TBP, and simultaneously elevated total protein and ADA can be explained by lymphocytic inflammation. Moreover, although mean total protein in the cirrhotic TBP group was significantly lower than that of the non-cirrhotic TBP group in this study, mean ADA levels were not significantly different. Compared with the cirrhosis control group, the WBC and lymphocyte counts were significantly higher in the cirrhotic TBP group, and the immune responses were predominant. Even in cirrhotic patients with a relatively immunocompromised status, TBP still activated strong immune reactions, which resulted in a sharp elevation of ADA in ascites, and this phenomenon indicates that ascites ADA may still be a valuable tool in the differential diagnosis of TBP.

We acknowledge several limitations in this study. Firstly, this study reflects the experience of a single medical center with a relatively small sample size, but the statistical power of the analysis was adequate. Secondly, cases with TBP were obtained from a computerized database search and retrospectively analyzed, so some TBP cases may have been missed due to incorrect coding in this long-term cohort study. Thirdly, we compared a historical TBP cohort with a prospectively-enrolled cirrhosis control group, and different time periods of study might produce some bias. However, patients were consecutively recruited, and the modalities for diagnosing TBP were not changed during the study period. The possible bias should be minimized.

In conclusion, even with lower ascites ADA activity in liver cirrhosis, ascites ADA levels could be significantly elevated due to strong immune responses when cirrhotic patients suffer from TBP. Owing to its high sensitivity and specificity, ascites ADA may be a valuable tool in the differential diagnosis of TBP in patients with underlying cirrhosis, and concomitant cirrhosis should not limit its clinical utility.

COMMENTS

Background

The risk of tuberculous peritonitis (TBP) is increased in patients with underlying liver cirrhosis. Adenosine deaminase (ADA) in ascites has been proposed to be a useful test for early detection of TBP, but its value among patients with underlying cirrhosis is uncertain.

Research frontiers

The utility of ascites ADA in the differential diagnosis of TBP in patients with underlying liver cirrhosis remains controversial due to conflicting results in previous studies. In addition, the relationship between ascites ADA and other parameters such as total protein has not been well discussed, and the mechanisms of ADA elevation among cirrhotic patients with TBP need further investigation.

Innovations and breakthroughs

This is the first study to investigate cirrhotic patients with TBP which includes a prospectively-enrolled cirrhosis control group, and ADA activity was strongly correlated with total protein in ascites. Even with lower ascites ADA activity in liver cirrhosis, ascites ADA levels could be significantly elevated due to strong immune responses when cirrhotic patients suffer from TBP.

Applications

Owing to its high sensitivity and specificity, ascites ADA may be a valuable tool in the differential diagnosis of TBP in patients with underlying cirrhosis, and concomitant cirrhosis should not limit its clinical utility. Furthermore, due to the high negative predictive value, invasive procedures such as laparoscopic peritoneum biopsy or laparotomy may be unnecessary when ascites ADA activity is low.

Terminology

ADA is an enzyme involved in purine metabolism, and it can be a product of immune responses relating to T lymphocyte activity in humans.

Peer review

This is a good case-control study and the message is clear. The authors examined ADA activity in TBP among patients with underlying liver cirrhosis, and a prospectively-enrolled cirrhosis control group was conducted to avoid the potential confounding effects of heterogeneous clinical conditions. Due to convincing data in this study, ascites ADA can still be a valuable tool in the differential diagnosis of TBP.

Abstract

AIM: To compare the volumetric-modulated arc therapy (VMAT) plans with conventional sliding window intensity-modulated radiotherapy (c-IMRT) plans in esophageal cancer (EC).

METHODS: Twenty patients with EC were selected, including 5 cases located in the cervical, the upper, the middle and the lower thorax, respectively. Five plans were generated with the eclipse planning system: three using c-IMRT with 5 fields (5F), 7 fields (7F) and 9 fields (9F), and two using VMAT with a single arc (1A) and double arcs (2A). The treatment plans were designed to deliver a dose of 60 Gy to the planning target volume (PTV) with the same constrains in a 2.0 Gy daily fraction, 5 d a week. Plans were normalized to 95% of the PTV that received 100% of the prescribed dose. We examined the dose-volume histogram parameters of PTV and the organs at risk (OAR) such as lungs, spinal cord and heart. Monitor units (MU) and normal tissue complication probability (NTCP) of OAR were also reported.

RESULTS: Both c-IMRT and VMAT plans resulted in abundant dose coverage of PTV for EC of different locations. The dose conformity to PTV was improved as the number of field in c-IMRT or rotating arc in VMAT was increased. The doses to PTV and OAR in VMAT plans were not statistically different in comparison with c-IMRT plans, with the following exceptions: in cervical and upper thoracic EC, the conformity index (CI) was higher in VMAT (1A 0.78 and 2A 0.8) than in c-IMRT (5F 0.62, 7F 0.66 and 9F 0.73) and homogeneity was slightly better in c-IMRT (7F 1.09 and 9F 1.07) than in VMAT (1A 1.1 and 2A 1.09). Lung V30 was lower in VMAT (1A 12.52 and 2A 12.29) than in c-IMRT (7F 14.35 and 9F 14.81). The humeral head doses were significantly increased in VMAT as against c-IMRT. In the middle and lower thoracic EC, CI in VMAT (1A 0.76 and 2A 0.74) was higher than in c-IMRT (5F 0.63 Gy and 7F 0.67 Gy), and homogeneity was almost similar between VMAT and c-IMRT. V20 (2A 21.49 Gy *vs* 7F 24.59 Gy and 9F 24.16 Gy) and V30 (2A 9.73 Gy *vs* 5F 12.61 Gy, 7F 11.5 Gy and 9F 11.37 Gy) of lungs in VMAT were lower than in c-IMRT, but low doses to lungs (V5 and V10) were increased. V30 (1A 48.12 Gy *vs* 5F 59.2 Gy, 7F 58.59 Gy and 9F 57.2 Gy), V40 and V50 of heart in VMAT was lower than in c-IMRT. MUs in VMAT plans were significantly reduced in comparison with c-IMRT, maximum doses to the spinal cord and mean doses of lungs were similar between the two techniques. NTCP of spinal cord was 0 for all cases. NTCP of lungs and heart in VMAT were lower than in

c-IMRT. The advantage of VMAT plan was enhanced by doubling the arc.

CONCLUSION: Compared with c-IMRT, VMAT, especially the 2A, slightly improves the OAR dose sparing, such as lungs and heart, and reduces NTCP and MU with a better PTV coverage.

INTRODUCTION

Esophageal cancer (EC) is one of the most common malignancies in the world. It was estimated that there were 16 470 newly diagnosed cases of EC, and 14 280 cases of death in America in 2008[1]. Squamous cell carcinoma is commonly seen in China, whereas adenocarcinoma is common in Europe and America. Radiotherapy is a major treatment method for EC because more than 60% of the patients are often diagnosed at locally advanced stages which could not be totally resected. Innovative technologies in radiation delivery such as intensity-modulated radiotherapy (IMRT) offer the potential for improved tumor coverage, while reducing the doses delivered to the surrounding normal tissues. Clinical studies have yielded good dosimetry and patient outcome by IMRT[2-6]. There are different IMRT delivery approaches, including "step and shoot", "sliding window" modes and the rotational technique. Volumetric-modulated arc therapy (VMAT), the novel form of IMRT that was first proposed by Yu in 1995[7], allowed for intensity-modulated radiation delivery during gantry rotation with dynamic multi-leaf collimator (MLC) motion, variable dose rates (DR) and gantry speed modulation. VMAT had already been investigated for prostate cancer, small brain tumors and cervix uteri cancer[8-10]. These studies have generally shown that VMAT is able to produce similar or better dose distributions, while achieving a reduction in treatment time and a reduction in monitor units (MU).

We performed a planning study to compare VMAT with conventional sliding window intensity-IMRT (c-IMRT) in EC of all locations and in dose distributions to planning target volume (PTV) and organs at risk (OAR). We also investigated the difference of normal tissue complication probability (NTCP) between the two techniques.

MATERIALS AND METHODS

Patients

Twenty EC patients treated with c-IMRT previously in our department were selected for this study, involving 5 cases of EC located in the cervical, the upper, the middle and the lower thorax, respectively. Five patients were staged Ⅱ, 10 were Ⅲ and 5 were Ⅳ according to the American Joint Committee (AJCC) on Cancer 2006 Guidelines. Details are shown in Table 1.

Target volume and organ at risk delineation

All patients were immobilized in a supine position and computed tomography scanned using a helical scanner (Siemens Somatom, Sensation Open Computed Tomography) with 1.25 mm thick slices over the neck and the entire thorax. The clinical target volume, including the esophageal tumor, with a margin for microscopic tumor extension, and the adjacent regional lymph nodes[11,12], was expanded with a 5-mm margin to create PTV. OAR, such as spinal cord, heart and lung, was outlined on each image. Details of the delineation of these volumes were recently described[13].

Planning techniques and objectives

All the treatment plans were designed to deliver 60 Gy to the PTV in 30 fractions using the Eclipse treatment planning system (Version 8.9, Varian Medical Systems, Palo Alto, CA), with 6 MV photon beam from a Varian Ⅸ (RapidArc) equipped with a Millennium MLC with 120 leaves. The Anisotropic Analytical Algorithm (Version 8.9) photon dose calculation algorithm and dose calculation grid of 2.5 mm were used for both c-IMRT and VMAT. When necessary, field size was minimized to 15.3 cm in the X direction. This dimension corresponded of the maximal displacement of a leaf in a MLC bank. By doing so, all the leave positions were possible during the optimization process increasing the degree of modulation even if in a beam eye view, a part of the volume was excluded of the beam at each gantry position. Globally rotational delivery permitted to irradiate all the volume of the PTV during rotation. All plans aimed to achieve a minimum dose larger than 95% and a maximum dose lower than 107% of the prescribed dose, and no 2-cc region (either in or outside of PTV) may receive > 110% of the dose. With regard to the OAR, the primary objectives were defined as follows: spinal cord: D_{max} < 45 Gy and lungs: V20 < 30%. The secondary objectives were: mean doses of lungs (MLD) < 15 Gy and heart: V40 ⩽ 50%, V50 ⩽ 40%. As a result of tumor coverage requirements, a waiver can be applied on these dose constraints.

VMAT plans

The VMAT plans using full arcs sharing the same isocenter, in which 1A consisting of a single 360° rotation

and 2A consisting of two coplanar arcs of 360° with opposite rotation (clock-wise or counter clock-wise), were optimized selecting a maximum DR of 600 MU/min. For 1A, starting at a gantry angle of 179° and rotating counter clockwise at 360° to stop at a gantry angle of 181°, field size and collimator rotation were determined by the automatic tool from Eclipse to encompass the PTV. And 2A, consisting of two coplanar arcs of 360°, was optimized simultaneously with opposite rotation. Since each individual arc is limited to a sequence of 177 control points, the application of two coplanar arcs that increase the modulation factor during optimization, could allow the optimizer to achieve a higher target homogeneity and lower OARs involvement at the same time. For the second arc, the collimator was rotated 5° extra to reduce overlapping tongue and groove effects with the first arc. Details about VMAT optimization process have been published elsewhere[14].

c-IMRT plans

The c-IMRT plans were optimized with a fixed DR of 400 MU/min. The MLC leaf sequences were generated using the dynamic sliding window IMRT delivery technique. Plans were individually optimized using five (5F), seven (7F) and nine (9F) coplanar fields. Beam geometry consisted of each treatment field with the following gantry angles: 0°/50°/153°/204°/310° (5F), 20°/60°/150°/180°/210°/300°/340° (7F), and 0°/35°/70°/130°/160°/200°/230°/290°/325° (9F).

Once the treatment planning was completed, the plan was normalized to cover 95% of the PTV with 100% of the prescribed dose. In the present study, we tried to modify constraints and priority factors in the c-IMRT and VMAT plans to improve the results. These parameters were modified in function of dose-volume histogram (DVH) results for each patient.

Evaluation tools

Analysis was performed on DVH computing several standard parameters[15], Dx was the specific dose computed for a fraction of a target or an organ volume, and Vx was the volume irradiated above a designated dose. For PTV, the mean dose (D_{mean}) was analyzed, and the conformity of dose distribution was assessed by means of conformity index (CI) which was defined as the ratio between the volume receiving at least 95% of 60 Gy and the volume of the PTV. Higher values of CI represented a better PTV conformity. CI = (VT95%/VT) × (VT95%/V95%)[16].

The homogeneity index (HI) of the PTV was computed as D5%-D95% (difference between the dose covering 5% and 95% of the PTV). Lower values of HI represented a more homogenous PTV dose distribution[17].

DVH parameters for OARs (spinal cord, lungs and heart) were calculated and compared. A set of Vx values, D_{mean}, D_{max} and MU was therefore reported.

Radiobiological comparison was analyzed by the NTCP. The risk of developing acute complications and other late complications was assessed using the Lyman-Kutcher-Burman model[18]. The parameters for NTCP calculations (volume effect, slope, and tolerance doses) were taken from Burman *et al*[19] and are shown in Table 2.

Statistical analysis

The Wilcoxon matched-pair signed-rank test was used to compare the results between the VMAT and IMRT plans. Difference was considered statistically significant at $P < 0.05$. All statistical tests were two-sided, and all statistical analyses were done using the SPSS software, Version 11.0 (Chicago, IL).

RESULTS

Target coverage, conformity and dose homogeneity

Clinically acceptable plans of VMAT and c-IMRT were completed by all the 20 patients. The dosimetric results of each position for PTV are listed in Table 3. The results were analogous in the cervical and upper EC, for which PTV was T-shaped from a posteroanterior view, while PTV was I-shaped in middle and lower EC. As the numbers of field in c-IMRT or arc in VMAT were increased, the conformity and homogeneity were improved.

For D_{mean} of PTV, VMAT (1A and 2A) yielded higher values than IMRT (5F, 7F and 9F). There was significant difference between VMAT and c-IMRT (7F and 9F) in cervical and upper thoracic EC and c-IMRT (5F and 7F) in the middle and lower thoracic EC, and only 1A achieved a higher D_{mean} as compared with IMRT ($P < 0.05$).

VMAT had a better CI than c-IMRT. Statistically significant difference was seen between VMAT and c-IMRT (5F, 7F and 9F) in cervical and upper thoracic EC, but between VMAT and c-IMRT (5F and 7F) in middle and lower thoracic EC ($P < 0.05$). Especially in cervical cases, 2A showed the best CI ($P < 0.05$), but there was no significant difference between 1A and 2A in thoracic cases.

Homogeneity was slightly better in c-IMRT than in VMAT. In cervical and upper thoracic EC, HI of 2A and 5F was equivalent, and 7F or 9F showed a significant trend for better results compared with VMAT ($P < 0.05$). In the middle and lower thoracic EC, the trend was not conspicuous, 9F also had a higher HI compared with

Table 2 Parameters used in normal tissue complication probability

other plans, and significant difference was found only in 9F and 1A ($P < 0.05$). Figure 1 depicts the dose distribution of c-IMRT and VMAT in a cervical EC patient.

OAR

The absolute plan parameters for lungs, heart and spinal cord are summarized in Table 4. DVH of OAR in one patient were shown in Figure 2.

The reduction trend of lung parameters (V5, V10, V20 and V30) was similar between the two techniques, except for MLD. In cervical and upper thoracic EC, MLD, V20 and V30 by VMAT were reduced by 0.6%-2.9%, 2.1%-10.7% and 13.2%-17.3%, respectively. V5 and V10 of lung by VMAT in cervical and upper thoracic EC were increased by 5.5%-7.7% and 10.5%-12.6%, respectively. In middle and lower thoracic EC, VMAT resulted in increased V5 (10.6%-13.3%), V10 (18.4%-21.8%) and MLD (2%-2.3%), but decreased V20 (5.5%-15.5%) and V30 (13.2%-18.2%). Statistically significant difference was found between VMAT (1A or 2A) and c-IMRT (5F, 7F and 9F) for V5, V10, V20 and V30, but for MLD, there was significant difference between VMAT (1A or 2A) and c-IMRT (5F, 7F) ($P < 0.05$).

For the heart, VMAT reduced V30, V40 and V50 as compared with c-IMRT, especially in thoracic cases. V30 by VMAT was reduced by 33.5%, 10.7% and 21.6%, V40 by 36%, 15.1% and 21.7%, and V50 by 39.3%, 29.7% and 38% in the upper, middle and lower thoracic EC, respectively. VMAT (1A or 2A) reduced V30 and V40 (5F, 7F and 9F) in thoracic EC, and V50 in middle and lower thoracic EC ($P < 0.05$). However, no difference was found in the D_{max} of spinal cord between VMAT and c-IMRT.

NTCP results are shown in Table 5. VMAT (1A or 2A) significantly lowered the NTCP in comparison with c-IMRT (5F, 7F and 9F) in cervical and upper thoracic cases, while there was significant difference between 2A and 5F in middle and lower thoracic cases ($P < 0.05$). The trend of cardiac NTCP in VMAT was similar with lungs in thoracic EC, especially in middle and lower thoracic EC ($P < 0.05$).

It was worth noting that D_{mean} and maximal doses to the humeral head (HH_{mean} and HH_{max}) in VMAT were dramatically increased in comparison with c-IMRT in cervical and upper thoracic EC (Table 4). Compared with c-IMRT, HH_{mean} in VMAT was increased by almost three times in cervical EC and four times in upper thoracic EC ($P < 0.05$). HH_{max} in VMAT was twice higher in cervical EC and three times higher in upper thoracic EC than that in c-IMRT (5F and 7F) ($P < 0.05$).

Table 4 Dosimetric comparison for organs at risk of conventional sliding window intensity-modulated radiotherapy and volumetric-modulated arc therapy in cervical and upper thoracic esophageal cancer, and in middle and lower thoracic esophageal cancer, mean value (range)

Wilcoxon's signed ranks test. [1]Cervical thoracic esophageal cancer; [2]upper thoracic esophageal cancer; [3]middle thoracic esophageal cancer; [4]lower thoracic esophageal cancer. c-IMRT: Conventional sliding window intensity-modulated radiotherapy; VMAT: Volumetric-modulated arc therapy; MLD: Mean dose of lungs; D_{max}: Maximal dose; D_{mean}: Mean dose; F: Coplanar field; A: Arc; Vx: The percentage of organ receiving a dose > X Gy; NS: Not significant.

Monitor units

The c-IMRT plans required an increased MU per fraction when the field was increased whereas the VMAT plans usually resulted in lower MU when rotating arcs were increased. 1A plans required at least 50% or 60% less than 9F in cervical and upper EC or middle and lower EC ($P < 0.05$). The difference between VMAT (1A and 2A) and c-IMRT (5F, 7F and 9F) remained significant ($P < 0.05$) in all the cases. Detailed information about MU is shown in Table 3.

DISCUSSION

In the present study, VMAT proved to be slightly better than c-IMRT for targeting dose distribution in EC of all locations, and to have equivalent or better OAR dose sparing and lower NTCP. We initiated a dosimetric and radiobiological comparison in the EC of all locations in this study. The results indicated that VMAT could generate better radiotherapeutic plans than sliding window IMRT.

VMAT is a complex form of IMRT that allows dose delivery in single or multiple arcs. Two arcs allowed superior modulation factor during optimization due to the independent optimization, and unrelated sequence of MLC shape, gantry speed and dose rate combinations. This approach provided adequate coverage of PTV and spare of OARs at least equivalent to c-IMRT,

while it could reduce significantly the treatment time and the number of MU required in the morbidities, such as head and neck cancer, intracranial tumor, breast cancer, glioma, and carcinoma of the anal canal[14,17,20,21]. In the present study, VMAT using 2A achieved better results than using 1A.

First, the PTV volumes were larger in cervical and upper EC series due to pathological characteristics and biological behavior of carcinoma in these regions, and presented T-shaped from a posteroanterior view. In head and neck carcinoma, due to more complex target volume, 7F or 9F are constantly used in c-IMRT to meet the requirements of dose distribution, HI and CI of PTV[22,23]. Our results were consistent with this. PTV coverage in c-IMRT with 5F was less qualified in comparison with 7F or 9F. Both VMAT and c-IMRT resulted in abundant D_{mean} in PTV (63.94 Gy and 63.53 Gy in 1A and 2A *vs* 63.49 Gy, 62.90 Gy, 62.46 Gy in 5F, 7F and 9F). VMAT proved to be superior to c-IMRT in terms of MU and CI, but slightly inferior to c-IMRT in terms of HI. We also confirmed that VMAT with 2A achieved better results than 1A in terms of conformity and homogeneity. For the heart, VMAT showed a lower percentage of V30, V40 or V50. For lungs, VMAT provided

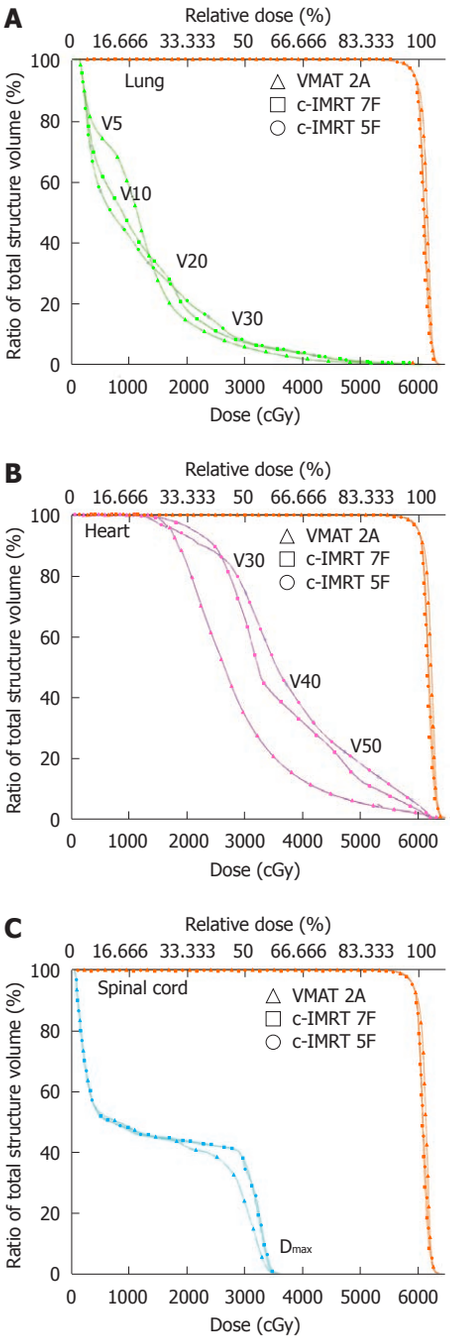

Figure 2 Dose-volume histogram of organs at risk and planning target volume for volumetric-modulated arc therapy and conventional sliding window intensity-modulated radiotherapy in a lower thoracic esophageal cancer patient. Volumetric-modulated arc therapy (VMAT) with double arcs (triangle) and conventional sliding window intensity-modulated radiotherapy (c-IMRT) with 7 fields (squares) and 5 fields (round). The planning target volume is shown in orange, the lungs in green (A), heart in red (B) and spinal cord in blue (C). F: Coplanar field; A: Arc; Vx: The percentage of organ receiving a dose > X Gy.

better sparing in terms of V20 and V30. The results of radiobiological NTCP comparison demonstrated that VMAT was superior to c-IMRT either in lungs or heart ($P < 0.05$). Yin *et al*[24] compared 7F in IMRT with VMAT plans for cervical EC, and found that there were differences between VMAT and IMRT in HI and MU, but not in CI, which are consistent with our results, but lung V5 in VMAT (1A 51.4, Ax 49.3 and 7F 50.9) was reduced while lung V30, V40, V50 and MLD were increased. In our study, lung V5 in VMAT was slightly increased (1A 51.37, 2A 51.03, and 7F 48.77), but V30 (1A 12.99, 2A 12.99, 7F 14.42) and MLD (1A 12.79, 2A 12.35 7F 12.52) were lower than in c-IMRT. The difference in V5, V30 and MLD may be due to that they avoided a certain angle in the VMAT plan with 2A, and this caused the reduction of the volume of irradiated lungs. One of the particular interesting phenomena in VMAT is the increase trends of mean or maximal radiation doses to the humeral head. This may be because that humeral head is adjacent to the target volume in the cervical and upper EC and the rotating mode of VMAT thus increased the irradiation volumes of the humeral head. However, clinical evidence on the acceptable humeral head constraints for IMRT remains scarce in literature. Nevertheless, according to the tolerated doses and clinical data of bone joints, such as femoral head and neck or temporomandibular joint[25,26], the maximum doses to humeral heads in the cervical EC (1A 34.00 Gy and 2A 33.82 Gy) or upper thoracic EC (1A 44.33 Gy and 2A 41.03 Gy) were considered acceptable, but we should pay attention to this performance and its potential risk.

Subsequently, the results obtained in cervical and upper thoracic EC were almost seen in middle and lower thoracic EC, with a PTV of smaller volume but surrounded by more lungs and heart. In thoracic and epigastric cases, except for a few complex cases, 5-7F of c-IMRT could meet most of the clinical dosimetric requirements. In our study, an ideal homogeneity was achieved in 5F or 7F of IMRT. With increase of the fields in c-IMRT or doubling arc in VMAT, dose distribution in PTV became more optimal in terms of better conformity and similar homogeneity. The trends were significantly different ($P < 0.05$) between VMAT(1A and 2A) and c-IMRT(5F and 7F). Recently, Van Benthuysen *et al*[27] demonstrated that VMAT had the advantage to decrease treatment times over c-IMRT, while providing similar OAR sparing and PTV coverage, but lower homogenous dose distribution in lower EC. In our study, we found that in the middle and lower thoracic EC, HI was similar in VMAT and c-IMRT. We did not find a significant difference between 5F or 7F IMRT and VMAT for these trends. For lesions in this region, more volumes of heart and lungs were involved in the irradiation area, mean doses to lungs and heart were elevated markedly and HI was also inferior to cervical and upper EC. Because lung tissue filled with air was significantly less dense than other body tissues, as a result of heterogeneity corrections in radiation treatment planning systems, optimization procedures produced substantial dose non-uniformity in PTV caused by the effect of surrounding lung tissues. To further optimize the dose in the target volume, dose heterogeneity was achieved by loosening the constraints on the maximum doses in PTV. It may result in insufficient dose in PTV or the creation of clinically significant hotspots in the PTV

and surrounding normal tissue structures. The National Comprehensive Cancer Network Guidelines recommend dose limits for selecting critical normal structures, i.e., the spinal cord doses should not exceed 45 Gy, and one-third of the heart should receive less than 50 Gy. The dosimetric parameters of lung injury risk were mainly studied on lung cancer irradiation, the increased risk of radiation pneumonitis correlated with heterogeneous parameters, such as MLD, the percentage of lung volume receiving at least 20 Gy (V20), 13 Gy (V13), 10 Gy (V10) or 5 Gy (V5), in which V20 was a recognized indicator confirmed by several studies. Based on pooled data from 540 patients irradiated for thoracic malignancy, the calculated risk of grade $\geqslant$ 2 pneumonitis was 43%, 18%, and 11% for the MLD of 24-36, 16-24 and 8-16 Gy, respectively. In our study, MLD was controlled below 16 Gy and it was acceptable. For conventionally fractionated regimens (2 Gy/fraction), V20 and MLD were the traditional parameters used to predict for lung toxicity, however, emerging data suggested that percentage of lung volume receiving lower doses may be predictive of pulmonary toxicity. VMAT plans offered the potential to significantly escalate the coverage of the low-dose area (V5 and V10) because all doses were deposited within the plane of the arc, instead of being spread out in non-coplanar directions. Mean V5 in VMAT was beyond 80% and it might increase the potential pulmonary toxicity. Wei *et al*[28] found that V30 > 46% and < 46% was associated with rates of pericardial effusion of 73% and 13%, respectively. The ischemic segments usually occur in volumes irradiated to a dose of 45 Gy or more. In our study, V40 and V50 were achieved in both VMAT and c-IMRT, but V30 was higher due to lower constrained priority. In VMAT, 1A achieved better results than 2A for less irradiation volumes of heart and lungs. In comparison with 5F or 7F, VMAT reduced V20 and V30 of lungs, and V30, V40 and V50 of heart. Besides, Hawkins *et al*[29] evaluated the capability of VMAT to reduce heart and cord dose while maintaining lung V20 < 20% in lower gastroesophageal tumors. IMRT (4F) and VMAT plans showed that VMAT provided a significant reduction in heart V30 (31% *vs* 55%) with a better CI in a shorter time. But V30 (2A 57.57 *vs* 5F 78.6) in our study was higher because our prescribed dose (60 Gy) was higher than theirs (54 Gy). NTCP of heart and lungs were common indicators in radiobiological assessment to indicate the tendency in plan comparison. VMAT had a trend with a lower NTCP of lungs and heart, but statistical significance only existed for lungs between 5F and 2A in lower EC, as for heart, between c-IMRT and 1A in middle thoracic EC, and between c-IMRT and 2A in lower EC ($P < 0.05$). Therefore, regarding the correlation between dosimetric parameters and OAR toxicity, we did find a superior trend in VMAT to c-IMRT. Wang *et al*[30] also conducted a planning comparison for EC between VMAT (1A and 2A) and 7F IMRT, and found that VMAT plan, especially using double arcs, could improve OAR sparing (lung V20 and V30, heart V30 and V40) and lower MUs without compromised target qualities as compared with IMRT. This was consistent with our findings.

VMAT reduced the number of required MU[31], because it was performed simultaneously with rotation by a dynamic MLC adaptation to the target volume during the rotation. Using double arcs, the rotation in clockwise and counter clock-wise directions allows diminished 25 s off-time between the two arcs[32]. The number of MU required is higher due to the sliding window technique. c-IMRT plans in this study offered wider than 15 cm in the direction of the MLC motion necessitating splitting into two sequences and doubling the number of fields. By contrast, one of the drawbacks of c-IMRT was the potential risk of second cancer. Theoretically, the significant reduction of MU by VMAT decreases scattered dose and may reduce the risk of secondary malignancies. The impact of irradiation of healthy tissues at low doses remains unresolved with the use of VMAT.

In conclusion, VMAT treatment plan was slightly better than c-IMRT in terms of PTV coverage. It provided an equivalent or better lungs and heart dose sparing, significant reduction of NTCP and MU per fraction. For cervical and upper EC, PTV was T-shaped across neck and chest, VMAT achieved fairly uniform dose distribution, but the 2A provided the best CI in all plans, and VMAT significantly increased the doses of humeral head. For middle and lower EC, in which PTV involved more lungs, VMAT plans offered the most conformal dose distribution and the potential to significantly escalate the coverage of lungs at low doses.

COMMENTS

Background

Esophageal cancer (EC) is very common in China and other developing countries. Radiotherapy is a major non-invasive treatment method with a high efficacy rate for EC. Innovative technologies have been developed in radiation delivery such as intensity-modulated radiotherapy (IMRT), and volumetric modulated arc therapy (VMAT) is a relatively new form of IMRT. There are several new interesting techniques in IMRT, but few evaluations have been available in term of their efficiency and safety.

Research frontiers

There have been few studies to compare the two radiotherapy techniques, particularly in EC. VMAT had already been investigated for some cancers. In this study, the authors further compared the VMAT plans and the conventional sliding window IMRT plans in EC of different anatomic regions.

Innovations and breakthroughs

Previous dose comparison studies showed that VMAT was able to produce similar or improved dose distributions, while achieving a reduction in treatment time and monitor units (MU). However, results are different in EC about dose to organs at risk (OAR) due to variable limitation conditions. Normal tissue complication probability (NTCP) of OAR in the VMAT plan, a common indicator in radiobiological assessment, is still not clear in EC. In the present study, the authors showed that VMAT, especially 2 arcs, slightly improved the OAR dose sparing for some organs, such as lungs and heart, and reduced the NTCP and MU with a better planning target volume coverage.

Applications

This study provides a new insight into better understanding of the VMAT plan characteristics in EC of different anatomical parts, and lays the foundation for further clinical studies in VMAT.

Terminology

IMRT is a three-dimensional conformal radiotherapy developed based on inverse planning optimization to modulate intensity beams using multi-leaf

collimator (MLC), this technique offers improvement in target dosimetric coverage. There are different IMRT delivery techniques, including "step and shoot", sliding window modes and a rotational technique (VMAT). Conventional sliding window IMRT, in which the leaves are adjusted with fixed gantry, is a common form which is being used in clinical practice. VMAT, in which dose rates, gantry speed and dynamic MLC motion are all variable during gantry arc rotation, is a novel form of IMRT in recent years.

Peer review

IMRT is developing a lot in Radiation Oncology Departments for a few years. There are several very interesting technics but still few real evaluations in terms of efficiency and safety. Comparing two technics is very interesting even if it's "only" a dosimetric comparison. This kind of comparisons of recent technics are not very frequent, particularly in EC but are developing a lot this last few years. The text of this manuscript is very clear and well presented.

Abstract

AIM: To investigate the association of polymorphisms of nur-related receptor 1 (*Nurr1*) and development of alcohol dependence in Mexican Americans.

METHODS: Peripheral blood samples were collected from 374 alcoholic and 346 nonalcoholic Mexican Americans; these two groups were sex- and age-matched. Sample DNA was extracted and genomic DNA was amplified by polymerase chain reaction. The *-2922(C) 2-3* polymerase chain reaction products were digested with *Sau96I*, alleles of *1345(G/C)*, and *-1198(C/G)* in the regulatory region as well as *Ex+132 (G/T/A/C)* and *Ex+715(T/-)* in exon 3 were studied by sequencing.

RESULTS: The *C2/C2, C2/C3, C3/C3* genotype distribution of *-2922(C) 2-3* was 34.4%, 38.2% and 27.5% in the nonalcoholic group compared to 23.3%, 51.2% and 25.4% in the alcoholic group (P = 0.001). The *C/C, C/G, G/G* genotype distribution of *-1198(C/G)* was 23.5%, 46.1% and 30.3% in the nonalcoholic group compared to 13.9%, 50.9% and 35.3% in the alcoholic group (P = 0.007). However, the *-1345 (G/C)*, *Ex3+132(G/T/A/C)* and *Ex3+715(T/-)* alleles were not polymorphic in Mexican Americans, and all those studied had *G/G, G/G* and *T/T* genotype for these three alleles, respectively. The *-2922(C) 2-3* did not show allele level difference between alcoholic and nonalcoholic individuals, but *-1198 (C/G)* showed a significant allele frequency difference between alcoholic (39.3%) and nonalcoholic (46.6%) populations (P = 0.005). Excluding obese individuals, significant differences were found at both genotypic and allelic levels for the *-2922(C) 2-3* polymorphism (P = 0.000 and P = 0.049) and the *-1198 (C/G)* polymorphism (P = 0.008 and P = 0.032) between nonobese alcoholics and nonobese controls. Excluding smokers, a significant difference was found only at the genotypic level for the *-2922(C) 2-3* polymorphism (P = 0.037) between nonsmoking alcoholics and nonsmoking controls, but only at the allelic level for the *-1198(C/G)* polymorphism (P = 0.034).

CONCLUSION: Polymorphisms in the regulatory region of *Nurr1* are implicated in pathogenesis of alcohol dependence and the *Nurr1*/dopamine signaling pathway might be important for this dependence development in Mexican Americans.

INTRODUCTION

It is widely accepted that genetic factors play an important role in the development of alcohol dependence. Family clustering surveys have shown that alcohol dependence rates are higher among persons who are biologically related to an alcoholic[1], and that a family alcohol history is a strong predictor of alcohol dependence[2]. Twin pair studies have revealed a significantly greater concordance rate for alcohol dependence in monozygotic compared with dizygotic twins[3]. Half sibling and adoption studies have demonstrated that half brothers with different fathers and adopted sons of alcoholic men show a rate of alcohol dependence more like that of the biological father than that of the foster father[4]. On the other hand, there is no classic Mendelian pattern of inheritance for alcohol dependence. Environmental factors are also linked to alcohol dependence. Thus, alcohol dependence is a polygenic complex disorder resulting from an intricate interaction of multiple genes and various environmental factors.

Genes encoding alcohol metabolizing enzymes alcohol dehydrogenase (*ADH1B)* and aldehyde dehydrogenase (*ALDH2*) are the only genes that have been firmly linked to alcoholism[5,6]. However, data suggest that genes involved in the brain reward pathways are also strong candidates for a predisposition to alcohol dependence. These pathways, in particular, those utilizing dopamine and opioids as neurotransmitters, mediate positive reinforcement of activities, such as eating, love and reproduction. When engaging in such activities, the "natural reward" center releases dopamine from brain pathways in the nucleus accumbency and frontal cortex[7,8]. However, these same pathways can also be activated by "unnatural rewards" such as alcohol abuse. Only a minority of individuals become addicted to these various substances and certain types of behavior, therefore, it should be possible to identify factors, such as genes, that distinguish them from others not affected. Dopamine is the primary neurotransmitter in the reward pathway, genes that control dopamine signaling, including dopamine receptors and transporters, are particularly tempting candidates. Alcohol dependence is likely to be a polygenic and multifactorial disease, therefore, certain genes might have a small effect, whereas others have a greater impact in terms of increasing the risk for this disorder.

Our previous studies have shown that certain alleles of the brain dopamine receptors 2 and 4 (*DRD2* and *DRD4*) and of the serotonin transporter (*5-HTT*) as well as of opioid receptor are associated with alcohol dependence[9-13]. These findings indicate the importance of polymorphism of the gene in the reward pathway in contributing to the development of alcohol dependence in Mexican Americans.

Alcohol consumption, compulsive overeating and smoking are all associated with dysfunction of rewards pathways; there might be common risk factors in reward genes for these behaviors. *DRD2 TaqI A1* allele was identified at a higher frequency in alcoholic and nonalcoholic smokers than nonsmoking controls[14]. Smoking and obesity related to overeating might serve as confounding factors when association is analyzed between reward genes and alcohol dependence.

The Nur-related receptor 1 (*Nurr1*), *NR4A2*, is a transcription factor in the orphan nuclear receptor family[15-17], and is important for development of dopaminergic neurons. Ablation of *Nurr1* leads to agenesis of midbrain dopaminergic neurons as demonstrated by an absence of dopaminergic cell markers including tyrosine hydroxylase, as well as a loss of striatal dopamine neurotransmitter[18]. *Nurr1* knockout mice failed to develop ventral mesencephalic dopaminergic neurons and died within 12-48 h[19]. In addition, *Nurr1* increases expression of the human dopamine transporter gene in the mature brain; whereas other members of the nerve growth factor-induced clone B subfamily of nuclear receptors have lesser or even no effects[19]. Expression of *Nurr1* continues in mature dopaminergic neurons during adulthood, suggesting that *Nurr1* is also required for normal function of mature dopaminergic neurons[20]. Thus, *Nurr1* is an upstream signaling molecule for regulating the dopamine pathway and plays a broad-spectrum role in brain development.

Nurr1 involvement in the regulation of the dopaminergic system makes it a good candidate to study neuropsychiatric disorders. Several polymorphisms in the gene have been identified: *-469delG*, *M97V*, *H103R*, *DY122*, *-2922(C)2-3*, *IVS6+17* approximately *+18insG* and *EX8+657(CA)9-10*[21-24]. Among these polymorphisms, *-2922(C)2-3*, *IVS6+17* approximately *+18insG* and *EX8+657* variants are common (frequency of minor alleles > 15%) in both Caucasian and Asian populations. Two variants (*-291Tdel* and *-245T→G*) of *Nurr1* are associated with Parkinson's disease[25]. However, another study failed to identify any of the described variants in Parkinson's patients or controls[26]. In the regulatory region of the *Nurr1* gene, at least five polymorphic sites [*P1(A/T*, reference SNP number rs1462374), *P2(G/C)*, *P3(C/G)*, *P4(C/A/G)*, *P5(del C)*] have been identified, with no significant association between the genotype or allele frequency of these variants and schizophrenia or Parkinson's disease. In addition, *P2(G/C)*, *P3(C/G)*, and *P5(del C)* are in linkage disequilibrium (LD) with each other[27]. Further investigation of common *Nurr1* variants [*-2922(C)2-3*, *IVS6+17* approximately *+18insG*, *EX8+657(CA) 9-10*] has not supported their pathogenic role for schizophrenia among Japanese individuals[28]. There are two coding synonymous polymorphism sites in exon 3 (rs16840266) and exon 5 (rs61748236), and three coding nonsynonymous polymorphism sites in exon 3 (rs36083712 and rs35100271) and exon 8 (rs61729997); some other rare missense mutations have been studied in psychiatric disorders[22], but none of them has been found to be associated with alcohol addiction.

The role of *Nurr1* in alcohol dependence was studied in Japanese individuals[29], and polymorphisms including *-2922(C) 2-3* and *EX8 +657(CA)9-10* were examined. They have reported that the genotypic distribution of these two polymorphisms was in Hardy-Weinberg equilibrium in the controls and alcoholics. The allele frequency of the *(C) 2* and *(CA) 9* and allele in the alcoholics was similar to that in the controls. Significant LD between these two polymorphisms was observed in both controls ($P = 0.007$) and alcoholics ($P < 0.0001$), but the LD was much stronger in alcoholics than in controls (D' = 0.84 *vs* D' = 0.30). There was a significant difference in haplotype distributions between the alcohol dependence and control groups. The haplotypic association was not based on an increased frequency of a specific haplotype, but rather based on stronger LD in alcoholics. This finding implies that more recent ancestral chromosome sharing by the alcoholics than by the controls, and that the *Nurr1* locus is one of the genome regions that contribute to alcohol dependence.

Nurr1 is involved in the regulation of the dopaminergic system, which is the primary neurotransmitter in the reward pathway. The dopamine signaling can be activated by alcohol. Thus, we hypothesize the presence of an association between the polymorphism of the *Nurr1* gene and alcohol dependence. We selected three alleles in the regulatory region of the *Nurr1* gene that include *-2922(C)2-3*, *-1345(G/C)* and *-1198(C/G)* (promoter P2 and P3 in reference literature from Andrea Carmine) as well as coding synonymous *Ex+132(G/T/A/C*, rs16840266) and coding nonsynonymous *Ex+715(T/-*, rs35100271) in exon 3. These alleles are supposed to contribute to the function of *Nurr1* and may have an impact on alcohol dependence in Mexican Americans.

MATERIALS AND METHODS

Participants

All participants in this project were enrolled from unrelated Mexican Americans who lived in Los Angeles County, CA. The study cohorts included 374 alcoholics and 346 nonalcoholics, and the ratio of cases to controls was about 1.08. The groups were sex- and age-matched. All subjects provided informed consent for their participation in this study. This study was approved by the University of Kansas Medical Center Human Subjects Committee. All participants were investigated, diagnosed, and assigned based on the Diagnostic and Statistical Manual of Mental Disorder, Fourth Edition (DSM-IV). The alcoholic participants were interviewed by the Semi-Structured Assessment for the Genetics of Alcohol dependence II in English or Spanish[30]. The inclusion criteria for alcoholic participants included: (1) the ability to give informed consent; (2) between 21 and 76 years of age; (3) no less than three of four biological grandparents of Mexican heritage; (4) fluency in either Spanish or English; (5) no current use of other substances (except tobacco and caffeine), or history of such use within the past 6 mo; (6) no current or past diagnosis of mental illness such as schizophrenia, schizophrenia disorder, schizoaffective disorder, schizotypal disorder, major depression, bipolar disorder, or Parkinson's disease; and (7) no other clinical unacceptable disease based on physical examinations. The inclusion criteria for nonalcoholic participants included: (1) no current or history of diagnosis of DSM-IV alcohol dependence or alcohol abuse; and (2) no other clinical unacceptable disease based on physical examinations. The interview information also covered body weight, height, smoking status, tea and coffee intake, as well as marriage, and education status. Body mass index (BMI) equals body weight in kilograms divided by height in square meters (kg/m^2). Smoking status was defined as having smoked one or more cigarettes per day during the past 30 d[31].

Genotyping

Participants' peripheral blood samples were collected into tubes containing K_2-EDTA. Genomic DNA was extracted with GeneCatcher gDNA Blood kits (Invitrogen, Carlsbad, CA, United States). The primers used for PCR were: *-2922(C)2-3*, forward: 5'-AAAAGGGGATGAACCGGGTAGG-3', reverse: 5'-TTTTCCGAAAGAGGTGTGACCT-3'; *-1345(G/C)* and *-1198(C/G)*, forward: 5'-ATCCCGAATAGTTCCACGGAG-3', reverse: 5'-CACGAGTTTTAAGGGAATAAATCG-3'; *Ex3+132(G/T/A/C)* and *Ex3+715(T/-)*, forward: 5'-GCTGAGTGTGTTATCACCTGTTT-3', reverse: 5'-GCTGAGTGTGTTATCACCTGTTT-3'.

PCR amplification was carried out in a 25-μL reaction mix containing 100 ng genomic DNA, 1× Go Taq Flexi buffer, 0.2 μmol/L each primer, 0.2 mmol/L dNTP, 2.0 mmol/L $MgCl_2$, 0.2 mmol/L dGTP, and 1 U GoTaq DNA polymerase. The thermal cycling conditions were set at 95 ℃ for 5 min, then 35 cycles for 30 s at 95 ℃, 30 s at 50 ℃ (for the three alleles in the regulatory region) or 55 ℃ (for the two alleles in exon 3), and 60 s at 72 ℃, with a final extension step of 10 min at 72 ℃. PCR products were examined on a 2% agarose gel.

The *-2922(C)2-3* PCR products were digested with *Sau96I*, which generated 176- and 158-bp fragments for wild-type alleles. Positive and negative digestion controls were set in each PCR and each agarose gel to ensure correct digest results. Retest was needed when results could not be read clearly. Other genotyping was studied by sequencing. All samples were sequenced in two directions. Results where two direction sequences did not match each other were excluded. Sequencing results were read by Finch TV (1.4 Version, Geospiza, Inc.) graphical viewer.

Statistical analysis

Statistical analyses were performed with SPSS Version 15.0 software (SPSS Inc., Chicago, IL, United States). Two-sided analyses were conducted and $P < 0.05$ was used as the significance threshold. Pearson's χ^2 tests were used to compare sex, BMI, smoking, genotype, and allele distribution between alcoholics and their controls.

Table 1 Genotype and allele frequency of the *-2922(C)2-3* and *-1198(C/G)* allele in Mexican American alcoholics and nonalcoholics *n* (%)

Groups	*-2922(C)2-3* allele					*-1198(C/G)* allele				
	Genotype			Allele frequency	Total	Genotype			Allele frequency	Total
	(C)2/(C)2	*(C)2/(C)3*	*(C)3/(C)3*	*(C)3*		*C/C*	*C/G*	*G/G*	*C*	
Non-alcoholic	119 (34.4)	132 (38.2)	95 (27.5)	322 (46.5)	346	76 (23.5)	146 (46.1)	98 (30.3)	298 (46.6)	320
Alcoholic	87 (23.3)	192 (51.3)	95 (25.4)[a]	382 (51.1)	374	48 (13.9)	176 (50.9)	122 (35.3)[a]	272 (39.3)[b]	346

[a]$P = 0.007$; [b]$P = 0.005$ *vs* nonalcoholic.

RESULTS

Population characteristics

There were 374 alcoholics and 346 nonalcoholic controls. The alcoholic group had 299 (79.9%) men and 75 (20.1%) women, and the nonalcoholic control group had 260 (75.1%) men and 86 (24.9%) women. The number of young (≤ 30 years), middle-aged (30-60 years), and old (> 60 years) participants in the control group was 93 (26.9%), 245 (70.8%), and 8 (2.3%), respectively, and 99 (26.5%), 266 (71.1%), and 9 (2.4%) in the alcoholic group. The mean ± SD age of the alcoholics and controls was 38.3 ± 10.5 years (range: 21-76 years) and 37.3 ± 10.4 years (range: 19-65 years), respectively. No significant differences were found between the two cohorts regarding sex or age distribution with Pearson's χ^2 test.

BMI is the measurement of choice to determine obesity, and the clinical diagnosis of obesity is BMI ≥ 30 kg/m^2. The BMI was not significantly different between the alcoholic and nonalcoholic groups [BMI < 30 kg/m^2, 198 (57.6%) *vs* 213 (63.6%); BMI ≥ 30 kg/m^2, 146 (42.4%) *vs* 122 (36.4%), $P = 0.108$]. However, the smoker distribution was significantly different between the alcoholic and nonalcoholic groups [non-smoker, 197 (52.7%) *vs* 282 (82.7%); smoker, 177 (47.3%) *vs* 59 (17.3%), $P = 0.000$]. The alcoholic group had more smokers than the control group had.

Genotypes of -2922(C)2-3, -1345(G/C), -1198(C/G), Ex3+132(G/T/A/C) and Ex3+715(T/-) in Mexican Americans

The genotypes of *-2922(C)2-3*, *-1345(G/C)*, *-1198(C/G)*, *Ex3+132(G/T/A/C)* and *Ex3+715(T/-)* were studied in Mexican American alcoholics and controls. The *-2922(C)2-3* and *-1198(C/G)* alleles were polymorphic in Mexican Americans, but *-1345(G/C)*, *Ex3+132(G/T/A/C)* and *Ex3+715(T/-)* were shown to be present in the studied population (*G/G*, *G/G*, and *T/T*, respectively). These results are consistent with reports which come from Swedish[27], Japanese[29] and Canadian[32] populations with neurological disorders. This is believed to be the first research reporting the absence of polymorphisms in Mexican Americans at the three genomic sites mentioned above.

The genotypes of *-2922(C)2-3* and *-1198(C/G)* as well as their minor allele frequencies are shown in Table 1. The Hardy-Weinberg equilibrium *P* values of *-2922(C)2-3* and *-1198(C/G)* in alcoholics were 0.6914 and 0.2751, respectively, and the *P* values for these two alleles in nonalcoholic controls were 0.00002 and 0.1854. The genotype distribution of the *-2922(C)2-3* allele was significantly different between alcoholics and nonalcoholics ($P = 0.001$); however, there was no significant difference at the allelic level. The genotype as well as the allele frequency of the *-1198(C/G)* allele was significantly different between alcoholics and nonalcoholics ($P = 0.005$ and $P = 0.007$), suggesting the importance of sequence variations in the regulatory region of the *Nurr1* gene in differentiating these two cohorts. In addition, the *-2922(C)2-3* and *-1198(C/G)* alleles showed a strong LD (D' = 0.88) in the alcoholic population, but not in the nonalcoholic population.

Association of -2922(C)2-3 and -1198(C/G) with alcohol dependence after controlling for confounding effect of smoking and obesity

Alcoholics and nonalcoholic controls were stratified according to the smoking and obesity status. When obese individuals were excluded, a significant difference was found at both the genotypic and allelic level between non-obese alcoholics and non-obese controls, for the *-2922(C)2-3* polymorphism (Table 2, $P = 0.000$ and $P = 0.049$) and *-1198(C/G)* polymorphism (Table 3, $P = 0.008$ and $P = 0.032$). When smokers were excluded, between alcoholics and controls, a significant difference was found only at the genotypic level for the *-2922(C)2-3* polymorphism (Table 2, $P = 0.037$), but only at the allelic level for the *-1198(C/G)* polymorphism (Table 3, $P = 0.034$).

DISCUSSION

Hispanics are one of the fastest growing ethnic groups in the United States and were expected to become the largest minority group by the year 2010[33]. About two-thirds of Hispanic population is of Mexican American or Mexican origin. These population demographics have shown evidence of a serious problem of alcohol dependence with a prevalence rate of heavy drinking in Mexican American men that is three times higher than in non-Hispanic male populations[34]. Excessive alcohol drinking carries a high risk of developing various types of chronic diseases. Alcohol-related problems in this population, such as alcoholic liver disease, malignant neoplasms, psychiatric conditions, neurological impairment, and cardiovascular disease show a significantly higher

incidence than when compared with those from other ethnic backgrounds[35]. Apart from environmental factors, using family, twin pair, half sibling, and adoption studies, alcohol dependence has been proved to be a polygenic disorder[1-4].

Candidate gene associations approach has been widely used to explore related genetic factors. We have previously studied genes involved in both alcohol metabolism and reward pathways in Mexican American alcoholics and have established associations between certain phenotypes of alcohol dependence and the polymorphism of these genes[9-13,36,37]. We showed that most Mexican Americans carry the *ADH1B*1* (95%) and *ALDH2*1* (99.4%) genes. Thus, the *ADH1* and *ALDH2* genotypes do not distinguish those more prone to alcohol drinking from those who are not[9]. Our data also showed the importance of polymorphism of *DRD2 (-141C Del/Ins)* and *5-HTTLPR* in contribution to alcohol dependence[9-12]. Other components of the dopamine pathway have also been associated with alcohol dependence. *DRD4 VNTR* genotypes without the 7-repeat allele have been found to be risk factors for alcohol dependence in Mexican Americans[13]. In the current study, to the best of our knowledge, we reported for the first time a significant association between the polymorphisms in the promoter region of the *Nurr1* gene and alcohol dependence in Mexican Americans. Our findings indicated that polymorphisms of *-2922(C)2-3* and *-1198(C/G)* are associated with alcohol dependence in the Mexican American population, even when the confounding effects of smoking and obesity were controlled, suggesting the reliability of our findings. The frequency of the *-1198 G* allele was significantly higher in alcoholics than in controls, suggesting that the *G* allele of *-1198(C/G)* might potentially have a pathogenic effect on alcohol drinking. The functional significance of these two polymorphisms still needs to be explored. Taken together, since *Nurr1* is upstream of the dopamine pathway, our data indicate the importance of *Nurr1*/dopamine signaling in alcohol abuse in this important minority group.

Smoking and obesity might represent significant confounding factors in the relationship between risk factors and alcohol dependence. Alcohol and constituents of tobacco are potent inducers of *CYP2E1*. When smokers were excluded from both the control and alcoholic groups, the **5B* allele of the *CYP2E1* gene was significantly associated with alcohol dependence[38]. Similar findings were observed for the *DRD2 -141C Ins/Del* allele[10]. In the present studied population, 47.3% of alcoholics and 17.3% of nonalcoholics were smokers. The distribution of smokers and nonsmokers in alcoholic and nonalcoholic groups showed a significant difference. When all participants were considered, distribution of both *-2922(C)2-3* and *-1198(C/G)* polymorphisms showed significant differences between the alcoholic and nonalcoholic groups. When smokers were excluded, the association of alcohol dependence with these two polymorphisms remained. When obesity was considered, *-2922(C)2-3* and *-1198(C/G)* polymorphisms were associated with alcohol dependence in the non-obese groups. Associations of these two polymorphisms and alcohol dependence are consistently found in the nonsmoking and non-obese group, therefore, this increases the reliability of our findings.

In conclusion, the polymorphism of *-2922(C)2-3* and *-1198(C/G)* in the regulatory region of the *Nurr1* gene were shown to be associated with alcohol dependence in Mexican Americans. The functional significance of these two polymorphisms still needs to be studied. Alcohol dependence is a multifactorial disease, therefore, it is also important to study the interaction of *Nurr1* with other components of the dopamine signaling pathway in contributing to alcohol dependence, which might lead to effective treatment strategies.

COMMENTS

Background

It is widely accepted that genetic factors play an important role in the development of alcohol dependence. Family clustering surveys have shown that alcohol dependence rates are higher among persons who are biologically related to an alcoholic. Nur-related receptor 1 (*Nurr1*) is a transcription factor in the orphan nuclear receptor family that can regulate dopamine neurotransmission and influence the expression of genes important for human brain development.

Research frontiers

Nurr1 regulates the dopaminergic system. Several polymorphisms in the gene have been identified. Two variants (*-291Tdel* and *-245T→G*) of *Nurr1* are associated with Parkinson's disease. The *Nurr1* locus is located in the genome region that contributes to alcohol dependence. Thus, the authors hypothesize the presence of an association between polymorphism of the *Nurr1* gene and alcohol dependence.

Innovations and breakthroughs

Several polymorphisms of *Nurr1* have been identified: *-469delG*, *M97V*, *H103R*, *DY122*, *-2922(C)2-3*, *IVS6+17* approximately *+18insG* and *EX8+657(CA)9-10*. *-2922(C)2-3*, *IVS6+17* approximately *+18insG* and *EX8+657* variants are common in both Caucasian and Asian populations. Two variants (*-291Tdel* and *-245T→G*) of *Nurr1* are associated with Parkinson's disease. Further investigation of common *Nurr1* variants did not support their pathogenic role, and none was found to be associated with alcohol addiction. In the present study, the authors showed that genotype distribution of *-2922(C) 2-3* and *-1198(C/G)* was significantly different between nonalcoholic and alcoholic Mexican Americans. The *-1198C* frequency was found to be significantly higher in nonalcoholics than that in alcoholics. However, the *-1345(G/C)*, *Ex3+132(G/T/A/C)*, and *Ex3+715(T/-)* alleles were not polymorphic in Mexican Americans; all the studied Mexican Americans had *G/G*, *G/G and T/T* genotype for these three alleles, respectively.

Applications

This study suggested that polymorphisms in the regulatory region of the *Nurr1* gene are implicated in pathogenesis of alcohol dependence of Mexican Americans. The *Nurr1*/dopamine signaling pathway might be important for the development of alcohol dependence in Mexican Americans.

Terminology

NR4A2 is a transcription factor in the orphan nuclear receptor family, and is important for development of dopaminergic neurons. *Nurr1* is an upstream signaling molecule for regulating the dopamine pathway and plays a broad-spectrum role in brain development.

Peer review

This is a good descriptive study in which the authors analyzed the polymorphisms of the *Nurr1* gene in 374 alcoholic and 346 nonalcoholic Mexican Americans. They found that the genotype distributions of *-2922(C) 2-3* and *-1198(C/G)* were different between alcoholics and non-alcoholics. The presented data suggest that the *Nurr1*/dopamine signaling pathway might be important for the development of alcohol dependence in Mexican Americans.

Abstract

AIM: To investigate the preventive effect of N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) on bile duct ligation (BDL)-induced liver fibrosis in rats.

METHODS: Liver fibrosis in rats was induced by BDL and AcSDKP was infused subcutaneously for 2 wk *via* a osmotic minipump (Alzet 2ML4) immediately after BDL operation. After scarifying, serum and liver specimens were collected. Hematoxylin and eosin staining, Sirius red staining, enzyme linked immunosorbent assay, Western blot or real-time polymerase chain reaction were used to determinate liver functions, histological alterations, collagen deposition, mRNA expression of markers for fibroblasts, transforming growth factor-β1 (TGF-β1) and bone morphogenetic protein-7 (BMP-7).

RESULTS: When compared to model rats, chronic exogenous AcSDKP infusion suppressed profibrogenic TGF-β1 signaling, α-smooth muscle actin positivity (α-SMA), fibroblast specific protein-1 (FSP-1) staining and collagen gene expression. Col Ⅰ, Col Ⅲ, matrix metalloproteinase-2, tissue inhibitors of metalloproteinase-1 and tissue inhibitors of metalloproteinase-2 mRNA expressions were all significantly downregulated by AcSDKP infusion (2.02 ± 1.10 *vs* 14.16 ± 6.50, 2.02 ± 0.45 *vs* 10.00 ± 3.35, 2.91 ± 0.30 *vs* 7.83 ± 1.10, 4.64 ± 1.25 *vs* 18.52 ± 7.61, 0.46 ± 0.16 *vs* 0.34 ± 0.12, respectively, $P < 0.05$). Chronic exogenous AcSDKP infusion attenuated BDL-induced liver injury, inflammation and fibrosis. BDL caused a remarkable increase in alanine transaminase, aspartate transaminase, total bilirubin, and prothrombin time, all of which were reduced by AcSDKP infusion. Mast cells, collagen accumulation, α-SMA, TGF-β1, FSP-1 and BMP-7 increased. The histological appearance of liver specimens was also improved.

CONCLUSION: Infusion of exogenous AcSDKP attenuated BDL-induced fibrosis in the rat liver. Preservation of AcSDKP may be a useful therapeutic approach in the management of liver fibrosis.

INTRODUCTION

N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) is an endogenous tetrapeptide normally present in the plasma and organs of humans and experimental animals[1-3]. It is released locally in tissues from its precursor thymosin-β4 (Tβ4) most likely by prolyl oligopeptidase (POP), a serine proteinase found in mammalian tissues[4,5]. AcSDKP is cleaved to an inactive form by the NH_2-terminal catalytic domain of angiotensin converting enzyme (ACE)[6].

Originally described as a natural inbibitor of hematopoietic stem cell proliferation, AcSDKP is now recognized as a critical negative regulator for extracellular matrix (ECM) accumulation in organs under both physiological and pathological conditions. Decreased basal levels of endogenous AcSDKP by ACE over expression or by POP inhibitors promote cardiac fibrosis and/or glomerulosclerosis[7,8]. Exogenous AcSDKP infusion reduces collagen deposition in rats heart and/or kidney under hypertensive and ischemic conditions[9]. AcSDKP also mediates the antifibrogenic effect of ACE inhibitors in the heart[10]. The mechanism of action of AcSDKP includes suppression of inflammation, ECM-producing cell proliferation, collagen production, and more importantly transforming growth factor-β1 (TGF-β1) signaling[7-9,11,12].

Indeed, these key cellular and molecular mechanisms are critical in regulating ECM accumulation in multiple organs, in particular the liver[13]. Moreover, ACE inhibition is beneficial in several liver fibrosis models where there is increased ACE activity and potentially excessive AcSDKP degradation, Tβ4 and significant POP activity are present in the liver, where AcSDKP is produced locally, and may play a role in the regulation of hepatic cell responses *in vivo*[14,15].

Our previous studies had revealed that AcSDKP ameliorated carbon tetrachloride (CCl_4)-induced liver fibrosis and liver functions in the rat liver. The current study was aimed to investigate the preventive effect of AcSDKP on bile duct ligation (BDL)-induced liver fibrosis in rats. The potential mechanisms involved were also examined.

We explored the effects of AcSDKP on liver fibrosis by infusion of exogenous AcSDKP into the BDL rat models. Our results demonstrate that exogenous AcSDKP preserves basal levels of AcSDKP in the liver and significantly reduces the development of liver fibrosis in this model. Based on these findings, we propose that AcSDKP plays an important role in attenuating liver fibrosis. The underlying mechanisms may involve decreased production of profibrotic cytokines and reduced collagen expression and accumulation.

MATERIALS AND METHODS

Materials

BDL-induced rat liver fibrosis models: all animal handling and experimental procedures were approved by the Animal Care and Use Committee of the Shanghai Jiaotong Uinversity School of Medicine. Male Sprague-Dawley rats (200-250 g) were obtained from the Shanghai Experimental Animal Center (Shanghai, China). The rat model of liver fibrosis was induced by BDL. Upon sacrifice, blood was collected and serum and/or plasma were obtained. Liver tissue was either fixed in 10% neutral buffered formalin, frozen in optimal cutting temperature, or snap frozen in liquid nitrogen and stored at -80 ℃.

Experiment: AcSDKP-infused BDL-treated rats and the BDL model were established as above (n = 8-10). AcSDKP-infused BDL-treated rats were infused with AcSDKP at 800 μg/kg per day through a subcutaneous osmotic minipump (Alza Corp, Palo Alto, CA) beginning simultaneously with BDL. Rats were sacrificed at 2 wk. This dosage was used because it increased plasma AcSDKP to a concentration similar to that induced by captopril (100 μg/kg per day, 3- to 5-fold-change), without any adverse effect on the circulatory system[9].

Serum assays

Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin, and albumin in serum and prothrombin time in plasma were measured using an automated analyzer.

Histological analysis

Formalin-fixed paraffin sections of the liver were stained with hematoxylin and esosin for pathological analysis or Sirius red for collagen. Collagen was quantified with Image Quant 5.1 software as previously described[16]. Positive cells were enumerated in 10 randomly selected fields at 400 × magnification.

Gene expression

Total RNA was extracted from livers using Trizol and was reverse-transcribed using an iscript cDNA synthesis kit. Real-time polymerase chain reaction (PCR) was performed on an iCycler system using the SYBR green Master Mix. Primer specificity was confirmed by sequencing PCR products. β-actin was the internal control. Data were presented according to the $\Delta\Delta C_t$ method.

Western blot

Frozen liver tissue was homogenized in ice-cold RIPA buffer containing protease and phosphatase inhibitors. A full list of antibodies is available in Supplemental data. Western blot was performed as previously described[17]. Bands were quantified by Scion Image 4.0.3. The loading control was tubulin.

Hydroxyproline content

Hydroxyproline content in liver tissue was determined as previously described[18].

Statistical analysis

Data are expressed as means ± SE. Comparisons were performed using analysis of variance. Least significant difference procedure analyses were performed when > 2 groups were present. $P < 0.05$ was considered statistically significant.

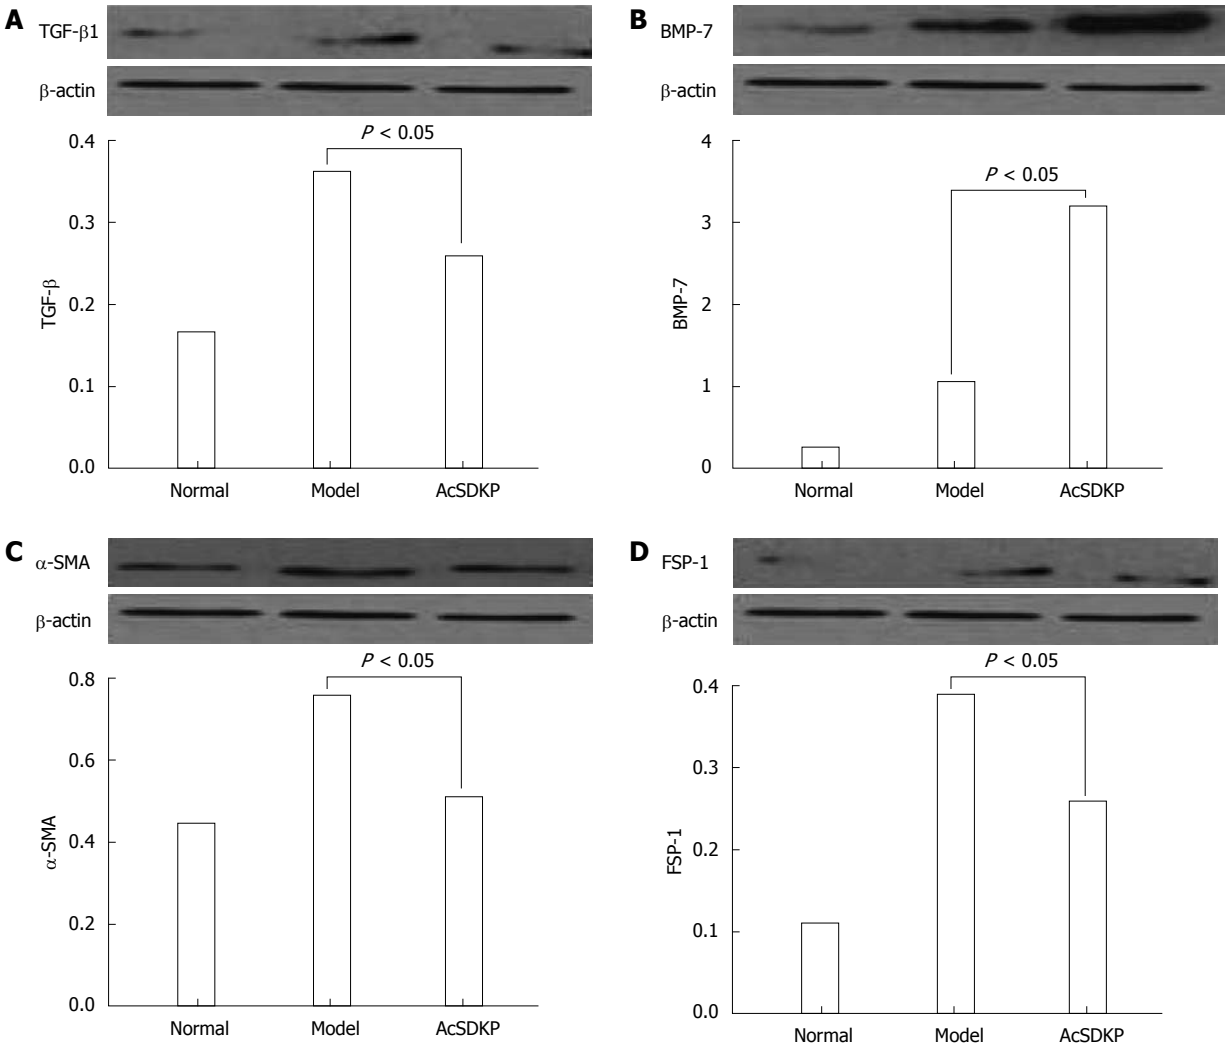

Figure 1 Western blotting and quantitive analysis. A: Transforming growth factor-β1 (TGF-β1); B: Bone morphogenetic protein-7 (BMP-7); C: α-smooth muscle actin positivity (α-SMA); D: Fibroblast specific protein 1 (FSP-1).

RESULTS

Chronic exogenous AcSDKP infusion suppressed profibrogenic TGF-β1 signaling, α-SMA, eibroblast specific protein-1 and bone morphogenetic protein-7 staining and collagen gene expression

When compared to model rats, TGF-β1 was significantly downregulated in AcSDKP-infused BDL-treated rats (Figure 1A). In contrast, bone morphogenetic protein-7 (BMP-7) staining in the liver of BDL-treated rats was increased by AcSDKP (Figure 1B). α-SMA, fibroblast specific protein-1 (FSP-1), collagen I, collagen Ⅲ, tissue inhibitor of metalloproteinase-1 and 2 mRNA all were downregulated by AcSDKP infusion (Figure 1C and D). Collagen Ⅰ, collagen Ⅲ, matrix metalloproteinases-2, tissue inhibitors of metalloproteinase-1 and tissue inhibitors of metalloproteinase-2 mRNA expressions were all significantly downregulated by AcSDKP infusion (2.02 ± 1.10 *vs* 14.16 ± 6.50, 2.02 ± 0.45 *vs* 10.00 ± 3.35, 2.91 ± 0.30 *vs* 7.83 ± 1.10, 4.64 ± 1.25 *vs* 18.52 ± 7.61, 0.46 ± 0.16 *vs* 0.34 ± 0.12, respectively, $P < 0.05$). Matrix metalloproteinase-2 expression was increased in BDL-treated rats but suppressed by AcSDKP.

Chronic exogenous AcSDKP infusion attenuated BDL-induced liver injury, inflammation and fibrosis

BDL caused a remarkable increase in ALT, AST, total bilirubin, and prothrombin time, all of which were reduced by AcSDKP infusion (Table 1). The histological appearance of liver specimens was also improved (Figure 2A-C). Marked collagen accumulation was observed in AcSDKP-infused BDL-treated *vs* model rats, which was attenuated by AcSDKP infusion (Figure 2D-F). The reduction in total collagen was further confirmed by decreased hydroxyproline content. When compared to model rats, hyaluronic acid, ammonia terminal procollagen β peptide and hydroxyproline were all significantly decreased by AcSDKP infusion (127.4 ± 31.8 *vs* 267.2 ± 99.4, 6.9 ± 0.5 *vs* 35.2 ± 4.3, 162.3 ± 42.4 *vs* 398.2 ± 60.4, respectively, $P < 0.05$). Total mast cells decreased in AcSDKP *vs* model BDL-treated rats (Figure 2G-I).

DISCUSSION

Here, we demonstrate that in the liver, chronic exogenous AcSDKP infusion preserves basal levels of AcSDKP and attenuates BDL-induced fibrosis. This is supported by

other studies showing an important role of AcSDKP in preventing heart[19,20] and kidney[21,22] fibrosis at basal concentrations. Our previous studies had also revealed that AcSDKP ameliorated CCl_4-induced liver fibrosis and liver functions in rats.

Attenuation of liver fibrosis by AcSDKP is associated with suppressed inflammation and TGF-β signaling. Our results show that AcSDKP suppressed mast cells infiltration, TGF-β1 signaling and myofibroblasts *in vivo*.

Recent evidence suggests that epithelial-to-mesenchymal transition (EMT) may also contribute to liver fibrogenesis[23]. TGF-β1 is still generally considered to be the main positive regulator of EMT and ECM accumulation[23]. Indeed, our results show that AcSDKP suppressed TGF-β signaling and reduced the EMT markers α-SMA and FSP-1 *in vivo*[24,25]. In addition, AcSDKP increased

BMP-7. BMP-7 counteracts the effects of TGF-β1 and is a prototypical negative regulator of EMT. Nevertheless, a more sophisticated study is required to fully elucidate the possible role of AcSDKP-induced inhibition of EMT in the attenuation of liver fibrosis.

There are some limitations in this study. We did not include a group of control rats infused with AcSDKP primarily because exogenous infusion of AcSDKP restored the peptide levels to control levels and this dose has been shown to have no adverse effects systemically. Secondly, the cellular mechanisms of AcSDKP action were not fully elucidated in our current study. The presence of an AcSDKP receptor on cells has been suggested[26]. We speculate that AcSDKP may directly affect liver cells by binding and activating its receptor on the cell surface, resulting in suppression of certain profibrogenic intracellular signaling pathways. Further studies to clone the receptor or develop specific receptor antagonists will enable full characterization of the cellular mechanisms involved in the antifibrotic effects of AcSDKP *in vivo* and *in vitro*.

In summary, this study shows that chronic exogenous AcSDKP infusion preserves basal levels of AcSDKP and attenuates liver fibrosis induced by BDL in rats. Our study strongly suggests a significant role for AcSDKP in the development of liver fibrosis and potentiates the usefulness of this tetrapeptide in the prevention of this disease. Additional studies are needed to gain further insight into the biological effect of AcSDKP in the liver and further studies are ultimately warranted in the human.

COMMENTS

Background

N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) is an endogenous tetrapeptide *in vivo* which has antifibrogenic effects on the heart, the lung and the kidney. The authors' previous studies had revealed that AcSDKP ameliorated carbon tetrachloride-induced liver fibrosis and liver functions in the rat liver.

Research frontiers

Originally described as a natural inhibitor of hematopoietic stem cell proliferation, AcSDKP is now recognized as a critical negative regulator for extracellular matrix accumulation in organs under both physiological and pathological conditions.

Innovations and breakthroughs

This is the first study to investigate the preventive effect of endogenous AcSDKP in bile duct ligation (BDL)-induced fibrosis in the rat liver and the potential mechanisms involved were also examined. The results strongly suggest a significant role for AcSDKP in the development of liver fibrosis and potentiates the usefulness of this tetrapeptide in the prevention of this disease.

Applications

Preservation of AcSDKP may be a useful therapeutic approach in the management of liver fibrosis.

Peer review

This is a good descriptive study in which authors analyze the preventive effect of AcSDKP on BDL-induced liver fibrosis in rats. The results are interesting and suggest that infusion of exogenous AcSDKP attenuated BDL-induced fibrosis in the rat liver. Preservation of AcSDKP may be a useful therapeutic approach in the management of liver fibrosis.

Abstract

AIM: To report our experience using mini-laparotomy for the resection of rectal cancer using the total mesorectal excision (TME) technique.

METHODS: Consecutive patients with rectal cancer who underwent anal-colorectal surgery at the authors' hospital between March 2001 and June 2009 were included. In total, 1415 patients were included in the study. The cases were divided into two surgical procedure groups (traditional open laparotomy or mini-laparotomy). The mini-laparotomy group was defined as having an incision length ≤ 12 cm. Every patient underwent the TME technique with a standard operation performed by the same clinical team. The multimodal preoperative evaluation system and postoperative fast track were used. To assess the short-term outcomes, data on the postoperative complications and recovery functions of these cases were collected and analysed. The study included a plan for patient follow-up, to obtain the long-term outcomes related to 5-year survival and local recurrence.

RESULTS: The mini-laparotomy group had 410 patients, and 1015 cases underwent traditional laparotomy. There were no differences in baseline characteristics between the two surgical procedure groups. The overall 5-year survival rate was not different between the mini-laparotomy and traditional laparotomy groups (80.6% *vs* 79.4%, $P = 0.333$), nor was the 5-year local recurrence (1.4% *vs* 1.5%, $P = 0.544$). However, 1-year mortality was decreased in the mini-laparotomy group compared with the traditional laparotomy group (0% *vs* 4.2%, $P < 0.0001$). Overall 1-year survival rates were 100% for Stage Ⅰ, 98.4% for Stage Ⅱ, 97.1% for Stage Ⅲ, and 86.6% for Stage Ⅳ. Local recurrence did not differ between the surgical groups at 1 or 5 years. Local recurrence at 1 year was 0.5% (2 cases) for mini-laparotomy and 0.5% (5 cases) for traditional laparotomy ($P = 0.670$). Local recurrence at 5 years was 1.5% (6 cases) for mini-laparotomy and 1.4% (14 cases) for traditional laparotomy ($P = 0.544$). Days to first ambulation (3.2 ± 0.8 d *vs* 3.9 ± 2.3 d, $P = 0.000$) and passing of gas (3.5 ± 1.1 d *vs* 4.3 ± 1.8 d, $P = 0.000$), length of hospital stay (6.4 ± 1.5 d *vs* 9.7 ± 2.2 d, $P = 0.000$), anastomotic leakage (0.5% *vs* 4.8%, $P = 0.000$), and intestinal obstruction (2.2% *vs* 7.3%, $P = 0.000$) were decreased in the mini-laparotomy group compared with the traditional laparotomy group. The results for other postoperative recovery function indicators, such as days to oral feeding and defecation, were similar, as were the results for immediate postoperative complications, including the physiologic and operative severity score for the enumeration of mortality and morbidity score.

CONCLUSION: Mini-laparotomy, as conducted in a single-centre series with experienced TME surgeons, is a safe and effective new approach for minimally invasive rectal cancer surgery. Further evaluation is required to evaluate the use of this approach in a larger patient sample and by other surgical teams.

INTRODUCTION

Laparoscopic surgery has become popular throughout the world[1-3]. This surgical method enhances early postoperative recovery with less pain, less analgesic use, an earlier return of gastrointestinal function, and fewer wound and pulmonary complications. Total mesorectal excision (TME) is acknowledged worldwide as the preferred technique for surgical resection of rectal cancer[4-6]. Multiple studies have reported marked reductions in local recurrence with the TME technique, including single-centre, multiple-centre, and population studies[7,8]. The laparoscopic approach to TME resection of rectal cancer is currently being evaluated in multicentre randomised trials[9-12].

A less-recognised surgical technique aimed at improving postoperative recovery is mini-laparotomy. With this technique, surgical dissection is performed under direct vision, as in open surgery; laparoscopic equipment and training is not required. Early experience with mini-laparotomy has been reported from a few medical centres in case series of colon and rectal resection[13-15]. Mini-laparotomy has been developed as a techniques based on the advanced recognition of more information about pelvic anatomy and the dissection of subtle perirectal structures in laparotomy[16,17].

In view of these circumstances, our surgical centre has performed mini-laparotomies for rectal cancer for approximately 8 years. The aim of this study is to report our experience using mini-laparotomy for the resection of rectal cancer using the TME technique. Furthermore, we aim to compare the oncologic findings and the postoperative recovery indexes of mini-laparotomy and traditional laparotomy, thus providing more evidence to help surgeons select an operating procedure.

MATERIALS AND METHODS

Included cases

This study is registered as an International Clinical Trial (ChiCTR-TRC-09000618) to compare TME resection of rectal cancer using traditional open laparotomy *vs* mini-laparotomy. This is a retrospective analysis of consecutive patients with rectal cancer observed at the Anal-colorectal Surgery Ward in West China Hospital of Sichuan University between March 2001 and June 2009. The inclusion criteria were as follows: (1) diagnosis of rectal cancer; (2) no previous history of lower abdominal operations or pelvic operations; (3) possibility of curative resection; and (4) intestinal continuity was restored by anastomosis. The exclusion criteria were (1) curative resection was not achieved; (2) resections without anastomosis (APR and Hartmann); and (3) actively exciting the study. All of the enrolled patients provided informed consent, which included information about (1) the different kinds of treatment available for their cancer; (2) the benefit of different operation procedures; and (3) their doctor's recommendation. Ultimately, the choice of surgical technique was left to the patient. The database from the anal-colorectal surgery of West China Hospital in Sichuan University provided the research data[18]. If any data required for the study were missing, the patient was excluded. Most of the patients who were excluded for this reason were missing data related to pathology and surgical baselines; 5-year survival and local recurrence; and the first time of aerofluxus, defecation, ambulation, oral feeding during the recovery phase. Ultimately, 1415 patients were included in the study.

A multimodal preoperative evaluation system was used to assess the preoperative clinical cancer stage[19]. Clinical Stages Ⅲ and Ⅳ patients were treated with neoadjuvant and adjuvant chemotherapy consisting of FOLFOX-4 (Oxaliplatin 85 mg/m^2 ivgtt 2 h, 1 d; LV 200 mg/m^2 ivgtt 2 h, 1-2 d; 5-Fu 400 mg/m^2 *iv*, 1-2 d). Perioperative radiation is not used at our centre.

Surgery was performed by traditional open laparotomy as the standard procedure. Mini-laparotomy was performed on an ad-hoc basis, with increasing frequency in the latter years of this study. No patient within the mini-laparotomy group was converted to a traditional laparotomy.

Short-term perioperative data were obtained in all cases. Long-term follow-up data were available from 7 to 103 mo. The follow-up methods used included telephone follow-up, outpatient department follow-up and follow-up letters. Follow-up data were obtained in 96.3% of cases (1362/1415).

Operation and clinical management procedures

TME and pelvic autonomic nerve preservation were performed in all cases in accordance with the Colorectal Surgery Guideline of West China Hospital of Sichuan University[20]. The surgery and perioperative management were performed by the same clinical team for both the traditional open laparotomy and mini-laparotomy groups.

A vertical incision was used for all cases. The traditional laparotomy incision extended from the pubis to above the umbilicus with a length of 13 to 18 cm, as in Figure 1. The mini-laparotomy incision extended from

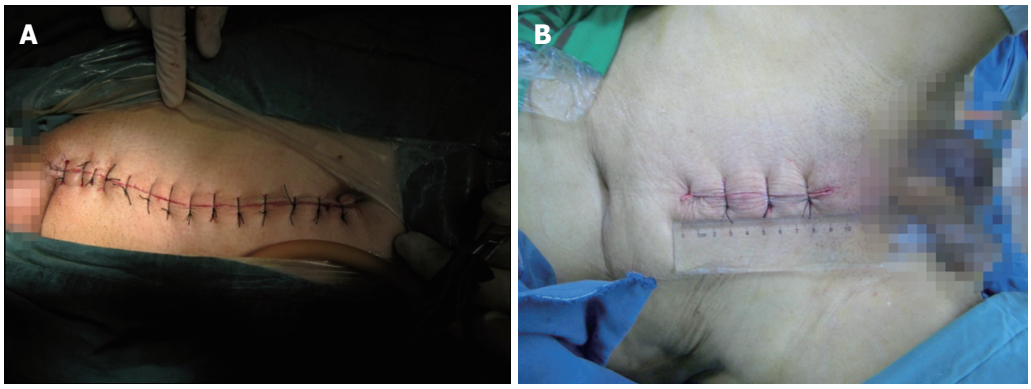

Figure 1 Mini-laparotomy (A) and traditional laparotomy (B).

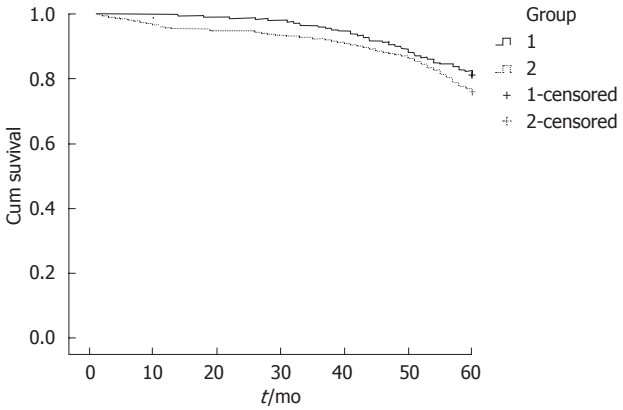

Figure 2 Survival rates of the mini-laparotomy (1) and traditional laparotomy groups (2).

the pubis for a length of 12 cm or less. For the traditional laparotomy, a fixed self-retaining retractor was used on the incision, and a moveable curved retractor was used for dynamic exposure during dissection. In mini-laparotomy, two curved retractors were used in dynamic exposure during dissection without a fixed abdominal wound retractor. Dissection was performed using electrocautery and an ultrasonic knife in both open laparotomy and mini-laparotomy. In both mini-laparotomy and traditional laparotomy, the splenic flexure was not mobilised. The superior rectal artery was ligated just below the bifurcation of the inferior mesenteric artery with clearing of the superior rectal artery lymph nodes.

A post-operative fast-track protocol was used[21,22] with early ambulation. Discharge criteria included eating a normal diet, normal ambulation, no fever, and no post-operative complications.

Definition of outcome

The primary outcome variables are 5-year survival and local recurrence. Local recurrence was classified as intro-/peri-anastomotic and pelvic recurrence. Secondary outcomes are immediate postoperative complications, including physiologic and operative severity score for the enumeration of mortality and morbidity (POSSUM) score[23], and recovery functions (the time of the first aerofluxus, defecation, ambulation, and oral feeding during the recovery phase). In addition, the patients' postoperative complications were recorded as important information about secondary outcomes, which included gastric retention, incision infection, pulmonary infection, anastomosis leakage, and intestinal obstruction.

Statistical analysis

The mini-laparotomy and traditional laparotomy data were compared and analysed with *t* tests, and the count data used the χ^2 test or Fisher's exact probability test. Local recurrence and overall survival were assessed using Kaplan-Meier survival curve analysis. The data are expressed as means ± SD. The significance level was 0.05. Statistical tests were performed using SPSS 15.0.

RESULTS

Baseline characteristics

The characteristics of the 1415 included patients (410 mini-laparotomy cases and 1005 traditional laparotomy cases) are presented in Table 1. There were no significant difference in the baseline data for the two groups ($P > 0.05$). The surgical and pathological findings are presented in Table 2, and there were no significant differences between the two surgical groups ($P > 0.05$).

Overall survival and local recurrence

Overall 5-year survival did not differ between the mini-laparotomy and traditional laparotomy groups (80.6% *vs* 79.4%, $P = 0.333$; Figure 2). The 5-year survival rates for the different clinical stages were also similar. One-year mortality was decreased in the mini-laparotomy group compared to the traditional laparotomy group (0% *vs* 4.2%, $P < 0.0001$). The overall 1-year survival rates in the traditional group were 100% for Stage Ⅰ, 98.4% for Stage Ⅱ, 97.1% for Stage Ⅲ, and 86.6% for Stage Ⅳ. Local recurrence did note differ between surgical groups at 1 or 5 years. Local recurrence at 1 year was 0.5% (2 cases) for the mini-laparotomy group and 0.5% (5 cases) for the traditional laparotomy group ($P = 0.670$). Local recurrence at 5 years was 1.5% (6 cases) for the mini-laparotomy group and 1.4% (14 cases) for the traditional laparotomy group ($P = 0.544$).

Table 1 Baseline characteristics of the mini-laparotomy and traditional laparotomy groups

	Minilaparotomy (n = 410)	Traditional laparotomy (n = 1005)	P value
Gender			0.125
Male	273 (66.6)	635 (63.2)	
Female	137 (33.4)	370 (36.8)	
Age (yr)	61.2 ± 12.1	57.8 ± 12.4	0.385
BMI (kg/m^2)	21.3 ± 3.0	22.0 ± 2.9	0.331
Distance to dentate line (cm)	8.2 ± 3.2	7.2 ± 4.0	0.118

BMI: Body mass index.

Distal margin of distance (cm)	7.0	6.9	0.780

TNM: Tumor-node-metastasis. Data are presented as n (%) or mean ± SD.

Short-term recovery and postoperative complications

The data regarding postoperative recovery functions (time of first aerofluxus, defecation, ambulation and oral feeding), length of hospital stay, and immediate postoperative complications, including POSSUM score, are shown in Table 3. Days to first ambulation and aerofluxus and hospital length of stay were reduced for the mini-laparotomy group compared with the traditional laparotomy group. Days to tolerating full oral diet and first defecation were similar between surgical groups. POSSUM scores predicting mortality and morbidity were not different between the surgical groups.

Gastric retention and wound and pulmonary infection were not different between the surgical groups. Anastomotic leakage and intestinal obstruction were decreased in the mini-laparotomy group compared with the traditional laparotomy group. Other postoperative complications,

Table 3 Postoperative recovery of the two groups

	Minilaparotomy group	Traditional laparotomy group	P value
Recovery			
Aerofluxus (d)	3.5 ± 1.1	4.3 ± 1.8	0.000
Oral feeding (d)	4.1 ± 1.2	4.6 ± 1.2	0.628
Defecation (d)	5.0 ± 1.4	5.4 ± 1.5	0.370

Jung *et al*[7]	8.0	62.0

including urinary retention (2 cases *vs* 6 cases), urinary tract infection (0 case *vs* 2 cases), anastomotic bleeding (1 case *vs* 2 cases), intra-abdominal haemorrhage (0 case *vs* 1 case), wound dehiscence (1 case *vs* 2 cases), sexual dysfunction (1 case *vs* 3 cases), deep vein thrombosis (0 case *vs* 0 case), cardiocerebral vascular accident (0 case *vs* 0 case), psychosis (2 cases *vs* 4 cases), liver dysfunction (1 case *vs* 2 cases), and unknown fever (5 cases *vs* 13 cases) also did not differ between the two surgical groups.

DISCUSSION

The overall 5-year survival and local recurrence rates were not different between the mini-laparotomy and traditional laparotomy groups. The local recurrence and survival rates for mini-laparotomy (1.4% and 79.7%) compare favourably to those reported for traditional laparotomy, as shown in Table 4.

In our study, the results confirmed that the mini-laparotomy and traditional laparotomy groups had similar overall 5-year survival and local recurrence rates, but the minilaparotomy group experienced faster postoperative recovery and fewer complications. It may be that mini-laparotomy surgery is the safer and more effective operation for rectal cancer.

An improved understanding of pelvic anatomy has enabled the switch to a mini-laparotomy approach to rec-

tal cancer resection. Whereas others have reported on the use of mini-laparotomy mostly for colon cancer, we are among the first to report on the use of mini-laparotomy for the resection of rectal cancer[8,9,12]. There is a learning curve for the mini-laparotomy approach. However, we speculate that the learning curve is lower than that of laparoscopic proctectomy because standard instrumentation, direct vision and tactile feedback are maintained for mini-laparotomy, but not for laparoscopy. We have used mini-laparotomy for rectal resection in Chinese patients with a body mass index (BMI) of 21.3 kg/m^2 as the Chinese population is generally thinner than North American and European populations[24]; however, we also treat patients with BMIs > 27 using mini-laparotomy. Additionally, although splenic flexure mobilisation was not required for any patient in this sample, it is likely that the surgeon would be disadvantaged by the suprapubic mini-laparotomy approach if splenic flexure mobilisation was required to perform a low tension-free anastomosis. Mini-laparotomy was not associated with an increase in operative blood loss or operation time. In fact, mini-laparotomy was associated with the successful resection of all levels of rectal cancer.

Like laparoscopic colorectal resection[25], mini-laparotomy showed advantages in decreasing the postoperative length of hospital stay and was associated with shorter times to ambulation and aerofluxus[1,11]. Mini-laparotomy was associated with significantly decreased anastomotic leaking, a finding for which we have no ready explanation other than increased experience over the time of the study. The anastomotic leak rate of 0.5% compares favourably to that reported in other studies[26-28]. In addition, mini-laparotomy was associated with decreased postoperative intestinal obstruction, which may have resulted from less peritoneal manipulation and a shorter incision length. A Japanese study suggested that the mini-laparotomy approach in colorectal cancer would result in a reduced inflammatory response[29]. Furthermore, mortality at 1 year was significantly increased in the traditional laparotomy group compared with the mini-laparotomy group.

Although postoperative management was intended to be similar for mini-laparotomy and traditional laparotomy patients, as indicated by the time before achieving a full oral diet and defecation, traditional laparotomy patients were slower to ambulate. Bias in favour of the mini-laparotomy group is likely, as this procedure has gained favour in our hands with our increasing experience over the time of this study. A randomised study design is indicated to minimise this bias. The study was a single-centre series with experienced TME surgeons and a patient sample with a relatively small BMI. Because our hospital is a medical centre in southwestern China, our patients are primarily advanced cancer cases, and we have more experienced surgeons and more advanced surgical instruments than other small-to-medium sized local hospitals. Consequently, the study and results had an obvious selection bias. Further evaluation is required to evaluate the use of this approach in a larger patient sample and by other surgical teams, and our conclusions are not definitive.

In conclusion, we have shown that mini-laparotomy is a safe and effective new approach for minimally invasive rectal cancer surgery. This was a single-centre series with experienced TME surgeons and a patient sample with a relatively low BMI. Further evaluation is required to evaluate the use of this approach in a larger patient sample and by other surgical teams.

COMMENTS

Background

Total mesorectal excision (TME) is acknowledged worldwide as the preferred technique for surgical resection of rectal cancer. The laparoscopic approach to TME resection of rectal cancer is currently being evaluated in multicentre randomised trials. A less-recognised surgical technique aimed at improving postoperative recovery is mini-laparotomy. With this technique, surgical dissection is performed under direct vision, as in open surgery; laparoscopic equipment and training is not required. Early experience with mini-laparotomy has been reported from a few medical centres in case series of colon and rectal resection. Mini-laparotomy has been developed as a techniques based on the advanced recognition of more information about pelvic anatomy and the dissection of subtle perirectal structures in laparotomy.

Research frontiers

An improved understanding of pelvic anatomy has enabled the switch to a mini-laparotomy approach to rectal cancer resection. Other studies have reported on the use of mini-laparotomy mostly for colon cancer, but for rectal cancer, it is still in blank. Like laparoscopic colorectal resection, mini-laparotomy showed advantages in decreasing the postoperative length of hospital stay and was associated with shorter times to ambulation and aerofluxus in past studies

Innovations and breakthroughs

Whereas others have reported on the use of mini-laparotomy mostly for colon cancer, the authors are among the first to report on the use of mini-laparotomy for the resection of rectal cancer. There is a learning curve for the mini-laparotomy approach. However, the authors speculate that the learning curve is lower than that of laparoscopic proctectomy because standard instrumentation, direct vision and tactile feedback are maintained for mini-laparotomy, but not for laparoscopy. Mini-laparotomy was associated with significantly decreased anastomotic leaking, a finding for which the authors have no ready explanation other than increased experience over the time of the study. The anastomotic leak rate of 0.5% compares favourably to that reported in other studies. In addition, mini-laparotomy was associated with decreased postoperative intestinal obstruction, which may have resulted from less peritoneal manipulation and a shorter incision length. Furthermore, mortality at 1 year was significantly increased in the traditional laparotomy group compared with the mini-laparotomy group.

Applications

The study results suggest that mini-laparotomy is a safe and effective new approach for minimally invasive rectal cancer surgery.

Terminology

Minilaparotomy is minimal invasive laparotomy for abdominal operations. It is different from laparoscopic operations, that minilaparotomy will have only one mini-incision, but not other holes from laparoscopic way. Minilaparotomy would be more better outcomes than traditional laparotomy.

Peer review

This is a good descriptive study conducted in a single-centre series with experienced TME surgeons, and mini-laparotomy is proved a safe and effective new approach for minimally invasive rectal cancer surgery. Minilaparotomy will be the future choice for rectal cancer care.

Abstract

AIM: To compare fluoroscopic, endoscopic and guide wire assistance with ultraslim gastroscopy for placement of nasojejunal feeding tubes.

METHODS: The information regarding nasojejunal tube placement procedures was retrieved using the gastrointestinal tract database at Tongji Hospital affiliated to Tongji Medical College. Records from 81 patients who underwent nasojejunal tubes placement by different techniques between 2004 and 2011 were reviewed for procedure success and tube-related outcomes.

RESULTS: Nasojejunal feeding tubes were successfully placed in 78 (96.3%) of 81 patients. The success rate by fluoroscopy was 92% (23 of 25), by endoscopic technique 96.3% (26 of 27), and by guide wire assistance (whether *via* transnasal or transoral insertion) 100% (23/23, 6/6). The average time for successful placement was 14.9 ± 2.9 min for fluoroscopic placement, 14.8 ± 4.9 min for endoscopic placement, 11.1 ± 2.2 min for guide wire assistance with transnasal gastroscopic placement, and 14.7 ± 1.2 min for transoral gastroscopic placement. Statistically, the duration for the third method was significantly different ($P < 0.05$) compared with the other three methods. Transnasal placement over a guidewire was significantly faster ($P < 0.05$) than any of the other approaches.

CONCLUSION: Guide wire assistance with transnasal insertion of nasojejunal feeding tubes represents a safe, quick and effective method for providing enteral nutrition.

Evaluation of a new method for placing nasojejunal feeding tubes. *World J Gastroenterol* 2012; 18(37): 5295-5299 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i37/5295.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i37.5295

INTRODUCTION

Enteral nutrition (EN) not only provides energy support as with parenteral nutrition, but also maintains the functional intestinal barrier, significantly reducing the incidence of infection and organ failure, shortens hospital

stays, and lowers treatment costs[1-4]. EN has therefore become an important nutritional therapy[5]. A nasogastric (NG) tube is often associated with some problems of large gastric residual volumes, reflux and vomiting, while a nasojejunal (NJ) tube and prokinetic agents are useful for circumventing the problems associated with upper gastrointestinal intolerance of NG feeding[6]. NJ feeding tubes positioned beyond the ligament of Treitz's have been shown to allow early attainment of caloric needs and a reduction in tube-feeding aspiration events in patients with gastric feeding intolerance[7,8]. There are presently several methods for placement of NJ feeding tubes[9-11]. Previously, we would use fluoroscopic placement under direct endoscopic visualization instead of using NJ tubes.

Recently, we have applied an ultrathin transnasal endoscope which afforded us a higher success rate and a shortened procedure time. Herein we evaluated the usefulness and safety of this new method compared with the other two traditional methods.

MATERIALS AND METHODS

Patients

This is a retrospective study involving the patients who were treated with enteral feeding from January 2004 through September 2011 at our hospital. Written informed consent was obtained from all patients or their representatives. The Ethics Committee of Tongji Hospital, Tongji Medical College of Huazhong University of Science and Technology, approved the study protocol. All subjects were $\geqslant$ 18 years of age. The technique, success rate, procedure duration, and complications were recorded for each patient. Patient sex, age and diseases were also recorded. According to the placement methods, the patients were divided into three groups as described below. A 130-cm long polyurethane nasoenteral feeding tube with a front-end opening (Flocare, Nutricia, Netherlands) was used in each case. All NG tubes were removed before the start of the procedure, as they might have interfered with placement of both the feeding tube and endoscope.

Fluoroscopic technique

The feeding tube was placed by one skilled doctor. Some gastroenterologists were also involved in the fluoroscopy. Additional sedation was not required for fluoroscopic tube placement. A portable C-arm fluoroscope was positioned over the supine patient's abdomen. The timing of the procedure began when the feeding tube entered the nares. When the tube was advanced to 50-55 cm, its position was evaluated by intermittent fluoroscopy. The operators rotated the feeding tube to facilitate passage to the pylorus. Fluoroscopy was used intermittently or continuously as needed. When the tip of the feeding tube was beyond the pylorus, it was gently advanced as far as possible. Placement of the tube beyond the third portion of the duodenum was preferred. Finally, a fluoroscopic print was obtained after 10-15 mL of meglumine diatrizoate was injected into the feeding tube.

Endoscopic technique

All feeding tubes were placed at the Endoscopy Center by one skilled endoscopist. The posterior oropharynx was anesthetized with topical 4% Xylocaine. The timing of the procedure began when the feeding tube entered the nares. The lubricated feeding tube was inserted into the stomach and advanced until resistance was encountered (usually 55-60 cm), and the wire stylet was left in place. At this point, a standard forward-viewing endoscope (Olympus GIF 240 or 260, Olympus Corporation, New York, NY, United States) was placed into the esophagus and then the stomach. The stomach was insufflated with air, and the feeding tube usually traveled along the greater curvature of the stomach. The feeding tube was advanced to the nasopharynx. The distal 10-20 cm of the feeding tube was grasped by the biopsy forceps, and then the tip of the catheter was directed into the pylorus under endoscopic visualization. The feeding tube was then advanced at the nasopharynx, its distal 10-20 cm grasped with biopsy forceps and the tip directed through the pylorus under direct vision. When the feeding tube was observed in a good position, the endoscope was carefully withdrawn with the feeding tube secured by the forceps, which was advanced along with the withdrawal of the endoscope. When the forceps could no longer advance, the endoscope movement was stopped and the forceps was gently pulled back to the end of the lens. Then the forceps was again used to grasp the feeding tube and the above process was repeated until the endoscope was removed completely from the throat. The wire stylet was removed and a fluoroscopic print was obtained after 10-15 mL meglumine diatrizoate was injected into the feeding tube to confirm placement of the feeding tube into the second or third portion of the duodenum.

Guide wire technique

Topical Xylocaine was sprayed into the nose and retropharynx in conscious patients. The tip of the ultraslim transnasal endoscope with an outer diameter of 5.0 mm (Olympus XP-260N, Olympus Corporation, New York city, NY) was then passed under direct vision into one of the nasal passages. Extreme care was taken to avoid traumatizing the mucous membranes. After the endoscope arrived at the third portion of the duodenum, a 260-cm long guide wire with a soft tip (Zebra Exchange Guidewire, Boston Scientific, United States) was inserted along the endoscopic biopsy channel. Using a pull-push technique, the endoscope was slowly withdrawn while the wire was simultaneously threaded forward, so that the wire stayed in a fixed position in the intestine. Before exiting the stomach, the path made by the wire was studied and adjusted to ensure that there were no coils or loops within the gastric body. After withdrawal of the endoscope, an open-ended feeding tube was lubricated and passed over the guide wire, ensuring that the wire remained taut and

Table 1 Patient characteristics

Patient characteristics	Fluoroscopic placement	Endoscopic placement	Guide wire placement
Age (yr), mean ± SD	54.4 ± 9.9	55.8 ± 9.7	56.2 ± 9.5
Gender			
Men	15	14	16
Women	10	13	13
Primary diagnoses			
Pancreatitis	25	14	8
Postoperative gastric cancer	0	6	10
Postoperative esophageal cancer	0	4	6
Abdominal injury	0	1	2
Pancreatic cancer after Whipple surgery	0	1	1
Thoracic esophageal fistula	0	1	1
Gastric perforation	0	0	1

in place. Care was taken not to over-advance the tubes because this often results in coiling in the stomach and loss of duodenal access. Finally, using the adjacent naris, the endoscope was reintroduced into the proximal stomach to check final placement. In most cases, the hub of the wider gastric aspiration tube was too short and had to be advanced gently into the antrum visually, making sure that the tube remained straight along the greater curvature and that the jejunal extension slid further through the pylorus. With an assistant securing the feeding tube to prevent displacement, the endoscope was then eased back into the apex of the body to check the final position before exiting the esophagus. Transnasal endoscopy was not feasible in patients with congestion or stenosis of the nasal passageway. Conventional per-oral endoscopy was used to place the guide wire, which consequently ended up emerging from the mouth. The wire was then redirected through the nose by nasopharyngo-oral cannulation with a small 2-mm internal diameter flexible tube, allowing final placement of the NJ feeding tube.

Statistical analysis

All data were presented as the mean ± SD. The SPSS 15.0 software package (SPSS, Inc., United States) was used for all statistical analyses. Differences between and among outcome groups were determined using the χ^2 test. Significance was determined at P <0.05.

RESULTS

Patient characteristics

Demographic data of the included patients are shown in Table 1. The mean age was 55.5 years (range: 24-70 years). There were 45 men and 36 women. Common primary diagnoses were pancreatitis, postoperative gastric cancer, postoperative esophageal cancer, abdominal injury, pancreatic cancer after Whipple surgery, thoracic esophageal fistula and gastric perforation. All patients demonstrated either high gastric residuals on attempted NG feeding or a physiologic requirement for postduodenal enteral feedings (i.e., pancreatitis), or they were believed to be at high risk for gastric aspiration.

Table 2 Outcome data of the patients

Variables	Fluoroscopic placement	Endoscopic placement	Guide wire placement	
			Transnasal	Transoral
Time to complete procedure (min)	14.9 ± 5.8	14.8 ± 4.9	11.1 ± 2.2[a]	14.7 ± 1.2
Successful placement	23/25 (92)	26/27 (96.3)	23/23 (100)	6/6 (100)
Complications	0/25 (0)	4/27 (14.8)	0/23 (0)	0/6 (0)

Data are presented as mean ± SD or *n/N* (%). [a]P < 0.05 *vs* the other three groups.

Patient outcomes

Outcome data of the patients are shown in Table 2. NJ feeding tubes were successfully placed in 78 of 81 (96.3%) patients. The success rate by fluoroscopy was 92% (23 of 25), by endoscopic technique was 96.3% (26 of 27), and by guide wire was 100% with either transnasal endoscopy or transoral endoscopy. Significant differences between the guide wire assistance with transnasal ultraslim endoscopy and the other three groups were noted in placement duration, whereas there were no significant differences among the other three treatment groups. No significant differences among all the groups were noted in the success or complication rate. No complications were reported from fluoroscopic placement. There were four instances of epistaxis related to replacement of the NG tube after endoscopic placement. All cases of epistaxis resolved without intervention. There was no death related to either procedure.

DISCUSSION

It is well known that malnutrition of critically ill patients is associated with poorer clinical outcomes, and early, sufficient nutritional support can significantly improve the outcomes of the patients[12-16]. EN support is indicated for patients who are unable to take foods orally but have normal intestinal function[17,18], such as those with severe acute pancreatitis, cerebrovascular accidents, traumatic brain injury, *etc*. EN can be delivered through NG tube or NJ tube. The complications of upper gastrointestinal intolerance to EN has been reported to occur in 31%-46% of the patients with NG feeding, some prokinetic agents such as metoclopramide and erythromycin were used to enhance gastric motility and tolerance of enteral feeding. Whether it should be reserved for those patients who are at high risk of upper gastrointestinal intolerance or have already experienced it while receiving NG feeding, requires further studies. Moreover, the optimal dose remains unknown. NJ feeding leads to fewer gastrointestinal complications, largely by reducing gastric residual volumes. So placement of a NJ feeding tube to provide energy support or medication, is increasingly used as a standard clinical practice for many patients[19-21].

But how to place the NJ feeding tube quickly and safely remains an important technique for doctors. The approaches of placing NJ tubes include placement at

surgery, under fluoroscopic or ultrasound-guidance, at endoscopy and blind introduction at the bedside with or without prokinetic administration. The Cathlocator™ is a novel device that permits real time localization of the end of feeding tubes through generating a low energy electromagnetic field from a coil incorporated in the tip of a modified enteral feeding tube connected by wires to a proximal interface. Previously, we would use fluoroscopic placement and/or under direct endoscopic visualization to place NJ tubes. Recently, we have used an ultrathin transnasal endoscope that afforded us a greater success and a shortened procedure time. We evaluated three common methods used to place NJ feeding tubes.

Many studies reported that fluoroscopic guidance in the placement of NJ feeding tubes had a success rate of > 84%[22-24], and endoscopic placement presented a success rate ranging from 90% to 100%[25,26], which are consistent with our outcome. However, fluoroscopic placement exposed patients and doctors to varying doses of radiation. Endoscopic placement procedures are often time consuming, technically cumbersome, and require a significant learning curve[27]. As a result, most gastroenterologists and surgical endoscopists are not satisfied with the current techniques of endoscopic placement. We therefore described a new method to place NJ tubes through guide wire assistance with ultraslim gastroscopy.

Our experience with 29 consecutive guide wire placements of feeding tubes showed that the technique was successful in most patients. Before the operation, we asked the patient whether he/she had received nasal surgery before, and whether accompanied by associated diseases, such as severe bending septum, nasal polyps, severe rhinitis, often epistaxis and other diseases. Six patients who had the aforementioned diseases and subsequently changed to transoral insertion also had the tube placed smoothly in the correct position. In 6 patients with the above complaints, where the assembly was inserted using the transoral route, this did not impair smooth passage of the feeding tube into the correct position. No complications were reported from these methods. Transnasal insertion possessed many advantages compared with other methods. Firstly, the total success rate in the feeding tube placement was high, up to 100%. The operative point was the retropulsion of the feeding tube from the small intestine to the stomach when the endoscope or guide wire was withdrawn. It is not easy to place the guide wire at or beyond the Treitz's ligament using a common endoscope. However, with the transnasal ultraslim endoscope, it became less difficult. Moreover, before inserting the feeding tube along the guide wire, it is very important to lubricate the inner lumen of the feeding tube with paraffin in advance. It not only makes the procedure of withdrawing the guide wire easier, but also avoids pulling out the feeding tube. Secondly, the procedure required less time. In 23 cases with successful one-time transnasal tube placement, the average time required from endoscopic transnasal insertion to the complete removal of the guide wire was only 11.1 ± 2.2 min. Thirdly, the procedure was safe and produced few complications.

In conclusion, our experience showed that the technique of placing NJ feeding tubes with the transnasal ultrathin endoscope is quick, effective and safe.

ACKNOWLEDGMENTS

We thank Professors Nan-Zhi Liu, De-An Tian and Yu-Zhen Yang for their invaluable help with the endoscopic procedures.

COMMENTS

Background

Enteral nutrition (EN) not only provides energy support as with parenteral nutrition, but also maintains the functional intestinal barrier, significantly reducing the incidence of infection and organ failure, shortening hospital stays, and lowering treatment costs. Placement of a nasojejunal (NJ) feeding tube with the aim of providing metabolic support or medication, is increasingly used as a standard clinical practice for many patients.

Research frontiers

NJ feeding tubes positioned beyond the ligament of Treitz's have been shown to allow early attainment of caloric needs and a reduction in tube-feeding aspiration events in patients with gastric feeding intolerance. There are presently several methods for placement of NJ feeding tubes.

Innovations and breakthroughs

The authors used guide wire assistance to place NJ tubes, using an ultrathin transnasal endoscope that afforded them a higher success rate and a shortened procedure time. The authors evaluated the usefulness and safety of the new method compared with the other two traditional methods.

Applications

The technique of placing NJ feeding tubes with the transnasal ultrathin endoscope is quick, effective and safe, which can be applied in clinical practice.

Terminology

Guide wire technology means through guide wire to place NJ feeding tubes. Guide wire was placed beyond the ligament of Treitz's under the ultraslim transnasal endoscope.

Peer review

This article directly compared guide wire method with other two old methods in the duration, success and complications, providing sufficient evidence to prove the superiority of the guide wire method.

Abstract

We recently presented the case of a first century AD young woman, found in the archaeological site of Cosa, showing clinical signs of malnutrition, such as short height, osteoporosis, dental enamel hypoplasia and cribra orbitalia, indirect sign of anemia, all strongly suggestive for celiac disease (CD). However, whether these findings were actually associated to CD was not shown based on genetic parameters. To investigate her human leukocyte antigen (HLA) class Ⅱ polymorphism, we extracted DNA from a bone sample and a tooth and genotyped HLA using three HLA-tagging single nucleotide polymorphisms for DQ8, DQ2.2 and DQ2.5, specifically associated to CD. She displayed HLA DQ 2.5, the haplotype associated to the highest risk of CD. This is the first report showing the presence of a HLA haplotype compatible for CD in archaeological specimens.

INTRODUCTION

In 2008, we were involved in the "case of Cosa", a skeleton of a young woman dating to the first century AD, found in the archaeological site of Cosa, southwest of Tuscany, Italy (Figure 1)[1]. Based on the physical anthropology description[2], she was a 18-20 year -old woman, dead in physical impairment, showing signs of failure to thrive and malnutrition, all signs of typical celiac disease (CD), in particular, she was slightly built and moderately short for her age (140 cm in height), with clear signs of bone fragility and osteoporosis. She showed on her orbital roof a pathological sign, the "cribra orbitalia" (yet published)[1], a bone porosity also well distinguished in the bone of the skull vault. This condition is generally linked to bone marrow hypertrophy following anemic conditions, such as iron deficient chronic anemia. This

excessive porosity could be also found in the external surface of the bones, in particular in the skull vault (Figure 2A). Furthermore she showed the bone marrow reactive hypertrophy associated to bone atrophy (Figure 2B). Although teeth structure and number were normal, she presented basal dental enamel hypoplasia (Figure 2C), a marker of nutritional or infectious stress. Measuring in the femur the angle between the neck and the diaphysis, it appears larger than normal adult angle (135° *vs* 125°), consistent with a diagnosis of coxa valga, typical of the hip subluxation, due to congenital dysplasia. This diagnosis is supported by the flattening of the postero-superior part of the acetabular cavity. All these signs, taken together, strongly suggested an advanced state of chronic malnutrition, consistent with a typical form of CD[3-5]. From the beginning, a poor availability of food was excluded as several signs indicated that she was member of a wealthy family, as suggested by the jewels she wore and by the overall quality of her tomb. Based on ethologic data[6], we considered that her diet was variegated and probably rich in wheat, and consequently in gluten. We hypothesized that the young woman suffered from CD. Moreover, her death was caused by severe malnutrition or by a complication of it.

The most ancient case of CD ever described was reported by Areteus of Cappadocia in the 1st-2nd centuries AD[7], indicating that CD could have a old origin. However the appearance of the predisposing haplotypes in humans as well as the origin of CD is still unknown.

Genetic susceptibility is a crucial step in the pathogenesis of CD, as demonstrated by studies on monozygotic twins, that show disease concordance rate of 75% compared with 11% in dyzigotic twins[8]. Furthermore siblings have an increased risk of CD, of which about 40% depends on human leukocyte antigen (HLA) genes[9]. The role of HLA class Ⅱ molecules as the major genetic risk factor for CD is well known, even if the genetic effect attributable to HLA is only 54%[10]. It has been reported that over 90% of CD patients express HLA-DQ2 heterodimer while the others express HLA-DQ8[11]. In Europe only fewer than 0.5% of celiac patients express neither DQ2 nor DQ8[12], making HLA genotyping a marker with a very powerful negative predictive value, excluding the diagnosis in people who do not have CD risk HLA haplotype. Until present no information were available on CD genetics in ancient time, since DNA analysis of human remains is technically difficult.

CASE REPORT

In order to confirm the clinical hypothesis that the young woman was actually suffering from CD, we extracted DNA from parts of the skeleton and studied HLA polymorphisms known to be involved in susceptibility to CD. In particular, we analyzed DQ2 (encoded by the *DQA1* 05* and *DQB1*02* alleles) and DQ8 (encoded by the *DQA1*03* and *DQB1*0302* alleles) HLA heterodimers[13,14].

Ancient DNA analysis of human remains is particularly challenging, therefore every attempt was made to ensure the generation of authentic and meaningful data following the strictest available criteria[15-19]. To extract the genetic material, a bone sample and the left mandibular third molar (Figure 2D) were chosen since they are the best sources of DNA. Bones and teeth consist of hard material that contains small hollow spaces with single cells that are less affected by diagenetic processes and by natural contamination (microorganisms, fungus), and modern contaminations are likely to be removed prior to extraction. Bone and tooth sample were firstly brushed and irradiated for 1 h under ultraviolet (UV) light. Afterwards, the entire surface was removed by using dental drills, and the samples were cut into smaller pieces with drill. The samples were again UV-irradiated for 45 min, grounded to fine powder and stored until use at 4 ℃. Only commercially certified DNA/RNA-free consumables were utilized and all tools and containers used were sterile and DNA-free. All workers wear gloves, safety masks, disposable coveralls, plus particular shoes. Every item entering is extensively washed with bleach and subsequently UV-irradiated.

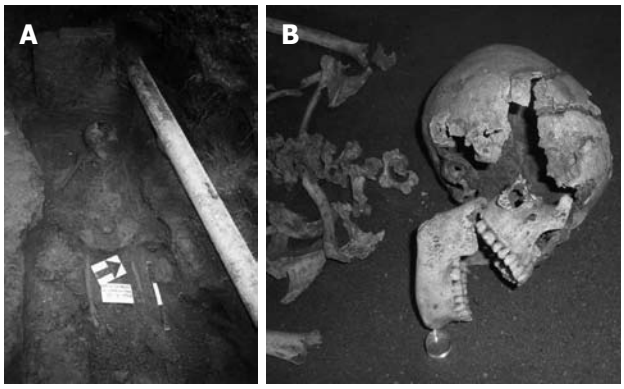

Figure 1 A particular of the skeleton of Cosa in the original site. A: The original site: The ancient remains of Cosa in the original site where they were found; B: The young girl: A particular of the skeleton of the young girl of Cosa.

As first step, we studied the preservation of bone collagen, one of the best indicator of bone preservation and therefore of DNA survival[16]. Collagen was extracted from a small bone fragment following the procedure reported in Craig *et al*[20]. The results obtained indicated the good state of preservation of the collagen. In fact, collagen yield expressed as weight percentage was 1.065% and the ratio C/N was in the range between 3.25 and 3.34 as expected when organic substances are saved from decay[21]. Based on these results, DNA extraction was performed in a laboratory physically isolated from all other laboratories which offers all the state-of-the-art facilities for aDNA studies[17,22,23]. They consist of a contamination resistant facility, which are maintained at positive pressure, frequently cleaned with HCl, NaClO and DNAzap™, UV and high-efficiency particulate arresting filtered, and have restricted access, designed to minimize the possibility of contamination with extant human DNA[23]. The laboratory has consecutive rooms, every room is fitted with UV-C light sources (254 nm) that can be switched on and off from outside the re-

SNPs: Single nucleotide polymorphism.

spective lab. The first room has an entry area for changing into suitable clean room clothing. The second room has bench space for handling sampling with fine scale for weighing of samples, a dentist drill for cutting and drilling samples as well as mortars and pestles for griding samples. Another two independent labs with hoods (with internal UV-C sources and biosafety cabinets) are used for DNA extraction and one other for polymerase chain reaction (PCR) setup.

Briefly five hundred milligrams of powder were digested in a proteinase K lysis buffer and DNA was extracted through silica-based spin columns[24]. At least two independent DNA extractions were performed on bone and teeth respectively; mock-extraction controls were carried out identically to those on the samples.

Three HLA-tagging single nucleotide polymorphism (SNPs) were genotyped in order to capture the DQ8, DQ2.2 and DQ2.5 HLA types as reported by Monsuur *et al*[25], using TaqMan chemistry and the on demand assays by Applied Biosystems (Foster City, CA, United States, www.appliedbiosystems.com: Assay IDC_29817179_10dbSNP ID rs7454108; Assay IDC_29315313_10dbSNP ID rs7775228; and Assay IDC_ 58662585_10dbSNP ID rs2187668). Negative controls for amplification (PCR without template DNA) were set up simultaneously to detect contamination and at least 4 independent amplifications of each fragment were performed.

TaqMan® single nucleotide polymorphism (SNP) genotyping assays provide optimized assays for genotyping SNPs and make it easy to perform SNP genotyping discrimination studies. Samples were amplified and genotyped using the manufacturer's instructions on an ABI Prism 7500 Fast Real Time PCR System (Applied Biosystems, Foster City, CA, United States). All SNPs were typed using the standard amplification protocol as supplied by Applied Biosystems (hold 10 min, at 95 ℃, and 40 PCR cycles with denature 15 s, at 92 ℃ and anneal/extend 1 min, at 60 ℃).

Moreover, in order to confirm the RT-PCR results, we amplified and sequenced the three predictive fragments.

The list of primers designed for the experiment and the length of each PCR fragment analyzed are reported in Table 1. PCR amplification was performed in 25 μL reaction containing 2 μL DNA extract, with a final concentration of 1XPCR Gold Buffer Ⅱ, 2.5 mmol $MgCl_2$, 1 mmol dNTPs, 100 nmol primers, 0.1 mg/mL bovine serum albumin, 1 U AmpliTaq Gold (Applied Biosystems). The PCR reaction was run for 35 cycles at 94° for 30 s, 60 ℃ for 30 s and 72 ℃ for 30 s, with a first denaturation step (94 ℃ for 5 min), and a final extension (72 ℃ for 10 min).

PCR products were visualized by gel electrophoresis on a 1.5% agarose gel stained with GelStar (Cambrex, Rockland, ME, United States). Positive amplification products were purified through ExoSap-IT (USB Affymetrix, Santa Clara, CA) according to manufacturer's specifications. Afterwards, they were labeled with fluorescent dyes, purified by the ethanol precipitation technique and submitted to sequencing reaction in an ABI Prism 3100 Avant (Applied Biosystems, Foster City, CA) following the recommended sequencing kit protocols. Sequences were verified through complete overlapping of forward and reverse strands.

Genetic results were independently reproduced multiple times and all sequences were confirmed by at least two different amplified products in order to identify possible contamination.

The young girl turned out to be homozygous FAM for rs7454108, homozygous FAM for rs7775228, and homozygous VIC for rs2187668. The result is compatible with DQ2.5 homozygous genotype which is associated with higher risk of CD. This finding supports on molecular basis our hypothesis that the skeleton found in the site of Cosa suffered from CD.

Finally, to verify the endogenous nature of aDNA and track down any possible modern contaminations, molecular sex and mtDNA characterizations were performed.

Sex determination was carried out by amplification of a segment of the X-Y homologous amelogenin gene using the primer system amelogenin A/B as described by Mannucci *et al*[26]. This method is usually applied for typing samples of a very degraded nature, since short X and Y-specific products of 106 and 112 bp, respectively are generated from a single primer pair. The result were resolved by 12% Acrylamide electrophoresis. Molecular data confirmed the morphological and morphometric sex diagnosis of being female.

Mitochondrial DNA (mtDNA) typing[27] was performed also on the DNAs of all molecular anthropologists and archaeologists who handled the ancient sample. All the extant sequences differed from the girl "Cosa" consensus mtDNA sequence (16270T, 16362C, 73G, 150T and 263G) excluding modern DNA contamination. The ancient haplotype was certainly phylogenetically assigned to U5b2b1a haplo-group following the classification proposed by van Oven *et al*[28]. This haplo-group is European specific and its PAML (Phylogenetic Analysis by Maximum Likelihood) based age estimate is 9325.2 ± 3443.5 years[29-31].

DISCUSSION

This is the first report of HLA typing in ancient remains and it could be considered a very intriguing result, although it does not allow us to diagnose definitively CD. The presence of CD associated-HLA is a necessary condition, although not sufficient to develop the disease. It fact, although about 30%-35% of the actual general population express CD associated HLA genotypes, it has been estimated that, only 2%-5% of risk gene carriers develop the disease[32]. The risk increases further in homozygous for DQ2.5 (*HLA-DQA1*05- DQB1*02*) as shown by a recent study in United States population[12] and by another study exploring relative risks for CD in European population[33]. Another study, on sibs and parents of Italian celiac children, shows that a DQ 2.5 homozigous sib had a risk of 28% of developing CD[34]. Recent advances indicate that other genetic factors may play a role in determining which HLA compatible people could develop CD[35], particularly genes involved in T-cell regulation and inflammation, but they have not been considered for this paper. It has been reported that these genes are contributing for 3%-4% in the risk of CD, together with environmental factors, like early introduction of gluten in infants diet, early infection with enteropathic viruses or the presence of a changed bacterial flora[32].

In the case of "Cosa", even without precise understanding of how environmental factors impacted the girl's life, HLA typing provide us a precious information. The presence of HLA-DQ2.5, in combination with the phenotypic observations, increases the likelihood that the young girl of Cosa suffered from CD and that CD existed already 2000 years ago, like Areteus hypothesized on clinical bases. Our results, strengthen the idea that CD was born a long time ago, walking along together with humans for a long stretch of their history, perhaps even since wheat feeding was introduced.

Abstract

Schwannoma is a tumor derived from Schwann cells which usually arises in the upper extremities, trunk, head and neck, retroperitoneum, mediastinum, pelvis, and peritoneum. However, it can arise in the gastrointestinal tract, including biliary tract. We present a 24-year-old male patient with obstructive jaundice, whose investigation with computed tomography abdomen showed focal wall thickening in the common hepatic duct, difficult to differentiate with hilar adenocarcinoma. He was diagnosed intraoperatively schwannoma of common bile duct and treated with local resection. The patient recovered well without signs of recurrence of the lesion after 12 mo. We also reviewed the common bile duct schwannoma related in the literature and evaluated the difficulty in pre and intraoperative differential diagnosis with adenocarcinoma hilar. Resection is the treatment of choice for such cases and the tumor did not recur in any of the resected cases.

INTRODUCTION

Although it is considered to be a rare tumor, adenocarcinomas are the most common malignant neoplasms of extrahepatic bile ducts[1,2]. However, other non-epithelial tumors can develop, whether they are malignant, such as lymphomas and neuroendocrine cancer[3], or benign, such as adenomas, lipomas, fibromas and schwannomas[4,5], which sometimes appear similar to hilar adenocarcinomas (cholangiocarcinomas).

The goal of this case study was to present a rare case of common bile duct schwannoma that simulated a hilar adenocarcinoma. It was diagnosed during surgery, which allowed only a local resection.

CASE REPORT

A 24-year-old male patient was clinically diagnosed with

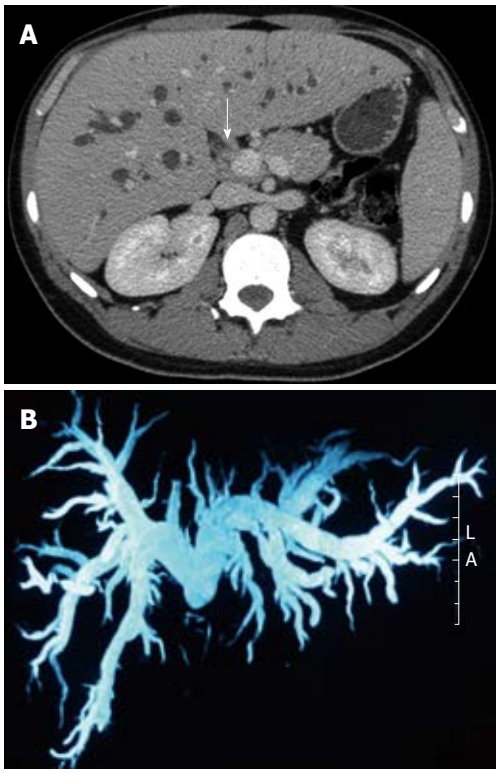

Figure 1 Large dilatation close to hepatic duct. A: Stenosis and thickening of the common hepatic duct (arrow) with upstream biliary dilation; B: Magnetic resonance cholangiography showing large dilatation close to the lesion in the common hepatic duct. A: Ahead; L: Left.

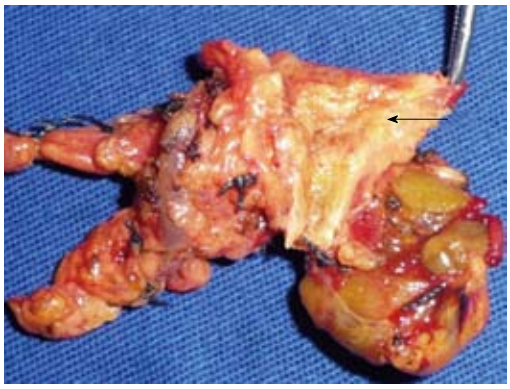

Figure 2 Hepatocholedochal tumor opened longitudinally with the affected area (arrow).

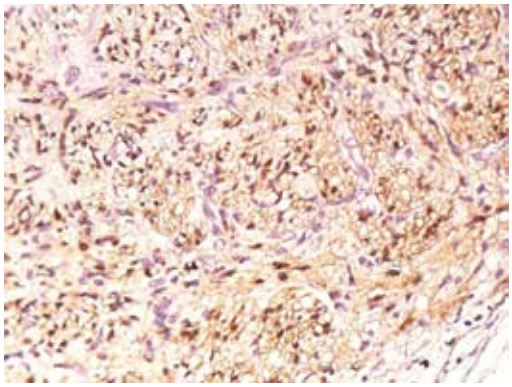

Figure 3 Immunohistochemical staining for the S-100 protein (40 ×).

obstructive jaundice, had 2 mo of epigastric pain and vomiting, and lost 15% of his body weight. The patient had a history of smoking and social drinking. A physical examination confirmed that the patient had jaundice with a flaccid, painless abdomen and palpable liver 4 cm below the right costal margin. There were no other relevant findings.

The laboratory studies revealed: total bilirubin 23.8 mg/dL; direct bilirubin 22.9; serum alkaline phosphatase 298 IU/L; and serum gamma-glutamyl transpeptidase 1052 IU/L; serum asparate aminotransferase 121 IU/L; serum alanine aminotransferase 249 IU/L; and carbohydrate antigen 19-9 was above normal range, 62.7 U/mL. Others laboratory tests were normal.

Imaging studies began with abdominal ultrasound sonography test, which revealed increased liver volume and dilation of the intra-and extrahepatic bile ducts up to the hepatic hilum.

A computed tomography scan of the abdomen showed focal wall thickening in the common hepatic duct 1.5 cm from the hepatic duct confluence. As a result, the diameter of the lumen was reduced, and there was upstream dilation (Figure 1A). The vascular structures and adjacent fat planes were preserved.

A magnetic resonance cholangiography showed biliary tract dilation with abrupt obstruction in the common hepatic duct (Figure 1B).

We opted for surgical treatment without biliary intervention for decompression or endobiliary biopsy, with a preoperative diagnosis of hilar adenocarcinoma. In the cavity, we discovered that the liver was enlarged and appeared to be cholestatic. There was a 1-cm nodular lesion that was palpable in the common hepatic duct; additionally, the proximal bile duct was dilated. A cholecystectomy dissection was performed from the common bile duct above the pancreas to the nodular lesion in the common hepatic duct. During the dissection of the affected area, we observed that the tumor was well defined and regular, with no signs of having infiltrated adjacent tissues (Figure 2). We performed frozen sections, which showed a mesenchymal tumor with free margins in the hepatic duct. In view of these findings, we opted for local resection and Roux-en-Y hepaticojejunostomy.

The patient recovered and was discharged in good condition on the 7th postoperative day. A pathological examination showed a 0.8-cm lesion in the common hepatic duct, which was diagnosed as benign schwannoma with free margins in the extrahepatic bile duct. The diagnosis was made through microscopic examination and immunohistochemistry (Figure 3). The patient was reexamined 12 mo after surgery and was in excellent general health with no signs of recurrence.

DISCUSSION

Benign schwannoma, which is also known as neurile-

F: Female; M: Male.

moma, is a tumor derived from Schwann cells, which form the inner portion of the peripheral nerve sheath[6]. Theoretically, the tumor can affect any organ or nerve trunk, except the optic and olfactory nerves, which lack Schwann cells[7]. The most common locations are the upper extremities, trunk, head and neck, retroperitoneum, mediastinum, pelvis, and peritoneum[8].

Schwannomas in peripheral nerves can be associated with neurofibromatosis type 2, while many schwannomas can occasionally be associated with neurofibromatosis type 1[5,9].

Schwannomas in the digestive tract are relatively rare. These tumors are most common in the stomach followed by the colon/rectum and esophagus[10-12]. Additionally, schwannomas can develop in the biliary tract because there is an abundant network of sympathetic and parasympathetic nerve fibers along the wall of the gallbladder and bile ducts, but these cases are extremely rare[4].

Diagnostic imaging tests do not allow preoperative diagnoses of biliary schwannoma because the findings are similar to those observed in most common lesions, particularly central cholangiocarcinoma. The most relevant finding in our case was that the preoperative examinations revealed a well-defined ductal injury with no signs of adjacent structural involvement or distant metastases[5].

A schwannoma is usually a macroscopically encapsulated solid globular or ovoid tumor. Degenerative cystic changes are occasionally observed within the tumor. Microscopically, the tumor has two components: a hypercellular component with areas of spindle cells forming palisades (Antoni type A) and a myxoid component containing cuboidal cells with clear cytoplasms (Antoni type B)[13].

We found 15 case studies of extrahepatic biliary schwannomas in the literature, which are shown in Table 1. Of these cases, the ages of the patients ranged from 15 to 64 years (with an average age of 44 years), and the patients were predominantly female (12/15). The most common symptom was jaundice (11/15 patients) followed by abdominal pain (7/15) and weight loss (4/15); two patients were asymptomatic. A preoperative diagnosis of hilar adenocarcinoma occurred in 3/15 patients. The lesion was resected in all but one case in which resection was not conducted because of the extensive involvement of the tumor[5]. In this case, endoscopic prosthesis was suggested, but the patient refused the procedure with clinical follow-up. The tumor did not recur in any of the resection cases.

Immunohistochemical analysis is necessary to distinguish schwannomas from neurofibromas, gastrointestinal stromal tumors and leiomyomas. Schwannomas are

strongly positive for vimentin and S100 protein and are negative for muscle cell markers and CD117 (kit), which are found in smooth muscle and gastrointestinal stromal tumors. The CD34 antigen is expressed by a distinct cell population in peripheral nerves, nerve sheath tumors, and related lesions. This antigen is also a useful parameter for the immunohistochemical diagnosis of gastrointestinal stromal tumors. Schwannomas in the digestive tract are usually negative for CD34, although Hou *et al*[14] identified 3 gastrointestinal schwannomas with CD34-positive spindle cells in 33 analyzed cases. Our patient was positive for both the S100 protein, as was expected, and CD34, as in the 3 cases described by Hou *et al*[14].

While there may be preoperative suspicion, the diagnosis of schwannoma requires intraoperative and histopathological confirmation[15]. Despite the possible complications, resection is the treatment of choice for such cases[16]. Schwannomas in the digestive tract have an excellent prognosis after surgical resection, as do schwannomas in other locations. To date, there is no evidence suggesting that these tumors are potentially malignant[4]. In keeping with these findings, our patient remains asymptomatic after 12 mo of postoperative follow-up.

Abstract

Herein, we present a case of pneumoaorta and aortoduodenal fistula (ADF) caused by an endoluminal aortic prosthesis infection. An 82-year-old man underwent endovascular aneurysm repair with a stent graft to exclude a 5.1-cm abdominal aortic aneurysm. Three months after the index procedure, the patient was taken to the emergency department at a medical university hospital. He presented with a 2-d history of bloody diarrhea. An endoluminal aortic stent graft infection was diagnosed, and an ADF was identified. The patient died of septic shock despite emergency surgery and intensive care. When encountered, stent graft infections require appropriate antibiotics and graft explantation. The diagnosis of an ADF is important, and surgery remains the most effective management if septic shock presents despite conservative treatment.

An endoluminal aortic prosthesis infection presenting as pneumoaorta and aortoduodenal fistula. *World J Gastroenterol* 2012; 18(37): 5309-5311 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i37/5309.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i37.5309

INTRODUCTION

The use of stent grafts to treat abdominal aortic aneurysms (AAAs) has recently become more widely used[1-3]. Stent graft infection rates associated with use of the endovascular technique appear to be lower than those for conventional open repair (range: 0.3%-0.4%)[1,2] as demonstrated by Ducasse *et al*[3], who reported a frequency of infection of 0.43%. However, the incidence of infection resulting from the implantation of an endoluminal aortic prosthesis has been reported to be as high as 6%[4,5]. Although prophylactic antibiotics are routinely prescribed prior to an operation, the incidence of infection and possible sequelae remain difficult to predict. Surgical intervention with complete stent graft removal may provide the best outcome for patients with an infection[3]. The overall treatment strategy can be optimized with the early detection of an endovascular stent graft infection. Herein, we present the case of an elderly male patient with an

endovascular stent graft infection who ultimately died of septic shock despite intensive care.

CASE REPORT

An 82-year-old male patient with type 2 diabetes initially presented with a bulging mass in the abdomen and localized pain. The patient underwent endovascular aneurysm repair with a stent graft (Zenith; Cook, Bloomington, IN) to exclude a 5.1-cm AAA in October 2010 (Figure 1A). The patient recovered without incident post-surgery and was discharged. Although the post-surgical protocol calls for an abdominal computed tomography (CT) scan at one month, the patient did not return to the cardiothoracic surgery clinic following his discharge.

Three months post-surgery, the patient was taken to an emergency department at a medical university hospital reporting a 2-d history of bloody diarrhea. Upon further examination, his blood pressure was measured at 121/55 mmHg, his body temperature was 37.8 ℃, his pulse was 68/min, and his oxygen saturation was 88% as measured using a nasal cannula with 3 L/min of oxygen flow. A physical exam revealed pale conjunctiva and a distended abdomen. Furthermore, blood analysis revealed leukocytosis with a white blood cell count of 21 250 cells/mm^3 and a hemoglobin level of 9.6 g/dL. Serum chemistry was unremarkable except for mildly elevated creatinine (1.3 mg/dL) with an estimated glomerular filtration rate of 56.45 mL/min. Empiric antibiotics were prescribed, including flomoxef and vancomycin. An abdominal CT scan disclosed a fistula between the aorta and the retroperitoneal duodenum, suggesting the formation of an aortoduodenal fistula (ADF) (Figure 1B). There was circumferential fluid collection with air surrounding the stent region, suggesting the presence of necrotic tissue and associated gas formation (Figure 1B-D). Due to the occurrence of refractory shock, an emergency operation was indicated. A bilateral axillary-femoral extra-anatomic bypass was performed with 8-mm polytetrafluoroethylene grafts. In addition, a retroperitoneal abscess and an abdominal aortic aneurysmal sac necrosis were debrided. The ADF was located at the bare-metal stent supra-renal fixation point. The stent graft was removed, and the aortic stump was closed just distal to the renal artery orifices. The tear at the third portion of the duodenum was repaired using LigaSure (Tyco-Healthcare, United States). A segmental resection of the duodenum and a side-to-end duodenojejunostomy were performed. The ADF was 1.5 cm × 1.3 cm in diameter.

Blood cultures revealed a mixed growth of *Salmonella* species, *Bacteroides fragilis*, *Clostridium* species and *Gemella morbillorum*. Bacterial culture of the necrotic tissue demonstrated a mixed Salmonella and Bacteroides infection. The patient died of septic shock two days after admission despite intensive care.

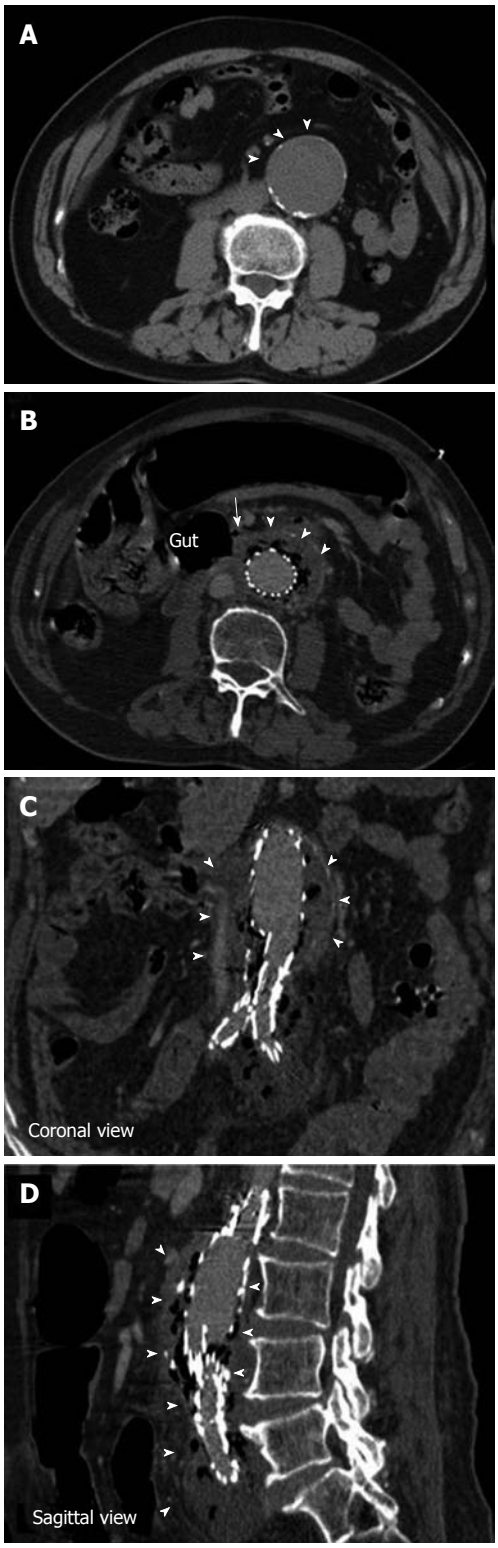

Figure 1 Abdominal computed tomography scans of the patient. A: The abdominal aortic aneurysm before stent-graft implantation (arrowheads); B: The aortoduodenal fistula (arrow); B-D: The necrotic tissue and associated gas formation (arrowheads).

DISCUSSION

In the current case, a gas-forming bacterial infection resulted in the development of a pneumoaorta, which is uncommon. In one recent report[6], a 77-year-old man was diagnosed with a stent graft infection, and his CT scan demonstrated soft-tissue thickening and air present in the right anterolateral aspect of the aneurysm sac. Ad-

ditionally, coagulase-negative staphylococci were identified in a blood culture. Another case report[7] described a stent graft infection due to *Bacteroides fragilis*. The patient's condition was successfully managed with staged extra-anatomic revascularization followed by graft excision.

ADF is a well-recognized and dangerous condition[8-15]. According to a single-center review, five patients developed an ADF between 18 d and 1 year after successful endovascular aneurysm repair[12]. ADF has also been shown to occur as late as five years after endovascular aneurysm repair[13]. The patient in this study presented with ADF and bloody stool passage three months after the index procedure. ADFs and aortic aneurysms can be caused by biliary stent-induced retroperitoneal perforation[14]. However, the current patient did not report any prior gastrointestinal (GI) procedures, such as biliary stenting. The ADF etiology might have included infection and endoleak[12], but an endoleak was not observed on the CT scan. An ADF might further act as a connecting route between the GI tract and the aorta, causing bacterial propagation and infection-related deterioration. Therefore, the bloody stool passage was a possible sequela of the ADF formation[15].

In conclusion, prompt diagnosis and intervention are crucial for effectively treating a patient with an endovascular stent graft infection. A combination of the appropriate antibiotics and surgical repair is the best course for avoiding a fatal outcome. The most effective surgical intervention consists of a complete stent graft explantation followed by *in situ* reconstruction. Endovascular prosthesis implantation is a challenging technique for AAA, but the early recognition and detection of a possible stent infection may be more critical.

Abstract

Penicillium marneffei (*P. marneffei*) infection usually occurs with skin, bone marrow, lung or hepatic involvement. However, no cases of *P. marneffei* infection with chylous ascites have been reported thus far. In this report, we describe the first case of acquired immune deficiency syndrome (AIDS) which has been complicated by a *P. marneffei* infection causing chylous ascites. We describe the details of the case, with an emphasis on treatment regimen. This patient was treated with amphotericin B for 3 mo, while receiving concomitant therapy with an efavirenz-containing antiretroviral regimen, but cultures in ascitic fluid were persistently positive for *P. marneffei*. The infection resolved after treatment with high-dose voriconazole (400 mg every 12 h) for 3 mo. *P. marneffei* should be considered in the differential diagnosis of chylous ascites in human immunodeficiency virus patients. High-dose voriconazole is an effective, well-tolerated and convenient option for the treatment of systemic infections with *P. marneffei* in AIDS patients on an efavirenz-containing antiretroviral regimen.

INTRODUCTION

Penicillium marneffei (*P. marneffei*) infection now represents one of the most common acquired immune deficiency syndrome (AIDS)-defining opportunistic infections in endemic areas of Southeast Asia[1-3]. The infection is associated with a high mortality rate if timely treatment with appropriate antifungal drugs is not administered[2,4]. *P. marneffei* usually occurs with skin, bone marrow, lung or hepatic involvement; however, no cases of *P. marneffei* infection with chylous ascites have yet been reported. In this report, we describe the first case of AIDS which has been complicated by a *P. marneffei* infection causing chylous ascites. We describe the details of the case with emphasis on treatment regimen.

CASE REPORT

A 47-year-old man, a native of Yunnan province, southwest China, infected with human immunodeficiency virus (HIV) who had a CD4 cell count of 66 cells/μL had a 1-year history of intermittent fever and a 6-mo history of abdominal distension. Culture of blood and ascitic fluid

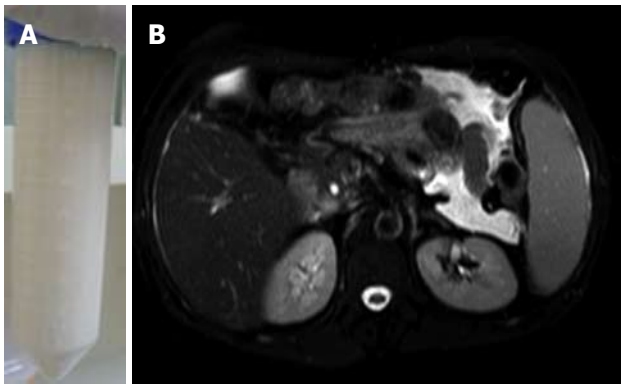

Figure 1 The auxiliary examination for the patient. A: The ascitic fluid had a milky appearance; B: Abdominal magnetic resonance imaging showed hepatosplenomegaly with ascites.

revealed *P. marneffei*. He was diagnosed with AIDS and *P. marneffei* infection. He had received antiretroviral therapy (ART) with stavudine (30 mg twice daily), lamivudine (300 mg once daily) and efavirenz (600 mg daily before bedtime). He was treated with amphotericin B 25 mg/d which was continued for 3 mo, but his condition did not improve. Persistent abdominal distension remained, so paracentesis was performed periodically to relieve the symptoms. Cultures in ascitic fluid were persistently positive for *P. marneffei*. He came to our hospital for further management. Examination revealed the presence of shifting dullness and paracentesis confirmed diagnosis of chylous ascites. Total serum protein, albumin, total cholesterol and triacylglycerol were 65.80 g/L, 37.70 g/L, 3.92 mmol/L and 0.95 mmol/L, respectively. The ascitic fluid had a milky appearance (Figure 1A) and showed 270 white blood cells/μL with 60% multinucleated cells and 40% lymphocytes, triglyceride 13.59 mmol/L (normal range < 1.70 mmol/L), and total protein 31.5 g/L. No malignant cells were found on pathology. Chest computer tomography scan showed no abnormalities while abdominal magnetic resonance imaging showed hepatosplenomegaly with ascites (Figure 1B). Treatment with oral voriconazole (400 mg every 12 h) was started and was continued for 3 mo. He continued on ART (stavudine, lamivudine and efavirenz), but he was recommended to take a lower dose of efavirenz (300 mg once daily before bedtime). In order to monitor efficacy and side effects, we performed therapeutic drug concentration monitoring (TDM) of both voriconazole and efavirenz. The results showed that the peak and trough concentrations of voriconazole were 2.31 mg/L and 1.42 mg/L, respectively and the peak and trough concentrations of efavirenz were 3720 ng/mL and 2680 ng/mL, respectively. While on voriconazole, he improved. All disease-related clinical symptoms and signs gradually disappeared. Fungal cultures of chylous ascites became negative after receiving 2 wk of voriconazole treatment. The values of laboratory tests including electrolytes, renal function and transaminases were within normal ranges during treatment. The infection resolved after treatment with voriconazole for 3 mo and was discontinued when recovery was thought to be achieved. He was recommended to take a normal dose of efavirenz (600 mg once daily) after discontinuation of voriconazole. Six months after initiation of ART, his CD4 cell count rose to 110 cells/μL. He refused to receive secondary prophylaxis with antifungal drugs. No relapse was found in an 8-mo follow-up.

DISCUSSION

Prior to the epidemic of AIDS, penicilliosis was a rare event. The incidence of this fungal infection has increased markedly during the past few years, paralleling the incidence of HIV infection[1]. In China, *P. marneffei* infection is endemic in Guangdong, Guangxi, Yunnan, HongKong and Taiwan[5-7]. In recent years, with the increase of HIV infection, cases have been reported from non-endemic regions[3,8].

Chylous ascites is a rare complication of AIDS. It is caused by the leakage of chyle into the peritoneum due to rupture or obstruction of the thoracic duct. *P. marneffei* is a systemic fungal infection which usually occurs with skin, bone marrow, lung or hepatic involvement. This patient is the first case of AIDS which has been complicated by a *P. marneffei* infection causing chylous ascites. This case suggests that *P. marneffei* should be an important differential diagnosis in chylous ascites in HIV patients, especially in visitors to, or residents of, endemic areas for *P. marneffei*.

The recommended treatment for *P. marneffei* is amphotericin B for 2 wk, followed by oral itraconazole for a subsequent duration of 10 wk[9]. ART should be administered simultaneously to improve outcome[9], but avoiding adverse drug interactions between antifungals and antivirals is also important as these can complicate therapy. This patient had failed to respond to initial amphotericin B treatment. *P. marneffei* is highly susceptible to miconazole, itraconazole, ketoconazole, and 5-flucytosine. Amphotericin B has intermediate antifungal activity[9] which means some patients may not respond to treatment with it. Up to now, alternative treatment options for penicilliosis have not been established. A small case series[10] reported good outcomes with voriconazole in AIDS patients with systemic *P. marneffei* infections, but none of the patients in that study received ART simultaneously. Efavirenz is a mixed inducer and inhibitor of CYP3A4, 2C9 and 2C19. Concomitant use of itraconazole and efavirenz may result in subtherapeutic levels of itraconazole[9], so use of an alternate antifungal treatment may be necessary. Alternatively efavirenz can be replaced with a noninducing class of antiretrovirals. The limited number of antiviral drugs limits the choice of treatment of AIDS in China. We chose voriconazole as the alternative treatment option for penicilliosis. Voriconazole is metabolized primarily by CYP2C19, as well as CYP2C9 and CYP3A4[11]. Voriconazole is also known to inhibit these enzymes[11], and the manufacturer reports an extensive list of drugs that interact with voriconazole. Efavirenz reduces the plasma concentration of voriconazole which increases the plasma concentration of efavirenz,

thus dose adjustments for voriconazole and efavirenz may be needed if concomitant use of these two agents is necessary[9]. It is recommended that clinicians increase voriconazole to 400 mg every 12 h and decrease efavirenz to 300 mg once daily before bedtime[9]. Therefore, we increased the voriconazole dose to 400 mg twice daily and decreased the efavirenz dose to 300 mg once daily before bedtime.

A relationship between progression of fungal infection and voriconazole concentrations was demonstrated in several studies[12-14]. They showed that monitoring voriconazole concentration and adjusting dosage to attain an appropriate plasma concentration is necessary to ensure antifungal effect and to avoid toxicity. TDM represents an important process to optimize the outcome of immunocompromised patients receiving triazoles[15]. The patient was treated with amphotericin B followed by 3 mo of high-dose voriconazole therapy, which resulted in a clinical cure. Treatment with high-dose voriconazole was well tolerated, with no discontinuations caused by drug-related adverse events. The patient also received ART containing low-dose efavirenz, without any relapse of *P. marneffei* infection. Treatment with low-dose efavirenz in this patient was also effective, with clinically significant increases in his CD4 counts. The results of this study suggest that high-dose voriconazole is an effective, well-tolerated, and convenient option for the treatment of systemic infections with *P. marneffei* in AIDS patients on efavirenz-containing ART. There may be a role for voriconazole and efavirenz serum concentration monitoring to ensure therapeutic efficacy when the drugs are used concomitantly.

All patients who successfully complete treatment for penicilliosis should receive oral itraconazole as maintenance therapy to prevent relapse[9]. Discontinuation of secondary prophylaxis is recommended for AIDS patients who receive ART and have CD4 count > 100 cells/μL for > 6 mo [9]. This patient did not receive secondary prophylaxis with antifungal drugs. He had a CD4 count > 100 cells/μL 6 mo after initiation of ART. During the follow-up, no relapse of the fungal infection was observed.

In conclusion, this case report indicates that penicilliosis marneffei should be considered in the differential diagnosis of chylous ascites in HIV patients. High-dose voriconazole is an effective, well-tolerated, and convenient option for the treatment of penicilliosis marneffei in AIDS patients on efavirenz-containing ART. Further research into alternative treatment options for penicilliosis in AIDS patients is required.

Abstract

Fatty liver, including non-alcoholic fatty liver disease, is closely associated with metabolic syndrome (MS). Thus, the presence of fatty liver without MS in some conditions may be clinically important. Many studies have shown that compared with no or occasional alcohol intake, moderate alcohol consumption is associated with lower prevalence rates of hypertension and type 2 diabetes, and lower levels of circulating C-reactive protein, a valuable marker for MS and insulin resistance. Considering these findings, light to moderate alcohol consumption has theoretical benefits on fatty liver and MS. Fatty liver, including non-alcoholic fatty liver disease, may be more clinically important than MS, particularly in non-obese individuals, because fatty liver can develop before MS in several conditions, such as regular alcohol consumers. Furthermore, most of the currently used MS criteria are unable to detect "true MS" because of variations in multiple factors such as age, height, medications, and complications.

TO THE EDITOR

We read the recent article by Hamaguchi *et al*[1] with much interest. The authors showed in a cross-sectional study that the effects of alcohol consumption differed between metabolic syndrome (MS) and fatty liver, and that light to moderate alcohol consumption had a favorable effect on fatty liver, but not on MS, in Japanese men and women. Habitual alcohol consumption, which generally impairs fatty acid oxidation and stimulates lipogenesis in the liver[2,3], substantially influences morbidity, all-cause mortality, and cardiovascular mortality rates[4,5]. Thus, the findings reported by Hamaguchi *et al*[1] are impressive in terms of public health and scientific interest. As described by the authors, fatty liver, including non-alcoholic fatty liver disease (NAFLD), is closely associated with MS and is a hepatic manifestation of MS or insulin resistance. This is based on the concept that MS is a leading cause for fatty liver in the cause-effect relationship.

In addition, many studies have shown that moderate alcohol consumption is associated with a low incidence of adverse health outcomes associated with hypertension[5] and type 2 diabetes[6], and with lower levels of cir-

culating C-reactive protein (CRP)[7,8], an important marker for MS, obesity, and insulin resistance[9,10]. The association between moderate alcohol consumption and lower CRP was independent of body mass index (BMI)[9,10] and alcohol-related effects on lipids[10].

Considering these findings, light to moderate alcohol consumption is hypothesized to have beneficial effects on fatty liver and MS. Plausible explanations for the lack of a beneficial effect of light to moderate alcohol consumption on the risk of MS include the characteristics of the subjects studied, the criteria used to define MS, or food patterns specific for light to moderate alcohol consumers. Of particular note, NAFLD also occurs, albeit relatively infrequently, in normal weight people who commonly have metabolic abnormalities and insulin resistance[11,12]. Most of the subjects in the study by Hamaguchi *et al*[1] were of normal weight (mean BMI 23.2-23.5 kg/m^2 for men and 20.9-21.4 kg/m^2 for women), in whom the prevalence of MS is likely to be reduced when waist circumference is dichotomized according to the criteria for MS with a fixed threshold. High waist circumference is necessary for the diagnosis of MS according to the International Diabetes Federation (IDF) criteria for MS, but not the adult treatment panel (ATP)-Ⅲ criteria for MS. This may help to explain the lower prevalence of people fulfilling the IDF criteria than the ATP-Ⅲ criteria in that study. By contrast, fatty liver can be diagnosed using ultrasound techniques irrespective of manufacturer-specific criteria, which likely resulted in the unexpected finding that more than half of the subjects with fatty liver did not have MS.

Furthermore, although the authors claimed in the discussion that there was no significant association between alcohol consumption and BMI > 25.0 kg/m^2, the prevalence of BMI > 25.0 kg/m^2 was actually lower, particularly in females with light to moderate alcohol consumption. This suggests that the observed association might be mediated by lower BMI, which is also affected by dietary patterns and nutrient intake in such alcohol consumers[13,14]. Sub-analyses of subjects divided into specific groups (e.g., overweight/obese groups) or analyses controlling for BMI, waist circumference, and dietary patterns (as assessed by food frequency questionnaires, for example) are needed to clarify whether the observed association is independent of obesity, MS criteria, or dietary patterns.

Taken together, the results of the study by Hamaguchi *et al*[1] provide meaningful insight into the etiological differences in metabolic abnormalities between liver and visceral adipose tissue, in which lipolysis is reduced by acetate produced in the liver[15]. In addition, the results indicate that fatty liver, including NAFLD, may be clinically more important than MS, particularly in non-obese people, because fatty liver can develop before MS in some conditions and that MS criteria are often unable to detect "true MS". The authors propose that fatty liver without MS is an important disease in the general population. Similarly, Stefan *et al*[16] proposed that fatty liver may be more important than visceral fat for the discrimination of benign obesity that is not accompanied by insulin resistance.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

We acknowledge our sincere thanks to our reviewers. Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of our World Series Journals. Both the editors of the journals and authors of the manuscripts submitted to the journals are grateful to the following reviewers for reviewing the articles (either published or rejected) over the past period of time.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/1007-9327office/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of Gastroenterology

A peer-reviewed, online, open-access journal of gastroenterology and hepatology

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1352 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 64 countries, including Albania (1), Argentina (8), Australia (33), Austria (15), Belgium (14), Brazil (13), Brunei Darussalam (1), Bulgaria (2), Canada (21), Chile (3), China (82), Colombia (1), Croatia (2), Cuba (1), Czech (6), Denmark (9), Ecuador (1), Egypt (4), Estonia (2), Finland (8), France (29), Germany (87), Greece (22), Hungary (11), India (32), Indonesia (2), Iran (10), Ireland (6), Israel (13), Italy (124), Japan (140), Jordan (2), Kuwait (1), Lebanon (4), Lithuania (2), Malaysia (1), Mexico (11), Morocco (1), Moldova (1), Netherlands (32), New Zealand (2), Norway (13), Pakistan (2), Poland (11), Portugal (6), Romania (4), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (11), Slovenia (1), South Africa (3), South Korea (46), Spain (43), Sri Lanka (1), Sweden (17), Switzerland (12), Thailand (1), Trinidad and Tobago (1), Turkey (30), United Arab Emirates (2), United Kingdom (95), United States (285), and Uruguay (1).

World Journal of Gastroenterology

Contents

Weekly Volume 18 Number 38 October 14, 2012

EDITORIAL

5317 Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy: Where are we?
Königsrainer I, Beckert S

FIELD OF VISION

5321 c-Met in pancreatic cancer stem cells: Therapeutic implications
Herreros-Villanueva M, Zubia-Olascoaga A, Bujanda L

5324 Magnets, children and the bowel: A dangerous attraction?
George AT, Motiwale S

TOPIC HIGHLIGHT

5329 Laparoscopic distal pancreatectomy: Up-to-date and literature review
Iacobone M, Citton M, Nitti D

REVIEW

5338 Theoretical basis of a beneficial role for vitamin D in viral hepatitis
Lương KVQ, Nguyễn LTH

ORIGINAL ARTICLE

5351 Anti-inflammatory effects of Lacto-Wolfberry in a mouse model of experimental colitis
Philippe D, Brahmbhatt V, Foata F, Saudan Y, Serrant P, Blum S, Benyacoub J, Vidal K

5360 Increased tumor necrosis factor receptor 1 expression in human colorectal adenomas
Hosono K, Yamada E, Endo H, Takahashi H, Inamori M, Hippo Y, Nakagama H, Nakajima A

5369 Axl glycosylation mediates tumor cell proliferation, invasion and lymphatic metastasis in murine hepatocellular carcinoma
Li J, Jia L, Ma ZH, Ma QH, Yang XH, Zhao YF

5377 Protection of ghrelin postconditioning on hypoxia/reoxygenation in gastric epithelial cells
Liu ZB, Fei SJ, Zhu SP, Zhu JZ, Han HX, Dong QJ, Zhang JF

BRIEF ARTICLE

5389 Carbon dioxide accumulation during analgosedated colonoscopy: Comparison of propofol and midazolam
Heuss LT, Sugandha SP, Beglinger C

5397 Similar fecal immunochemical test results in screening and referral colorectal cancer
van Turenhout ST, van Rossum LGM, Oort FA, Laheij RJF, van Rijn AF, Terhaar sive Droste JS, Fockens P, van der Hulst RWM, Bouman AA, Jansen JBMJ, Meijer GA, Dekker E, Mulder CJJ

5404 Different risk factors influence peptic ulcer disease development in a Brazilian population
Suzuki RB, Cola RF, Cola LTB, Ferrari CG, Ellinger F, Therezo AL, Silva LC, Eterovic A, Sperança MA

5412 Argon plasma coagulation for superficial esophageal squamous-cell carcinoma in high-risk patients
Tahara K, Tanabe S, Ishido K, Higuchi K, Sasaki T, Katada C, Azuma M, Nakatani K, Naruke A, Kim M, Koizumi W

5418 Hepatitis B virus pre-S2 start codon mutations in Indonesian liver disease patients
Utama A, Siburian MD, Fanany I, Intan MDB, Dhenni R, Kurniasih TS, Lelosutan SAR, Achwan WA, Zubir N, Arnelis, Lukito B, Yusuf I, Lesmana LA, Sulaiman A

5427 Oxaliplatin-induced severe anaphylactic reactions in metastatic colorectal cancer: Case series analysis
Wang JH, King TM, Chang MC, Hsu CW

5434 Myofibrillogenesis regulator-1 overexpression is associated with poor prognosis of gastric cancer patients
Guo J, Dong B, Ji JF, Wu AW

5442 Identification of deregulated miRNAs and their targets in hepatitis B virus-associated hepatocellular carcinoma
Wang W, Zhao LJ, Tan YX, Ren H, Qi ZT

5454 Correlation between circulating myeloid-derived suppressor cells and Th17 cells in esophageal cancer
Jiao ZJ, Gao JJ, Hua SH, Chen DY, Wang WH, Wang H, Wang XH, Xu HX

5462 Effect of the ginsenoside Rb1 on the spontaneous contraction of intestinal smooth muscle in mice
Xu L, Huang SP

5470 Tumor size as a prognostic factor in patients with advanced gastric cancer in the lower third of the stomach
Wang HM, Huang CM, Zheng CH, Li P, Xie JW, Wang JB, Lin JX, Lu J

CASE REPORT

5476 Metachronous penile metastasis from rectal cancer after total pelvic exenteration
Kimura Y, Shida D, Nasu K, Matsunaga H, Warabi M, Inoue S

World Journal of Gastroenterology
Volume 18 Number 38 October 14, 2012

Contents

5479 Primary hepatic leiomyosarcoma with liver metastasis of rectal cancer
Takehara K, Aoki H, Takehara Y, Yamasaki R, Tanakaya K, Takeuchi H

5485 Duodenal obstruction following acute pancreatitis caused by a large duodenal diverticular bezoar
Kim JH, Chang JH, Nam SM, Lee MJ, Maeng IH, Park JY, Im YS, Kim TH, Park IY, Han SW

ACKNOWLEDGMENTS I Acknowledgments to reviewers of *World Journal of Gastroenterology*

APPENDIX I Meetings

I-VI Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Gastroenterology*, Timothy R Koch, MD, FACG, Professor of Medicine (Gastroenterology), Washington Hospital Center, Georgetown University School of Medicine, Washington, WA 20010, United States

FLYLEAF I-IX Editorial Board

EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Yuan Zhou*
Responsible Electronic Editor: *Dan-Ni Zhang*
Proofing Editor-in-Chief: *Lian-Sheng Ma*
Responsible Science Editor: *Xin-Zhen Huang*
Proofing Editorial Office Director: *Jin-Lei Wang*

Abstract

Peritoneal surface malignancies are generally associated with poor prognosis. In daily clinical routine, systemic chemotherapy is still considered the only reasonable therapy despite of encouraging results of cytoreductive surgery (CRS) along with intraperitoneal hyperthermic chemotherapy (HIPEC). The Achilles heel of CRS and HIPEC is appropriate patient selection and precise surgical technique preventing patients from excessive morbidity and mortality. Given these findings, new concepts of second look surgery for high risk patients allow detection of peritoneal spread ahead of clinical symptoms or presence of peritoneal masses reducing perioperative morbidity. In addition, personalized intraperitoneal chemotherapy might further improve outcome by appreciating individual tumor biology. These days, every physician should be aware of CRS and HIPEC for treatment of peritoneal surface malignancies. Since there is now sufficient data for the superiority of CRS and HIPEC to systemic chemotherapy in selected patients, our next goal should be providing this strategy with minimal morbidity and mortality even in the presence of higher tumor load.

INTRODUCTION

In Peritoneal surface malignancies (PSM), tumor location is restricted to the abdominal cavity as opposed to systemic metastatic disease. In the past, the majority of PSM patients underwent systemic chemotherapy which was associated with poor quality of life and was ineffective with respect to prolonging survival.

Thanks to the pioneer work of Professor Paul Sugarbaker, a proactive surgical approach termed cytoreductive surgery (CRS), aiming for maximal tumor resection, along with hyperthermic intraperitoneal chemotherapy (HIPEC) evolved into a highly relevant treatment option for selected patients with limited peritoneal spread of various tumor entities[1-3]. The rationale for this particular approach is the restriction of tumor dissemination to the peritoneal compartment justifying a radical surgical procedure followed by HIPEC.

Although there is now evidence for the superiority of

CRS and HIPEC to systemic chemotherapy, this strategy has not made its way into clinical routine since peritoneal spread is still considered as stage Ⅳ cancer when surgical resection is not an option any more. However, there was a similar thinking for colorectal liver metastasis for a long time. Now, surgery represents the main strategy even though its superiority has never been proven in a randomized phase Ⅲ trial.

If cytoreductive surgery is scheduled, proactive surgery achieving total or almost total (remaining nodules < 2.5 mm) cytoreduction has to be the main aim In addition, hyperthermic intraperitoneal chemotherapy is administered for eradication of microscopic residual disease. The most frequently cited paper on this topic was published by Verwaal *et al*[4,5] who first proved the benefit of this multimodal approach in a phase Ⅲ trial comparing patients with colorectal cancer undergoing CRS and HIPEC followed by systemic chemotherapy with systemic chemotherapy. Up to now, there are several reports on long term survival if radical resection was performed[4-7]. Other entities for which this treatment is accepted are pseudomyxoma peritonei and mesothelioma[8]. For selected patients with ovarian and gastric cancer this option can be offered with good results[9-12].

Since survival does not significantly differ between completeness of cytoreduction CC0 or CC1, an oncologic resection with wide resection margins seems not necessary in this content except for primary gastrointestinal cancer with peritoneal carcinomatosis PC.

INTERDISCIPLINARY CONCEPT

The implementation of many new centers for PSM could mean that more and more patients are asking for this therapeutic option. However, the perioperative setting has to be established first rather than the surgical one. An experienced radiologist is mandatory to assess preoperative tumor load and to rule out contraindications such as diffuse infiltration of the small bowel or extraperitoneal disease. The anaesthesiologists, nurses and HIPEC technicians should visit centers and participate in workshops for HIPEC before initiating the program. Lastly, the medical oncologist becomes more and more important because there are numerous different intraperitoneal as well as pre- and postoperative chemotherapy regimens. The founding of a peritoneal surface malignancy group which meets regularly has had a great impact on scientific discussion between surgeons, radiologists, anaesthesiologists. In addition, this facilitates the initiation of clinical multi-center and experimental studies.

HYPERTHERMIC INTRAPERITONEAL CHEMOTHERAPY

In most cases, intraperitoneal chemotherapy is administered after cytoreductive surgery and completion of intestinal anastomoses, either immediately intraoperatively (HIPEC) or early postoperatively (EPIC). Technically, this chemotherapy can be applied to an open or closed abdomen which varies between the different centers.

The rationale of HIPEC is the synergistic cytotoxic effect of heat, ideally 42-43 degree Celcius, and the chemotherapeutic agent itself on tumor cells.

There are various concepts varying in duration of exposition, in combination with for example intraoperative intravenous therapy and in type of the administered chemotherapy.

The effect of hyperthermic intraperitoneal chemotherapy itself has never been proven in a randomized controlled trial and is still the focus of ongoing investigations. Nevertheless, there are numerous data of how HIPEC might work and most surgeons, medical oncologists and last but not least patients believe in the effect of local chemotherapy.

The rationale for applying intraoperative chemotherapy under hyperthermic conditions is improving both tissue as well as tumor oxygenation by vasodilation enhancing the cytotoxic effect of chemotherapeutic agents. So far, however, nobody has demonstrated an effect on hyperthermia on tissue oxygenation and there is no data whether this putative effect on pO_2 (oxygen) might be sustained throughout the entire HIPEC period. As learned from wound healing research, supplemental oxygen during HIPEC might further enhance cytotoxicity since it has been shown to increase tissue oxygen tension. In addition of thinking about the best timing for HIPEC, HIPEC in combination with supplemental oxygen could be a worthwhile option in the future.

Another future important issue could be testing chemotherapeutic sensitivity to improve the cytotoxic effect of HIPEC. Such particular tests already exist for ovarian cancer with respect to platinum resistance[13,14]. This further strengthens the need for personalized intraoperative chemotherapy regimens.

NEOADJUVANT CHEMOTHERAPY

A quite high percentage of patients is not eligible for cytoreductive surgery at the time of surgical exploration. Therefore, tumor downsizing by systemic chemotherapy and subsequent surgery might be an option. In liver surgery, the concept of secondary resection after chemotherapy, both intravenous as well as regionally, is accepted and response to preoperative chemotherapy can be considered as a prognostic factor[15-17]. In PSM, neoadjuvant chemotherapy might also aid in categorizing patients in responders and non-responders with responders being more likely to profit from CRS and HIPEC. One limitation is the difficulty to evaluate response to chemotherapy since computed tomography (CT) or positron emission tomography (PET)/CT often do not sufficiently show tumor spread. One ongoing phase Ⅱ trial in Germany addressing perioperative chemotherapy is the COMBATAC trial (multimodality treatment including neoadjuvant and adjuvant chemotherapy with cetuximab and CRS and HIPEC).

ORGAN PRESERVING CYTOREDUCTIVE SURGERY

Radical cytoreduction is many times associated with multivisceral resection because of diffuse organ infiltration. When performing cytoreductive surgery, the surgeon should, however, aim for preserving as many organs as possible. Moreover, the surgeon should leave as much as possible behind but without any oncological compromise. This approach seems quite unfamiliar to surgeons who do not deal with peritoneal metastases. In many cases, the small/large bowel can be preserved when addressed with patience for meticulous tumor resection since tumor nodules are mainly located on the peritoneal surface and can be removed without opening the bowel in most cases unless there is infiltrative growth.

From an oncologic point of view, a radical oncologic colon resection, except in primary colorectal cancer with peritoneal spread is not necessary in our opinion.

The surgical expertise should ideally include a broad surgical spectrum especially colorectal surgery. One technical challenge is certainly the liver hilus with the sulcus rex, sulcus arancii and segment 1 region which is very demanding to dissect with the risk of biliary or vascular damage when a certain experience in liver surgery is helpful.

SECOND LOOK SURGERY

Peritoneal carcinomatosis index (PCI), representing intraabdominal tumor load is a prognostic factor for survival. The lower the PCI, the better the prognosis maybe also due to the fact that a complete cytoreduction becomes more likely. Clinical signs of peritoneal metastases are often not specific and current imaging methods often do not detect small tumor nodules[18,19]. Given these findings, a second look protocol with a re-laparotomy within one year of colorectal surgery in high risk patients was proposed. The high risk patient for developing PSM suffers from either a perforated tumor or a local peritoneal spread at the time of primary surgery. Current data revealed quite a high percentage of PSM in those patients.

The second look protocol was firstly described by Elias *et al*[20]. Predicting the development of PSM in high risk patients is certainly a mile stone in the treatment of peritoneal metastases[20]. Although this approach is proactive, it may further prolong survival in those patients.

The administration of HIPEC even in a patient without macroscopic peritoneal disease needs further to be elucidated in randomized trials but seems to be promising so far. The "ProphyloCHIP" trial (Trial Comparing Simple Follow-up to Exploratory Laparotomy Plus "in Principle" HIPEC in Colorectal Patients) run by Prof Elias is addressing this particular point. In this randomised phase Ⅲ trial, colorectal cancer patients at risk to develop PC receive standard adjuvant chemotherapy after curative resection. After having excluded recurrent disease within 6 mo of follow-up they are randomised to either surveillance alone or explorative laparotomy and HIPEC. With this proactive approach, disease free and overall survival may be increased.

CONCLUSION

With newer imaging modalities such as PET/CT and PET/magnetic resonance tomography a better location of the tumor may be realized in future. Pro-active second look surgery, as far as there is no optimal imaging method, realizes the anticipation of diffuse peritoneal spread.

Making "unresectable patients" resectable is one challenging goal of neoadjuvant chemotherapy protocols in the future.

Using new protocols including intraperitoneal antibodies or even intraperitoneal virotherapy in patients with unresectable disease may further improve results.

Lastly and most importantly, a dedicated surgeon, an experienced anaesthesiologist and cooperating medical oncologists are mandatory to achieve excellent results and develop new concept in the treatment of peritoneal metastases.

Abstract

Pancreatic cancer is the deadliest solid cancer and currently the fourth most frequent cause of cancer-related deaths. Emerging evidence suggests that cancer stem cells (CSCs) play a crucial role in the development and progression of this disease. The identification of CSC markers could lead to the development of new therapeutic targets. In this study, the authors explore the functional role of c-Met in pancreatic CSCs, by analyzing self-renewal with sphere assays and tumorigenicity capacity in NOD SCID mice. They concluded that c-Met is a novel marker for identifying pancreatic CSCs and c-Met^{high} in a higher tumorigenic cancer cell population. Inhibition of c-Met with XL184 blocks self-renewal capacity in pancreatic CSCs. In pancreatic tumors established in NOD SCID mice, c-Met inhibition slowed tumor growth and reduced the population of CSCs, along with preventing the development of metastases.

INVITED COMMENTARY ON HOT ARTICLES

Pancreatic adenocarcinoma is one of the most aggressive neoplasias and the fourth leading cause of cancer death in the United States, with 5 year survival being less than 5%[1]. Part of the reason for the fatal prognoses of patients with pancreatic adenocarcinoma is the lack of response to the available therapies. In addition to achieving early diagnosis, the identification of markers for prognosis and response to therapy is necessary for the development of specific targeting agents for the management of patients with pancreatic cancer[2].

Conventional chemotherapy is directed at tumor cells that have limited tumorigenic potential, instead of targeting the cancer stem cell population.

Cancer stem cells (CSCs) conform to a subpopulation of tumoral cells that contribute mainly to drug resistance; since they can self-renew indefinitely and are charac-

terized by their relative quiescence. These properties, together with the contribution of the epithelial to mesenchymal transition, allow them to avoid conventional chemotherapy induced-cell death, and thus patients often suffer from tumor relapse[3,4].

A better understanding and characterization of these cells will be a helpful tool in the future for designing new therapies, since the CSC hypothesis predicts that only therapies that efficiently eliminate the CSC fraction of a tumor are able to induce long-term response and halt tumor progression. Novel therapeutic strategies that could target pancreatic CSCs will allow us to induce drug sensitivity, the inhibition of invasion, and the metastasis of pancreatic cancer, which will ultimately yield better treatment outcomes[5].

Although there have many studies attempting to establish markers for these CSCs, there is no complete or defined panel for the identification of these cells. Isolated CSCs have been reported to show increased tumorigenicity, chemoresistance, stationary phase, and asymmetric division to differentiate into non-stem progeny[6,7]. Based on these characteristics, pancreatic CSCs are identified by flow cytometry using cell surface markers such as CD44, CD24, ESA, CD133, ALDH1 and low proteosome activity[8-13].

In this study, new data is presented about CSC characterization and possible related therapies that should be considered for pancreatic cancer clinical trials.

c-Met is a receptor of the tyrosine kinase family that acts as a proto-oncogene and is stimulated by hepatocyte growth factor to mediate motility, invasion, and metastasis[14]. The levels of c-Met are increased in pancreatic carcinoma where c-Met signaling induces growth and invasion. Some authors have reported c-Met as a stem cell marker in pancreatic tissue[15], as well as in other tissues and organs such as the brain and gastrointestinal tract where the molecule regulates stem cell proliferation and cell renewal[16,17].

In this study, the authors conclude that c-Met is a novel marker for pancreatic CSCs and they show the functional role of this molecule in pancreatic tumors.

Using xenografts (immunodeficient mice NOD-SCID) and injecting pancreatic cancer cells from patients, they show that there is a subpopulation of cells that express high levels of c-Met (c-Met^{high}), while another subpopulation expresses low levels or does not express this maker at all (c-Met^{low}). Part of the c-Met^{high} population also expresses other previously described CSCs makers such as CD44, CD24, CD133, and ALDH1, but compared with these other markers, c-Met^{high} is better at identifying higher tumorigenic cancer cell populations (when injecting the same number of cells, c-Met^{high} cells produce tumors in 35% of the mice, while CD133+ produces tumors in 16% and CD44+ in 25%).

The population of positive cells for both the markers c-Met and CD44 (c-Met^{high}CD44+) enhances the *in vivo* tumorigenicity compared with the population with CD44+ alone. These data together show that c-Met is an important and novel marker of pancreatic CSCs.

Using sphere formation assay, it can be shown that c-Met^{high} cells have a self-renewal capacity, as they can form tumorspheres while c-Met^{low} are unable to do so.

On the other hand, treatment with the chemical inhibitor XL184 (a small molecule kinase inhibitor for c-Met) or the inhibition of c-Met with a specific shRNA impairs sphere formation, leading to apoptosis and cell cycle arrest; showing that c-Met activity is required to maintain a CSC population.

XL184 inhibits tumor growth and reduces the number of CSCs in xenograft mice with subcutaneous tumors and in orthotopic models.

When compared with Gemcitabine, the effect produced by XL184 is different. Although both XL184 alone and Gemcitabine alone treatments can inhibit tumor growth during the period that the animal is receiving treatment, some days after the end of treatment, the tumor growth continues at the same rate as the control tumors. By contrast, when the treatments are combined (XL184 in combination with Gemcitabine), tumor growth is prevented for up 32 d following cessation of treatment. This effect is due to the cells that each treatment targets. While Gemcitabine treatment results in an increase of the c-Met^{high}CD44+ population (likely because these cells are resistant to cell death with this chemotherapy) c-Met inhibition with XL184 leads to a decrease in c-Met^{high}CD44+ cells. Combination treatment prevents the increase in the CSC population observed with Gemcitabine alone and also contributes to a decrease in c-Met^{high}CD44+ population, suggesting that XL184 targets the CSC population specifically. Additionally, using an intracardiac injection model with pancreatic cancer cells, the authors demonstrated that XL184 treatment prevents metastasis development.

A study by Li *et al*[5] contributes significantly to the investigation into the stemness of pancreatic cancer cells. The study in question shows that c-Met is a new human pancreatic CSC marker. The results demonstrate that, in addition to identifying the population of cells with a self-renewal capacity in a pancreatic tumor, c-Met is a molecule necessary for maintaining tumoral cell growth and has capacity for metastasize.

Previous experiments had characterized CSCs as EpCAM+, CD44+, CD24+, CD133, low proteosome activity, ALDH+ for pancreatic CSCs, and CD133+ CXCR4+ for CSCs with higher metastatic potential. The addition of the new marker c-Met, already identified in other types of tumor, directs research towards the development of therapies targeting this tyrosine kinase receptor. In addition to its role as a biomarker of pancreatic CSCs, the authors purpose a potential therapy, showing reduced tumor growth in xenograft mice. They also demonstrated that c-Met has an important role in metastasis development, and that this process could be blocked by targeting c-Met specifically with XL184 treatment. XL184 (Cabozantinib) is a small-molecule kinase inhibitor with potent activity toward c-Met and vascular endothelial growth

factor receptor 2, as well as a number of other receptor tyrosine kinases including rearranged during transfection, kinase receptor, axl receptor tyrosine kinase, and fms like tyrosine kinase 3[18].

The authors demonstrated that XL184 targeting c-Met could be a promising therapy in combination with Gemcitabine treatment for pancreatic cancer. This is a very important achievement, since pancreatic cancer has a fatal prognosis due to its resistance to the currently available chemotherapy and radiotherapy. Although Gemcitabine is the most common chemotherapy used in pancreatic cancer patients, it has been demonstrated that it may not be particularly useful due to the properties that CSCs confer to the tumor. Some studies have demonstrated that, after Gemcitabine treatment, the subpopulation of CSC CD133+ is enriched[11] and that pancreatic cancer cell lines can undergo epithelial to mesenchymal transition after this treatment, resulting in an increased population of CD44+CD24+ESA+ cells[19].

Li *et al*[5] showed that the combination treatment of XL184 and Gemcitabine is an effective therapy for pancreatic cancer treatment. As different studies have shown, using a combination of therapies that target CSCs and the non-tumorigenic population of pancreatic cancer cells, this neoplasia can be effectively treated.

Collectively, these data and other recently published studies concerning different tumors, suggest that c-Met is a promising CSC marker for pancreatic cancer and XL184 is effective at inhibiting tumor growth, angiogenesis, and metastasis, and both should be seriously considered for clinical trials in combination with other available chemotherapy.

Abstract

Reports of magnet ingestion are increasing rapidly globally. However, multiple magnet ingestion, the subsequent potential complications and the importance of the early identification and proper management remain both under-recognized and underestimated. Published literature on such cases could possibly represent only the tip of an iceberg with press reports, web blogs and government documents highlighting further occurrence of many more such incidents. The increasing number of complications worldwide being reported secondary to magnet ingestion point not only to an acute lack of awareness about this condition among the medical profession but also among parents and carers who will be in most cases the first to pick up on magnet ingestion. There still seems to be no consensus on the management of magnet ingestion with several algorithms being proposed for management. Prevention of this condition remains a much better option than cure. Proper education and improved awareness among parents and carers and frontline medical staff is key in addressing this rapidly emerging problem. The goal of managing such cases of suspected magnet ingestion should be aimed at reducing delays between ingestion time, diagnosis time and intervention time.

INVITED COMMENTARY ON HOT ARTICLES

Background

Ingestion of foreign bodies is a common clinical problem; the occurrence of which has been steadily increasing all over the world. More than three quarters of such cases occur in children[1]. Of particular concern is the diagnostic and management dilemma that is posed by the ingestion of magnetic elements. Ingestion of a confirmed single magnet by itself does not pose a problem because it behaves just as an isolated foreign body. The single magnet in most cases moves through the gut harmlessly and silently and usually gets expelled without complications[2,3]. However, the ingestion of multiple magnets or a single magnet along with another metallic piece poses a totally different challenge as these magnetic elements can get attracted to each other with forces up to 1300 G[4] and any intervening bowel wall between the attracted parts eventually undergoing pressure necrosis. Subsequent fistulization between bowel loops can remain silent until it

leaks and peritonitis intervenes.

Magnitude of the problem

The issues of foreign body ingestion have been well discussed in the literature. However, multiple magnet ingestion, the subsequent potential complications and the importance of the early identification and proper management remain both under-recognized and underestimated. Reports of multiple magnet ingestion and its complications have been steadily increasing over the past few years, with over 15 cases being reported in the literature over 7 mo in 2012 compared to 10 cases in 2010, and two cases per year about a decade ago[3,5-8]. Published literature on such cases may represent only the tip of an iceberg with press reports, web blogs and government documents highlighting further occurrence of many more such incidents[5]. The extent of the problem is highlighted as a total of 128 published cases across 18 countries assimilated in 2010 have now expanded to over 150 cases over 22 countries in 2012[6-10]. The majority of such cases have involved the ingestion of either two or three magnetic elements, although there is one reported case of nearly 100 pieces[11].

Initial reports of this condition more than a decade ago were mainly confined to infants and toddlers. Children with a variety of psychological conditions including autism, developmental delays, history of pica, schizoid characteristics, Angelman syndrome, behavioral problems, Beckwith-Wiedemann syndrome with developmental delays, 4p syndrome, congenital hydrocephalus, mental retardation, reactive attachment, and anxiety were thought to be at a higher risk for accidental ingestion[11]. Of interest was the fact that this group comprised < 15% of the total cases reported so far.

Presently, the incidence of this problem no longer remains confined to these groups. Recent reports suggest that multiple magnet ingestion seem to be occurring with increasing frequency in fully developed older age groups[5,11,12].

The origin of most of these magnetic elements has been traced to toys, either directly belonging to the child or to an elder sibling[9,11-13]. A possible cause for the increase of such cases is the easy availability of cheap toys that contain magnetic elements[14]. New-generation magnets are made of combinations containing iron, along with other rare earth elements including boron and neodymium, and such magnets tend to be nearly 10 times stronger than standard iron magnets. This has enabled the miniaturization of magnets for inclusion in various small toys[3,15]. In many of these toys, the magnetic elements are poorly embedded in plastic moulds from which they can easily become detached[16].

Diagnosis

The key to diagnosis is to obtain a reliable history of magnet ingestion. A credible history of ingestion is crucial in the early recognition and correct management of this condition. The lack of a documented history of ingestion in nearly half of the reported cases even among the older age groups is of concern[5]. Younger children or those with developmental delays may be hindered by their inability to communicate effectively to their parents due to their limited linguistic or developmental abilities. Older children may hesitate to inform parents due to a sense of guilt or embarrassment or a fear of the consequences[9,17]. This may have a direct bearing on the time interval between ingestion and intervention. This may be shorter if there is evidence of ingestion or longer when only the occurrence of bowel complications may highlight an underlying magnetic pathology. Time intervals between ingestion and intervention have varied from a few hours to a few months[5].

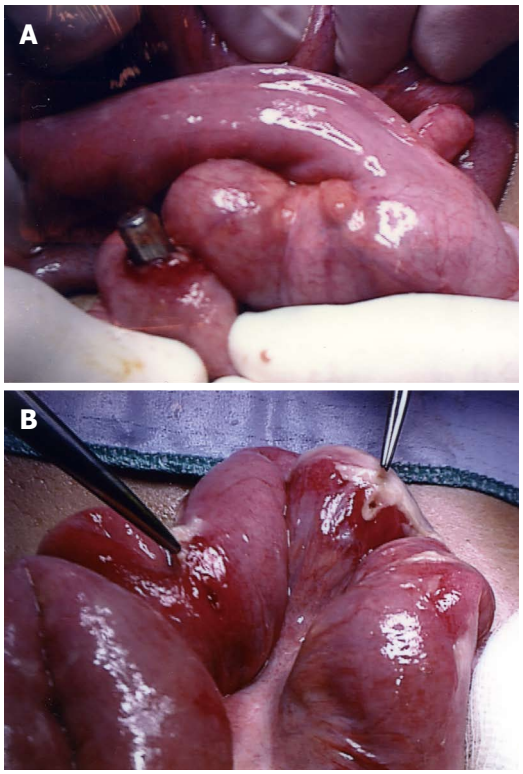

Figure 1 Symptoms may vary from totally asymptomatic or an unrelated pain to a mild flu-like illness with nonspecific symptoms of nausea, vomiting, cramps, or abdominal pain, to features of bowel obstruction or localized peritonitis. A: Magnetic cause for an acute appendicitis in an 8-year-old child; B: Laparotomy for peritonitis showed small bowel fistulation caused by two magnets.

Symptoms may vary from totally asymptomatic or an unrelated pain to a mild flu-like illness with nonspecific symptoms of nausea, vomiting, cramps, or abdominal pain to features of bowel obstruction or localized peritonitis[3,5,12,18] (Figure 1A, B).

Plain abdominal radiographs almost always pick up these objects and is a simple and quick screening test if a history of ingestion is obtained[19-21]. Plain radiography is a sensitive tool to screen and identify such cases but is poor in differentiating whether the ingested magnet is truly only single or is actually composed of multiple densely adherent magnetic elements. Although radiographs can be taken at different angles and planes, the

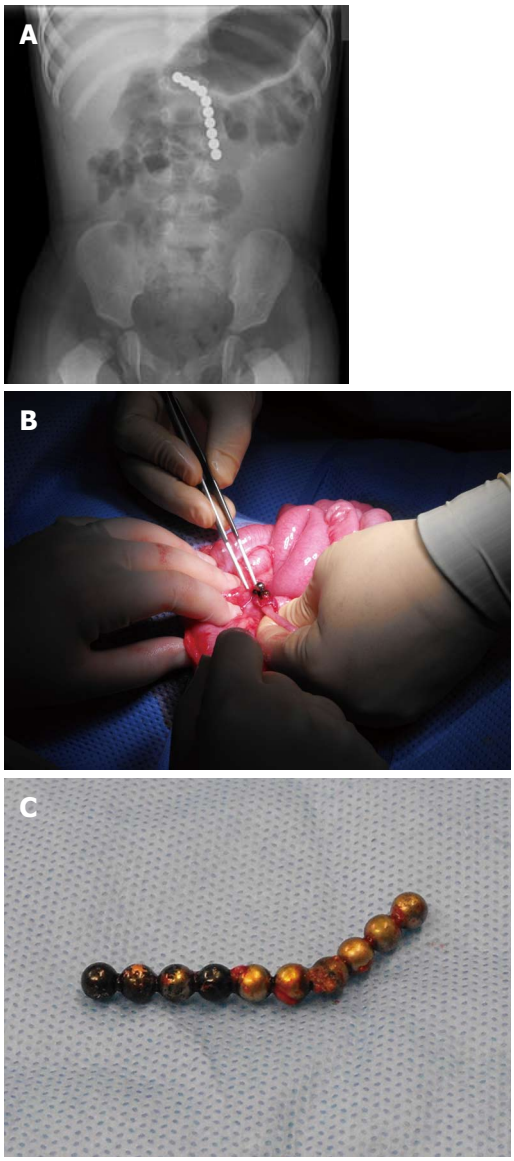

Figure 2 If multiple magnet ingestion is suspected, the entire gastrointestinal tract remains at risk of perforation even if the child is asymptomatic. A: Asymptomatic 18-mo-old child 96 h after ingestion of magnet; B: Silent gastro-jejeno-colic fistula at laparotomy; C: Ten strongly attracted magnetic balls lying across the fistula.

differences in radiographic appearances between a single magnet and multiple magnets adhered to each other may be subtle and impossible to differentiate[2]. Subtle separations or gaps between otherwise individual metallic pieces may point to the presence of multiple magnetic elements or the presence of intervening bowel between the magnets. However, this is by no means diagnostic and the absence of any gaps within the imaged magnet does not exclude more than one magnet nor the absence of bowel wall involvement[2]. In addition, the failure of the ingested magnetic element to progress through the bowel on subsequent follow-up radiographs should raise the suspicion of multiple magnetic elements with entrapped bowel, although this is not diagnostic because the multiple magnets can move *en bloc*[2,17,22,23]. Documenting the size and shape of the swallowed object on radiography and confirming the presence of only a single magnet may be challenging because such ingested magnets tend to be miniature and they usually originate from children's toys[3,12].

Computed tomography and ultrasound can be performed but may not contribute greatly because they generally lack the sensitivity to determine the multiplicity of or the presence of trapped bowel between the magnetic objects. Magnetic resonance imaging (MRI) scans should not be performed due to the magnetic nature of the ingested foreign body and bowel perforation secondary to inadvertent MRI has been reported[8].

Management

Management of ingested foreign bodies still relies to a great extent on "masterly inactivity", whereby the ingested foreign body traverses the gut and is expelled without any complications.

There still seems to be no consensus on the management of magnet ingestion, with several algorithms being proposed[2,3,5,21]. A common underlying theme is that in cases of multiple magnet ingestion, conservative management may have no appreciable role. Surgical exploration and removal remains the preferred management irrespective of the size or shape of the magnet[19].

A diagnostic and management dilemma arises if there is a doubt as to whether one or more magnets were ingested. A proper history is important to help identify between single or multiple magnet ingestion, but reliable documentation of ingestion may not always be present[5]. Clear differentiation is not always possible between the two because multiple magnets may tend to be densely adherent to each other and can mimic a single object on imaging.

Conservatively discharging the child back to the community without reliable evidence of single magnet ingestion may have the potential to cause unnecessary morbidity[3,5]. Undiagnosed multiple magnets can tend to remain asymptomatic for several weeks or months until potentially disastrous complications intervene[5].

Close observation of such cases even if they are asymptomatic may be prudent given the lack of any investigation which can effectively rule out multiple adherent magnets. If single magnet ingestion is suspected, normal progression through the bowel can be monitored closely with expulsion of the magnet through a bowel movement[21].

If multiple magnet ingestion is suspected, the entire gastrointestinal tract remains at risk of perforation even if the child is asymptomatic (Figure 2A-C). All such cases should be reviewed urgently by the surgeon with a view to magnet removal. If pediatric surgery expertise is not available, urgent transfer to an appropriate specialist center is important (Figure 3).

The aim of management in cases of suspected multiple magnet ingestion should be to shorten the delays between ingestion time, diagnosis time and intervention

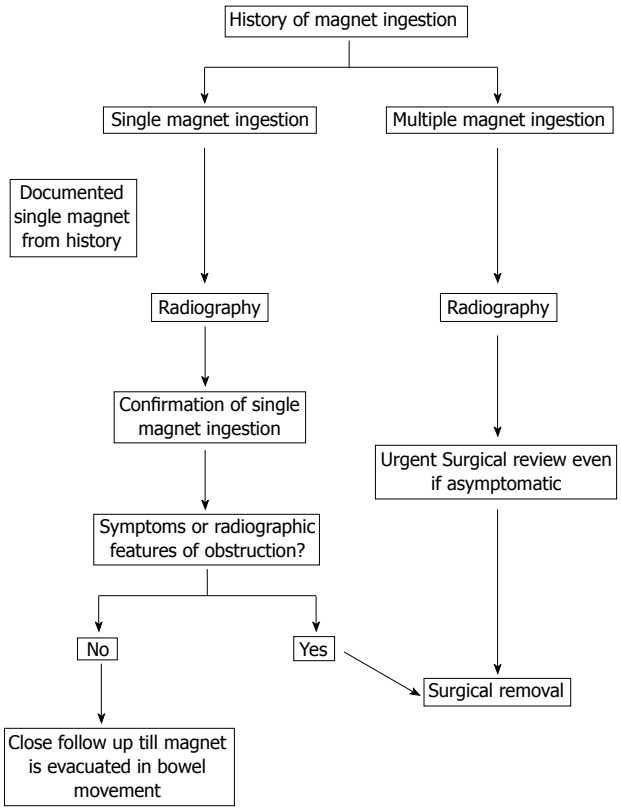

Figure 3 A view for magnet removal.

time.

Removal of the magnets is seminal and delaying the removal or waiting for evidence of bowel obstruction to develop may lead to unnecessary morbidity and even mortality[3,5]. All such reported cases with the exceptions of a few sporadic cases[11,18] have been managed with the surgical removal of the magnetic parts. Bowel injury following multiple magnet ingestion in a few conservatively managed cases may have been avoided possibly due to a near-simultaneous ingestion of the magnetic elements, which may have then behaved as a single large magnet. This however, would not be sufficient reason to recommend conservative management in such cases.

Removal of the ingested magnets can be retrieved endoscopically if they are in the esophagus, stomach or proximal duodenum[5]. Once the magnets move further into the small bowel, surgical removal either through an exploratory or a laparoscopic assisted laparotomy is required to localize and remove the magnets.

Field of vision

The field of vision regarding this condition is highly myopic. Prevention remains a much better option than cure for this rapidly increasing problem.

The increasing number of complications worldwide being reported secondary to magnet ingestion point not only to an acute lack of awareness about this condition among the medical profession but also among parents and carers who will be, in most cases, the first to pick up on magnet ingestion. Parents need to be alerted to the potential risk of silent bowel perforation and fistulation from accidental ingestion of magnets. The importance of increasing awareness regarding the potential complications of magnet ingestion is crucial. This could prompt parents and carers to identify earlier cases of suspected magnet ingestion and rapidly seek appropriate medical attention, and considerably reduce the delay between ingestion and diagnosis.

There also exists a lack of awareness among the medical profession about the potential of multiple magnet ingestion to do great harm. Improving awareness among frontline medical staff can help to reduce the time delay between ingestion and diagnosis, as well as between diagnosis and intervention.

There is also a need for tighter control and regulation of toys with magnetic components. Since 2006, there have been numerous alerts and recalls from Canadian and United States consumer product safety commissions issued in relation to children and the sale of toys with small ingestible magnetic parts[2,24]. The occurrence of such cases from over 21 countries worldwide highlights that this is no longer confined to a localized geographical region or population. Toy manufacturers all over the world can incorporate easily visible warnings regarding the presence of small magnetic parts in the toys on the labels. Highlighting age restriction on toys may not by itself cover much ground without improved awareness because younger children can accidentally ingest magnetic elements from toys that may have been appropriately bought for elder siblings in the family.

Parents, carers and medical staff globally remain under-informed and largely unaware regarding this rapidly increasing potential public health problem. The goal of managing such cases of suspected magnet ingestion should be to reduce the delays between ingestion time, diagnosis time and intervention time.

Abstract

Pancreatic surgery represents one of the most challenging areas in digestive surgery. In recent years, an increasing number of laparoscopic pancreatic procedures have been performed and laparoscopic distal pancreatectomy (LDP) has gained world-wide acceptance because it does not require anastomosis or other reconstruction. To date, English literature reports more than 300 papers focusing on LDP, but only 6% included more than 30 patients. Literature review confirms that LDP is a feasible and safe procedure in patients with benign or low grade malignancies. Decreased blood loss and morbidity, early recovery and shorter hospital stay may be the main advantages. Several concerns still exist for laparoscopic pancreatic adenocarcinoma excision. The individual surgeon determines the technical conduction of LDP, with or without spleen preservation; currently robotic pancreatic surgery has gained diffusion. Additional researches are necessary to determine the best technique to improve the procedure results.

PANCREATIC SURGERY AND LAPAROSCOPY

Pancreatic surgery represents one of the most challenging areas in digestive surgery, and it has been historically associated with up to 50% morbidity and 5% mortality[1,2]. It is usually performed by open approaches, but following the increased experience in laparoscopic surgery of other districts and the availability of new technological devices, an increasing number of laparoscopic pancreatic procedures has been performed[3,4].

Laparoscopy has initially been used only for staging

pancreatic cancer. Cuschieri reported the first description of laparoscopic pancreatic resection in 1994[5]; few years later, Gagner published his initial experience with laparoscopic distal pancreatectomy (LDP) with spleen preservation including eight cases[6]. Actually, LDP has gained world-wide acceptance because the procedure does not require anastomosis or other reconstruction[7,8].

A comparison between open surgery and LDP confirms advantages commonly ascribed to minimal-access surgery such as reduced postoperative pain, faster recovery, fewer wound related and general morbidity[9-19]. Although the laparoscopic approach to distal pancreatectomy has become a feasible option over the last few years, it still faces two problems: firstly, sparing the spleen with or without ligation of the splenic vessels, and secondly, controlling the leak from the pancreatic remnant and pancreatic fistula[20]. However, some controversy about its indications and safety concerning long-term oncologic outcome, still exist[21-23].

Literature concerning LDP is relatively poor: Case reports, small case series and few multicentric larger studies have been published[21,24-26]. The aim of this paper is to review the most recent literature, in order to offer an up-to-date concerning the indications, the results and some technical controversial issues concerning LDP.

LAPAROSCOPIC DISTAL PANCREATECTOMY: LITERATURE REVIEW

A web search, focusing on humans, was performed by PubMed database, including papers published in the English language up to 20 November 2011, using the key words "laparoscopic distal pancreatectomy" or "left-side pancreatectomy". A total of 388 papers were found. The bibliographic research was further expanded considering the related references cited by the above-mentioned papers.

In order to avoid the confounding effect of case reports and small series, a more refined research, including series of at least 30 cases, was performed. Results published only in the abstract form were excluded; in case of multiple publications from the same authors or institutions, only the latest and largest series were considered, in order to avoid the duplication of cases.

Twenty-two papers, including 2016 operated patients were found when literature search was reviewed. The median number of cases included were 70 (range: 30-359). The results are summarized in the Table 1. Eighteen papers included retrospective series; patients were prospectively included only in four studies. Eight papers derived from multicentre group studies.

The review of the literature confirms that LDP may be considered a feasible and safe technique[21,27,28]. It represents more than 70% of the laparoscopic pancreatic resections actually performed[29]. However, the major part of the studies on LDP is represented by case series with a relatively small number of patients[23,30]; only 6% of papers includes more than 20 cases. Most of the studies have a retrospective design; subsequently, it is still difficult to trace any conclusion from the results of these experiences because of the insufficient level of evidence.

Several comparative studies have shown that the average operative time, blood loss, morbidity, mortality and length of hospital stay after laparoscopic access might favourably comparable with those after open surgery[9,11-19,29].

In particular Mehta *et al*[17] describes a tendency toward a shorter duration of surgery in laparoscopic resection compared to open, although without a significance level ($P = 0.071$).

By contrast, with these optimistic prospects, Baker has published a single-institution comparison between laparoscopic and open distal pancreatectomy, focusing on post-discharge readmission. The laparoscopic approach has been associated with a shorter hospital stay, but a higher rate of late readmission requiring interventional procedures[31]. Furthermore, LDP cannot be considered a routine laparoscopic procedure, since it requires an advanced technical laparoscopic skill.

To date, several aspects are still controversial, mainly related to the indications, the results of the procedure and some technical details.

INDICATIONS TO LAPAROSCOPIC DISTAL PANCREATECTOMY

The indications for LDP vary, depending on the study, although most operations of LDP have been performed because of benign lesions, neuroendocrine tumors or low-grade malignancies (in particular cystic tumors)[29,32]. However some cases of pancreatic adenocarcinoma have been reported[33]; the results of laparoscopic resection for left pancreatic adenocarcinoma are limited, and its safety for long-term oncologic outcome is strongly debated. This approach for the treatment of pancreatic carcinoma still requires prospective validation[34] (Table 2).

LDP has also been performed in patients with chronic pancreatitis[35]; laparoscopic necrosectomy for acute necrotizing pancreatitis has been also described[36]. Steering wheel injury typically involves pancreatic parenchyma in front of the vertebra; LDP preferably with spleen preservation, has been indicated for patients with pancreatic trauma[37-39].

Persistent hyperinsulinemic hypoglycemia of infancy is a rare disease due to focal islet cell adenomatosis that may cause severe neurogenic damage. LDP or enucleation of the focal lesion has been performed in pediatric patients, while an open near-total pancreatectomy has been indicated in an infant with sustained hypoglycemia[40,41].

Surgery is the only curative modality currently available for resectable pancreatic neuroendocrine tumors[26,42]. Spleen-preserving LDP is feasible and can be achieved in

n: Number of patients; SCN: Serous cystic neoplasm; MCN: Mucinous cystic neoplasm; ADK: Adenocarcinoma; SPT: Solid pseudopapillary tumor; IPMN: Intraductal papillary mucinous neoplasm; NA: Not available; NET: Neuroendocrine tumor; P: Pancreatitis. Number of case for each pathology are report between parenthesis.

Table 2 Indications to laparoscopic distal pancreatectomy

Benign disease	Borderline disease	Malignant disease
Acute/chronic pancreatitis	Neuroendocrine tumor	Invasive carcinoma
Trauma	Mucinous cystic neoplasm	Metastatic renal cell carcinoma
Persistent hyperinsulinemic hypoglycemia of infancy	Intraductal papillary mucinous neoplasm	
Serous cystic neoplasms		
Transplantation in the living donor		

most cases; it is indicated for insulinomas of the pancreatic body and tail. Intraoperative laparoscopic ultrasonography is essential to localize the tumor and to evaluate the gland for additional tumors. If the insulinoma is benign, solitary, and not close to the main duct, a laparoscopic enucleation of the neoplasm may be indicated[25,43,44].

Laparoscopic resections have been also performed in some patients with gastrinoma, VIPoma, glucagonoma[45], pancreatic polypeptidoma[46], or other islet neoplasms including so-called non-functioning tumors[6]. However, some of these neuroendocrine neoplasms are often malignant and conversion to open surgery is necessary in cases of gastrinomas and VIPomas complicated by lymph node metastasis[6,47,48].

In case of potentially malignant neuroendocrine neoplasms in the pancreatic body/tail, LDP might be indicated, but laparoscopic en bloc splenectomy with resection of the spleen vessels and regional lymph-nodes dissection are recommended[4]. In case of multiple endocrine neoplasia-1 (MEN-1) patients, multiple neoplasms are common (especially gastrinomas); in these cases tumors are also located at gastroduodenal sites; the intraoperative localization of the tumors by laparoscopic approach, is not always possible even by the laparoscopic ultrasound; subsequently it is not usually indicated[48]. Furthermore, since a prolonged postoperative follow-up (at least 10 years) is required in case of potentially malignant neuroendocrine tumors, consistent data concerning the cure and recurrences rate, are still not available.

Pancreatic mucinous cystic neoplasm (MCN) represents a further possible indication to LDP. It groups a spectrum of lesions ranging from benign mucinous cystadenoma to mucinous cystadenocarcinoma. MCN is characterized by a distinct ovarian type stroma; patients with these lesions are usually relatively young women, with the peak around in the fifth decade of life. These neoplasms are more common in the body/tail of pancreas and a complete resection of the lesion is indicated. In patients with MCN several authors[49,50] have reported successful treatments by LDP.

The pancreatic serous cystic neoplasms are usually benign cystic neoplasms. When serous cystic neoplasms are symptomatic or when a differential diagnosis from potentially malignant cystic neoplasm is not possible,

a resection (possibly LDP) is indicated[49-52]. In a large comparative study between open and LDP, cystic lesions represented 59% of the laparoscopically resected tumors and 46% of the tumor excised by a laparotomic approach[19].

Intraductal papillary mucinous neoplasms (IPMN), non-invasive mucin-producing, predominantly papillary, or rarely flat epithelial neoplasms arising from the main pancreatic duct (MD-IPMN) or its secondary branches (BD-IPMN), are grossly visible[53]. They involve the head of the pancreas more commonly than the body/tail and they affect older patients with the peak age in the seventh decade. For IPMN in the body/tail of the pancreas, LDP has been performed, but one should be aware that some IPMN is associated with invasive carcinoma, as it is for MCN[53,54].

LDP has also been carried out in patients with pancreatic invasive carcinoma[23], although the questions about the oncological consequences of laparoscopic pancreatic surgery remain strongly controversial[21].

The positive margin resection rate in pancreatectomy for ductal adenocarcinoma is difficult to understand because there is no defined standard for histologic margin assessment. A recent review of the large randomized trials highlight that positive margin rates ranged from 0% to 83%[55].

A prospective observational study comparing open *vs* LDP has shown that the number of lymph nodes removed during the laparoscopic procedure was significantly inferior in comparison to the open approach[10]. Another recent analysis from a multicentre group, has compared the results of laparoscopic and open distal pancreatectomy applied to pancreatic ductal carcinoma. Cancer outcomes in short-term (lymph nodes harvest and margin status) and long-term (survival) were found to be similar in both groups[32,33]. Finally, LDP have been sporadically described also for metastatic renal cell carcinoma[56] and for pancreas transplantation in the living donors[57,58].

SURGICAL TECHNIQUES

The individual surgeon determines the technical conduction of LDP; it is usually performed in a supine or in a right lateral position[59]. However, several technical variants may be used, and some controversies still exist. The main controversial aspects in LDP are related to the preservation of the spleen, by the number and location of orifices needed for approaching the pancreas, the extent of the resection and the technique used for the parenchymal transection.

Traditionally, distal pancreatectomy has been performed with splenectomy. However the spleen plays an important role in the immune system and spleen-preserving distal pancreatectomy is preferable, in patients with benign diseases or non-invasive neoplasms[8,21,51,60].

The rate of splenic conservation of LDP is reported to be between 32% and 84%[14,17,42]. Some comparative studies have assessed the outcomes preoperative intent of splenic conservation in distal pancreatectomies performed by laparoscopic and open approaches, with a higher success rate of preservation in the first group[14,17]. This is surely due to the better vision afforded by the magnification, used in laparoscopy.

Preservation of the spleen with distal pancreatectomy can be undertaken either with preservation or with sectioning of the splenic vessels by maintaining the blood flow to the spleen *via* short gastric vessels (technique of Warshaw[61]). The latter method is associated with a shorter operation time, less blood loss, and a shorter hospitalization. The subsequent appearance of gastric varices is a consequence of loss of the splenic vein but no bleeding from these collaterals during long-term follow up, has been described. However, a splenic infarction after the laparoscopic procedure of Warshaw[62] has been documented in several case reports[63].

A technical difficulty during the preservation of splenic vessels is the division of numerous shorts tributaries from the splenic vein spreading toward the pancreatic body/tail, that requires special caution[64]. The appropriate usage of modern technologies (electro thermal bipolar vessel sealer, ultrasonic coagulating shears) can achieve secure haemostasis of tributaries from splenic vessels.

The hand-assisted laparoscopic surgical techniques have been utilized in LDP, in order to facilitate the splenic vessel preservation, because incidental bleeding can be immediately stopped by finger compression, and in large cystic tumors for a safe mobilization of the tumor and adjacent tissue. Hand ports for the insertion of operator's left hand are placed through an upper midline incision, right subcostal incision, or right lower-quadrant transverse incision according to the preference of surgeons[65-68].

Single incision laparoscopic surgery has gained attention for its minimal invasiveness and aesthetic results. This approach has been commonly described for cholecystectomy and appendectomy[69-71]; recently it has also been reported for LDP[72]. It may be effective as conventional laparoscopic pancreatectomy, when performed by expert hands although it is still a challenging procedure[58]. Further studies are necessary to determine the advantages of this procedure in comparison with standard laparoscopy.

Even though laparoscopic surgery of the pancreas remains a very challenging technique, the classically available instruments have some relevant limits. Today, following the increasing use of the robotic surgery in other fields of general surgery, some robot-assisted pancreatic resections have been reported[73-75]. Robotic surgery, can bridge the gap between minimally invasive surgery and complex pancreatic surgery, thus extending the indications for minimally invasive pancreatic surgery.

Robot-assisted surgery increases the degrees of freedom of forceps manipulation and yields three-dimensional images[22,73,76-79]. It is a procedure with some technical

and oncological advantages over other minimally invasive techniques for distal pancreatic tumors, due to the stability of the operative field, the 3D, magnified vision, and the articulated robotic arms. Moreover, the robotic articulated arms permit a superior handling of vascular structures and articulated instruments minimizing manipulation of the pancreatic gland. This technique minimizes the risk of pancreatic capsule rupture as well as tumor cell dissemination, respecting oncological surgical standards and it could provide an increased chance for spleen preservation. Giulianotti *et al*[80] has highlighted that robot-assisted laparoscopic pancreatic surgery achieves complication and mortality rates comparable to open surgery approaches, but offers the advantages of minimally invasive surgery. However, robotic surgery has high costs especially concerning the installation and the operation time, which is longer than open surgery; at the same time, it also needs an adequate learning curve.

The extent of a resection in LDP is another controversial topic. It varies depending on the pathology. For example, when a non-invasive MCN is located in the tail of the pancreas, the gland can be divided to the right of the cystic lesion with a minimal margin and only the tail of the pancreas removed. For chronic pancreatitis, it is typically divided at the pancreatic neck anterior to the superior mesenteric vein[4,35]. Recently, pancreatic surgeons have performed parenchyma-sparing resections more frequently in order to decrease the rate of postoperative pancreatic insufficiency. Oncological radicality is essential and extended resections may be necessary in the setting of IPMNs, which encompass a spectrum of lesions from adenoma to invasive carcinoma.

Intraoperative examination of the transection margin is of paramount importance in the management of MD-IPMNs[81-83]. The International Association of Pancreatology guidelines for the management of IPMNs suggest that when adenoma or low-grade pancreatic intraepithelial neoplasia is found intraoperatively in a resection margin, no further resection is needed. In case of borderline neoplasms, high-grade dysplasia or invasive carcinoma, an extension of the surgical resection to a negative margin, requires total pancreatectomy[53].

MORBIDITY

The most frequent complications after distal pancreatectomy are the fistula formation and collection[21,84,85]; they are usually related to pancreatic parenchymal transection techniques, that is another controversial topic.

In 2005 the International Study Group on Pancreatic Fistula Definition consensus paper defined a postoperative pancreatic fistula as the existence of any fluid output after postoperative day three with amylase content greater than three times the upper normal serum value[86].

Mabrut reviewed a total of 897 patients who underwent open distal pancreatectomy and reported the incidence of pancreatic fistula to be 3.5%-26% (average 13%)[21]. The incidence of pancreatic fistula with laparoscopy in studies that involved at least ten patients ranged from 0% to 27%[85].

Various risk factors for fistula formation have been reported after distal pancreatectomy. It is likely to occur in a pancreas with a soft texture[21,84,85,87], and when a selective identification and ligation of the main pancreatic duct has not been performed[87-89].

Some authors have suggested that the selective ligation may be more difficult during laparoscopy and may contribute to increased fistula rates[21]. Nevertheless, comparative studies showed that the laparoscopic approach results in a similar rate of fistula formation than the open approach[14,15,17]. A meta-analysis of studies comparing minimally invasive (laparoscopic or laparoscopically assisted) to the open approach, showed a lower rate of pancreatic fistula formation for minimally invasive approach[11]. However these results need cautious interpretation, because they depend on the study by Kooby, that relied on a definition different from that of the other studies[27].

The debate regarding the technique of stump closure after distal pancreatectomy continues. All approaches, including fibrin glue, sealants, patches, stapler closure, electrocautery and suture have been tested in numerous studies[90,91].

The distal pancreatectomy trial included 352 patients that were randomly assigned to stapler or hand-sewn closure of the pancreatic remnant: both groups showed equal fistula rates of 30% and 36%[92].

The main duct ligation and parenchymal transection during LDP is most commonly performed using endoscopic linear staplers. The surgeon may oversew the staple line to ensure pancreatic ductal closure and haemostasis. In such cases, ultrasonic coagulating shears can be used, usually followed by a monofilament suture to secure the closure of the main pancreatic duct[21,63,93,94].

In a recent study, Sartori *et al*[95]describes a new technique of pancreatic transection by the electrothermal bipolar vessels sealer, which seals vessels and other tubular structures by reforming parietal collagen and elastin, particularly suitable for laparoscopic left pancreatectomy; but a possible suitability in terms of fistula reduction is still under investigation.

When using the hand assisted laparoscopic technique, the pancreas can be divided through the hand port wound as for conventional open surgery.

To prevent post-operative fistula, octreotide and its analogues, have also been used since 1990. However, despite twenty years of clinical use and performance in numerous studies, a recent Cochrane meta-analysis concluded that evidence is still lacking to give clear recommendations[96].

Intraabdominal drains are commonly used in most centres after pancreatic resections. There is no evidence that persisting drainage of postoperative wound fluid has a positive effect in avoiding fistulae; on the contrary, a recent study sustains that drains kept in situ for more than three days enhance fistula development[97].

The management of postoperative fistula remains a therapeutic challenge. Depending on patient's clinical conditions, it ranges from persisting drainage without any further measures, up to revision surgery. However in literature, after LDP, a conservative management of pancreatic fistula is usually described[85,87].

In conclusion, LDP is a feasible and safe procedure in patient with benign or low grade malignancies. Decreased blood loss and morbidity, early recovery and shorter hospital stay may be the main advantages. The introduction in particular of robotic surgery, can bridge the gap between minimally invasive surgery and complex pancreatic surgery. On the other hand, additional researches are necessary to determine the best technique for minimizing pancreatic fistula formation and to improve the results of procedure.

Abstract

Abnormal bone metabolism and dysfunction of the calcium-parathyroid hormone-vitamin D axis have been reported in patients with viral hepatitis. Some studies suggested a relationship between vitamin D and viral hepatitis. Genetic studies have provided an opportunity to identify the proteins that link vitamin D to the pathology of viral hepatitis (i.e., the major histocompatibility complex class Ⅱ molecules, the vitamin D receptor, cytochrome P_{450}, the renin-angiotensin system, apolipoprotein E, liver X receptor, toll-like receptor, and the proteins regulated by the Sp1 promoter gene). Vitamin D also exerts its effects on viral hepatitis *via* non-genomic factors, i.e., matrix metalloproteinase, endothelial vascular growth factor, prostaglandins, cyclooxygenase-2, and oxidative stress. In conclusion, vitamin D could have a beneficial role in viral hepatitis. Calcitriol is best used for viral hepatitis because it is the active form of the vitamin D_3 metabolite.

INTRODUCTION

Abnormal bone metabolism and dysfunction of the calcium-parathyroid hormone (PTH)-vitamin D axis have been reported in patients with viral hepatitis. In these patients, bone mineral density (BMD) was reduced in the lumbar spine and femoral neck[1-4]. The prevalence and severity of bone loss increases based on the severity of the liver disease[2]. Biochemical markers of bone resorption, such as urinary telopeptide (NTX) and pyridinoline, bone-specific alkaline phosphatase, and serum levels of PTH, were increased in patients with chronic viral hepatitis[1,4-9]. Serum insulin-like growth factor-1 (IGF-1) and 25-hydroxyvitamin D_3 (25OHD) were lower in patients with viral hepatitis[1,8-10]. However, other studies demonstrated contradictory results with respect to bone metabolism in patients with chronic viral hepatitis. Osteosclerosis was reported in patients with hepatitis C virus (HCV) and was associated with normal levels of IGF-1. It is also associated with an increased levels of osteoproterin (OPG) and the ligand for receptor activator of nuclear factor-κB (RANK)[11,12]. Serum levels of PTH were lower in patients with HCV compared to controls[6,13]. These findings suggested that there might be a relationship between vitamin D and viral hepatitis. In this paper, we review the role of vitamin D in patients with viral hepatitis.

GENETIC FACTORS RELATED TO VITAMIN D IN VIRAL HEPATITIS

The major histocompatibility complex (MHC) class Ⅱ molecules play an important role in immune functioning

and are essential to the body's defense against infection. The human MHC class Ⅱ is encoded by three different isotypes, *HLA-DR*, *HLA-DQ*, and *HLA-DP*. Studies have suggested that several genes in the MHC region promote susceptibility to viral hepatitis. Human leukocyte antigen (HLA) genes, which are located in the MHC region, have been implicated in viral hepatitis susceptibility. *HLA-DRB1*12* is significantly more common in children with autoimmune hepatitis with positive hepatitis A IgM than in children with negative hepatitis A IgM[14]. In addition, the *HLA-DPA1* and *HLA-DPB1* genes are known to be associated with hepatitis B virus (HBV) infection in Han Chinese, Japanese, and Thai populations[15-18]. However, *HLA-DPA1* was not associated with the development of cirrhosis or hepatocellular carcinoma (HCC) in Han Chinese populations[19]. Genetic variants in the *HLA-DPA1* region may also affect treatment-induced hepatitis B e antigen (HBeAg) sero-conversion[20]. In the normal human liver, mRNA expression of *HLA-DPA1* and *HLA-DPB1* are important for control of HBV[21]. *HLA-DRB1*1101* correlates with less severe hepatitis in Taiwanese male carriers of HBV[22]. *HLA-DRB1*1302* was reported to be associated with protection against persistent HBV infection in Gambian populations[23]. In South Indian populations, a significantly higher frequency of *HLA-DRB1*0701* was observed in patients with chronic viral illness compared with individuals who spontaneously recover (SR), but *HLA-DRB1*0301* was noted to be of higher frequency in the SR group than the chronic HBV group[24]. In patients from Eastern Turkey, *DQ2* and *DQ8* have been noted to be markedly higher in patients with chronic HBV than those with SR[25]. The presence of *DQw1* may protect against chronic active HBV infection[26]. In addition, patients with chronic HBV infection and the *DQB1*0303* and *DRB1*08* haplotypes may be less responsive to interferon alpha (IFNα) treatment[27]. Moreover, *DRB1*11*, *DRB1*0301*, and *DRB1*04* were found to confer a significant protective advantage against HCV infection[28-31]. These alleles might be responsible for the selection of viral epitopes for presentation to $CD4^+$ T cells, leading to a more efficient immune response against the virus. In a meta-analysis study, both *DQB1*0301* and *DRB1*1101* were protective alleles and presented HCV epitopes more effectively to $CD4^+$ T lymphocytes than other epitopes, Indeed, subjects with these two alleles were at a lower risk of developing chronic HCV infection[32]. On the other hand, calcitriol is known to stimulate phagocytosis but suppresses MHC class Ⅱ antigen expression in human mononuclear phagocytes[33,34]. In peripheral blood leukocytes, the expression of *HLA-DR* decreased after calcitriol administration in renal transplant recipients[35]. Calcitriol also decreases interferon-gamma-induced HLA-DR antigen expression on normal and transformed human keratinocytes and cultured epithelial tumor cell lines[35,36]. Both DR and DQ protein levels on the surface of a myeloma cell line were decreased after calcitriol treatment[37]. Moreover, calcitriol inhibits the expression of all three subtypes of MHC class Ⅱ antigens (*HLA-DR*, *HL-ADP*, and *HLA-DQ*) as well as the accessory activity of monocytes, both in a dose- and time-dependent manner[38]. These findings suggest that calcitriol may have an impact on viral hepatitis by suppressing the expression of MHC class Ⅱ antigens.

Genetic studies provide an opportunity to link molecular variations with epidemiological data. DNA sequence variations, such as polymorphisms, exert both modest and subtle biological effects. Vitamin D exerts immunomodulatory and anti-proliferative effects through the vitamin D receptor (VDR) in numerous diseases. VDR gene polymorphisms are reported to be associated with distinct clinical phenotypes in Taiwanese hepatitis B virus (HBV) carriers[39]. There is an association between *Taq1* and *Fok1* polymorphisms of VDR and HBV outcomes in Chinese patients[40]. The *tt* genotype of VDR polymorphism is linked to persistent HBV infection in African patients[41]. Polymorphisms in the *TT* allele of exon 9 of VDR are associated with occult HBV infection in Iranian patients[42]. Significant differences in the frequency of the allelic distribution of the *Apa1* of VDR are reported to occur more frequently in patients with HBV complicated by severe liver disease as well as those with higher viral loads[43]. These observations suggest that alterations in VDR function may play a role in viral hepatitis.

The cytochrome P_{450} (*CYP*) system is responsible for the oxidation, peroxidation, and/or reduction of vitamins and for the metabolism of steroids, xenobiotics, and various drugs. The *CYP27B1-1260* promoter polymorphism has been reported to be associated with vitamin D deficiency and an increased risk of fracture in the elderly[44]. Reduced 25OHD levels associated with the *CYP27B1-1260* promoter polymorphism results in reduced 1,25OHD levels and are associated with failure to achieve sustained virologic response (SVR) in patients with hepatitis C virus (HCV) genotypes 1, 2, and 3[45]. In Huh7.5 hepatoma cells, HCV infection increased calcitriol production by inhibiting *CYP24A1* induction, the enzyme responsible for the first step in calcitriol catabolism[46]. *CYP24A1* methylation tended to correlate with better prognosis in HCV-related HCC[47].

The primary function of the renin-angiotensin system (RAS) is to maintain fluid homeostasis and regulate blood pressure. Angiotensin converting enzyme (ACE) is a key enzyme in the RAS and converts angiotensin (AT) I to the potent vasoconstrictor AT Ⅱ[48]. Hepatic stellate cells (HSCs) are recognized as the main collagen-producing cells in injured hepatic tissue. Angiotensin Ⅱ (AT Ⅱ) mediates key biological actions involved in hepatic tissue repair, including myofibroblast proliferation, infiltration of inflammatory cells, and collagen synthesis. Activated HSCs secrete AT Ⅱ[49]. ACE2 expression is significantly increased in the context of liver injury, in both humans and rats[50]. In addition, AT Ⅱ levels are much higher in patients with HBV when compared to controls. These levels were directly related to the severity of the illness and decrease markedly with captopril, which is an ACE inhibitor[51]. A statistically significant correlation has been

noted between polymorphisms in the promoter region of the *AT* gene and the development of progressive hepatic fibrosis in patients with chronic HCV[52]. In recurrent hepatitis C infection, male liver recipients who were carriers of the *D* allele of *ACE* appeared to gain more weight after liver transplantation; in female recipients, however, carriers of the *D* allele appear to experience more severe allograft fibrosis[53]. Losartan, an AT1 receptor blocker, attenuates liver fibrosis in experimental models and in patients with chronic hepatitis C and significantly decreases the expression of several profibrogenic and NADPH oxidase (NOX) genes[54]. The administration of AT-blocking agents reduced the development of graft fibrosis in hepatitis C recurrence after liver transplantation[55]. However, there is also an interaction between vitamin D and the RAS. The combination of ACE inhibitors with the ACE *DD* genotype has been shown to decrease the level of calcitriol[56]. In Turkish populations of hypertensive patients, the presence of the *ACE D* allele is associated with a higher risk of left ventricular mass index and ambulatory blood pressure measurement, which is negatively correlated with serum 25OHD levels[57]. In addition, genetic disruptions of the VDR gene result in overstimulation of the RAS, resulting in increased renin and AT Ⅱ productions and subsequently leading to elevated blood pressure and cardiac hypertrophy. Treatment with captopril reduced cardiac hypertrophy in VDR knockout mice[58], suggesting that calcitriol could function as an hormonal suppressor of renin biosynthesis. Moreover, calcitriol suppresses renin gene transcription by blocking the activity of the cyclic AMP response element in the renin core promoter[59] and decreases ACE activity in bovine endothelial cells[60].

Apolipoprotein E (ApoE) is critical to systemic and local lipid transport and is a major genetic factor in viral hepatitis. The hepatitis virus is associated with serum lipoproteins, including ApoE and ApoB, and may enter cells *via* the low-density lipoprotein receptor (LDL-R). In *in vitro* models, the co-culture of hepatocytes with liver sinusoidal endothelial cells (LSEC) significantly increases the ability of hepatocytes to uptake low-density lipoprotein (LDL) and also results in a high level of HCV-like particle uptake[61]. The cell surface expression of LDL-R has been reported to correlate well with LDL-cholesterol and HCV-viral load[62]. ApoE antibody can block both HCV entry an the knockdown of the LDL-R reduced HCV infection of cells[63]. Human ApoE is required for the infectivity and assembly of HCV[64,65]. The *ApoE ε4* allele protects against severe liver disease caused by HCV[66], while *ApoE ε3* is associated with persistent HCV infection[67]. In addition, patients with chronic hepatitis C who do not carrying an *ApoE* ε3 allele, as well as carriers of a single *ApoE* ε3 allele with a serum cholesterol concentration over 190 mg/dL, were more likely to have a favorable outcome[68]. Moreover, lipoprotein abnormalities found in the early phases of acute hepatitis; low levels of serum cholesterol and ApoA associated with the severity of liver cell injury in chronic liver disease[69]. The nonstructural protein 5A (NS5A) of the HCV has been shown to interact with $ApoA_1$[70]. A decreased level of $ApoA_1$ was found in the LDL fractions of HCV-infected patients; the specific siRNA-mediated down-regulation of $ApoA_1$ led to a reduction in both HCV RNA and viral particle levels in culture[71]. On the other hand, the *ApoE4* allele is reported to be associated with decreased bone mass in postmenopausal Japanese women[72]. The common *ApoE* polymorphism has a complex effect on bone metabolism in peri-menopausal Danish women: those with *ApoE2* have lower bone mineral losses in the femoral neck and hip region than other women, whereas those with *ApoE4* gain more bone mineral than other women[73]. Calcitriol has been shown to induce macrophages to exhibit specific saturable receptors for LDL and acetyl-LDL; the LDL receptor of 1,25OHD-induced macrophages has been found to exhibit specificity for ApoB and E-containing lipoproteins[74]. In ApoE knockout mice, an animal model of dyslipidemia, high oxidative stress, and pronounced atherosclerosis after unilateral nephrectomy, animals developed less plaque growth and calcification with vitamin D analog treatment (paricalcitol) compared to healthy controls[75,76]. *ApoE ε4*, however, is associated with higher serum 25OHD levels[77]. Moreover, hypovitaminosis D is associated with reductions in serum $ApoA_1$[78] and a highly significant positive correlation was found between serum concentrations of 25OHD and *$ApoA_1$*[79]. In addition, calcitriol was reported to suppress *$ApoA_1$* gene expression at the transcriptional level in hepatocytes[80].

Lipids have been shown to play important roles in the viral life cycle and pathogenesis of infection. HBV infection of primary hepatocyte cultures is dependent on the presence of cholesterol in the viral envelope. The extraction of cholesterol from HBV purified from the plasma of HBV-infected patients leads to a strongly reduced level of infection, whereas infectivity is only regained by adding cholesterol back[81]. A number of lipid metabolic pathways were disrupted by HCV infection, resulting in an increase in cholesterol and sphingolipid levels[82]. Higher serum triglycerides, total cholesterol and LDL levels were correlated with higher HCV RNA levels[83]. Ceestatin, a novel small molecule inhibitor of hepatitis C virus replication, inhibits 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase in a dose-dependent manner[84]. Polyunsaturated liposomes are reported to be antiviral against hepatitis B and C viruses by decreasing cholesterol levels in infected cells[85]. Moreover, HCV and HBV X protein increases the hepatic lipogenesis is mediated predominantly by the liver X receptor (LXR)[86-88]. LDL receptor-related protein 5 (LRP5) is essential for normal cholesterol and glucose metabolism. Mice lacking LRP5 develop both increased plasma cholesterol levels when fed a high-fat diet markedly impaired glucose tolerance when fed a normal diet[89]. HCV core protein activates Wnt/β-catenin signaling molecules, such as LRP5/6 co-receptors[90], whereas calcitriol regulates the expression of LRP5 *via* DNA sequences elements located downstream of the transcription start site[91]. Notably,

high serum 25OHD concentrations are associated with a favorable serum lipid profile, e.g., total cholesterol and high-density cholesterol (HDL-C)[92]. Low levels of active vitamin D (calcitriol) are also associated with low HDL-C levels[93]. Moreover, calcitriol has been shown to suppress foam cell formation by reducing acetylated LDL (AcLDL) and oxidized LDL (oxLDL) cholesterol uptake by macrophages[94]. In addition, calcitriol also inhibits the activity of HMG-CoA reductase, an enzyme required for cholesterol biosynthesis[95]. In male VDR knockout mice, serum total cholesterol and LXRβ levels were significantly higher than those in wild type mice[96]. The crosstalk between LXRα and VDR signaling in the regulation of bile acid metabolism suggests a possible contribution of the VDR to the modulation of bile acid and cholesterol homeostasis[97].

Toll-like receptors (TLRs) are a group of glycoproteins that functions as surface trans-membrane receptors and are involved in innate immune responses to exogenous pathogenic microorganisms. Substantial evidence supports an important role for TLRs in the pathogenesis and outcomes of viral hepatitis. There is a correlation between hypo-responsiveness to TLR ligands and liver dysfunction in HCV infection[98]. The disruption of TLR-3, TLR-7, and TLR-9 signaling was reported in viral hepatitis[99-101]. *In vivo*, TLR signaling also inhibits HBV replication[102]. TLR-2 polymorphisms that impair the recognition of HCV core and nonstructure 3 proteins may be associated with allograft failure and mortality after liver transplantation for chronic HCV[103,104]. These polymorphisms affect HCV viral loads and increase the risk of HCC in patients infected with HCV genotype 1[105]. The TLR-3 polymorphism may predispose Asian Indian populations to HCV infection[106] and protect Han Chinese populations from HBV recurrence after liver transplantation[107]. TLR-7 polymorphisms are protective against from development of inflammation and fibrosis in male patients with chronic HCV infection and are predictive of the response to IFN treatment[108-110]. TLR-2 and TLR-4 polymorphisms are not associated with liver cirrhosis in HCV infected Korean patients[111]. RNA levels of TLRs 2, 4, 6, 7, 8, 9 and 10 were up-regulated in both the monocytes and T cells of HCV-infected patients when compared to controls[112,113]. In obese rats, vitamin D deficiency increases the expression of hepatic mRNA levels of TLR-2, TLR-4, and TLR-9[114]. However, calcitriol is also known to suppress the expression of the TLR-2 and TLR-4 protein and mRNA in human monocytes; it also triggers hypo-responsiveness to pathogen-associated molecular patterns[115]. Calcitriol has also been shown to down-regulate intracellular TLR-2, TLR-4 and TLR-9 expression in human monocytes[116]. TLR activation results in the expression of VDR and 1α-vitamin D hydroxylase in human monocytes[117]. Calcitriol can cause vitamin D-induced expression of cathelicidin in bronchial epithelial cells[118] and may enhance the production of cathelicidin LL-37[119]. The addition of a VDR antagonist has been shown to inhibit the induction of cathelicidin mRNA by more than 80%; consequently, the protein expression of this antimicrobial agent was reduced by approximately 70%[118].

The HBV major surface antigen promoter contains four functional transcription factor Sp1 binding sites, which likely contribute to the level of expression from this promoter during viral infection[120-122]. HCV-core protein functions as a positive regulator of IGF-Ⅱ transcription *via* the protein kinase C (PKC) pathway, and Sp1 and Egr1 are direct targets of the transcriptional regulation of the IGF-Ⅱ, which plays an important role in HCV pathogenesis during the formation of HCC[122,123]. Steatosis is an important clinical manifestation of HCV infection. Sp1 is involved in sterol regulatory element-binding protein-1c (SREBP-1c) activation, which activates the transcription of lipogenic genes by HCV-3a NSSA[124]. Moreover, Sp1 might participate in triggering HCV core protein up-regulation of the extracellular matrix metalloproteinase (MMP) inducer expression and progression of metastasis[125]. On the other hand, binding sites for the transcription factor Sp1 have been implicated in the hormone-dependent transcription of several genes. In cultured human fibroblasts, the level of CYP24 (25-OHD 24-hydroxylase) mRNA plays a key role in the metabolism of 1,25OHD and increases responsiveness to calcitriol by 20 000-fold. Two vitamin D-responsive elements (VDREs) located upstream of the *CYP24* gene are primarily responsible increased mRNA levels, and Sp1 has been noted to act synergistically with these VDREs in this induction[126]. The mVDR promoter is controlled by Sp1 sites[127] and functions as the transactivation component of the VDR/Sp1 complex to trigger gene expression[128]. Moreover, the genes encoding Sp1, VDR, the locus for the vitamin D-dependent rickets type Ⅰ, and hepatitis B virus-positive hepatocellular carcinomas from Thai patients were mapped to human chromosome 12q[129,130].

THE NON-GENETIC ROLE OF VITAMIN D IN HEPATITIS

A high prevalence of vitamin D deficiency was reported in HCV patients[10,131]. Low serum 25OHD levels are also found in patients with human immuno-deficient virus (HIV) and HCV and are correlated with severe liver fibrosis[132,133]. Preparations containing vitamin D_3 were shown to be effective in reducing the severity of the syndrome associated with osteo-arthropathy, including a decrease in BMD in Ukrainians with chronic hepatitis B and C[134]. The combination of vitamin A (25 000 IU) and vitamin D_2 (2500 IU) enhances the re-vaccination reaction against HBV in Chinese children[135]. *In vitro*, vitamin D_2 is reported to inhibit HCV RNA replication and its combination with β-carotene and linoleic acid also causes an additive and/or synergistic effect with respect to HCV RNA replication[136]. VDR mRNA and protein were found in the rat liver throughout the animal's life span[137]. In another study, however, human and mouse hepato-

cytes were found to have very low nuclear VDR (nVDR) mRNA and protein levels, whereas the sinusoidal endothelial, Kupffer, and stellate cells of the normal rat liver as well as a mouse biliary cell line clearly expressed the nVDR gene transcript[138]. Vitamin D_3 dramatically inhibits HCV production in Huh7.5 hepatoma cells and in combination with INF-α, also synergistically suppresses HCV production in human hepatocytes[47]. Serum vitamin D levels are complimentary to the IL-28B polymorphism in enhancing the accurate prediction of the SVR in patients undergoing treatment for chronic HCV[139]. Low vitamin D is linked to severe liver fibrosis and low SVR in response to IFN-based therapy in genotype 1 chronic HCV patients[10]. Vitamin D supplementation also improves SVR in chronic HCV-naïve patients[140] and in response to antiviral treatment for recurrent HCV infection in liver transplant patients[141]. These findings suggest that vitamin D may play a role in the treatment of HCV. Chronic infection with viral hepatitis is a major risk factor worldwide for the development of HCC. Vitamin D analogs have been reported to reduce tumor volume in patients with inoperable HCC[142] and to increase apoptosis of hepatocarcinoma cells by 21.4%[143]. In another pilot study, an intra-arterial injection of calcitriol in lipiodol into the hepatic artery was given to eight refractory HCC patients and led to the stabilization of α-fetoprotein levels[144].

MMPs are proteolytic enzymes that are responsible for extracellular matrix remodeling and the regulation of leukocyte migration through the extracellular matrix, which is important step for inflammatory processes and infectious diseases. MMPs are produced by many cell types including lymphocytes, granulocytes, astrocytes and activated macrophages. During the course of chronic HCV infection, hepatic mRNA expression of MMPs has been shown to either increase steadily with disease progression (MMP-1, MMP-2, MMP-7, and MMP-14) or increase transiently (MMP-9, MMP-11, and MMP-13), depending on the type of MMP[145]. Serum and tissue MMP-9 expression were reported to decrease in chronic HCV patients treated with pegylated INF-α2b and ribavirin[146]. The ratio of MMP-9 to MMP-2 is useful in distinguishing between patients with early stage and advanced HCC[147]. Serum TIMP-1 levels decreased significantly during and after treatment in sustained responders[148]. MMP-3 polymorphisms are associated with persistent HBV infection and advanced liver cirrhosis in Korean populations[149,150]. MMP-1, MMP-3, and MMP-9 polymorphisms are associated with the progression of HCV-related chronic liver disease in Japanese populations and may be a risk factor for poor prognosis in HCC patients[151,152]. However, VDR knock-out mice demonstrated an increased influx of inflammatory cells, phospho-acetylation of NF-κB associated with increased pro-inflammatory cells, and up-regulation of MMP-2, MMP-9, and MMP-12 in the lung[153]. The VDR *TaqI* polymorphism is associated with a decreased production of TIMP-1, which is a natural inhibitor of MMP-9[154]. Calcitriol modulates tissue MMP expression under experimental conditions[155], down-regulates MMP-9 levels in keratinocytes, and may attenuate the deleterious effects caused by the excessive TNF-α-induced proteolytic activity associated with cutaneous inflammation[156]. Calcitriol inhibits both basal and the staphylococcus-stimulated production of MMP-9 in human blood monocytes and alveolar macrophages[157]. Moreover, a vitamin D analog was also reported to reduce the expression of MMP-2, MMP-9, vascular endothelial growth factor (VEGF) and PTH-related peptide in Lewis lung carcinoma cells[158]. Furthermore, calcitriol significantly attenuated *Mycobacterium tuberculosis* (*M. tuberculosis*)-induced increases in the expression of MMP-7 and MMP-10, while suppressing the secretion of MMP-7 by *M. tuberculosis*-infected PBMCs. MMP-9 gene expression, secretion and activity were significantly inhibited, irrespective of infection status[159]. Calcitriol also suppressed the production of MMPs (MMP-7 and MMP-9) and enhanced the level of TIMP-1 in tuberculosis patients[160]. In human articular chondrocytes, calcitriol significantly suppresses the increased production of MMP-9 that is induced by phorbol myristate acetate (PMA)[161]. These studies suggest that calcitriol may play an important role in the pathological process of viral hepatitis by down-regulating the levels of MMPs and regulating the levels of TIMPs.

Angiogenesis is a complex process involving the coordinated steps of endothelial cell activation, proliferation, migration, tube formation and capillary sprouting, which require the participation of intracellular signaling pathways. VEGF is a key mediator of angiogenesis. Vascular changes associated with angiogenesis usually occur in cancer; however, they have also been reported to occur in inflammatory disease processes. HCV C protein can activate the expression of VEGF in hepatoma cell lines ($HepG_2$) and might contribute to viral carcinogenesis[162]. Co-expression of the HBV X gene and the HCV core gene also increase the expression of VEGF in $HepG_2$ cells and act synergistically in carcinogenesis[163]. The expression levels of TNFα mRNA and VEGF mRNA showed a positive correlation with the progression of viral hepatitis to cirrhosis, i.e., the higher levels of TNFα and VEGF mRNA, the higher the prevalence of HCC[164]. HBV X protein is known to up-regulate the expression of VEGF, thereby promoting angiogenesis in HCC *via* NFκB signaling pathway[165]. Serum VEGF concentration is a predictor of invasion and metastasis in HCC[166] and positively correlates with the recurrence rate of HCC after curative resection[167]. In contrast, calcitriol was reported to inhibit angiogenesis *in vitro* and *in vivo*[168]. Calcitriol significantly inhibits VEGF-induced endothelial cell spouting and elongation in a dose-dependent manner and decreases the production of VEGF[169]. Calcitriol is a potent inhibitor of retinal neovascularization in a mouse model of oxygen-induced ischemic retinopathy[170]. Vitamin D and its analog also reduce the expression of VEGF in various cancer cell lines[158,171]. Moreover, *DBP-maf* was reported to inhibit angiogenesis and tumor

growth in mice[172] and inhibits the VEGF signaling by decreasing VEGF-mediated phosphorylation of VEGF-2 and ERK1/2, a downstream target of the VEGF signaling cascade[173]. These findings suggested that vitamin D modulates angiogenesis in viral hepatitis and may impact the mechanism of progression to HCC in patients with viral hepatitis.

Prostaglandins (PGs) play a role in inflammatory processes. Cyclooxygenase (COX) participates in the conversion of arachidonic acid to PGs. HBV X protein was reported to up-regulate levels of COX-2, 5-lipoxygenase and phosphorylated extracellular signal-regulated protein kinase ½ (p-ERK1/2) and releases arachidonic acid metabolites in liver cells[174]. In liver samples from patients with chronic HCV infection, there is a significant correlation between the dominant intensity of COX-2 and the presence of histological steatosis and an inverse correlation was observed between COX-2 and viral load[175]. COX-2 up-regulates VEGF expression and tumor angiogenesis in HBV-associated HCC *via* PG production; selective COX-2 inhibitors may block HCC-associated angiogenesis and an increase in platelet counts when used with pegylated TFNα2a[176,177]. Indomethacin also cleared HBV DNA in chronic healthy carriers, and 5 patients with positive HBeAg became negative after 4 mo[178]. On the other hand, calcitriol has been reported to regulate the expression of several key genes involved in the PG pathway, resulting in a decrease in PG synthesis[179]. Calcitriol and its analogs have been shown to selectively inhibit the activity of COX-2[180]. These findings suggested that vitamin D plays a role in modulating the inflammatory process in viral hepatitis.

Reactive oxygen species (ROS) are produced by activated phagocytes as a part of their microbicidal activities. Intracellular hydrogen peroxide (H_2O_2) levels are significantly higher in patients with chronic HCV infection than in asymptomatic carriers and positively correlates with alanine amino-transferase (ALT) levels[181]. ROS can also modulate the intracellular level of HBV X protein. The direct addition of H_2O_2 to cells significantly increased the level of HBV X protein in HBV X protein ChangX-34 cells, while antioxidants completely abolished the increase in HBV X protein[182]. There is a significant decrease glutathione (GSH) levels in the patients with HBV-infected[183]. Superoxide dismutase (SOD) was present in peripheral blood mononuclear cells (PBMC) but was absent in the liver of patients with chronic HCV infection[184]. Levels of lipid peroxidation products are increased in serum, leukocyte, and liver specimens in HCV patients[185]. Similarly, calcitriol has been reported to exert a receptor-mediated effect on the secretion of H_2O_2 by human monocytes[186]. Human monocytes in culture gradually lose their capacity to produce superoxide when stimulated. The addition of calcitriol, lipopolysaccharide or lipoteichoic acid restored the ability of stimulated monocytes to produce superoxide and increased their oxidative capacity when compared with unstimulated monocytes[187]. Calcitriol can also protect nonmalignant prostate cells from oxidative stress-induced cell death by eliminating ROS-induced cellular injuries[188]. Vitamin D metabolites and vitamin D analogs were reported to induce lipoxygenase mRNA expression, lipoxygenase activity and ROS in a human bone cell line[189]. Vitamin D can also reduce the extent of lipid peroxidation and induce SOD activity in the hepatic anti-oxidant system of rats[190]. These findings suggested that vitamin D modulates oxidative stress in viral hepatitis.

Nitric oxide (NO) is a reactive nitrogen species (RNS) that is critical in the redox biology of hepatocytes and is formed by nitric oxide synthase (NOS). In the liver, iNOS was found to be important in the development and propagation of inflammation. Viral hepatitis is associated with an increased iNOS expression[191,192]. HCV infection can also stimulate the production of iNOS through the activation of the iNOS gene by the viral core protein and the NS3 protein[191]. In patients with HCC, the combined negative expression of iNOS and COX-2 on histology has a significant impact on patient survival[193]. Oxidative DNA damage has been reported to increase chromosomal aberrations associated with cell transformation, and oxidative stress has also been suggested in the development of HCV-associated HCC. Oxidative DNA damage was observed in circulating leukocytes and occurs as an early event in chronic HCV infection[194]. NO often damage mitochondria, leading to the induction of double-stranded DNA breaks and the accumulation of oxidative DNA damage[195]. The viral core and NS3 proteins were shown to be responsible for inhibition of DNA repair, which is mediated by NO and ROS[196]. On the other hand, the activation of macrophage 1α-hydroxylase results in an increase in 1,25 OHD, which inhibits iNOS expression and reduces the NO produced by LPS-stimulated macrophages[197]. This calcitriol production by macrophages could provide protection against the oxidative injuries caused by the NO burst. Calcitriol is known to inhibit LPS-induced immune activation in human endothelial cells[198]. Calcitriol enhances intracellular GSH pools and significantly reduces the nitrite production induced by LPS[199]. In human macrophage-like cells, calcitriol induces iNOS and suppresses the growth of *M. tuberculosis*[200]. Moreover, calcitriol protects against doxorubicin-induced chromosomal aberrations in rat bone marrow cells[201]. Calcitriol also acts synergistically with vanadium in inhibiting diethylnitrosamine-induced chromosomal aberrations and DNA-strand breaks in the rat liver[202]. In regenerating liver cells, calcitriol regulates the synthesis of DNA polymerase-alpha, generates functional ribonucleotide reductase subunits, and induces DNA replication[203,204]. In addition, calcitriol appears to be effective in suppressing liver-specific early chromosomal damage as well as DNA damage during the process of rat hepatocarcinogenesis[205].

CONCLUSION

The relationship between vitamin D and viral hepatitis

has been discussed. Vitamin D may have a beneficial role in viral hepatitis. Genetic studies have provided the opportunity to determine what proteins link vitamin D to the pathology of viral hepatitis. Vitamin D also exerts its effect on viral hepatitis *via* non-genomic mechanisms. As a result, it is imperative that vitamin D levels in patients with viral hepatitis be followed. Many studies use the relationship between serum PTH and 25OHD to define the normal range of serum 25OHD. According to the report on Dietary Reference Intakes for vitamin D and calcium by the Institute of Medicine (IOM), persons are at risk of deficiency at serum 25OHD levels less than 30 nmol/L. Recently, Saliba *et al*[206] suggested that a 25OHD threshold of 50 nmol/L is sufficient for PTH suppression and prevention of secondary hyperparathyroidism in persons with normal renal function. Calcitriol is best used for viral hepatitis, because of its active form of vitamin D_3 metabolite and inhibits inflammatory cytokine expression. Adjusting dose for calcitriol depends on serum calcium and PTH levels. However, monitoring of serum 25OHD after calcitriol intake is not necessary because calcitriol inhibits the production of serum 25OHD in the liver[207,208]. Further investigation with calcitriol in viral hepatitis is needed.

Abstract

AIM: To investigate the anti-inflammatory properties of Lacto-Wolfberry (LWB), both *in vitro* and using a mouse model of experimental colitis.

METHODS: The effects of LWB on lipopolysaccharide (LPS)-induced reactive oxygen species (ROS) and interleukin (IL)-6 secretion were assessed in a murine macrophage cell line. *in vitro* assessment also included characterizing the effects of LWB on the activation of NF-E2 related 2 pathway and inhibition of tumor necrosis factor-α (TNF-α)-induced nuclear factor-κB (NF-κB) activation, utilizing reporter cell lines. Following the in vitro assessment, the anti-inflammatory efficacy of an oral intervention with LWB was tested *in vivo* using a preclinical model of intestinal inflammation. Multiple outcomes including body weight, intestinal histology, colonic cytokine levels and anti-oxidative measures were investigated.

RESULTS: LWB reduced the LPS-mediated induction of ROS production [+LPS *vs* 1% LWB + LPS, 1590 ± 188.5 relative luminescence units (RLU) *vs* 389 ± 5.9 RLU, $P < 0.001$]. LWB was more effective than wolfberry alone in reducing LPS-induced IL-6 secretion *in vitro* (wolfberry *vs* 0.5% LWB, 15% ± 7.8% *vs* 64% ± 5%, $P < 0.001$). In addition, LWB increased reporter gene expression *via* the anti-oxidant response element activation (wolfberry *vs* LWB, 73% ± 6.9% *vs* 148% ± 28.3%, $P < 0.001$) and inhibited the TNF-α-induced activation of the NF-κB pathway (milk *vs* LWB, 10% ± 6.7% *vs* 35% ± 3.3%, $P < 0.05$). Furthermore, oral supplementation with LWB resulted in a reduction of macroscopic (-LWB *vs* +LWB, 5.39 ± 0.61 *vs* 3.66 ± 0.59, $P = 0.0445$) and histological scores (-LWB *vs* +LWB, 5.44 ± 0.32 *vs* 3.66 ± 0.59, $P = 0.0087$) in colitic mice. These effects were associated with a significant decrease in levels of inflammatory cytokines such as IL-1β (-LWB *vs* +LWB, 570 ± 245 μg/L *vs* 89 ± 38 μg/L, $P = 0.0106$), keratinocyte-derived chemokine/growth regulated protein-α (-LWB *vs* +LWB, 184 ± 49 μg/L *vs* 75 ± 20 μg/L, $P = 0.0244$), IL-6 (-LWB *vs* +LWB, 318 ± 99 μg/L *vs* 117 ± 18 μg/L, $P = 0.0315$) and other pro-inflammatory proteins such as cyclo-oxygenase-2 (-LWB *vs* +LWB, 0.95 ± 0.12 AU *vs* 0.36 ± 0.11 AU, $P = 0.0036$) and phosphorylated signal transducer and activator of transcription-3 (-LWB *vs* +LWB, 0.51 ± 0.15 AU *vs* 0.1 ± 0.04 AU, $P = 0.057$). Moreover, antioxidant biomarkers, including expression of gene encoding for the glutathione peroxidase, in the colon and the plasma anti-oxidant capacity were significantly increased by supplementation with LWB (-LWB *vs* +LWB, 1.2 ± 0.21 mmol/L *vs* 2.1 ± 0.19 mmol/L, $P = 0.0095$).

CONCLUSION: These results demonstrate the anti-inflammatory properties of LWB and suggest that the underlying mechanism is at least in part due to NF-κB inhibition and improved anti-oxidative capacity.

INTRODUCTION

Inflammatory bowel disease (IBD), which includes Crohn's disease (CD) and ulcerative colitis (UC), represents a group of chronic disorders characterized by inflammation of the gastrointestinal tract, typically with a relapsing and remitting clinical course. They affect between 0.5%-1% of the Western world's population[1]. The primary focus of IBD therapy is to induce remission of acute inflammatory flare ups and to maintain the state of remission.

The innate immune system plays a central role in the acute inflammatory process. As part of the innate immune response, neutrophils are one of the early responders to local injury. Both, the circulating levels and activation of neutrophils, are increased in IBD patients with active disease[2,3]. Activated neutrophils and monocytes release a plethora of mediators including reactive oxygen species (ROS), eicosanoids and proinflammatory cytokines. In fact, the therapeutic benefit of depleting granulocytes in CD patients has been demonstrated[4]. Apart from neutrophils, monocytes and mucosal macrophages play an important role in the development of IBD as shown by an increase of the number of recruited monocytes and activated macrophages in the inflamed gut of patients with IBD[5]. Indeed during active inflammation, neutrophils recruit and activate monocytes which themselves secrete pro-inflammatory mediators such as tumor necrosis factor (TNF-α), interleukin (IL)-1β and IL-6[6].

A vast body of literature supports the role of nutritional therapy in IBD, particularly in CD (reviewed in[7,8]). While enteral nutrition is not as effective as steroid therapy in induction of remission in CD, the benefit to the patient is well established[9]. Thus, identification and characterization of novel anti-inflammatory foods may aid in improving the currently available nutritional formulations.

A variety of functional nutrients, such as glycosides[10], alkaloids[11] and black tea extracts[12], have been shown to exert their beneficial effects through inhibition of Nuclear factor-κB (NF-κB) activation. NF-κB is one of the most important regulators of pro-inflammatory cytokine expression and reducing its activity may have beneficial effects under acute inflammatory conditions[13]. Besides NF-κB, phytochemicals are also known to activate NF-E2 related 2 (Nrf2) pathway through the anti-oxidant response element causing an increase in the anti-oxidative enzymes such as catalase (CAT), superoxide dismutase (SOD) and glutathione peroxidase[14].

Wolfberry, the fruit of *Lycium barbarum*-also called as Goji (Gouqi or Gou QZ in Romanized Chinese), is a sweet red berry, which has been traditionally used in Chinese medicine. It is also one of the richest sources of zeaxanthin, an antioxidant that has been postulated to improve visual acuity[15]. Apart from antioxidant activity, wolfberry juice has also been demonstrated to have immunomodulatory effects[16]. However, a large part of the supporting evidence is derived either from *in vitro* experiments or animal studies wherein, wolfberry extracts were delivered parenterally. We believe that this might be due to reduced bioavailability of active ingredients when given enterally. Therefore, to improve bioavailability of its anti-oxidant components, wolfberry was processed with skimmed milk and freeze-dried to generate Lacto-Wolfberry (LWB), a water-dispersible powder[17]. This novel preparation, which contains approximately 50% wolfberry and 25% skimmed milk, has been clinically demonstrated to improve the bioavailability of zeaxanthin[17]. Subsequently, the immune-enhancing properties of LWB in both, young-adult and aged mice, have been characterized[18]. Recent studies have demonstrated that dietary supplementation with LWB enhances immune response to flu vaccine[19] and plasma oxidative capacity in elderly[20]. The aim of this study was to characterize the anti-inflammatory and anti-oxidative properties of LWB. We first demonstrate that LWB inhibits lipopolysaccharide (LPS)-induced ROS and IL-6 production in a murine macrophage cell line. Next, using reporter cell lines we show that LWB activates Nrf2 pathway, while inhibiting the NF-κB pathway. Finally, using a mice model of colitis, we demonstrate that LWB reduces the severity of colitis by mediating a reduction in pro-inflammatory cytokines, namely IL-6, IL1β and keratinocyte-derived chemokine/growth regulated protein-α (KC/GRO-α).

MATERIALS AND METHODS

Inflammatory response in LPS-challenged RAW cells

The murine macrophage cell line RAW 264.7 (ATCC, United States) was maintained in Dulbecco's modified Eagle medium (DMEM, Amimed, Bioconcept, Switzerland) supplemented with 10% heat-inactivated fetal-calf serum (FCS, Amimed) at 37 ℃ in a 50 mL/L CO_2/air incubator. Intracellular ROS was measured using a ROS-sensitive fluorescent dye, 2',7'-dichlorofluorescin diacetate (DCFH2-DA, Sigma, United States). Cells (10^5

cells/well in 96 well plates) were incubated overnight with LPS, from *Escherichia coli* serotype 055:B5 (Sigma, United States) at 0.5 mg/L, either in the absence or presence of LWB (0.1% or 1% final concentration). Control cells in the absence of LPS were also included. Cells were then treated with 10 μmol DCFH2-DA for 30 min at 37 ℃ and washed twice with phosphate-buffered saline (PBS). Fluorescence was measured at 485 nm excitation and 538 nm emission by a Fluoroskan enzyme linked immunosorbent assay plate reader (Labsystems Oy, Finland) at the indicated time points. For experiments measuring IL-6, RAW 264.7 cells were seeded in 96 well plates at 10^4 cells/well. After 3 d (approximately 80% of confluence), cells were stimulated with LPS at 0.5 mg/L and incubated in the presence of either LWB (1% final concentration), wolfberry (0.5%) or skimmed milk (0.25%) for 24 h at 37 ℃. Cell culture supernatants were then harvested and IL-6 secretion was quantified using commercial enzyme linked immunosorbant assay (ELISA) kit according to manufacturer's protocol (Murine IL-6 Eli-pair, Diaclone, France). Cell viability was determined by CellTiter-Glow Luminescent assay (Promega, United States) according to manufacturer's instructions. It should be noted that the same lots of wolfberry and skimmed milk that were used in the preparation of LWB were used for all experiments described.

NF-κB inhibition assay

The human colonic adenocarcinoma cell line, HT-29 (ATCC, United States), was stably transfected with the plasmid pNF-κB-SEAP-NPT. The plasmid was a kind gift from Prof. Kim (Natural Products Research Institute, Seoul). It contains a secreted alkaline phosphatase (SEAP) encoding sequence downstream of four tandem copies of NF-κB binding sites. Stably transfected cells (HT-29 clone 34) were maintained in high glucose (4.5 g/L) DMEM containing 1% L-glutamine, 10% heat-inactivated FCS, 1% penicillin/streptomycin, 500 mg/L G418 (Invitrogen, Switzerland) and 100 mg/L Normocin (Invivogen, France) at 37 ℃ in a 50 mL/L CO_2/air incubator. For the NF-κB inhibition assay, HT-29 clone 34 cells were seeded at 10^4 cells/well in 96-flat bottom well plates. After 3-4 d of culture (approximately 80% confluence), cells were washed with PBS and stimulated with recombinant TNF-α (10 μg/L, RD systems, England) in the absence or the presence of either LWB (1% final concentration), wolfberry (0.5%) or skimmed milk (0.25%) for 24 h at 37 ℃. SEAP release was assessed in the supernatants using the Phospha-Light™ System (Applied Biosystems, United States) according to manufacturer's protocol.

Nrf2 activation assay

AREc32 (CXR biosciences, United Kingdom) is a reporter cell line that stably expresses the anti-oxidant response element (ARE)-driven luciferase gene[21]. These cells were cultured at 12 000 cells/well in 96 well plates (Nunc) at 37 ℃ and 50 mL/L CO_2/air incubator in DMEM supplemented with 10% FCS. After 1 d, cells were washed with PBS and treated, in the absence of serum, with either, LWB (1% final concentration), wolfberry (0.5%) or skimmed milk (0.25%) for 24 h at 37 ℃. Luciferase activity was measured using the Luciferase Assay™ (Promega, United States) following manufacturer's instructions.

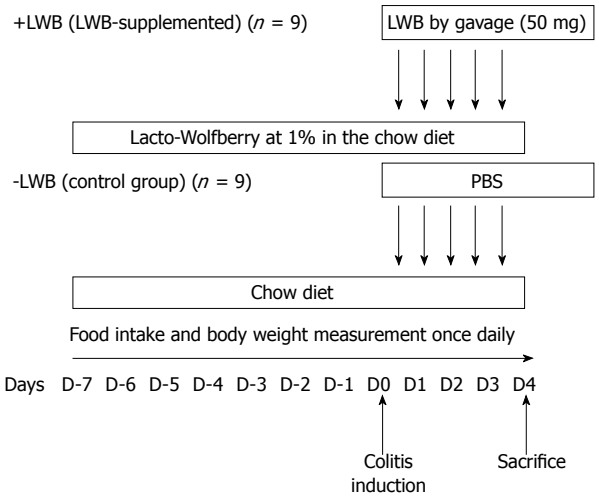

Figure 1 Animal study design. Body weight and food intake was monitored throughout the duration of the experiment (i.e., D-7 to D4). Colitis was induced on D0. For the Lacto-wolfberry (LWB) fed group, diet was supplemented with 1% LWB from D-7 until D4 and 50 mg of LWB was also gavaged from D0 to D4. Control animals were fed regular diet for the same period and gavaged with equal volume of control solution from D0 to D4. PBS: Phosphate buffered solution.

Experimental colitis model

Male mice (C57BL/6J), aged 7 wk, were obtained from Charles River Laboratories Inc. (France) and housed five per cage in a temperature-controlled room with free access to food and water. The overall study design is provided in Figure 1. Mice (n = 9 per group) were randomly assigned to either the control (LWB, chow fed) or the LWB-supplemented group (+LWB, 1% in the diet) 7 d prior to colitis induction (D-7), which was induced on D0, as previously described[22]. Chemically induced colitis was performed as described earlier[23]. Briefly, colitis was induced with an intrarectal administration of 2,4,6-trinitrobenzene sulfonic acid (TNBS) at 125 mg/kg dissolved in 50% ethanol solution. In order to compensate for reduced food intake after colitis induction, mice were also supplemented by daily gavage with 50 mg of LWB from D0 to D4. Control mice were gavaged with an equal volume of PBS. Food intake and body weight measurements were taken once daily from D-7 to D4. Animals were sacrificed on D4. All experimental protocols were conducted in accordance with Swiss law and Nestlé policy on ethics and animal welfare.

Macroscopic and histological assessment

The distal colon tissue was washed with PBS and macroscopic scoring was performed using the system of Wallace *et al*[24]. Samples of the inflamed tissues (1 cm above the anal canal) were collected for histological analysis. The tissues were fixed in 4% paraformaldehyde at 4 ℃

for 24 h. Sections were prepared, stained with hematoxylin and eosin, and graded according to Ameho *et al*[25].

mRNA expression analysis

Colon tissue homogenization, RNA extraction and reverse transcription were performed as described earlier[22]. Custom-made Low Density Array (LDA) cards were purchased from Applied Biosystems (United States) and used according to manufacturer's instructions. Briefly, mixes (100 μL), containing 100 ng of cDNA, 2X TaqMan Mix and nuclease-free water, were prepared and loaded onto the LDA card. The LDA cards were then processed using an automated fluorometer ABI Prism 7900HT. Gene expression was calculated using the relative quantification method with SDS 2.2.2 software.

Electrophoresis and Western blotting analysis

Colon tissue homogenization, protein extraction, electrophoresis and Western blotting analysis were performed as described earlier[22]. Briefly, after tissue homogenization, protein was quantified using the RC DC Protein Assay (Bio-Rad, United States). Proteins were loaded and separated on a 4%-12% bis-tris gel (Invitrogen). The blot was probed with antibodies against murine cyclooxygenase-2 (COX-2) (Cayman, United States), signal transducer and activator of transcription-3 (STAT-3) and phosphorylated STAT-3 (pSTAT-3, Cell Signalling Technology, United States) and β-Actin (Sigma, United States). Relative quantitation of bands was determined using Scion Image Densitometry System (Scion Corp., United States), with normalization to β-Actin.

Myeloperoxidase assay

Protein levels for myeloperoxidase (MPO) were measured in colon protein extracts by ELISA following the manufacturer's instructions (Hycult biotechnology, The Netherlands).

Cytokine analysis

IL-1β, IL-6, IL-10, IL-12p70, KC/GRO-α, interferon-γ (IFN-γ) and TNF-α were measured in the colon protein extracts using multiplex assay kits (Meso Scale Discovery, United States) according to manufacturer's protocol. Cytokine concentrations were determined with Discovery Workbench 3.0 software, using curve 4-PL as suggested by the manufacturer.

Plasma anti-oxidant capacity

Total anti-oxidant capacity of plasma was performed using an assay, which measures inhibition of 2,2'-azino-di-(3-ethylbenzthiazoline sulphonate) (ABTS®) to ABTS®+ by metmyoglobin as Trolox equivalents (Cayman, United States), according to manufacturer's protocol.

Statistical analysis

Data were analyzed by means ± SE either the Mann-Whitney test or where appropriate, a two-way analysis of variance with a Bonferroni post test. *P* values of less than 5% were considered as significant.

RESULTS

Effects of LWB in vitro

Anti-oxidant effects: ROS production from LPS-stimulated RAW 264.7 cells was evaluated in the presence and absence of LWB (Figure 2A). As expected, LPS increased ROS production, in a time dependent manner, as compared to the untreated controls (-LPS). Interestingly, LWB was able to reduce LPS-induced ROS production. The inhibitory effect of LWB was significant from the 2 h time point at both 0.1% and 1% final concentration. At the 6 h time point, LWB reduced the amount of LPS-induced ROS production by about 25% and 75%, at the concentrations of 0.1% and 1%, respectively ($P < 0.001$ for both concentrations). Next, the effects of LWB on Nrf2 activation, using a stable ARE-driven reporter gene expressing cell line, *AREc32*[21], were evaluated (Figure 2B). The data show that LWB at 1% final concentration increased Nrf2 activity by approximately 200%, whereas its individual components, i.e., wolfberry (0.5%) and milk (0.25%), induced only a mild or almost no increase in Nrf2 activity, respectively.

Anti-inflammatory effects: Finally, the effects of LWB (1%), wolfberry (0.5%) and milk (0.25%) on LPS-induced IL-6 production (Figure 2C) and TNF-α-induced NF-κB activity (Figure 2D) were assessed. As shown, LWB inhibited LPS-induced IL-6 production in RAW 264.7 cells by approximately 80% and TNF-α-induced NF-κB activity by approximately 35%. These were significantly different from the values obtained for milk, approximately 20% and 10%, respectively ($P < 0.001$ and $P < 0.05$, respectively). However, no significant differences were observed from wolfberry, which inhibited IL-6 production by approximately 65% and NF-κB activation by 10%.

Anti-inflammatory effects of LWB in vivo

The anti-inflammatory effects of LWB were characterized in chemically-induced colitis model as described in materials and methods section.

LWB attenuates colitis-induced body weight loss: Body weight and food intake of each mouse was monitored daily. Following colitis induction at D0, the percentage mean change in body weight of control mice was -6.4, -9.5, -8.9 and -7.6 at D1, D2, D3 and D4, respectively (Figure 3, LWB). The mice fed with LWB had a percentage mean change in body weight of -4.7, -4.6, -1.9 and -0.5 at D1, D2, D3 and D4, respectively (Figure 3, +LWB). Thus, while both mice have a reduction in body weight at D1, the reduction in body weight loss of the LWB fed mice were significantly lower from D2-D4 ($P < 0.05$ at D2 and $P < 0.01$ at D3 and D4). The total food intake between the two groups did not change (data not shown).

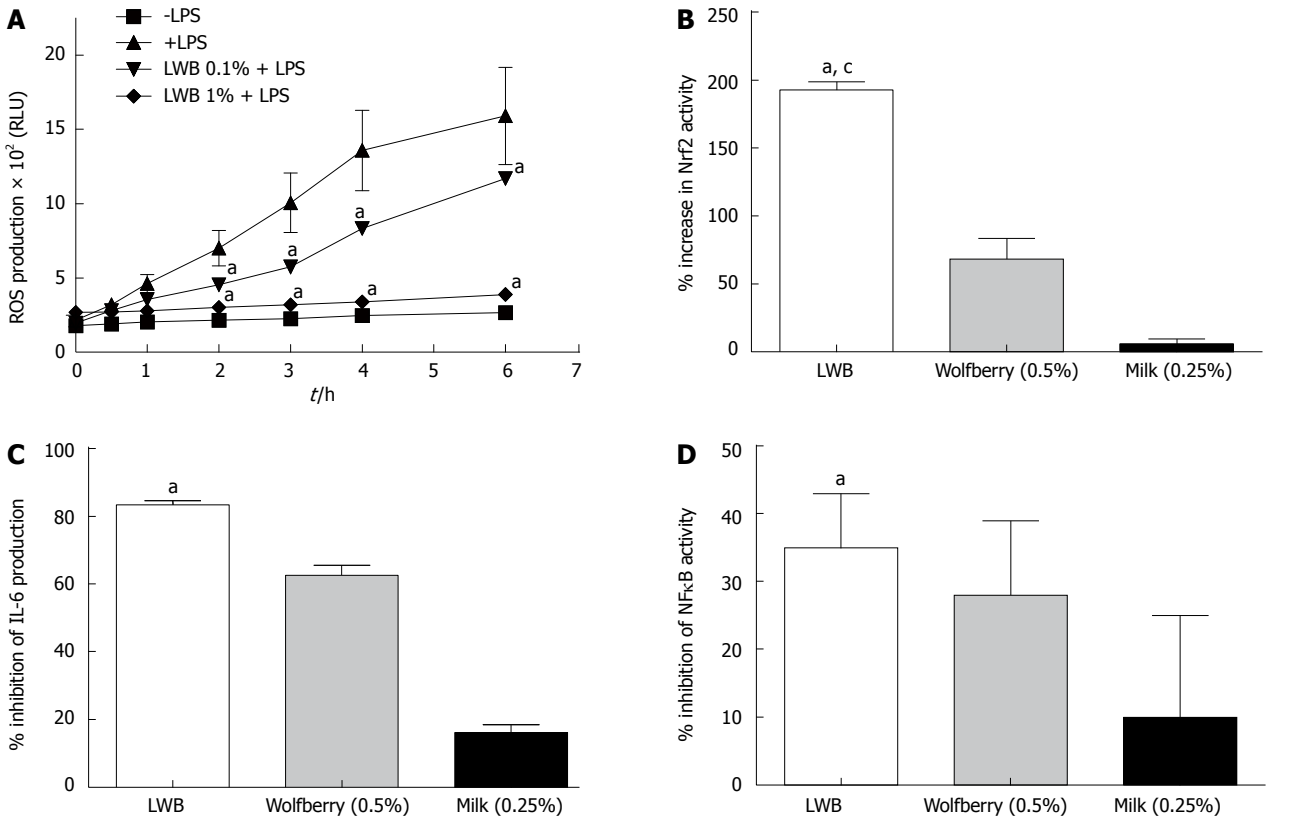

Figure 2 Anti-inflammatory and anti-oxidative effects of Lacto-Wolfberry *in vitro*. A: The effect of Lacto-Wolfberry (LWB) on lipopolysaccharide (LPS)-induced reactive oxygen species (ROS) production in RAW 264.7 cells was measured as described in the methods section. Results are expressed in relative luminescence units (RLU). $^{a}P < 0.05$ at the given time points and dose as compared to LPS-stimulated ROS production (+LPS); B: Effects of given concentrations of LWB, milk and wolfberry on NF-E2 related 2 activity in AREc32 cells. Results are expressed as percentage of increase compared to control conditions. $^{a}P < 0.05$ *vs* milk; $^{c}P < 0.05$ *vs* wolfberry; C: Effects of given concentrations of LWB, milk and wolfberry on LPS-induced interleukin-6 production in RAW 264.7 cells. Results are expressed as percentage of inhibition compared to induction after LPS stimulation. $^{a}P < 0.05$ *vs* milk; D: Effects of given concentrations of LWB, milk and wolfberry on tumor necrosis factor-α-induced nuclear factor- κB activation in a reporter cell line. Results are expressed as percentage of inhibition compared to induction after TNF-α stimulation. All results are depicted as mean ± SE. $^{a}P < 0.05$ *vs* milk.

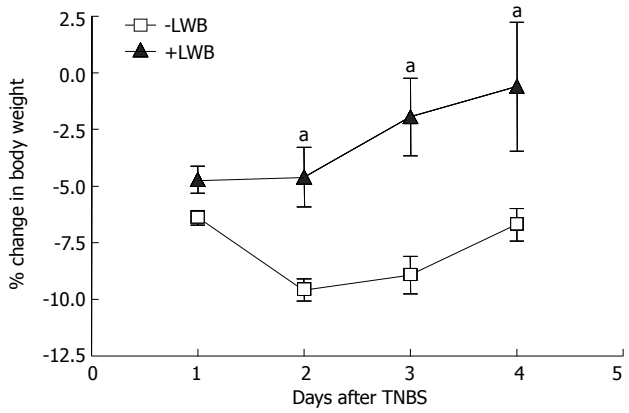

Figure 3 Lacto-Wolfberry attenuates colitis-induced body weight loss. Percentage change in body weight was calculated from a ratio of body weight measured at each day after colitis induction and body weight at D0. Results are depicted as mean ± SE. $^{a}P < 0.05$ *vs* -Lacto-Wolfberry (LWB) at the respective time points. TNBS: 2,4,6-trinitrobenzene sulfonic acid.

LWB reduces colonic inflammation: Supplementation with LWB significantly reduced the colonic inflammation as judged by macroscopic (Figure 4A) and histological (Figure 4B, C and D) evaluation of intestinal inflammation. Macroscopic lesions were assessed as delineated by Wallace *et al*[24]. Colons of control mice (-LWB) presented significantly higher scores compared to mice fed with LWB, 5.39 ± 0.61 and 3.66 ± 0.47, respectively (Figure 4A, $P < 0.05$). In agreement with the macroscopic assessment, histological evaluation showed lower inflammatory infiltrates and better mucosal integrity in mice fed with LWB (+LWB, Figure 4D) as compared to the control (-LWB, Figure 4C). This difference was reflected in the histological score, 5.44 ± 0.32 and 3.66 ± 0.59, for the control and LWB-fed mice, respectively, which was significantly different (Figure 4B, $P < 0.01$). The 70% reduction of MPO content in the LWB treated group (+LWB) as compared to control mice (-LWB) provides further support to reduced neutrophil infiltration in the LWB group (Figure 4E, $P < 0.05$).

LWB reduces pro-inflammatory effector proteins: To delve deeper into the effect of LWB, levels of various effector proteins were measured in the colon tissue. As shown in Table 1, levels of IL-1β, IL-6 and KC/GRO-α were significantly reduced in colitic mice fed with LWB (+LWB) compared to the control (-LWB). Moreover IL-10, IFN-γ, TNF-α and IL-12p70 levels were also re-

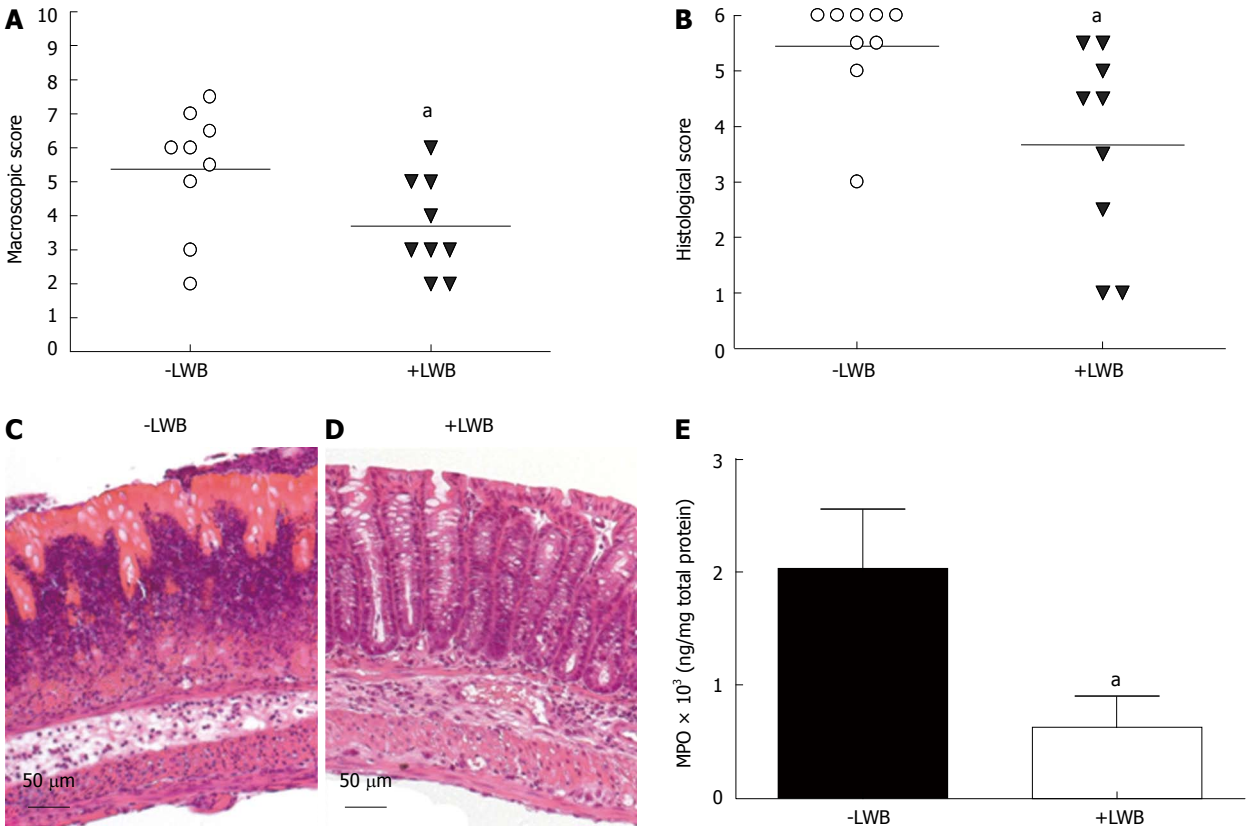

Figure 4 Lacto-Wolfberry reduces colonic inflammation. A: Macroscopic evaluation of the colon was performed according to Wallace criteria. Results are expressed in individual values and the mean value is represented by the horizontal black line; B: Histological evaluation and scoring of the colon was performed according to the Ameho criteria. The individual scores of the mice in the two groups are provided, with the mean value being represented by the horizontal line; C: Representative section of score 6 from the control fed mice [-Lacto-Wolfberry (LWB)]; D: Representative section of score 1 from LWB fed mice (+LWB); E: Colonic myeloperoxidase (MPO) levels were measured by enzyme linked immunosorbant assay. The values are represented as mean ± SE. $^{a}P < 0.05$ *vs* -LWB.

Table 1 Cytokine levels in colon samples (mean ± SE)

Cytokines (μg/L)	-LWB	+LWB	Reduction (%)	*P* value
TNF-α	80 ± 24	31 ± 4	61	0.0770
IL-1β	570 ± 245	89 ± 38	84	0.0106
IL-6	318 ± 99	117 ± 18	63	0.0315
KC/GRO-α	184 ± 49	75 ± 20	59	0.0244
IL-12p70	415 ± 129	89 ± 38	79	0.1135
IFN-γ	18 ± 6	7 ± 1	61	0.0770
IL-10	428 ± 141	165 ± 27	61	0.0625

LWB: Lacto-Wolfberry; TNF-α: Tumor necrosis factor-α; IL-1β: Interleukin-1β; IL-6: Interleukin-6; KC/GRO-α: Keratinocyte-derived chemokine/growth regulated protein-α; IL-12p70: Interleukin-12p70; IFN-γ: Interferon-γ; IL-10: Interleukin-10.

duced by more than 50%, however these were not statistically significant. COX-2 and pSTAT3 levels were assessed semi- quantitatively by Western blotting analysis and densitometry. As shown in Figure 5A, colon of mice fed with LWB had approximately 65% reduction of COX-2 levels ($P < 0.01$). Mice fed with LWB also demonstrated an 80% reduction in pSTAT3 expression (Figure 5B) in the colon. However, this difference didn't reach statistical significance ($P = 0.057$).

LWB improves anti-oxidative capacity: Finally, changes in mRNA expression of Nrf2 target genes, such as CAT, SOD2 and glutathione peroxidase (GPx1) were examined in the colon tissue. GPx1 mRNA expression was higher by more than 20% in mice fed with LWB (+LWB) compared to control (-LWB) (Figure 6A, $P < 0.02$). No difference of gene expression was detected for CAT and SOD2 (data not shown). Finally, the measures of anti-oxidant capacity in the plasma demonstrated that mice supplemented with LWB (+LWB) had more than 70% increase in anti-oxidative capacity compared to control mice (-LWB) (Figure 6B, $P < 0.01$).

DISCUSSION

The aim of the study was to investigate the anti-inflammatory properties of LWB *in vitro* and in an animal model of intestinal inflammation. Initial experiments showed that LWB reduces LPS-induced ROS generation. The anti-oxidant effects of wolfberry are well characterized[16]. Moreover, LWB has also been proposed to have ROS scavenging activity[26]. Thus, this finding was not surprising. However, phytochemicals have also been shown to activate the Nrf2 pathway[14]. Nrf2 is a redox-sensitive transcription factor, which regulates the expression of ARE-driven anti-oxidant enzymes[14]. Thus, the effect of LWB on Nrf2 activation was tested. Interestingly, LWB

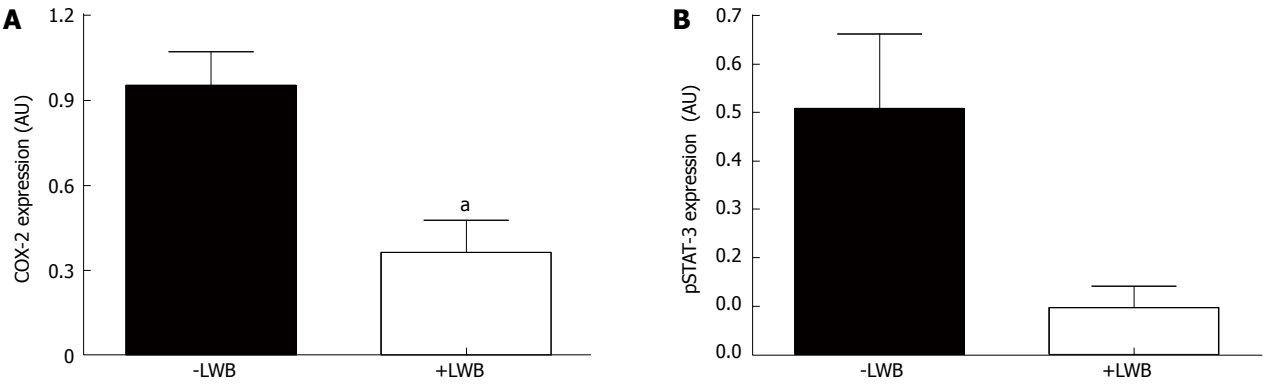

Figure 5 Effect of Lacto-Wolfberry on cyclooxygenase-2 and phosphorylated- signal transducer and activator of transcription-3 levels. A: Cyclooxygenase-2 (COX-2) levels were assessed semi-quantitatively by Western blotting and densitometry. COX-2 levels were normalized to β-actin. Results are expressed in mean ± SE. [a]*P* < 0.05 *vs* -Lacto-Wolfberry (LWB); B: Phosphorylated-signal transducer and activator of transcription-3 (pSTAT3) levels were assessed by Western blotting and densitometry. The results are expressed as a ratio of pSTAT3 to STAT3 (mean ± SE). *P* = 0.057 *vs* -LWB group.

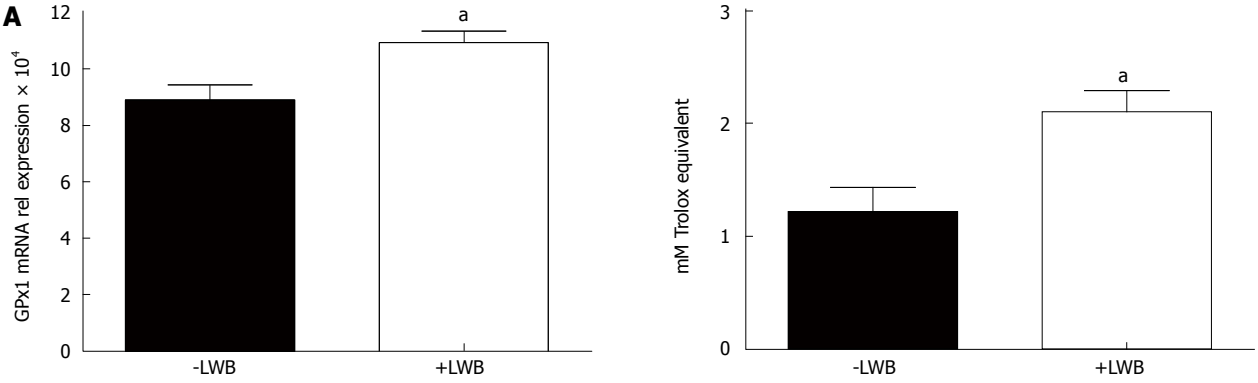

Figure 6 Anti-oxidant effect of Lacto-Wolfberry in murine colitis. A: mRNA expression of glutathione peroxidase 1 (GPx1) was measured as described in methods section. Results are expressed as mean ± SE; B: Anti-oxidant ability in plasma was measured in mmol/L Trolox equivalent. Results are expressed in mean ± SE. [a]*P* < 0.05 *vs* -Lacto-Wolfberry (LWB).

had a two fold increase in Nrf2 activation, however this effect was not fully replicated by its major components tested separately, i.e., either, wolfberry or milk. Hence, this could suggest a synergistic effect between the two major components of LWB resulting from the LWB manufacturing process. Finally, LWB demonstrated wolfberry-equivalent inhibition of LPS-induced IL-6 secretion and TNF-α-induced NF-κB activation. The beneficial effects observed *in vitro* prompted a further examination of LWB in an animal model of colitis.

The pro-inflammatory roles of ROS production, NF-κB activation and cytokines, such as IL-1β, IL-6, IL-8 and TNF-α, have been firmly established in IBD pathology[13,27,28]. Thus, the effects of LWB were tested in a murine model of colitis. Firstly, LWB supplementation attenuated colitis-induced body weight loss. Secondly, both colonic parameters, macroscopic and microscopic, confirmed a reduction in the severity of colitis after LWB intervention. In further support, supplementation with LWB reduced neutrophil infiltration in the colon tissue. In this experimental model, the secretion of Th1 cytokines, namely, IL-1β, IL-6, TNF-α and IFN-γ, play an important role in the propagation of colitis[29]. As NFκB activation controls expression of most of these genes[13] and considering the *in vitro* inhibitory effects of LWB on NF-κB activation, the cytokine levels were measured to gain mechanistic insight. Supplementation with LWB resulted in reduced levels of majority of these cytokines, while significantly reducing the levels of IL-1β and IL-6. Further, LWB supplementation reduced not just the levels of IL-6, but also the downstream signaling *via* STAT-3 activation. Interestingly however, there was only non significant trend observed in the reduction of TNF-α. It is possible that this could be either due to technical variability or due to different kinetics of this cytokine. Moreover, the significant reduction in KC/GRO-α, an established chemokine involved in neutrophil chemotaxis[30], can explain the reduction in neutrophil infiltration. Thus, modulation of cytokine levels, perhaps *via* a decrease in NF-κB activation, is responsible for the anti-inflammatory effects of LWB in this study. The increase of Nrf2 activation *in vitro* as well as an increase in the plasma anti-oxidative capacity and upregulation of GPx1 after LWB supplementation in colitic mice also suggests a possibility of an anti-oxidant mechanism underlying the anti-inflammatory effects of LWB. However, the lack of upregulation of other Nrf2 target genes, such as, CAT and SOD2 means that the anti-oxidative properties explains only part of

the overall effects observed.

Wolfberry is believed to contain at least three different biologically active components: (1) Lycium Barbarum polysaccharides (LBP); (2) zeaxanthin dipalmitate; and (3) 2-O-β-D-glucopyranosyl-L-ascorbic acid (a Vitamin C analogue)[16]. The anti-oxidative properties of all three active ingredients of wolfberry are well documented[16]. LWB is prepared by a milk based extraction process of wolfberry, which is believed to increase bioavailability of its active ingredients, as demonstrated for zeaxanthin[17]. In addition, the *in vitro* assays suggest that the anti-inflammatory activity of LWB is attributable to wolfberry rather than its milk component. However, to the best of our knowledge, wolfberry has not been shown to reduce cytokine levels under inflammatory conditions, as observed in our present study. In fact, wolfberry has been shown to up-regulate cytokine expression[31] and both LWB and wolfberry have a demonstrated immune-enhancing effect[18,19,32-34]. On the other hand, the anti-inflammatory properties of milk components are well established[35,36]. Overall, it seems that depending on the physiological environment LWB may provide support to recover homeostasis and/or immune competence. In the present study, we can speculate that a synergistic effect between the anti-oxidative ingredients of wolfberry and the anti-inflammatory components in milk can also be a potential mechanism of the benefits observed in our model. In that respect, further studies are required to identify the active anti-inflammatory ingredients in LWB. Nutritional therapies are an effective and safe form of intervention to induce remission in active state of CD[7,8]. Despite this profile of effectiveness and safety, they have not gained widespread usage, particularly in the area of adult IBD. One of the reasons for this could be that while they are effective, a review of the clinical trials comparing the efficacy of nutritional therapies to steroids concluded that, they are not as effective as steroids in induction of remission[9]. Thus, clearly more needs to be done in this area. Our findings suggest that addition of LWB to enteral diet formulations might help improve disease outcomes in IBD patients. However, it should be noted that further work addressing efficacy in different colitis models and in-depth confirmation of mechanism of action is necessary before clinically relevant research can be undertaken.

COMMENTS

Background

Inflammatory bowel disease (IBD) consists of a group of disorders, such as Crohn's disease (CD) and ulcerative colitis (UC). The incidence of IBD is increasing throughout the world. Both, CD and UC are characterized by relapsing-remitting disease progression. Currently, there is no known cure for IBD and the various available therapies are only palliative. Herein, the authors have identified the anti-inflammatory properties of a nutritional ingredient in a preclinical model of colitis.

Research frontiers

Due to the chronic nature of IBD and the adverse effects of existing therapies, nutritional ingredients with anti-inflammatory properties may benefit the patient in the long term. With this in mind, the characterization of anti-inflammatory properties of novel or traditional food ingredients is an important field of research.

Innovations and breakthroughs

Previously, the authors have characterized the benefits of Lacto-Wolfberry (LWB) on the adaptive immune system. In this article, they have characterized the anti-inflammatory properties of LWB. The authors first demonstrate the anti-inflammatory and anti-oxidative properties of LWB in cellular models and subsequently show that LWB can ameliorate chemically-induced colitis.

Applications

The identification of the anti-inflammatory properties of LWB raises new possibilities of developing novel nutritional solutions for patients with IBD.

Terminology

LWB is a skimmed milk extract of the traditional Chinese ingredient, wolfberry, specifically developed to increase the bioavailability of its active ingredients.

Peer review

In the original article, the authors examined the complex anti-inflammatory effect of LWB administration in 2,4,6-trinitrobenzene sulfonic acid induced colitis and in selected cell lines. The study is well designed and the results and conclusions are clear and logical.

Abstract

AIM: To determine the expression statuses of tumor necrosis factor (TNF)-α, its receptors (TNF-R) and downstream effector molecules in human colorectal adenomas.

METHODS: We measured the serum concentrations of TNF-α and its receptors in 62 colorectal adenoma patients and 34 healthy controls. The protein expression of TNF-α, TNF-R1, TNF-R2 and downstream signals of the TNF receptors, such as c-Jun N-terminal kinase (JNK), nuclear factor-κ B and caspase-3, were also investigated in human colorectal adenomas and in normal colorectal mucosal tissues by immunohistochemistry. Immunofluorescence confocal microscopy was used to investigate the consistency of expression of TNF-R1 and phospho-JNK (p-JNK).

RESULTS: The serum levels of soluble TNF-R1 (sTNF-R1) in adenoma patients were significantly higher than in the control group (3.67 ± 0.86 ng/mL *vs* 1.57 ± 0.72 ng/mL, $P < 0.001$). Receiver operating characteristic analysis revealed the high diagnostic sensitivity of TNF-R1 measurements (AUC was 0.928) for the diagnosis of adenoma, and the best cut-off level of TNF-R1 was 2.08 ng/mL, with a sensitivity of 93.4% and a specificity of 82.4%. There were no significant differences in the serum levels of TNF-α or sTNF-R2 between the two groups. Immunohistochemistry showed high levels of TNF-R1 and p-JNK expression in the epithelial cells of adenomas. Furthermore, a high incidence of co-localization of TNF-R1 and p-JNK was identified in adenoma tissue.

CONCLUSION: TNF-R1 may be a promising biomarker of colorectal adenoma, and it may also play an important role in the very early stages of colorectal carcinogenesis.

INTRODUCTION

The proinflammatory cytokine, tumor necrosis factor (TNF), plays an important role in diverse cellular events, such as the induction of other cytokines' expression, cell proliferation, differentiation, necrosis and apoptosis[1,2]. Many of the TNF-induced cellular responses are mediated by one of two specific cellular membrane receptors, tumor necrosis factor receptor 1 (TNF-R1) and TNF-R2, both of which belong to the TNF receptor superfamily[3]. In response to TNF treatment, activation of nuclear factor-κ B (NF-κB), a transcription factor, as well as mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase, p38, and c-Jun N-terminal kinase (JNK) have been reported in most cell types and, in some cases, after apoptosis or necrosis had been induced[4,5].

Overexpression of TNF-α and its receptors often accompanies tumor development and progression, and their important role in the pathogenesis of cancer is now increasingly recognized. Several studies have reported on the status of TNF-α expression in various malignancies. For example, TNF-α mRNA and protein have been detected in both malignant and stromal cells in human ovarian cancer biopsies[6,7]. The plasma levels of TNF-α have been reported to be increased in some cancer patients, especially those with poor prognoses[8-11]. Blood TNF-α concentrations have been reported to be higher in prostate cancer patients with advanced, cachectic disease[12]. These findings suggest that TNF-α might also have an important role in carcinogenesis. We now know that many of the cells and mediators of inflammation that have been detected in human and experimental cancers and inflammatory conditions increase the risk of cancer development[13-16]. There is strong evidence to suggest that cancer-related inflammation aids in the proliferation and survival of malignant cells, stimulates angiogenesis and metastasis[17-19], subverts adaptive immunity[20-22], and modulates their responses to hormones and chemotherapy[23,24].

In colitis-related colon cancer, TNF-α has been demonstrated to promote carcinogenesis, and anti-TNF-α drugs are being used therapeutically[25,26]. Moreover, serum TNF-α is known to serve as an important pathophysiologic marker for the presence and severity of inflammatory bowel disease[27]. However, TNF-α has a short half-life (20 min); therefore, accurate measurement of the blood levels is difficult[28]. There is some debate about whether TNF-α can actually be measured using some sort of physiologically active substance[28,29]. On the other hand, TNF-R1 and TNF-R2 are released into the blood as soluble TNF-R1 (sTNF-R1) and soluble TNF-R2 (sTNF-R2) after proteolysis of their extracellular domains in response to activators, including TNF-α itself[30,31]. Their presence in the peripheral blood is reflective of an inflammatory response occurring within the body. sTNF-R1 and sTNF-R2 also have very long half-lives; thus, they are more stable than TNF-α[32,33]. These receptors may provide better serum biomarkers than TNF-α. Spoettl *et al*[34] found that serum sTNF-R1 levels were significantly increased in ulcerative colitis (UC) patients compared with that of healthy controls. However, there have been few reports of the association between TNF-R1 and TNF-R2 and sporadically occurring colorectal neoplasms[35]. Thus, the association of these receptors with the risk of colorectal adenoma has not yet been fully clarified. The aim of this study was to investigate the serum levels of TNF-α, sTNF-R1 and sTNF-R2 in adenoma patients and also to investigate the expressions of downstream molecules in the TNF-α signaling pathway, including TNF-R1, TNF-R2, JNK, NF-κB and caspase-3 in adenoma tissues in comparison to those in normal colorectal mucosa.

MATERIALS AND METHODS

Patients

The study population consisted of 62 consecutive patients with colorectal adenoma who underwent colonoscopy from January 2008 to January 2009 at the Division of Gastroenterology, Yokohama City University School of Medicine. Patients with concomitant diseases, including infectious diseases, inflammatory bowel diseases, autoimmune conditions, allergy or asthma, that were likely to elevate serum TNF-α levels were excluded from the study. The patients ranged in age from 54 to 86 years (mean ± SD: 67.7 ± 8.2 years) and consisted of 39 males and 23 females. The control group consisted of 34 healthy people, matched for age. The control group consisted of people undergoing colonoscopy after positive fecal occult blood test but not found to have adenomas. The study was carried out in accordance with the Declaration of Helsinki (revised 1989) and with the approval of the Ethics Committee of Yokohama City University School of Medicine. Informed consent was obtained from each patient participating in this study and for the use of the obtained data for research purposes.

Serum samples

Before colonoscopy, blood samples were obtained from all participants after an overnight fast to determine the serum concentrations of TNF-α, sTNF-R1 and sTNF-R2. The blood samples were centrifuged at 800 g for 5 min. Serum was separated as soon as possible from the clot of red blood cells by centrifugation to avoid TNF-α production by the blood cells, which would have led to falsely increased values[36]. Then, the serum specimens were stored at -80 ℃ until the biochemical analyses.

Biochemical determinations

Serum concentrations of human TNF-α, sTNF-R1 and sTNF-R2 were determined by enzyme-linked immunosorbent assay (ELISA) kit (R and D Systems Inc., Minneapolis, MN, United States). The minimum limits of detection of the assay were as follows: TNF-α, 1.6 pg/mL; sTNF-R1, 0.77 pg/mL; and sTNF-R2, 0.6 pg/mL. The tests were carried out as described in the product manuals.

Immunohistochemical analysis

Immunohistochemical analysis was performed in the adenomatous polyps retrieved from the study patients (n = 62). Adenomatous polyps removed during colonoscopy, together with normal colorectal mucosal biopsies from the same patients when possible, were examined. Four-micrometer sections were prepared from the formalin-fixed, paraffin-embedded tissues and mounted on slides coated with polylysine. We examined only sporadically occurring polyps by excluding specimens from patients with familial adenomatous polyposis (FAP) or hereditary non-polyposis coli (HNPCC). The protein expression levels were determined in all 62 normal and colorectal adenomatous tissue sections by immunohistochemistry. Sections were deparaffinized in xylene and rehydrated. The sections were then heated in a 750 W microwave three times for 7 min. Inhibition of endogenous peroxidase activity was performed by treating sections with 3% hydrogen peroxide for 10 min. After washing three times with Tris-Buffered Saline (TBS), the blocking of non-specific interactions was accomplished by incubating the samples with blocking serum for 30 min at room temperature. Sections were then probed with the primary antibodies (Table 1) and subsequently incubated with the Histofine simple stain max PO kit for 30 min (Nichirei Laboratories, Tokyo, Japan) in accordance with the manufacturer's instructions. The signals were visualized by treatment with diaminobenzidine (peroxidase substrate kit, Vector Laboratories, Burlingame, CA, United States), and the sections were counterstained with hematoxylin. Six random microscopic fields per sample of approximately 250 cells were counted at a magnification of 400 × under a bright-field microscope. The results were expressed as the percentage of positive cells with separating epithelial cells and stromal cells.

Immunofluorescence confocal microscopy

For immunofluorescence studies, the sections were stained with anti-TNF-R1 rabbit polyclonal antibody (Santa Cruz Biotechnology, Santa Cruz, CA, United States) at a dilution of 1:50, anti-TNF-R2 rabbit polyclonal antibody (Santa Cruz Biotechnology) at a dilution of 1:50, and anti-p-JNK mouse monoclonal antibody at Thr 183 and Tyr 185 (Santa Cruz Biotechnology) at a dilution 1:50. After thorough washes in TBS, sections were incubated with their respective Alexa594-conjugated anti-rabbit IgG secondary antibodies (Invitrogen, Carlsbad, CA, United States) or Alexa488-conjugated anti-mouse IgG secondary antibodies (Invitrogen) for 1 h, washed, and mounted.

The confocal imaging was carried out on a FV1000-D (Olympus, Tokyo, Japan) confocal laser scanning microscope. Excitation and detection of the samples were carried out in sequential modes to avoid overlapping of signals. Sections were scanned simultaneously at both wavelengths (488/594 nm) with appropriate laser intensity, confocal aperture, and gain. The Black-level setting was kept constant for all samples.

Table 1 Summary of the specific antibodies used and immunohistochemistry

Protein	Antibody (catalog number)	Dilution	Incubation
TNF-α	Rabbit polyclonal (Abcam, ab6671)	1:100	Overnight
TNF-R1	Rabbit polyclonal (Abcam, ab19139)	1:2000	1 h
TNF-R2	Rabbit polyclonal (Abcam, ab15563)	1:50	30 min
p-JNK	Rabbit polyclonal (CST, #9251)	1:100	Overnight
NF-κB	Rabbit polyclonal (CST, #3034)	1:50	Overnight
Caspase-3	Rabbit polyclonal (CST, #9661)	1:200	Overnight

Table 2 Comparison of the clinical data and measured biochemical parameters in the serum of patients with adenomas and control subjects (mean ± SD)

Parameters	Control (n = 34)	Adenoma (n = 62)	P value
Age (yr)	67.6 ± 15.9	67.7 ± 8.2	NS
Sex (F/M)	14/20	23/39	NS
BMI	23.5 ± 5.0	23.9 ± 3.4	NS
TNF-α (pg/mL)	5.56 ± 1.3	4.83 ± 1.9	NS
sTNF-R1 (ng/mL)	1.57 ± 0.72	3.67 ± 0.86	< 0.001
sTNF-R2 (ng/mL)	2.72 ± 1.15	3.09 ± 0.91	NS

P < 0.05 was denoted significance. NS: Non-significant; TNF-α: Tumor necrosis factor-α; sTNF-R1/2: Soluble tumor necrosis factor receptor 1/2; F/M: Female/male; BMI: Body mass index.

Statistical analysis

Data were expressed as the mean ± SD unless otherwise indicated. The significances of the differences in clinical characteristics between patients with adenomas and controls were evaluated by the χ^2-test for categorical variables and Welch's test for continuous variables. One-way analysis of variance was performed to compare the prevalence of each variable between groups. To assess the diagnostic sensitivity and specificity of the sTNF-R1 and sTNF-R2 measurements, receiver operating characteristic (ROC) curve analysis was performed. P < 0.05 was considered to indicate statistical significance.

RESULTS

Biochemical determinations

Table 2 shows a comparison of the clinical data and laboratory parameters between the 62 patients with adenoma and the 34 normal controls. No differences in

Table 3 Association between the measured biochemical parameters and the number of colorectal adenomas per person

	Control (n = 34)	≤ 3 (n = 34)	≥ 4 (n = 28)	P value
TNF-α (pg/mL)	5.63 ± 1.3	4.31 ± 1.9	4.95 ± 2.0	NS
sTNF-R1 (ng/mL)	1.57 ± 0.72	3.37 ± 0.93	4.05 ± 0.55	< 0.001
sTNF-R2 (ng/mL)	2.72 ± 1.15	3.13 ± 0.88	3.04 ± 0.95	NS

Values are expressed as the mean ± SD; $P < 0.05$ denoted significance. NS: Non-significant; TNF-α: Tumor necrosis factor-α; sTNF-R1/2: Soluble tumor necrosis factor receptor 1/2.

the age, sex or body mass index were found between the two studied groups. The mean serum levels of sTNF-R1 were significantly higher in the adenoma patients compared to the control group patients. On the other hand, there were no significant differences in the serum levels of TNF-α or sTNF-R2 between the two groups. Linear contrast analysis was conducted to evaluate the correlation between each variable and the number of adenomas per person (Table 3). The serum levels of sTNF-R1 were positively correlated with the number of adenomas in the colorectum ($P < 0.001$). As assessed by nonparametric analysis of the ROC curves, sTNF-R1 measurements showed a high diagnostic sensitivity at a value of 0.928 (Figure 1). The best cut-off level for TNF-R1 as 2.08 ng/mL, which showed a sensitivity of 93.4% and a specificity of 82.4%.

Immunohistochemical analysis

Immunohistochemistry showed varying expression intensities of TNF-α, TNF-R1, TNF-R2, p-JNK, NF-κB and caspase-3 in different areas of the samples. The expression of TNF-α in the stromal area of adenomas was significantly higher than that in the stromal areas of the normal mucosa ($P < 0.05$); however, the expression of TNF-α in the epithelial cells of adenomas was not as high as that in the epithelial cells of the normal mucosa (Figure 2). The expression of TNF-R1 in the epithelial cells of the adenomas was significantly higher than that in the epithelial cells of the normal mucosa ($P < 0.05$); however, in the stromal areas, the expression of TNF-R1 was equivalent between the adenomas and the normal mucosa. No significant difference in the expression of TNF-R2 was noted in either the epithelial cells or the stromal areas between the adenomas and the normal mucosa. In relation to the expressions of the downstream molecules in the TNF-α signaling pathway, the expression of p-JNK in both the epithelial cells and stromal areas of the adenoma were significantly higher than those in the normal mucosa ($P < 0.05$) (Figure 3). However, there were no significant differences in the expressions of NF-κB or caspase-3 in either the epithelial cells or stromal areas between the adenomas and the normal mucosa.

To investigate the consistency of TNF-R1 and p-JNK expression, we performed immunofluorescence staining of the adenoma tissues, because the results of immunohistochemistry revealed high levels of TNF-R1 and p-JNK expression in the epithelial cells of the adenomas. The results revealed expression of TNF-R1 and p-JNK co-localized predominantly in the epithelial cells of the adenomas. Merged images of TNF-R1 and p-JNK immunofluorescence staining demonstrated this co-localization (Figure 4). On the other hand, the expression of TNF-R2 was localized predominantly to the stromal area of the adenomas, and merged images of TNF-R2 and p-JNK immunofluorescence staining showed a lack of co-localization.

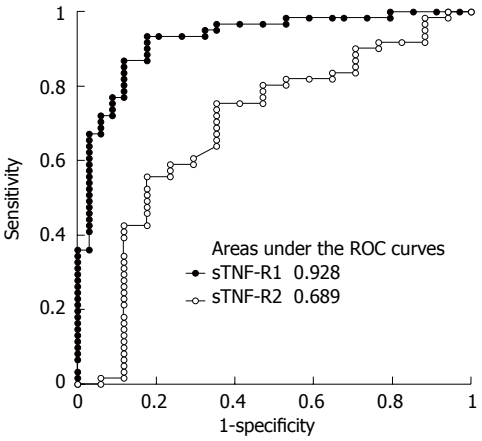

Figure 1 Receiver operating characteristic curves for soluble tumor necrosis factor receptor-1 and 2 in patients with adenomas. ROC: Receiver operating characteristic.

DISCUSSION

This is the first study to show marked changes in the expression levels of TNF-R1 in colorectal adenoma tissues. The serum sTNF-R1 levels were also significantly higher in colorectal adenoma patients than in the control subjects. To evaluate the possible usefulness of TNF-R1 as a biomarker for colorectal adenoma, we evaluated the correlation between the number of adenomas in the colorectum and the serum sTNF-R1 level. The results showed that the serum sTNF-R1 level positively correlated with the number of colorectal adenomas. A ROC analysis revealed the high diagnostic sensitivity and specificity of sTNF-R1 measurements for diagnosis of colorectal adenoma. These results may suggest that TNF-R1 is a promising biomarker for colorectal adenomas. In addition, our results agreed with the Kaminska *et al*[37] study, which showed that sTNF-R1 had the highest diagnostic sensitivity in colorectal cancer patients. Other previous reports have shown a high diagnostic and prognostic accuracy of serum sTNF-R1 levels for various diseases. Determination of the TNF-R1 levels in several body fluids, including the serum, provides valuable insight into a variety of pathological conditions. For example, in cervical adenocarcinoma patients, serum sTNF-R1 is reported to be a useful marker, especially in the early stages of disease[38]. In patients with breast cancer, serum sTNF-R1 is considered to be an independent and clinically useful

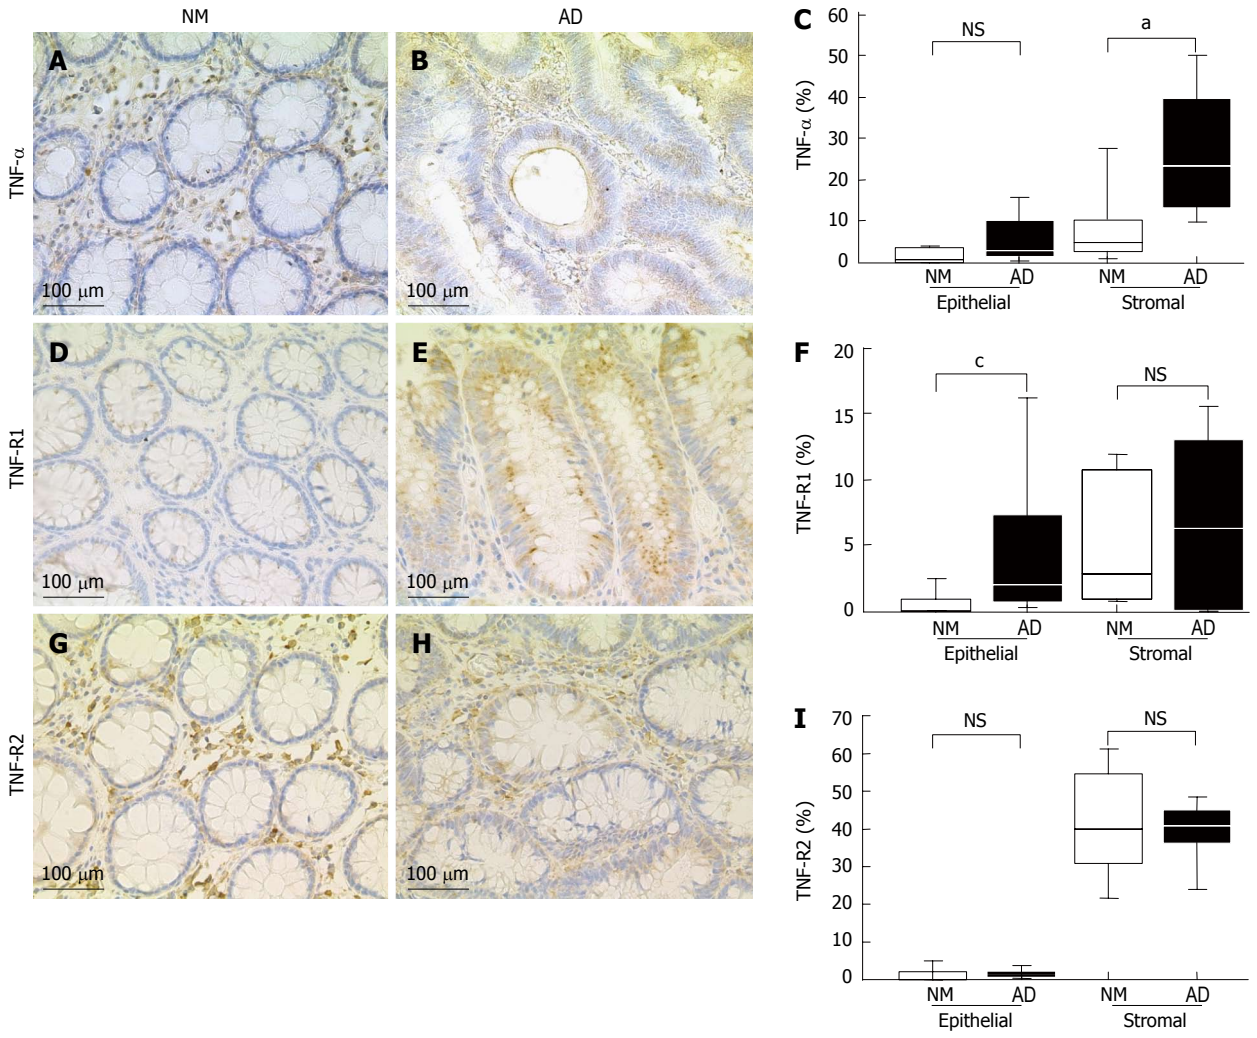

Figure 2 Immunohistochemical analyses in the normal colorectal mucosa and adenoma tissues. indicator of a poor prognosis[39].

TNFR-1 is an important member of the death receptor family, which is capable of inducing apoptotic cell death[40]. In addition to its involvement in apoptotic signaling, TNF-R1 has been widely studied because it is a dual-role receptor. In addition to inducing apoptosis, it also has the ability to transduce cell survival signals. When TNF-R1 transduces cell survival signals, TNFR-associated factor 2 (TRAF-2) is recruited to the complex, which inhibits apoptosis *via* the cytoplasmic inhibitor of apoptosis protein (cIAP). The binding of TRAF-2 initiates a sequence of phosphorylation steps resulting in the activation of cFos/cJun transcription factors *via* MAPK and JNK[41]. The cFos/cJun transcription factors induce transcription of antiapoptotic, proliferative, immunomodulatory, and inflammatory genes.

TNF-α is a major mediator of cancer-related inflammation[13,42], and most of the pro-tumor actions of TNF-α appear to be mediated by TNF-R1. Mouse experiments have revealed that the development of primary cancers and metastases is attenuated in mice deficient in TNF-R1. For example, TNF-R1-/- mice are resistant to DMBA-TPA carcinogenesis, as are TNF-α-/- mice[43]. Experimental formation of lung and liver metastases was attenuated in TNF-R1-/- mice compared with that in their normal counterparts[44,45]. In wild-type mice with bone marrow cells repopulated using cells from TNF-R1-/- mice, the likelihood of colitis and colon cancer development was reduced[46] suggesting that TNF-α in the tumor microenvironment enhanced tumor development through its actions on TNF-R1-positive myeloid cells. In various pathologic states, it has been reported that the production and release of TNF-R1 may mediate host responses and determine the course and outcome of the disease by binding with TNF-α and competing with cell surface receptors.

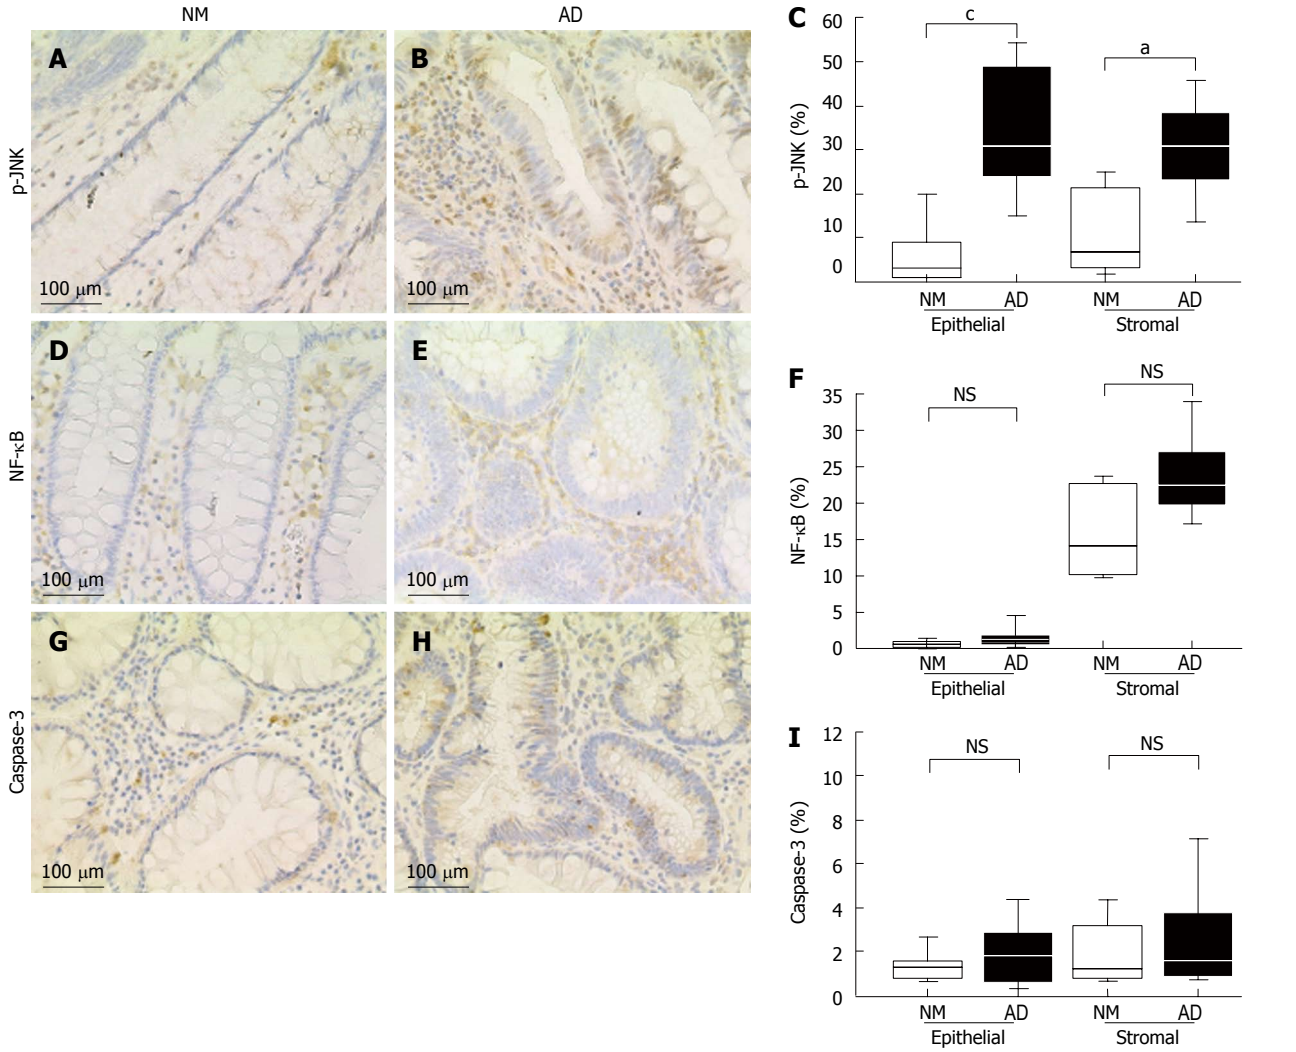

Figure 3 Immunohistochemical analyses in the normal colorectal mucosa and adenoma tissues. A: Phospho-c-Jun N-terminal kinase (p-JNK) expression in the normal colorectal mucosa; B: p-JNK expression in the adenoma tissues; C: The percentage of p-JNK positive cells; D: Nuclear factor-κ B (NF-κB) expression in the normal colorectal mucosa; E: NF-κB expression in the adenoma tissues; F: The percentage of NF-κB-positive cells; G: Caspase-3 expression in the normal colorectal mucosa; H: Caspase-3 expression in the adenoma tissues; I: The percentage of caspase-3-positive cells. Box plots display median values and interquartile ranges (C, F, I). The non-outlier range is also shown. $^{a}P < 0.05$ between NM and AD in stromal of p-JNK; $^{c}P < 0.05$ between NM and AD in epithelial of p-JNK. NS: Non-significant; NM: Normal mucosa; AD: Adenoma.

In addition to the systematic analysis of serum sTNF -R1, we also investigated, by immunohistochemical analysis, the local expressions of downstream molecules in the TNF-α signaling pathway in normal colorectal mucosa and adenoma tissues. The results revealed high levels of TNF-R1 and p-JNK expression in the epithelial cells of adenomas. Moreover, we identified co-localization of TNF-R1 and p-JNK in adenomas by immunofluorescence confocal microscopy. In the past, expression of p-JNK in adenomas has only been described by Hardwick *et al*[47]. These authors found that the expression of p-JNK was observed mainly in stromal T-lymphocytes, and epithelial cells were not stained. The discrepancy in our results was presumably due to differences in the immunohistochemical staining protocol used. The Hardwick study used phosphate- buffered saline (PBS) as the wash buffer, while we used TBS. Additionally, different antibodies were used in the two studies, which may have resulted in the absence of phospho-JNK staining in the epithelial cells of their study.

Our results suggest that the TNF-R1/p-JNK pathway is upregulated in adenomas and that this pathway may play an important role in adenoma formation, which represents the very early stages of colorectal carcinogenesis because this pathway is not upregulated in the normal colorectal mucosa. Expression of JNK in colon cancer has already received some attention[48,49]; studies have found increased activity of JNK in both rat models of colon cancer and human colorectal tumors. In addition, Zhang *et al*[50] indicated that the TNF-R1/JNK signaling cascade can functionally promote tumorigenesis of human epithelial cancers, such as squamous cell carcinomas. Moreover, a recent study conducted by our group showed that JNK/c-Jun may play an important role in promoting colorectal carcinogenesis and epithelial cell proliferation under high-fat dietary conditions[51].

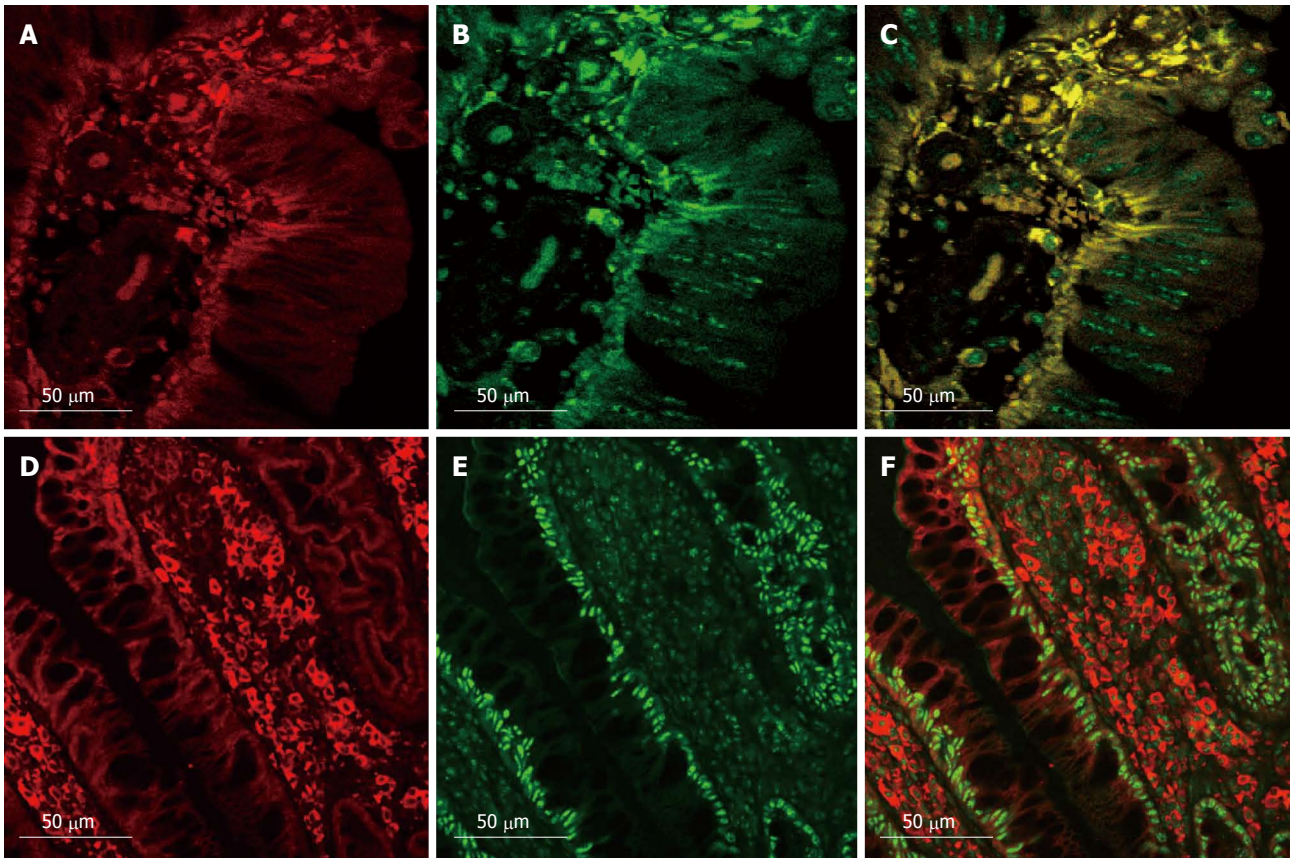

Figure 4 Confocal laser microscopic analyses of colorectal adenoma sections. A: Tumor necrosis factor receptor 1 (TNF-R1) expression; B: Phospho-c-Jun N-terminal kinase (p-JNK) expression; C: Merged image of A and B. Co-localized expression of TNF-R1 and p-JNK was noted predominantly in the epithelial cells of adenomas. Merged images showing co-localization; D: TNF-R2 expression; E: p-JNK expression; F: Merged image of D and E. Expression of TNF-R2 was localized predominantly to the stromal area of the adenoma. Merged images showed a lack of co-localization.

Our study had several important novelties. We showed for the first time that the serum levels of sTNF-R1 may have high diagnostic sensitivity and specificity as a biomarker for colorectal adenoma. Second, TNF-R1 was relatively undetectable in the normal colorectal mucosa, whereas adenomas showed high expression levels of TNF-R1. In addition, co-expression of p-JNK with TNF-R1 was observed in adenomas, although a previous study reported that the epithelial cells of adenoma showed a lack of p-JNK staining[47]. These results suggest that the TNF-R1/JNK pathway may play an important role in the development/progression of colorectal adenoma.

The present study also had some limitations. First, our research target was colorectal adenoma and not colorectal cancer. Thus, further studies targeting colorectal cancer are needed. Secondly, the control population was small. Third, different cell death receptors are able to activate JNK. Therefore, the increased p-JNK expression in adenoma tissue may be related to TNF-R1 or other effectors. The expression of cell death receptors may also be altered in inflammatory cells, which may certainly be involved in cancer progression. Fourth, it was considered that TNF-R1 may directly stimulate JNK activation, but this would also be difficult to prove.

In conclusion, this is the first study to report elevated serum levels of sTNF-R1 in patients with adenomas compared to a control group. We also found, by immunohistochemical analysis, enhanced expression of TNF-R1 in colorectal adenomas. These results suggest that TNF-R1 may not only be a promising biomarker of colorectal adenoma but also plays an important role in the very early stages of colorectal carcinogenesis. More studies are needed to elucidate the exact functions of TNF-R1 in colorectal adenomas.

We thank Machiko Hiraga for her technical assistance.

COMMENTS

Background

The proinflammatory cytokine, tumor necrosis factor (TNF)-α, is a major mediator of cancer-related inflammation. However, little has been reported on the relationship between TNF-α and sporadically occurring colorectal neoplasms. Studies on human colorectal adenoma were performed to determine the expression statuses of TNF-α and its receptors.

Research frontiers

Overexpression of TNF-α and its receptors often accompanies tumor development and progression, and their important role in the pathogenesis of cancer is

now increasingly recognized.

Innovations and breakthroughs

The authors show, for the first time, that the serum levels of tumor necrosis factor-receptor 1 (TNF-R1) may have high diagnostic sensitivity and specificity as a biomarker of colorectal adenoma. TNF-R1 was hardly detected in the normal colorectal mucosa, whereas adenomas showed high expression levels of TNF-R1. In addition, co-expression of phospho-c-Jun N-terminal kinase (p-JNK) with TNF-R1 was observed in adenomas. These results suggest that the TNF-R1/JNK pathway may play an important role in the development/progression of colorectal adenoma.

Applications

TNF-R1 may be a promising biomarker of colorectal adenoma, and further studies may show that TNF-R1 expression can be used to screen for adenomas in patients as an alternative or in addition to hemoccult screening or colonoscopy screening.

Terminology

TNF-R1 belongs to the TNF receptor superfamily. In response to TNF treatment, activation of the transcription factor nuclear factor-κ B and mitogen-activated protein kinase, as well as Extracellular Signal-regulated Kinase, p38, and JNK, has been reported in most types of cells and, in some cases, apoptosis or necrosis was also induced.

Peer review

This is an interesting study investigating the importance of TNF-R1/JNK co-expression in colorectal adenoma. The major finding of the study was that serum levels of TNF-R1 were higher in patients with colorectal adenomas, while immunohistochemistry showed high expression of both TNF-R1 and p-JNK in the adenomatous tissues.

Abstract

AIM: To investigate the effects of Axl deglycosylation on tumor lymphatic metastases in mouse hepatocellular carcinoma cell lines.

METHODS: Western blotting was used to analyze the expression profile of Axl glycoprotein in mouse hepatocellular carcinoma cell line Hca-F treated with tunicamycin and PNGase F 3-(4,5)-dimethylthiazol(-zyl)-3,5-diphenyltetrazolium bromide (MTT) assay, extracellular matrix (ECM) invasion assay (*in vitro*) and tumor metastasis assay (*in vivo*) were utilized to evaluate the effect of Axl deglycosylation on the Hca-F cell proliferation, invasion and lymphatic metastasis.

RESULTS: Tunicamycin and PNGase F treatment markedly inhibited Axl glycoprotein synthesis and expression, proliferation, invasion, and lymphatic metastasis both *in vitro* and *in vivo*. In the MTT assay, proliferation was apparent in untreated Hca-F cells compared with treated Hca-F cells. In the ECM invasion assay (*in vitro*), treated cells passed through the ECMatrix gel in significantly smaller numbers than untreated cells (tunicamycin 5 μg/mL: 68 ± 8 *vs* 80 ± 9, $P = 0.0222$; 10 μg/mL: 50 ± 6 *vs* 80 ± 9, $P = 0.0003$; 20 μg/mL: 41 ± 4 *vs* 80 ± 9, $P = 0.0001$); (PNGase F 8 h: 66 ± 7 *vs* 82 ± 8, $P = 0.0098$; 16 h: 49 ± 4 *vs* 82 ± 8, $P = 0.0001$; 24 h: 34 ± 3 *vs* 82 ± 8, $P = 0.0001$). In the tumor metastasis assay (*in vivo*), average lymph node weights of the untreated Hca-F group compared with treated Hca-F groups (tunicamycin 5 μg/mL: 0.84 ± 0.21 g *vs* 0.72 ± 0.19 g, $P = 0.3237$; 10 μg/mL: 0.84 ± 0.21 g *vs* 0.54 ± 0.11 g, $P = 0.0113$; 20 μg/mL: 0.84 ± 0.21 g *vs* 0.42 ± 0.06 g, $P = 0.0008$); (PNGase F 8 h: 0.79 ± 0.15 g *vs* 0.63 ± 0.13 g, $P = 0.0766$; 16 h: 0.79 ± 0.15 g *vs* 0.49 ± 0.10 g, $P = 0.0022$; 24 h: 0.79 ± 0.15 g *vs* 0.39 ± 0.05 g, $P = 0.0001$). Also, average lymph node volumes of the untreated Hca-F group compared with treated Hca-F groups (tunicamycin 5 μg/mL: 815 ± 61 mm^3 *vs* 680 ± 59 mm^3, $P = 0.0613$; 10 μg/mL: 815 ± 61 mm^3 *vs* 580 ± 29 mm^3, $P = 0.0001$; 20 μg/mL: 815 ± 61 mm^3 *vs* 395 ± 12 mm^3, $P = 0.0001$); (PNGase F 8 h: 670 ± 56 mm^3 *vs* 581 ± 48 mm^3, $P = 0.0532$; 16 h: 670 ± 56 mm^3 *vs* 412 ± 22 mm^3, $P = 0.0001$; 24 h: 670 ± 56 mm^3 *vs* 323 ± 11 mm^3, $P = 0.0001$).

CONCLUSION: Alteration of Axl glycosylation can attenuate neoplastic lymphatic metastasis. Axl N-glycans may be a universal target for chemotherapy.

Axl glycosylation mediates tumor cell proliferation, invasion and lymphatic metastasis in murine hepatocellular carcinoma. *World J Gastroenterol* 2012; 18(38): 5369-5376 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i38/5369.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i38.5369

INTRODUCTION

The receptor tyrosine kinases (RTKs) constitute a large family of transmembrane proteins that relay signals from extracellular growth factors into the cell[1,2]. The Tyro-Axl-Mer (TAM) subfamily shares the vitamin K-dependent ligand Gas6 (growth arrest specific 6). TAM receptors contain a combination of two immunoglobin-like domains and dual fibronectin type Ⅲ repeats in the extracellular region, and a cytoplasmic kinase domain[3,4]. The TAM receptors regulate a diverse range of cellular responses including cell survival, proliferation, autophagy, migration, angiogenesis, platelet aggregation, and natural killer cell differentiation[4].

The Axl receptor (also called UFO, Tyro7, and Ark) is a RTK originally identified as a transforming gene in chronic myeloid leukemia[5,6]. Axl is expressed in various organs, including the brain, suggesting its involvement in mesenchymal and neural development[7,8]. Axl has been shown to have transforming potential when overexpressed during development. Axl overexpression is clearly associated with invasiveness and metastasis in several cancer cell types, including myeloid leukemia[6,9], esophageal[10], metastatic lung[11], metastatic colon[12], renal cell[13], prostate[14], breast[15], gastric[16], and thyroid[17] cancers. Axl also affects multiple pathways in angiogenesis[11]. Thus, Axl may play an important role in tumor progression, although its mechanism remains unknown.

Protein glycosylation is one of the major types of posttranslational modifications that has profound biological implications[18,19]. Specific changes in the glycosylation pattern of cell surface glycoproteins have been shown to correlate with metastatic efficiency in tumor cells[20]. In particular, protein N-glycosylation is one of the most prominent biochemical alterations in tumorigenesis and metastatic spread[21,22]. A cell surface transmembrane glycoprotein, little is known about the mechanism of Axl deglycosylation.

The mouse hepatocellular carcinoma cell line Hca-F is highly aggressive, with a metastasis rate over 80%. Hca-P, on the other hand, has a lymphatic metastasis rate of less than 30%. Both cell lines are derived from 615-mice ascites-type hepatocellular carcinoma cells. Hca-F and Hca-P cells metastasize only to lymph nodes, and not extrahepatic organs. However, the relationship between Axl glycosylation and lymphatic metastasis of mouse hepatocellular carcinoma cells remains unclear.

Our aim was to investigate whether Axl glycosylation regulates lymphatic metastasis. We demonstrated a possible correlation, based upon regulation of Axl glycosylation in mouse hepatocellular carcinoma cells.

MATERIALS AND METHODS

Cell culture and animals

Mouse hepatocellular carcinoma cell lines Hca-F and Hca-P, grown and stored in our institution (Department of Pathology, Dalian Medical University) were cultured in 90% Roswell Park Memorial Institute (RPMI)-1640 (Gibco) and supplemented with antibiotics (1 × penicillin/streptomycin 100 U/mL, Gibco) and 10% fetal bovine serum (FBS) (Gibco). Cells were incubated at 37 ℃ in a humidified atmosphere containing 5% CO_2. 615-mice (8 wk old males) were obtained from the Experimental Animal Center of Dalian Medical University.

Whole protein extract

10^7 cells were centrifuged at room temperature at 1000 × *g* for 10 min. Cells were rinsed twice with phosphate buffered saline (PBS) at 1000 × *g* for 5 min, and lysed with a protease inhibitor cocktail (whole protein extraction kit KGP2100, KeyGEN). Cells were suspended on a swing bed at 4 ℃ for 15 min, and centrifuged at 4 ℃ at 14 000 × *g* for 15 min. Protein concentration of the whole cells was measured with a bicinchoninic acid protein assay kit (KGPBCA, KeyGEN).

Western blotting analysis

Western blotting analysis was performed to evaluate Axl (with or without tunicamycin or PNGase F treatment) protein levels. Extracted proteins were subjected to 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and blotted onto polyvinylidene fluoride membranes (Pall Corporation). After blocking for 2 h with 5% skimmed milk in PBS containing 0.1% Tween 20 (PBST), membranes were incubated with rabbit anti-mouse Axl polyclonal antibody (Santa Cruz Biotech Inc., 1/200 diluted) overnight in 5% powdered skim milk buffer, washed thrice with PBS with 0.1% Tween 20, and then incubated with secondary antibody anti-rabbit-HRP (Santa Cruz Biotech Inc., 1/3000 diluted). Glyceraldehyde-3-phosphate dehydrogenase antibody (Santa Cruz Biotech Inc., 1/200 diluted) was used as controls. All blot analysis was performed with a ECL Western blotting kit (Amersham Biosciences, United Kingdom).

Tunicamycin treatment

To inhibit N-linked glycosylation of newly synthesized proteins, Hca-F cells were washed once with PBS and cultivated for 12 h in fresh culture media (90% RPMI 1640 supplemented with antibiotics) with or without tunicamycin (Sigma Aldrich, St. Louis, MO) in a dose-dependent manner (0 μg/mL, 5 μg/mL, 10 μg/mL, or 20 μg/mL). Cells were washed with PBS and subjected to Western blotting analysis, 3-(4,5)-dimethylthiazol(-zyl)-3,5-diphenyltetrazolium bromide (MTT), migration *in*

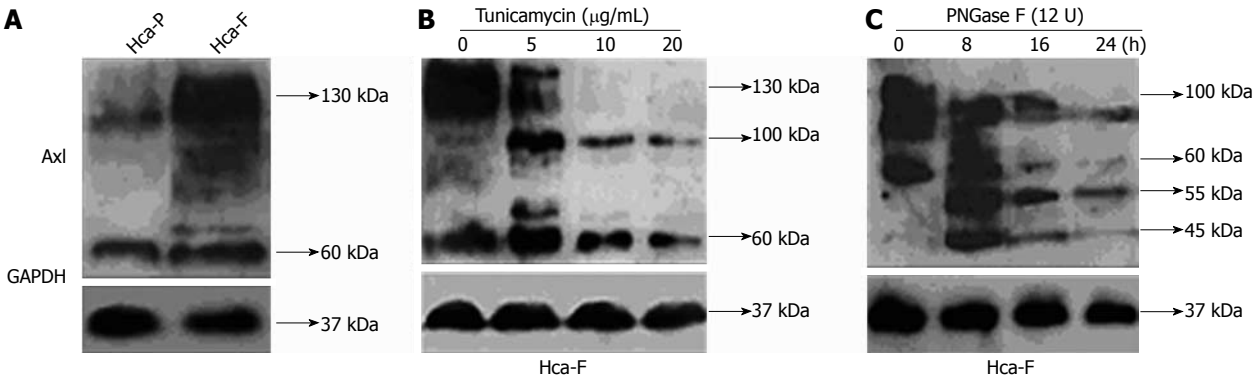

Figure 1 Expression profile of Axl glycoprotein in mouse hepatocellular carcinoma cell lines. A: Axl glycoprotein levels by Western blotting analysis in Hca-P and Hca-F cell lines. Relative signal intensities of Axl protein were compared with GAPDH by LabWorks (TM ver4.6, UVP; BioImaging Systems), ($^{a}P < 0.05$ *vs* untreated Hca-F cells); B: Hca-F cells were treated with 0 μg/mL, 5 μg/mL, 10 μg/mL, and 20 μg/mL tunicamycin for 12 h. Total protein extracts were loaded for each sample; C: Hca-F cell protein was deglycosylated with 12 units of PNGase F in lysis buffer. Probes were incubated at 37 ℃ in a time-dependent manner (0 h, 8 h, 16 h, 24 h). Protein was separated on a gel for Western blotting Analysis. After sodium dodecyl sulfate-polyacrylamide gel electrophoresis, proteins were transferred to a polyvinylidene fluoride membrane, and were detected by rabbit anti-mouse Axl polyclonal antibody. GAPDH blotting was used as the control. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

vitro, and tumor metastasis *in vivo* assays.

PNGase F treatment

To remove N-glycans, protein fractions (100 μg) from Hca-F cells were deglycosylated with 25 units of PNGase F (Elizabethkingia meningoseptica; Sigma Aldrich, St. Louis, MO) in lysis buffer. Probes were incubated for 8 h, 16 h and 24 h at 37 ℃. The reaction was terminated with Laemmlie's sample buffer and proteins were separated on a gel as described earlier.

For deglycosylation of membrane proteins, intact Hca-F cells were incubated with 25 units of PNGase F for 24 h, washed, and treated as described for the MTT, migration *in vitro*, and tumor metastasis *in vivo* assays.

3-(4,5)-dimethylthiazol(-zyl)-3,5-diphenyltetrazolium bromide assay

10^6 cells in 200 μL RPMI 1640 were seeded in duplicate into 96-well culture plates, and 100 μL MTT (5 mg/mL, Sigma) was added at 24 h, 48 h, 72 h, 96 h, and 120 h, respectively. After 4 h incubation at 37 ℃ in 5% CO_2, 100 μL/well DMSO (final concentration 25%, Gibco) was pipetted to solubilize the formazan product for 30 min at room temperature. Absorbency (490 angstroms) was measured using a microplate reader (Bio-Rad).

In vitro extracellular matrix invasion assays

Cell invasion *in vitro* was demonstrated using 24-well transwell units (Corning, NY, United States) with a 8 μm pore size polycarbonate filter coated with ECMatrix gel (Chemicon) to form a continuous thin layer[23]. Cells (3×10^5) were harvested in serum-free medium containing 0.1% BSA and added to the upper chamber. The lower chamber contained 500 μL RPMI 1640. Cells were incubated for 24 h at 37 ℃, 5% CO_2 incubator. At the end of incubation, cells on the upper surface of the filter were completely removed with a cotton swab. The filters were fixed in methanol and stained with Wright-Giemsa. Cells invading the matrigel that reached the lower surface of the filter were counted with light microscopy at a magnification of 400 ×. Samples were acquired in triplicate and data expressed as the average cell number in 5 fields.

In vivo tumor metastasis assay

Forty eight 615-mice were provided with sterilized food and water and equally divided into eight groups. 10^7 Hca-F cells (with or without tunicamycin or PNGase F treatment) were subcutaneously inoculated into the footpads. After 3 wk, mice were sacrificed and their axillary lymph nodes were isolated, weighed, and photographed.

Statistical analysis

Each assay was performed at least three times. Data were presented as the mean ± SD. Statistical differences between test groups was assessed by one-way analysis of variance and Scheffe's test for post hoc analysis. A *P*-value of less than 0.05 was considered statistically significant. SPSS version 13.0 software was used for statistical analysis.

RESULTS

Expression profile of Axl glycoprotein in mouse hepatocellular carcinoma cell lines

Axl glycoprotein relative expression was determined by Western blotting analysis using whole-cell extracts (Figure 1A). Axl expression varied among cell lines, with higher and lower levels in Hca-F and Hca-P cells, respectively (Figure 1A, $P < 0.05$).

Tunicamycin, an inhibitor of endogenous N-linked glycosylation of newly synthesized proteins, was used to inhibit Axl glycosylation of Hca-F cells. Treatment in a dose dependent manner (0 mg/mL, 5 mg/mL, 10 mg/mL, and 20 mg/mL) for 12 h showed N-linked glycosylation to be highly sensitive to tunicamycin inhibition (Figure 1B).

Axl appears as broad bands, with molecular weights ranging from 60 kDa to 140 kDa. With tunicamycin treatment, 130 kDa Axl band density decreased, 60 kDa

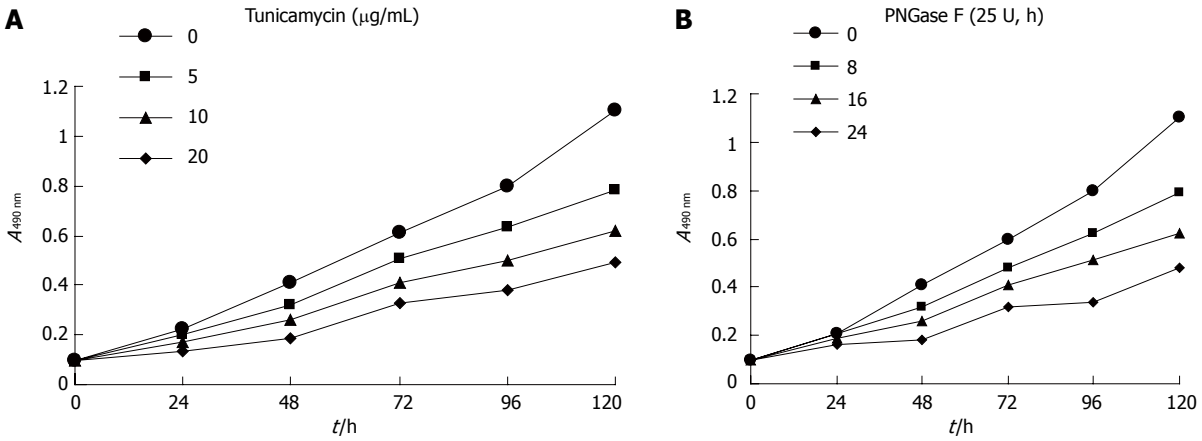

Figure 2 Axl deglycosylation effects on cell proliferation *in vitro*. Hca-F cells were exposed to tunicamycin or PNGase F and harvested at 24 h, 48 h, 72 h, 96 h, and 120 h. Cell proliferation was measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. Decreased proliferative ability was detected in cells treated with tunicamycin (A) or PNGase F (B), compared with untreated Hca-F cells. Data was obtained in triplicate.

band density increased, and a 100 kDa band appeared. As the dose of tunicamycin increased, the 130 kDa Axl band completely disappeared.

Whole protein aliquots extracted from Hca-F cells were exposed to exogenous PNGase F for deglycosylation (Figure 1C). 55 kDa and 45 kDa Axl bands appeared with PNGase F treatment. However, 60-140 kDa Axl band density significantly decreased. These results suggest that the N-glycosylation process for Hca-F cells responded to tunicamycin and PNGase F treatment.

Axl deglycosylation reduces cell proliferation in vitro

Hca-F cells treated with tunicamycin or PNGase F were measured for proliferative activity. Proliferation was apparent in untreated Hca-F cells compared with treated Hca-F cells (Figure 2A, B). Thus, Axl deglycosylation inhibited Hca-F cell proliferation *in vitro*.

Axl deglycosylation alters invasiveness of Hca-F cells in vitro

To examine whether Axl deglycosylation affects invasiveness of Hca-F cells, we performed *in vitro* ECMatrix gel analysis. We found that untreated and tunicamycin (Figure 3A) or PNGase F (Figure 3B) treated Hca-F cells or PNGase F had differing abilities to pass through an ECMatrix coated filter; therefore, the numbers of invading cells were unequal. Treated cells with tunicamycin passed through the ECMatrix gel in significantly smaller numbers than untreated cells (5 μg/mL: 68 ± 8 *vs* 80 ± 9, $P = 0.0222$; 10 μg/mL: 50 ± 6 *vs* 80 ± 9, $P = 0.0003$; 20 μg/mL: 41 ± 4 *vs* 80 ± 9, $P = 0.0001$). Similar results were shown with PNGase F treated Hca-F cells at 8 h, 16 h, and 24 h compared with untreated cells (66 ± 7 *vs* 82 ± 8, $P = 0.0098$; 49 ± 4 *vs* 82 ± 8, $P = 0.0001$; 34 ± 3 *vs* 82 ± 8, $P = 0.0001$). These results indicated that Axl deglycosylation reduced the invasiveness of Hca-F cells *in vitro*.

Axl deglycosylation inhibits the metastatic ability of Hca-F cells to peripheral lymph nodes in vivo

To further evaluate whether Axl deglycosylation was essential for tumor lymphatic metastasis *in vivo*, we tested the effect of Axl deglycosylation on the metastatic ability of Hca-F cells in mice peripheral lymph nodes. Treated and untreated Hca-F cells were injected in the footpads of 615-mice. After 3 wk' inoculation, a significant reduction in positive lymph nodes in the deglycosylation groups was observed, compared with untreated controls (Figure 4). Average lymph node weights of the untreated Hca-F group compared with dose-adjusted tunicamycin treated Hca-F groups (5 μg/mL: 0.84 ± 0.21 g *vs* 0.72 ± 0.19 g, $P = 0.3237$; 10 μg/mL: 0.84 ± 0.21 g *vs* 0.54 ± 0.11 g, $P = 0.0113$; 20 μg/mL: 0.84 ± 0.21 g *vs* 0.42 ± 0.06 g, $P = 0.0008$) (Figure 4A left). The average lymph node volumes of these groups were 815 ± 61 mm^3 *vs* 680 ± 59 mm^3, $P = 0.0613$; 815 ± 61 mm^3 *vs* 580 ± 29 mm^3, $P = 0.0001$; 815 ± 61 mm^3 *vs* 395 ± 12 mm^3, $P = 0.0001$ (Figure 4A right).

The average lymph node weights in the untreated Hca-F compared with PNGase F treated groups were: 8 h: 0.79 ± 0.15 g *vs* 0.63 ± 0.13 g, $P = 0.0766$; 16 h: 0.79 ± 0.15 g *vs* 0.49 ± 0.10 g, $P = 0.0022$; 24 h: 0.79 ± 0.15 g *vs* 0.39 ± 0.05 g, $P = 0.0001$ (Figure 4B left). The average lymph node volumes of these groups were: 670 ± 56 mm^3 *vs* 581 ± 48 mm^3, $P = 0.0532$; 670 ± 56 mm^3 *vs* 412 ± 22 mm^3, $P = 0.0001$; 670 ± 56 mm^3 *vs* 323 ± 11 mm^3, $P = 0.0001$ (Figure 4B right). These results demonstrate Axl deglycosylation may reduce Hca-F cells to peripheral lymph nodes *in vivo*.

DISCUSSION

Axl has garnered attention because of its high expression in many tumor cells, and its key role in neoplastic invasion and metastasis. In this study, we demonstrated Axl protein expression varied based on antineoplastic treatment of mouse hepatocellular carcinoma cell lines Hca-F and Hca-P. We found Axl protein expression to be higher in Hca-F cells, which have high lymphatic metastasis potential compared with Hca-P cells, which have low lymphatic metastasis potential. This confirms previ-

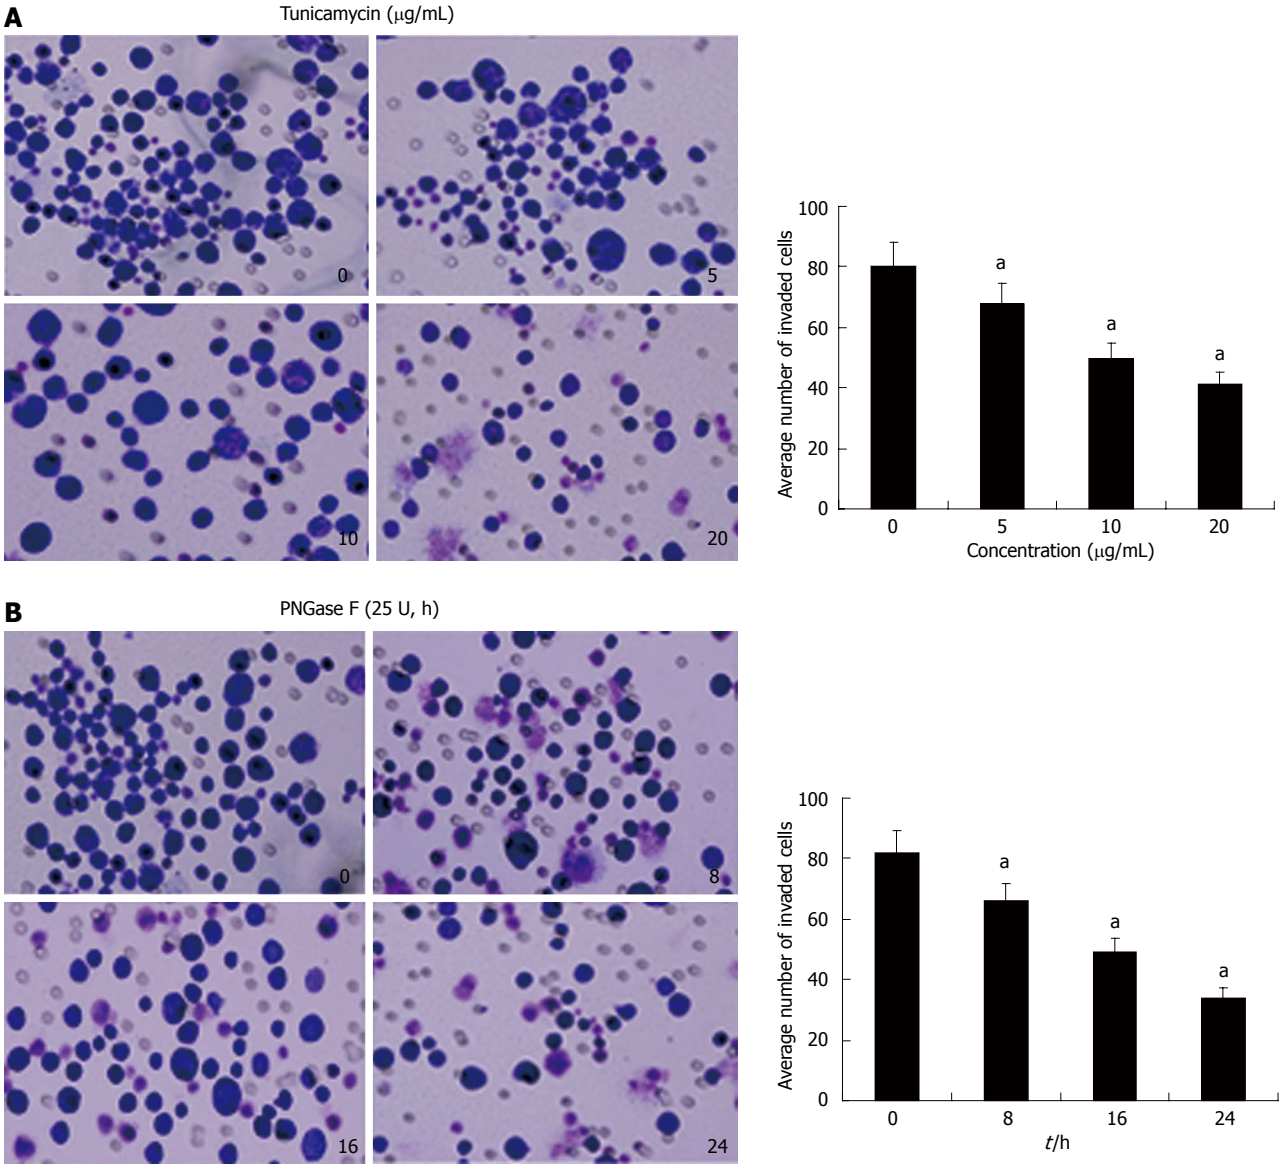

Figure 3 Axl deglycosylation alters the invasive ability of Hca-F cells *in vitro*. *In vitro* ECMatrix gel analysis. Wright-Giemsa staining results of the lower surface filter showed that the cells passed through the filter and attached to the lower side (400 ×). The average number of cells invading the filter was counted. Cells treated with tunicamycin (A) or PNGase F (B) were significantly less invasive ($^aP < 0.05$ *vs* untreated Hca-F cells) than untreated Hca-F cells. Data was obtained in triplicate.

ously reported findings of Axl overexpression in highly invasive lung adenocarcinoma cell lines, compared with their less invasive counterparts[11]. This suggests that high Axl expression may be associated with tumor lymphatic metastasis, and that Axl may be associated with tumor metastatic potential.

In our study, we achieved Hca-F deglycosylation with two methods. First, we inhibited N-glycan biosynthesis with tunicamycin; secondly, we extracted protein in the presence of PNGase F enzyme, which digests N-glycans. Both treatments resulted in significant effects on cell surface N-glycans by Western blotting assays.

Among post-translational modification reactions involving proteins, glycosylation is the most common; nearly 50% of all proteins are glycosylated[24]. Alterations of glycan structures are frequently observed in various cancer cells[25]; and this appears to be one association in cancer invasion and metastasis. We found Axl deglycosylation to be a possible factor in tumor progression, including cell proliferation, invasion, and lymphatic metastasis. In this study, we detected a significant inhibition of proliferation and invasion in Axl deglycosylated Hca-F cells *in vitro*, by both MTT and extracellular matrix assays. These results confirmed prior reports that cell proliferation requires growth factors signalling through cell surface glycoprotein receptors, which may be inactive when underglycosylated[26]. Although our findings support the role of Axl deglycosylation in reducing cell proliferation and invasion *in vitro*, its mechanism had not been elucidated. Further experiments showed that Axl deglycosylation led to a significant reduction in metastatic lymph node burden *in vivo*. These results were consistent previous reports of changes in N-linked oligosaccharide branching associated with malignancy and metastasis[27].

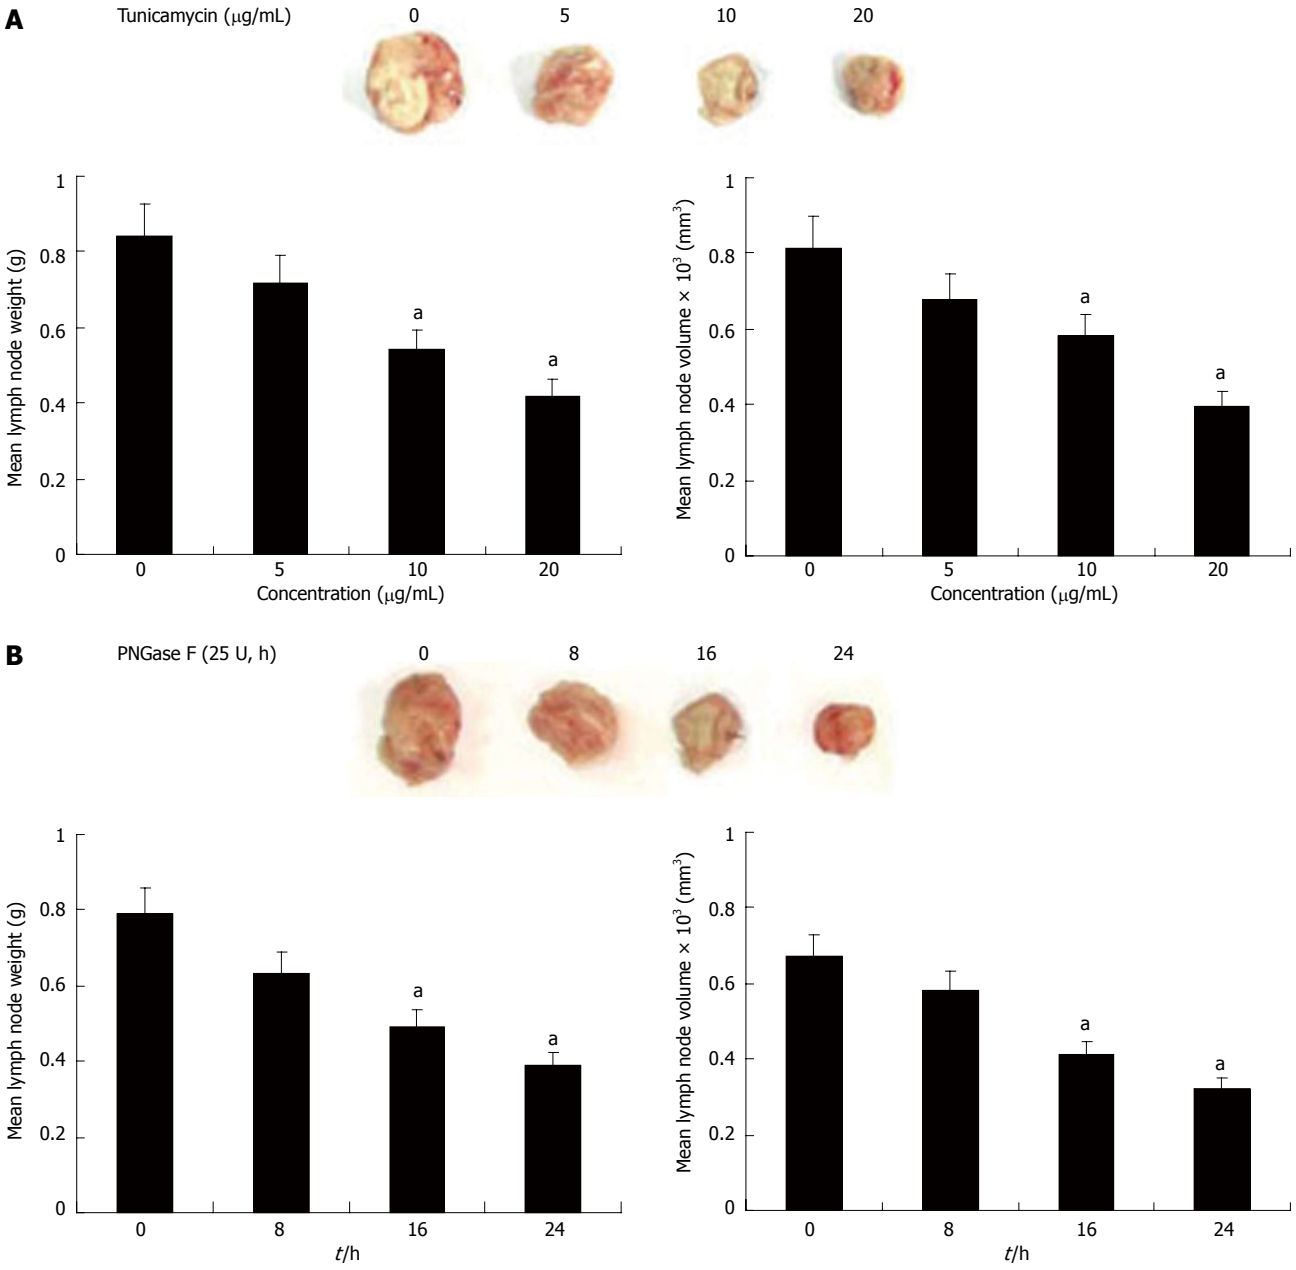

Figure 4 Axl deglycosylation inhibits the ability of Hca-F cells to metastasize to peripheral lymph nodes *in vivo*. Untreated and treated Hca-F cells were injected into the footpads of 615-mice. After 3 wk' inoculation, the mice were sacrificed and axillary lymph nodes isolated, weighed, measured, and photographed. A significant reduction in mean tumor weight ($n = 6$) of Axl tumor deglycosylation was observed, as compared with untreated Hca-F cells ($^aP < 0.05$ *vs* untreated Hca-F cells).

Some authors reported that the addition of exogenous Gas6 mediated the migration and invasion of Hca-F cells both *in vitro* and *in vivo* through the Axl pathway[28]. RNAi-mediated knockdown of Axl expression decreased the ability of YAP-expressing MIHA cells and of the primary HCC cell line to proliferate and invade[29]. In our study, we were unable to elucidate the mechanism by which Axl deglycosylation inhibits lymphatic metastasis in murine Hca-F cells. However, in many glycoproteins, N-linked oligosaccharides contribute to the folding, stability, and biological function of adhesion molecules and growth factor receptors on cell surfaces[30-32]. An increasing body of evidence indicates that glycoprotein glycans are involved in the regulation of cellular functions, including cell-cell communication and signal transduction[33,34]. The products of N-acetylglucosaminyltransferase (GnT)-IV, GnT-V and 1,6-fucosyltransferase (1,6-FucT) are all increased in hepatocellular carcinoma[35]. The presence of 1,6-GlcNAc structures in N-glycans and the expression of GnT-V, which catalyzes the addition of the 1,6-branching, were shown to promote metastasis[36-39]. At the very least, these reports demonstrate the relationship between metastasis and N-glycans to be extremely complicated. This area requires additional research.

In conclusion, we have found a role of Axl glycosylation in mediating tumor cell proliferation and invasion, and have provided the first evidence that Axl deglycosylation is required for lymphatic metastasis in murine

hepatocellular carcinoma cell lines. These results may at least partially explain the role of Axl glycosylation in the promotion of lymphatic metastasis. This study may provide new insights into regulatory mechanisms of mouse hepatocellular carcinoma with lymphatic metastasis.

COMMENTS

Background

Axl has been shown to have transforming capability when overexpressed. Prior studies have revealed Axl overexpression to be clearly associated with cancer invasiveness and metastasis. Axl also has multiple effects in angiogenesis. While Axl may play an important role in tumor progression, its mechanisms of action have not been understood.

Research frontiers

The authors investigated the potential effect of Axl deglycosylation the regulation of tumor lymphatic metastasis in mouse hepatocellular carcinoma cell lines. The authors evaluated the expression profile of Axl glycoprotein in the mouse hepatocellular carcinoma cell line Hca-F, which was treated with tunicamycin and PNGase F. Furthermore, the authors analyzed the effect of Axl glycosylation by tunicamycin and PNGase F treatment in Hca-F cells with regards to proliferation, invasion, and lymphatic metastasis both *in vitro* and *in vivo*.

Innovations and breakthroughs

Protein N-glycosylation is increasingly being recognized as one of the most prominent biochemical alterations in tumorigenesis and metastatic spread. However, as a cell surface transmembrane glycoprotein, little is known about Axl deglycosylation and its mechanism of action. Axl glycosylation was attenuated by tunicamycin and PNGase F to determine the effect on Hca-F cell proliferation, invasion, and lymphatic metastasis.

Applications

The authors have found the role of Axl glycosylation in mediating tumor cells proliferation, invasion and provided the first evidence that deglycosylation of Axl is required for metastasis of hepatocellular carcinoma cells to lymph nodes. This study may provide new insights into regulatory mechanisms of mouse hepatocellular carcinoma with lymphatic metastasis.

Terminology

The Axl receptor (also named UFO, Tyro7, and Ark) is a receptor tyrosine kinase (RTK) originally identified as a transforming gene in chronic myeloid leukemia. The RTKs constitute a large family of transmembrane proteins that relay signals from extracellular growth factors into the cell.

Peer review

In this study, the effect of Axl deglycosylation on lymphatic metastasis was investigated in mouse hepatocellular carcinoma cell lines. Differing Axl expression levels were found in mouse Hca-F and Hca-P cell lines, which are characterized by high and low metastatic potential, respectively. A decrease in Axl glycosylation by tunicamycin or PNGase F treatment resulted in a reduced proliferation, invasion, and lymphatic metastasis, both *in vitro* and *in vivo*. This work is potentially relevant in understanding hepatocellular carcinoma.

Abstract

AIM: To investigate the protective effect and mechanisms of ghrelin postconditioning against hypoxia/reoxygenation (H/R)-induced injury in human gastric epithelial cells.

METHODS: The model of H/R injury was established in gastric epithelial cell line (GES-1) human gastric epithelial cells. Cells were divided into seven groups: normal control group (N); H/R postconditioning group; DMSO postconditioning group (DM); ghrelin postconditioning group (GH); D-Lys3-GHRP-6 + ghrelin postconditioning group (D + GH); capsazepine + ghrelin postconditioning group (C + GH); and LY294002 + ghrelin postconditioning group (L + GH). 3-(4,5-dimethylthazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay was used to detect GES-1 cell viability. Hoechst 33258 fluorochrome staining and flow cytometry were conducted to determine apoptosis of GES-1 cells. Spectrophotometry was performed to determine release of lactate dehydrogenate (LDH). Protein expression of Bcl-2, Bax, Akt, and glycogen synthase kinase (GSK)-3β was determined by western blotting. Expression of vanilloid receptor subtype 1 (VR1), Akt and GSK-3β was observed by immunocytochemistry.

RESULTS: Compared with the H/R group, cell viability of the GH group was significantly increased in a dose-dependent manner (55.9% ± 10.0% *vs* 69.6% ± 9.6%, 71.9% ± 17.4%, and 76.3% ± 13.3%). Compared with the H/R group, the percentage of apoptotic cells in the GH group significantly decreased (12.38% ± 1.51% *vs* 6.88% ± 0.87%). Compared with the GH group, the percentage of apoptotic cells in the D + GH group, C + GH group and L + GH groups significantly increased (11.70% ± 0.88%, 11.93% ± 0.96%, 10.20% ± 1.05% *vs* 6.88% ± 0.87%). There were no significant differences in the percentage of apoptotic cells between the H/R and DM groups (12.38% ± 1.51% *vs*13.00% ± 1.13%). There was a significant decrease in LDH release following ghrelin postconditioning compared with the H/R group (561.58 ± 64.01 U/L *vs* 1062.45 ± 105.29 U/L). There was a significant increase in LDH release in the D + GH, C + GH and L + GH groups compared with the GH group (816.89 ± 94.87 U/L, 870.95 ± 64.06 U/L, 838.62 ± 118.45 U/L *vs* 561.58 ± 64.01 U/L). There were no significant differences in LDH release between the H/R and DM groups (1062.45 ± 105.29 U/L *vs* 1017.65 ± 68.90 U/L). Compared with the H/R group, expression of Bcl-2 and Akt increased in the GH group, whereas expression of Bax and GSK-3β decreased. Compared with the GH group, expression of Bcl-2 decreased and Bax increased in the D + GH, C + GH and L + GH groups, and Akt decreased and GSK-3β increased in the L + GH group. The H/R group also upregulated expression of VR1 and GSK-3β and downregulated Akt. The number of VR1-positive and Akt-positive cells in the GH group significantly increased, whereas the number of GSK-3β-positive cells significantly decreased. These effects of ghrelin were

reversed by capsazepine and LY294002.

CONCLUSION: Ghrelin postconditioning protected against H/R-induced injury in human gastric epithelial cells, which indicated that this protection might be associated with GHS-R, VR1 and the PI3K/Akt signaling pathway.

Protection of ghrelin postconditioning on hypoxia/reoxygenation in gastric epithelial cells. *World J Gastroenterol* 2012; 18(38): 5377-5388 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i38/5377.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i38.5377

INTRODUCTION

Gastric ischemia-reperfusion (GI/R) injury is a common clinical pathophysiological process. In case of clinical multiple organ dysfunction syndrome, gastrointestinal mucosal ischemia due to the redistribution of blood is the earliest to occur, and is more obvious than other organ ischemia-reperfusion (I/R) injury. Thus, the stomach is considered the earliest organ to be involved[1,2]. In recent years, ischemic postconditioning (Ipost) has been discovered to be an important endogenous protective mechanism and hypoxia postconditioning (HPost) can be elicited after hypoxia and reoxygenation in cell culture[3-5]. It has been demonstrated that IPost can effectively reduce myocardial injury[6]. Pharmacological postconditioning is the extension of Ipost, in which a drug is applied to the ischemic myocardium or hypoxic cardiomyocytes during the first few minutes of reperfusion or reoxygenation, significantly reducing organ reperfusion injury[7].

Ghrelin is a 28-amino-acid peptide, which was initially identified from rat stomach[8]. In humans, it acts as the endogenous ligand for the growth hormone secretagogue receptor (GHSR)[9]. GHSR, a seven transmembrane-domain G-protein coupled receptor was cloned and identified as the receptor for a family of synthetic ligands. GHSR has been observed in the human gastrointestinal tract[10]. Ghrelin is predominantly produced in the stomach by endocrine cells of the fundic mucosa, formerly known as X/A-like cells[9,11,12]. Several studies have suggested that the many physiological actions are associated with ghrelin, including neuroendocrine, cardiovascular and gastrointestinal functions[13,14]. Ghrelin plays an important role in mucosal defense, such as resistance against a variety of ulcerogenic stimuli, including ethanol, stress and I/R[15-17].

Vanilloid receptor subtype 1 (VR1) is a nonselective cation channel, primarily expressed in central and peripheral terminals of nonmyelinated primary afferent neurons[18]. VR1 may be activated by physical and chemical mediators that contain noxious thermal stimulation, noxious protons, and vanilloid compounds such as capsaicin[19,20]. Our study aimed to establish whether the effect of ghrelin was mediated by VR1, and whether ghrelin served as a new activator of VR1.

The phosphoinositide 3-kinase (PI3K/Akt) signaling pathway has been implicated in the control of major cellular responses including cell proliferation, survival, development, differentiation, cell cycle, and apoptosis[21,22]. The PI3K/Akt signaling pathway is a type of significant antiapoptotic factor that plays an important protective role by reducing apoptosis-associated protein kinase caspase family, Bcl-2 and other apoptotic factors[23].

The primary aim of this study was to investigate whether ghrelin postconditioning had a protective effect on hypoxia/reoxygenation (H/R) injury in human gastric epithelial cells, and whether GHSR, VR1 and the PI3K/Akt signaling pathway are involved in this protection.

MATERIALS AND METHODS

Materials

The materials and reagent were as follows: human gastric epithelial cell line (GES-1) from Beijing Cancer Hospital; ghrelin, D-Lys3-GHRP-6, capsazepine and LY294002 (Sigma-Aldrich, United States) were dissolved in 100% DMSO and stored at -20 ℃; Dulbecco's Modified Eagle's Medium) (DMEM; Gibco Service Co., United States); fetal bovine serum (FBS) from Tianjin Hao Yang Biological Manufacture Co. Ltd. (China); 3-(4,5-dimethylthazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) from Amresco (United States); Hoechst 33258 from Beyotime Institute of Biotechnology (China); Annexin V-fluorescein isothiocyanate (FITC) Apoptosis Assay kit from Beijing Biosea Biotechnology Co. Ltd. (China); lactate dehydrogenase (LDH) assay kit from Nanjing Jiancheng Bioengineering Institute (China).

Cell culture

Cells were cultured in phenol-red-free DMEM containing 10% FBS at a density of 10^5 cells/mL, and placed in a humidified incubator with 95% air and 5% CO_2 at 37 ℃ until cells reached 70%-80% confluence.

Experimental protocol

The complete medium was replaced with DMEM containing 1% FBS 1 d before the experiment for cell synchronization. The cells were randomized into five groups and treated as follows. Cells in the normal control group (N) were kept in normoxic culture for 6 h. In the H/R group, DMEM was replaced with Krebs-Ringer bicarbonate buffer prior to hypoxia induction, and the cells

were transferred into a hypoxic incubator in a humidified atmosphere equilibrated with 94% N_2 + 1% O_2 + 5% CO_2 for 2 h (hypoxia). Afterwards, the Krebs-Ringer bicarbonate buffer was replaced with DMEM for reperfusion simulation, followed by 4 h normoxic culture (for reoxygenation). In the DMSO vehicle postconditioning group (DM), the Krebs-Ringer bicarbonate buffer was replaced with DMEM containing 0.05% DMSO prior to reoxygenation, with no modification of other procedures in the H/R group. In the ghrelin postconditioning group (GH), the Krebs-Ringer bicarbonate buffer was replaced with DMEM containing 10^{-9}, 10^{-8} and 10^{-7} mol/L ghrelin before reoxygenation, with no modification of other procedures in the H/R group. In the D-Lys3-GHRP-6 + ghrelin postconditioning group (D + GH), capsazepine + ghrelin postconditioning group (C + GH) and LY294002 + ghrelin postconditioning group (L + GH), the DMEM was replaced with Krebs-Ringer bicarbonate buffer containing D-Lys3-GHRP-6, capsazepine and LY294002, respectively, followed by 2 h hypoxia. Thereafter, the buffer was replaced with DMEM containing 10^{-7} mol/L ghrelin before reoxygenation, with no modification of other procedures in the H/R group.

MTT assay

The cells in logarithmic growth phase were cultured in a 96-well plate at a density of 10^4 cells/well. Following the experiment in each group, 20 μL MTT (5 mg/mL) was added to each well and incubated for 4 h. Then, 200 μL DMSO was added to each well and the plate was vortexed for 10 min at 37 ℃. A 96-well microplate reader (Thermo, United States) was used to determine $A_{490\ nm}$. Viability (%) was determined as (experimental group $A_{490\ nm}$/normal control group $A_{490\ nm}$) × 100%. Each assay was repeated at least three times.

Hoechst 33258 staining assay

Cells were cultured in six-well plates at a density of 104 cells/well and incubated for 48 h. Following each experiment, cells were fixed with paraformaldehyde for 20 min and washed with 0.01 mol/L phosphate buffered solution (PBS) twice for 3 min, followed by Hoechst 33258 (0.5 mL) staining at 37 ℃ in darkness for 15 min, and rewashed with 0.01 mol/L PBS for 2 min to remove excess background stain. Apoptotic cells were observed by fluorescence microscopy, with excitation wavelength at 350 nm and emission wavelength at 460 nm. The photographs were preserved.

Flow cytometric analysis

Cells were plated in 100 mL culture flasks and incubated for 48 h. Following each experiment, cells were collected, washed twice with ice-cold PBS, followed by cell density determination and dilution in 1 × Annexin-binding buffer to 10^6 cells/mL. Cells was suspended in 200 μL binding buffer and 5 μL Annexin V-FITC for 15 min in darkness. Finally, 300 μL binding buffer and 5 μL propidium iodide (PI) were added to each sample. Apoptosis percentage was analyzed by flow cytometry (Becton Dickinson, United States).

LDH assay

The cells were cultured in 96-well plates at a density of 10^4 cells/well. At the end of each experiment, 20 μL supernatant was drawn from each well and transferred into test tubes, followed by determination of LDH release using the LDH assay kit.

Western blotting

Cells were plated in 100 mL cell culture flasks and incubated for 48 h. At the end of each experiment, the cells were washed thrice in ice-cold PBS prior to lysis with lysis buffer containing 150 mL/L protease inhibitor, followed by cell collection and centrifugation at 4 ℃ for 15 min. The resulting protein-containing supernatant was collected for protein quantification or storage at -80 ℃. The protein contents were determined by bicinchoninic acid assay. Protein samples were adjusted to equal concentration and volume by lysis buffer and then mixed with sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) sample buffer. The protein samples were heated at 100 ℃ for 5 min, and then 100 μg protein was loaded into each well for 12.5% SDS-PAGE, and the targeted protein was transferred onto a nitrocellulose membrane. Immunoblotting was performed with the following antibodies: mouse anti-Bcl-2 (Zhongshan Golden Bridge Biotechnology Co. Ltd., China), mouse anti-Bax (Zhongshan Golden Bridge Biotechnology), mouse anti-β-actin (Zhongshan Golden Bridge Biotechnology), rabbit anti-VR1 (Zhongshan Golden Bridge Biotechnology), rabbit anti-Akt (Zhongshan Golden Bridge Biotechnology), and rabbit anti-glycogen synthase kinase (GSK)-3β (Wuhan Boshide Biotechnology Co. Ltd., China). The secondary antibodies were alkaline phosphatase goat anti-rabbit IgG (Zhongshan Golden Bridge Biotechnology) and alkaline phosphatase horse anti-mouse IgG (Zhongshan Golden Bridge Biotechnology). Protein expression was quantified by Image J software.

Immunocytochemistry assay

Exponentially growing cells were cultured in a 24-well plate. Immunohistochemistry detection reagent and DAB kit (Zhongshan Golden Bridge Biotechnology) were used to examine the expression of VR1, Akt and GSK-3β in human gastric epithelial cells. Following each experiment, cells were washed thrice in PBS and fixed with 4% paraformaldehyde at 4 ℃ for 30 min. Cells were incubated with 0.3% Triton X-100 for 20 min and 3% H_2O_2 for 10 min. Cells were blocked with 10% normal goat serum for 1 h at room temperature. Primary antibodies were added and incubated at 4 ℃ overnight. With cells washed thrice in cold PBS, the secondary antibody was added and incubated at room temperature for 3 h. Finally, cells were washed thrice in 0.01 mol/L PBS, followed by incubation with DAB complexes for 20 min. Cells were observed for

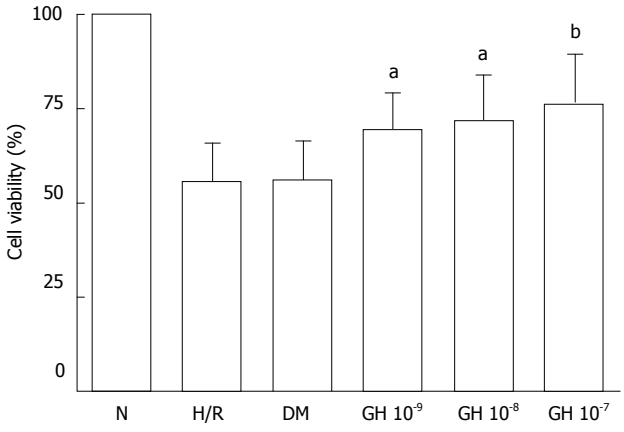

Figure 1 Effects of different doses of ghrelin on cell viability in human gastric epithelial cells induced by H/R. Cells were grouped as follows: normoxic culture for 6 h (N), 2 h hypoxia/4 h reoxygenation (H/R), alcohol vehicle postconditioning (DM) and ghrelin postconditioning at three doses (10^{-9} mol/L, 10^{-8} mol/L and 10^{-7} mol/L). Cell viability was detected by 3-(4,5-dimethylthazol-2-yl)-2,5-diphenyl tetrazolium bromide assay. mean ± SD. $n = 6$. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* H/R.

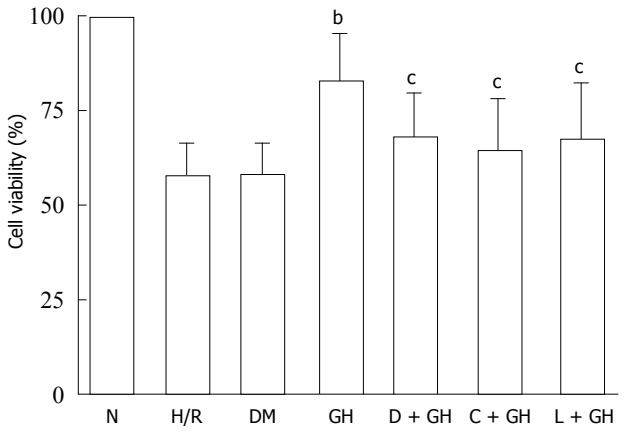

Figure 2 Effects of D-Lys3-GHRP-6, capsazepine and LY294002 in ghrelin postconditioning on cell viability in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (N), 2 h hypoxia/4h reoxygenation (H/R), DMSO vehicle postconditioning (DM), ghrelin postconditioning (10^{-7} mol/L) (GH), D-Lys3-GHRP-6 + ghrelin postconditioning (D + GH), capsazepine + ghrelin postconditioning (C + GH) and LY294002 + ghrelin postconditioning (L + GH). photography under a phase contrast microscope.

Statistical analysis

All data were presented as mean ± SD. One-way analysis of variance was performed to determine differences among groups and LSD test was performed to determine differences between groups. All statistical analyses were performed with the SPSS version 13.0 (SPSS, Chicago, IL, United States). The difference was considered statistically significant at $P < 0.05$.

RESULTS

Effects of different doses of ghrelin on cell viability in human gastric epithelial cells induced by H/R

The MTT assay indicated that the GES-1 cells were treated with ghrelin postconditioning at 10^{-9} mol/L, 10^{-8} mol/L and 10^{-7} mol/L. The viability of the GH group was 69.6% ± 9.6%, 71.9% ± 17.4%, and 76.3% ± 13.3%, respectively, in a dose-dependent manner. Compared with the H/R group (55.9% ± 10.0%), the viability significantly increased ($P < 0.05$), suggesting that 10^{-7} mol/L ghrelin was the optimal protective dose, which was used in the subsequent experiments. There were no significant differences between the H/R and DM groups (55.9% ± 10.0% *vs* 56.1% ± 10.5%, $P > 0.05$, Figure 1).

Effects of ghrelin postconditioning on viability of human gastric epithelial cells induced by H/R

To investigate whether GHS-R, VR1 and the PI3K/Akt signaling pathway were related to this effect, their inhibitors D-Lys3-GHRP-6, capsazepine and LY294002 were administered prior to ghrelin postconditioning. The GH group had significantly increased cell viability ($P < 0.01$ *vs* H/R group), whereas the D + GH, C + GH and L + GH groups had significantly decreased cell viability ($P < 0.05$ *vs* GH group, Figure 2), which indicated that D-Lys3-GHRP, capsazepine and LY294002 could reverse the protective effect of ghrelin postconditioning on GES-1 cell viability induced by H/R.

Effects of ghrelin postconditioning on apoptosis of human gastric epithelial cells induced by H/R

Hoechst 33258 staining showed that apoptotic cells were apparent in normal gastric epithelial cells. Compared with the H/R group, there were fewer apoptotic cells in the GH group, whereas many apoptotic cells were observed in the D + GH, C + GH and L + GH groups compared with the GH group (Figure 3).

Flow cytometric analysis showed that the percentage of apoptotic cells in the GH group significantly decreased (12.38% ± 1.51% *vs* 6.88% ± 0.87%, $P < 0.01$) compared with the H/R group. Compared with the GH group, the D + GH, C + GH and L + GH groups had a significantly increased percentage of apoptotic cells (11.70% ± 0.88%, 11.93% ± 0.96%, 10.20% ± 1.05% *vs* 6.88% ± 0.87%, $P < 0.05$). There were no significant differences in the percentage of apoptotic cells between the H/R and DM groups (12.38% ± 1.51% *vs* 13.0% ± 1.13%, $P > 0.05$, Figure 4).

Effects of ghrelin postconditioning on LDH release in human gastric epithelial cells induced by H/R

There was a significant decrease in LDH release in the GH group compared with the H/R group (561.58 ± 64.01 U/L *vs* 1062.45 ± 105.29 U/L, $P < 0.01$). There was a significant increase in LDH release in the D + GH, C + GH and L + GH groups compared with the GH group (816.89 ± 94.87 U/L, 870.95 ± 64.06 U/L, 838.62 ± 118.45 U/L *vs* 561.58 ± 64.01 U/L, $P < 0.01$). There were no significant differences in LDH release between the H/R and DM groups (1062.45 ± 105.29 U/L

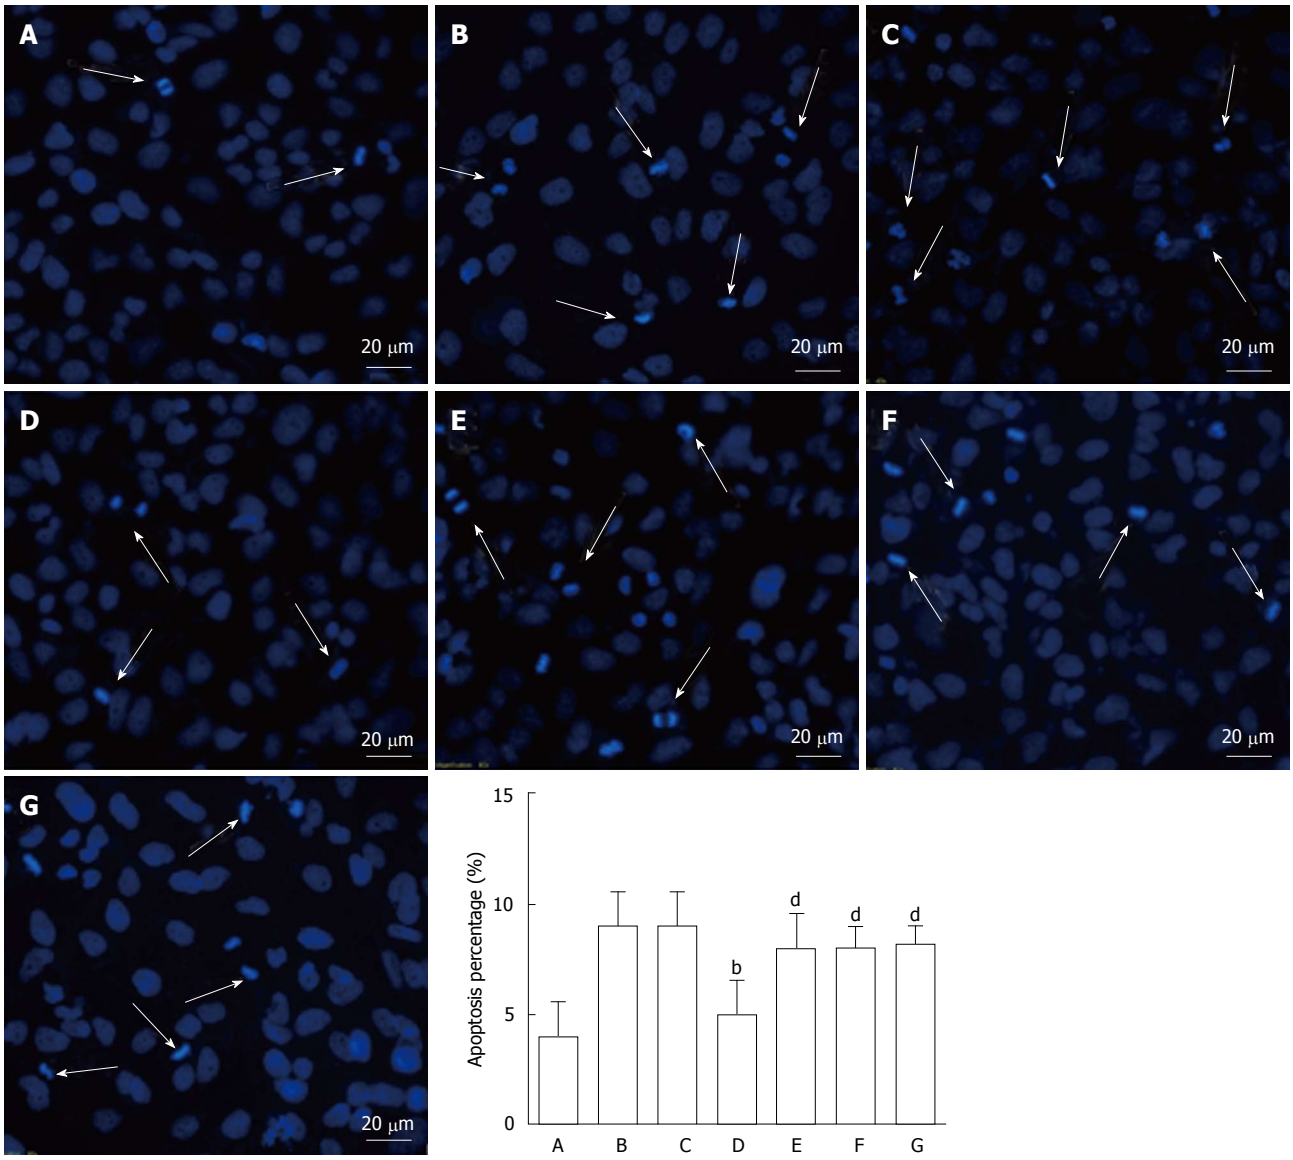

Figure 3 Effects of D-Lys3-GHRP-6, capsazepine and LY294002 in ghrelin postconditioning on cell apoptosis in human gastric epithelial cells induced by H/R. Cells were grouped as follows: normoxic culture for 6 h (A), 2 h hypoxia/4 h reoxygenation (B), DMSO vehicle postconditioning (C), ghrelin postconditioning (10^{-7} mol/L) (D), D-Lys3-GHRP-6 + ghrelin postconditioning (E), capsazepine + ghrelin postconditioning (F), and LY294002 + ghrelin postconditioning (G). mean ± SD. n = 6. $^{b}P < 0.01$ *vs* B; $^{d}P < 0.01$ *vs* D. Cells were then stained by Hoechst33258. The arrows indicate apoptotic cells.

vs 1017.65 ± 68.90 U/L, $P > 0.05$, Table 1).

Effects of ghrelin postconditioning on expression of Bcl-2, Bax, VR1, Akt and GSK-3β in human gastric epithelial cells induced by H/R

Western blotting demonstrated that Bcl-2, Bax, Akt and GSK-3β were expressed in normal gastric epithelial cells. Compared with the H/R group, expression of Bcl-2 and Akt increased in the GH group, whereas there was a decrease in expression of Bax and GSK-3β ($P < 0.01$). Compared with the GH group, Bcl-2 expression decreased and Bax expression increased in the D + GH, C + GH and L + GH groups ($P < 0.01$). Expression of Akt decreased and expression of GSK-3β increased in the L + GH group ($P < 0.01$, Figure 5).

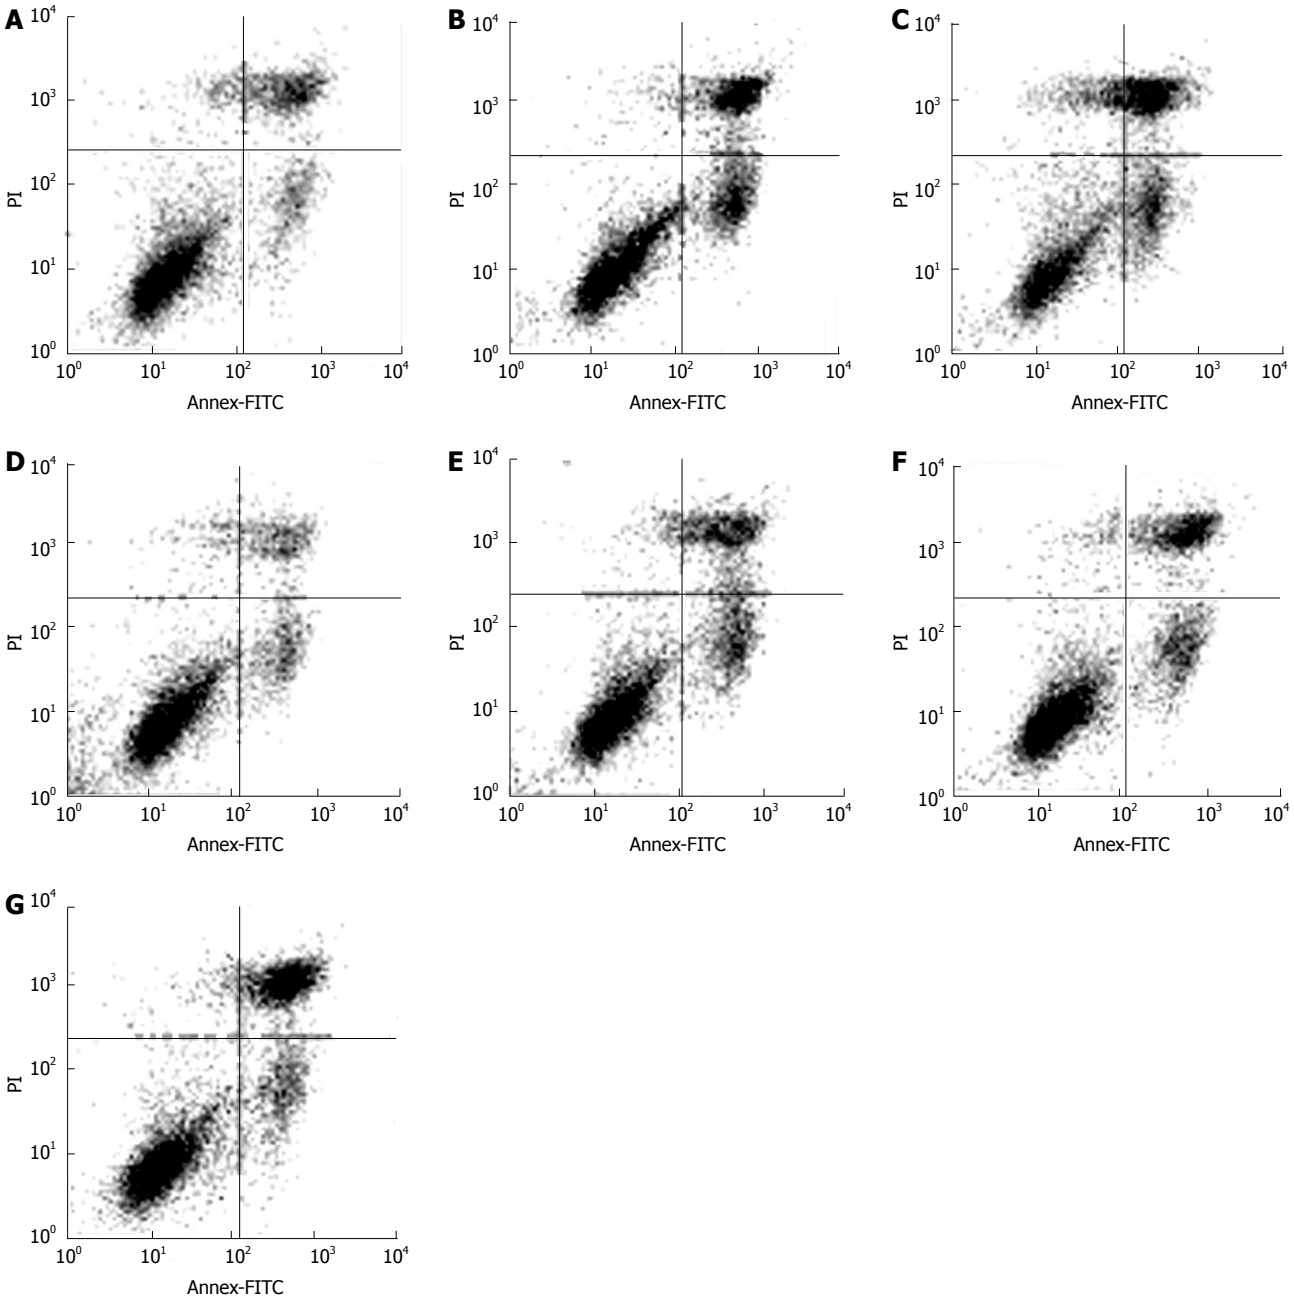

Figure 4 Effects of D-Lys3-GHRP-6, capsazepine and LY294002 in ghrelin postconditioning on cell apoptosis in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (A), 2 h hypoxia/4 h reoxygenation (B), DMSO vehicle postconditioning (C), ghrelin postconditioning (10^{-7} mol/L) (D), D-Lys3-GHRP-6 + ghrelin postconditioning (E), capsazepine + ghrelin postconditioning (F), and LY294002 + ghrelin postconditioning (G). Subsequently, the cells were stained by annexin V-fluorescein isothiocyanate (FITC) and propidium iodide (PI). Apoptosis was detected by flow cytometry.

Immunocytochemistry demonstrated expression of VR1 (Figure 6A), Akt (Figure 7A) and GSK-3β (Figure 8A) in normal human gastric epithelial cells. Two hours hypoxia followed by 4 h incubation under normoxic conditions also upregulated expression of VR1 (Figure 6B) and GSK-3β (Figure 8B) and downregulated Akt (Figure 7B). There was a significant increase in the number of VR1-positive (Figure 6D) as well as Akt-positive (Figure 7D) cells in the GH group, whereas the number of GSK-3β-positive cells significantly decreased (Figure 8D). However, these effects of ghrelin were reversed by capsazepine and LY294002 (Figures 6E, 7E and 8E).

DISCUSSION

Gastric mucosal lesions are frequently observed in clinical situations, such as stress-induced GI/R injury, a major cause of acute gastric mucosal lesions[2,24]. GI/R injury is a common clinical pathophysiological process, which is associated with such factors as excessive generation of oxygen free radicals (OFRs) in gastric mucosa, intracellular calcium overload, increased gastric acid secretion and gastric microcirculation disturbance[25]. Excessive generation of OFRs and intracellular calcium overload may lead to apoptosis[26]. In recent years, there

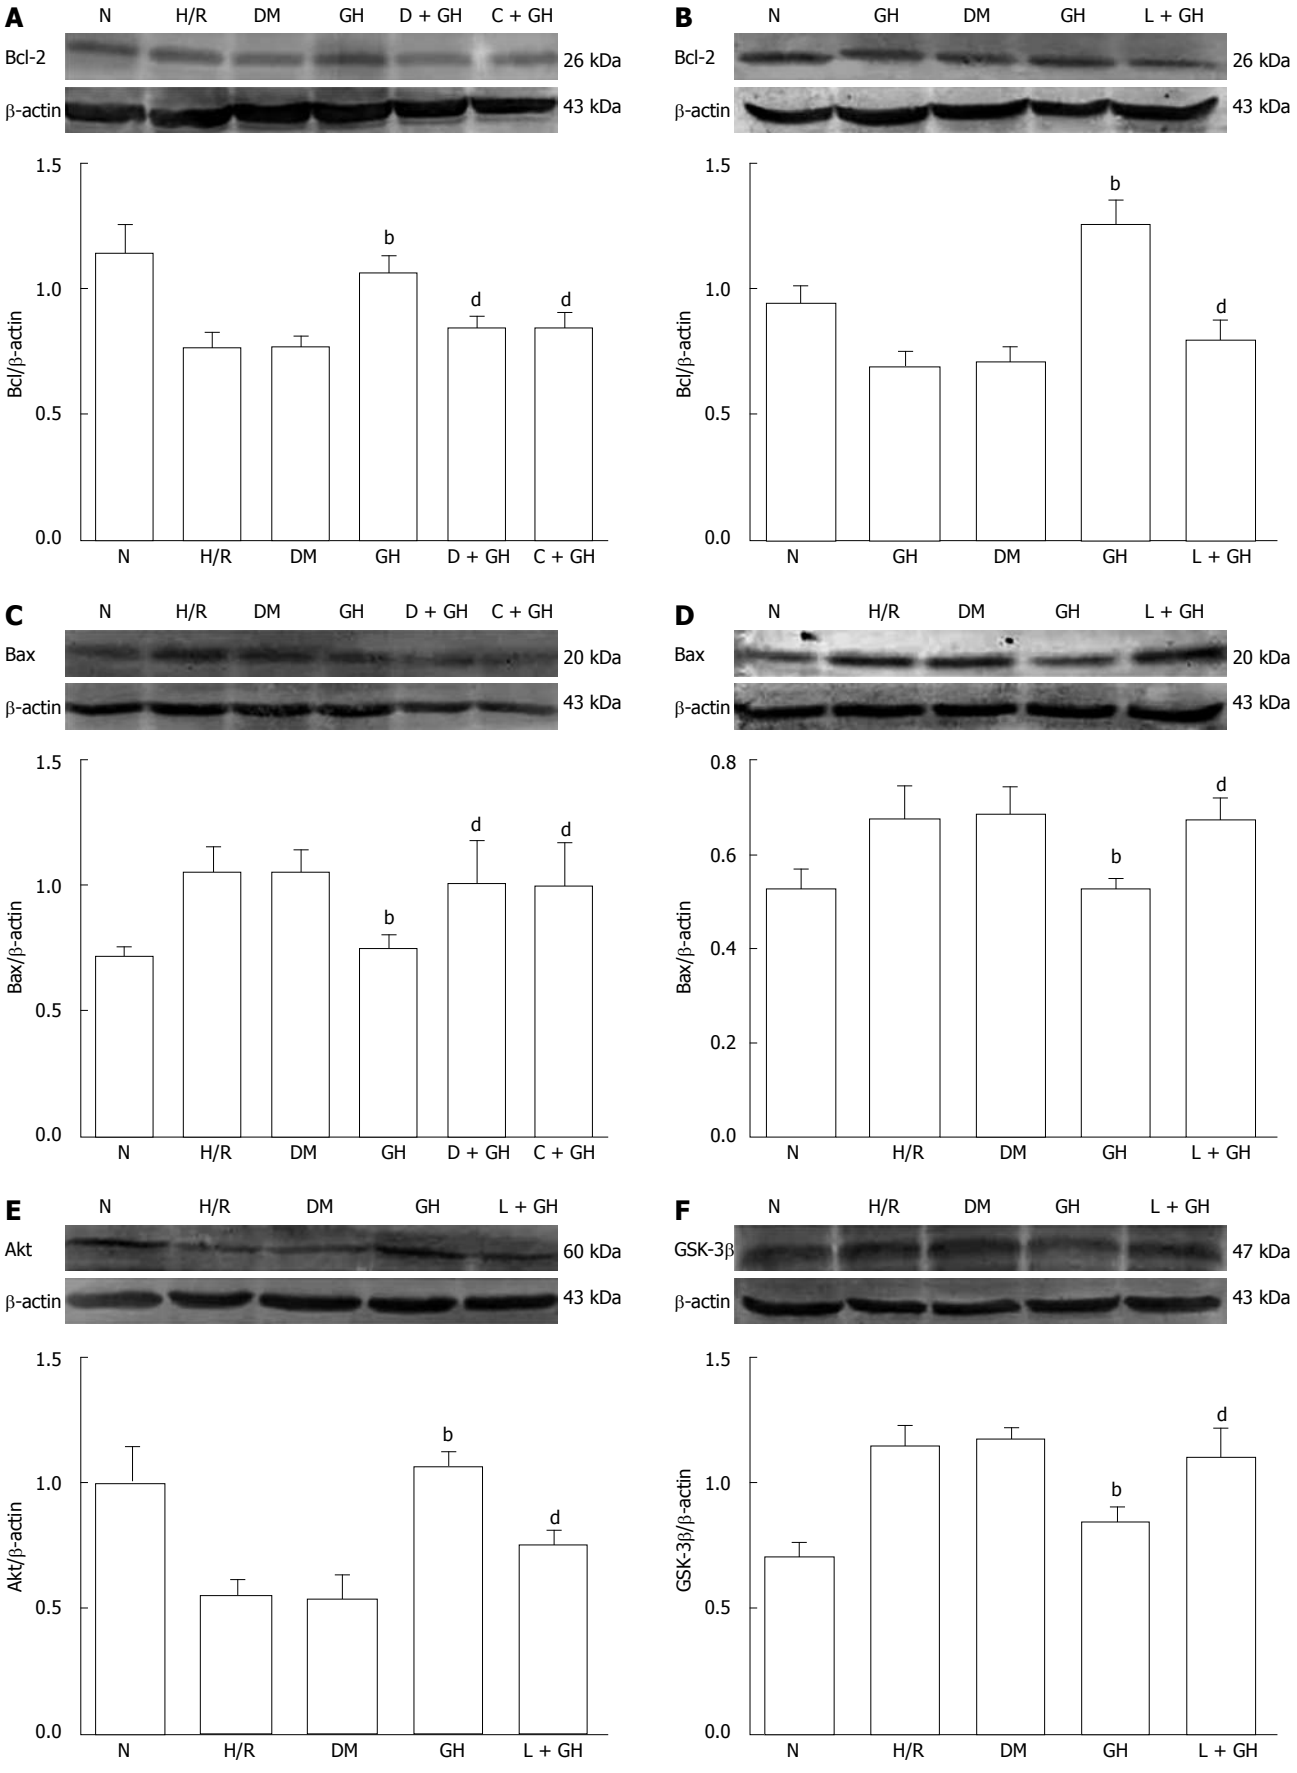

Figure 5 Effects of D-Lys3-GHRP-6, capsazepine and LY294002 in ghrelin postconditioning on the expression of Bcl-2, Bax, Akt and glycogen synthase kinase-3β in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (N), 2 h hypoxia/4 h reoxygenation (H/R), DMSO vehicle postconditioning (DM), ghrelin postconditioning (10^{-7} mol/L) (GH) D-Lys3-GHRP-6 + ghrelin postconditioning (D + GH), capsazepine + ghrelin postconditioning (C + GH) and LY294002 + ghrelin postconditioning (L + GH). Figure 6 Effects of capsazepine in ghrelin postconditioning on the expression of vanilloid receptor subtype 1 in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (A), 2 h hypoxia/4 h reoxygenation (B), DMSO vehicle postconditioning (C), ghrelin postconditioning (10^{-7} mol/L) (D), and capsazepine + ghrelin postconditioning (E). The expression of vanilloid receptor subtype 1 (VR1) in each group was observed by immunocytochemistry. Cells were observed for photography under a phase contrast microscope (× 400). The arrows indicate the positive cells which express VR1.

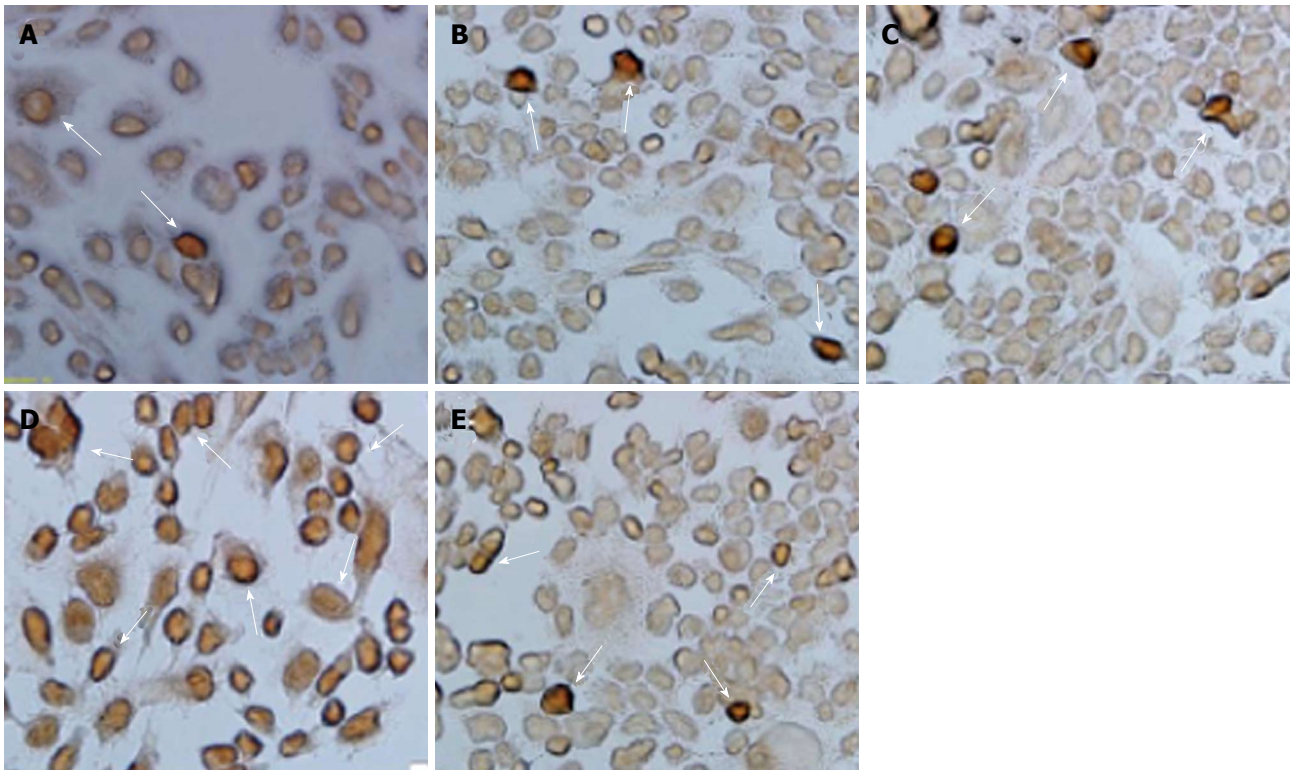

Figure 7 Effects of LY294002 in ghrelin postconditioning on the expression of Akt in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (A), 2 h hypoxia/4 h reoxygenation (B), DMSO vehicle postconditioning (C), ghrelin postconditioning (10^{-7} mol/L) (D), and LY294002 + ghrelin postconditioning (E). The expression of Akt in each group was observed by immunocytochemistry. Cells were observed for photography under a phase contrast microscope (× 400). The arrows indicate the positive cells which express Akt.

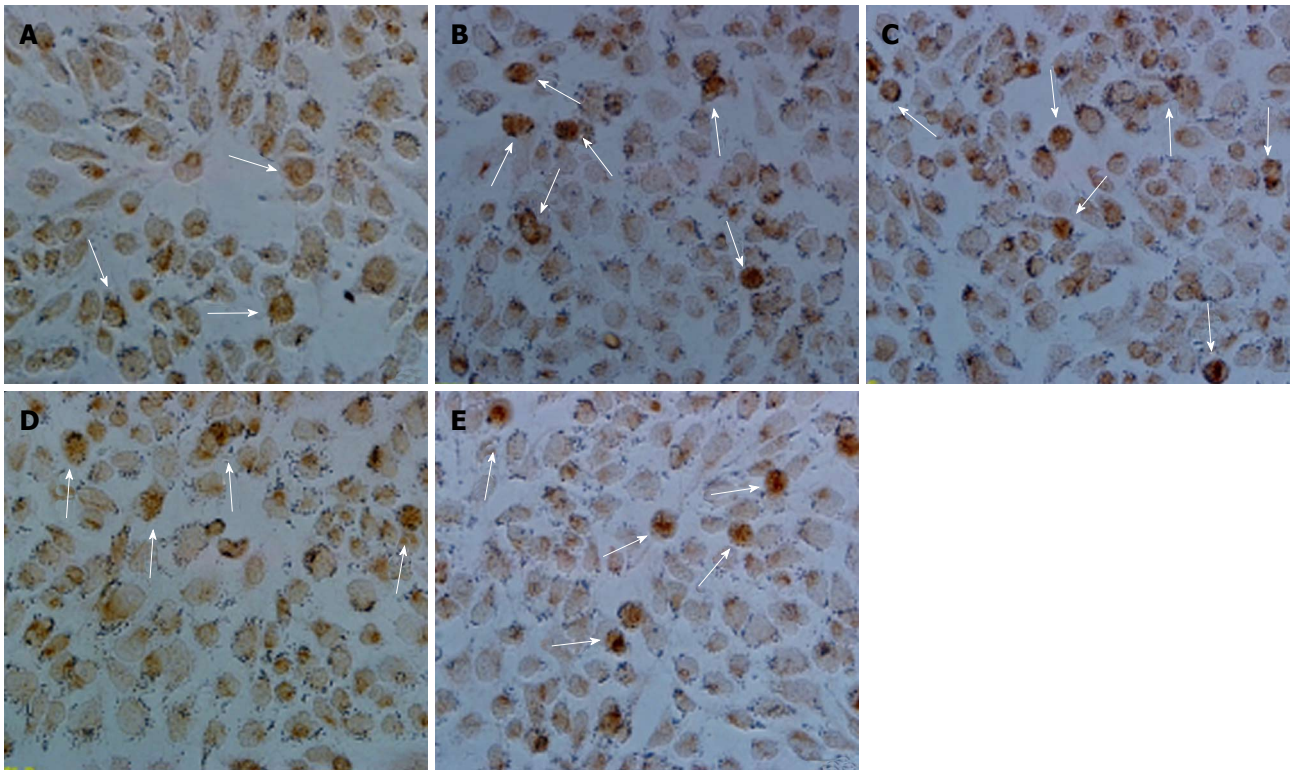

Figure 8 Effects of LY294002 in ghrelin postconditioning on the expression of glycogen synthase kinase-3β in human gastric epithelial cells induced by hypoxia/reoxygenation. Cells were grouped as follows: normoxic culture for 6 h (A), 2 h hypoxia/4 h reoxygenation (B), DMSO vehicle postconditioning (C), ghrelin postconditioning (10^{-7} mol/L) (D), and LY294002 + ghrelin postconditioning (E). Expression of glycogen synthase kinase (GSK)-3β in each group was observed by immunocytochemistry. Cells were observed for photography under a phase contrast microscope (× 400). The arrows indicate the positive cells which express GSK-3β.

has been a significant rise in the gastric mucosa cell apoptosis in gastric mucosa injury due to alcohol and nonsteroidal anti-inflammatory drugs, suggesting that there is a process of programmed cell death in acute gastric mucosal injury[27].

Apoptosis is the main mechanism of cell death, and is mediated by a cell-intrinsic suicide program, with the relative balance of pro- and antiapoptotic signaling pathways determining the fate of the cell. There are two main pathways in mammals, one of which is the mitochondrial signaling pathway, in which Bcl-2 plays an important role and Bcl-2/Bax is the key point of apoptosis[28]. In our study, the cell viability significantly decreased and apoptosis percentage increased in the model of 2 h hypoxia/4 h reoxygenation compared with normal control group. They also show that, in the same model, the expression of antiapoptotic protein (Bcl-2) decreased and the expression of proapoptotic protein (Bax) increased. These results suggest that we have successfully established a model of H/R-induced injury in a human GES-1. MTT assays, flow cytometric analysis, LDH assays and western blotting were used to test cell viability, apoptotic percentages, cell LDH release, and apoptosis-related protein expression.

Ghrelin is well known as a potent activator of growth hormone release[8,9]. Given the implication of growth hormone in the tissue regeneration and maintenance of integrity, ghrelin is supposed to contribute to the processes of healing and regeneration. A number of studies have confirmed the effect of ghrelin in gastroprotection. Brzozowski *et al*[17] have found that ghrelin inhibits stress-induced gastric injury[15]. Ghrelin can also inhibit I/R injury. Sibilia *et al*[16] have reported that ghrelin inhibits ethanol-induced gastric ulcers. Unfortunately, all of these were studies *in vivo*. In recent years, many studies have demonstrated that ghrelin confers protection in some cell types *in vitro*, but no study has clearly elucidated the effects of ghrelin in human gastric epithelial cells[29,30]. Therefore, in our study, we demonstrated that ghrelin post-conditioning has protective effects against H/R injury in human gastric epithelial cells, and confirmed that ghrelin could increase cell viability, and decrease apoptosis and LDH release. We also found that ghrelin post-conditioning increased VR1, Akt and Bcl-2 expression, and attenuated GSK-3β and Bax expression subsequent to H/R in gastric epithelial cells *in vitro*. The results showed that ghrelin seems to be involved in the regulation of gastroprotection, which also supports our hypothesis that ghrelin could effectively attenuate H/R-induced injury via the mitochondrial antiapoptotic pathway in human gastric epithelial cells.

In our study, we also demonstrated that the protective effects of ghrelin against H/R-induced injury might be mediated by GHS-R, VR1 and activation of the PI3K/Akt pathway, in that the protective effects of ghrelin were reversed by the GHS-R antagonist D-Lys3-GHRP-6, VR1 antagonist capsazepine and PI3K/Akt antagonist LY294002 during H/R. The result showed that ghrelin in combination with D-Lys3-GHRP-6, capsazepine and

LY294002 decreased cell viability, and increased the percentage of apoptotic cells and LDH release compared with ghrelin post-conditioning. The result also showed a decrease in Bcl-2 expression and increase in Bax expression. In the C + GH group, expression of VR1 was downregulated, and in the L + GH group, expression of Akt decreased, and GSK-3β expression increased. These data suggested that GHS-R, VR1 and the PI3K/Akt signaling pathway might be involved in ghrelin-induced antiapoptotic effects. However, the precise underlying mechanism of their activation by ghrelin remains to be determined.

Ishii *et al*[31] showed that treatment with GHS-R antagonist, D-Lys3-GHRP-6 could partially reverse diabetic hyperphagia. GHS-R mRNA is mainly expressed in the arcuate nucleus of the brain, ventral median nucleus and the hippocampus. It has been demonstrated that GHS-R mRNA is also expressed in peripheral organs[32]. The multifunction of ghrelin coincides with the distribution of GHS-R in various tissues[33]. GHS-R acts as the receptor for a family of synthetic ligands known as growth hormone secretagogues. Therefore, GHS-R is involved in the regulation of physiological actions when activated by its ligands, such as ghrelin. On the grounds of its distribution in the gastrointestinal tract, GHS-R plays an important role in the regulation of gastrointestinal functions[10]. Some studies have shown that GHS-R mediates ghrelin gastroprotection against I/R-induced injury, while this protective effect is inhibited by the GHS-R antagonist D-Lys3-GHRP-6[17].

Capsazepine is a specific and competitive antagonist of the VR. VR1 is a nervous-system-specific receptor. However, recent studies have indicated that VR1 is also distributed in some non-nervous tissues, such as the liver, gastric epithelial cells, bronchi, and bladder epithelium[34-37]. These findings suggest that VR1 might be related to the regulation of a variety of physiological functions of different tissues and organs. Many studies have demonstrated that activation of VR1 by its agonists exerts a gastroprotective effect[35,38-40].

PI3K antagonists, such as LY294002, at low concentrations are considered to be selective PI3K inhibitors and valuable tools for the study of cardioprotection[41]. Many studies have discovered that the activation of the PI3K/Akt signaling pathway is involved in the antiapoptotic effect of ghrelin in many cell types[42-44]. Some studies have shown that the PI3K/Akt pathway is a significant antiapoptotic factor that has an important protective role in reducing the apoptosis-associated protein kinase caspase family, Bcl-2 and other apoptotic factors[23]. The PI3K/Akt pathway has been implicated in the control of major cellular responses including cell proliferation, survival, development, differentiation, cell cycle, and apoptosis[21,22]. GSK-3β is a multifunctional Ser/Thr kinase that plays important roles in necrosis and apoptosis of cardiomyocytes. GSK-3β activity has been associated with many cell processes, including the regulation of multiple transcription factors, the Wnt pathway, nuclear factor κB, endoplasmic reticulum stress, embryogenesis, apoptosis and cell survival, cell cycle progression, and cell migration[45,46]. GSK-3β, serving as an Akt downstream effector, plays an important role during I/R-induced apoptosis of cells in the heart and brain[47,48].

In summary, our study demonstrated that ghrelin postconditioning had a protective effect against H/R-induced injury in human gastric epithelial cells *in vitro*, and the effect might be mediated by the receptors GHS-R and VR1 as well as activation of the PI3K/Akt signaling pathway, resulting in activation of the intracellular antiapoptotic signaling pathway, hence the inhibition of apoptosis.

COMMENTS

Background

Gastric ischemia-reperfusion injury is a common clinical pathophysiological process, and the mobilization of the endogenous protection is the most effective manner against ischemia-reperfusion (I/R) injury. In recent years, ischemic postconditioning has been regarded as important endogenous protection.

Research frontiers

Ghrelin is a 28-amino-acid peptide that was initially identified in rat stomach. Several studies have shown the effect of ghrelin in gastroprotection. In recent years, many studies have demonstrated that ghrelin confers protection in some cell types *in vitro*. Unfortunately, no study has clearly shown the effect of ghrelin in human gastric epithelial cells. In this study, the authors demonstrated that ghrelin post-conditioning has protective effect against hypoxia/reoxygenation (H/R)-induced injury in human gastric epithelial cells.

Innovations and breakthroughs

The injury of visceral I/R is a common pathological occurrence. Nowadays, ischemic preconditioning and ischemic postconditioning have been confirmed to be important approaches in endogenous protection. The notion of ischemic postconditioning was first proposed in 2003. Pharmacological postconditioning is the extension of ischemic postconditioning in which a drug is applied to the ischemic myocardium or hypoxic cardiomyocytes during the initial few minutes of reperfusion or reoxygenation, significantly reducing organ reperfusion injury. This study suggests that the authors have successfully established a model of H/R-induced injury in the human gastric epithelial cell line gastric epithelial cell line (GES-1), and have demonstrated that ghrelin postconditioning has protection against H/R-induced injury in human gastric epithelial cells *in vitro*.

Applications

The results of the study suggest that the ghrelin postconditioning is a potential therapeutic approach that could be applied to the prevention of gastric mucosal lesions induced by ethanol, stress and I/R.

Terminology

Ghrelin, a 28-amino-acid peptide initially identified in rat stomach, is noted for its potent activation of growth hormone release. Pharmacological postconditioning is the extension of ischemic postconditioning in which a drug is applied to the ischemic myocardium or hypoxic cardiomyocytes during the initial few minutes of reperfusion or reoxygenation, significantly reducing organ reperfusion injury.

Peer review

The present study was well-organized and well-investigated. The authors demonstrated the antiapoptotic effects of ghrelin against H/R-induced apoptosis of human gastric epithelial cells.

Abstract

AIM: To characterize the profiles of alveolar hypoventilation during colonoscopies performed under sedoanalgesia with a combination of alfentanil and either midazolam or propofol.

METHODS: Consecutive patients undergoing routine colonoscopy were randomly assigned to sedation with either propofol or midazolam in an open-labeled design using a titration scheme. All patients received 4 μg/kg per body weight alfentanil for analgesia and 3 L of supplemental oxygen. Oxygen saturation (SpO_2) was measured by pulse oximetry (POX), and capnography ($PcCO_2$) was continuously measured using a combined dedicated sensor at the ear lobe. Instances of apnea resulting in measures such as stimulation of the patient, a chin lift, a mask maneuver, or withholding of sedation were recorded. $PcCO_2$ values (as a parameter of sedation-induced hypoventilation) were compared between groups at the following distinct time points: baseline, maximal rise, termination of the procedure and 5 min after termination of the procedure. The number of patients in both study groups who regained baseline $PcCO_2$ values (± 1.5 mmHg) five minutes after the procedure was determined.

RESULTS: A total of 97 patients entered this study. The data from 14 patients were subsequently excluded for clinical procedure-related reasons or for technical problems. Therefore, 83 patients (mean age 62 ± 13 years) were successfully randomized to receive propofol (n = 42) or midazolam (n = 41) for sedation. Most of the patients were classified as American Society of Anesthesiologists (ASA) Ⅱ [16 (38%) in the midazolam group and 15 (32%) in the propofol group] and ASA Ⅲ [14 (33%) and 13 (32%) in the midazolam and propofol groups, respectively]. A mean dose of 5 (4-7) mg of Ⅳ midazolam and 131 (70-260) mg of Ⅳ propofol was used during the procedure in the corresponding study arms. The mean SpO_2 at baseline (%) was 99 ± 1 for the midazolam group and 99 ± 1 for the propofol group. No cases of hypoxemia (SpO_2 < 85%) or apnea were recorded. However, an increase in $PcCO_2$ that indicated alveolar hypoventilation occurred in both groups after administration of the first drug and was not detected with pulse oximetry alone. The mean interval between the initiation of sedation and the time when the $PcCO_2$ value increased to more than 2 mmHg was 2.8 ± 1.3 min for midazolam and 2.8 ± 1.1 min for propofol. The mean maximal rise was similar for both drugs: 8.6 ± 3.7 mmHg for midazolam and 7.4 ± 3.2 mmHg for propofol. Five minutes after the end of the procedure, the mean difference from the baseline values was significantly lower for the propofol treatment compared with midazolam (0.9 ± 3.0 mmHg *vs* 4.3 ± 3.7 mmHg, P = 0.0000169), and significantly more patients in the propofol group had regained their baseline value ± 1.5 mmHg (32 of 41 *vs* 12 of 42, P = 0.0004).

CONCLUSION: A significantly higher number of patients sedated with propofol had normalized $PcCO_2$ values five minutes after sedation when compared with patients sedated with midazolam.

INTRODUCTION

Colonoscopies are usually performed under sedation with an intravenous sedative that is often combined with an analgesic drug[1,2]. A combination of the benzodiazepine midazolam with an opioid is the most commonly used regimen in Western countries[3]. During the last few years, propofol (2,6-diisopropylphenol) sedation has gained increasing attention among endoscopists as an alternative sedative in GI endoscopy[4-6]. With a fast onset of action of 30-60 s, a distribution half-life of 2-4 min, and a rapid recovery time, propofol combines the major characteristics of an ideal sedative[7].

In recent years, several randomized trials have compared midazolam *vs* propofol with regard to patient safety and satisfaction[4,8-10]. In most studies, recovery time, measured as completely regained alertness after the endoscopic procedure, was used as the main endpoint. Although the advantages of propofol regarding these pharmacokinetic properties are unquestionable, there is still an ongoing debate on the potential respiratory impairment hazards of propofol when used by non-anesthesiologists. In contrast to benzodiazepines, a reversal agent for propofol does not exist; consequently, the use of propofol requires special attention. Furthermore, a deeper level of sedation may be reached with propofol that carries the risk of unintentional deep sedation or even general anesthesia[11,12].

Standard monitoring with pulse oximetry (POX) may miss hypoventilation, which is much better reflected by an increase in arterial carbon dioxide tension[13,14]. Arterial blood gas analysis is the 'gold standard' method to measure the arterial partial pressure of carbon dioxide ($PaCO_2$). However, arterial sampling, including arterial catheterization, is invasive and expensive. Transcutaneous carbon dioxide tension ($PcCO_2$) measurement is used as a noninvasive surrogate measure of $PaCO_2$ and to estimate $PaCO_2$ or determine trend changes in the measurement. Recently, considerable progress has been made in the technical aspects of $PcCO_2$ monitoring. A single earlobe sensor can now measure $PcCO_2$ and pulse oximetry simultaneously. Transcutaneous carbon dioxide tension measurement has been shown to be a reliable monitoring technique that corresponds well with $PaCO_2$ values measured in arterial blood gas samples[15-17].

The aim of this study was to evaluate the profile of $PcCO_2$ as a marker of hypoventilation during sedation with propofol or midazolam in colonoscopies.

MATERIALS AND METHODS

This was an open-labeled, blinded, randomized prospective study. Consecutive outpatients undergoing elective colonoscopy and opting for sedation were randomly assigned to receive propofol or midazolam. The patients were assigned using randomly numbered opaque envelopes. As a standard procedure, all patients received 3 L/min supplemental oxygen and analgesia with 4 μg/kg per body weight (BW) alfentanil (Rapifen®, Janssen-Cilag, Baar, Switzerland) prior to sedation[18]. The first bolus of the sedative drug was administered exactly one minute after the alfentanil. Midazolam (Dormicum®, Hoffmann La Roche AG, Basel, Switzerland) was administered in a first dose of 2 mg; further boluses of 1 mg were administered with an interval of at least 1 min or more depending on the clinical outcome. Propofol (Disoprivan®, AstraZeneca, Zug, Switzerland) was administered in two boluses of 20 mg followed by further boluses of 10 mg after an interval of at least 20 s. The sedative drugs were administered by registered nurses under the supervision of the endoscopist based on the clinical response of the patient; the nurses followed our institutional protocol as published elsewhere (nurse-administered propofol sedation or NAPS)[18]. The nurse administering the sedation had no tasks except to monitor the patient and administer sedation. A different nurse assisted the endoscopist with the technical performance of the procedure. Monitoring consisted of the measurement of continuous oxygen saturation, electrocardiography and heart rate, as well as regular measurements of blood pressure. The primary method of monitoring was the nurse's clinical assessment of the patient, including measurement of respiratory effort by visual assessment and by palpation of the chest wall and abdominal excursion and/or palpation of exhaled breath.

A short personal history was obtained from all the patients, and their general physical condition was assessed using the American Society of Anesthesiologists (ASA) classification. Exclusion criteria were as follows: (1) a known history of intolerance to propofol (including sensitivity to eggs and soybeans); (2) an age less than 18 or more than 85 years; (3) an ASA score of Ⅳ or Ⅴ; (4) a known high grade of aortic (gradient > 80 mmHg) or carotid stenosis (> 75%); and (5) intravenous drug abuse.

All endoscopic examinations were performed according to the department's standard operating procedures with different types of Pentax video colonoscopies (Pentax, Hamburg, Germany) using regular room air to insufflate the colon. The colonoscopies were conducted by seven different expert endoscopists, including four experienced gastroenterologists and three residents in their last year of gastroenterology training, who all had performed more than 400 colonoscopies each. The pro-

cedures were performed in an x-ray suite equipped for fluoroscopy (straightening maneuvers and confirming instrument position when necessary). The decision to perform an ileal intubation or an endoscopic intervention (e.g., polypectomy) depended on the clinical situation and was decided by the endoscopist.

The local ethics committee approved the study protocol, and written informed consent was obtained from the patients before study enrollment.

We used a recently developed combined POX/$PcCO_2$ sensor (V-Sign™, Sentec AG, Therwil, Switzerland) weighing 3 g that was placed at the right earlobe with a dedicated ear clip. We used a recently developed combined POX/$PcCO_2$ sensor (V-Sign™, Sentec AG, Therwil, Switzerland) weighing 3 g that was placed at the right earlobe with a dedicated ear clip[17]. This fully digital sensor combines the elements of an electrochemical Severinghaus-type carbon dioxide tension sensor with those of conventional optical POX sensors, thus providing noninvasive and continuous estimation of $PaCO_2$ and SaO_2[19]. The sensor was warmed to a constant surface temperature of 42 ℃ to improve local arterialization and to accelerate carbon dioxide diffusion. After the sensor was positioned, the SpO_2 values were available immediately, whereas the $PcCO_2$ values required an equilibration time of approximately 4-5 min. The system is designed to be "ready-for-use" by automated recalibration every time the sensor is placed on the docking station between measurements. The system was previously shown to deliver accurate and reproducible results for $PcCO_2$ and POX[17]. The system was also shown to have an excellent correlation between oxygen saturation and carbon dioxide measurements when the combined sensor was compared with arterial blood gas analysis[17,20].

Readings from the POX/$PcCO_2$ sensor (placed at the right ear lobe) were continuously recorded and stored on a personal computer. An independent observer who was blinded to the type of sedation recorded the readings. Similarly, the procedural personnel were blinded to the $PcCO_2$ data. All collected data were visualized using statistic graphics software (Igor Pro 4.01, WaveMetrics Inc., Lake Oswego, OR). Values at defined time points were thereafter identified manually. $PcCO_2$ values (as a parameter of sedation-induced hypoventilation) were compared between the study groups at the following distinct time points: at baseline, at the time point of maximal increase, at the time point when the cecum was reached, at the end of the procedure and 5 min after the end of the procedure.

The primary endpoint was defined as the number of patients in both study groups who regained their baseline $PcCO_2$ value (± 1.5 mmHg) five minutes after the end of the procedure. Secondary end points included the mean time lag between the application of the sedative drug and an increase of the $PcCO_2$ curve of more than 2 mm Hg, safety parameters defined as apnea with the need for intervention (in case of a decrease in SaO_2 values below 85% for more than 20 s), the frequency of SaO_2 decreases below 90% and a decrease of the heart rate below 50 bpm. Apnea was defined as a lack of spontaneous respiratory effort for more than 20 s and was assessed clinically by the nurse administrating the sedation. An increase of $PcCO_2$ above the baseline was defined as hypoventilation. The target sedation level was a quiet patient in both of the groups as implemented using our NAPS protocol, which has been in practice at this center for several years. The recovery time for all of the patients was defined as the time required for completion of the procedure, i.e., a complete withdrawal of the instrument and simultaneous conclusion of all sedation. As a standard of practice, the patients were transferred to a quiet recovery room following the final 5-min recording of the$PcCO_2$ readings in the endoscopy suite.

All of the parameters were analyzed using descriptive statistics (mean, standard deviation). Categorical outcomes were analyzed using the χ^2 or F test as appropriate. Continuous parameters were analyzed using an analysis of variance, and for non-continuous parameters, the Mann-Whitney Test was used. $P < 0.05$ was defined as statistically significant. All tests were two-sided. For all statistical calculations, SPSS software (SPSS for Windows, Version 11.0, SPSS Inc., Chiago, Illinois) was used. The sample size calculation was based on the primary outcome of this study of detecting a $PcCO_2$ difference of < 1.5 mmHg from the baseline at 5 min after the end of the procedure in the propofol group. In a pilot study in a similar population, a difference in values between midazolam and propofol was observed in 4 of 26 patients (15.4%). As we expected a clinical/physiological relevant effect, the sample size was determined to detect an ad-

ditional increase of 75% in the midazolam group with a power of 80%. Thirty-eight patients in each group would be required to detect such a difference ($P = 0.05$) (nQuery Advisor, Version 5.0, Statistical Solutions, Saugus, MA, United States).

RESULTS

Among the 133 colonoscopies performed during the study period, 97 patients were successfully randomized to the study. Fourteen randomized patients had to be subsequently excluded for the following reasons: in 5 patients, the procedure was not completed because of incomplete bowel preparation; in 5 patients, a short disconnection of the sensor provided no continuous data; in two patients, a calibration fault occurred because of the prototype calibration unit used, and the endoscopist refrained from recalibration; and in two patients, the sedative drug was not correctly administered according to the protocol. Therefore, the final study population contained 83 patients. Demographic characteristics of the study groups are shown in Table 1. The mean duration of the procedures was 26 ± 13 min for the midazolam group and 27 ± 18 min for the propofol group (not significant).

Decreased ventilation activity was detected in all patients to whom a sedative was administered; on average, the $PcCO_2$ values increased by 8.0 ± 3.7 mmHg. The mean SpO_2 values at baseline and the mean maximal decrease during sedation are shown in Table 2.

When comparing midazolam and propofol, different profiles were observed for the $PcCO_2$ readings, as shown in Figure 1. The increase in $PcCO_2$ was mostly related to a short delay in the administration of incremental dosages of the sedatives. The mean time interval after the first application of the drug until the $PcCO_2$ value had increased by more than 2 mmHg was 2.8 ± 1.3 min for midazolam and 2.8 ± 1.1 min for propofol. Although there was no significant difference in the mean increase in $PcCO_2$ following administration of midazolam or propofol, the patients who received midazolam tended to remain in a prolonged state of decreased ventilation when compared with the patients receiving propofol. The difference in $PcCO_2$ values (baseline compared with the end of the procedure) was significantly higher in the patients receiving midazolam. Therefore, the patients who received propofol had a $PcCO_2$ level that was significantly closer to the baseline five minutes after the end of the procedure when compared with the patients who received midazolam (Tables 2, 3, Figure 2).

None of the study patients manifested apnea or hypoxemia below 85%. Drops in oxygen saturation below 90% tended to occur more often during sedation with midazolam than with propofol (Table 3).

DISCUSSION

Achieving higher safety standards for sedation in routine endoscopy has been a priority over the last few years. In keeping with this objective, the present study showed that patients undergoing colonoscopy under sedation developed relative hypoventilation (as reflected by retention of CO_2) that persisted for a significantly longer period in patients sedated with midazolam than in patients sedated with propofol. The results support the findings of a meta-analysis that suggested that propofol sedation during colonoscopy is associated with a lower risk of complications when compared with traditional sedative agents[21].

Although the use of oxygen saturation monitoring during sedation is routinely used by most gastroenterologists and the administration of supplemental oxygen has become a widely accepted practice, little attention has been paid to the development of alveolar hypoventilation[17]. Because of the buildup of CO_2 in the patient's alveoli and blood, hypoventilation can be effectively detected by capnography, which has recently become a focus of interest as an additional monitoring parameter during gastrointestinal procedures. This procedure has become

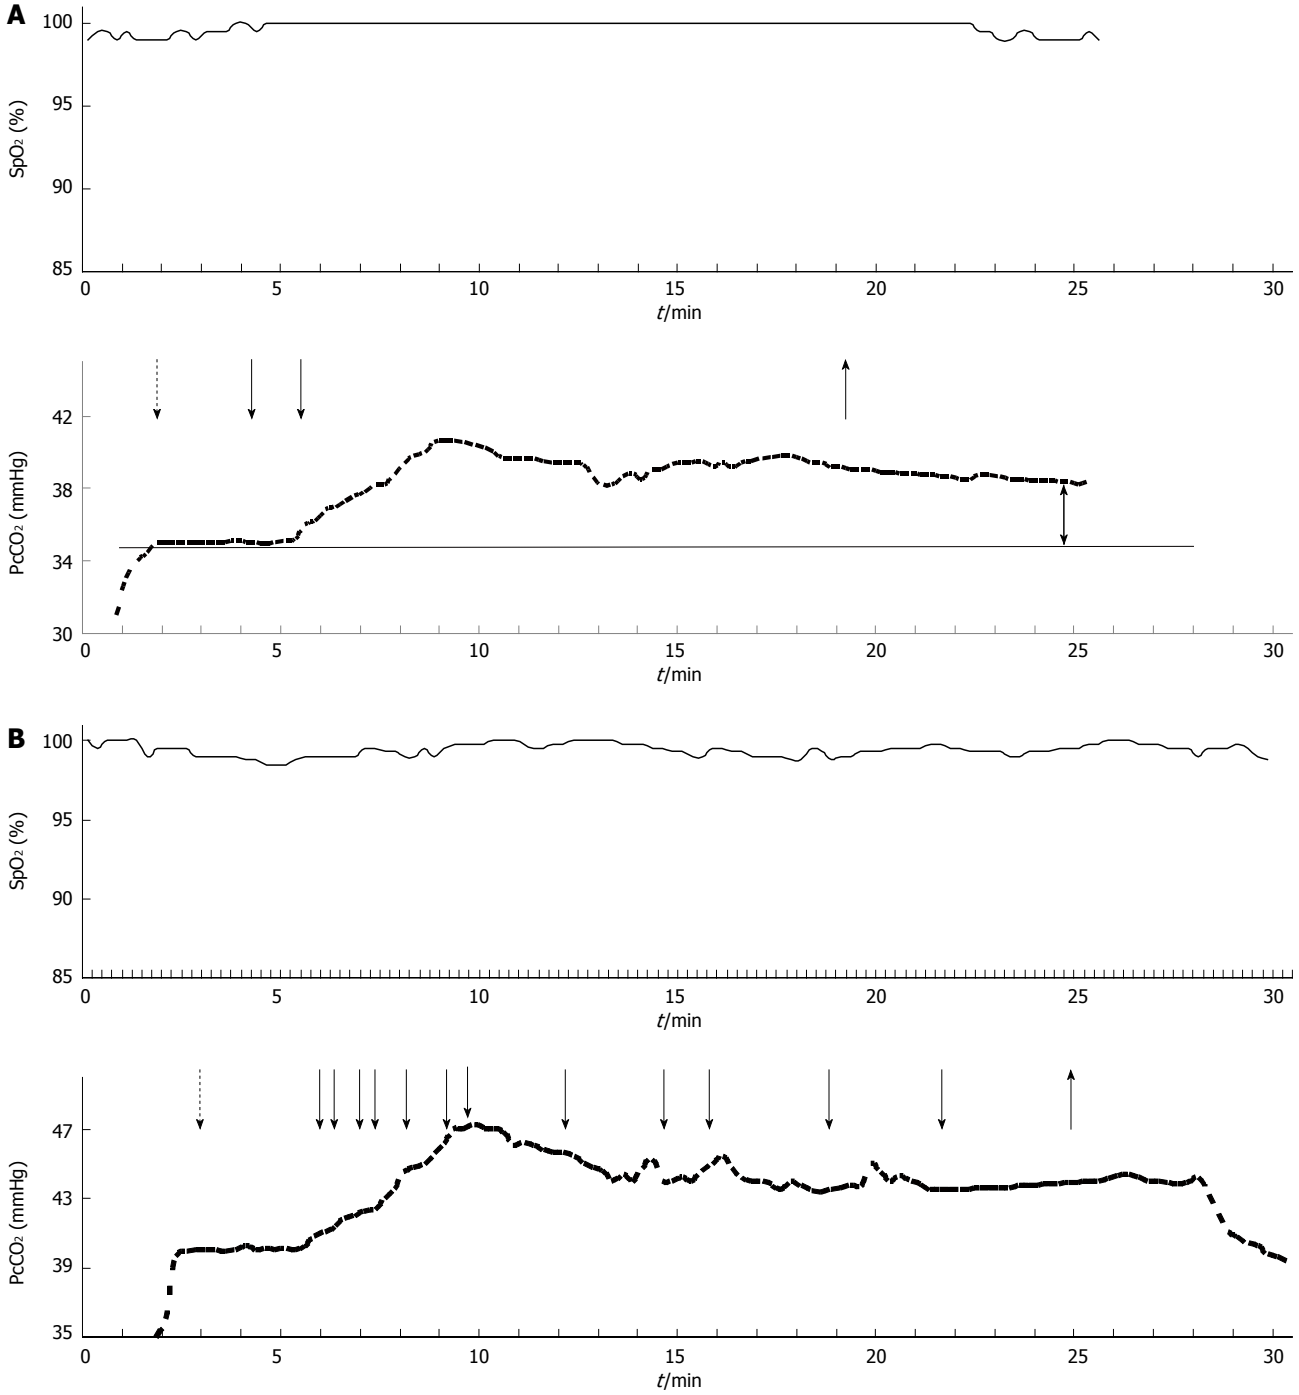

Figure 1 A typical course of oxygen saturation measured by pulse oximetry and transcutaneous carbon dioxide tension following administration of alfentanil (dashed arrow) and midazolam (A) or propofol (B) (solid arrows as indicated). The upright arrow indicates the end of the procedure. The double arrow highlights the difference after termination of the procedure.

relevant as the use of newer anesthetic drugs such as propofol has increased[15].

Several studies to date have evaluated the importance of CO_2 buildup during endoscopic procedures[14-16,22]. Freeman *et al*[15] were the first to show that profound hypoventilation may frequently occur undetected during a gastrointestinal endoscopy, especially if additional oxygen is given and the decline of oxygen saturation is thus prevented; we observed a similar effect in our study. Freeman *et al*[15] also found that the degree of hypoventilation was more closely related to the sedative drug dose than to the underlying medical illness. In 30 colonoscopies, with 90% receiving fentanyl and 37% additionally receiving midazolam, Freeman *et al*[15] recorded a mean PCO_2 increase of 6.4 ± 3.8 mmHg, whereas during ERCP with a higher rate of deeper sedation, the mean values were 14.2 ± 10.2 mmHg. Our results showed a mean increase in $PcCO_2$ of 8.6 ± 3.7 mmHg despite a continuous SpO_2 above 90%; these results are similar to the experience of Freeman *et al*[15].

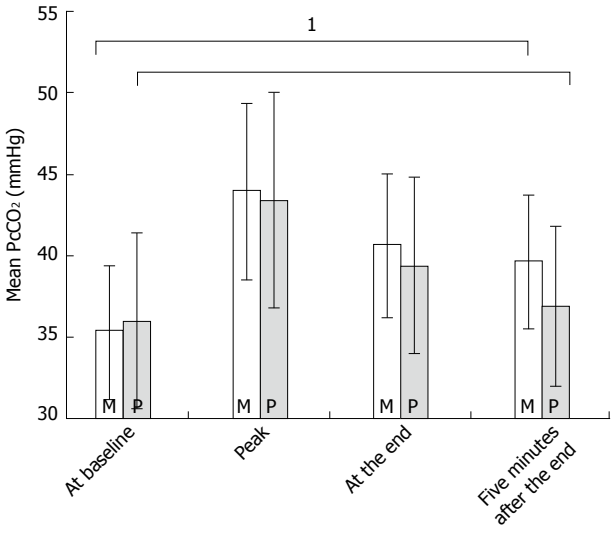

Figure 2 Mean transcutaneous carbon dioxide tension values in mmHg (± SD) at four distinct time points during colonoscopies according to sedative use (for the whole group). [1]A significant difference in the transcutaneous carbon dioxide tension values measured five minutes after the end of the procedure when compared with the baseline values. M: Midazolam; P: Propofol.

The pattern of the registered $PcCO_2$ readings differed noticeably in our study according to the pharmacological properties of the administered drugs. The pattern of the initial rise of $PcCO_2$ was similar, but the $PcCO_2$ level decreased much earlier after the administration of propofol than after the administration of midazolam. Although propofol had to be administered more often in a repeated fashion to maintain the desired sedation level, its effect ceased much faster than the effect of midazolam. This pharmacologic pattern seems to be reflected by the shape of the $PcCO_2$ curve.

We did not observe severe hypoxemia or apnea in either of the study groups; the increase in CO_2 could, however, indicate silent risk during poor sedative practice. In the study by Freeman *et al*[15]. We did not observe severe hypoxemia or apnea in either of the study groups; the increase in CO_2 could, however, indicate silent risk during poor sedative practice. In the study by Freeman *et al*[15], one case demonstrated an increase of the $PcCO_2$ curve above 80 mmHg prior to respiratory arrest. Nelson *et al*[16] showed that the monitoring of $PcCO_2$ may be useful for the endoscopist to guide sedation using midazolam and fentanyl and that this monitoring can help to prevent severe carbon dioxide retention. Thus, we believe that determining the $PcCO_2$ level can be helpful for the endoscopist when deciding whether to administer a further incremental dose of the sedative.

The combination used in this study of alfentanil, which is a potent opioid with a rapid onset of action, and midazolam is uncommon. Typically, this substance alfentanil is administered in combination with propofol for patient-controlled sedation or for short sedoanalgesia in emergency medicine[23]. The rationale to use this substance alfentanil as a single bolus at the beginning of the procedure was (1) to provide the patients with optimal analgesia during the most painful passage of the sigmoid colon; and (2) to determine whether differences in alveolar hypoventilation at the end of the procedure can be completely attributed to the pharmacologic effect of the sedatives. Furthermore, if propofol is used in outpatient procedures, alfentanil may be an ideal drug to use in combination because of its pharmacokinetic properties and analogous profile of action. Because alfentanil (similarly to all opioids) can induce or enhance alveolar hypoventilation, our protocol prescribed a single low dose of 4 μg/kg per BW of alfentanil and a strict time interval of administration one minute before the first titration dose of the sedative was given.

Alveolar hypoventilation exists when the arterial $PaCO_2$ increases above 45 mmHg, which can occur as the result of various underlying factors. Sedation directly or indirectly influences alveolar hypoventilation by a predominant central effect, thereby causing an increase in the $PaCO_2$. Therefore, recognition and adequate monitoring of this physiological change through indirect means such as transcutaneous monitoring of $PcCO_2$ could play an important role during sedation. The peak $PcCO_2$ value may not be clinically relevant; however, the time period during which reduced ventilation occurs may represent a period of increased risk for some patients. Because of the S-shape of the oxygen dissociation-curve, hypoventilation accompanied by a decrease in PaO_2 may remain unnoticed over time. Although a patient would have adequate arterial saturation with the administration of supplemental oxygen, an adverse physiologic trend that may be reflected by changes in the $PaCO_2$ may go unnoticed.

Transcutaneous CO_2 monitoring in adults has yielded conflicting results because of technological limitations, such as the time required for calibration, the need to warm the skin to 42 degrees, the effect of sweating and the influence of skin metabolism and thickness. Technical problems precluded an accurate interpretation of the data in 7 of the 97 patients and thus represent a limitation in our study.

warm the skin to 42 degrees, the effect of sweating and the influence of skin metabolism and thickness. Technical problems precluded an accurate interpretation of the data in 7 of the 97 patients and thus represent a limitation in our study.

The main focus of this study was to evaluate the impairment of ventilation induced by midazolam or propofol during colonoscopies. Most trials comparing the use of propofol and midazolam in the endoscopy suite have focused on differences in recovery time (assessed using a discharge scoring system, for example)[24]. The present study suggests that there is also a significant difference in the duration of hypoventilation during the post-procedural period. Although alveolar hypoventilation is generally well tolerated by most patients, it may nevertheless be of clinical relevance in patients with compromised health. Iber *et al*[25] showed that in 4% of patients sedated with midazolam, a relevant decrease of oxygen saturation below 89% occurred during the 30 min after the endoscopic procedure, which is contrast to our practical experience with propofol, where the effect occurs exclusively during the time when the attention on the patient is greatest. During the endoscopic procedure, the $PcCO_2$ monitoring indicated no increased hypoventilation risk for propofol when compared with midazolam.

Insufflation of the colon with carbon dioxide (CO_2) rather than air has been shown to reduce pain and discomfort because CO_2 is rapidly absorbed by the intestinal lining. In previous studies, measurement of end tidal CO_2 ($ETCO_2$) and the mean pCO_2 demonstrated these procedures to be safe. However, no studies have used transcutaneous continuous pCO_2 monitoring, which could be valuable given the increasing use of this insufflation technique for pain relief during colonoscopies[26].

A metanalysis by Qadeer *et al*[21] showed that propofol sedation had a lower rate of cardiopulmonary complications than traditional agents used during colonoscopy procedures. This current study highlights another physiological mechanism that may be detrimental when propofol is used in larger cohorts. Therefore, assessing the $PcCO_2$ during sedation could serve as an added safety measure to detect alveolar hypoventilation.

In conclusion, hypoventilation occurs frequently during sedation for colonoscopy and is often undetected during routine pulse oximetry. A significantly higher number of patients sedated with propofol had normalized $PcCO_2$ values five minutes after sedation when compared with patients sedated with midazolam. Understanding the role of CO_2 retention will be important in increasing the further safety standards of sedation during endoscopy. More studies are required to identify and prevent hypercapnia and thus ensure the safe practice of sedation during routine gastrointestinal endoscopies.

COMMENTS

Background

Colonoscopies are usually performed under sedation and monitored by pulse oximetry. With the increasing use of newer sedative agents such as propofol, there is an ongoing discussion about safety and monitoring requirements.

Research frontiers

The surveillance of carbon dioxide tension (e.g., measuring end tidal CO_2 by capnography) could provide more accurate information than pulse oximetry regarding ventilation impairment. Until now, little experience has been reported for transdermal CO_2 measurement systems used for this purpose.

Innovations and breakthroughs

Monitoring studies with capnography showed that hypoventilation and even short apneas that are not detected by pulse oximetry (POX) may occur during endoscopic sedation. However, an increasing body of scientific data shows that sedation during endoscopy with benzodiazepines and propofol is a safe procedure. The development of a new sensor combining transcutaneous carbon dioxide and pulse oximetry measurements provides the opportunity to explore a new monitoring method during endoscopic sedation.

Applications

The study results suggest that hypoventilation occurs often during endoscopic sedation but lasts for a shorter period if patients are sedated with propofol rather than midazolam.

Terminology

$PcCO_2$: Transcutaneous carbon dioxide tension is measured electrochemically using a Severinghaus-type sensor placed on the earlobe; POX: Pulse oximetry measures the oxygen saturation of the blood using an optical sensor.

Peer review

In this study, the authors investigated carbon dioxide accumulation after sedation with propofol or midazolam during colonoscopies. Non-invasive, continuous transcutaneous carbon dioxide tension ($PcCO_2$) monitoring was performed using a recently developed $POX/PcCO_2$ sensor that was placed at the earlobe. The results of the study show that a significantly higher number of patients sedated with propofol had normalized $PcCO_2$ values five minutes after sedation when compared with the patient group sedated with midazolam. The study is well designed and performed, and the $POX/PcCO_2$ sensor could be used in future studies rather than capnography.

Abstract

AIM: To improve the interpretation of fecal immunochemical test (FIT) results in colorectal cancer (CRC) cases from screening and referral cohorts.

METHODS: In this comparative observational study, two prospective cohorts of CRC cases were compared. The first cohort was obtained from 10 322 average risk subjects invited for CRC screening with FIT, of which, only subjects with a positive FIT were referred for colonoscopy. The second cohort was obtained from 3637 subjects scheduled for elective colonoscopy with a positive FIT result. The same FIT and positivity threshold (OC sensor; ⩾ 50 ng/mL) was used in both cohorts. Colonoscopy was performed in all referral subjects and in FIT positive screening subjects. All CRC cases were selected from both cohorts. Outcome measurements were mean FIT results and FIT scores per tissue tumor stage (T stage).

RESULTS: One hundred and eighteen patients with CRC were included in the present study: 28 cases obtained from the screening cohort (64% male; mean age 65 years, SD 6.5) and 90 cases obtained from the referral cohort (58% male; mean age 69 years, SD 9.8). The mean FIT results found were higher in the referral cohort (829 ± 302 ng/mL *vs* 613 ± 368 ng/mL, P = 0.02). Tissue tumor stage (T stage) distribution was dif-

ferent between both populations [screening population: 13 (46%) T1, eight (29%) T2, six (21%) T3, one (4%) T4 carcinoma; referral population: 12 (13%) T1, 22 (24%) T2, 52 (58%) T3, four (4%) T4 carcinoma], and higher T stage was significantly associated with higher FIT results ($P < 0.001$). Per tumor stage, no significant difference in mean FIT results was observed (screening *vs* referral: T1 498 ± 382 ng/mL *vs* 725 ± 374 ng/mL, $P = 0.22$; T2 787 ± 303 ng/mL *vs* 794 ± 341 ng/mL, $P = 0.79$; T3 563 ± 368 ng/mL *vs* 870 ± 258 ng/mL, $P = 0.13$; T4 not available). After correction for T stage in logistic regression analysis, no significant differences in mean FIT results were observed between both types of cohorts ($P = 0.10$).

CONCLUSION: Differences in T stage distribution largely explain differences in FIT results between screening and referral cohorts. Therefore, FIT results should be reported according to T stage.

INTRODUCTION

Colorectal cancer (CRC) is a disease well suited for population-based screening. In industrialized countries, CRC is one of the three malignancies with the highest incidence and mortality[1,2]. CRC and adenomas can cause lower gastrointestinal bleeding, and early detection by guaiac-based fecal occult blood tests (g-FOBTs) can decrease mortality[3-5]. Recently, fecal immunochemical tests (FITs) have been found to be superior over g-FOBTs[6-10].

Studies on FITs have used different designs, e.g., in terms of populations studied. Screening and referral cohorts each have their pros and cons in this respect[6,7]. Studies in screening cohorts, consisting of individuals with average-risk for CRC, best reflect the true target population. However, in most such studies, only subjects who test positive on FIT are referred for colonoscopy, which means that sensitivity and specificity cannot be determined directly[6]. In addition, the number of cases detected, particularly cancers, is usually low. Other designs include high risk or referral cohorts. Here, an important advantage is that colonoscopy is performed in all patients allowing for calculation of direct sensitivity and specificity[7]. In addition, these studies often yield more cases, allowing for more detailed subgroup analyses[7,11].

It has been suggested that conclusions from referral studies cannot be extrapolated to the screening setting[12,13]. So far, no comparative data have been published to verify or falsify this hypothesis, and arguments both in favor of, as well as against this hypothesis exist. Due to the higher pretest likelihood and presence of symptomatic individuals included in referral cohorts, the risk of work-up bias exists, limiting extrapolation to population-based screening. On the other hand, CRC stage distribution has been shown to influence sensitivity of blood-based CRC markers[14], and is likely to have a large influence on FIT results[15]. Therefore, the aim of the present study was to compare FIT results between subjects with CRC found in either a screening or a referral cohort, and determine if differences can be explained by tumor characteristics.

MATERIALS AND METHODS

Study design

The present study aimed to compare FIT results in CRC cases derived from two methodologically different cohorts. Here, CRC cases with a FIT result ⩾ 50 ng/mL from both a screening and a referral cohort were compared for mean FIT result, age, sex and tumor stage. Both these studies were initiated in the same time period in the same country, and both used the same FIT.

Setting

Screening population: The screening cohort in this study was prospectively selected from June 2006 to February 2007 by a randomized selection from a Dutch population. Details from this study are described elsewhere[6,16]. In short, eligible individuals 50-75 years of age were invited by mail to perform either a g-FOBT or a FIT ($n = 20\,623$). Participants with a positive test were offered colonoscopy in two academic centers. Exclusion criteria were institutionalization and bowel symptoms[6]. In the current study, only participants enrolled in the FIT arm ($n = 10\,322$) were included.

Referral population: The referral cohort in this study was derived from a previous and ongoing study on FIT performance, and a more detailed description can be found elsewhere[7]. In short, from June 2006 to October 2009, all ambulatory patients (aged ⩾ 18 years) scheduled for elective colonoscopy in five Dutch hospitals (including an academic center and large teaching hospital), were selected regardless of the indication for colonoscopy. Eligible subjects were invited to participate in a prospective study on FIT performance. All participants performed a FIT before bowel preparation. Until June 2008, subjects were invited to perform both a g-FOBT and an FIT[7]. In

an ongoing study after that period, subjects were invited to perform an FIT only, but twice (on two consecutive days). From the latter cohort, the FIT performed 1 d before colonoscopy was selected for the current study for comparability with the screening population. Exclusion criteria were hospitalization, colostomy, inflammatory bowel disease or total colectomy.

Outcomes and measurements

FIT: In both cohorts, an identical semi-quantitative FIT was used: OC-sensor (Eiken Chemical Co., Tokyo, Japan). No restrictions for diet or medication in the week prior to FIT were given. Participants were educated by illustrated and written instructions to sample their feces, ensuring that no contamination with water or urine occurred. In the screening population, participants were asked not to perform the test if blood was visible.

The FIT used in this study consists of a sampling tube, filled with stabilizing buffer. Participants were instructed to scrape the probe at different parts of the stool. The amount of feces that can be inserted into the sample bottle is regulated to approximately 10 mg[17]. In the referral population, subjects performed the FIT within 72 h before colonoscopy, and returned the test and informed consent form on the day of colonoscopy. All samples were placed at -5 ℃ on arrival and analyzed according to the manufacturer's instructions within 1 wk, or were frozen at -20 ℃. The analyses were performed by two experienced technicians, blinded to the clinical data[18]. In the screening population, participants were instructed to return the test by mail as soon as possible. If the test could not be returned immediately, storage in a refrigerator was advised. Again, two specially trained technicians who were blinded to the clinical data processed all samples.

All FITs were analyzed with the OC sensor MICRO desktop analyzer (Eiken Chemical Co.). The agglutination reaction is dependent on the hemoglobin concentration in the sample. A prozone effect may occur if the concentration is too high and the excess amount of antigen limits its agglutination. Measured values can then be higher or lower than the actual concentration in the sample[19]. The risk of the prozone effect gradually increases well above 1000 ng/mL. Therefore, every measurement above 1000 ng/mL was classified as 1000 ng/mL. The quantitative nature of the test was maintained, because 1000 ng/mL is at least 10 times higher than the most usual cut-off values between 50 ng/mL and 100 ng/mL.

Colonoscopy and detected malignancies: Colonoscopies were performed under conscious sedation with midazolam and fentanyl at the discretion of the endoscopist. In both cohorts, all colonoscopies were performed or supervised by experienced gastroenterologists. Colonoscopy was considered complete if the cecum was intubated with visualization of the ileocecal valve or the appendiceal orifice, or by intubation up to CRC. Incomplete colonoscopies were excluded. In addition, subjects were excluded in case of insufficient bowel cleansing, as judged by the individual endoscopist. In the screening cohort, an incomplete colonoscopy was followed by a second colonoscopy with propofol anesthesia. If necessary, a computed tomographic colonoscopy was performed followed by a second colonoscopy. If an incomplete colonoscopy in the referral cohort was followed by a complete second colonoscopy, virtual colonoscopy or x-colon within 6 mo, the results were included in analysis.

In the screening study, histology of tissue samples obtained during colonoscopy was evaluated by one experienced pathologist. In the referral cohort, lesions were evaluated according to routine procedures. In both studies, the outcome variable CRC was classified according to tissue tumor stage (T stage) of the TNM-classification (6th edition) according to the AJCC cancer staging manual[20].

Statistical analysis

The primary aim of the study was to compare mean FIT scores in CRC cases found in the referral and screening setting, with and without correction for CRC T stage. For analyses, only individuals with CRC and a FIT result $\geqslant$ 50 ng/mL were selected, because this cut-off value was used for colonoscopy referral in the screening population.

FIT scores do not follow a Gaussian curve. On average, even after correction for the prozone effect[19], the curve is considerably skewed to the left. Logarithmic transformation of the FIT scores allowed for using the *t* test, as a normal distribution was achieved. Multivariate logistic regression analysis was used to evaluate which variables could explain the differences in FIT scores between CRC patients found in the screening and referral cohorts. In logistic regression analysis, the outcome variable was mean FIT score, and the independent variables were population of origin, T stage, age, and sex. Logistic regression analysis was performed both by forward and backward selection.

Statistical analysis was performed with SAS for Windows, version 8.02 (SAS Institute Inc., Cary, NC). Two-sided P values < 0.05 were considered statistically significant.

Ethical approval and consent

In both studies, informed consent was obtained from all participants. Approval and consent from the screening arm of this study was obtained by the Dutch Health Council (2005/03WBO, The Hague, The Netherlands, www.gezondheidsraad.nl)[6]. In all centers participating in the referral arm of this study, local Medical Ethics Review Board approval was obtained prior to the start of the study[7].

RESULTS

Participants

In the screening population, 10 322 subjects were invited to FIT sampling. Of these, 6157 completed and returned the test. Five hundred and twenty-six participants were scheduled for colonoscopy because the FIT result was $\geqslant$ 50 ng/mL (i.e., positivity rate of 8.5%). In 428 patients, colonoscopy was performed, and considered complete in

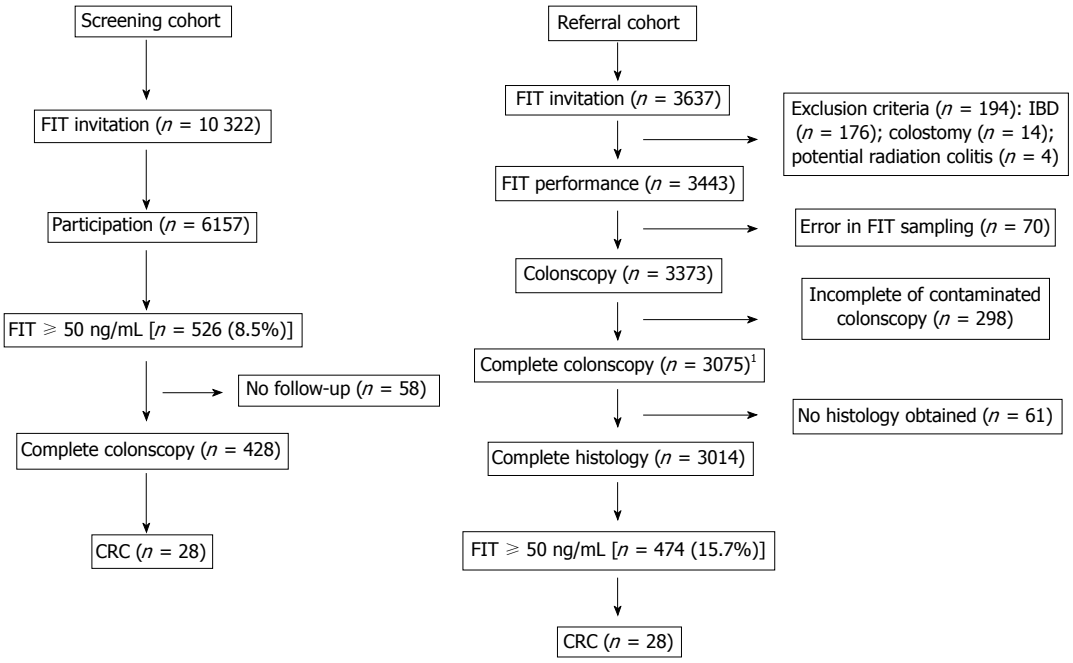

Figure 1 Study flow of the screening and referral cohort compared in the present study. [1]This includes cases in which an incomplete initial colonoscopy was followed by a second complete colonoscopy, virtual colonoscopy or x-colon. FIT: Fecal immunochemical test; CRC: Colorectal cancer; IBD: Inflammatory bowel disease.

Table 1 Primary indications for colonoscopy

Indication group	Indication for colonoscopy	*n*
Symptomatic/suspect	Weight loss	52

	Familial history of CRC	387
	Lynch syndrome	42
	Polyp surveillance	491
	Post CRC surveillance	157
	Total	1146
Other	Not specified/others	143
Grand total		3014

Primary indications for colonoscopy among 3014 patients included in the referral arm of this study in a comparison of fecal immunochemical test results in screening and referral colorectal cancer (CRC) cases (exclusion criteria used in the referral arm of the study were age < 18 years, hospitalization, colostomy, inflammatory bowel disease (IBD) or total colectomy).

402 (colonoscopy completion rate 94%; Figure 1). In the 26 cases in which the cecum was not visualized, a second complete colonoscopy was performed. In total, 28 cases of CRC were detected.

In the referral population, 3637 subjects were invited for participation. Six hundred and 23 subjects were excluded because of FIT sampling violating the study protocol, incomplete or contaminated colonoscopy, or missing histology of lesions found. Therefore, 3014 individuals who had a complete colonoscopy and histology remained for analysis (completion rate colonoscopy 91%, Figure 1). The indication for colonoscopy was evaluation of symptoms in 57%, screening and surveillance in 38%, and unspecified in 5% (Table 1). The positivity rate (⩾ 50 ng/mL) was 15.7%. In total, 105 subjects with CRC were found, of whom 96 (91.4%) had a positive FIT. The sensitivity of FIT for detection of CRC at cut-off values of 50 mg/mL, 75 mg/mL and 100 mg/mL was 91.4%, 90.5% and 89.5%, respectively. The respective specificity for these cut-off values was 83.7%, 85.7% and 87.0%.

In total, 124 patients with CRC and a positive FIT result were found: 28 derived from the screening population and 96 from the referral population. From the referral population, six cases were excluded because the actual T stage could not be determined due to neoadjuvant radiotherapy or palliative treatment. The mean age of the remaining 90 CRC cases from the referral cohort was significantly higher compared with the 28 cases from the screening cohort; 69 (SD 9.8) *vs* 65 (SD 6.5) years, respectively ($P = 0.04$). As expected, the proportion of males was higher in both populations and not statistically significantly different between the referred and screened population (58% and 64%, $P = 0.54$, Table 1). Other abnormalities that might cause (minor) mucosal bleeding in the colon in addition to CRC, potentially influencing the FIT results were seen in 64% of the referral and 79% (not significant) of the screening population (Table 2).

T stage distribution and FIT results

The 28 CRC cases from the screening population had a

Table 2 Colorectal cancer patient characteristics and potential explanations for positive fecal immunochemical test results in addition to colorectal cancer

	Screening population (*n* = 28)	Referral population (*n* = 90)
Male %	64	58[1]
Age (yr, mean ± SD)	65 ± 6.5	69 ± 9.8[2]
Location of CRC (% left sided)	64	62
CRC only (%)	6 (21)	32 (36)
CRC including (%)		
Advanced adenomas	16 (57)	14 (16)
Other adenomas	5 (18)	17 (19)
Other polyps	0 (0)	14 (16)
Diverticula	1 (4)	9 (10)
Hemorrhoids	0 (0)	4 (4)

[1]χ^2 test: $P = 0.54$; [2]t test: $P = 0.04$. The percentages of other abnormalities in addition to colorectal cancer (CRC) in the referral population totaled 65% due to rounding. The total percentage of CRC cases with additional pathology was 64%.

mean FIT score of 613 ng/mL (SD 368 ng/mL), which was significantly lower ($P = 0.02$) than the mean FIT score of the 90 CRC cases from the referral population 829 ng/mL (SD 302 ng/mL, Table 3).

The CRC stage distribution was different between the populations: early stages were more frequently found in the screening population (Figure 2). Of the 28 cases from the screening population, 13 cases were classified as T1 (46%), eight as T2 (29%), six as T3 (21%) and one as T4 carcinoma (4%). In the referral population, 12 patients had stage T1 tumor (13%), 22 stage T2 (24%), 52 stage T3 (58%) and four stage T4 (4%).

After stratifying mean FIT scores by T stage, none of the tumor stages had a significant difference in FIT results (Table 2): T1, $P = 0.22$; T2, $P = 0.79$; T3, $P = 0.13$. There was only one T4 case in the screening population, therefore, T4 cases were combined with T3 cases. Again, for the combined T3 and T4 stage category, no significant difference in FIT score was seen between both populations ($P = 0.19$).

Logistic regression analysis

By univariate analysis, FIT results from the referral cohort were significantly higher compared with the screening cohort ($P < 0.01$). However, after adding T stage to the model, the difference in FIT results lost statistical significance ($P = 0.10$). The P values per T stage were 0.23 (T1), 0.79 (T2), and 0.11 (T3/T4). By multivariate analysis including the variables sex, age, T, N and M stage, only T stage ($P < 0.001$) and (marginally) age ($P = 0.05$) could significantly explain the differences between the screening and referral cohorts.

DISCUSSION

The current study compared FIT results in individuals with CRC from two different prospective study designs, i.e., a population-based screening study and a referral cohort, to study the uncertainty about the link between the results obtained from these kind of studies. Cases of CRC from the screening cohort were found to have significantly lower FIT results compared to those from the referral cohort, but after stratifying for tissue tumor stage, no difference remained. In the screening cohort, 75% (21/28) and in the referral cohort only 38% of cases had a T1 or T2 tumor (34/90). Logistic regression analysis confirmed that not the type of population, but only T stage and to a lesser extent age could explain the differences in FIT results of CRC patients between these screening and referral cohorts.

The results of this study are relevant for the evaluation of CRC screening tests and guidance of future study designs. Several studies in screening populations have been performed comparing, e.g., FIT with g-FOBT[6,9,12,21]. However, despite the large number of screened individuals in these studies, the absolute number of individuals with CRC was relatively low, hampering subgroup analysis. Furthermore, colonoscopy was missing in subjects with a negative FIT, impeding calculation of sensitivity and specificity. Indeed, for the investigation of the performance of a screening test like FIT, the ultimate prospective study design would contain full colonoscopic evaluation of all participants. However, in a screening population, this is considered unethical or unfeasible because the capacity and/or funds are lacking. In referral populations, FIT negatives do indeed all undergo colonoscopy, and in addition, in much less time and at a substantially lower cost, a much larger number of CRC patients can be included. This enables, e.g., more elaborate subgroup analysis of early stage CRC. The present study shows that tumor stage is the major contributor to the outcomes of FIT between cohorts. Possible differences in characteristics between the cohorts did not have much influence on FIT outcomes. It is indicated here that, if correction or stratification for CRC tumor stage distribution is applied, both screening as well as referral cohorts can be used to answer several important screening-related research questions. Research questions on accuracy of screening tests with sufficient power, could therefore initially be explored using referral populations. In line with Tao and colleagues, who found that sensitivity of blood-based CRC markers is dependent on tumor stage[14], results for test characteristics should be presented per tumor stage. By merging results from different sources, the strength of the evidence available will be enlarged.

Some considerations need to be discussed for proper interpretation of the present results. For evaluation of sensitivity and specificity, data from referral studies could be extrapolated, or the incidence of interval cancers could be used as false negatives. The latter requires intensive follow-up over many years before sensitivity can be estimated; time in which tumors may further evolve. Second, the number of screening cases is limited, although comparable with other screening studies[9,12,21]. This limits the power to determine any existing differences. However, from Figure 2 and Table 2 it is clear that it is unlikely that adding more screening cases could change the results substantially. Supported by the results from other

Table 3 Fecal immunochemical test results in patients with colorectal cancer derived from a screening and referral cohort according to tissue tumor stage

	Population	*n*	mean ± SD	25th %	Median	75th %	*P* value[1]

[1]*t* test after logarithmic transformation because of non-normality of fecal immunochemical test results (ng/mL). All results ⩾ 1000 ng/mL were classified as 1000 ng/mL. T: Tumor stage; NA: Not available. (i.e., values like mean and median having a single observation are meaningless and a *t* test cannot be performed because no error term can be estimated for a single observation).

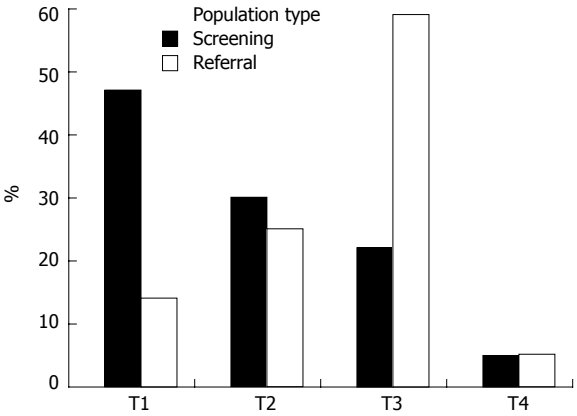

Figure 2 Colorectal cancer tumor stage distribution in screening (*n* = 28) and referral (*n* = 90) populations in studies on diagnostic performance of an fecal immunochemical test. Difference between screening and referral $P < 0.001$.

studies[13,16,17,22], CRC was considered the major contributor to the overall FIT results. Still, it cannot be excluded that other sources of bleeding (like minor polyps) could have contributed to the overall FIT result. In addition, although probably limited considering the moderate temperatures in the Netherlands, time lag between sampling and analysis could have influenced FIT results found[23]. In this study, the existing difference between both cohorts could therefore be even less, because time to analysis in the screening cohort was on average somewhat longer. Finally, in the screening cohort, no information about preoperative radiotherapy was available and therefore tumor stage could have been underestimated in a few cases. In summary, the correction for other potential bleeding sources, time lag to analysis, and radiotherapy would even decrease the differences between the referral and screening cohorts and therefore support our conclusions.

The present study aimed to compare test performance in two study designs, each with pros and cons, knowing the essential differences between the two cohorts. It can be concluded that T stage reflects the majority of the differences in overall FIT results between the two studied cohorts.

In conclusion, apparent differences in FIT results between screened and referred CRC patients can be attributed to tissue tumor stage. Based on these findings, we conclude that results from both cohorts could strengthen the evidence available. Using referral populations for studying FIT, and potentially also new CRC screening tests, can be useful to stimulate progress in CRC research. Here, sensitivity and specificity should be studied as these measures are independent of the prevalence of the disease[24], and test characteristics should be stratified by tumor stage. This will be of particular benefit in research questions that require large numbers of cases or colonoscopy confirmation in all individuals, and do not seek predictive values as outcome.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the participants, technical analysts, supporting data managers and the endoscopy units for their contributions to both initial studies; van Oijen MGH, Verbeek ALM, van Krieken HH and the Comprehensive Cancer Center Amsterdam are especially acknowledged for their contribution to the initial screening study; the authors especially acknowledge Loffeld RJLF, Wesdorp ICE, van Heukelem HA, and van Hengel E for their contribution to the original studies from the referral arm of the present study; the OC sensor MICRO desktop analyzer used in the referral study was provided by Eiken Chemical co., Tokyo, Japan.

COMMENTS

Background

Colorectal cancer (CRC) is a disease well suited for population-based screening. Subjects who test positive on fecal immunochemical tests (FITs) should be referred for colonoscopy. FIT performance has been studied in two different types of populations. In studies in screening cohorts, only subjects who test positive on FIT are referred for colonoscopy. Sensitivity and specificity cannot be calculated directly. In addition, the number of cases detected is usually low. Designs with referral cohorts do not study average but high-risk individuals. However, as colonoscopy is performed in all subjects direct sensitivity and specificity can be calculated. In addition, in referral populations, more cases are found. The aim of the present study was to compare FIT results between subjects with CRC found in a screening and a referral cohort.

Research frontiers

FITs detect occult human blood, what might be derived from adenomas or CRC. FITs are more sensitive than guaiac fecal occult blood tests, by which screening has been shown to decrease CRC-related mortality. However, exact FIT characteristics are the subject of debate.

Innovations and breakthroughs

The present study is the first to compare results obtained from both screening and referral populations to gain insight into the comparability of results derived from both study designs. It was shown that referral populations have a different tumor stage (T stage) distribution compared to screening populations (i.e., a higher percentage of high T stage cancers). This was accompanied by higher mean FIT results. After correction for T stage, mean FIT results were similar in both populations.

Applications

Apparent differences in FIT results between screened and referred CRC patients can be attributed to tissue tumor stage. Results from both cohorts could strengthen the evidence available. Using referral populations for studying FIT, and potentially also new CRC screening tests, can be useful to stimulate progress in CRC research, when test characteristics are stratified by tumor stage.

Peer review

This is an important study comparing the appropriate interpretation of FIT in screening population and in patients referred for colonoscopy regardless of the indication. According to the authors' conclusion differences in T-stage distribution largely explained differences in FIT results between screening and referral cohorts. Therefore the absolute value of the FIT results should be reported according to T-stage.

Abstract

AIM: To investigate age, sex, histopathology and *Helicobacter pylori* (*H. pylori*) status, as risk factors for gastroduodenal disease outcome in Brazilian dyspeptic patients.

METHODS: From all 1466 consecutive dyspeptic patients submitted to upper gastroscopy at Hospital das Clinicas of Marilia, antral biopsy specimens were obtained and subjected to histopathology and *H. pylori* diagnosis. All patients presenting chronic gastritis (CG) and peptic ulcer (PU) disease localized in the stomach, gastric ulcer (GU) and/or duodenal ulcer (DU) were included in the study. Gastric biopsies (n = 668) positive for *H. pylori* by rapid urease test were investigated for vacuolating cytotoxin A (*vacA*) medium (m) region mosaicism by polymerase chain reaction. Logistic regression analysis was performed to verify the association of age, sex, histopathologic alterations, *H. pylori* diagnosis and *vacA* m region mosaicism with the incidence of DU, GU and CG in patients.

RESULTS: Of 1466 patients submitted to endoscopy, 1060 (72.3%) presented CG [male/female = 506/554; mean age (year) ± SD = 51.2 ± 17.81], 88 (6.0%) presented DU [male/female = 54/34; mean age (year) ± SD = 51.4 ± 17.14], and 75 (5.1%) presented GU [male/female = 54/21; mean age (year) ± SD = 51.3 ± 17.12] and were included in the comparative analysis. Sex and age showed no detectable effect on CG incidence (overall χ^2 = 2.1, P = 0.3423). Sex [Odds ratios (OR) = 1.8631, P = 0.0058] but not age (OR = 0.9929, P = 0.2699) was associated with DU and both parameters had a highly significant effect on GU (overall χ^2 = 30.5, P < 0.0001). The histopathological results showed a significant contribution of ageing for both atrophy (OR = 1.0297, P < 0.0001) and intestinal metaplasia (OR = 1.0520, P < 0.0001). Presence of *H. pylori* was significantly associated with decreasing age (OR = 0.9827, P < 0.0001) and with the incidence of DU (OR = 3.6077, P < 0.0001). The prevalence of m1 in DU was statistically significant (OR = 2.3563, P = 0.0018) but not in CG (OR = 2.678, P = 0.0863) and GU (OR = 1.520, P= 0.2863).

CONCLUSION: In our population, male gender was a risk factor for PU; ageing for GU, atrophy and metapla-

sia; and *H. pylori* of *vacA* m1 genotype for DU.

INTRODUCTION

Helicobacter pylori (*H. pylori*), a Gram-negative microaerophylic bacterium, is associated with a broad spectrum of digestive tract diseases such as chronic gastritis, gastric and duodenal ulcers, gastric cancer and lymphoproliferative disorders[1]. *H. pylori* infection prevalence and clinical outcome of the colonized patients varies according to several considerations including bacterial factors and host and environmental characteristics such as age, ethnic group, genera, geography and socioeconomic conditions[2].

The role of *H. pylori* in the interaction with the host has an impact on the pattern and severity of gastritis and its clinical outcome[3]. The physiologic mechanisms involved in these *H. pylori*-induced pathological differences are still unknown; however, one of the major bacterium virulence factors, the vacuolating cytotoxin A (*vacA*), seems to be involved. The vacA protein encoded by the polymorphic *H. pylori vacA* gene, is produced and secreted by all bacterium strains and induces the formation of intracellular vacuoles in epithelial cell lines *in vitro*[4-6]. Polymorphism of the *vacA* gene is distributed in three principal regions: the signal (s), intermediate (i), and middle (m) regions, each being divided in two main types, numbered 1 and 2[7,8], which are differently associated with several mechanisms of pathogenicity *in vitro* and *in vivo*[6,9-15]. The s1, i1, and m1 types have been shown to be independently associated with more severe forms of *H. pylori*-induced diseases[8,16].

Studies conducted in several countries have shown that type 1 and 2 alleles of *vacA* polymorphisms are both widespread in all populations examined, except in the Japanese, among whom type 2 alleles are rare[17,18]. Thus, outside Asia, *vacA*-type 1 and *cagA*-positive *H. pylori* strains are more frequently associated with severe *H. pylori*-induced peptic ulcer diseases than *vacA*-type 2 *cagA*-negative bacterium strains[7,19-22]. In Brazil, a country of continental dimensions, this association has been observed in children[23,24] but is controversial in the adult population[25-27].

Environmental and demographic data also interfere with the pathophysiology of *H. pylori*-associated gastric diseases. In the adult population of Brazil, *H. pylori* infection can range from 60%-90%[28-31]. In Marilia, a city of São Paulo State, the serological prevalence of *H. pylori* determined in blood donors was 57% and a risk factor associated with IgG and/or IgA *H. pylori* antibodies was low educational level[32]. Considering the large geographical dimensions of Brazil, with its regionally specific socioeconomic and cultural conditions reflected by the high and variable prevalence of *H. pylori*, there are few epidemiological studies on gastric diseases.

So far, all comparative Brazilian studies on gastric disease epidemiology, *H. pylori* prevalence and *vacA* gene mosaicism have generally been carried out on small populations and on *H. pylori* strains isolated in culture. Therefore, considering that gastric and duodenal ulcer diseases depend on different physiological trigger mechanisms, we comparatively investigated the role of age, gender, histopathologic antral gastric alterations and the *H. pylori* status, including the *vacA* m region mosaicism detected directly in biopsies, as risk factors for gastric ulcer (GU), duodenal ulcer (DU) and chronic gastritis (CG) in patients consecutively attending at Hospital das Clinicas of Marilia, São Paulo, Brazil, during a period of four years.

MATERIALS AND METHODS

Patients

Adult patients (n = 1466) resident in Marilia city, São Paulo State, Brazil, aged 19 to 91 years, underwent esophagogastroduodenoscopy (EGD) for upper abdominal pain or dyspeptic symptoms from January 2003 through December 2006 at the Gastroenterology Outpatient Clinic of the Hospital das Clínicas of Marília Medical School. All who presented GU, DU (by endoscopy) and/or CG (by histology), were enrolled in this study.

Endoscopy and biopsies

The EGD was accomplished by fibroendoscope (GIF-XP20, GIF-XQ20) or video-endoscope (GIF-100), both from Olympus Medical Systems, Shinjuku-ku, Tokyo, Japan. Gastric or duodenal ulcer diagnosis was defined by endoscopy and two fragments of the antrum were collected to perform rapid urease (RUT) and histopathological tests. The biopsy used for RUT was further submitted to DNA extraction. The protocol used is in agreement with the Helsinki Declaration and was approved by the Ethical Committee in Human Research from Marilia Medical School, under reference number 388/01.

Histology

One antral specimen was fixed in 40 g/L of formaldehyde and embedded in paraffin. Sections were Giemsa stained for *H. pylori* evaluation and were stained with he-

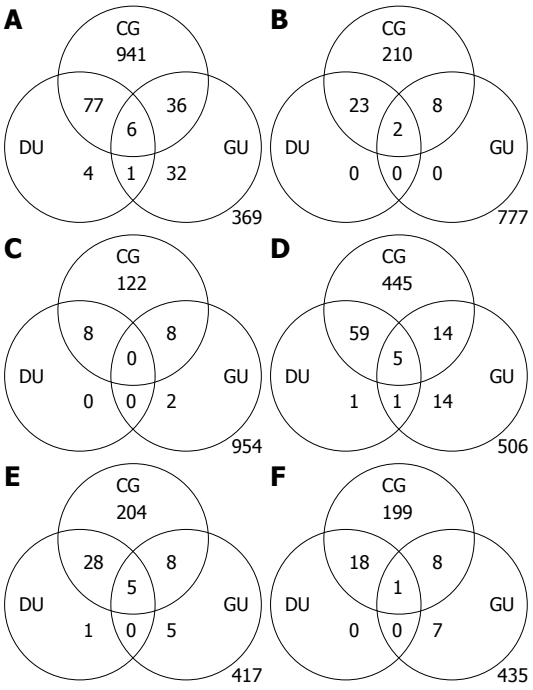

Figure 1 Incidence of chronic gastritis, duodenal ulcer and gastric ulcer disease and distribution of the investigated independent variables. A: Incidence of gastric diseases in patients who underwent endoscopy (n = 1466); B: Distribution of the histopathological parameters of atrophy (n = 1020); C: Intestinal metaplasia (n = 1094); D: Positive histological diagnosis of *Helicobacter pylori* (*H. pylori*) (n = 1045); E: *H. pylori vac*A m1 genotypes (n = 668); F: *H. pylori vacA* m2 genotypes (n = 668). CG: Chronic gastritis; DU: Duodenal ulcer; GU: Gastric ulcer; *vacA*: Vacuolating cytotoxin A. Values outside circles are negative tests.

matoxylin and eosin for assessment of histopathologic alterations according to the Sydney classification[33].

Helicobacter pylori vacA genotyping

The same biopsy used for RUT was submitted to DNA extraction with the employment of the GFx DNA extraction kit purchased from Amersham/Pharmacia Biotec, following the manufacturer's instructions. DNA was quantified in agarose gel electrophoresis using the Invitrogen low mass ladder and 50-100 μg of total DNA were used in the polymerase chain reaction (PCR) reactions with the oligonucleotides[34]: MA sense (5'CACAGCCACTTTYAATAACGA3') and MB antisense (5' CGTCAAAATAATTCCAAGGG3'), which amplify a fragment of 400 bp or 476 bp corresponding to the *vacA* m regions 1 and 2, respectively. PCR condition was 94 ℃ for 5 min followed by 40 cycles of 94 ℃ 1 min/60 ℃ 1 min/72 ℃ 1 min and one cycle at 72 ℃ 7 min, with a total volume of 25 μL containing 1 × PCR buffer, 200 μmol dNTPs, 2.0 mmol $MgCl_2$, 1 μmol of each oligonucleotide, 1.25 U Taq DNA Polimerase Platinum Brazil (Invitrogen). In all PCR reactions a negative and a positive control were used corresponding to, respectively, sterile water and *H. pylori vacA* m1 and/or m2 PCR positive gastric biopsies. The products of PCR reactions were resolved in 15 g/L agarose gels, stained with ethidium bromide and photographed under ultraviolet light.

Statistical analysis

Incidences of CG, DU, and GU in patients submitted to endoscopy were investigated using age (in years) and sex as independent factors. Only for patients who developed at least one of these diseases, the role of age, sex, CG, GU, and DU were verified as independent factors to evaluate the presence of atrophy, intestinal metaplasia, *H. pylori* and *vacA* m1 and m2 genotypes, each assessed individually. Incidences were coded as "1" and absences (of evidence) as "0" (males were also coded as "1", females as "0"). Cases without the complete records needed for each analysis were discarded. Multivariable screenings were performed by additive logistic regression models for detection of significant effects of the independent factors on each response variable. New models were made after discarding irrelevant variables and significant parameters of these last models were used to describe the relationship among factors and responses by means of logit functions. Critical P-values were considered after a Bonferroni correction based on the number of similar tests. All logistic regression analyses were performed using a free on-line device for Logistic Regression calculation provided by Pezzulo (2012)[35].

RESULTS

Among 1466 patients submitted to endoscopy, 1060 (72.3%) presented CG [male/female = 506/554; mean age (year) ± SD = 51.2 ± 17.81], 88 (6.0%) presented DU [male/female = 54/34; mean age (year) ± SD = 51.4 ± 17.14], and 75 (5.1%) presented GU [male/female = 54/21; mean age (year) ± SD = 51.3 ± 17.12], and were included in the comparative analysis. More than one of these diseases was presented by 120 (8.2%) individuals and 369 (25.2%) patients were free of them (Figure 1). Most of the other endoscopic and histopathologic alterations were related to gastroesophageal tract diseases (data not shown). Mean age and gender of the included CG, GU and GC patients are summarized.

Distribution of atrophy, intestinal metaplasia, *H. pylori* histological diagnosis and *vacA* m region mosaicism in patients presenting CG, DU and GU are summarized in Figure 1.

Atrophy and intestinal metaplasia were investigated among antral gastric biopsies of 1020 and 1094 patients, respectively, with 243 (23.8%) positive for atrophy and 140 (12.8%) for intestinal metaplasia.

Detection of *H. pylori* was performed directly from biopsy specimens by two different tests: histology and RUT. Histology is the gold standard *H. pylori* diagnostic test employed in our clinical routine which together with histopathological analysis is used to decide for *H. pylori* eradication therapy. RUT showed a very low positive predictive value for *H. pylori*-associated gastric diseases and a high discrepancy when compared to histology; consequently these data were excluded from the study (data not shown). Among 1045 patients investigated for *H. pylori* by histology, 539 (51.6%) were positive.

Among 668 biopsies of patients positive for RUT in-

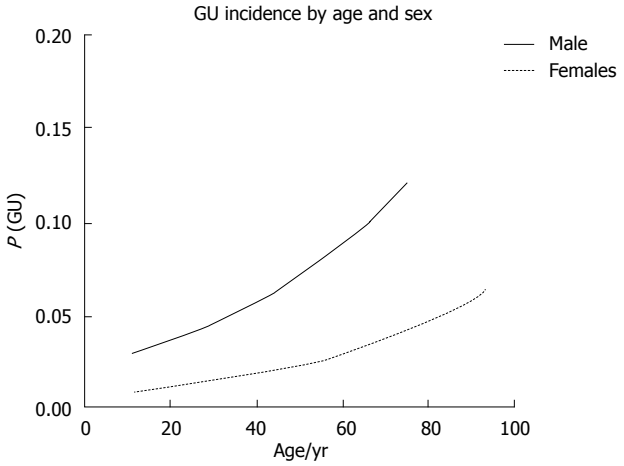

Figure 2 Logistic regression curves of age and sex as independent factors to explain gastric ulcer disease incidence. The model has a significant fit, with contributions of both coefficients (χ^2 = 30.5, P < 0.0001). Additional test for the age/sex interaction had a nonsignificant result (β_3 = -0.011, SE = 0.0161, P = 0.4844, OR = 0.989, CI- = 0.958, CI+ = 1.021). OR: Odds ratios; CI: Confidence intervals; GU: Gastric ulcer.

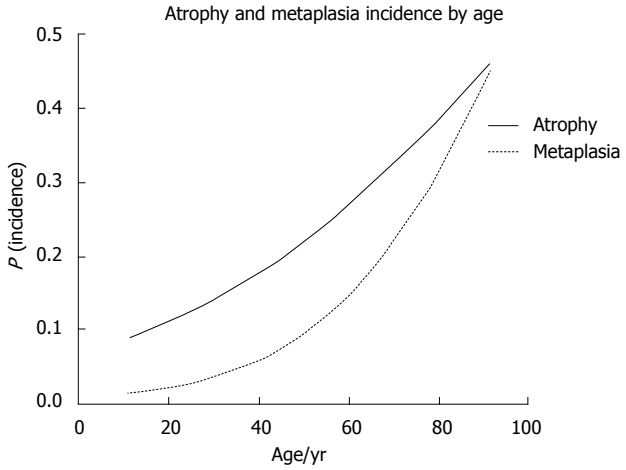

Figure 3 Logistic regression curves of age as an independent factor to explain atrophy and intestinal metaplasia incidences. All patients who underwent endoscopy and who had at least one of the three diseases were included in the analysis. Both models had highly significant fits (atrophy OR = 1.0297, P < 0.0001; intestinal metaplasia OR = 3.6077, P < 0.0001). OR: Odds ratios.

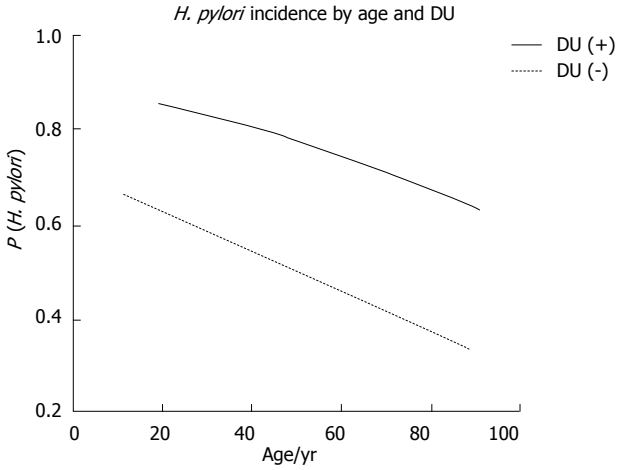

Figure 4 Logistic regression curves of age and duodenal ulcer disease as independent factors to explain *Helicobacter pylori* incidence. The model had a highly significant fit (age OR = 0.9827, P < 0.0001; DU OR = 3.6077, P < 0.0001). A posterior test for the age/DU interaction had a nonsignificant result (β_3 = 0.0085, SE = 0.0168, P = 0.6142, OR = 1.0085, CI- = 0.9758, CI+ = 1.0423). DU: Duodenal ulcer; OR: Odds ratios; CI: Confidence intervals; *H. pylori*: *Helicobacter pylori*.

vestigated for *vacA* m region mosaicism by PCR directly on biopsy specimens, 484 were positive, with 251 (51.8%) of m1 and 233 (48.2%) of m2 genotypes.

Results of the additive logistic regression models to evaluate the contribution of age and sex to the incidence of CG, DU and GU among patients who underwent gastroscopy are summarized in Table 1. Sex and age showed no detectable effect on CG incidence (overall χ^2 = 2.1, P = 0.3423). Sex (OR = 1.8631, P = 0.0058) but not age (OR = 0.9929, P = 0.2699) affected DU, and both parameters had a highly significant association with GU (overall χ^2 = 30.5, P < 0.0001), with contributions of both coefficients (age OR = 1.0233, P = 0.0017; sex OR = 3.0790, P < 0.0001). A posterior test for the age/sex interaction showed it to be nonsignificant (OR = 0.9888, P = 0.4844). The incidence of GU increased with age and further, at a given age, males had a higher probability of developing GU (Figure 2).

Additive logistic regression models were constructed to investigate the contribution of age, sex, CG, DU and GU to atrophy, intestinal metaplasia, *H. pylori* presence and *vacA* m1 and m2 mosaicism (Table 2).

The results for histopathological parameters showed a significant contribution of age for both atrophy (OR = 1.0297, P < 0.0001) and intestinal metaplasia (OR = 1.0520, P < 0.0001). Atrophy incidence increased with age (Figure 3) and a new model with only age as the independent factor also had a highly significant fit (overall χ^2 = 35.2, P < 0.0001; age OR = 1.0273, P < 0.0001) though more parsimonious (Table 2). In the case of intestinal metaplasia, it was necessary to check for the contribution of CG, which was discarded after the Bonferroni correction. A new model with only age as the independent factor also had a highly significant fit (overall χ^2 = 71.7, P < 0.0001; age OR = 1.0509, P < 0.0001) though more parsimonious (Table 2). Intestinal metaplasia increased with age, but at a lower level than atrophy for a given age (Figure 3).

Presence of *H. pylori* was significantly associated with age (OR = 0.9827, P < 0.0001) and occurrence of DU (OR = 3.6077, P < 0.0001) (Table 3). A new model with only age and DU as independent factors also had a highly significant fit (overall χ^2 = 47.8, P < 0.0001; age OR = 0.9826, P < 0 .0001; DU OR = 3.5063, P < 0.0001) but was more parsimonious (Table 3). An additional model showed that age/DU had no effect on the presence of *H. pylori* (β_3 = 0.0085, SE = 0.0168, P = 0.6142, OR = 1.0085, CI- = 0.9758, CI+ = 1.0423). *H. pylori* incidence decreased with age and DU incidence contributed to higher probabilities in developing detectable levels of the bacterium, despite individual age (Figure 4).

The five independent factors studied for the *H. pylori* *vacA* m1 and m2 genotypes resulted in nonsignificant ad-

ditive regression logistic models after Bonferroni correction. However, the evaluation of the contribution of the variables indicates a possible effect of DU (Table 3). A new model with only DU as the independent factor had a highly significant fit (overall χ^2 = 9.9, P = 0.0017) (Table 2). The incidence probability of m1 in DU patients was 0.5667 and in DU negative patients was 0.3569 (OR = 2.3563, P = 0.0018). In the case of m2, the evaluation of the variable contributions indicated a possible effect of age (Table 2). A new model with only age as the independent factor also had a nonsignificant fit, and was discarded by the adopted critical P-value (overall χ^2 = 5.8, P = 0.0156; age OR = 0.9885, P = 0.0162) (Table 2).

DISCUSSION

In order to verify the differential contribution of age, gender, histopathological outcome, *H. pylori* and *vacA* m region mosaicism with incidence of PU and CG, we investigated comparatively all cases of DU (88), GU (75) and CG (1060) found after analysis of 1466 patients consecutively submitted to gastroscopy in Hospital das Clinicas of Marilia, São Paulo, Brazil, over four years.

The most prevalent gastric disease found in our consecutive dyspeptic patients was CG (72.3%) followed by gastroesophageal alterations not included in this study. Peptic ulcer disease was prevalent in 11.1% of the patients, with 6.0% of GU and 5.1% of DU. Male gender had a statistically significant association with both PU incidences. Our results are in accordance with research done in the southern region of Brazil where DU and GU had a similar prevalence and were associated with male gender[36]. However, in a recent large scale PU epidemiological study carried out in a tertiary care hospital in another city of São Paulo State, Brazil, the prevalence of DU was four times higher than GU[37] and in this population there was a significant predominance of woman in the PU group[38]. These regional differences reinforce the specificity of risk factors associated with severe gastric diseases and the need to perform local investigations to improve health care strategies.

There are differences in the gastrointestinal physiological modifications that lead to gastric and duodenal ulcers, whose causes are multifactorial and also related to population characteristics and to specific gastroduodenal alterations due to association of *H. pylori* with host mucosa[39]. In our study, increasing age was a risk factor for the development of GU. The mean age of GU and DU patients in the Brazilian ulcer study performed in a hospital in São Paulo also differed significantly, being higher in GU[37]. Thus, more epidemiological studies have to be done in order to identify the risk factors associated with age and the onset of GU in the Marilia population.

The eradication of *H. pylori* infection cured both gastric and duodenal ulcers, and the cure rates are similar, suggesting that *H. pylori* is the key factor in peptic ulcer diseases independent of the ulcer site[40]. However, a number of studies have shown the participation of other risk factors such as smoking, alcohol intake, and nonsteroidal antiinflammatory drug (NSAID) use in the etiology of PU, which are principally associated with GU[39,41,42]. In our study the prevalence of *H. pylori* infection observed by histology was significantly higher in DU than in GU and CG (P < 0.0001). Also, in the Danish epidemiologic PU study, IgG against *H. pylori* was higher in DU (87.2%) when compared to GU (60%) patients. In another city of São Paulo, there was also

[1]Significant effects. n_{total}: Number of investigated cases; n (+): Number of positive cases; CG: Chronic gastritis; DU: Duodenal ulcer; GU: Gastric ulcer; OR: Odds ratios; CI: Confidence intervals; *H. pylori*: *Helicobacter pylori*. Critical *P*-values were adopted after a Bonferroni correction for the number of similar tests: $P = 0.05/5 = 0.01$ for overall model and for each independent factor.

found to be a higher prevalence of *H. pylori* in DU (64%) than in GU (57%) patients[37]. These results suggest the participation of a major number of risk factors not associated with *H. pylori* involved in the development of GU rather than DU. Moreover, a very important and large scale follow-up study of ulcer patients performed in Europe[43] showed that GU can be a risk factor in the development of gastric cancer, while in DU this relationship was inversely observed, which suggests that GU and gastric cancer have etiologic factors in common that are not found in DU.

As a consequence of *H. pylori* gastric mucosa colonization, gastric acid secretion is altered with it being induced or impaired in response to the release of factors produced or induced by the bacterium, resulting in different topographic phenotypes of gastritis and the presence of atrophy. Gastritis associated with atrophy in the corpus is accompanied by hypochlorhydria and carries the highest risk for GU and cancer, whereas hyperchlorhydria produced by gastritis in the antrum predisposes to DU[43,44]. In our patients, antrum atrophy was more prevalent in DU than in GU, corroborating the hypothesis that DU can be a result of antral gastric atrophy. However, increasing age and not *H. pylori* presence was significantly related to the occurrence of atrophy and intestinal metaplasia. These results are in agreement with an epidemiological study performed in a rural population of Korea[45] and also in previous gastric physiological studies which have demonstrated the association of atrophic gastritis with increasing age[46,47].

In Northern Peninsular Malaysia, the prevalence of *H. pylori* increased in adult old-age groups, even when old and geriatric adults were compared[48]. In our investigated population, *H. pylori* incidence decreased significantly with age (Figure 4). These results can be indicative of a populational specific characteristic associated with the clearing of *H. pylori* during the course of a chronic infection, or can be related to the diagnosis of *H. pylori* in antrum biopsies since the expression of gastritis in the antrum, but not in the cardia or corpus, seems to decrease with age[49]. New research is necessary to answer these questions.

Polymorphisms in the m region of the *H. pylori vacA* gene affect the cell tropism of the toxin[50]; the m1 type of *vacA* shows toxicity toward a broader range of cells than the m2 type[51,52]. In Asia, where there is a high predominance of s1 alelle in the s region polymorphism of the *vacA* gene, the *vacA* m region mosaicism shows a variation within East Asia[53], with m1 strains being more prevalent in regions where there is a higher prevalence of gastric cancer, suggesting that m1 strains of *H. pylori* are more pathogenic. In Brazil, the involvement of *vacA* gene mosaicism with gastric diseases in adults is controversial[25-27]; in all these studies the size of investigated patient populations has been small and bacterium strains were isolated before genotyping which can cause a bias due to selection pressure by *in vitro* growth conditions. Our work was performed during a period of four years and the investigation of *vacA* m region mosaicism was done directly on biopsy specimens by PCR. Our results are the first in Brazil to find association of *vacA* m1 allele specific to adult DU patients when compared to GU and CG ($P < 0.0018$), indicating that in our region high prevalence of *H. pylori* and the strains harboring the *vacA* m1 genotype are more frequently associated with the development of DU.

Nowadays, PU remains the cause of significant morbidity, especially in older age groups, representing an important world health problem[54]. Its etiology in either the stomach (GU) or duodenum (DU) is multifactorial and depends on the interplay of a gastritis phenotype and of physiological gastroduodenal alterations as a result of environment, *H. pylori* genetic background and host interactions, which vary regionally. In this study we found that PU is associated with male gender when compared to CG and that there were risk factor differences associated with DU and GU. *H. pylori* and *vacA* m1 genotype

were associated with DU while older age at disease commitment was associated with GU. Thus, in spite of the few large scale Brazilian studies on epidemiological characteristics of gastric diseases with stratification of PU in GU and DU, we find high regional variation, indicating that local population investigation has to be carried out in order to improve treatment and prevention of severe gastric diseases.

COMMENTS

Background

Helicobacter pylori (*H. pylori*), a Gram-negative microaerophylic bacterium, is associated with a broad spectrum of digestive tract diseases such as chronic gastritis, gastric and duodenal ulcers, gastric cancer and lymphoproliferative disorder. *H. pylori* infection prevalence and clinical outcome of the colonized patients varies according to several considerations including bacterial factors and host and environmental characteristics such as age, ethnic group, genera, geography and socioeconomic conditions.

Research frontiers

The physiologic mechanisms involved in these *H. pylori*-induced pathological differences are still unknown; however, one of the major bacterium virulence factors, the vacuolating cytotoxin A (*vacA*), seems to be involved. The s1, i1, and m1 types have been shown to be independently associated with more severe forms of *H. pylori*-induced diseases.

Innovations and breakthroughs

Gastric biopsies positive for *H. pylori* by rapid urease test were investigated for *vacA* medium (m) region mosaicism by polymerase chain reaction. Logistic regression analysis was performed to verify the association of age, sex, histopathologic alterations, *H. pylori* diagnosis and *vacA* m region mosaicism.

Applications

These results can be indicative of a populational specific characteristic associated with the clearing of *H. pylori* during the course of a chronic infection, or can be related to the diagnosis of *H. pylori* in antrum biopsies since the expression of gastritis in the antrum, but not in the cardia or corpus, seems to decrease with age. New research is necessary to answer these questions.

Peer review

This is a good descriptive study in which authors analyze age, sex, histopathology and *H. pylori* status, as risk factors for gastroduodenal disease outcome in Brazilian dyspeptic patients. The results are interesting and suggest that male gender was a risk factor for peptic ulcer; ageing for gastric ulcer, atrophy and metaplasia; and *H. pylori* of *vacA* m1 genotype for duodenal ulcer.

Abstract

AIM: To evaluate the usefulness and safety of argon plasma coagulation (APC) for superficial esophageal squamous-cell carcinoma (SESC) in high-risk patients.

METHODS: We studied 17 patients (15 men and 2 women, 21 lesions) with SESC in whom endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD), and open surgery were contraindicated from March 1999 through February 2009. None of the patients could tolerate prolonged EMR/ESD or open surgery because of severe concomitant disease (e.g., liver cirrhosis, cerebral infarction, or ischemic heart disease) or scar formation after EMR/ESD and chemoradiotherapy. After conventional endoscopy, an iodine stain was sprayed on the esophageal mucosa to determine the lesion margins. The lesion was then ablated by APC. We retrospectively studied the treatment time, number of APC sessions per site, complications, presence or absence of recurrence, and time to recurrence.

RESULTS: The median duration of follow-up was 36 mo (range: 6-120 mo). All of the tumors were macroscopically classified as superficial and slightly depressed type (0-Ⅱc). The preoperative depth of invasion was clinical T1a (mucosal cancer) for 19 lesions and clinical T1b (submucosal cancer) for 2. The median treatment time was 15 min (range: 10-36 min). The median number of treatment sessions per site was 2 (range: 1-4). The median hospital stay was 14 d (range: 5-68 d). Among the 17 patients (21 lesions), 2 (9.5%) had recurrence and underwent additional APC with no subsequent evidence of recurrence. There were no treatment-related complications, such as bleeding or perforation.

CONCLUSION: APC is considered to be safe and effective for the management of SESC that cannot be resected endoscopically because of underlying disease, as well as for the control of recurrence after EMR and local recurrence after chemoradiotherapy.

INTRODUCTION

In Japan, 329 314 persons died of malignant neoplasms in 2006; esophageal cancer was the cause of death in 11 345 persons (3.45%). Esophageal cancer is the sixth most common type of cancer in men[1]. Squamous-cell carcinoma accounts for 90% of all esophageal carcinomas. Other histologic types, including adenocarcinoma, account for approximately 5%[2]. Approximately 90% of all esophageal cancers arise in the thoracic esophagus, and the middle thoracic esophagus is the most frequent location.

Progress in endoscopic diagnostic techniques, such as iodine staining and magnifying endoscopy with narrow band imaging, has led to the detection of increased numbers of superficial carcinomas of the esophagus[3-8]. In Japan, endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) are widely used as standard procedures for the treatment of superficial esophageal squamous-cell carcinoma (SESC)[9-13]. Radiofrequency ablation (RFA) is used as an endoscopic treatment for superficial esophageal cancer in Western countries, but it is not used in Japan because this procedure is not covered by the National Health Insurance system for the treatment of superficial esophageal carcinoma[14].

Several studies have reported that argon plasma coagulation (APC) is useful for the management of Barrett's esophagus[15], Barrett's esophageal cancer[16] and early gastric cancer[17,18], but few studies have evaluated APC in patients with SESC[19,20]. We retrospectively studied the safety and usefulness of APC for SESC in high-risk patients with underlying diseases that precluded EMR and ESD and in those in whom APC was performed to control local recurrence after EMR or chemoradiotherapy.

MATERIALS AND METHODS

The study group comprised 17 patients (15 men and 2 women; 21 lesions) who underwent ablation of their tumors by APC at the Department of Gastroenterology, Kitasato University East Hospital, from March 1999 through February 2009 (Table 1). The median age of the subjects was 68 years (range: 57-80 years). At the time of diagnosis, 11 patients were asymptomatic, and SESC was diagnosed incidentally on screening examinations for other diseases (peptic ulcer in 5 patients, esophageal varices in 2, gastritis in 2, after surgery for gastric cancer in 1, and after surgery for tongue cancer in 1). The other 6 patients exhibited symptoms (epigastric pain in 3, heartburn in 2, and hoarse voice in 1), and SESC was diagnosed upon further evaluation. All of the tumors were macroscopically classified as superficial and slightly depressed type (0-Ⅱc). The tumor diameter ranged from approximately 1 cm to approximately half of the circumference of the esophagus. The preoperative depth of invasion was clinical T1a (mucosal cancer) for 19 lesions and clinical T1b (submucosal cancer) for 2. Histopathologically, all of the tumors were confirmed to be esophageal squamous-cell carcinomas. EMR and ESD could not be performed because of underlying disease in 11 patients (15 lesions). APC was used to treat local recurrence after EMR or multiple metachronous tumors in 4 patients (4 lesions) and to manage local recurrence after chemoradiotherapy in 2 patients (2 lesions). Of the 17 patients, 13 (76.5%) had the following underlying diseases: liver cirrhosis in 5 patients, heart disease in 4, cerebral infarction in 1, after right lung resection with thrombophlebitis in 1, colon cancer operation in 1, and dementia in one patient. After informed consent was obtained from patients in whom anticoagulants could not be discontinued, those in whom prolonged endoscopic therapy was precluded by respiratory failure, and a patient aged 80 years, these patients asked to undergo APC among other possible treatment options. APC was therefore performed.

Table 1 Patient and lesion characteristics

Gender (men/women)	15/2
Mean age (range), yr	68 (57-80)
Location Ce/Ut/Mt/Lt/Ae	0/0/14/7/0
Macroscopic type	0-Ⅱc 21
Depth of invasion	T1a (m) 19
	T1b (sm) 2
Previous treatment	6 (35.3%) (EMR 3, ESD 1, and CRT 2)
Concomitant disease	13 (76.5%) (liver cirrhosis 5, heart disease 4, cerebral infarction 1, other 3)

EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; CRT: Chemoradiotherapy.

Before APC, endoscopy was performed to evaluate the macroscopic characteristics of the tumor. Next, 1.5% Lugol's solution (a diluted iodine-potassium solution) was sprayed on the mucosa to assess the lesion margins, and a biopsy specimen was taken and examined histopathologically. Endoscopic ultrasonography (probe, UM-DP20-25R, Olympus, Tokyo, Japan) was also performed before treatment to assess the depth of invasion. The absence of metastasis was confirmed by computed tomography. All of the tumors were macroscopically classified as superficial in type according to the Guidelines for Clinical and Pathologic Studies on Carcinoma of the Esophagus by the Japanese Society for Esophageal Disease[21]. If possible, oral anticoagulants and antiplatelet agents were discontinued before treatment. APC was performed using an Olympus videoscope, a high-frequency oscillator unit (Erbotom ICC200, 1999 to 2004 or APC 2, 2004 to 2009, Elektromedizin Co. Ltd., Tuebingen, Germany), an argon gas supply unit, and a flexible argon plasma coagulator with an argon gas flow of 2 L/min and a high-frequency output of 40 W. The treatment technique was as follows. After conventional endoscopy, the lesion was stained with iodine (Figure 1A, B), and its circumference was marked by APC (Figure 1C). Subsequently, the entire

mo. Recurrence was confirmed by endoscopic examination after the application of iodine staining and biopsy. We retrospectively studied the treatment time, the number of APC sessions per site, the presence or absence of recurrence, the time to recurrence, and complications. The median follow-up period was 36 mo (range: 6-120 mo). Informed consent was obtained from all patients in accordance with the ethical guidelines of the Declaration of Helsinki.

RESULTS

The patients' demographic characteristics are shown in Tables 1 and 2. The results of treatment and follow-up are shown in Table 3. The median time per one-treatment session was only 15 min (range: 10-36 min). The median number of treatment sessions per site was 2 (range: 1-4). There were no treatment-related complications, such as bleeding or perforation. The median duration of follow-up was 36 mo (range: 6-120 mo). Among the 21 lesions, 19 (90.0%) showed no evidence of recurrence. The 2 other lesions recurred locally 3 mo and 7 mo after APC, respectively. Both recurrences were treated by repeat APC ablation. At the time of this writing, 1 patient had died of tongue cancer and the others were alive, with no distinct evidence of metastasis or recurrence.

Case presentation

The patient was a 71-year-old man who had 4 lesions. APC was selected for treatment because prolonged ESD would have been difficult. Superficial and slightly depressed type (0-Ⅱc) lesions unstained with iodine staining were found at 4 sites, located 27 cm, 30 cm, 34 cm, and 36 cm from the incisor teeth (all of the lesions were classified as clinical T1a) (Figure 2A). APC ablation was performed at all 4 sites (Figure 2B). Follow-up endoscopy after 2 years showed no lesions *via* iodine staining and no other evidence of recurrence (Figure 2C).

DISCUSSION

APC is a non-contact technique that uses argon gas to induce tissue coagulation. In the field of gastrointestinal endoscopy, APC has been used to arrest gastrointestinal bleeding[22], ablate Barrett's esophagus[14], perform sclerotherapy of esophageal varices, and treat early gastric cancer[17,18]. At present, EMR and ESD are the endoscopic treatments of choice for superficial esophageal cancer, and studies of APC in patients with SESC are scarce[19,20].

However, EMR and ESD are associated with an increased risk of bleeding in patients with liver cirrhosis or esophageal varices and those who are receiving anticoagulant therapy[23]. Akiyama *et al*[24] used endoscopic variceal ligation for minute cancer of the esophagogastric junction accompanied by esophageal varices associated with a high risk of bleeding. ESD is thus often difficult to perform safety[25,26].

In this study, we evaluated the usefulness and safety of APC in 11 patients (15 lesions) in whom EMR was precluded by concurrent disease, 4 with recurrence after EMR, and 2 with local recurrence after chemoradiotherapy. Of the 17 patients, 13 (76.5%) had underlying diseases, such as cardiopulmonary disease and liver cirrhosis (Table 1). Two patients (9.5%) experienced tumor recurrence but received repeat APC with no subsequent recurrence. No patient experienced complications such as bleeding or perforation.

Gastrointestinal perforation caused by APC has been reported[27,28]. Grund *et al*[29] performed APC in a large series of patients and reported that the incidences of gastrointestinal perforation and intestinal emphysema were 0.25% and 0.46%, respectively. The possibility of complications should thus be borne in mind when APC ablation is performed.

Patients with recurrence after EMR or local recurrence after chemoradiotherapy have scars caused by prior treatment, increasing the risk of perforation on repeat EMR. Nomura *et al*[30] used APC to control local recurrence after chemoradiotherapy and recurrence after EMR. Both conditions could be treated safely within a short time. Two of 10 patients experienced recurrence, but APC exhibited a low risk of perforation and allowed oral intake to be resumed earlier than EMR. APC was therefore recommended for patients in whom EMR is difficult to perform. In our study, APC was completed safely and within a short time.

Photodynamic therapy is another option for the endoscopic treatment of superficial esophageal cancer but requires pretreatment and light shielding after application[31,32]. In contrast, APC is more convenient and straightforward, with a simple treatment procedure.

In conclusion, our results showed that APC effectively ablated SESC in patients with underlying disease and in those in whom EMR and ESD were not feasible. By repeating APC as required, the tumors were reliably ablated. APC is thus considered to be a safe and effective treatment that can be accomplished within a relatively short time. To confirm our results, additional prospective studies of larger numbers of patients are needed.

COMMENTS

Background

In Japan, endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) are standard treatments for superficial esophageal squamous-cell carcinoma (SESC). However, the use of these procedures is contraindicated by underlying disease in certain patients.

Research frontiers

Argon plasma coagulation (APC) is useful for the management of Barrett's esophageal cancer and early gastric cancer, but few studies have evaluated APC in patients with SESC.

Innovations and breakthroughs

APC effectively ablated SESC in patients with underlying disease, as well as in those for whom EMR and ESD were not feasible.

Applications

APC is considered to be safe and effective for the management of superficial carcinoma of the esophagus that cannot be resected endoscopically because of underlying disease, as well as for the control of recurrence after EMR and local recurrence after chemoradiotherapy.

Peer review

In this study, the authors performed retrospective study that assessed the clinical usefulness and safety of APC for SESC in high risk patient. This study showed APC would be one of the good option to treat SESC especially in high risk patient, although further prospective study in large sample size is necessary to conclude it.

Abstract

AIM: To identify the prevalence of pre-S2 start codon mutations and to assess their association with liver disease progression.

METHODS: The mutations were identified by direct sequencing from 73 asymptomatic carriers, 66 chronic hepatitis (CH), 66 liver cirrhosis (LC) and 63 hepatocellular carcinoma (HCC) patients. Statistical significances were determined using Fisher's exact test, χ^2 test, and *t*-test analyses whenever appropriate. Pre-S mutation as a risk factor for advanced liver disease was estimated by unconditional logistic regression model adjusted with age, sex, and hepatitis B e antigen (HBeAg). $P < 0.05$ was considered significant.

RESULTS: Mutation of the hepatitis B virus (HBV) pre-S2 start codon was found in 59 samples from 268 subjects (22.0%), with higher prevalence in patients with cirrhosis 27/66 (40.9%) followed by HCC 18/63 (28.6%), chronic hepatitis 12/66 (18.2%) and asymptomatic carriers 2/73 (2.7%) ($P < 0.001$). Logistic regression analysis showed that pre-S2 start codon mutation was an independent factor for progressive liver disease. Other mutations, at T130, Q132, and A138, were also associated with LC and HCC, although this was not statistically significant when adjusted for age, sex, and HBeAg. The prevalence of pre-S2 start codon mutation was higher in HBV/B than in HBV/C (23.0% *vs* 19.1%), whilst the prevalence of T130, Q132, and A138 mutation was higher in HBV/C than in HBV/B. The prevalence of pre-S2 start codon mutation was higher in LC (38.9%) and HCC (40.0%) than CH (5.6%) in HBeAg(+) group, but it was similar between CH, LC and HCC in HBeAg(-) group.

CONCLUSION: Pre-S2 start codon mutation was higher in Indonesian patients compared to other Asian countries, and its prevalence was associated with advanced liver disease, particularly in HBeAg(+) patients.

INTRODUCTION

Hepatitis B virus (HBV) infection is one of the most important infectious diseases worldwide. It is the major cause of chronic hepatitis (CH), liver cirrhosis (LC), and hepatocellular carcinoma (HCC). About 40% of the world's population has had contact with, or are carriers of, HBV and it is estimated that more than 350 million people world wide have chronic liver infection[1]. Indonesia has a moderate to high endemnicity of HBV infection[2], perhaps due to the lack of proper health facilities, poor economical status, less public awareness, or incomplete vaccination.

HBV is a relaxed circular, partially double stranded 3.2 kb DNA virus[3]. It has four overlapping reading frames that encode Polymerase, Core, X and Envelope proteins[4]. The Envelope proteins are produced from a single open reading frame with three different translation sites, pre-S1, pre-S2, and S. It produces three forms of HBV surface proteins (HBs), which are the large (L), middle (M) and small (S) HBs[5]. The major component of the Envelope protein is S protein which consists of 226 amino acids and drives particle budding. The M protein is composed of the S protein with an additional of 55 amino acids termed pre-S2 attached to the N-terminus. The L protein is the M protein with an additional 108 or 119 genotype-dependent amino acids attached to the N-terminus[6].

The pre-S1 and pre-S2 region is the region with the most variability in the HBV genome[7]. This variability is in the form of deletions, insertions, or synonymous or non-synonymous nucleotide substitutions. The pre-S1 and pre-S2 regions encode the T- and B-cell epitopes which play roles in allowing neutralizing antibodies to bind, and consequent immune protection[8,9]. Therefore, HBV pre-S mutant variants may emerge as a result of selective immune pressure.

The high prevalence of HBV pre-S mutations in Asia, including pre-S deletion and pre-S2 start codon mutations, has been reported, and it has been demonstrated that these mutations were associated with progressive liver disease[10]. In addition, amino acid substitution from Phenylalanine to Lysine at codon 141 in pre-S2 region (F141L) is also associated with HCC in patients infected with HBV genotype C[11]. Furthermore, study of hepatitis B e antigen (HBeAg) (-) patients in China revealed that pre-S deletions alone, or in combination with mutations in precore and basal core promoter (BCP) of HBV, are also associated with advanced liver disease[12].

Studies on the prevalence of HBV genotypes, BCP and precore mutations, and their association with severity of liver disease in Indonesia have previously been reported[13-15]. We have recently published a molecular epidemiological study on the prevalence of pre-S deletion mutation in Indonesian subjects[16], but this paper did not describe the incidence of synonymous and non-synonymous mutations in the pre-S region. Therefore, we extended this study to investigate the prevalence of pre-S2 start codon mutation and its association with severe liver disease in Indonesian patients. In addition, other mutations in the pre-S2 regions were analyzed.

MATERIALS AND METHODS

Samples

Blood samples were obtained from 270 HBV carriers. Two subjects with genotype D were excluded due to its relatively low prevalence in the collective samples and also in Asian population in general. A total of 268 subjects were included in the study: 73 asymptomatic carriers (AC) and 195 liver disease patients which composed of 66 CH, 66 LC, and 63 HCC. Asymptomatic carrier samples were taken from donors with positive HBsAg from the Blood Transfusion Unit (Red Cross Makassar, South Sulawesi, Indonesia), between February and August 2007. Chronic hepatitis samples were from patients positive for HBsAg for more than six months, and who had more than twice the normal alanine aminotransferase (ALT) level. Liver cirrhosis was diagnosed by liver function tests and ultrasonography, whilst the diagnosis of HCC was either on the basis of ultrasonography as well as an elevated serum-fetoprotein (AFP) level (≥ 200 ng/mL), or by needle aspiration liver biopsy for samples in which the AFP level was low. Samples from CH, LC, and HCC patients were collected from Cipto Mangunkusumo Hospital, Gatot Soebroto Hospital, Klinik Hati, Jakarta, Siloam Hospital Lippo Karawaci, Tangerang, Mataram General Hospital, Mataram, Wahidin Sudirohusodo Hospital, Makassar, and M. Djamil Hospital, Padang, from May 2006 to February 2010. None of the samples had coinfection with hepatitis C virus. The HBsAg test for all samples was performed using a commercially available enzyme-linked immunosorbent assay, kit (Abbott Laboratories, Chicago, IL, United States). The HBeAg status of samples was tested by using rapid test (Intec, Xiamen, China) as described previously[16]. Blood samples were separated into plasma and stored at -70 ℃ until use. The study was

approved by the Committee on Health Research Ethics of the Mochtar Riady Institute for Nanotechnology and informed consent was obtained from each subject.

Viral DNA extraction, polymerase chain reaction and sequencing

HBV DNA was extracted from 200 μL plasma using the QIAamp DNA blood mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions, and 80 μL of eluted DNA was stored at -70 ℃ until use. Pre-S region was amplified by nested polymerase chain reaction (PCR) using PCR Core System (Promega, Madison, WI, United States) and two sets of primers as previously described[16]. The first round was performed with primers PS1 (5'-GGGTCACCTTATTCTTGGGA-3', position 2814-2833) and PS2 (5'-CCCCGCCTGTAACACGAGCA-3', position 208-189). For the second round, primers PS3 (5'-TTGGGAACAAGATCTACAGC-3', position 2828-2847) and PS4 (5'-GTCCTGATGCGATGTTCTCC-3', position 176-157) were used. First and second round PCR were performed with the same profile for 36 cycles of 94 ℃ for 1 min, 58 ℃ for 30 s and 72 ℃ for 1 min in a thermal cycler. The PCR products were purified with Wizard® SV Gel and PCR Clean-Up System (Promega, Madison, WI, United States), directly sequenced employing an ABI 3130xl Genetic Analyzer (Applied Biosystems, Inc., Foster City, CA, United States) with the Big Dye Terminator V3.1 Cycle Sequencing kit (Applied Biosystems, Inc.) using primers PS3 and PS4[13-16].

Hepatitis B virus genotyping and pre-S mutations analysis

The HBV genotype was determined by phylogenetic analysis of the pre-S sequences. The sequences were compared to 74 HBV reference strains of eight HBV genotypes (A-H) from GenBank. Alignment and phylogenetic trees were constructed using molecular evolutionary genetics analysis 4 software (Center for Evolutionary Functional Genomics, Tempe, AZ, United States)[17]. Pre-S amino acid sequences were aligned and compared between each group to detect the mutations.

Statistical analysis

All statistical analyses were performed using SPSS 17.0 software for Windows (SPSS Inc., Chicago, IL, United States). Statistical significances were determined using Fisher's exact test, χ^2 test, and *t*-test analyses whenever appropriate. The odds ratio and 95% CI were estimated by unconditional logistic regression model to evaluate the association of Pre-S mutation as a risk factor for advanced liver disease adjusted with age, sex and HBeAg. $P < 0.05$ was considered to be statistically significant.

RESULTS

Demographic data of subjects

Demographic data of subjects are shown in Table 1. A total of 268 subjects comprising 73 AC, 66 CH, 66 LC and 63 HCC were included in the study. The male/female ratio was significantly different among the groups ($P = 0.002$). The mean of ages for AC, CH, LC, and HCC was 32.3 ± 9.1, 41.9 ± 13.3, 50.1 ± 10.9 and 48.6 ± 11.6 years, respectively, and it was significantly different among the group ($P < 0.001$). Ratio of HBV/B to HBV/C showed no significant difference among the groups ($P = 0.267$). Of 268 subjects, 235 subjects were available for HBeAg rapid test analysis. Of 235 subjects, 82 (34.9%) had HBeAg(+) and 153 (65.1%) had HBeAg(-) and the distribution was significantly different among the group ($P < 0.001$).

Prevalence of pre-S2 start codon mutation and its association with the risk of advanced liver disease

Pre-S2 start codon mutations were found in 22.0% (59/268) of the total samples (Table 1). The mutation

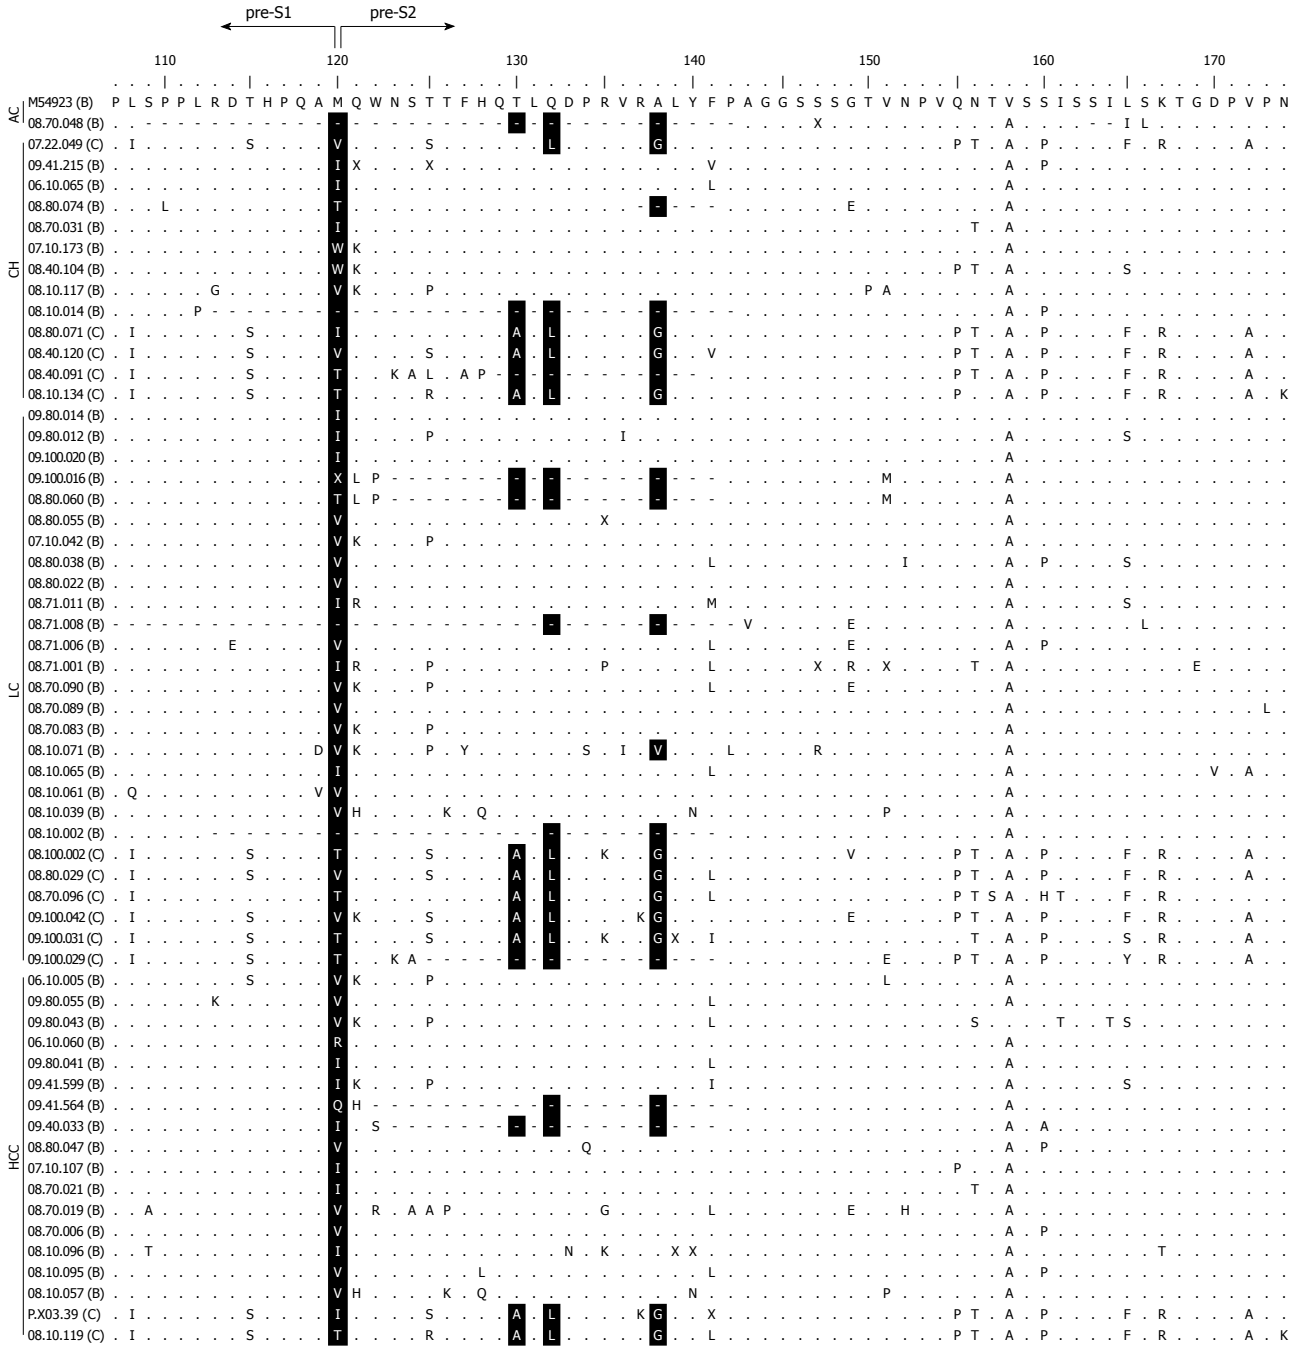

Figure 1 Amino acid alignment of 59 hepatitis B virus sequences harboring pre-S2 start codon mutation with wild type reference M54923 (genotype B). Positions of mutations are shown in black shades (M120, T130, Q132, and A138). Dots represent identical amino acids to the consensus sequence. Dashes represent deletion mutation. The names of the samples are indicated with each respective genotype in parentheses. AC: Asymptomatic carrier; CH: Chronic hepatitis; LC: Liver Cirrhosis; HCC: Hepatocellular carcinoma.

(M120) was either an amino acid substitution from Methionine to other amino acids or a deletion mutation (Figure 1). The prevalence of this mutation was significantly different among the groups ($P < 0.001$), and was increasingly common as disease progressed from AC (2.7%) to CH (18.2%) and LC (40.9%), but was less common in those with HCC (28.6%) than with LC but this difference was not statistically significant (Figure 2A). Multivariate regression analysis (based on 235 subjects with complete HBeAg) adjusted with age, gender and HBeAg demonstrated that M120 mutation was an independent factor in the development of progressive liver disease [OR 3.996 (1.830-8.729), $P = 0.0005$] (Table 2). These results implied that this mutation was associated with progressive liver disease and more particularly with LC than HCC.

Prevalence of other mutations in the pre-S2 region

Beside the pre-S2 start codon (M120) mutation, other mutations in the pre-S region were also analyzed. It was found that the prevalence of three amino acid changes in

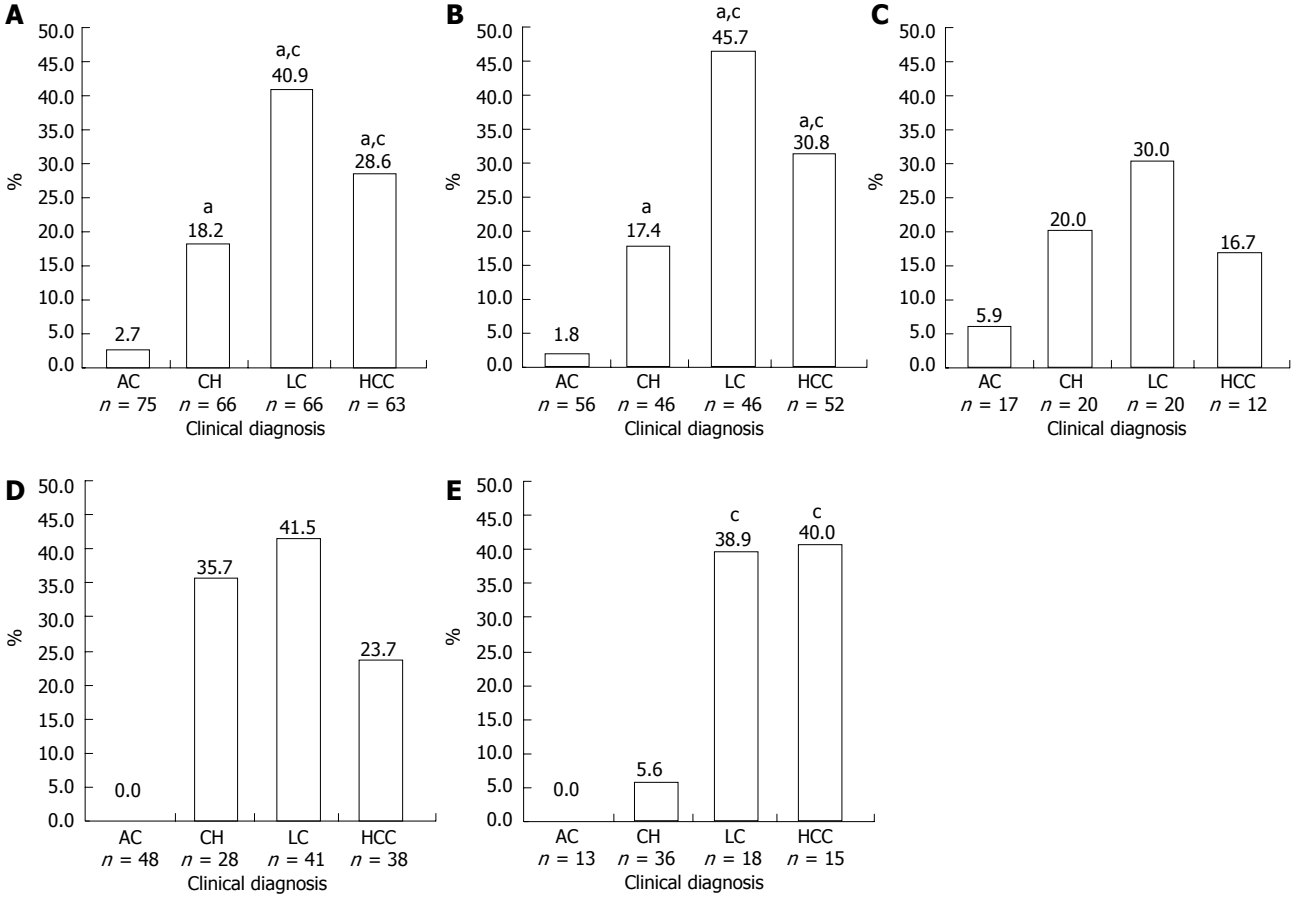

Figure 2 Prevalence of pre-S2 start codon mutation in all samples and in patients infected with hepatitis B virus/B, hepatitis B virus/C, hepatitis B e antigen (+), hepatitis B e antigen (-). A: Prevalence of pre-S2 start codon mutation in all samples; B: Prevalence of pre-S2 start codon mutation in patients infected with hepatitis B virus (HBV)/B; C: Prevalence of pre-S2 start codon mutation in patients infected with HBV/C; D: Prevalence of pre-S2 start codon mutation in patients with hepatitis B e antigen (HBeAg) (-); E: Prevalence of pre-S2 start codon mutation in patients with HBeAg(+). $^{a}P < 0.05$ *vs* AC; $^{c}P < 0.05$ *vs* CH. AC: Asymptomatic carrier; CH: Chronic hepatitis; LC: Liver cirrhosis; HCC: Hepatocellular carcinoma.

the pre-S2 region showed significant differences among the groups (Table 1). Amino acid substitution from Threonine to other amino acids or deletion at codon 130 (T130) was detected in 26.1% of the samples, and the percentage increased in more severe liver disease ($P = 0.002$). Changes from Glutamine to other amino acids, or deletion at codon 132 (Q132), was found in 28.7% of the samples, and the prevalence was also increased with the severity of liver disease ($P = 0.008$). Similarly, amino acid substitution or deletion at Alanine 138 (A138) was found in 29.5% of samples and was highly prevalent in advanced liver disease ($P = 0.003$). Multivariate regression analysis showed that none of the mutations had significant association with progressive liver disease (Table 2).

Comparison of pre-S mutations in hepatitis B virus genotypes B and C

The samples were grouped into HBV/B and HBV/C and there were no significant differences in male/female ratios, mean age, or pattern of clinical diagnoses between the two groups (data not shown). Pre-S2 start codon mutation (M120) was more prevalent in HBV/B (23.0%) than in HBV/C (19.1%) (Table 3). In HBV/B, M120 mutation was associated with severity of liver disease ($P < 0.001$), but no association was found in HBV/C. The highest prevalence of M120 mutation in HBV/B was found in the LC group (45.7%), which was higher than that in the HCC group (30.8%), although not statistically significant (Figure 2B). Two other mutations in pre-S2 region (T130 and A138) showed significant association with the progress of liver disease in HBV/B ($P = 0.017$ and $P = 0.042$, respectively). In HBV/C, there was no association of the M120 mutation or the other mutations with progressive liver disease (Table 3, Figure 2C).

Comparison of pre-S mutations in HBeAg(-) and in HBeAg(+) patients

As shown in Table 4, the HBeAg(-) and HBeAg(+) groups differed significantly in the ratio of males to females, mean age, and pattern of clinical diagnoses. More male subjects were found in the HBeAg(-) group than in the HBeAg(+) group (83.0% *vs* 70.7%, $P = 0.035$). The mean age of subjects in the HBeAg(-) was greater than in HBeAg(+) group (44.7 ± 13.9 years *vs* 39.2 ± 11.9 years, $P = 0.003$). The prevalence of M120 mutations was higher in the HBeAg(-) group than in the HBeAg(+) group (23.5% *vs* 18.3%) (Table 5). The prevalence of this mutation was significantly different among the samples

with different clinical diagnoses both in HBeAg(-) and HBeAg(+) patients. In the HBeAg(-) group, the highest prevalence of M120 mutation was found in LC (41.5%), followed by CH (35.7%) and HCC (23.7%), and no mutations were found in the AC group. However, no statistically significant differences were found between CH, LC and HCC (Figure 2D). Among HBeAg(+) patients, the highest frequency of M120 mutation was detected in those with HCC (40.0%), followed by those with LC (38.9%), and CH (5.6%), and no mutations were found in the AC group. Significant differences were found between those with CH and LC and CH and HCC, but not between those with LC and HCC (Figure 2E). On the other hand, no significant correlation of T130, Q132 and A138 mutations with severity of liver disease was found in either the HBeAg(+) or HBeAg(-) groups (Table 5).

DISCUSSION

Many studies have been reported on the association of pre-S mutations with severity of liver disease. Studies from Taiwan and China demonstrated that the pre-S deletion mutation is associated with HCC[18-20]. In addition, the pre-S2 deletion mutation was also specifically associated with increased risk of HCC in Asian children[21]. Other studies also reported that pre-S deletion and pre-S2 start codon mutations was found to be significantly associated with HCC[22,23]. A meta analysis study including 43 reports found that mutations at the promoter sites of pre-S1 and pre-S2 are significantly associated with an increased risk of HCC[24]. However, the diagnostic or predictive value of those mutations for HCC is limited because the frequencies of these mutations in the pa-

tients with HCC were low; pre-S1 and pre-S2 promoter mutations were 19.7% and 15.3%, respectively[24].

Recently, we reported on the prevalence of pre-S deletion mutation in Indonesian HBV carriers. The prevalence of pre-S deletion was 12.1% which is considered low compared to previous reports from other populations[16]. In the present study, which extends the analysis of this group of patients, pre-S2 start codon mutations were found in 22.0% of the samples. In Indonesia, it therefore appears that the pre-S2 start codon mutation is a more common type of mutation compared to the pre-S deletion mutation. The prevalence of pre-S2 start codon mutations was higher in the cirrhosis group than the HCC group, which is in accordance with the previous report[22]. Both pre-S2 deletion and start codon mutations cause alterations or loss of the M-protein, which has the T- and B-cell epitopes. These altered M-proteins can stimulate hepatocyte proliferation, and cause the formation of type II ground glass hepatocytes[25,26]. In this study, it was found that this mutation is more prevalent in the liver cirrhosis group, which was older than the other groups, indicating prolonged infection by HBV in this group. It has been suggested that pre-S2 deletion mutations, which affect the T-cell epitope and hence the ability of the virus to be neutralized, represent mutants that are selected under immune pressure, and are thus able to persist during chronic HBV infection[26]. Pre-S2 start codon mutations may have the same effect, since the mutation prevents production of M-protein. Furthermore, it has been reported that the loss of M-protein does not affect virus infectivity, but instead it may function as a spacer that supports conformational changes of L protein, or as a subdomain of the L protein in virus entry[6]. In this way it might allow mutants that lack M protein to emerge without affecting the virus life cycle.

Other mutations in the pre-S2 region were shown to be significantly associated with progressive liver disease. However regression analysis showed these amino acid changes or deletion at three codon sites, T130, Q132, and A138 were not statistically significantly associated with the increased risk of cirrhosis and HCC. The prevalence of these three mutations was considerably higher in the HCC group (38.5%-40.0%). Few studies on amino acid substitutions in the pre-S2 region and their association with progressive liver disease have been reported. An amino acid change from Glycine to Arginine at pre-S2 at codon 149 (G149R) was found in 52.9% of chronic carriers with spontaneous clearance of HBV surface antigen[27]. More recently it was found that a mutation at position 141 (F141L mutation) was associated with increased risk of HCC in patients with HBV/C infections[11]. However the mutation found in this study did not correlate with coexistence of HBsAg and anti-HBs, but may alter the B- and T-cell epitopes of the S protein, and thereby increase the risk of cirrhosis and HCC by decreasing immune recognition.

In the present study, the prevalence of pre-S2 start codon mutation was higher in HBV/B than HBV/C, although the difference was not statistically significant. In addition, a significant association of pre-S2 start codon mutation with severe liver disease was found in HBV/B, while there was no significant difference in the frequency of this mutation in HBV/C. A study in Thailand revealed a higher prevalence of pre-S2 deletions and preS2 start codon mutation in HBV/C than in HBV/B[28]. Another recent report showed a higher prevalence of pre-S2 deletions in HBV/C and this was associated with HCC in children[29]. The differences between previous studies and the present study are probably due to the difference in percentage of HBV/C samples in subjects included in the studies (the number of HBV/C infections was lower in the present study). On the other hand, in the present study, the prevalence of the three other mutations in the pre-S2 region (T130, Q132, and A138) was higher in those with HBV/C than those with HBV/B. In those with HBV/B, the incidence of T130 and A138 mutations was significantly different between the disease groups, and was increased with advanced liver disease (Table 3). However, the prevalence of these mutations was not significantly different between disease groups with HBV/C, possibly due to the low number of HBV/C samples included in this study.

The prevalence of pre-S2 start codon mutations was higher in HBeAg(-) samples than in HBeAg(+) samples (23.5% *vs* 18.3%), but interestingly in the HCC group the prevalence of this mutation was higher in HBeAg(+) samples than in HBeAg(-) samples (40.0% *vs* 23.7%) (Table 5). No mutations were found in asymptomatic carriers of either group. The prevalence of mutations in the HBeAg(+) group showed significant association between chronic hepatitis and cirrhosis as well as HCC, while in the HBeAg(-) group there were no differences found among CH, LC and HCC. Previous studies have described the roles of pre-S deletions on the progression of liver disease in HBeAg(-) patients in longitudinal study, and found that pre-S deletions were significantly associated with the development of liver cirrhosis[12]. In

another longitudinal study observing the natural course of HBV there was no clear relationship between HBeAg seroconversion and pre-S deletions[30]. The present study was a cross-sectional study which is limited by uncertainty whether these mutations preceded the development of advanced liver disease. However, it does suggest that pre-S2 start codon mutations can be used as a predictor for development of advanced liver disease in HBeAg(+) patients (Figure 2E), but not in HBeAg(-) patients (Figure 2D). Interestingly, the frequency of T130, Q132, and A138 mutations was similar between the two groups (Table 5), indicating that the mutations in this region are not related to HBeAg seroconversion. In summary, our study demonstrated that the pre-S2 start codon mutation has high prevalence in Indonesia. This mutation may serve as biomarker for prediction of development of advanced liver disease in HBeAg(+) patients who are infected with HBV genotype B.

COMMENTS

Background

Hepatitis B virus (HBV) infection is a serious worldwide health problem. Indonesia is one of the countries with high endemicity of hepatitis B related disease caused by HBV. Particular mutations of the HBV genome have been associated with severe liver disease. Studies on HBV molecular epidemiology associated with the development of progressive liver disease in Indonesia are still very scarce. This study is to characterize the prevalence of pre-S2 mutation in HBV associated with advanced liver disease in Indonesia.

Research frontiers

Pre-S mutations have been reported to be associated with advanced liver disease. Pre-S deletion and pre-S2 start codon mutations were the most common form of mutations at the pre-S region of HBV. Previous study had shown the low prevalence of pre-S deletion in Indonesian patients; however the prevalence of the pre-S2 start codon mutation has not been fully investigated. In this study, the authors demonstrated that the pre-S2 start codon mutation could serve as a biomarker for liver disease progression.

Innovations and breakthroughs

Previous studies have reported the high prevalence of HBV pre-S deletions and its association with advanced liver disease. But contrary to reports from studies of other populations, previous and current studies showed that pre-S2 start codon mutations and not pre-S deletion may serve as potential biomarkers for progressive liver disease in Indonesia.

Applications

By characterizing the prevalence of the HBV pre-S2 start codon mutation among different clinical diagnoses of different HBV genotype and hepatitis B e antigen (HBeAg) presence, the pre-S2 start codon mutation may serve as a potential biomarker for prediction of development of advanced liver disease in HBeAg(+) patients who are infected with HBV genotype B.

Terminology

HBV surface (HBs) gene has three different translation sites, pre-S1, pre-S2, and S, which produce large-, middle-, and small-HBs protein, respectively. Pre-S2 start codon mutation is a substitution or deletion of Methionine at the pre-S2 translation site which abolished the M HBs protein.

Peer review

The manuscript is interesting because the authors suggest a way to predict liver disease progression according to the appearance of a mutation at pre-S2 start codon in a subset of HBV infected patients.

Abstract

AIM: To investigate oxaliplatin-induced severe anaphylactic reactions (SAR) in metastatic colorectal cancer in a retrospective case series analysis and to conduct a systemic literature review.

METHODS: During a 6-year period from 2006 to 2011 at Kaohsiung Veterans General Hospital, a total of 412 patients exposed to oxaliplatin-related chemotherapy were retrospectively reviewed. Relevant English-language studies regarding life-threatening SAR following oxaliplatin were also reviewed in MEDLINE® and PubMed® search.

RESULTS: Eight patients (1.9%, 8 of 412 cases) were identified. Seven patients were successful resuscitated without any sequelae and one patient expired. We changed the chemotherapy regimen in five patients and rechallenged oxaliplatin use in patient 3. Twenty-three relevant English-language studies with 66 patients were reported. Patients received a median of 10 cycles of oxaliplatin (range, 2 to 29). Most common symptoms were respiratory distress (60%), fever (55%), and hypotension (54%). Three fatal events were reported (4.5%). Eleven patients (16%) of the 66 cases were rechallenged by oxaliplatin.

CONCLUSION: SAR must be considered in patients receiving oxaliplatin-related chemotherapy, especially in heavily pretreated patients. Further studies on the mechanism, predictors, preventive methods and management of oxaliplatin-related SAR are recommended.

INTRODUCTION

Colorectal cancer (CRC) accounts for 10% to 15% of all cancers and is the third leading cause of cancer deaths in Taiwan. Oxaliplatin is a third generation platinum compound frequently used in the treatment of stage Ⅲ CRC as adjuvant chemotherapy[1] and stage Ⅳ advanced CRC[2]. Similar to other platinum compounds, oxaliplatin interacts with DNA to form intra-strand/inter-strand

DNA cross-linking that can affect DNA base pairing, replication, and gene transcription and cause cell death[3]. Among the common reasons for its withdrawal are frequent peripheral neuropathy, a delayed hypersensitivity reaction, and most troublesome, anaphylaxis when patients receive accumulated doses of oxaliplatin[4]. Hypersensitivity reaction and anaphylaxis refers to undesirable reactions produced by the normal immune system, including allergies and autoimmunity. These reactions may be damaging, uncomfortable, or occasionally fatal.

Multiple mechanisms of action have been proposed including the use of various neuroprotective agents in the hope of achieving adequate oxaliplatin doses with less neuropathy[5]. Much less is known about acute reactions such as anaphylaxis, and it is generally considered to be associated with immune-mediated effects[6,7]. The percentage of hypersensitivity reactions quoted in different studies ranges from 8% to 20%, but is usually around 10% to 12%[8]. Life-threatening severe anaphylactic reactions (SAR) have been reported but no systemic review of their incidence has been undertaken. Therefore, we performed a retrospective analysis of our patients who had been exposed to oxaliplatin and selected those who developed SAR requiring hospitalization with medical intervention. We also conducted a systemic literature review on this issue.

MATERIALS AND METHODS

Chart review

During a 6-year period from 2006 to 2011 at Kaohsiung Veterans General Hospital, a total of 412 patients exposed to oxaliplatin-related chemotherapy were retrospectively reviewed. Life-threatening SAR was defined as side effects including symptomatic bronchospasm, allergy-related edema/angioedema, hypotension or anaphylaxis (grade Ⅲ/Ⅳ anaphylactic reactions reference by NIH common Toxicity Criteria v3.0) requiring hospitalization and medical interventions[9]. The oxaliplatin-related chemotherapy regimen (FOLFOX) consisted of leucovorin 200 mg/m^2 as a 2-h infusion, and oxaliplatin 85 mg/m^2 given as a 2-h infusion in 500 mL of dextrose 5% *via* a Y-connector, followed by a 46-h infusion of 5-fluorouracil 2500 mg/m^2, repeated every 2 wk. Antiemetic prophylaxis with a 5HT3-receptor antagonist was administered. The use of implantable ports and disposable or electronic pumps allowed chemotherapy to be administered on an inpatient basis.

Data collection and literature review

Information collected included age, sex, allergy history, primary CRC site, tumor, nodes, metastasis classification, CRC stage, previous chemotherapy regimens, previous oxaliplatin-related chemotherapy cycles, oxaliplatin dosage, tumor response, onset time after oxaliplatin infusion, and outcome. Relevant English-language studies regarding life-threatening SAR following oxaliplatin were also reviewed. We searched the relevant studies by entering keywords "severe side effect after oxaliplatin", "life-threatening reaction after oxaliplatin" and "severe anaphylactic reaction after oxaliplatin" in MEDLINE® and PubMed® searches.

RESULTS

Patient characteristics

Eight patients (1.9%, 8 of 412 cases) were identified who developed life-threatening SAR, which occurred after infusion of oxaliplatin-related chemotherapy. The patients' characteristics were described in Table 1. There were 4 females and patients' age ranged from 36 to 72 years. Three patients had rectal cancer, 4 patients had sigmoid colon cancer, and 1 patient had descending colon cancer. Two patients had an allergy history to alcohol and flurbiprofen respectively. All patients had stage Ⅳ metastatic disease and received several lines of different chemotherapy regimens. Patients had received 5-29 cycles of oxaliplatin-related chemotherapy. Oxaliplatin dosages were 85 mg/m^2 in six patients and 90 mg/m^2 in one patient. Stable disease was achieved in three patients and progressive disease in five patients. Onset time after oxaliplatin infusion ranged from immediate to two hours. Seven patients were successfully resuscitated with oxygen support and medical interventions and fully recovered without any sequelae. However, one patient suffered from SAR and shock status 20 min after infusion of oxaliplatin. Despite cardiopulmonary resuscitation and use of inotropic agents, this patient expired 50 min later. We changed the chemotherapy regimen in five patients and rechallenged oxaliplatin use in patient 3. Because the patient 3's disease manifestations responded well to FOLFOX chemotherapy regimen, continuation was felt to be desirable. We have thus decided to attempt rechallenge of oxaliplatin by prolonging the infusion rate and using premedication with an additional 100 mg hydrocortisone plus diphenhydramine before the next treatment course. Fortunately, no anaphylactic reactions developed thereafter.

Literature review

Twenty-three relevant English-language studies, published from 1997-2011, regarding SAR following oxaliplatin-related chemotherapy were reported (Table 2). All studies were retrospective; few included the same patients. We found 59 reported cases that fitted the definition of life-threatening SAR from MEDLINE® and PubMed®[8-30]. Together with the 8 cases we presented, the median cycles of oxaliplatin given before SAR developed was 10 (range, 2-29). Most common symptoms were respiratory distress (60%), fever (55%), and hypotension (54%). Three fatal events were reported (4.5%). Eleven patients from these 66 cases were rechallenged with oxaliplatin.

DISCUSSION

According to previous studies, the estimated incidence of oxaliplatin-induced SAR was less than 2%[10,17,18,24,31]. In 2007, Lee *et al*[24] reported the incidence of SAR as 1.32%

Table 1 Clinical characteristics of patients with life-threatening severe anaphylactic reactions following oxaliplatin chemotherapy (n = 8)

Patient	Sex	Age (yr)	Allergy history	Primary CRC site	TNM classification	Stage	Previous chemotherapy regimens	Previous oxaliplatin chemotherapy cycles	Oxaliplatin dose (mg/m^2)	Tumor response	Presenting symptoms	Onset time	Outcome	Rechallenge
1	F	50	Alcohol	Rectum	T4N0M1	Ⅳ	FOLFIRI x12, FOLFOX x10	10	85	SD	Consciousness loss, dizziness, shock	30 min	Recovery	No
2	M	71	Nil	Rectum	T2N1M1	Ⅳ	FOLFOX x12, FOLFIRI + Bevacizumabx12, FOLFOX x1	13	85	PD	Consciousness loss, shock	20 min	Fatal	No
3	M	36	Nil	Sigmoid colon	T4N2M1	Ⅳ	FOLFIRI x13, FOLFOX + Bevacizumab x5, FOLFIRI + Cetuximab x5, FOLFOX x7	12	90	PD	Consciousness loss, respiratory distress, cold sweating	Immediate	Recovery	Yes
4	F	57	Nil	Sigmoid colon	T1N0M1	Ⅳ	FOLFIRI x5, FOLFOX x7, FOLFIRI + Bevacizumabx18, FOLFOX + Bevacizumab x1	8	85	PD	Respiratory distress, cold sweating	2 h	Recovery	No
5	F	68	Nil	Sigmoid colon	T3N2M1	Ⅳ	FOLFIRI x12, FOLFOX x8	8	85	SD	Angioedema, slurred speech, respiratory distress	30 m	Recovery	No
6	F	72	Nil	Descending colon	T4N1M1	Ⅳ	FOLFIRI x7, FOLFOX x3, FOLFIRI x12, FOLFOX x2	5	85	PD	Nausea, vomiting, shock,	10 min	Recovery	No
7	M	59	Flurbiprofen	Rectum	T3N2M1	Ⅳ	FOLFOX x19, FOLFIRI x8, FOLFOX x10	29	85	SD	Consciousness loss, respiratory distress, cold sweating	Immediate	Recovery	No
8	M	62	Nil	Sigmoid colon	T3N1M1	Ⅳ	FOLFIRI + Bevacizumabx6, FOLFOX x7	7	85	PD	Consciousness loss, respiratory distress, cold sweating	20 min	Recovery	No

M: Male; F: Female; CRC: Colorectal cancer; TNM: Tumor, nodes, metastasis; PD: Progressive disease; SD: Stable disease; FOLFIRI: Chemotherapy regimen including 5-fluorouracil, leucovorin, irinotecan; FOLFOX: Chemotherapy regimen including 5-fluorouracil, leucovorin, oxaliplatin.

Table 2 Studies on severe anaphylactic reactions following oxaliplatin, including data published from 1997 to 2012 in English (24 studies, *n* = 66)

Ref.	Published year/region	Patient No.	Age (yr)	Male/female	Previous oxaliplatin cycles	Oxaliplatin dose (mg/m^2)	Presenting symptoms	Onset time after oxaliplatin infusion	Outcome

(4 of 303 cases) in Taiwan. In our study, the incidence is 1.9% (8 of 412 cases). Multiple suggestions to reduce the incidence of adverse reactions have been proposed, including the use of various neuroprotective agents, in the hope of achieving adequate oxaliplatin doses with less neuropathy[5]. Much less is known about acute reactions such as anaphylaxis, but this is generally considered to be associated with immune-mediated effects, as evidenced by detection of drug-dependent IgG antibodies with or without complement[6,7]. Two independent pathogenetic mechanisms have been proposed for this toxicity. Some authors described the formation of autoantibodies to erythrocytes and, more rarely, to platelets and neutrophils as a result of oxaliplatin adsorption on blood cells[32]. By contrast, other authors reported high levels of cytokines [i.e., interleukin (IL) 6, IL10 and tumor necrosis factor-α] suggesting that oxaliplatin-dependent toxicity may be triggered by a massive release of pro-inflammatory molecules[33].

In literature reviews, SAR developed after several cycles of oxaliplatin chemotherapy (median cycles before SAR is 10), suggesting a sensitization process of type I hypersensitivity due to the rapid appearance of symptoms[22,34]. Based on Chay *et al*[9], females appeared more prone to severe oxaliplatin reactions for which the reason remains unclear, and all females manifested acute hypokalemia. Recently reported ex-vivo work suggests that oxaliplatin may interfere with voltage-gated potassium channels[35] and hypothesizes that axonal membrane hyperpolarization[36,37] may account for the observed hypokalemia, with potassium ion channel activation resulting in an intracellular influx of potassium. However, in our study there were no such findings including female predominance and hypokalemia after the episode.

Theoretically, prolongation of the infusion rate with premedication including steroids and antihistamines could be a method to prevent SAR after oxaliplatin use. We adopted this strategy before rechallenging oxaliplatin in patient 3. However, in 2001 Stahl *et al*[38] reported that allergic reactions to oxaliplatin may still occur after steroid prophylaxis. In 2006, Siu *et al*[8] reported premedications with steroid and chlorpheniramine seemed ineffective in preventing SAR. In 2011, Siu *et al*[39] developed a simple rechallenge protocol for mild hypersensitivity reactions, including intravenous dexamethasone, diphenhydramine and ranitidine, as well as prolongation of the oxaliplatin infusion time with a high success rate of 70%. Why did the anaphylactic reactions disappear after rechallenge of oxaliplatin in patient 3? A possible explanation for the disappearance of symptoms may be the much lower peak plasma concentrations of the platinum compound and its metabolites in case of a protracted infusion[3], thus resulting in a minor and/or delayed, clinically negligible cytokine release reaction. In literature reviews, five of eleven rechallenged patients could tolerate oxaliplatin with no or minimal discomfort. However, there were still three patients developing SAR after receiving prolonged infusion of oxaliplatin. There were also reported cases initially having only a mild hypersensitivity reaction to oxaliplatin, who developed SAR after rechallenge with prolonged infusion schedule[22]. Therefore, it seems that prolonged infusion of oxaliplatin or using a desensitization program could only benefit a few patients who developed SAR. So, changing the chemotherapy regimen might be a better choice.

The mortality rate of oxaliplatin-related SAR was 4.5% (3 of 66 patients). In 2008, Shao *et al*[27] reported a fatal thrombocytopenia with a large intracranial hemorrhage with brain herniation after oxaliplatin chemotherapy. In 2011, Teng *et al*[30] reported another fatal pancytopenia with intracranial hemorrhage after oxaliplatin treatment. In our study, the patient who died initially presented with anaphylactic shock and loss of consciousness immediately after oxaliplatin infusion. All these three patients had been heavily pretreated with oxaliplatin and had received 23, 17 and 13 cycles of oxaliplatin treatment, respectively. To counteract the underlying immune-mediated mechanism, the use of steroids seems to be one of the most cost-effective approaches, especially when the patient's condition is life threatening[7,40]. This may also explain the fatalities in the patients reported by Shao *et al*[27], Teng *et al*[30] and our patient, who did not receive a steroid. Are there any predictors or risk factors for this rare but life-threatening event before oxaliplatin use? In 2011, Seki *et al*[41] reported a higher neutrophil count and lower monocyte count were two risk factors for grade 3/4 reactions in oxaliplatin-induced hypersensitivity reactions in Japanese patients. However, we didn't observe such a relationship in our study and the literature review.

Target therapy with monoclonal antibodies, including bevacizumab, cetuximab, and panitumumab, can also result in SAR[42]. Up till April 2012, there have been 14 698 people reported to have side effects when taking bevacizumab. Among them, 87 people (0.59%) have SAR[43]. In our study, one patient (patient 4) developed SAR after bevacizumab and oxaliplatin infusion. In our hospital, bevacizumab was started first and infused over 1-h. Oxaliplatin was infused after bevacizumab infusion. This patient developed SAR about 3 h after bevacizumab infusion and 2 h after oxaliplatin infusion. It is very difficult to differentiate the cause of SAR in this patient. But due to the time of onset of SAR, it is reasonable to suspect oxaliplatin.

Our study does have several limitations. First, being a retrospective review, it is difficult to confirm now whether those observed reactions are genuine hypersensitivity reactions or whether they developed as a result of oxaliplatin infusion only, although the temporal relationship between infusion and onset of reaction is suggestive. Therefore, it is possible that the risk may have been overestimated. We can also argue the other way round, that is, some mild reactions may have been missed resulting in underestimation.

In conclusion, SAR is rare but serious, and must be considered in patients receiving oxaliplatin-related che-

motherapy, especially in heavily pretreated patients. Physicians should be cautious when patients have repeated symptoms or signs of allergic reaction to oxaliplatin. At the moment, the mechanisms underlying oxaliplatin-related SAR remain uncertain. Prevention with prolongation of the infusion rate, steroid use and antihistamines are still in debate. Rechallenge with oxaliplatin is suggested only in carefully selected patients and should be used with caution. We recommend changing the chemotherapy regimen in patients experiencing oxaliplatin-induced SAR. Further extensive examinations with a large number of patients to determine the mechanism, the predictors, preventive methods and management strategy of oxaliplatin-induced SAR are recommended.

COMMENTS

Background

Oxaliplatin is a third generation platinum compound frequently used in the treatment of stage Ⅲ and stage Ⅳ colorectal cancer. Among the side effects of this agent, hypersensitivity reaction and anaphylaxis refers to undesirable reactions produced by the normal immune system, including allergies and autoimmunity. These reactions may be damaging, uncomfortable, or occasionally fatal. The percentage of hypersensitivity reactions quoted in different studies ranges from 8% to 20%. The authors presented their experience in this retrospective study and conducted a systemic review.

Research frontiers

Much less is known about acute reactions such as anaphylaxis, but it is generally considered to be associated with immune-mediated effects, as evidenced by detection of drug-dependent IgG antibodies with or without complement. Further extensive examination with a large number of patients to determine the mechanism, the predictors, preventive methods and management strategy of oxaliplatin-induced severe anaphylactic reactions (SAR) are recommended.

Innovations and breakthroughs

Life-threatening SAR have been reported but no systemic review had been performed. Here, the authors performed a retrospective analysis of the patients who had been exposed to oxaliplatin and selected those who developed SAR requiring hospitalization with medical intervention and conducted a systemic literature review on this issue.

Applications

Physicians should be cautious when patients have repeated symptoms or signs of allergic reaction to oxaliplatin. The effectiveness of prevention with prolongation of the infusion rate, steroid use and antihistamines is still in debate. Rechallenge of oxaliplatin is suggested only in highly selected patients and should be used with caution. The authors recommend changing the chemotherapy regimen in patients experiencing oxaliplatin-induced SAR.

Peer review

This manuscript is a retrospective analysis of oxaliplatin chemotherapy-induced SAR at Kaohsiung Veterans General Hospital in Taiwan. In addition, the authors have conducted a literature review on the same issue. This side effect is rare but is a life-threatening event; the authors have made some recommendations on the use of oxaliplatin as chemotherapy. This is important information which needs to be reported.

Abstract

AIM: To investigate the expression of myofibrillogenesis regulator-1 (MR-1) in relation to clinicopathological parameters and postoperative survival in a group of Chinese patients with gastric cancer.

METHODS: In our previous study of human whole-genome gene expression profiling, the differentially expressed genes were detected in the gastric cancer and its adjacent noncancerous mucosa. We found that MR-1 was associated with the location and differentiation of tumors. In this study, MR-1 protein expression was determined by immunohistochemistry in specimens of primary cancer and the adjacent noncancerous tissues from gastric cancer patients. A set of real-time quantitative polymerase chain reaction assays based on the Universal ProbeLibrary-a collection of 165 presynthesized, fluorescence-labeled locked nucleic acid hydrolysis probes-was designed specifically to detect the expression of MR-1 mRNA. The correlation was analyzed between the expression of MR-1 and other tumor characteristics which may influence the prognosis of gastric cancer patients. A retrospective cohort study on the prognosis was carried out and clinical data were collected from medical records.

RESULTS: MR-1 mRNA and protein could be detected in gastric cancer tissues as well as in matched noncancerous tissues. MR-1 was up-regulated at both mRNA (5.459 ± 0.639 *vs* 1.233 ± 0.238, $P < 0.001$) and protein levels (34.2% *vs* 13.2%, $P = 0.003$) in gastric cancer tissues. Correlation analysis demonstrated that high expression of MR-1 in gastric cancer was significantly correlated with clinical stage ($P = 0.034$). Kaplan-Meier analysis showed that the postoperative survival of the MR-1 positive group tended to be poorer than that of the MR-1 negative group, and the difference was statistically significant ($P = 0.002$). Among all the patients with stage Ⅰ-Ⅳ carcinoma, the 5-year survival rates of MR-1 positive and negative groups were 50.40% and 12.70%, respectively, with respective median survival times of 64.27 mo (95%CI: 13.41-115.13) and 16.77 mo (95%CI: 8.80-24.74). Univariate and multivariate analyses were performed to compare the impact of MR-1 expression and other clinicopathological parameters on prognosis. In a univariate analysis on all 70 specimens, 6 factors were found to be significantly associated with the overall survival statistically: including MR-1 expression, depth of invasion, distant metastasis, lymph node metastasis, vascular invasion and the tumor node metastasis (TNM) stage based on the 7th edition of the International Union against Cancer TNM classification. To avoid the influence caused by univariate analysis, the expressions of MR-1 as well as other parameters were examined in multivariate Cox analysis. Clinicopathological variables that might affect the prognosis of gastric cancer patients were analyzed by Cox regression analysis, which showed that MR-1 expression

and TNM stage were independent predictors of postoperative survival. The best mathematical multivariate Cox regression model consisted of two factors: MR-1 expression and TNM stage. Our results indicated that MR-1 protein could act as an independent marker for patient overall survival [Hazard ratio (HR): 2.215, P = 0.043].

CONCLUSION: MR-1 is an important variable that can be used to evaluate the outcome, prognosis and targeted therapy of gastric cancer patients.

Guo J, Dong B, Ji JF, Wu AW. Myofibrillogenesis regulator-1 overexpression is associated with poor prognosis of gastric cancer patients. *World J Gastroenterol* 2012; 18(38): 5434-5441 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i38/5434.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i38.5434

INTRODUCTION

Gastric cancer remains the fourth most common malignancy, and the second leading cause of cancer-related death worldwide. It is estimated that one million new cases of gastric cancer occur each year[1,2], and most of them come from Asia (China, Japan and South Korea) and parts of Central and South America (Costa Rica, El Salvador and Columbia)[1]. More new cases of gastric cancer are diagnosed in China than in any other countries each year[3]. Many patients are found at an advanced stage with lymph node invasion and metastasis at their initial diagnosis. Despite a curative surgery and postoperative adjuvant therapy, nearly 60% of those patients succumb to the disease[4-6]. Cancer progression and metastasis is a highly complex multi-stage process. It involves increased cell adhesion, alterations in gene expression, and changes in cell motility. During invasion and metastasis, cancer cells move within tissues, and the invasion involves multiple processes regulated by various molecules[7]. As gastric cancer is featured as a heterogeneous disease in both histology and genetics, it is hard to predict patient outcome using the classic histological classifications. Gastric carcinogenesis is thought to be a multifactorial and multistep process involving the activation of oncogenes and the inactivation of tumor suppressor genes at different stages of gastric cancer progression. However, promising molecules that have clinicopathological/prognostic significance in gastric cancer are substantially limited. It is crucial to further understand the molecular mechanisms of cancer progression and the development involved in gastric cancer and to identify more valuable prognostic markers in order to improve patient prognosis as well as to provide novel promising therapy targets[8-11].

In our recent study, we utilized human whole-genome gene expression BeadChip of Illumina Company (Human 6-V2) to compare the differentially expressed genes between the adenocarcinoma of the esophagogastric junction (AEG) group and the distal gastric cancer group, and analyzed the difference of the genes related to gastric cancer and its adjacent noncancerous mucosa. There are 1121 differentially expressed genes from the BeadChip. By further analyzing the cDNA microarray data, we found that 15 genes were differentially expressed in AEG and distal gastric cancer, 90 genes were related to the differentiation of tumors. Myofibrillogenesis regulator-1 (MR-1) was associated with the location and differentiation of tumors simultaneously. In this study, we focused on the expression of MR-1 mRNA and protein in gastric cancers.

MR-1, which is mapped to 2q35, was first cloned from a human skeletal muscle cDNA library using polymerase chain reaction (PCR) and rapid amplification of cDNA ends (Genbank™ accession no. AF417001). MR-1 is composed of three distinct exons, in which exon 3 is unique when compared with other two genes, and encodes a protein of 142 amino acids with a hydrophobic transmembrane structure from 75 to 92 amino acids[12-15]. The transcription level of MR-1 in human tissues is especially high in myocardium and skeletal muscles as revealed by Northern blot and serial analysis of gene expression[12]. Overexpression of MR-1 could promote cancer cell proliferation and migration in human hepatoma G2 (HepG2) cells[16]. MR-1 might promote cancer cell proliferation by binding to specific proteins, such as eukaryotic initiation factor 3 that is highly correlated with tumor cell growth and invasion regulation[17]. Also, overexpression of MR-1 can activate the nuclear factor κB signaling pathway, which is correlated with a wide variety of diseases, including cancer, inflammation, and autoimmune diseases[18].

Taking all the evidences listed above into account, we hypothesized that MR-1 may take part in the development and progression of gastric cancer. On the basis of these studies, we used real-time quantitative reverse transcriptase-polymerase chain reaction (qPCR) and immunohistochemistry to examine the expression of MR-1 in gastric cancer samples and adjacent normal tissues. Our study was the first attempt to investigate the relationship between MR-1 expression and prognosis of gastric cancer patients with complete clinical and follow-up data. We analyzed MR-1 protein expression and studied the relationship between MR-1 expression and survival. We also evaluated the possible associations between MR-1 protein expression and clinicopathological characteristics.

MATERIALS AND METHODS

Patients and tissue specimens

In this retrospective study, a consecutive series of 70 paired tissue specimens were collected from the patients with gastric cancer who received subtotal or total gastrec-

tomy at the Peking University Cancer Hospital in Beijing between January 2004 and December 2005. Written informed consent was obtained before sample collection and this study was approved by the Ethics Committee of Peking University. There were 45 males and 25 females with a mean age of 56 years (range: 26-81 years). None of the patients had undergone either chemotherapy or radiotherapy before surgery and there was no other co-occurrence of diagnosed cancers. A number of clinicopathological variables such as gender, age, tumor location, histological type, tumor-node-metastasis (TNM) stage, depth of tumor invasion, lymph node metastasis, distant metastasis and vascular invasion were obtained from the histopathological records and included for survival analysis.

We classified the postoperative staging of gastric cancer according to 7th American Joint Committee on Cancer (AJCC) TNM staging classification for carcinoma of the stomach[19]. There were 6 patients with stage Ⅰ, 15 patients with stage Ⅱ, 43 patients with stage Ⅲ, and 6 patients with stage Ⅳ carcinoma. After gastrectomy, resected specimens were processed routinely for histopathological assessment; necrotic hemorrhage and connective tissues were removed and each paired bulk sample [tumor samples (T)/matched normal samples (N)] was immediately put into liquid nitrogen and stored at -80 ℃ until processed. The resected specimens of gastric cancer were also routinely subjected to macroscopic pathological assessment and fixed with 10% formalin in phosphate buffered saline (PBS) for immunohistochemistry. All tissue specimens were formalin-fixed and paraffin-embedded. Formalin fixed tissue sections were stained with haematoxylin and eosin and classified by a pathologist. These results were compared with the histopathologial records from Peking University Cancer Hospital. Final pathology was determined by consensus and reviewed if necessary. The patients were followed up from a period of 2.23 to 89.07 mo (mean, 30.78 mo). Follow-up was managed through correspondence, over the telephone or in the clinic every 3 to 6 mo for 5 years and half a year thereafter. In the clinic, history enquiry, physical examination, complete blood count, biochemical tests, imaging studies and endoscopy were routinely completed. All gastric cancer patients in our study were followed up regularly and follow-up information was complete. The primary endpoint of the follow-up was death of gastric cancer patients. Patients who did not die as a result of gastric cancer were excluded.

Isolation of total RNA

Total RNA was extracted according to the manufacturer's instructions (TRIzol, Invitrogen, United States). The integrity of the RNA samples was determined by electrophoresis through agarose gels and staining with ethidium bromide, and the 18S and 28S RNA bands were visualized under ultraviolet (UV) light. The RNA was stored at -80 ℃ in RNase-free water until reverse transcription or fluorescence labeling.

Semiquantitative reverse transcription-polymerase chain reaction

Reverse transcription (RT) was performed in a 25 μL reaction volume with 2 μg total RNA treated with 0.5 μg of Oligo (dt), 200 U Moloney murine leukemia virus reverse transcriptase, 25 U RNase inhibitor and 2.5 mmol dNTP to synthesize the first-strand cDNA (Promega, United States), according to the manufacturer's recommendations. The reaction system was incubated at 70 ℃ for 5 min (primer annealing), 42 ℃ for 1 h (synthesis) and resulting cDNA was stored at -20 ℃. The resulting cDNA was subjected to PCR for the evaluation of the relative expression levels of β-actin (as an internal control) and MR-1. PCR was done using 1 unit HotMaster Taq DNA polymerase (Qiagen, Germany) and 1:20 of the reverse transcription reaction, with an initial hot start of 5 min at 95 ℃ followed by 30 s denaturation. Primers, annealing and extension temperatures, and number of cycles used (chosen for the exponential phase of amplification) were as follows: (1) β-actin forward primer: CATGCCATCCTGCGTCTGGAC, reverse primer: CACGGAGTACTTGCGCTCAGGAGG; 55 ℃, 45 s, 72 ℃, 45 s, 28 cycles, 72 ℃, 5-min bands of 275 bp; and (2) MR-1 forward primer: GCTTTGCAGGTGTGGTGGAG, reverse primer: AGGAACGGGTTGTAGGAGCG; 52 ℃, 40 s, 72 ℃, 45 s, 35 cycles, 72 ℃, 5-min bands of 133 bp. Two bands were detected at 133 bp and 275 bp corresponding to the molecular weight marker. PCR products were electrophoresed on 1.5% agarose gels with 0.01% ethidium bromide. Band intensities were measured under UV light using Gel Analyst software (UVP, Upland, United States).

Real-time quantitative reverse transcription-polymerase chain reaction

Real-time qPCR was performed in an ABI Prism 7500 HT (Applied Biosystems, Foster City, CA) with a Universal ProbeLibrary (UPL) probe (Roche). Primers and probe were designed by online Roche Assay Design Center (https://www.roche-applied-science.com/sis/rtpcr/upl/index.jsp?id=uplct_030000). The primers for real-time qPCR were: MR-1 forward: 5'-CTTCTCAGGGGACCTGCTCT-3', reverse: 5'-TCAGCATGGTCTCTGCATTG-3'; β-actin forward: 5'-CCAACCGCGAGAAGATGA-3', reverse: 5'-CCAGAGGCGTACAGGGATAG-3'. UPL probe #76 was designed for MR-1 and UPL probe #64 for β-actin. All other reaction conditions were as described by the manufacturer. The cDNA was denatured and the Taq DNA polymerase was activated for 10 min at 95 ℃, and the cycling conditions were set as follows: 40 cycles of denaturation at 95 ℃ for 30 s, annealing at 52 ℃ for 30 s, extension at 72 ℃ for 30 s and a final step at 42 ℃ for 2 min. Standard curves were determined by running a dilution series on the housekeeping gene (β-actin) and target gene. The experiments were repeated three times independently.

Immunohistochemistry

Immunohistochemical analysis was done to study the altered protein expression in the 70 specimens of human gastric cancer tissues and non-cancerous gastric tissue controls. Four μm sections from formalin-fixed and paraffin-embedded tissues were mounted on poly-L-lysine-coated slides, baked overnight at 50 ℃ and then deparaffinized in xylene and rehydrated through alcohol to distilled wa-

ter. After hydration, endogenous peroxidase activity was blocked by incubation with 3% (v/v) hydrogen peroxidase (H_2O_2) for 20 min at room temperature. Standard antigen retrieval was then performed with heat-induced epitope retrieval (HIER) by heating the slides immersed in retrieval solution (pH 6.0) in a pressure boiler. After boiling, the slides remained in the pressure boiler for 3 min and then gradually cooled at room temperature. For the detection of MR-1, after washing with PBS three times, the sections were incubated with the polyclonal goat anti-human MR-1 antibody (HPA017068-100UL, Sigma, Germany) at 4 ℃ overnight. Then, the slides were incubated with peroxidase-labeled polymer conjugated to poly peroxidase-anti-mouse/rabbit IgG (PV-9000, Zhongshan Biotechnology Company, Beijing, China) at 37 ℃ for 30 min followed by a gentle rinse with washing buffer three times. 3,3'-diaminobenzidine tetrahydrochloride (DAB) staining reaction was then performed and followed by Meyer hematoxylin counterstaining. The slides were then dehydrated, cleared and mounted as usual. For negative controls, the primary antibody was replaced by non-immune rabbit serum to confirm the specificity. Internal positive control was used for quality assurance. MR-1 staining was principally evaluated according to the scoring criteria. The information recorded was: subcellular location (nuclear and/or cytoplasmic), intensity of staining (negative, weak, moderate or strong) and percentage of positive immunoreactive cells. The positive group referred to the cases with > 10% cells having positive immunoreactivity. The rest was defined as negative. The slide evaluation was performed by two pathologists, and both pathologists gave almost identical reports with only minor differences. A consensus regarding controversial cases was reached after discussion.

Statistical analysis

All statistical analyses were performed using SPSS statistical analysis software, version 16.0 (SPSS, Chicago, IL, United States). A paired-samples *t* test was used to compare the MR-1 mRNA levels in the tumor tissue samples and their paired adjacent non-tumor tissue samples. Regarding MR-1 expression and the clinicopathological variables, data were cross-tabulated and a χ^2 test was performed. Cumulative survival was estimated by the Kaplan-Meier method and comparisons between groups were made with a log-rank test. Postoperative survival was measured from the date of first surgery to the date of death of gastric cancer, or the last date of information collection if no end event was documented. A multivariate analysis of Cox proportional hazards regression model (backward, stepwise) was performed to assess the influence of each variable on survival. $P < 0.05$ was considered statistically significant.

RESULTS

Myofibrillogenesis regulator-1 mRNA levels are increased in gastric cancers

We randomly selected 60 specimens from the total samples, including 30 gastric cancer tissues and 30 matched noncancerous tissues to investigate the *MR-1* mRNA expression level using semiquantitative RT-PCR. As shown in Figure 1A, *MR-1* mRNA could be detected in both gastric cancer tissues and matched noncancerous tissues. However, a significant increase in the levels of *MR-1* mRNA expression was observed in primary gastric cancer compared with matched normal tissues.

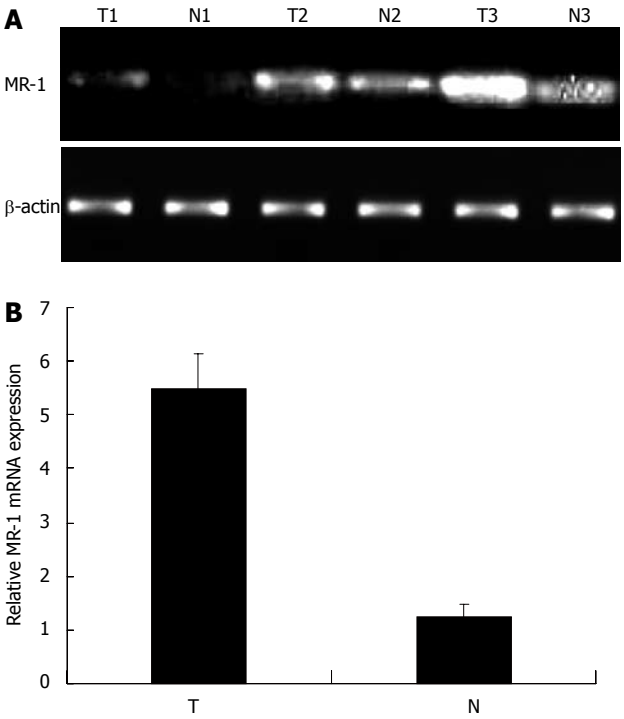

Figure 1 Expression of myofibrillogenesis regulator-1 mRNA in adjacent noncancerous mucosa and gastric cancers. A: Expression pattern of myofibrillogenesis regulator-1 (MR-1) in gastric cancer specimens by semiquantitative reverse transcription-polymerase chain reaction (PCR) (representative PCR results from 3 patients). The expression level of MR-1 mRNA showed significant difference between gastric cancer tissues and corresponding noncancerous gastric tissues; B: Results of real-time quantitative PCR assay. MR-1 mRNA expression in tumor tissue was frequently higher than that in matched normal mucosa ($P < 0.001$; Student's *t* test). β-actin was used as a control. N: Noncancerous gastric tissues; T: Gastric cancer tissues.

To validate the results of semiquantitative RT-PCR, we examined the *MR-1* mRNA expression level with real-time qPCR in the 30 paired clinical samples chosen randomly from the total cases. By real-time qPCR analysis, we found that the level of *MR-1* mRNA was increased remarkably in gastric cancer tissues. Expression of *MR-1* mRNA was measured in triplicate, and then normalized relative to the reference gene β-actin (divided by the expression level of human β-actin). The average ratios of *MR-1* mRNA to *β-actin* mRNA in gastric cancer tissues and noncancerous gastric tissues were 5.459 ± 0.639 and 1.233 ± 0.238, respectively (Figure 1B), which suggested that the expression level of *MR-1* mRNA was significantly higher in gastric cancer tissues than in the corresponding noncancerous gastric tissues ($P < 0.001$).

Myofibrillogenesis regulator-1 protein expression pattern in primary gastric cancer

MR-1 protein expression was detected in the nuclei and cytoplasm of both adjacent noncancerous mucosa and gastric cancer cells. However, the positive rate of MR-1

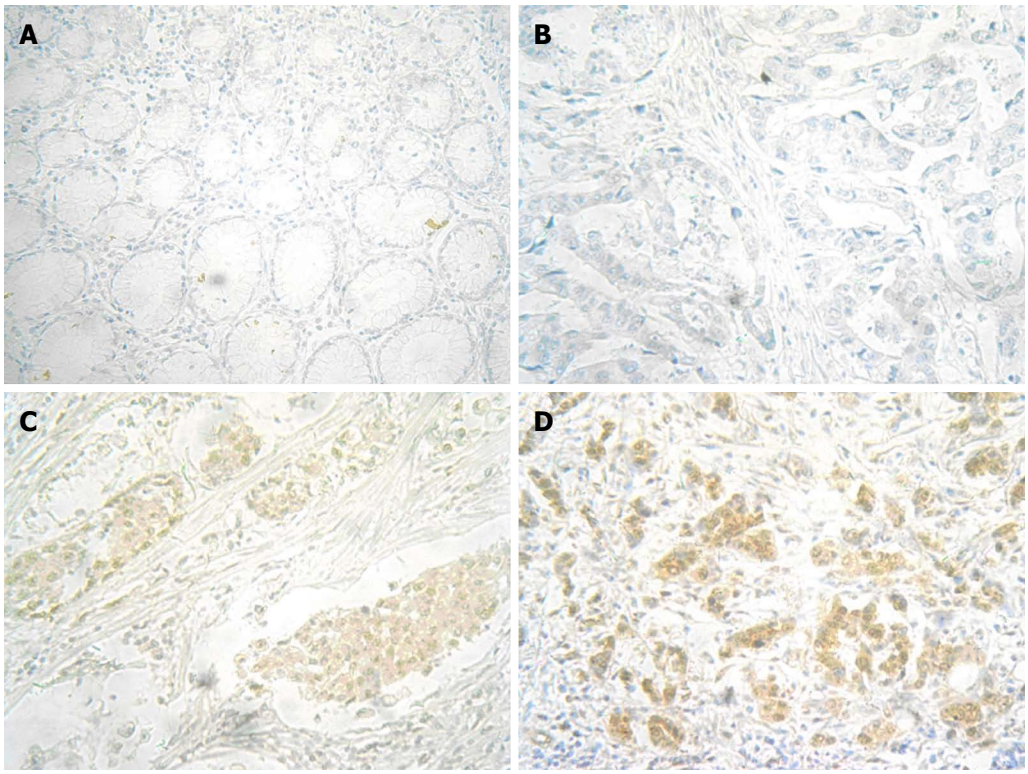

Figure 2 Myofibrillogenesis regulator-1 protein expression determined by immunohistochemical staining in adjacent noncancerous mucosa and gastric cancers. A: Negative expression in adjacent noncancerous mucosa (× 200). No myofibrillogenesis regulator-1 (MR-1) expression was detected; B: Negative expression in gastric cancers (× 200). No MR-1 expression was detected; C: Weak positive expression in gastric cancer (× 200); D: Moderate positive expression in gastric cancer (× 200). MR-1 protein was expressed in cytoplasm of the cells in (C) and (D).

expression in gastric cancer cells was much higher than that in adjacent noncancerous mucosa (34.2% *vs* 13.2%, $P = 0.003$, Figure 2).

Association of myofibrillogenesis regulator-1 protein expression with clinicopathological variables and postoperative survival in gastric cancer

We investigated the association of MR-1 protein expression with clinicopathological variables and postoperative survival. Correlation analysis demonstrated that high expression of MR-1 in gastric cancer was significantly correlated with TNM stage ($P = 0.034$). It suggested that MR-1 protein expression had no obvious association with other clinicopathological variables except TNM stage (Table 1).

Kaplan-Meier analysis showed that the postoperative survival of the MR-1 positive group tended to be poorer than that of the MR-1 negative group, and the difference was statistically significant ($P = 0.002$). For all the patients with stages I -IV carcinoma, the 5-year survival rates of MR-1 positive and negative groups were 50.40% and 12.70%, respectively, with respective median survival times of 64.27 mo (95%CI: 13.41-115.13) and 16.77 mo (95%CI: 8.80-24.74, Figure 3).

We performed univariate and multivariate analyses to compare the impact of MR-1 expression and other clinicopathological parameters on prognosis. In the univariate analysis on all 70 specimens, 6 factors were found to have statistically significant associations with overall survival: MR-1 expression, depth of invasion, distant metastasis, lymph node metastasis, vascular invasion and the TNM stage based on the 7th edition of the International Union Against Cancer TNM classification (Table 2). To avoid the influence caused by univariate analysis, the expressions of MR-1 as well as other parameters were examined in multivariate Cox analysis. Clinicopathological variables that might affect the prognosis of gastric cancer patients were analyzed by Cox regression analysis, which showed that MR-1 expression and TNM stage were independent predictors of postoperative survival (Table 2). Therefore, the best mathematical multivariate Cox regression model consisted of two factors: MR-1 expression and TNM stage. In the testing set, MR-1 was again found to be a significant independent prognostic factor for poor prognosis (hazard ratio, 2.125; 95%CI: 1.023-4.410, $P = 0.043$; Table 2) in Chinese gastric cancer patients.

DISCUSSION

Gastric cancer is reported to be the second most common cause of cancer-related death worldwide. For most cases, at the advanced stage when diagnosed, surgery is the only curative procedure for localized gastric cancer. A high recurrence rate, a low survival rate, and a poor prognosis were found in the advanced gastric cancer patients because currently available agents are not very effective. Thus, treatment of gastric tumors remains a challenge for physicians. To identify more effective approaches for cancer treatment, new targeted therapies for advanced gas-

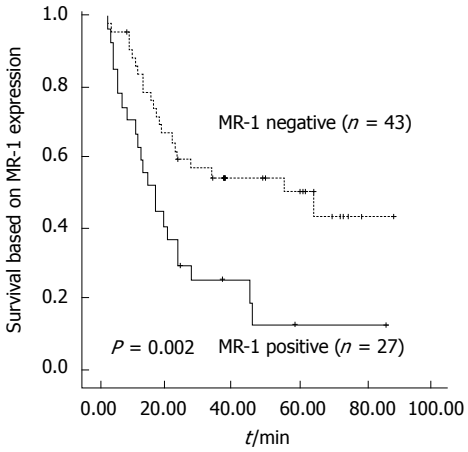

Figure 3 Postoperative survival curves in patients with stage Ⅰ-Ⅳ carcinoma. Myofibrillogenesis regulator-1 (MR-1) protein positive expression refers to cases showing weak and moderate staining.

tric cancers are needed. Right now, targeted therapy for advanced gastric carcinoma relies on target gene status evaluation[20,21]. Because of the cellular migration and metastasis, the mortality rate of gastric cancer remains high. The development of gastric cancer is a comprehensive action associated with multiple factors, such as inhibition of tumor suppressor genes, overexpression of related genes, and a failure to regulate cell proliferation. Therefore, it is urgently needed to find a sensitive biomarker for the detection of gastric cancer at the curative stage.

Li *et al*[12] identified a novel human gene, MR-1, from a human skeletal muscle cDNA library. MR-1 is located on human chromosome 2q35, having three alternatively spliced forms[22]. Based on our recent findings that MR-1 was associated with the location and differentiation of tumors simultaneously, and that MR-1 played a role in promoting the proliferation and invasion in some types of human cancers[14,18], we designed this study to comprehensively investigate the association between MR-1 and gastric cancer and the roles it may play in the pathogenesis or disease progression.

Real-time qPCR procedure combined with the Universal ProbeLibrary (UPL) technology has been successfully employed for both detection and quantification of expression levels of numerous genes, and mammalian and human viral pathogens[23-27]. UPL is a collection of 165 presynthesized, fluorescence-labeled DNA/locked nucleic acid (LNA) hybrid hydrolysis probes, which have been selected carefully to detect 8- and 9-mer motifs that are very prevalent in the transcriptomes, ensuring optimal coverage of all transcripts in a given transcriptome. On the basis of the MR-1 and β-actin sequences, UPL probe #76 and #64 with each specific PCR primer pairs were obtained from universal probe library database (Roche Diagnostics). In the present study, the prognostic relevance of MR-1 expression in gastric cancer was reported for the first time. It has been shown that MR-1 mRNA was overexpressed in gastric tumors compared with adjacent normal gastric tissues from the same individuals, in agreement with the data obtained from our microarray analysis.

In this study, immunohistochemistry was used to analyze the levels of MR-1 expression in 70 clinicopathologically characterized gastric cancer cases. The positive rate of MR-1 protein expression in gastric cancer cells was found much higher than in adjacent noncancerous mucosa. The results indicate that there are certain functions of MR-1 protein that are highly expressed in gastric cancer cells, which was confirmed by postoperative survival analysis in our study. To the best of our knowledge, there has been no report examining the role of MR-1 in gastric cancer. This is the first study showing that expression of MR-1 is increased in gastric cancer tissues compared with benign control tissues.

Table 1 Association of myofibrillogenesis regulator-1 protein expression with clinicopathological variables of gastric cancer patients

Variables	Cases	MR-1 negative *n* = 43 (%)	MR-1 positive *n* = 27 (%)	*P* value
Gender				0.855
Male	45	28 (62.22)	17 (37.78)

Poorly	60	36 (60.00)	24 (40.00)	
Others	5	4 (80.00)	1 (20.00)	

TNM: Tumor node metastasis; MR-1: Myofibrillogenesis regulator-1.

The clinical significance of MR-1 protein expression was studied. The result reveals that high expression of MR-1 in gastric cancer is significantly correlated with TNM stage (P = 0.034), but has no obvious association with other clinicopathological variables related to the prognosis of gastric cancer patients, such as depth of invasion and vascular invasion[28,29].

AEG has a different clinicopathological feature and poor prognosis compared with the distal gastric cancer. In this study, 5 (62.50%) of 8 cases of AEG highly expressed MR-1 protein, whereas weak expression was detected only in 22 (35.48%) of 62 cases of the distal gastric cancer. Expression was detected in two (66.67%) of three cases of well and moderately differentiated gastric cancers, whereas 24 (40.00%) of 60 cases of the poorly differentiated gastric cancer expressed MR-1 protein. These findings were in accordance with the data obtained from our microarray

Table 2 Multivariate survival analysis of the prognosis factors by Cox regression analysis

Variables	Univariate analysis		Multivariate analysis	
	HR (95%CI)	*P* value	HR (95%CI)	*P* value

HR: Hazard ratio; CI: Confidence interval; TNM: Tumor node metastasis; MR-1: Myofibrillogenesis regulator-1.

analysis. However, data derived from these studies were statistically not significant, which may be because of the small sample size. Therefore, the accuracy of this first explorative result should be further tested in a larger validation study.

With respect to the results of survival analysis, in patients with stages Ⅰ-Ⅳ gastric cancer, the 5-year survival rate for those with high MR-1 expression was significantly lower than that of patients with low MR-1 expression. The results showed that MR-1 was up-regulated in gastric cancer tissues compared with normal gastric tissues and correlated significantly with prognosis. Multivariate analysis suggested that MR-1 expression and TNM stage were independent prognostic indicators for gastric cancer. The relative risk of death in patients with MR-1-positive tumors was 2.125 times higher than that in the patients with MR-1-negative tumors [hazard ratio (HR) = 2.125, 95%CI: 1.023-4.410]. Depth of invasion, distant metastasis, lymph node metastasis and vascular invasion, which were significant prognostic factors in the univariate analysis, showed no significant influence on survival in the multivariate analysis, possibly because their prognostic value was overlapped by the TNM stage. Thus, MR-1 is a potentially novel therapeutic target for the treatment of gastric cancer.

The mechanism by which MR-1 promotes tumorigenesis and cancer progression has not been well elucidated. The interaction of MR-1 with sarcomeric structural proteins involved in muscle contraction and its presence in human myocardial myofibrils indicate that MR-1 could regulate contractile proteins in the myocardium and might be associated with cardiac hypertrophy. Myosin light chain-2 (MLC-2) plays an important role in cell migration from solid cancers such as ovarian tumor, and its dephosphorylation could induce apoptosis[30]. A study showed that MLC-2 may regulate cell proliferation and migration by interacting with MR-1[31]. Knockdown of MR-1 expression in human hepatoma HepG2 cells inhibits cell migration and proliferation both *in vitro* and *in vivo*. The mechanism underlying this action is that MR-1 induces MLC-2 activation, subsequently stimulates stress fiber formation, and indirectly activates the focal adhesion kinase/protein kinase B (FAK/Akt) signaling pathway to promote cell migration and proliferation[15]. Further studies are needed to define the molecular mechanisms that govern the potential role of MR-1 expression in gastric cancer progression, clarify whether MR-1 is an early diagnostic marker for gastric cancer and to assess its full therapeutic potential.

In conclusion, our data show that a subset of patients with gastric cancer have MR-1 overexpression, which is associated with an aggressive clinical course and poor overall survival. Thus, MR-1 may be a novel biological marker and potential therapeutic target for the treatment of gastric cancer. It could also be used to monitor the effect of anti-cancer therapies. The results of our study suggest that overexpression of MR-1 in gastric cancer tissues might play an important role in the progression and metastases of the disease and that MR-1 may be a useful prognostic and survival indicator. These findings may help us explore novel therapeutic modalities and prognostic predictors for gastric cancer patients, thus improving the treatment outcomes. This is the first report to suggest a relationship between MR-1 and prognosis of patients with gastric cancer, and further prospective investigations would be worth doing in clinical settings.

COMMENTS

Background

Gastric cancer is one of the commonest malignant tumors in the alimentary tract and is characterized by delayed clinical presentation, rapid progression, and poor survival. Although this neoplasm is a serious public health problem due to its high incidence and mortality, little is known about the molecular events involved in gastric carcinogenesis.

Research frontiers

Gastric cancer, similar to other neoplasms, is a multifactorial disease that results from a combination of environmental factors and the accumulation of generalized and specific genetic and epigenetic alterations. Myofibrillogenesis regulator-1 (MR-1) protein family has been recently found associated with carcinogenesis, but not in the stomach. In this study, the authors evaluated mRNA and protein expression of MR-1 in gastric neoplasms and corresponding non-neoplastic samples.

Innovations and breakthroughs

No previous study has evaluated the gene and protein expression of MR-1 in gastric carcinogenesis. The findings from this study suggested that MR-1 may play an important role in the development of gastric cancer and it is a potential indicator that could be used to evaluate the outcome of gastric cancer treatment.

Applications

These results suggest that overexpression of MR-1 is associated with clinical stage and serves as a prognostic factor in patients with gastric cancer.

Terminology

MR-1, which is mapped to 2q35, was first cloned from a human skeletal muscle cDNA library using PCR and rapid amplification of cDNA ends (Genbank™ accession no. AF417001). It encodes a protein of 142 amino acids with a hydrophobic transmembrane structure from 75 to 92 amino acids.

Peer review

The study discovered some differential expression genes through bioinformatics and elucidated the expression level of MR-1 in gastric cancer and evaluated the link between MR-1 and the poor outcome of gastric cancer. The major finding of this study was that MR-1, which up-regulated in gastric cancer tissues comparing with matched non-tumor tissues, might be a novel prognostic marker for gastric cancer.

Abstract

AIM: To identify the differentially expressed miRNAs and their targets in hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC).

METHODS: Six hundred and sixty seven human miRNAs were quantitatively analyzed by Taqman low-density miRNA array (TLDA) in HBV-HCC tissues. Gene ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analyses were used to analyze the significant function and pathway of the differentially expressed miRNAs in HBV-HCC. TargetScan software was used to predict the targets of deregulated miRNAs. Western blotting and luciferase assay were performed to verify the targets of these miRNAs.

RESULTS: Ten up-regulated miRNAs (miR-217, miR-518b, miR-517c, miR-520g, miR-519a, miR-522, miR-518e, miR-525-3p, miR-512-3p, and miR-518a-3p) and 11 down-regulated miRNAs (miR-138, miR-214, miR-214#, miR-199a-5p, miR-433, miR-511, miR-592, miR-483-3p, miR-483-5p, miR-708 and miR-1275) were identified by Taqman miRNAs array and confirmed quantitatively by reverse transcription polymerase chain reaction in HCC and adjacent non-tumor tissues. GO and KEGG pathway analysis revealed that "regulation of actin cytoskeleton" and "pathway in cancer" are most likely to play critical roles in HCC tumorigenesis. MiR-519a and ribosomal protein S6 kinase polypeptide 3 (RPS6KA3) were predicted as the most significant candidates by miRNA-mRNA network. In addition, cyclin D3 (CCND3) and clathrin heavy chain (CHC), usually up-regulated in HCC tissues, were validated as the direct target of miR-138 and miR-199a-5p, respectively.

CONCLUSION: Our data suggest an importance of miR-138 and miR-199a-5p as well as their targets CCND3 and CHC in HCC tumorigenesis, and may provide more evidence for reliability of integrative bioinformatics analysis.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide[1]. The development and progression of HCC is characterized by a multi-stage process, which is believed to involve the deregulation of genes that are critical to cellular processes such as cell cycle control, cell growth, apoptosis, and cell migration and spreading. In the past decades, studies have focused on investigating the effect of genes and proteins on the development and progression of HCC[2]. Recently, an increasing number of reports have described microRNAs (miRNAs) that are implicated in HCC progression[3].

MiRNAs are endogenous non-coding RNAs (20-22 nucleotides) which regulate gene expression by catalyzing the cleavage of messenger RNA (mRNA) or repressing mRNA translation[4]. Increasing evidence showed that miRNAs play significant roles in cell development, differentiation and communication[5]. Deregulation of miRNAs has also been observed in a wide range of human diseases, including cancer[6]. In human cancer, miRNAs can function as oncogenes or tumor suppressor genes during tumor development and progression[7].

In this study, the expression of 667 miRNAs was profiled in human HCC and adjacent non-tumor tissues. A set of significantly differentially expressed miRNAs was identified in HCC tissues. Furthermore, a global analysis of miRNA-regulated signaling pathways and related genes was performed on the basis of miRNA expression profiles and bioinformatics interpretation. Cyclin D3 (CCND3) and clathrin heavy chain (CHC) which had been previously described in HCC tumorigenesis were further validated to be the direct target of miR-138 and miR-199a-5p, respectively.

MATERIALS AND METHODS

Tissue specimens

Eighteen pairs of human HCC and adjacent non-tumor tissues were obtained from surgical specimens immediately after resection from patients undergoing primary surgical treatment of HCC in the Eastern Hepatobiliary Surgery Hospital, Shanghai, China. No patient had received preoperative irradiation or chemotherapy. The samples were frozen in liquid nitrogen and stored at -80 ℃ until use. Among these samples, three pairs were used for Taqman low-density miRNA array (TLDA) analysis and all were used for quantitative real-time polymerase chain reaction (qRT-PCR) analysis. Clinical and pathological information was extracted from the patients' medical charts and pathological reports (Table 1). Written consent for tissue donation (for research purposes) was obtained from the patients before tissue collection and the protocol was approved by the Institutional Review Board of Eastern Hepatobiliary Surgery Hospital and Second Military Medical University.

Taqman low-density miRNA array

Total RNA was isolated using mirVana miRNA isolation kit (Ambion, Austin, TX, United States). For miRNA cDNA synthesis, RNA was reversely transcribed using the miRNA reverse transcription kit (Applied Biosystems, Foster City, CA, United States) in combination with the stem-loop Megaplex primer pool (Applied Biosystems). TLDA v2.0 (Applied Biosystems) was performed on the 7900HT real-time PCR system (Applied Biosystems) according to the manufacturer's protocol (667 small RNAs were profiled for each cDNA sample). PCR cycling conditions were as follows: 95 ℃ for 10 min followed by 40 cycles of 95 ℃ for 15 s and 60 ℃ for 1 min. Human U6 small RNA was used as an internal control to normalize RNA input. The data were analyzed using SDS v2.3 software. The Ct value was defined as the fractional cycle number at which the fluorescence passed the fixed threshold. The fold change was calculated using the $2^{-\Delta\Delta Ct}$ method and presented as the fold-expression change in tumors and their adjacent normal tissues after normalization to the endogenous control.

Table 1 Characteristics of patients (n = 18)

No.	Gender	Age (yr)	Tumor size[1] (cm)	Cirrhosis	Tumor grade[2]	TNM stage
1	M	55	1.9	No	G3	T2N0M0

Quantitative real-time PCR

For miRNA expression analysis, synthesis of cDNA and qRT-PCR was carried out with TaqMan microRNA assay kits (Applied Biosystems) according to the manufacturer's protocol. Briefly, total RNA was extracted using TRIzol Reagent (Invitrogen, Carlsbad, CA, United States) from HCC and adjacent non-tumor tissues and used to synthesize cDNAs with gene-specific primers. Reverse transcriptase reactions contained 100 ng RNA, 50 nmol/L stem-loop RT primers, 1 × RT buffer, 0.25 mmol/L each of the dNTPs, 3.33 U/μL MultiScribe reverse transcriptase and 0.25 U/μL RNase inhibitor. The 15 μL reactions were incubated for 30 min at 16 ℃, 30 min at 42 ℃, 5 min at 85 ℃, and then kept at 4 ℃. The cDNA product was used for the following qRT-PCR analysis. The 20 μL

PCR reaction included 1.33 μL RT product, 1 × TaqMan universal PCR master mix and 1 μL primers and probe mix of the TaqMan microRNA assay kit. Reactions were incubated in a 96-well optical plate at 95 ℃ for 5 min, followed by 40 cycles at 95 ℃ for 15 s and 60 ℃ for 1 min. PCR reactions were run on a StepOne Plus real-time PCR machine (Applied Biosystems) and the data were analyzed using SDS v2.3 software, the same as in TLDA.

Prediction of miRNA targets

The target genes of the deregulated miRNAs were predicted by TargetScan (http://www.targetscan.org/).

Gene oncology and Kyoto encyclopedia of genes and genomes pathway analysis based on miRNA expression profile

The miRNA targets were subjected to gene oncology (GO) analysis in order to organize genes into hierarchical categories and uncover the miR-gene regulatory network on the basis of biological process and molecular function[8]. Fisher's exact test and χ^2 test were used to classify the GO category, and the false discovery rate (FDR)[9] was calculated to correct the *P* value, the lower the FDR, the slight the error in judging the *P* value. The FDR was defined as $FDR = 1 - \frac{N_k}{T}$, where N_k refers to the number of Fisher's test *P* values less than χ^2 test *P* values. *P* values were computed for the GOs of all the differential genes. Enrichment provides a measure of the significance of the function: as the enrichment increases, the corresponding function becomes more specific, which can help find those GOs with more concrete function description in the experiment. Within the significant category, the enrichment Re was given by: $Re = (n_f/n) / (N_f/N)$ where n_f is the number of differential genes within the particular category, n is the total number of genes within the same category, N_f is the number of differential genes in the entire array, and N is the total number of genes in the array[10]. Similarly, pathway analysis was used to find out the significant pathway of the differential genes according to Kyoto encyclopedia of genes and genomes (KEGG), Biocarta and Reatome. The Fisher's exact test and χ^2 test were also used to select the significant pathway, and the threshold of significance was defined by *P* value and FDR. The enrichment Re was calculated using the same equation mentioned above[11-13]. The network of miRNA-mRNA interaction, representing the critical miRNAs and their targets, was established according to the miRNA degree.

Construction of luciferase reporter plasmids

The fragment of 3'-untranslated region (UTR) of CCND3 (1054-2061nt, Genbank accession no. NM_001136017.2) containing the two putative miR-138 binding sequences (1279-1285nt and 1346-1352nt) was amplified with the primers 5'-CCCTGGAGAGGCCCTCTGGA-3' and 5'-TTCCAAGAAGCCAAAGCCAG-3'. The partial fragment of 3'-UTR of CHC (5472-6480nt, Genbank accession no. NM_004859) containing the two putative miR-199a-5p binding sequences (5979-5986nt and 5915-5922nt) was amplified with the primers 5'-GATGAAGCGCTGATCCTGTAG-3' and 5'-TGCCTCCCTAATGCCTCAG-3'. The PCR products were cloned into firefly luciferase reporter vector pGL3 (Promega Corporation, Madison, WI, United States) respectively, termed as pGL3-CCND3-3'UTR or pGL3-CHC-3'UTR. The plasmids carrying the mutated sequence in the complementary sites for the seed region of miR-138 or miR-199a-5p, were generated based on pGL3-CCND3-3'UTR and pGL3-CHC-3' UTR plasmids by site-specific mutagenesis, termed as pGL3-CCND3-3'UTR-mut or pGL3-CHC-3'UTR-mut.

Transfection

The transfection was carried out using FuGene HD transfection reagent (Roche, Indianapolis, IN, United States) following the manufacturer's protocol. In brief, 2 × 10^4 HepG2 cells or 5 × 10^4 HEK293T cells in 24-well plate were transfected with indicated miRNA mimic (50 nmol/L, GenePharma, Shanghai, China) or plasmid DNA (100 ng) and collected 24-48 h after transfection for assay.

Dual-luciferase reporter assay

HEK293T cells were cotransfected with pGL3-CCND3-3'UTR or pGL3-CCND3-3'UTR-mut and miR-138 mimic or nonrelative control RNA duplex [non-relative control (NC) duplex, GenePharma] using FuGene HD transfection reagent. In another well, HEK293T cells were cotransfected with pGL3-CHC-3'UTR or pGL3-CHC-3'UTR-mut and miR-199a-5p mimic or nonrelative control RNA duplex using FuGene HD transfection reagent. The pRL-TK (Promega Corporation, Madison, WI, United States) was also transfected as a normalization control. Cells were collected 48 h after transfection, and luciferase activity was measured using a dual-luciferase reporter assay kit (Promega Corporation) and recorded by multi-plate reader (Synergy 2, BioTek).

Western blotting

Protein extracts from HCC tissues and their adjacent non-tumorous tissues or HepG2 cells were prepared by a modified radioimmunoprecipitation buffer with 0.5% sodium dodecyl sulfate in the presence of proteinase inhibitor cocktail (Complete Mini, Roche). Twenty-five micrograms protein were electrophoresed in 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis mini-gels and transferred onto polyvinylidene fluoride membranes (Immobilon P^{SQ}, Millipore, Billerica, MA, United States). After blocking with 5% nonfat milk, the membranes were incubated with rabbit anti-CCND3 antibody (1:1000 dilution, Epitomics, Inc., Burlingame, CA, United States), rabbit anti-clathrin heavy chain (CHC) antibody (1:1000 dilution, Abcam, Cambridge, United Kingdom) or mouse anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) antibody (1:5000 dilution, Epitomics, Inc.) at 4 ℃ overnight, followed by incubation with horserad-

ish peroxidase-conjugated goat anti-rabbit or goat anti-mouse antibody (1:10 000 dilution, KPL, Gaithersburg, MA, United States) for 1h at room temperature. Finally, signals were developed with Super Signal West Pico chemoluminescent substrate (Pierce, Rockford, Ill, United States) and visualized by the Gene Gnome HR Image Capture System (Syngene, Frederick, MD, United States).

Statistical analysis

Data were presented as mean ± SD. Comparisons were made using a two-tailed *t* test or one-way analysis of variance for experiments with more than two subgroups. $P < 0.01$ was considered statistically significant.

RESULTS

Patient characteristics

HCC and adjacent non-tumor tissues were obtained from 18 patients, whose average age was 48.5 years (ranged from 35 years to 71 years) (Table 1). All of the patients were HBsAg positive and with the diagnosis of HCC. In tumor grades, 7 (38.9%) cases were well differentiated (G1 + G2) and 11 (61.1%) cases were moderately differentiated (G3) HCC. In clinical stage, 4 (22.2%) were at invasion T1, 7 (38.9%) at invasion T2, and 6 (33.3%) at invasion T3 and 1 (5.6%) at invasion T4.

Differential expression of miRNAs in HCC

There were 86 deregulated miRNAs in total between HCC tumor and non-tumor tissues by TLDA analysis. In order to select the most significant candidates, miRNAs altered by at least 3-fold in all three pairs of the samples were selected. Under these strict criteria, 11 up-regulated miRNAs and 13 down-regulated miRNAs were identified (Figure 1A and Table 2). To validate the miRNA array data, qRT-PCR was performed in 18 pairs of HCC tissues. Four up-regulated (miR-217, miR-520g, miR-522 and miR-525-3p) (Figure 1B) and 4 down-regulated miRNAs (miR-199a-5p, miR-138, miR-483-5p and miR-511) showed consistent changes in more than 70% tumorous tissues (Figure 1C). Six up-regulated (miR-517c, miR-512-3p, miR-518a-3p, miR-519a, miR-518e and miR-518b) and 7 down-regulated miRNAs (miR-214, miR-214#, miR-592, miR-483-3p, miR-433, miR-708 and miR-1275) showed consistent changes in more than 50% tumorous tissues (data not shown). No significant difference was found between one up-regulated (miR-888) and two down-regulated miRNAs (miR-21# and miR-27a#) in paired tumorous tissues (data not shown).

Gene oncology and Kyoto encyclopedia of genes and genomes pathway analysis of the deregulated miRNAs

The targets of the 21 deregulated miRNAs (Table 2) were predicted by TargetScan. To identify the most significant candidates and investigate the cellular function, the signaling pathway and GOs of the target genes were analyzed. The results showed that a wide variety of cellular processes were featured significantly in signaling pathways (Figure 2A and B). Many of these signaling pathways, such as insulin, MAPK, TGF-β and Wnt signaling pathway, participated in the tumorigenesis[14-17]. However, some other signaling pathways have never been reported to play a role in tumorigenesis, e.g., axon guidance. Among all these differentially regulated signaling pathways, "regulation of actin cytoskeleton" and "pathway in cancer" appeared to be the most enriched one among both up-regulated and down-regulated miRNA groups. A similar phenomenon was observed in GOs analysis. Many cellular functions were featured significantly, of which the "signal transduction" appeared to be the most enriched one (Figure 2C and D). The miRNA-mRNA interaction network analysis integrated these miRNAs and GOs by outlining the interactions of miRNA and GO-related genes (Figure 3A). MiR-519a and miR-199a-5p showed the target genes of 53 (degree 53) in up-regulated miRNAs and target genes of 32 (degree 32) in down-regulated miRNAs. MiR-138 had a degree of 30, which was the second place in down-regulated miRNAs. These results indicated that miR-138 and miR-199a-5p as well as their targets, might be of great importance to the HCC tumorigenesis. Twenty-six target genes, including *RPS6KA3*, *SMAD4*, *ACVR2A*, *CHC*, and *MAPK1*, *etc*., had more than 3 miRNAs (degree > 3) (Figure 3B).

CCND3 is a direct target of miR-138

Among these deregulated miRNAs, miR-138 was most abundant in non-tumor tissues and miR-199a-5p was most significant in paired HCC tissues (Figure 4A). Thus, miR-138 and miR-199a-5p were selected for the further study. CCND3 was predicted as a potential target of miR-138 by TargetScan. The 3'-UTR of CCND3 mRNA contained a complementary site for the seed region of miR-138 (Figure 4B). CCND3 was found to be up-regulated in 4 specimens of HCC tissues compared with adjacent non-tumor liver tissues (Figure 4C), showing a negative correlation with down-regulated miR-138. These results indicated that miR-138 may be associated with CNND3 and both of them may be involved in HCC tumorigenesis.

To validate whether CCND3 is a direct target of miR-138, a human CCND3 3'-UTR fragment containing wild-type or mutant miR-138 binding sequence (Figure 4B) was cloned downstream of the firefly luciferase reporter gene in pGL3. In HEK293 cells cotransfected with the reporter plasmids and miR-138 mimic or NC duplex, the luciferase activity of the reporter that contained wild-type 3'-UTR was significantly suppressed by miR-138 mimic, but the luciferase activity of mutant reporter was unaffected (Figure 4D), indicating that miR-138 may suppress gene expression through miR-138 binding sequence at the 3'-UTR of CCND3. Furthermore, transfection of miR-138 mimic decreased CCND3 expression in HepG2 cells at protein level (Figure 4E). All these results showed that miR-138 could regulate the expression of endogenous human CCND3 by directly

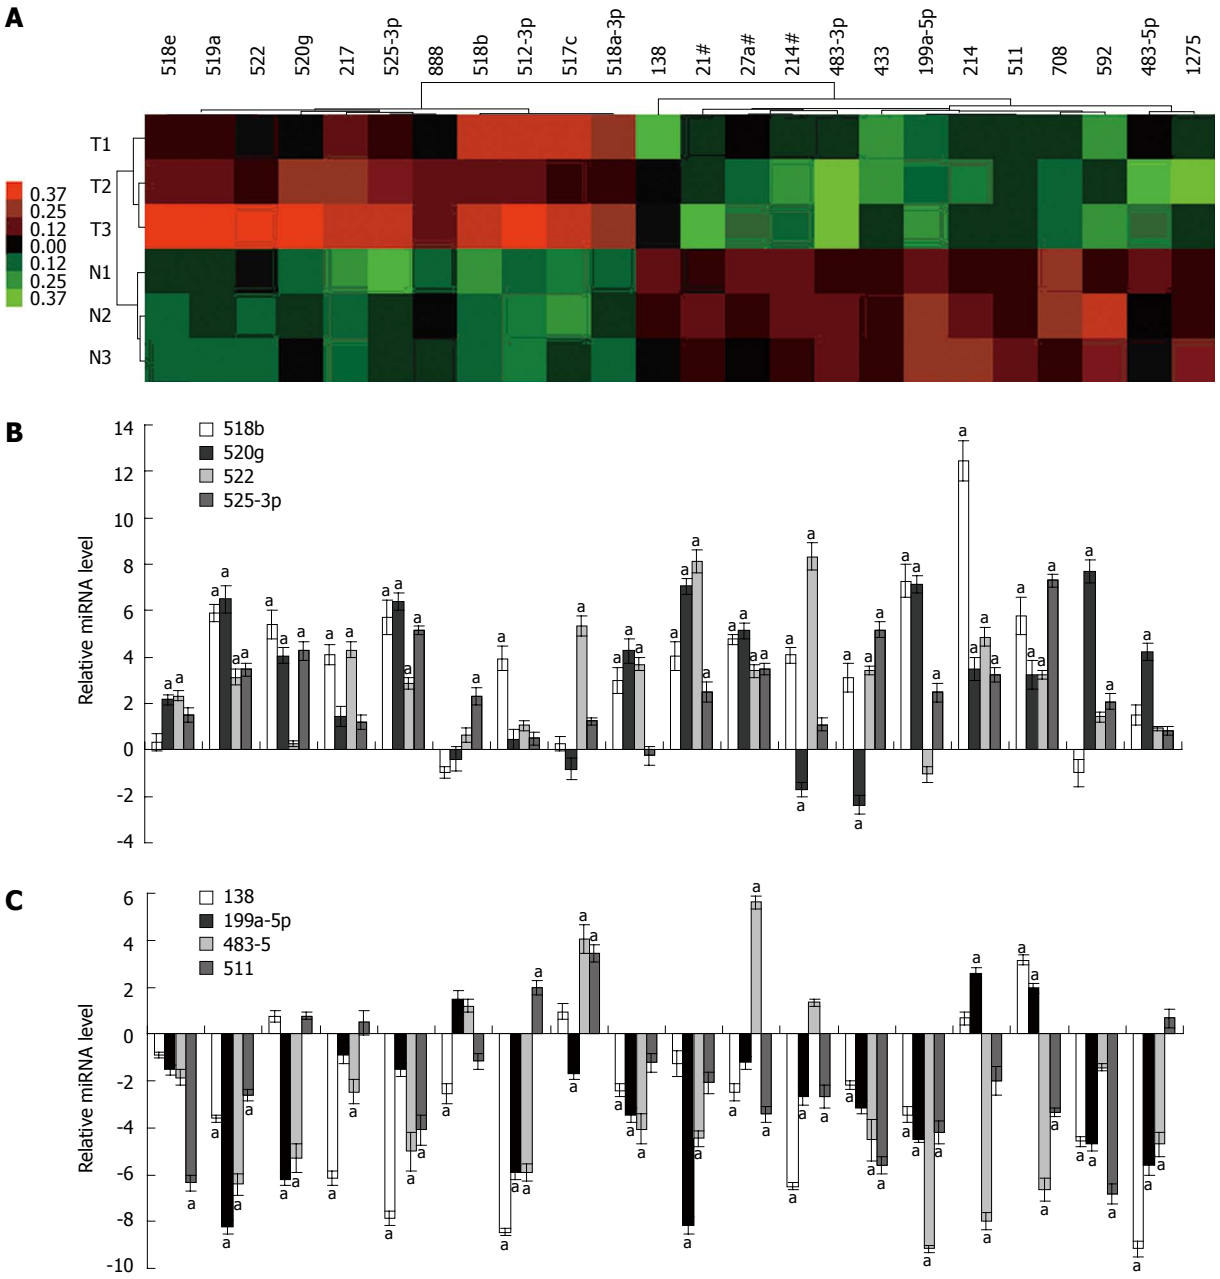

Figure 1 MiRNA profiles differentiate hepatitis B virus-associated hepatocellular carcinoma from adjacent non-tumor tissues. A: The cluster analysis of down-regulated (green) and up-regulated (red) miRNAs identified in hepatocellular carcinoma (hepatitis B virus-hepatocellular carcinoma). Samples consist of paired samples from three patients; B: Validation of Taqman array data using quantitative reverse transcription polymerase chain reaction (RT-PCR) for up-regulated miRNA; C: Validation of Taqman array data using quantitative RT-PCR for down-regulated miRNA. Triplicate assays were done for each RNA sample and the relative amount of each miRNA was normalized to U6 snRNA. $^{a}P < 0.01$ *vs* control group.

targeting the 3'-UTR of CCND3 mRNA and human CCND3 was a new target of miR-138.

Clathrin heavy chain is a direct target of miR-199a-5p

CHC was found to be a direct target of miR-199a-5p. CHC was predicted as a potential target of miR-199a-5p by TargetScan (Figure 4B). CHC was up-regulated in 4 specimens of HCC tissues as compared with adjacent non-tumor liver tissues (Figure 4C). The luciferase activity of the reporter containing wild-type 3'-UTR of CHC was significantly suppressed by miR-199a-5p mimic (Figure 4D). Furthermore, transfection of miR-199a-5p mimic decreased CHC expression in HepG2 cells at protein level (Figure 4E). The results showed that miR-199a-5p could regulate the expression of endogenous human CHC by directly targeting the 3'-UTR of CHC mRNA, and human CHC is a new target of miR-199a-5p.

DISCUSSION

MiRNAs were frequently deregulated in HCC, and some specific miRNAs were associated with the clinicopatho-

logical features of HCC, such as metastasis, recurrence, and prognosis[18-20]. Moreover, compelling evidence has demonstrated that miRNAs play an important role in HCC progression and directly contribute to the cell proliferation, avoidance of apoptosis, and metastasis of HCC. Identifying the miRNAs and their targets that are essential for HCC progression may provide promising therapeutic opportunities.

In this study, with Taqman miRNAs array and real-time RT-PCR confirmation, 10 up-regulated miRNAs (miR-217, miR-518b, miR-517c, miR-520g, miR-519a, miR-522, miR-518e, miR-525-3p, miR-512-3p, and miR-518a-3p) and 11 down-regulated miRNAs (miR-138, miR-214, miR-214#, miR-199a-5p, miR-433, miR-511, miR-592, miR-483-5p, miR-483-3p, miRNA-708 and miRNA-1275) were identified in HCC. More importantly, of these 21 deregulated miRNAs, only miR-199a-5p was involved in HCC[21,22], and the other 20 deregulated miRNAs were first reported to be involved in HCC tumorigenesis. No report of MiR-214#, miR-518a-3p and miR-518e has been available in the literature. The rest 17 miRNAs were reported in various cancer but not HCC. For example, the up-regulated miR-512-3p and miR-525-3p were associated with a cisplatin resistant phenotype in human germ cell tumors[23]. The up-regulated miR-519a and down-regulated miR-511 and miR-485-5p were associated with histological subtypes in ovarian cancers[24]. MiR-517c and 520 g promote *in vitro* and *in vivo* oncogenicity, modulates cell survival, and robustly enhances growth of untransformed human neural stem cells (hNSCs) in neuroectodermal brain tumors[25]. MiR-433 could regulate tumor-associated proteins GRB2 in gastric carcinoma[26]. MiR-592 was reported to be associated with the stepwise progression for transformation from normal colon to carcinoma[27].

On the contrary, some well known HCC-related miRNAs were not found in this study, possibly due to the very strict criteria of selection defined in TLDA (significant difference in all three pairs of HCC tissues). For example, miR-21[28], miR-122[29,30], miR-16[31] and miR-29[32,33] were excluded for their significantly differential expression only in 2 pairs of HCC tissues, and miR-181[34], miR-221[35,36], miR-125[37] and miR-101[38] were excluded for their differential expression in only 1 pair of HCC tissues or no differential expression at all. Using such strict criteria, we might miss some important candidates, but catch some unique ones. Fortunately, quantitative RT-PCR and follow-up studies proved that our strategy helped find the above new deregulated miRNAs. All of the HCC patients in this study were HBsAg positive. Therefore, the expression patterns of identified miRNAs may mainly represent the alterations in hepatitis B virus (HBV)-positive HCC, which may partially account for the inconsistency between our results and results from other studies.

KEGG pathway and GO enrichment analysis based on the reported and predicted target genes of these deregulated miRNAs, was applied to identify which particular functions and pathways were enriched among the genes controlling distinctive characters between HCC and adjacent non-tumor tissues. As a result, KEGG pathway analysis showed that proliferative (cell cycle, MAPK and Wnt), adhesive (actin cytoskeleton, adherens junction and focal adhesion), survival (TGF-β and ErbB) and oncogenic (renal cell carcinoma and pancreatic cancer) signaling pathways were abundant among the significantly enriched ones. Furthermore, the GOs related to signal transduction (signal transduction, small GTPase-mediated signal transduction, protein amino acid phosphorylation and nerve growth factor receptor signaling pathway) and cell growth (cell differentiation, cell division, positive regulation of cell proliferation, cell cycle and multicellular organism development) represented up to 37% of the significantly enriched GOs. As expected, various cell process and signal pathways were involved in HCC tumorigenesis. To narrow the scope of study and evaluate the most significant candidates, miRNAs and their target genes which were in the intersection of "signal transduction" and "regulation of actin cytoskeleton and pathway in cancer" might be the focus of the future studies.

Although computational analysis indicates that one miRNA may directly modulate hundreds of mRNAs, and a single gene may be regulated by multiple miRNAs, such regulation has not been convincingly demonstrated experimentally. As shown in Figure 3, miR-138 had 30 target genes and miR-199a-5p had 32 target genes. The

target genes are involved in different cellular processes, thus individual miRNAs play multi-faceted roles in HCC progression. Down-regulated miR-138 has been observed in different types of cancers but not in HCC[39-43]. MiR-138 plays an important role in tongue squamous cell carcinoma cell migration and invasion by concurrently targeting RhoC and ROCK2[39]. MiR-138 could inhibit the expression of HIF-1a and regulate the apoptosis and migration of clear-cell renal cell carcinoma 786-O cells[40]. MiR-138 enhanced cell migration and invasion by targeting enhancer of zeste homologue 2 (EZH2) in squamous cell carcinoma cell lines[41]. MiR-138 may play an important role in cancer initiation and progression by regulating Fos-like antigen 1 in squamous cell carcinoma[42] or G protein alpha inhibiting activity polypeptide 2(GNAI2) in tongue squamous cell carcinoma[43]. Different from miR-138, the down-regulated miR-199a-5p has been reported in HCC[21,22]. MiR-199a-5p contributes to the increase of cell invasion by functional deregulation of discoidin domain receptor-1 (DDR1) activity in HCC[21]. MiR-199a-5p regulates Brm subunit of SWI/SNF in human cancers[22]. We identified CCND3 as a target of miR-138 and CHC as a target of miR-199a-5p in HCC, which may provide new insights into the mechanisms underlying tumorigenesis. CCND3 is expressed in nearly all proliferating cells and can promote the cell cycle progres-

sion[44,45]. Liu Q reported that miR-16 family (including miR-16, miR-195 and miR-424) could induce cell cycle arrest by targeting CCND3, CCNE1 and Cdk6[46]. CHC is a part of clathrin expressed ubiquitously and exerts important functions in endocytosis and mitosis[47]. CHC has been reported to play an important role in inflammation disorder and tumorigenesis[48-51]. CHC functions as a co-activator for p53[48] and contributes to the regulation of basal NF-κB activity in epithelial cells[49]. CHC was identified as immunohistochemical tumor markers for primary HCC[50] and served as a biomarker for early diagnosis of small HCC[51]. Whether CCND3 and CHC regulated by miR-138 and miR-199a-5p respectively are involved in HCC tumorigenesis or other cell functions needs further studies.

In summary, we reported 21 deregulated miRNAs in HCC and CCND3 as the target of miR-138 and CHC as the target of miR-199a-5p. Our findings indicated that the novel miRNAs might be involved in HCC tumorigenesis and provide more evidence for the reliability of integrative bioinformatics analysis.

COMMENTS

Background

MiRNAs are endogenous non-coding RNAs (20-22 nucleotides) that have been identified as post-transcriptional regulators of gene expression. The miRNAs mainly bind to the 3' untranslated regions (UTRs) of target mRNAs, resulting in mRNA degradation or the blockade of mRNA translation. Increasing evidence has demonstrated that miRNAs play an important role in hepatocellular carcinoma (HCC) progression and directly contribute to the cell proliferation, avoidance of apoptosis, and metastasis of HCC. Identifying the miRNAs and their targets that are essential for HCC progression may provide promising therapeutic opportunities.

Research frontiers

Most recently identified miRNAs were found to be frequently deregulated in HCC, and some specific miRNAs were found to be associated with the clinicopathological features of HCC, such as metastasis, recurrence, and prognosis. Moreover, compelling evidence has demonstrated that miRNAs play an important role in HCC progression and directly contribute to the cell proliferation, avoidance of apoptosis, and metastasis of HCC.

Innovations and breakthroughs

In this study, 10 up-regulated miRNAs (miR-217, miR-518b, miR-517c, miR-520g, miR-519a, miR-522, miR-518e, miR-525-3p, miR-512-3p, and miR-518a-3p) and 10 down-regulated miRNAs (miR-138, miR-214, miR-214#, miR-27a#, miR-199a-5p, miR-433, miR-511, miR-592, miR-483-5p and miR-483-3p) were identified in HCC. Of the 20 deregulated miRNAs, only miR-199a-5p was reported to contribute to the increase of cell invasion by functional deregulation of discoidin domain receptor-1 activity in HCC and regulate Brm subunit of SWI/SNF in human cancers, and the other 19 deregulated miRNAs were first reported to be involved in HCC tumorigenesis. MiR-27a#, miR-214#, miR-518a-3p and miR-518e have never been reported in literatures. The rest 15 miRNAs were reported in various cancers, but not in HCC. Compared with the previous version, the newly found miRNAs (337 updated miRNAs) were profiled in Taqman low-density miRNA array v2.0, which helped the authors identify many new differentially expressed miRNAs in this study.

Applications

This study provides new insights into the understanding of the molecular mechanisms of hepatic carcinogenesis regulated by miRNA, and helps develop personalized miRNA-based therapeutics against HCC.

Terminology

MiRNAs are endogenous non-coding 20 to 22 nucleotide RNAs that have been identified as post-transcriptional regulators of gene expression. MiRNAs are processed from precursor molecules (pri-miRNAs), which are either transcribed from independent miRNA genes or are portions of introns of protein-coding RNA polymerase Ⅱ transcripts. A single pri-miRNA often contains sequences of several different miRNAs. Pri-miRNAs fold into hairpin structures containing imperfectly base-paired stems and are processed in two steps, catalyzed by the RNase III type endonucleases Drosha (also known as RN3) and Dicer. The Drosha-DGCR8 complex processes pri-miRNAs to ~70-nucleotide hairpins known as pre-miRNAs. In animals, premiRNAs are transported to the cytoplasm by exportin5, where they are cleaved by Dicer to yield ~20-bp miRNA duplexes. One strand is then selected to function as a mature miRNA, while the other strand is degraded. Occasionally, both arms of the pre-miRNA hairpin give rise to mature miRNAs.

Peer review

This article aimed to reveal microRNAs and target genes associated with hepatocellular carcinogenesis using miRNA array and network/pathway analyses combined with integrative bioinformatical analysis. The topic is of significant clinical importance as HCC is a very common and usually lethal liver tumor, and all researches that may reveal some potential target genes/miRNAs that offer new therapeutic possibilities are useful for the better understanding of the disease and related molecular biological mechanisms.

Abstract

AIM: To perform a comprehensive investigation into the potential correlation between circulating myeloid-derived suppressor cells (MDSCs) and Th17 cells in esophageal cancer (ECA).

METHODS: A total of 31 patients newly diagnosed with ECA and 26 healthy subjects were included in the current study. The frequencies of MDSCs and Th17 cells in peripheral blood were determined by flow cytometry. The mRNA expression of cytokines, arginase 1 (Arg1) and inducible NO synthase (iNOS) in peripheral blood mononuclear cells (PBMCs) and plasma Arg1 were assessed by real-time polymerase chain reaction and enzyme-linked immunosorbent assay, respectively.

RESULTS: There was an increased prevalence of MDSCs in the peripheral blood from ECA patients (15.21% ± 2.25%) when compared with healthy control (HC) (1.10% ± 0.12%, $P < 0.0001$). The plasma levels of Arg1 in ECA patients were significantly higher than those in HC (28.28 ± 4.10 ng/mL *vs* 9.57 ± 1.51 ng/mL, $P = 0.0003$). iNOS mRNA levels in the peripheral blood of ECA patients also showed a threefold increase compared with HC ($P = 0.0162$). The frequencies of Th17 cells ($CD4^+IL\text{-}17A^+$) were significantly elevated in ECA patients versus HC (3.50% ± 0.33% *vs* 1.82% ± 0.19%, $P = 0.0001$). Increased mRNA expression of IL-17 and ROR-γt was also observed in ECA patients compared with HC ($P = 0.0041$ and $P = 0.0004$, respectively), while the mRNA expression of IL-6 and tumor necrosis factor-α (TNF-α) showed significant decreases ($P = 0.0049$ and $P < 0.0001$, respectively). No obvious correlations were found between the frequencies of MDSCs and Th17 cells in the peripheral blood from ECA patients($r = -0.1725$, $P = 0.3534$). Arg1 mRNA levels were positively correlated with levels of IL-6 ($r = 0.6404$, $P = 0.0031$) and TNF-α ($r = 0.7646$, $P = 0.0001$). Similarly, iNOS mRNA levels were also positively correlated with levels of IL-6 ($r = 0.6782$, $P = 0.0007$) and TNF-α ($r = 0.7633$, $P < 0.0001$).

CONCLUSION: This study reveals the relationship between circulating MDSCs and Th17 cells, which may lead to new immunotherapy approaches for ECA based on the associated metabolites and cytokines.

INTRODUCTION

Myeloid-derived suppressor cells (MDSCs) represent a heterogeneous population of cells comprised of myeloid progenitor cells and immature myeloid cells, which exert suppressive functions, regulating T cell responses through the production of arginase 1 (Arg1), nitric oxide and reactive oxygen species. These cells are suspected to play a crucial role in local and systemic tumor development, providing a beneficial microenvironment in which tumor cells can proliferate, expand, acquire new mutations and escape host immunosurveillance[1]. Elevated numbers of MDSCs in peripheral blood have been demonstrated in a substantial number of studies in different types of cancer, including malignant gliomas[2], head and neck cancer[3,4], invasive breast carcinomas[4], colon carcinoma[5], pancreatic cancer[6] and mesothelioma[7].

In esophageal cancer (ECA), it has recently been shown that there is a significant increase in the levels of circulating MDSCs, which is correlated with elevated numbers of regulatory T cells (Tregs) and associated with an increased expression of Arg1[6]. A recent report has also identified that MDSCs not only modulate the de novo induction of Tregs and Th17 cells from $CD4^+$ T cells but also catalyze the transdifferentiation of $Foxp3^+$ regulatory T cells from monocyte-induced Th17 cells[8]. These findings suggested that the interaction between MDSCs and T cell subsets may play an important role in the balance of anti- and pro-tumor immune responses. As a new member of the $CD4^+$T-cell family, Th17 cells have been characterized as preferential producers of interleukin (IL)-17A, IL-17F, IL-21, IL-22, and tumor necrosis factor-α (TNF-α) and have been found in increased numbers in tumor-bearing hosts, including ECA[9-11]. However, it is still controversial whether these Th17 cells promote or inhibit tumor progression[12-14]. Furthermore, whether there is a correlation between circulating MDSCs and Th17 cells in ECA remains unclear. The present study was designed to evaluate the relationship between circulating MDSCs and Th17 cells by examining the cell frequencies and related cytokines and other associated products in the peripheral blood from patients with ECA.

MATERIALS AND METHODS

Patients and healthy controls

Thirty-one patients (25 male, 6 female) newly diagnosed with ECA were included in the current study. These patients ranged from 50 to 78 years of age (average age, 61.97 ± 1.24 years). Twenty-six healthy subjects, matched for age and sex with the ECA patients, were studied as the controls. No subject was treated preoperatively or had a history of autoimmune disease, and no healthy control had a prior history of cancer. This study was approved by the research ethics committee of the Affiliated Hospital of Jiangsu University, and written informed consent was obtained from all individuals.

Flow cytometric quantification of myeloid-derived suppressor cells

The MDSC population was defined as $HLA\text{-}DR^-/CD14^-/CD33^+/CD11b^+$. Heparinized venous blood was freshly obtained from either the ECA patients or the healthy donors. One hundred microliters of blood was mixed with 5μl of each antibody (BD Bioscience, San Jose, CA or eBioscience, San Diego, CA, United States), then incubated in a dark room for 15 min. Each sample was then mixed with 1 mL of 1 × lysing buffer (BD Biosciences). After incubation, the samples were washed with phosphate buffered saline (PBS), and the pellets were resuspended in 250 μL of PBS. Labeled cells were washed and analyzed with a FACSCalibur flow cytometer (Becton-Dickinson) using CellQuest software (Becton-Dickinson). In each case, staining was compared with that of the appropriately labeled isotype control antibody.

Flow cytometric quantification of Th17 cells

Following centrifugation, the plasma was removed and stored at -70 ℃, while peripheral blood mononuclear cells (PBMC) were isolated by Ficoll density gradient centrifugation. PBMCs were used in two parts. Some PBMCs were frozen at -70 ℃ after mixing with TRIzol (Invitrogen, Carlsbad, CA, United States) for extracting total RNA, while the remaining cells was used for analysis of Th17 cells. Briefly, PBMCs were stimulated for 5 h using 50 ng/mL of phorbol myristate acetate (PMA, Sigma-Aldrich, MO, United States) and 1 g/mL ionomycin (Sigma-Aldrich, MO, United States) in the presence of 5 g/mL brefeldin A (Sigma-Aldrich, MO, United States) at

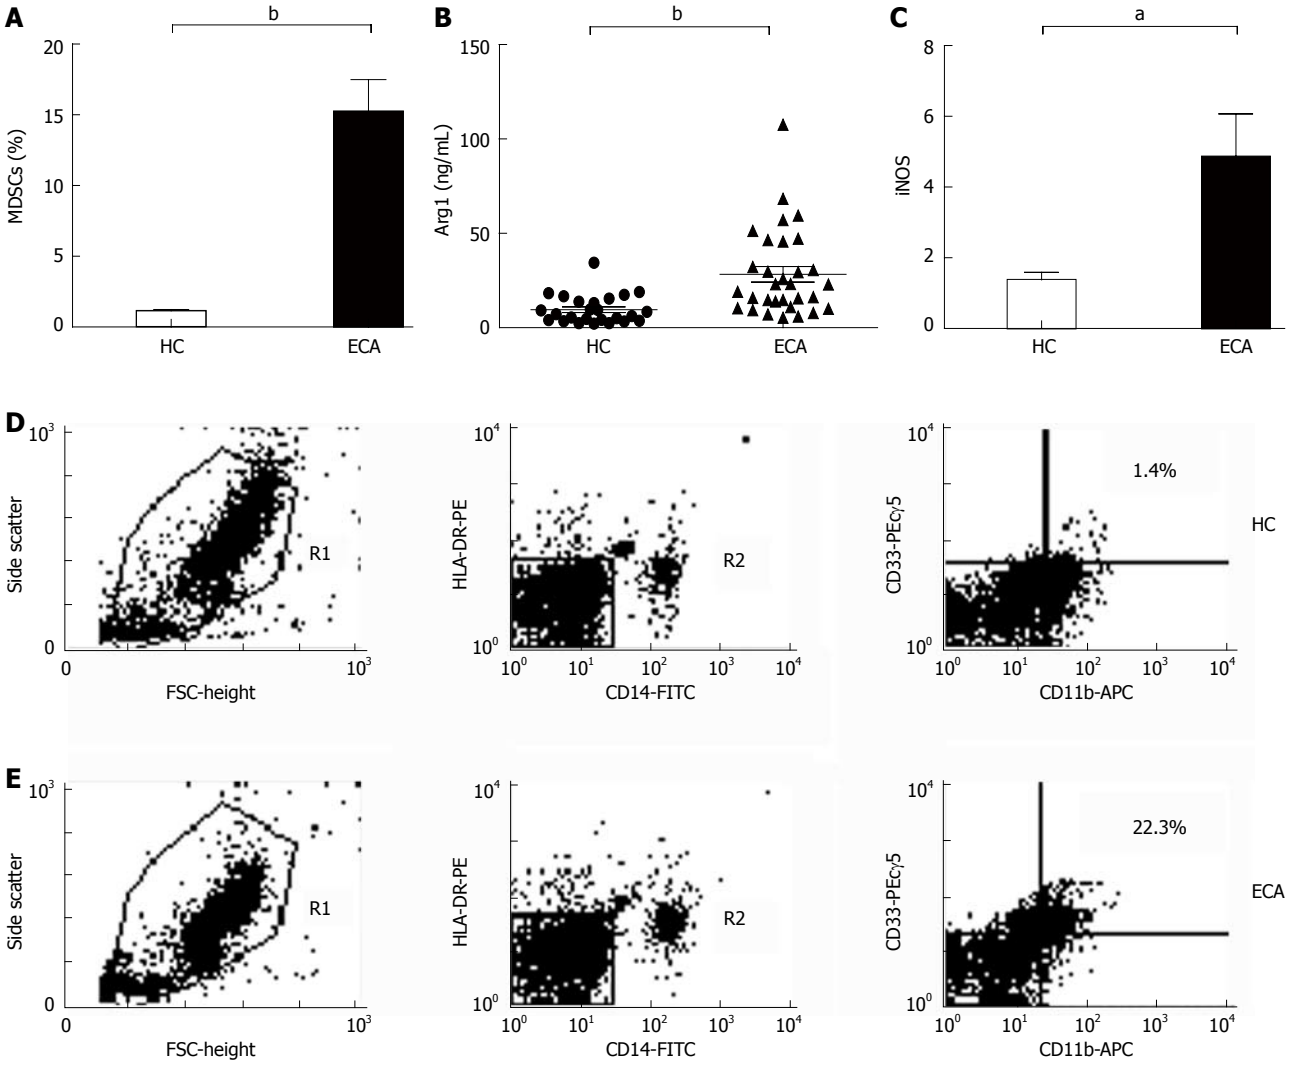

Figure 1 Elevated levels of myeloid-derived suppressor cells and their products, arginase 1 and inducible NO synthase, in esophageal cancer compared with healthy controls. Data were analyzed by the Student's *t*-test. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* HC group. ECA: Esophageal cancer; MDSCs: Myeloid-derived suppressor cells; ELISA: Enzyme linked immunosorbent assay; iNOS: Inducible NO synthase; PCR: Polymerase chain reaction; FITC: Fluorescein isothiocyanate; FSC: Forward scatter; HLA-DR-PE: HLA-DR-phycoerythrin; APC: Allophycocyanin.

37 ℃ and 5% CO_2. The cells were then washed in PBS and surface-labeled with CD4-FITC (eBioscience, San Diego, CA, United States). Following surface staining, the cells were fixed and permeabilized using IntraPrep Permeabilization Reagent (Beckman Coulter Inc., Fullerton, CA, United States) and then stained with IL-17A-PE (eBioscience, San Diego, CA, United States)[11]. Labeled cells were washed and analyzed with a FACSCalibur flow cytometer (Becton-Dickinson) using the CellQuest software (Becton-Dickinson).

RNA extraction, cDNA synthesis and polymerase chain reaction

Total RNA was extracted from individual PBMC preparations using the TRIzol reagent (Invitrogen, Carlsbad, CA, United States). cDNA was prepared by reverse transcription with oligo (dT) from total RNA extraction. Real-time polymerase chain reaction (PCR) for IL-17, IL-6, TNF-α, Arg1, iNOS and a reference gene (β-actin) was performed in a LightCycler instrument (Roche Molecular Diagnostics, Mannheim, Germany) using the SYBRgreen mastermix kit (TaKaRa, Ohtsu, Japan). The expression data for each target gene were then normalized relative to β-actin. All primer sequences are shown in Table 1.

Enzyme-linked immunosorbent assay

Plasma levels of Arg1 were measured using an enzyme-linked immunosorbent assay (ELISA) following the manufacturer's protocols (eBioscience, San Diego, CA, United States). Hemolyzed samples were excluded. All samples were assayed in triplicate, and the mean absorbance was calculated from the standard curve.

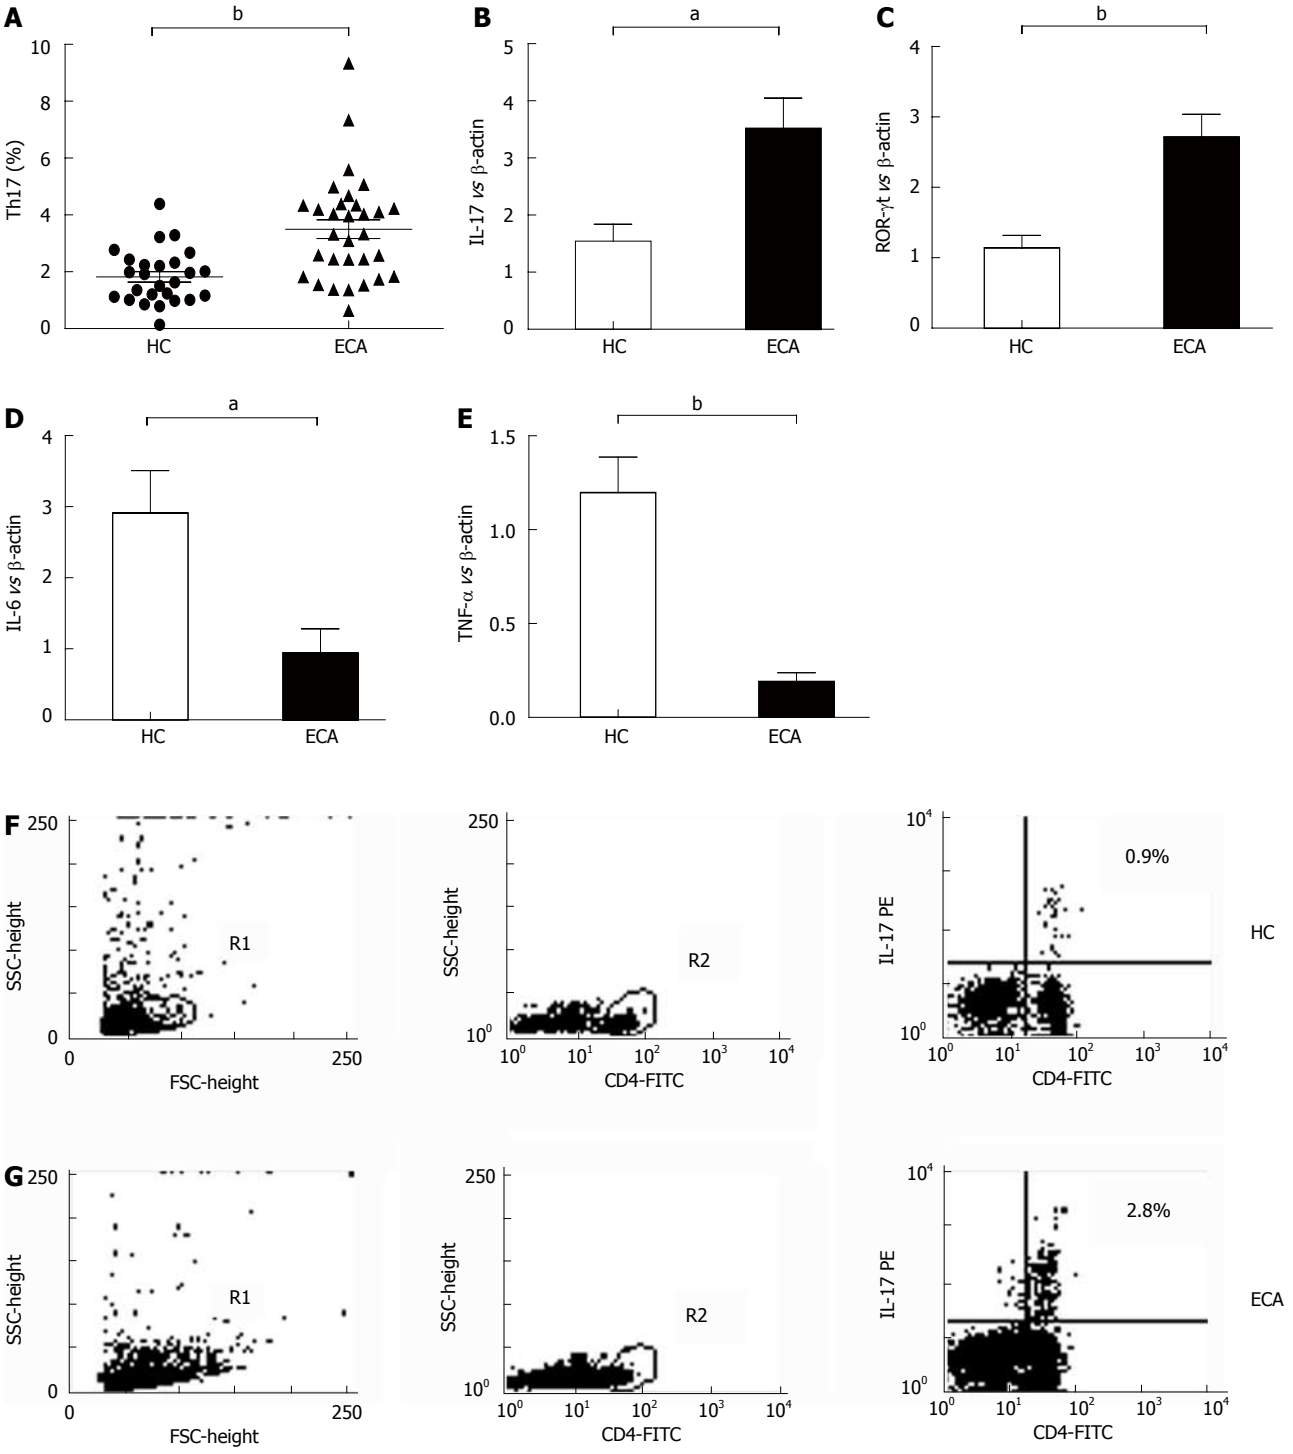

Figure 2 Levels of Th17 cells and Th17-related cytokines and transcriptional factor in the peripheral blood of esophageal cancer compared with healthy controls. Version 5.0, software (San Diego, CA, United States).

RESULTS

Increased frequencies of myeloid-derived suppressor cells in the peripheral blood of esophageal cancer patients

In the present study, MDSCs was defined as HLA-DR$^-$/CD14$^-$/CD11b$^+$/CD33$^+$ cells. The frequencies of MDSCs were determined by multicolor flow cytometry and calculated as the percent (%) of total nucleated cells in whole blood samples. As shown in Figure 1A, D and E, there was an increased prevalence of MDSCs in the peripheral blood from ECA patients (15.21% ± 2.25%) when compared with healthy control (HC) (1.10% ± 0.12%, $P < 0.0001$).

Increased plasma arginase 1 and inducible NO synthase mRNA expression in the peripheral blood from esophageal cancer patients

To investigate whether the products of MDSCs were also elevated in ECA patients, we determined the plasma levels of Arg1 by ELISA and the mRNA levels of iNOS by real-time PCR. As shown in Figure 1B, the plasma levels of Arg1 in ECA patients were significantly higher than those in HC (28.28 ± 4.10 ng/mL *vs* 9.57 ± 1.51 ng/mL, $P = 0.0003$). iNOS mRNA levels in the peripheral blood of ECA patients also showed a threefold increase compared with HC ($P = 0.0162$, Figure 1C).

Increased frequency of Th17 cells in the peripheral blood mononuclear cells of esophageal cancer patients

The frequencies of Th17 cells in PBMCs of ECA patients and HC were also determined by flow cytometry. As shown in Figure 2A, C and D, the frequencies of Th17 cells (CD4$^+$IL-17A$^+$) were significantly elevated in ECA patients when compared with HC (3.50% ± 0.33% *vs* 1.82% ± 0.19%, $P = 0.0001$).

mRNA expression analyses in peripheral blood mononuclear cells from esophageal cancer patients showed increased interleukin-17 and ROR-γt and decreased interleukin-6 and tumor necrosis factor-α

We also determined the mRNA levels of the Th17-related molecules IL-17, ROR-γt, IL-6 and TNF-α by real-time PCR. As shown in Figure 2B, increased mRNA expression of IL-17 and ROR-γt was observed in ECA patients compared with HC ($P = 0.0041$ and $P = 0.0004$, respectively), while the mRNA expression of IL-6 and TNF-α showed significant decreases ($P = 0.0049$ and $P < 0.0001$, respectively).

Correlation between myeloid-derived suppressor cells and Th17 cells in the peripheral blood from esophageal cancer patients and HC

We next analyzed the possible correlation between the frequencies of MDSCs and Th17 cells in the peripheral blood from ECA patients and HC. As shown in Figure 3, no obvious difference was found between the two groups ($r = -0.1725$, $P = 0.3534$).

Correlation of arginase 1, inducible NO synthase and Th17 cell-related molecules in the peripheral blood from HC and esophageal cancer patients

We examined the possible correlations between the mRNA levels of Arg1, iNOS and Th17-related molecules (IL-17, ROR-γt, IL-6 and TNF-α) in ECA patients. As shown in Figure 4D and E, Arg1 mRNA levels were positively correlated with levels of IL-6 ($r = 0.6404$, $P = 0.0031$) and TNF-α ($r = 0.7646$, $P = 0.0001$). Similarly, as shown in Figure 4I and J, iNOS mRNA levels were also positively correlated with levels of IL-6 ($r = 0.6782$, $P = 0.0007$) and TNF-α ($r = 0.7633$, $P < 0.0001$). However, no obvious correlations were observed with Arg1 or iNOS with IL-17 or ROR-γt (Figure 4A-C and 4F-G).

DISCUSSION

MDSCs are a heterogeneous cell population that was recently identified as a pivotal factor in the immunosuppressive network described in cancer, autoimmune disease, sepsis, infectious disease and trauma[1,15,16]. In cancer, MDSCs are responsible for T cell defects as well as angiogenesis and tumor cell motility. In this study, we evaluated the frequencies of MDSCs in the peripheral blood in ECA patients. Our study confirms previous findings about the significant increase of circulating MDSCs in a variety of cancers. An early study reported the accumulation of immature cells, including early stage myeloid cells and immature monocytes and DCs, in the blood of patients with head and neck, breast, and lung cancer[4]. Myeloid cells with immunosuppressive properties can also be found among monocytes and neutrophils circulating in the peripheral blood of patients with colon cancer and melanoma[5]. Patients with glioblastoma have increased MDSC counts (CD33$^+$HLADR$^-$) in their blood that are composed of neutrophilic (CD15$^+$, > 60%), lineage-

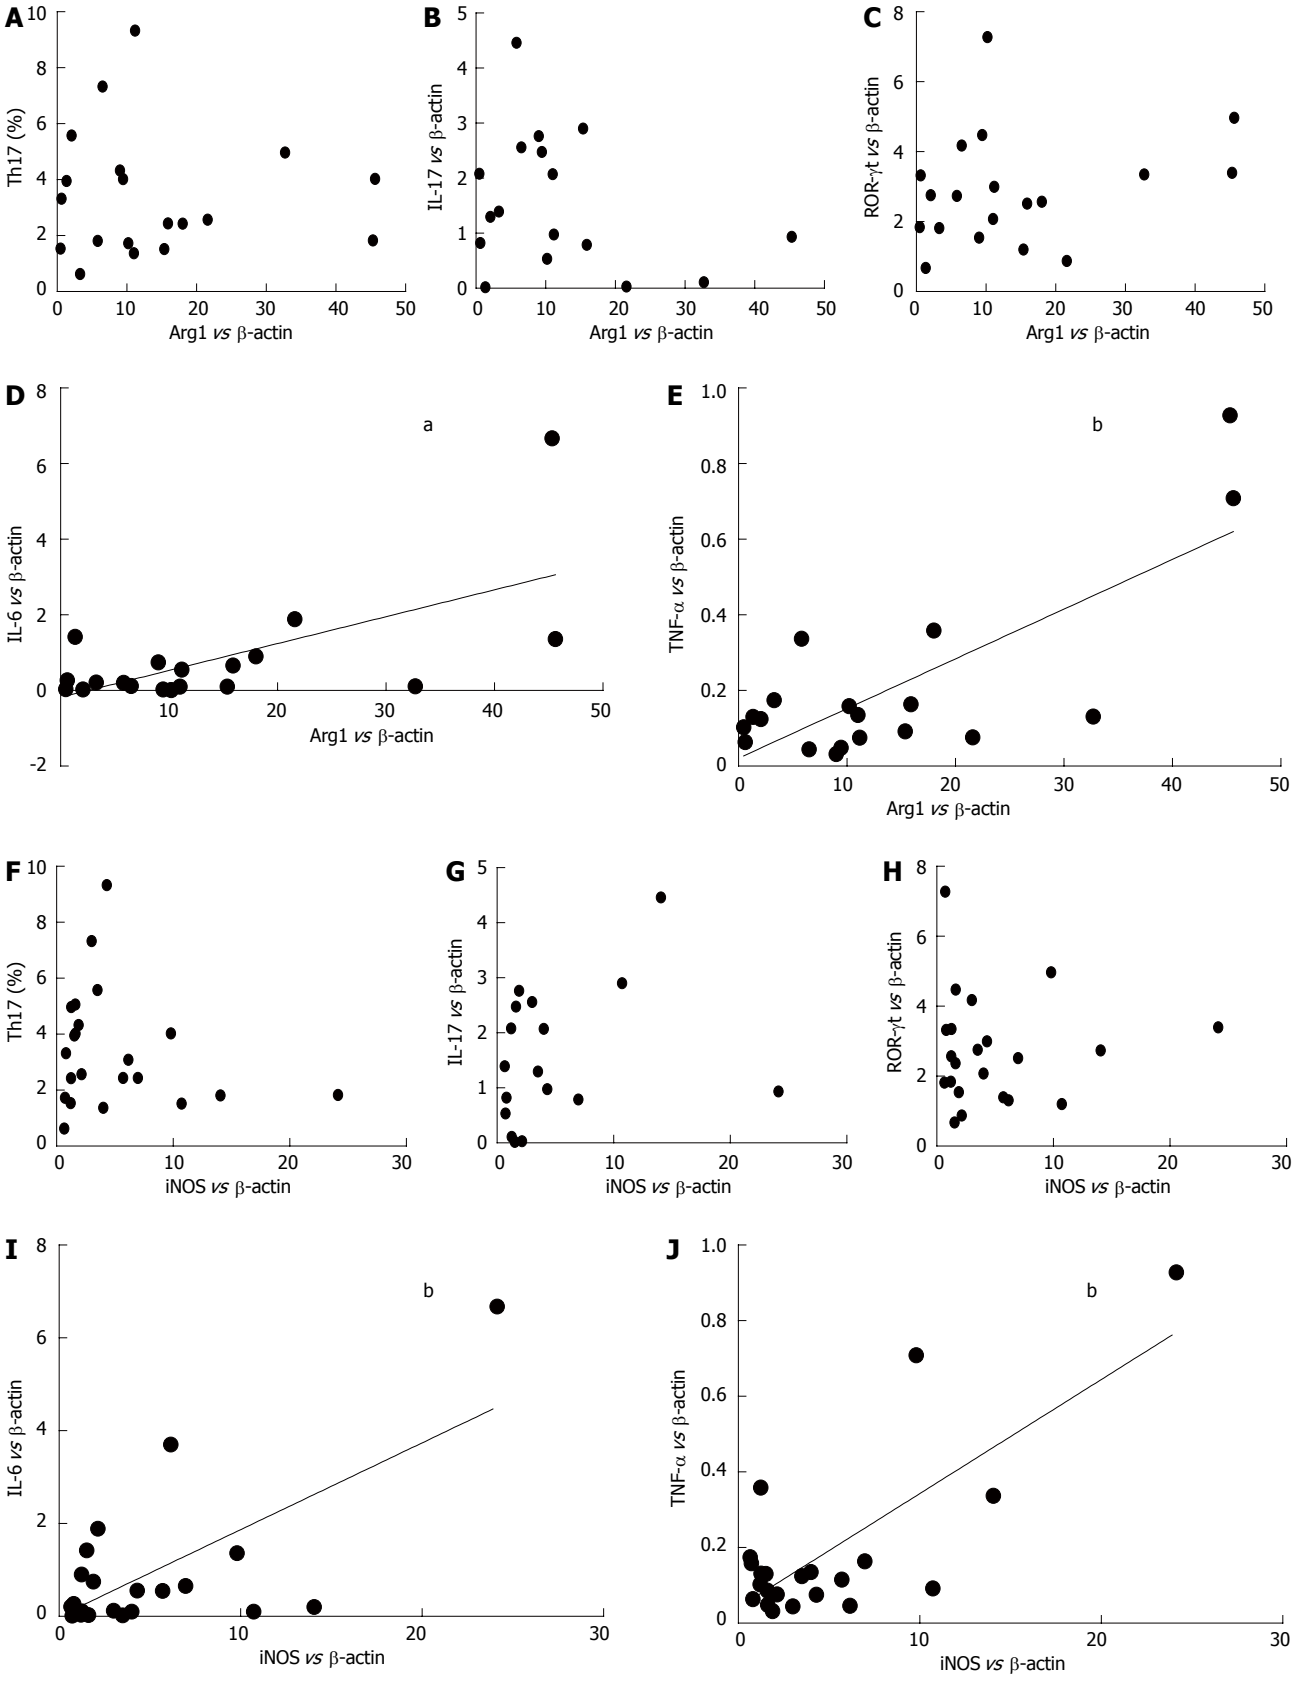

Figure 4 Correlations between the mRNA level of arginase 1 or inducible NO synthase and Th17-related molecules (interleukin-17, ROR-γt, interleukin-6 and tumor necrosis factor-α) in the peripheral blood of esophageal cancer patients. Data were analyzed by the Spearman test. [a]$P < 0.05$, [b]$P < 0.01$ *vs* β-actin. TNF-α: Tumor necrosis factor-α; IL: Interleukin; iNOS: Inducible NO synthase; Arg1: Arginase 1.

negative ($CD15^-CD14^-$, 31%), and monocytic ($CD14^+$, 6%) subsets[2]. It has also been reported that there was an accumulation and persistence of long-lived immature granulocytic MDSC with T cell-suppressive function and impaired migratory properties in the peripheral blood of squamous cell carcinoma of the head and neck (HNSCC), lung cancer and cancers of bladder and ureter[3]. Overall, these studies demonstrated the increase of circulating MDSCs in cancers, although the levels of MDSCs in peripheral blood varied across studies. These varying levels may partly be the result of differences in the type of cancers. Another explanation for these discrepancies may be methodological differences in which different markers and cell preparations were used to identify MDSCs.

In human, MDSCs are most prevalently considered as cells expressing CD11b but lacking the expression of CD14 or more narrowly defined as $HLA\text{-}DR^-CD33^+$ cells[4,17]. In this study, we used $CD14^-HLA\text{-}DR^-CD33^+CD11b^+$ as specific markers for human MDSCs in lysed whole blood. A recent study also reported elevated MDSCs in pancreatic, esophageal and gastric cancer and demonstrated that these cells were an independent prognostic factor and associated with the significant elevation of the Th2 cytokine interleukin-13[6]. The authors of such study focused on circulating MDSCs defined as $HLADR^-Lin1^{low/-}CD33^+CD11b^+$ and used a cell preparation of PBMCs rather than lysed whole blood, as was used in our study. However, both studies demonstrated elevations of plasma Arg1, which is the functional product of MDSCs, in ECA patients, compared with the controls. In addition to Arg1, we also found that iNOS mRNA levels in the peripheral blood of ECA patients showed a threefold increase compared with HC ($P = 0.0162$).

It is generally believed that Th17 cells and their associated cytokines IL-6, TNF, IL-1β, IL-23 and TGF-β may play important roles in promoting the growth and survival of cancer. Consistent with other previous reports, our study demonstrated that ECA patients exhibited a remarkable increase in the frequency of circulated Th17 cells. Furthermore, the mRNA levels of Th17-related cytokines, IL-17 and ROR-γt, have also been shown to be significantly increased[18]. Deans *et al*[19]reported that proinflammatory cytokines IL-6 and TNF-α were significantly overexpressed both at the mRNA and protein levels in cancer specimens compared with the mucosa from controls. However, in contrast to Deans's study, we found that the mRNA levels of IL-6 and TNF-α were obviously decreased in ECA patients. One possible explanation for this discrepancy may result partly from the limited scale of ECA subjects and determination methods. Another explanation is that, as is the case for most cancers, changes in peripheral blood could reflect partly or rather poorly the changes in tumor microenvironment. Further investigation should be performed to confirm the above inferences.

Recent data demonstrated that *in vivo* transfer of G-MDSCs inhibited Th17 immune responses and ameliorated experimental autoimmune encephalomyelitis (EAE)[20]. *In vitro*, $CD14^+HLA\text{-}DR^+$ monocytes promote the generation of IL-17-secreting $RORc^+$ Th17 cells when cocultured with naive CD4+ T cells[8]. These results suggest that the interaction of MDSC with Th17 cells would help to explain the pathogenesis of autoimmune diseases and cancers. In fact, the initial question that motivated our study was to determine whether there would be a positive correlation between circulating MDSCs and Th17 cells in individual ECA patient. As expected, there were high correlations between the mRNA levels of Arg1 or iNOS and IL-6 or TNF-α, which represent the products of MDSCs and Th17 cells, respectively. Although both the frequencies of MDSCs and Th17 cells in ECA were much higher than those in healthy controls, there was surprisingly no obvious correlation between the frequency of circulation MDSCs and Th17 cells. Consistently, there were no significant correlations between Arg1 or iNOS and Th17 cells, IL-17 or ROR-γt. There is no clear explanation for such unexpected results. Further studies are necessary to explore whether the peripheral increase of these cells could be found in local cancer tissue and whether a correlation between MDSCs and Th17 cells exist.

In conclusion, we have demonstrated a significant increase in circulating MDSCs and Th17 cells in ECA patients. The frequency of MDSCs is not correlated with Th17 cells. Arg1 and iNOS, the products of MDSCs, are consistently not associated with Th17 cells, IL-17 or ROR-γt but are positively correlated with Th17-related cytokines, including IL-6 and TNF-α. These results may bring new lines of investigation on the role of MDSCs and Th17 cells in ECA, possibly leading to new immunotherapy approaches based on the regulation of metabolites and cytokines.

COMMENTS

Background

Esophageal cancer (ECA) occurs when the tissue that lines the esophagus becomes malignant. Cancer of the esophagus is the sixth leading cause of cancer mortality worldwide, constituting approximately 2% of all malignant tumors. The precise mechanisms of initiation and progression of this disease are unclear. Recently, a suppressor cell population of myeloid lineage was identified, named myeloid-derived suppressor cells (MDSCs), which is capable of reducing antitumor as well as inflammatory immune responses. However, the characterization of MDSCs and their correlation with the newly identified pro-inflammatory Th17 cells in esophageal cancer remains unclear.

Research frontiers

MDSCs have gained much attention in recent years, mainly in the tumor immunology community. Because MDSCs are still a very poorly defined cell population, it will be difficult to specifically target these cells in cancer patients with the aim of engaging tumor-specific immune responses. The current research priority is how to identify better markers and the interaction of MDSCs with other cell types in different clinical settings, including in esophageal cancer.

Innovations and breakthroughs

Although the distribution of MDSCs and Th17 cells in esophageal cancer has been previously reported, a comprehensive correlation between circulating MDSCs and Th17 cells in ECA remains unclear. The present study was designed to evaluate the relationship between circulating MDSCs and Th17 cells by examining the cell frequencies and related cytokines and other products in the peripheral blood from patients with ECA. The authors confirmed previous findings about significant increases in circulating MDSCs and Th17 cells in ECA patients. However, the frequency of MDSCs is not correlated with Th17 cells.

Arginase I (Arg1) and inducible NO synthase (iNOS), the products of MDSCs, are consistently not associated with Th17 cells, IL-17 or ROR-γt but are positively correlated with Th17-related cytokines, including interleukin (IL)-6 and tumor necrosis factor-α (TNF-α). The results reveal the association between circulating MDSCs and Th17 cells, which may lead to new immunotherapy approaches for ECA based on the regulation of metabolites and cytokines.

Applications

Although it is difficult to specifically target these cells for immunotherapy, the results suggest that the regulation of metabolites and cytokines would be a potential therapeutic approach for esophageal cancer.

Terminology

MDSCs: Myeloid-derived suppressor cells (MDSCs), a heterogeneous population of cells that consists of immature myeloid cells, immature granulocytes, monocytes-macrophages, dendritic cells and myeloid progenitor cells, is capable of reducing anti-tumor as well as inflammatory immune responses; Th17 cells: a new member of the $CD4^+$T cell family that have been characterized as preferential producers of interleukin-17A (IL-17A), IL-17F, IL-21, IL-22, and TNF-α and have been found in increased numbers in tumor-bearing hosts.

Peer review

This paper reported on the relationship between MDSCs and Th17 cells in ECA patients. The presented data are preliminary but novel.

Abstract

AIM: To investigate the effect and the possible mechanism of ginsenoside Rb1 on small intestinal smooth muscle motility in mice.

METHODS: Intestinal smooth muscle strips were isolated from male ICR mice (5 wk old), and the effect of ginsenoside Rb1 on spontaneous contraction was recorded with an electrophysiolograph. The effect of ginsenoside Rb1 on ion channel currents, including the voltage-gated K^+ channel current (IK_V), calcium-activated potassium channel currents (IK_{Ca}), spontaneous transient outward currents and ATP-sensitive potassium channel current (IK_{ATP}), was recorded on freshly isolated single cells using the whole-cell patch clamp technique.

RESULTS: Ginsenoside Rb1 dose-dependently inhibited the spontaneous contraction of intestinal smooth muscle by 21.15% ± 3.31%, 42.03% ± 8.23% and 67.23% ± 5.63% at concentrations of 25 μmol/L, 50 μmol/L and 100 μmol/L, respectively (n = 5, P < 0.05). The inhibitory effect of ginsenoside Rb1 on spontaneous contraction was significantly but incompletely blocked by 10 mmol/L tetraethylammonium or 0.5 mmol/L 4-aminopyridine, respectively (n = 5, P < 0.05). However, the inhibitory effect of ginsenoside Rb1 on spontaneous contraction was not affected by 10 μmol/L glibenclamide or 0.4 μmol/L tetrodotoxin. At the cell level, ginsenoside Rb1 increased outward potassium currents, and IK_V was enhanced from 1137.71 ± 171.62 pA to 1449.73 ± 162.39 pA by 50 μmol/L Rb1 at +60 mV (n = 6, P < 0.05). Ginsenoside Rb1 increased IK_{Ca} and enhanced the amplitudes of spontaneous transient outward currents from 582.77 ± 179.09 mV to 788.12 ± 278.34 mV (n = 5, P < 0.05). However, ginsenoside Rb1 (50 μmol/L) had no significant effect on IK_{ATP} (n = 3, P < 0.05).

CONCLUSION: These results suggest that ginsenoside Rb1 has an inhibitory effect on the spontaneous contraction of mouse intestinal smooth muscle mediated by the activation of IK_V and IK_{Ca}, but the K_{ATP} channel was not involved in this effect.

INTRODUCTION

Sijunzi decoction (SJZD) is one of the most famous and widely used traditional prescriptions. This prescription contains four common herbs, including Panax ginseng, Poria cocos, Atractylodes macrocephala and Glycyrrhiza uralensis, and it has been used either alone to replenish or invigorate intestinal and stomach function or as a complement to other herbs during treatment of other diseases, such as poor health and cancer[1,2]. Ginseng, the root of Panax ginseng C. A. Meyer (Araliaceae), is a principal component of SJZD. Ginsenoside, a component of ginseng, has a four-ring steroid-like structure with attached sugar moieties. Recently, ginseng's chemical and pharmacological properties have been reported by many investigators[3,4]. Approximately 30 ginsenosides have been isolated and identified from the Panax ginseng root. These ginsenosides appear to be responsible for most of the pharmacological effects of ginseng. Many reports made it evident that ginseng saponins, or ginsenosides, have various effects on gastrointestinal motility. Ginsenosides modulate the pacemaker activities of the interstitial cells of Cajal (ICCs), making the ICCs targets for ginsenosides, and their interaction can affect intestinal motility[5]. The aqueous extract of Ginseng Radix possesses ameliorative properties and improves carbachol-induced accelerated small intestinal transit, and Rb1 contributed to the suppressive effects of Ginseng Radix on intestinal motility. Rb1 is one representative of the compounds contained in Ginseng Radix that is capable of ameliorating the accelerated transit of the small intestine[6]. However, the mechanism of Rb1 modulation of gastrointestinal motility has not been clearly demonstrated. Based on the studies cited above, it could be deduced that ICCs and gastrointestinal smooth muscle cells might be targets for Rb1. In this study, we attempted to determine the effect of ginsenoside Rb1 on the motility of intestinal smooth muscle and determine its mechanism.

MATERIALS AND METHODS

Preparation of intestinal smooth muscle and isometric measurement

Five-week-old male ICR mice (provided by the Experimental Animal Centre of the Chinese Academy of Sciences, Shanghai) weighing approximately 30 g were sacrificed by cervical dislocation. The small intestines were removed and kept in Krebs solution. After removing the mucosal and submucosal layers, single circular muscle bundles with the attached longitudinal muscle layer were prepared. Approximately 2 mm × 6 mm muscle strips were needed and were fixed in a vertical chamber (5-mL capacity containing 5 mL CO_2/bicarbonate-buffered Krebs solution bubbled with 5% CO_2/95% O_2). The chamber was maintained at 37 ℃ using a water jacket. One end of the chamber was attached to an isometric force transducer (RM6240C, Chengdu Instrument Factory, China) to record the contraction. The muscle strip was incubated at the appropriate tension[7].

Cell preparation and electrophysiological recording

Intestinal smooth muscle cells were freshly isolated from mice. The intestine was rapidly cut, and the mucosal layer was separated from the muscle layers in a Ca^{2+}-free physiological salt solution (Ca^{2+}-free PSS). The circular muscle layer was dissected from the longitudinal layer using fine scissors and was cut into small segments (2 mm × 3 mm). These segments were incubated in a medium modified from Kraft-Bruhe (K-B) solution for 30 min at 4 ℃. The segments were subsequently incubated for 10-12 min at 36 ℃ in Ca^{2+}-free PSS digestion medium containing collagenase (0.5 mg/mL, Worthington), DTT [0.5 mg/mL, Sigma Aldrich (St. Louis, MO, United States)], papain [1.5 mg/mL, Sigma Aldrich (St. Louis, MO, United States)] and bovine serum albumin (4 mg/mL, Biotech Grade)[7,8]. After digestion, the supernatant was discarded, and the softened muscle segments were transferred into the modified K-B solution. The single cells were dispersed by gentle trituration using a wide-bore fire-polished glass pipette. The isolated intestinal smooth muscle cells were incubated in a modified K-B solution at 4 ℃ until use on the same day. Several drops of the cell suspension were dropped into a perfusion bath, which was fixed on the stage of an inverted phase-contrast microscope for 15-20 min before the experiments. Next, the cells were perfused with PSS at a rate of 1-1.5 mL/min. A single 4-channel perfusion system (BPS-4, ALA, United States) was used to exchange the solution.

A conventional whole-cell patch clamp configuration was used to record the K_{ATP} channel current (IK_{ATP}), the spontaneous transient outward currents (STOC) and the voltage-gated K^+ channel current (IK_V). To record IK_{ATP}, the membrane potential was clamped at -60 mV. The pipette solution consisted of the following (mmol/L): KCl 107, KOH 33, Hepes 10, $MgCl_2$ 1, Na_2ATP 0.1, NaADP 0.1, and GTP 0.3, adjusted to a pH of 7.2 with NaOH. To observe the effect of Rb1 on IKv, we applied a depolarising step pulse to the cells, and the membrane potential was clamped at -60 mV. The pipettes were filled with solution containing the following (mmol/L): KCl 20, potassium-aspartic acid 110, di-tris-creatine phosphate 2.5, disodium creatine phosphate 2.5, MgATP 5, Hepes 5, $MgCl_2$ 1.0, and EGTA 10, adjusted to a pH of 7.3 with KOH. To record STOC, the holding potential was clamped at -20 mV. The pipettes were filled with a solution containing the following (mmol/L): KCl 140, $MgCl_2$ 5, K_2ATP 2.7, Na_2GTP 0.1, disodium salt 2.5, Hepes 5, and EGTA 0.1, adjusted to a pH of 7.2 with Tris. The patch pipettes were pulled from borosilicate glass capillaries using a pipette puller (PC-10, Narishige Group, Japan). The current was amplified with an EPC-10 patch

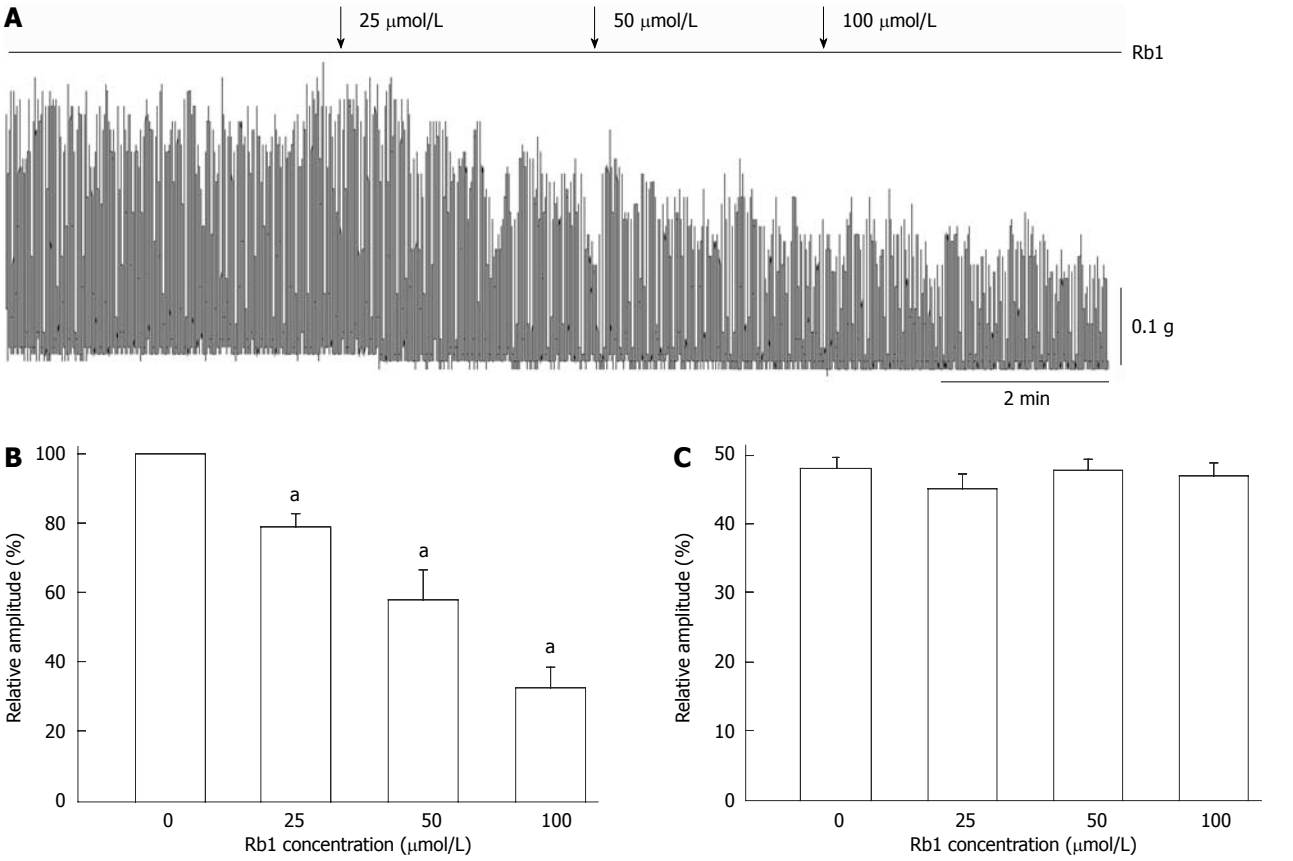

Figure 1 Effect of Rb1 on spontaneous contraction of intestinal smooth muscle. A: The representative effects of Rb1 on spontaneous contraction of intestinal smooth muscle in a dose-dependent manner; B, C: The amplitude of spontaneous contraction was decreased after Rb1 administration, but the frequency was unaffected. Values are expressed as means ± SE. $n = 5$, $^aP < 0.05$ *vs* control group.

clamp amplifier (HEKA Instruments, Germany) and digitised with a PCI-16 A/D converter (HEKA Instrument). All pipettes had a resistance of 3-5 MΩ[7,9,10].

All experimental protocols included in this manuscript were approved by the local animal care committee and conformed to the Guide for the Care and Use of Laboratory Animals published by the Science and Technology Commission of the PRC (STCC Publication No. 2, revised 1988).

Solutions and drugs

Chemicals used included Ginsenoside Rb1 (purchased from Sichuan Weiqi Biological Technology CO., Ltd.), Glibenclamide [a K_{ATP} channel blocker, purchased from Tocris (Ellisville, Misso6yuri, United States)], tetraethylammonium (TEA, a non-selective potassium channel blocker), 4-aminopyridine (4-AP, a voltage-gated K^+ channel blocker), and tetrodotoxin (TTX, a blocker of voltage-dependent Na^+ channels) purchased from Sigma Aldrich (St. Louis, MO, United States). Ginsenoside Rb1 was dissolved first in dimethyl sulphoxide (DMSO) at a concentration of 200 mmol. For the intestinal smooth muscle isometric measurements, all chemicals were further diluted with Krebs solution to prepare the desired concentrations before use. In the electrophysiological recording experiment, Ginsenoside Rb1 was diluted with PSS to the final concentration immediately before use.

The ionic composition of the Krebs solution was as follows (in mmol/L): Na^+ 137.4, K^+ 5.9, Ca^{2+} 2.5, Mg^{2+} 1.2, HCO_3^- 15.5, $H2PO_4^-$ 1.2, Cl^- 134, and glucose 11.5. The solution was aerated with O_2 containing 5% CO_2, and the pH was maintained at 7.2-7.3. The composition of Kraft-Bruhe (K-B) solution was as follows (in mmol/L): EGTA 0.5, Hepes 10, $MgCl_2$ 3, KCl 50, glucose 10, KH_2PO_4 20, Taurine 20, and L-Glutamic acid 50, adjusted to a pH of 7.4 with KOH. The composition of Ca^{2+}-free PSS was as follows (in mmol/L): NaCl 134.8, KCl 4.5, Hepes 10, $MgCl_2$ 1, and glucose 10, adjusted to a pH of 7.4 with Tris. The composition of PSS was as follows (in mmol/L): NaCl 134.8, KCl 4.5, Hepes 10, $MgCl_2$ 1, glucose 10, and $CaCl_2$ 2, adjusted to pH 7.4 with Tris. The pipette solution for recording the K_{ATP} channel current contained the following (mmol/L): KCl 107, KOH 33, Hepes 10, $MgCl_2$ 1, Na_2ATP 0.1, NaADP 0.1, and GTP 0.3, adjusted to a pH of 7.2 with NaOH. The pipettes were filled with a solution for IK_{Ca} containing the following (in mmol/L): KCl 140, $MgCl_2$ 5, K_2ATP 2.7, Na_2GTP 0.1, disodium salt 2.5, Hepes 5, and EGTA 0.1, adjusted to a pH of 7.2 with Tris. The pipettes were filled with solution for IK_V containing the following (in mmol/L): KCl 20, potassium-aspartic acid 110, di-tris-creatine phosphate 2.5, disodium-creatine phosphate 2.5, MgATP

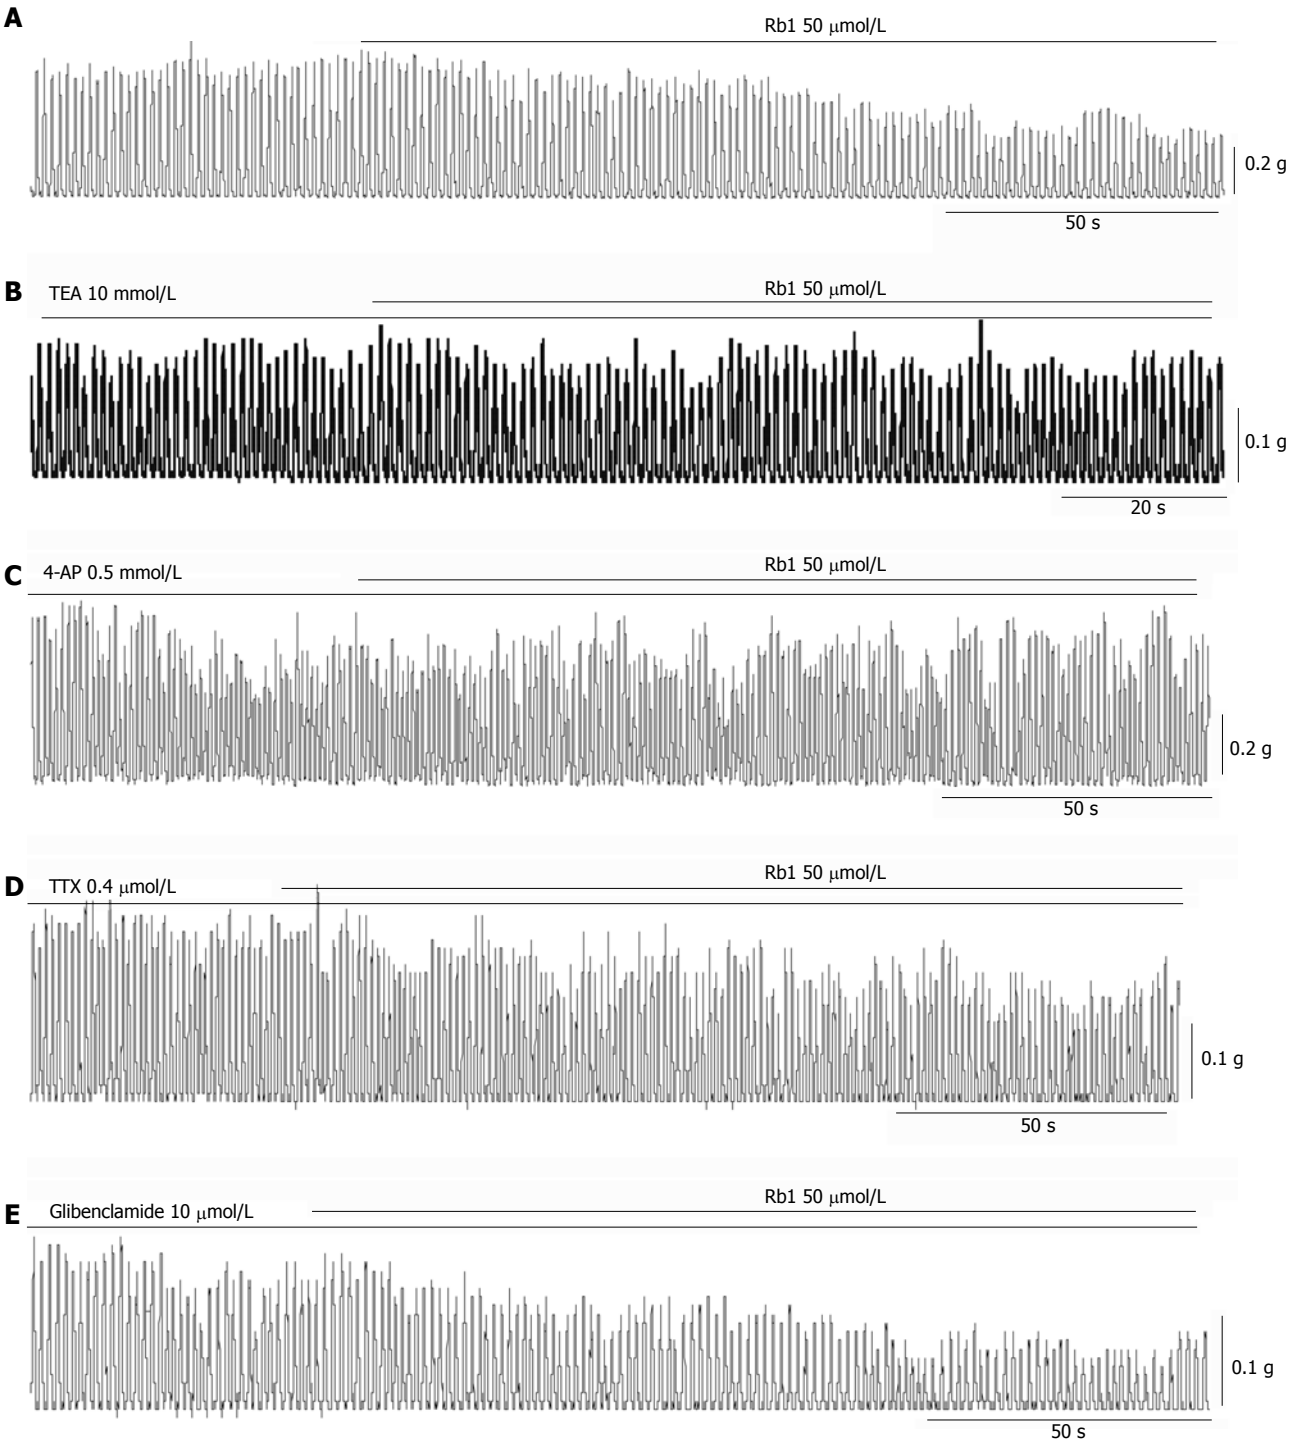

Figure 2 Effect of Rb1 on spontaneous contraction of the intestinal smooth muscle. A: Effect of Rb1 on spontaneous contraction of the intestinal smooth muscle; B-F: Effects of Rb1 (50 μmol/L) on spontaneous contraction of the intestinal smooth muscle pretreated with TEA (10 mmol/L), 4-AP (0.5 mmol/L), TTX (0.4 μmol/L) and Glibenclamide (10 μmol/L) respectively. TEA: Tetraethylammonium; 4-AP: 4-aminopyridine; TTX: Tetrodotoxin.

Statistical analysis

Experimental values were expressed as the mean ± SD. Statistical significance was tested using Student's *t*-test, and probabilities of less than 5% ($P < 0.05$) were considered to be significant.

RESULTS

Effect of Rb1 on the spontaneous contraction of intestinal smooth muscle

In this study, Rb1 exhibited an inhibitory effect on the spontaneous contraction of intestinal smooth muscle strips in a dose-dependent manner (Figure 1). Rb1 suppressed spontaneous contraction by 21.15% ± 3.31%,

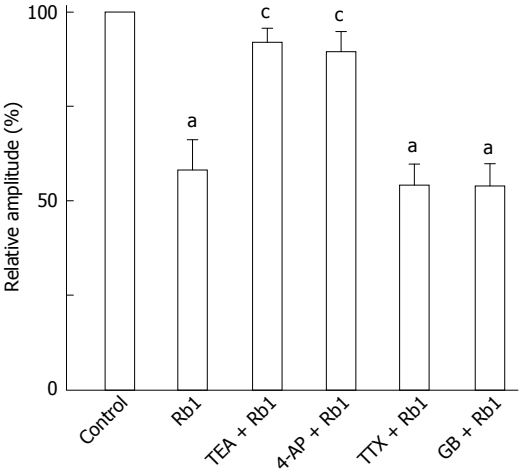

Figure 3 Summary in effect of Rb1on spontaneous contraction. Summary in effect of Rb1on spontaneous contraction of normal intestinal smooth muscles and those pretreated with TEA (10 mmol/L), 4-AP (0.5 mmol/L), Glibenclamide (10 μmol/L) and TTX (0.4 μmol/L) respectively. Values are expressed as means ± SE. $n = 5$, $^aP < 0.05$ *vs* control group; $^cP < 0.05$ TEA + Rb1 or 4-AP + Rb1 *vs* Rb1 group. TEA: Tetraethylammonium; 4-AP: 4-aminopyridine; TTX: Tetrodotoxin.

42.03% ± 8.23% and 67.23% ± 5.63% (Figure 1B, $n = 5$, $P < 0.05$) at concentrations of 25 μmol/L, 50 μmol/L and 100 μmol/L, respectively. Rb1-induced inhibition of spontaneous contraction appeared to decrease the amplitude of spontaneous contractions (Figure 1B), but the frequency was not changed (Figure 1C).

The Rb1-induced inhibitory effect on spontaneous contractions was almost completely abolished by 10 mmol/L TEA (a non-selective potassium channel blocker) and 0.5 mmol/L 4-AP (Figure 2B, C). The inhibitory percentage of Rb1 decreased from 42.03% ± 8.23% to 9.17% ± 3.54%, and the inhibitory percentage decreased from 10.90% ± 5.19% with TEA and 4-AP, respectively (Figure 3, $n = 5$, $P < 0.05$). After pre-treatment with 0.4 μmol/L TTX and 10 μmol/L glibenclamide, the inhibitory effect of Rb1 on spontaneous contraction was stable (Figure 2D, E). The inhibition percentages of Rb1 were 42.03% ± 8.23%, 46.12% ± 5.66% and 47.16% ± 3.99% in the control, TTX and glibenclamide groups, respectively (Figure 3, $n = 5$, $P > 0.05$).

Effect of Rb1 on voltage-gated K^+ channel current of intestinal smooth muscle cells

Previous experiments demonstrated that both TEA, a non-specific potassium channel blocker, and 4-AP, a specific delayed potassium channel blocker, significantly suppressed the inhibitory effect of RB1 on the spontaneous contraction of intestinal smooth muscle strips. These results indicate that Rb1-induced inhibition might be mediated by calcium-activated potassium channels and delayed repolarisation of the potassium channel. The effect of Rb1 on the IKv in intestinal smooth cells was observed in succession using the conventional whole-cell patch clamp technique. IKv was elicited by a step voltage command pulse from -40 mV to +100 mV at 20-mV increments for 400 ms at 10 s intervals. The membrane potential was clamped at -60 mV. Rb1 significantly increased IKv elicited by the step voltage command pulse (Figure 4A). Furthermore, based on the I-V relation curve, Rb1 increased IKv at all command potentials from +20 mV to +100 mV (Figure 4B). The IKv at +60 mV increased from 1137.71 ± 171.62 pA to 1449.73 ± 162.39 pA, which represented 132.11% ± 7.77% of the level in the control concentration (100%) of 50 μmol/L Rb1 (Figure 4C, $n = 6$, $P < 0.05$).

Effect of Rb1 on the Ca^{2+}-sensitive K^+ channel current of intestinal smooth muscle cells

IK_{Ca} is activated by intracellular Ca^{2+} and can be monitored by spontaneous transient outward currents (STOCs). STOCs are believed to represent the spontaneous, sporadic release of Ca^{2+} from storage sites in the cell in relation to Ca^{2+}-sensitive K^+ channels[8,11]. In this study, we observed that Rb1 (50 μmol/L) enhanced the amplitude of STOCs from 582.77 ± 179.09 mV to 788.12 ± 278.34 mV, which represented a 137.76% ± 11.95% increase from the control level (100%) (Figure 5A, C, $n = 5$, $P < 0.05$) without changing the frequency.

Effect of Rb1 on K_{ATP} channel current of intestinal smooth muscle cells

We investigated the effect of Rb1 on K_{ATP} channels using a whole-cell patch clamp. The inward current was activated at a holding potential of -60 mV following perfusion with a symmetrical 140 mmol/L K^+ solution (140 mmol/L KCl, 10 mmol/L glucose, 10 mmol/L Hepes, 1 mmol/L molgCl_2, and 0.1 mmol/L $CaCl_2$). Rb1 (50 μmol/L) did not change the K_{ATP} current (IK_{ATP}), which increased from 79.04 ± 35.88 pA to 81.32 ± 37.84 pA, representing a 102.29% ± 1.15% increase from the control level (100%) (Figure 5B, D, $n = 3$, $P < 0.05$).

DISCUSSION

Sijunzi decoction (SJZD) is widely used as a regular decoction in Chinese Traditional Medicine that can invigorate Pi viscera and replenish Qi. Conventionally, SJZD is useful for treating hypofunction of the spleen, a symptom that is partially equivalent to that of gastrointestinal motility disorders (e.g., abdominal distension and dyspepsia). The mechanism by which SJZD improves gastrointestinal disorder symptoms may relate to gastrointestinal hormones and motility. SJZD could correct deficiencies of the spleen and stomach, which are caused by digestive dysfunction to some extent[5]. Symptoms of rat models with Pi-deficiency could be significantly corrected to the normal level by SJZD treatment[4]. External nutrition plus SJZD treatment can improve and optimise cellular immune function and nutritional status in post-operative gastric cancer patients[12]. Recently, the major active components of SJZD, including ginsenoside, flavonoid, and triterpenoid, have been identified using LC/MS/MS[13]. Kim *et al*[14] reported that ginsenosides modulate the pace-

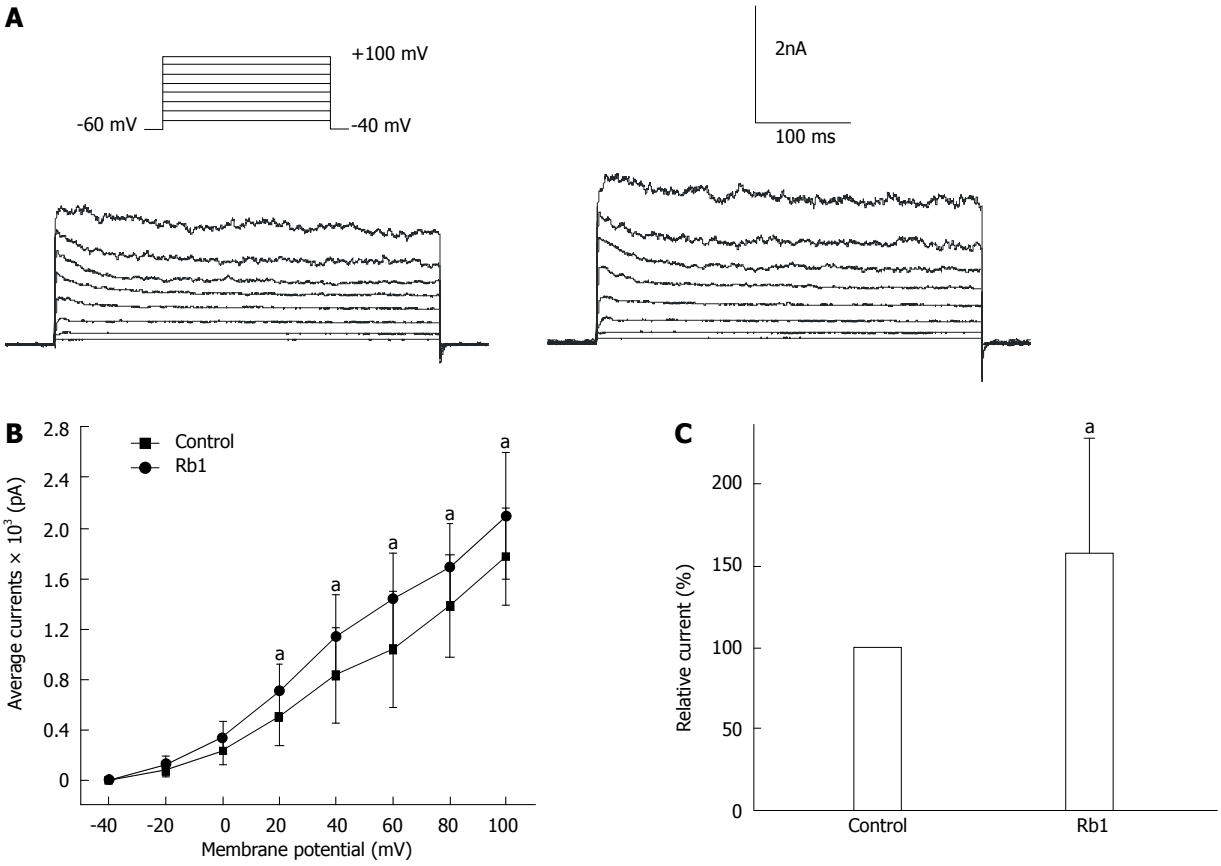

Figure 4 Effect of Rb1 on the voltage-gated K^+ channel current of intestinal smooth muscle cell in mouse. A: The raw trace; B: The I-V relation curve; C: Summary in effect of Rb1 (50 μmol/L) on the voltage-gated K^+ channel current at +60 mV. Values are expressed as means ± SE. $n = 6$, $^aP < 0.05$ *vs* control group.

maker activities of the ICCs. The ICCs can be targets for ginsenosides, and their interaction can affect intestinal motility. The ICCs and smooth muscle cells (SMCs) are coupled electrically, forming a multicellular syncytium. Activation of depolarising or hyperpolarizing ionic conductances in either cell type affects the total input resistance and excitability of the syncytium. For example, activation of K^+ channels in ICCs reduces excitability of coupled SMCs and reduces the likelihood of reaching the action potential threshold. Responses to other stimuli, such as hormones and paracrine substances, are likely to target both ICCs and SMCs, depending upon the expression of appropriate receptors and second-messenger pathways[15]. Hashimoto *et al*[16] reported that Rb1 was one representative of the compounds contained in Ginseng Radix that were capable of ameliorating the accelerated transit of the small intestine. To date, the mechanism of ginsenoside action on gastrointestinal (GI) smooth muscle has not been fully studied.

In this study, we found that ginsenoside Rb1 exerted an inhibitory effect on the spontaneous contraction of intestinal smooth muscles in mice by decreasing the amplitude of spontaneous contractions in a dose-dependent manner (Figure 1). The presence of TEA (10 mmol), a non-selective potassium channel blocker, partially blocked the inhibitory effect of Rb1 on spontaneous contraction (Figure 2B). This finding suggested that the inhibitory effect of ginsenoside Rb1 on the spontaneous contraction of intestinal smooth muscle in mice might be associated with K^+ channels; importantly, at least 20 species of potassium channel types are expressed by SMCs of the GI tract[15,17]. These species include voltage-gated K^+ channels, ATP-dependent K^+ channels, and Ca^{2+}-activated K^+ channels. We evaluated 4-AP, a voltage-gated K^+ channel blocker, which partially blocked the inhibitory effect of Rb1 on spontaneous contraction (Figure 2C). In contrast, glibenclamide, an ATP-dependent K^+ channel blocker, did not influence the inhibitory effect of Rb1 on spontaneous contraction (Figure 2E). In addition, the presence of TTX, a blocker of voltage-dependent Na^+ channels that can block enteric nerves, did not affect the inhibitory effect of Rb1 on spontaneous contraction (Figure 2D). Thus, the results indicated that the inhibitory effect of Rb1 on spontaneous contraction was associated with activation of K^+ channels in intestinal smooth muscle cells. A conventional whole-cell patch clamp configuration showed that Rb1 activated IK_V and IK_{Ca} (Figures 4, 5) without any influence on IK_{ATP} (Figure 5B, D). We concluded that Rb1 inhibited the spontaneous contraction of intestinal smooth muscles *via* increased Ca^{2+}-dependent K^+ channel currents and voltage-dependent K^+ channel currents. However, enteric nerves and K_{ATP} channels were not involved in this process. Next, to determine the Rb1-

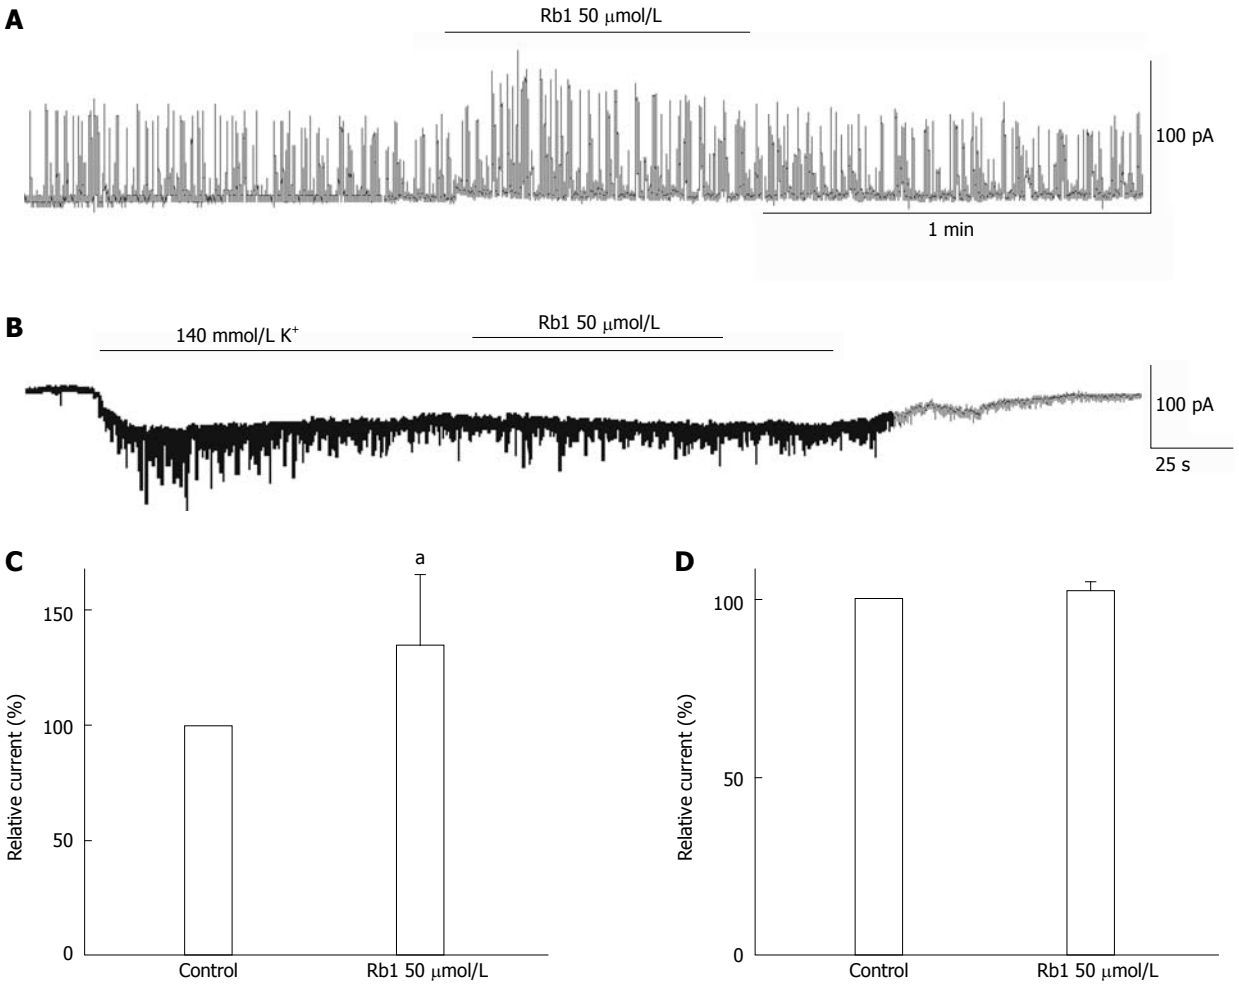

Figure 5 Effect of Rb1 on spontaneous transient outward currents and ATP sensitive potassium channel current of intestinal smooth muscle cell in mouse (*n* = 5). A: The raw trace of Rb1-induced effect on STOC of intestinal smooth muscle cell; B: The raw trace of Rb1-induced effect on IK_{ATP} of intestinal smooth muscle cell; C: Relative current evoked by Rb1 (50 μmol/L) on STOC, $n = 5$, $^aP < 0.05$ *vs* control group; D: Relative current evoked by Rb1 (50 μmol/L) on IK_{ATP} comparing with control group. induced inhibitory effect on the spontaneous contraction of intestinal smooth muscle, the effect of Rb1 on the slow wave contraction of intestinal smooth muscle was observed. However, the amplitude and frequency of slow wave contraction was not affected by Rb1 (50 μmol/L, 100 μmol/L or 200 μmol/L, data not shown). The results indicated that the inhibitory effect of Rb1 on spontaneous contraction relies on the direct action of the compound with smooth muscle and not the ICCs themselves.

The broad ranges of resting potentials and electrical patterns of GI muscles are partly a function of the variable expression of K^+ channels in SMCs. At least 20 species of K^+ channels are expressed by SMCs in the GI tract[15]. The activation of potassium channels is the main determinant of cell membrane potential. Therefore, potassium channels participate in the regulation of smooth muscle tone. Activation of K^+ channels in the cell membrane allows K^+ efflux, causing a decrease in membrane potential and hyperpolarization. As a consequence, voltage-gated calcium channels in the cell membrane close, and the smooth muscle relaxes[18].

It has been reported that ginsenosides, including Rb1, regulate Ca^{2+} channels in chromaffin cells[19], sensory neurons[20] and ventricular myocytes[21]. Rb1 can alleviate cardiac hypertrophy *in vitro*, mediated by an inhibitive effect on elevated $[Ca^{2+}]i$[3]. The ginsenoside Rb1 suppressed ventricular myocyte shortening and intracellular Ca^{2+} in isolated cardiac myocytes[22]. These results indicate that the primary physiological or pharmacological targets of ginsenosides are Ca^{2+} channels. Li *et al*[23] reported that ginsenosides increased IK_{Ca} activity in endothelial cells. The modulation of IK_{Ca} activity stimulated by ginsenosides was inhibited by 0.5 mmol TEA but not by 0.5 mmol glibenclamide. In our study, we first discovered that potassium channels, especially the Ca^{2+}-dependent K^+ channels and voltage-dependent K^+ channels, were involved with the effects of Rb1 on the spontaneous contraction of intestinal smooth muscles in mice. This result is partially in accordance with the report of the action of ginsenosides by Li *et al*[23] and Kang *et al*[24].

In conclusion, ginsenoside Rb1 exerted an inhibitory effect on the spontaneous contraction of intestinal smooth muscles in mice by decreasing the amplitude of spontaneous contractions in a dose-dependent manner. The inhibitory effect of Rb1 is mediated by potentiating IKv and IK_{Ca} channel currents.

ACKNOWLEDGMENTS

These experiments were performed in the Department of Physiology of the Shanghai Jiaotong University School of Medicine. We thank Professor Wen-Xie Xu for expert technical assistance concerning the experiments.

COMMENTS

Background

Gastrointestinal motility is a prominent research field of traditional Chinese medicine. Chinese herbal compounds, single Chinese erode drugs, Chinese herb extracts, and natural products have been experimentally investigated for their roles in promoting gastrointestinal motility.

Research frontiers

Ginsenosides, which are isolated from the root of Panax ginseng, appear to be responsible for most of the pharmacological effects of ginseng. Ginsenosides modulate the pacemaker activities of the interstitial cells of Cajal (ICCs), and the ICCs can be targets for ginsenosides, thereby affecting intestinal motility. Rb1 was one representative of the compounds contained in Ginseng Radix that was capable of ameliorating accelerated transit in the small intestine. Until now, the mechanism by which ginsenosides affect gastrointestinal smooth muscle had not been fully studied. This study focused on the mechanism by which ginsenosides affect gastrointestinal smooth muscle.

Innovations and breakthroughs

The results suggested that the ginsenoside Rb1 exerted an inhibitory effect on the spontaneous contraction of intestinal smooth muscle in mice in a dose-dependent manner. The inhibitory effect of Rb1 is mediated by current potentiation in the voltage-gated K^+ channel current (IK_V), calcium-activated potassium channel currents (IK_{Ca}) channels. This effect may be involved in the mechanism by which ginseng mediates gastrointestinal motility.

Applications

This study illustrates the mechanism by which Rb1 affects spontaneous contraction of intestinal smooth muscle in mice. These findings may clarify the pharmacological action of ginseng.

Peer review

This is a good descriptive study in which authors analyze the effect and the possible mechanism of ginsenoside Rb1 on small intestinal smooth muscle motility in mice. The results are interesting and suggest that ginsenoside Rb1 has an inhibitory effect on the spontaneous contraction of mouse intestinal smooth muscle mediated by the activation of IK_V and IK_{Ca}, but the ATP-sensitive potassium channel current channel was not involved in this effect.

Abstract

AIM: To explore the impact of tumor size on outcomes in patients with advanced gastric cancer in the lower third of the stomach.

METHODS: We retrospectively analyzed the clinical records of 430 patients with advanced gastric cancer in the lower third of the stomach who underwent distal subtotal gastrectomy and D2 lymphadenectomy in our hospital from January 1998 to June 2004. Receiver-operating characteristic (ROC) curve analysis was used to determine the appropriate cutoff value for tumor size, which was measured as maximum tumor diameter. Based on this cutoff value, patients were divided into two groups: those with large-sized tumors (LSTs) and those with small-sized tumors (SSTs). The correlations between other clinicopathologic factors and tumor size were investigated, and the 5-year overall survival (OS) rate was compared between the two groups. Potential prognostic factors were evaluated by univariate Kaplan-Meier survival analysis and multivariate Cox's proportional hazard model analysis. The 5-year OS rates in the two groups were compared according to pT stage and pN stage.

RESULTS: The 5-year OS rate in the 430 patients with advanced gastric cancer in the lower third of the stomach was 53.7%. The mean ± SD tumor size was 4.9 ± 1.9 cm, and the median tumor size was 5.0 cm. ROC analysis indicated that the sensitivity and specificity results for the appropriate tumor size cutoff value of 4.8 cm were 80.0% and 68.2%, respectively (AUC = 0.795, 95%CI: 0.751-0.839, P = 0.000). Using this cutoff value, 222 patients (51.6%) had LSTs (tumor size ⩾ 4.8 cm) and 208 (48.4%) had SSTs (tumor size < 4.8 cm). Tumor size was significantly correlated with histological type (P = 0.039), Borrmann type (P = 0.000), depth of tumor invasion (P = 0.000), lymph node metastasis (P = 0.000), tumor-nodes metastasis stage (P = 0.000), mean number of metastatic lymph nodes (P = 0.000) and metastatic lymph node ratio (P = 0.000). Patients with LSTs had a significantly lower 5-year OS rate than those with SSTs (37.1% *vs* 63.3%, P = 0.000). Univariate analysis showed that depth of tumor invasion (χ^2 = 69.581, P = 0.000), lymph node metastasis (χ^2 = 138.815, P = 0.000), tumor size (χ^2 = 78.184, P = 0.000) and metastatic lymph node ratio (χ^2 = 139.034, P = 0.000) were significantly associated with 5-year OS rate. Multivariate analysis revealed that depth of tumor invasion (P = 0.000), lymph node metastasis (P = 0.019) and tumor size (P = 0.000) were independent prognostic factors. Gastric cancers were divided into 12 subgroups: pT2N0; pT2N1; pT2N2; pT2N3; pT3N0; pT3N1; pT3N2; pT3N3; pT4aN0; pT4aN1; pT4aN2; and pT4aN3. In patients with pT2-3N3 stage tumors and patients with pT4a stage tumors, 5-year OS rates were significantly lower for LSTs than for SSTs (P < 0.05 each), but there were no significant differences in the 5-year OS rates in LST and SST patients with pT2-3N0-2 stage tumors (P > 0.05).

CONCLUSION: Using a tumor size cutoff value of 4.8

cm, tumor size is a prognostic factor in patients with pN3 stage or pT4a stage advanced gastric cancer located in the lower third of the stomach.

INTRODUCTION

Gastric cancer is a common gastrointestinal malignancy in China and is the second most common cause of cancer-related deaths worldwide[1,2]. The identification of prognostic factors may be helpful in predicting and improving outcomes in patients with gastric cancer. Lymph node metastasis[3-5] and depth of tumor invasion[6-8] are the most important prognostic factors and are included in the Japanese Classification of Gastric Carcinoma (JCGC) and the American Joint Committee on Cancer tumor-nodes metastasis classification (AJCC TNM). Tumor size is another valuable clinicopathological feature because it can be measured easily before or during surgery and may be prognostic for survival in patients with gastric cancer[9-11]. Although tumor size is included in staging systems for lung and breast cancer, it has not been considered prognostic in gastric cancer. We therefore, retrospectively, analyzed the impact of tumor size on the prognosis of patients with advanced gastric cancer located in the lower third of the stomach.

MATERIALS AND METHODS

Patients

Patients undergoing curative resection (distal subtotal gastrectomy and D2 lymphadenectomy) for advanced gastric carcinoma (pT2-T4a stage) in the lower third of the stomach at the Department of Gastric Surgery, Affiliated Union Hospital of Fujian Medical University, Fuzhou, China, between January 1998 and June 2004 were included. Patients with gastric stump cancer, infiltration of surrounding organs (T4b) or distant metastases (hepatic, lung, peritoneal dissemination, or extraregional lymph nodes such as retropancreatic, mesenteric, and para-aortic lymph nodes) were excluded. After applying these criteria, 430 patients were included.

A surgical procedure was defined as curative if no grossly visible tumor tissue remained after the resection and the resection margins were histologically normal. Dissected lymph nodes were classified according to JCGC[12] criteria by specialist surgeons who reviewed the excised specimens after surgery. A total of 10 400 lymph nodes were dissected. The median number of dissected lymph nodes per patient was 24 (range, 6-61; mean 24.3 ± 8.8). Depth of tumor invasion, lymph node metastasis and tumor-nodes metastasis (TNM) stage were classified with respect to the seventh edition of AJCC TNM classification[13]. The metastatic lymph node ratio (MLR) was defined as the ratio of metastatic lymph nodes to the total number of dissected lymph nodes and categorized as MLR 0 (0%), MLR 1 (1%-9%), MLR 2 (10%-25%), MLR 3 (> 25%).

Routine follow-up consisted of physical examination, laboratory tests (including measurements of CEA, CA19-9 and CA125 concentrations), chest radiography, abdominopelvic ultrasonography and computed tomography (CT). Patients were followed-up every 3 mo during the first year, and every 6 mo or 12 mo thereafter, for a total of 5 years. Endoscopy was performed every 6 mo or 12 mo. All surviving patients were followed for more than five years. Survival was calculated from the date of diagnosis to last contact, date of death, or date when the survival information was collected. Of the 430 patients, 394 (93.0%) were followed-up.

Measurement of tumor diameter

In accordance with JCGC criteria[12], the resected stomach was opened along the greater curvature so that the whole mucosa could be observed. If the tumor was located on the greater curvature, the stomach was opened along the lesser curvature. The opened stomach was placed on a flat board with the mucosal side up and examined macroscopically. The lengths of the greater and lesser curvatures, as well as the attached portion of the esophagus and/or the duodenum and the size and thickness of the tumor, were recorded. Tumor size was measured as maximum tumor diameter (Figure 1). If tumor margins were unclear, the resected stomach was fixed in formalin for 1 h to make the margins clearer.

Statistical analysis

All statistical analyses were performed using the Statistical Package for Social Science (SPSS) version 16.0 for Windows. The appropriate cutoff value for tumor size predicting 5-year survival was determined using the receiver-operating characteristic (ROC) curve, from which the area under the curve (AUC) was determined and the Youden index corresponding to each size was calculated. χ^2 tests were used to evaluate differences in proportions, and Student's *t*-tests were used to evaluate continuous variables. Five-year overall survival (OS) rates were calculated by the Kaplan-Meier method, with

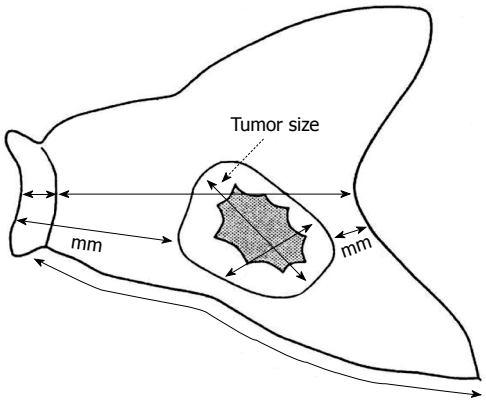

Figure 1 Resected stomach (mucosal side).

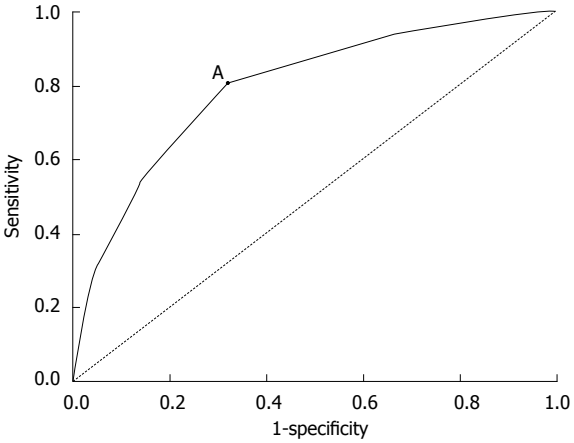

Figure 2 Receiver-operating characteristic curve. A: Shows sensitivity and specificity for a tumor size cutoff value of 4.8 cm were 80.0% and 68.2%, respectively (area under the curve = 0.795, *P* = 0.000).

groups compared by log-rank tests. Multivariate analysis was performed using a Cox's proportional hazard model. *P* values < 0.05 were considered statistically significant.

RESULTS

Clinicopathological characteristics of patients

We retrospectively analyzed a total of 430 patients with pT2-T4a gastric cancer located in the lower third of the stomach. Of these, 132 patients (30.7%) were women and 298 (69.3%) were men, with 187 patients (43.5%) ⩾ 60 years old. Postoperatively, 45 patients (10.5%) were classified as stage ⅠB, 49 (11.4%) as stage ⅡA, 78 (18.1%) as stage ⅡB, 65 (15.1%) as stage ⅢA, 82 (19.1%) as stage ⅢB and 111 (25.8%) as stage ⅢC. In addition, 117 patients (27.2%) were classified as stage pT2, 40 (9.3%) as pT3 and 273 (63.5%) as pT4a, while 105 patients (24.4%) were stage pN0, 92 (21.4%) were pN1, 94 (21.9%) were pN2, and 139 (32.3%) were pN3. Of the 430 patients, 325 (75.6%) had undifferentiated tumors. Based on the MLR classification, 70 patients (16.3%) were classified as MLR 0, 118 (27.4%) as MLR 1, 93 (21.6%) as MLR 2, and 149 (34.7%) as MLR 3.

LST: Large-sized tumor; SST: Small-sized tumor; MLR: Metastatic lymph node ratio; TNM: Tumor-nodes metastasis.

Cutoff value of tumor size

The mean ± SD tumor size was 4.9 ± 1.9 cm, and the median tumor size was 5.0 cm (range, 1.0-12.0 cm). ROC analysis indicated that a cutoff value of 4.8 cm yielded a sensitivity of 80.0% and a specificity of 68.2% in predicting survival after gastric surgery (AUC = 0.795, 95%CI: 0.751-0.839, *P* = 0.000) (Figure 2). Based on this cutoff value, the patients were divided into 2 groups, with 222 (51.6%) having large-sized tumors [large-sized tumors (LSTs), ⩾ 4.8 cm] and 208 (48.4%) having small-sized tumors [small-sized tumors (SSTs), < 4.8 cm].

Correlation analysis

When we analyzed the correlation between other clinicopathologic factors and tumor size (Table 1), we found that tumor size was significantly correlated with histological type (*P* = 0.039), Borrmann type (*P* = 0.000), depth of tumor invasion (*P* = 0.000), lymph node metastasis (*P* = 0.000), TNM stage (*P* = 0.000), mean number of metastatic lymph nodes (*P* = 0.000) and metastatic lymph node ratio (*P* = 0.000). SSTs were associated with dif-

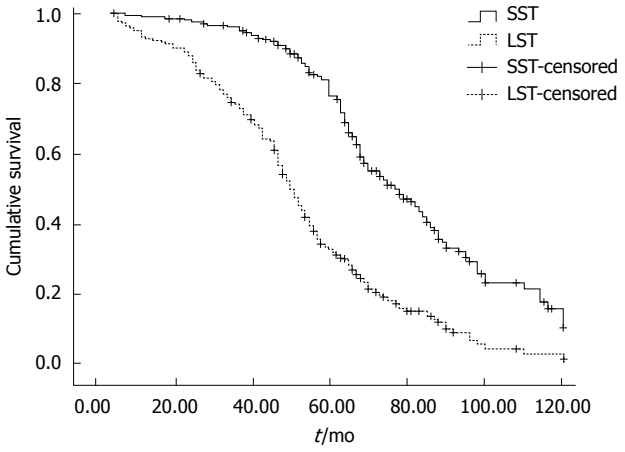

Figure 3 Overall survival curves of patients with large-sized tumor were significantly lower than those of patients with small-sized tumor. SST: Small-sized tumor; LST: Large-sized tumor.

ferentiated and Borrmann Ⅰ / Ⅱ types ($P < 0.05$ each), whereas LSTs were deeper and were associated with more extensive lymph node metastasis ($P < 0.05$). The mean number of metastatic lymph nodes was greater in patients with LSTs than with SSTs ($P < 0.05$).

Survival

The 5-year OS rate of all patients was 53.7%, being significantly lower in patients with LSTs than with SSTs (32.9% *vs* 76.7%; $\chi^2 = 78.184$, $P = 0.000$; Figure 3).

Univariate and multivariate survival analysis for all patients

Univariate analysis showed that depth of tumor invasion ($\chi^2 = 69.581$, $P = 0.000$), lymph node metastasis ($\chi^2 = 138.815$, $P = 0.000$), tumor size ($\chi^2 = 78.184$, $P = 0.000$) and metastatic lymph node ratio ($\chi^2 = 139.034$, $P = 0.000$) were significantly associated with 5-year OS rate, whereas patient age ($P = 0.613$), gender ($P = 0.240$) and histological type ($P = 0.361$) were not (Table 2). Multivariate analysis using a Cox's proportional hazards model revealed that depth of tumor invasion ($P = 0.000$), lymph node metastasis ($P = 0.019$) and tumor size ($P = 0.000$) independently predicted poor prognosis (Table 3).

Survival based on pT and pN stages in the LST and SST groups

Gastric cancers were divided into 12 subgroups: pT2N0; pT2N1; pT2N2; pT2N3; pT3N0; pT3N1; pT3N2; pT3N3; pT4aN0; pT4aN1; pT4aN2; and pT4aN3. The 5-year OS rates in these subgroups were compared in patients with LSTs and SSTs. We found that the 5-year survival rates of patients with pT2-3N3 stage and pT4a stage tumors were significantly lower in the LST than in the SST group ($P < 0.05$ each), but did not differ significantly in patients with pT2-3N0-2 stage tumors in the LST and SST groups ($P > 0.05$) (Table 4).

DISCUSSION

The prognostic value of tumor size in gastric cancer patients has recently received greater attention because tumor size can be measured easily before or during surgery; however, there is as yet no consensus formula to calculate the appropriate cutoff value for gastric tumor size. For example, tumor size of gastric cancer patients has been stratified into four subgroups (≤ 2 cm, ≤ 3 cm, ≤ 5 cm, and > 5 cm) by minimizing the estimated average expected distance (AED) objective function[14]. In another study of gastric cancer patients that used Cox's proportional hazards model to compare survival rates, a significant difference in survival was observed in patients with tumors < 10 cm and ≥ 10 cm[15]. We utilized ROC curve analysis to determine the appropriate tumor size cutoff value predicting 5-year OS rate in patients with advanced gastric cancer in the lower third of the stomach. In clinical and epidemiological fields, ROC analysis is frequently used to determine the cutoff values and reflect the correctness of a method of evaluation. According to the basic principle of ROC curves[16], when the Youden index is maximum, and the sensitivity is maximum, the corresponding tumor size is the appropriate cutoff value; besides, the method of evaluation can reflect predicted efficiency only when AUCs range between 0.7 and 0.9. From our ROC curves, a maximum sensitivity (0.800) at a tumor size cutoff value of 4.8 cm; our finding, of an AUC of 0.795 ($P = 0.000$), suggests that tumor size can reliably predict postoperative outcomes in patients with gastric cancer. Tumor size has shown positive associations with histological type, depth of tumor invasion, lymph node metastasis, peritoneal metastasis, blood vessel invasion and perineural inva-

sion[17-20]. We found that LSTs were highly aggressive and malignant, with high disease stages. Compared with SSTs, LSTs showed deeper infiltration and were associated with more extensive lymph node metastasis, as well as having a significantly lower 5-year OS rate (37.1% *vs* 63.3%, $P < 0.05$), indicating that a cutoff of 4.8 cm could be used as a size criterion for gastric cancers.

The prognostic role of tumor size in gastric cancer remains unclear. An examination of 697 patients with gastric cancer who had undergone gastrectomy with curative intent found that tumor size was a predictor of survival in univariate analysis, but not in multivariate analysis[21]. In contrast, other researchers found that tumor size was an independent predictor of prognosis. For example, when patients were divided by tumor size into three subgroups, ⩽ 4 cm, ⩽ 10 cm, and > 10 cm in diameter, tumor size independently predicted patient survival[20]. Similarly, using a cutoff of 8 cm, tumor size was independently prognostic of survival[22]. We found that tumor size was significantly correlated with patient prognosis in both univariate and multivariate analysis, as were depth of tumor invasion and lymph node metastasis. Another study hypothesized that it was difficult to identify the most important variables associated with prognosis, and that the precise evaluation of the impact of tumor size on prognosis was feasible only when depth of invasion was specified[23]. Therefore, that study evaluated survival in patients with pT3 stage gastric cancer relative to pN stage in patients with LSTs and SSTs, finding that tumor size significantly influenced prognosis in pT3N2-3 stage tumors ($P = 0.004$). To eliminate depth of tumor invasion and lymph node metastasis as factors, we compared survival in patients in the LST and SST groups according to pT and pN stages. We observed no significant differences in 5-year OS of patients with pT2-3N0-2 stage tumors classified as LSTs and SSTs. In contrast, the 5-year OS rates were significantly lower in LST than in SST patients with pN3 stage or pT4a stage tumors ($P < 0.05$). In patients with pT2-3N0-2 stage tumors, the tumors likely did not infiltrate the serosa and had less extensive lymph node metastasis, reducing the likelihood of free cancer cells in the peritoneal cavity and decreasing the possibility of peritoneal recurrence. Tumor size, therefore, did not significantly affect postoperative survival in these patients. In patients with pN3 stage or pT4a stage LSTs, however, the interactions between tumors and lymphatic tissue were enhanced, thus increasing the likelihood of lymph node micrometastasis and diffusion to lymphatic vessels; the larger the area of the serosa invaded by tumor, the greater the likelihood for intraperitoneal dissemination, and the poorer the prognosis[24-26]. Tumor size was therefore correlated with survival of patients with pN3 stage or pT4a stage gastric cancer.

In conclusion, using a cutoff value of 4.8 cm, tumor size may be a prognostic factor in patients with pN3 stage or pT4a stage advanced gastric cancer located in the lower third of the stomach.

COMMENTS

Background

In addition to lymph node metastasis and depth of tumor invasion, tumor size is an important clinicopathological feature of gastric cancer because it can be measured easily before or during surgery. To date, however, the prognostic role of tumor size on survival in patients with gastric cancer remains unclear, with no consensus formula to calculate an appropriate cutoff value.

Research frontiers

Tumor size is included in the staging systems of many malignant diseases such as lung and breast cancer. Although tumor size has been reported to independently influence prognosis in patients with gastric cancer, an appropriate cutoff size has not been determined, especially for advanced gastric cancers located in the lower third of the stomach.

Innovations and breakthroughs

The authors utilized receiver-operating characteristic (ROC) curve analysis to determine the appropriate tumor size cutoff value and assessed the relationship between tumor size and overall survival rate.

Applications

The authors found that, using a cutoff of 4.8 cm, tumor size was a prognostic factor in patients with pN3 stage or pT4a stage advanced gastric cancers located in the lower third of the stomach. That is, patients with pN3 stage or pT4a stage tumors ⩾ 4.8 cm had a poorer prognosis than those with tumors < 4.8 cm.

Peer review

In assessing the effect of tumor size in a large number of patients (430) with advanced gastric cancer located in the lower third of the stomach, the authors

found that tumor size, using a cutoff of 4.8 cm, was prognostic in patients with pN3 stage or pT4a stage tumors. This finding has important clinical implications for gastrointestinal surgeons and for patient prognosis.

Abstract

Despite its abundant vascularization and extensive circulatory communication with neighboring organs, metastases to the penis are a rare event. A 57-year-old male, who had undergone total pelvic exenteration for rectal cancer sixteen months earlier, demonstrated an abnormal uptake within his penis by positron emission tomography/computed tomography. A single elastic nodule of the middle penis shaft was noted deep within Bucks fascia. No other obvious recurrent site was noted except the penile lesion. Total penectomy was performed as a curative resection based on a diagnosis of isolated penile metastasis from rectal cancer. A histopathological examination revealed an increase of well differentiated adenocarcinoma in the corpus spongiosum consistent with his primary rectal tumor. The immunohistochemistry of the tumor cells demonstrated positive staining for cytokeratin 20 and negative staining for cytokeratin 7, which strongly supported a diagnosis of penile metastasis from the rectum. The patient is alive more than two years without any recurrence.

INTRODUCTION

The penis is an uncommon site of metastasis, and only around 300 such cases have been reported in the English-language literature[1,2]. A comprehensive review of the 305 reported cases showed the most frequent primary sites of metastatic penile tumors to be the bladder (34.7%), prostate (29.8%), rectum and sigmoid colon (15.7%), and kidney (6.5%)[1]. Approximately 50 cases of penile metastasis from either rectal or sigmoid colon cancer have been reported[1-3]. Ketata *et al*[4] reported the 20th case of penile metastasis from rectal cancer in 2007, and thereafter five other cases have been reported[5-9]. One-third of all penile metastases are synchronous, whereas the remaining two-thirds are detected a mean of 18 mo after discovery of the primary tumor[7]. About 90% of reported cases of penile metastasis are a part of widespread disease[2], thus isolated metastatic penile carcinomas are exceptionally rare. This report presents a case of metachronous isolated penile metastasis from rectal cancer after total pel-

vic exenteration, which was treated with a curative penile resection.

CASE REPORT

A 57-year-old male had a large rectal cancer which occupied the pelvis minor with massive invasion to both the bladder and prostate. He underwent sigmoid colostomy twenty three months previously. Nine courses of chemotherapy [oxaliplatin 100 mg intravenous (*iv*) on day 1, levofolinate 125 mg *iv* on day 1, 5-fluorouracil (5-FU) 500 mg *iv* bolus on day 1 and 5-FU 750 mg *iv* continuous infusion on days 1 and 2] had been administered after the first operation and the tumor slightly decreased in size without showing any distant metastasis. The patient underwent total pelvic exenteration, ileal conduit and pelvic reconstruction with a gracilis muscular flap sixteen months ago. There was no clinical or radiological evidence of distant metastasis at the time of resection. The histopathological examination revealed a moderately differentiated adenocarcinoma of the rectum invading to the bladder and prostate without lymph node metastasis (none out of 57). The disease was staged as T4 N0 M0 stage Ⅱ (Dukes Classification B). He made an uneventful recovery and was discharged on the nineteenth postoperative day.

No clinical or radiological evidence of recurrence was observed for nine months after total pelvic exenteration until he started complaining of intermittent bloody discharge from his penis. Positron emission tomography/computed tomography (PET/CT) showed high 18-F fluorodeoxyglucose uptake in the penis (Figure 1A). A physical examination at that time showed a single 4 cm elastic nodule of the penis shaft in the middle, deep within Bucks fascia, which had slight tenderness. Penile magnetic resonance imaging (MRI) showed a low intensity lesion on a gadolinium-enhanced fat-suppressed T1-weighted image (Figure 1B). Contrast enhanced computed tomography (CECT) revealed neither other distant metastases nor local recurrence, and the serum tumor marker carcinoembryonic antigen was within normal limits.

The patient underwent total penectomy based on the diagnosis of penile metastasis from rectal cancer with the resection of all the residual urethra, as a curative resection. The tumor was localized in the corpus spongiosum, and had almost completely replaced it (Figure 2). A histopathological examination of the resected specimen revealed an increase of well differentiated adenocarcinoma in the corpus spongiosum, consistent with his primary rectal tumor. Immunohistochemistry of tumor cells demonstrated positive staining for cytokeratin 20 and negative staining for cytokeratin 7 (Figure 3), which supported the diagnosis because the majority of rectal cancer does not stain for cytokeratin 7, but instead does stain for cytokeratin 20, and also because urothelial cells commonly shows positive staining for cytokeratin 7[4]. He underwent adjuvant chemotherapy, and now is good in health for more than two years since the last surgery with no recurrence.

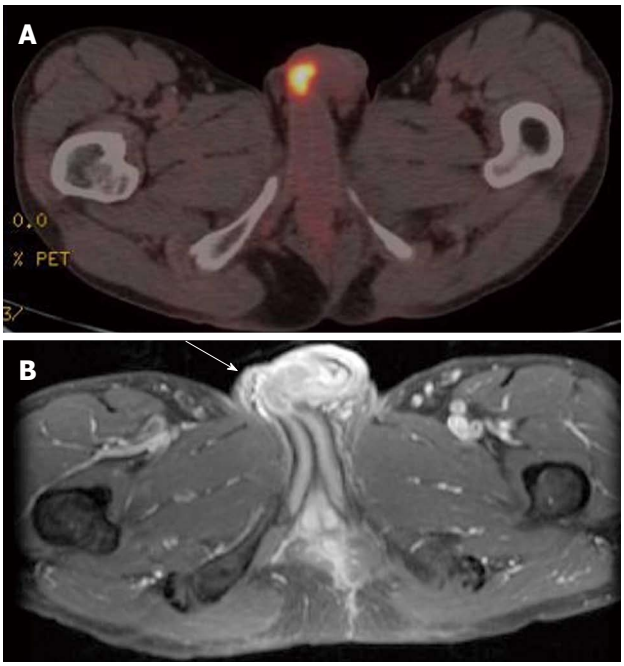

Figure 1 Positron emission tomography and magnetic resonance imaging image. A: Positron emission tomography/computed tomography showing high 18-F fluorodeoxyglucose uptake in the penis; B: Gadolinium-enhanced fat-suppressed T1-weighted image showing a low intensity lesion on the middle penis shaft (white arrow).

Figure 2 Resected specimen showing penile metastasis. A: Total penectomy with all the residual urethra; B: The tumor was localized in the corpus spongiosum, and had almost completely replaced it.

DISCUSSION

A metastatic penile tumor is rare despite the rich vascularity and the end arterial nature of its supply. Various mechanisms of penile metastasis have been suggested; retrograde venous spread, retrograde lymphatic spread,

Figure 3 Histopathological findings of the tumor. A histopathological examination revealing well differentiated adenocarcinomas in the corpus spongiosum (A) with negative staining for cytokeratin 7 (B) and positive staining for cytokeratin 20 (C) by immunostaining.

arterial spread, implantation and secondary to instrumentation or direct extension[1]. Among these mechanisms, retrograde venous spread from the pudendal venous system into the dorsal venous system of the penis appears to be the most common mode of spread[7]. Retrograde lymphatic spread into penile lymphatic channels after obstruction of inguinal and hypogastric nodes, is also considered[2]. One or both corpora cavernosa is the most common site of penile metastasis, and the glans penis and corpus spongiosum are rarely involved[1,10]. However, the current tumor was localized not in the corpora cavernosa but in the corpus spongiosum without widely disseminated disease, which seems to be extremely rare. These findings suggest that cancer cells in the residual urine at the time of total pelvic exenteration had likely become implanted in the corpus spongiosum.

Penile metastasis tends to show a poor prognosis because metastasis to the penis, in most cases, tends to be part of widely disseminated disease. The majority of patients die within one year[5]. Therefore, many treatment algorithms against penile metastases are described. The treatment is essentially palliative, and the combination of radiotherapy with chemotherapy produces only occasional responses. Some cases are treated by penectomy, an aggressive surgical excision, in order to palliate such symptoms as priapism and pain. Penectomy can offer the possibility of cure in patients with disease localized to the penis, like the current patient, even though such cases may be rare.

In conclusion, this report described a case of penile metastasis from rectal cancer. The patient underwent a complete cure resection with subsequent adjuvant chemotherapy, rather than palliative treatment. Penile involvement is usually a marker of widespread hematogenous dissemination which indicates a poor prognosis, but such a prognosis does not seem applicable in the current case.

Abstract

Primary hepatic leiomyosarcoma is a particularly rare tumor with a poor prognosis. Curative resection is currently the only effective treatment, and the efficacy of chemotherapy is unclear. This represents the first case report of a patient with primary hepatic leiomyosarcoma co-existing with metastatic liver carcinoma. We present a 59-year-old man who was diagnosed preoperatively with rectal cancer with multiple liver metastases. He underwent a curative hepatectomy after a series of chemotherapy regimens with modified FOLFOX6 consisting of 5-fluorouracil, leucovorin and oxaliplatin plus bevacizumab, FOLFIRI consisting of 5-fluorouracil, leucovorin and irinotecan plus bevacizumab, and irinotecan plus cetuximab. One of the liver tumors showed a different response to chemotherapy and was diagnosed as a leiomyosarcoma following histopathological examination. This case suggests that irinotecan has the potential to inhibit the growth of hepatic leiomyosarcomas. The possibility of comorbid different histological types of tumors should be suspected when considering the treatment of multiple liver tumors.

INTRODUCTION

Hepatic sarcomas constitute only 1%-2% of primary malignant tumors of the liver, and primary hepatic leiomyosarcoma is particularly rare[1]. The prognosis of primary hepatic leiomyosarcoma is poor, but long-term survival is possible if complete resection can be achieved[2]. We herein report a case of primary hepatic leiomyosarcoma co-existing with synchronous liver metastases of rectal cancer. The patient was treated by a curative hepatectomy following chemotherapy.

CASE REPORT

A 59-year-old man with a history of hypertension and

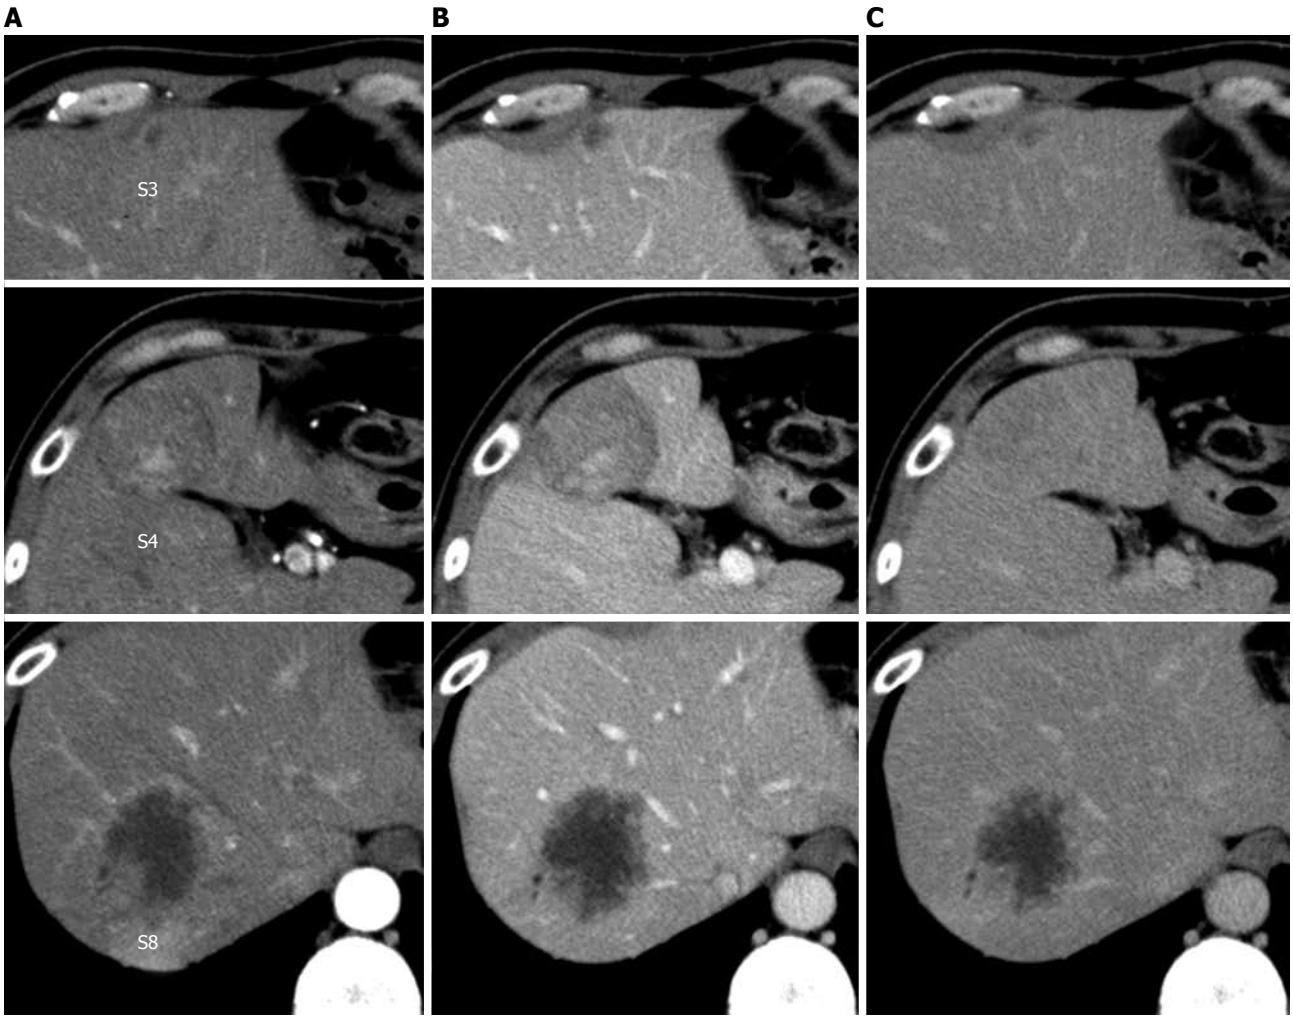

Figure 1 Dynamic computed tomography of the liver. A: Arterial phase; B: Portal phase; C: Venous phase. A hypo- or iso-dense tumor with heterogeneous enhancement in segment 4, a hypodense tumor with peripheral enhancement in segment 8, and a small hypodense tumor in segment 3.

hyperuricemia demonstrated fecal occult blood and multiple liver tumors in a comprehensive medical examination in October 2009 and was observed at our hospital. There were no remarkable physical findings. Laboratory examinations revealed a slight increase in uric acid (7.4 mg/dL). Hepatitis B and C viral markers were negative. Of the tested tumor markers, only carcinoembryonic antigen was elevated (17.9 ng/mL).

Dynamic computed tomography (CT) of the liver revealed a well-defined, hypo- or isodense tumor, 42 mm in diameter, with early enhancement and delayed washout or gradual enhancement in segment 4. Segment 8 contained an ill-defined, hypodense tumor, 52 mm in diameter, with continuous peripheral enhancement, and segment 3 contained a hypodense tumorthat was 11 mm in diameter (Figure 1).

The tumor in segment 4 appeared to be isointense throughout the dynamic phase on gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid-enhanced magnetic resonance imaging (MRI), while the tumors in segments 3 and 8 appeared hypointense. All of the tumors appeared hypointense in pre-enhancement scans and the hepatocellular phase on T1-weighted images (Figure 2). Additionally, all of the tumors appeared hyperintense on T2-weighted images and diffusion-weighted images. Ultrasonography demonstrated that the tumors were hypo- or isoechoic heterogeneous masses without halos (Figure 3).

Colonoscopy revealed a Borrmann type 2 tumor at the rectosigmoid junction. Histology of the biopsy tissue revealed a moderately differentiated adenocarcinoma.

The patient was diagnosed with rectal cancer and multiple liver metastases. Because the simultaneous resection of the primary tumor and liver metastases would be a high-risk procedure, we performed an initial high anterior resection with D3 dissection in December 2009. A histopathological examination revealed extraserosal invasion by a moderately differentiated adenocarcinoma and metastases in 8 of 14 resected lymph nodes. A genetic analysis confirmed wild-type KRAS. The patient received chemotherapy with modified FOLFOX6 (mFOLFOX6) plus bevacizumab after the initial surgery. The liver tumor in segment 3 vanished, and the tumor in segment 8 decreased in size from 52 mm to 25 mm in diameter. However, the tumor in segment 4 increased

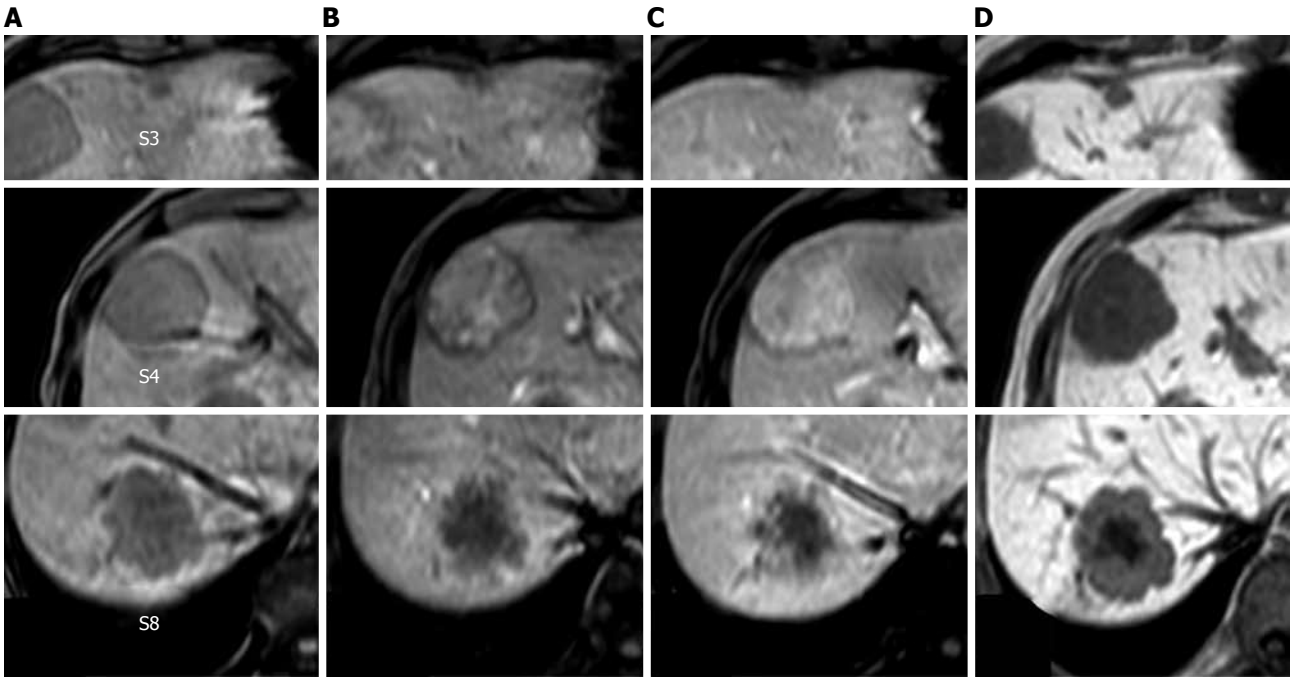

Figure 2 T1-weighted gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid-enhanced magnetic resonance imaging. A: Pre-enhancement; B: 30 s; C: 120 s; D: Hepatocellular phase. in size from 42 mm to 60 mm in diameter. He then underwent seven courses of FOLFIRI plus bevacizumab, followed by a course of irinotecan plus cetuximab; the tumor in segment 4 decreased in size from 60 mm to 55 mm in diameter, and the tumor in segment 8 decreased in size from 25 mm to 22 mm in diameter (Figure 4). With the exception of the liver tumors, positron emission tomography-CT after the chemotherapy series showed no significant uptake of fluorodeoxyglucose.

The patient then underwent a central two-segment resection and a partial resection of segment 3 in September 2010. The resected specimen from the two central segments weighed 380 g, while that from segment 3 weighed 3.8 g. The tumors from segments 4, 8 and 3 measured 56 mm × 44 mm, 24 mm × 22 mm and 7 mm × 4 mm, respectively (Figure 5). A histopathological examination revealed fibrosis and calcification in the tumors from segments 3 and 8, with a few degenerated residual adenocarcinoma cells, which was compatible with rectal cancer metastasis. In contrast, the tumor from segment 4 consisted of irregular fascicles of spindle-shaped cells with eosinophilic cytoplasms and nuclear atypia (Figure 6). Chemotherapy had no apparent effect histologically. An immunohistochemical examination demonstrated that the tumor cells in segment 4 were positive for α-smooth muscle actin and desmin, and negative for CD34, S-100, c-kit and cytokeratin AE1/3 (Figure 7). Based on these findings, the tumor in segment 4 was diagnosed as a leiomyosarcoma.

The patient underwent six courses of FOLFIRI plus bevacizumab as adjuvant chemotherapy, and had no recurrence of leiomyosarcoma or rectal cancer at 16 mo after the hepatectomy.

DISCUSSION

Primary hepatic leiomyosarcoma is a particularly rare tumor. Most hepatic leiomyosarcomas are metastatic

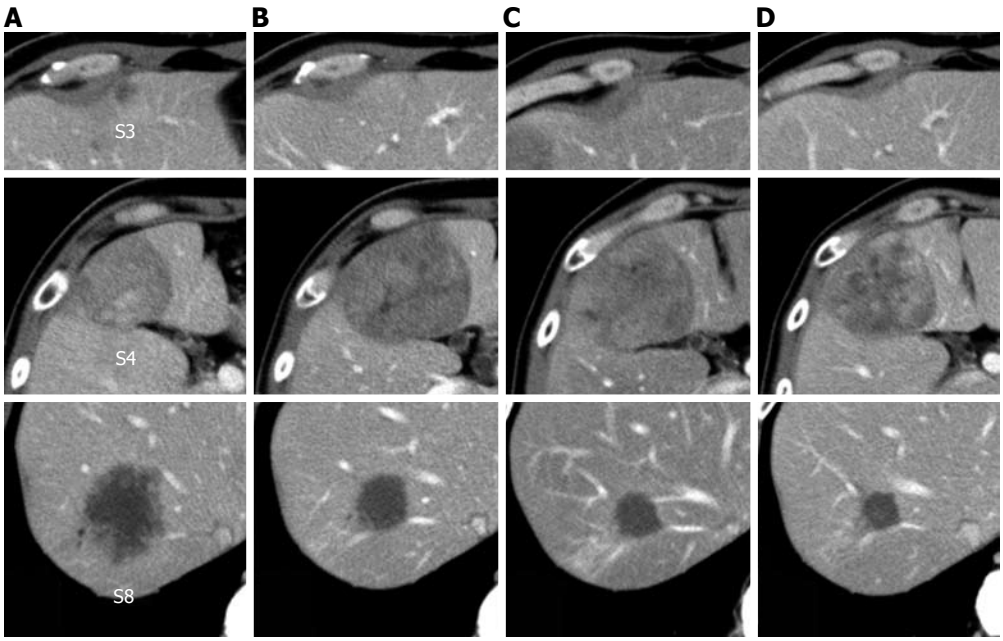

Figure 4 Change in tumor size observed using computed tomography during the clinical course. A: Before treatment; B: After six courses of modified FOLFOX6 plus bevacizumab; C: After seven courses of FOLFIRI plus bevacizumab; D: After one course of irinotecan plus cetuximab.

tumors, and the exclusion of metastatic leiomyosarcoma is therefore essential for an accurate diagnosis[3]. To our knowledge, this represents the first case report in the literature to describe a primary hepatic leiomyosarcoma co-existing with metastatic liver tumors of another origin, but the clinical and histological relevance is unclear. Surgery is considered to be the best treatment for primary hepatic leiomyosarcomas, if an R0 resection can

be performed[3,4]. Doxorubicin has been the standard chemotherapy for soft tissue leiomyosarcomas, with gemcitabine and docetaxel or trabectedin as possible alternatives[5,6]. However, the efficacy of chemotherapy for primary hepatic leiomyosarcoma has not been confirmed. In our case, mFOLFOX6 plus bevacizumab did not inhibit the growth of the leiomyosarcoma, while FOLFIRI plus bevacizumab and irinotecan plus cetuximab did. Some studies have demonstrated the efficacy of irinotecan combined with other anticancer agents in some types of sarcomas, such as Ewing's sarcoma[7] or rhabdomyosarcoma[8], but little is known about the effect of irinotecan on leiomyosarcomas. The present case suggests that irinotecan exerted a growth-inhibiting effect on this leiomyosarcoma.

In a randomized controlled trial, Portier *et al*[9] demonstrated a disease-free survival benefit of adjuvant chemotherapy with 5-fluorouracil and leucovorin after liver resection for patients with liver metastases from colorectal cancer compared to surgery alone. In another randomized controlled trial, Nordlinger *et al*[10] demonstrated that perioperative chemotherapy with FOLFOX4 in patients with resectable liver metastases improved progression-free survival compared to surgery alone. However, adjuvant chemotherapy after hepatectomy for patients converted from unresectable liver metastases is still controversial. We selected FOLFIRI plus bevacizumab for adjuvant chemotherapy with the expectation of an effect of irinotecan on the leiomyosarcoma and because the patient developed grade 3 peripheral neuropathy with mFOLFOX6.

The preoperative diagnosis of primary hepatic leiomyosarcoma is challenging because of the non-specific nature of the symptoms and the lack of serological markers[11]. CT usually shows a well-defined hypodense heterogeneous mass with peripheral enhancement. MRI shows hypointensity on T1-weighted images and hyperintensity on T2-weighted images[12]. Some cases of hepatic leiomyosarcoma diagnosed by fine-needle aspiration cytology have been reported[13]. However, the preoperative histological diagnosis of liver tumors, especially hepatocellular carcinoma, is controversial because of the risk of needle-track seeding. In the current case, the complication of liver metastases from rectal cancer made preoperative diagnosis more difficult. In retrospect, however, the leiomyosarcoma lesion showed slightly different CT and MRI findings compared to the metastatic tumors.

In conclusion, this case suggests the potential of irinotecan to inhibit the growth of hepatic leiomyosarcomas. Irinotecan may be a chemotherapy option for hepatic leiomyosarcomas. The possibility of different histological types of tumors should be considered when planning the treatment of multiple liver tumors, especially when the tumors might have heterogeneous responses to chemotherapy.

Abstract

Bezoars are concretions of indigestible materials in the gastrointestinal tract. It generally develops in patients with previous gastric surgery or patients with delayed gastric emptying. Cases of periampullary duodenal diverticular bezoar are rare. Clinical manifestations by a bezoar vary from no symptom to acute abdominal syndrome depending on the location of the bezoar. Biliary obstruction or acute pancreatitis caused by a bezoar has been rarely reported. Small bowel obstruction by a bezoar is also rare, but it is a complication that requires surgery. This is a case of acute pancreatitis and subsequent duodenal obstruction caused by a large duodenal bezoar migrating from a periampullary diverticulum to the duodenal lumen, which mimicked pancreatic abscess or microperforation on abdominal computerized tomography. The patient underwent surgical removal of the bezoar and recovered completely.

INTRODUCTION

Bezoars are concretions of foreign bodies found in the gastrointestinal tract. They are usually detected after gastric operations because of reduced gastric motor activity and delayed gastric emptying[1]. Bezoars in a periampullary duodenal diverticular without previous surgery are rare. The presence of bezoars may or may not be accompanied by gastrointestinal manifestations, such as epigastric pain and postprandial fullness. Major complications of bezoars include gastritis, gastric ulcer, gastric perforation, and intestinal obstruction[2]. Small bowel obstruction is a rare complication usually due to the migration of gastric bezoars. It could also be caused by formation of primary bezoars in the small bowel in association with underlying diseases such as diverticulum, stricture or tumor[3]. Acute pancreatitis secondary to a bezoar is rare, but can present as a possible complication[4]. However, duodenal obstruction by a diverticular bezoar following acute pancreatitis

has not been reported.

We report a case of acute pancreatitis and subsequent duodenal obstruction caused by a large duodenal bezoar migrating from periampullary diverticulum to duodenal lumen, which was difficult to diagnose by radiological study.

CASE REPORT

A 75-year-old female visited our hospital with epigastric pain, nausea and vomiting for 4 d. She was diagnosed with diabetes 15 years ago and was taking oral hypoglycemic agents for the control of blood sugar level. There were no specific findings from her social history. Her blood pressure on admission was 130/80 mmHg, pulse rate 70/min, respiratory rate 20/min, and body temperature 36.4 ℃. On physical examination, she appeared acutely ill, with a soft abdomen but with tenderness in the epigastric area and right upper quadrant. Complete blood count test showed a leukocyte count of 10 340/mm^3, a hemoglobin level of 13.1 g/dL, and a platelet count of 174 000/mm^3. Blood chemistry showed total protein 7.1 g/dL, albumin 4.3 g/dL, total bilirubin 1.1 mg/dL, aspartate aminotransferase 491 IU/L, alanine aminotransferase 375 IU/L, alkaline phosphatase 154 IU/L, γ-glutamyl transpeptidase 213 IU/L, amylase 1730 IU/L, and lipase over 300 IU/L. Abdominal computerized tomography (CT) taken on the day of admission revealed a 5 cm sized subtle rim enhancing mass with air bubbles in the pancreatic head which raised the suspicion of an air forming abscess of the pancreatic head or a duodenal diverticulum of the second duodenal portion (Figure 1A and B). Following this, magnetic resonance cholangiopancreatography (MRCP) showed no evidence of abnormality in the common bile duct or pancreatic duct. The medical treatments including intravenous fluids, parenteral alimentation, and antibiotics were started, and abdominal pain improved thereafter. Additionally, the elevated serum transaminase and pancreatic enzymes progressively improved. However, nine days after admission, the patient's body temperature rose to 40.4 ℃, her blood pressure was 80/50 mmHg, leukocyte count 47 620/mm^3, erythrocyte sedimentation rate 66 mm/h, and C-reactive protein 166 mg/dL. The follow-up abdominal CT revealed aggravation of duodenal wall thickening and stranding of the surrounding soft tissues with some tiny extraluminal air bubbles indicating possible micro-perforation (Figure 1C). She received fluid resuscitation through rapid intravenous administration of crystalloid fluid and vasopressor support, and antibiotic therapy with meropenem was started for the management of septic shock. After vigorous treatment, the patient's state became stabilized, but more than 1500 cc of dark-colored fluid was drained through the Levin tube per day. Esophagogastroduo- denoscopy (EGD) was performed for suspected duodenal obstruction. On entering the duodenum, a huge dark yellowish mass was found obstructing the lumen of the second portion of the duodenum. This mass was thought

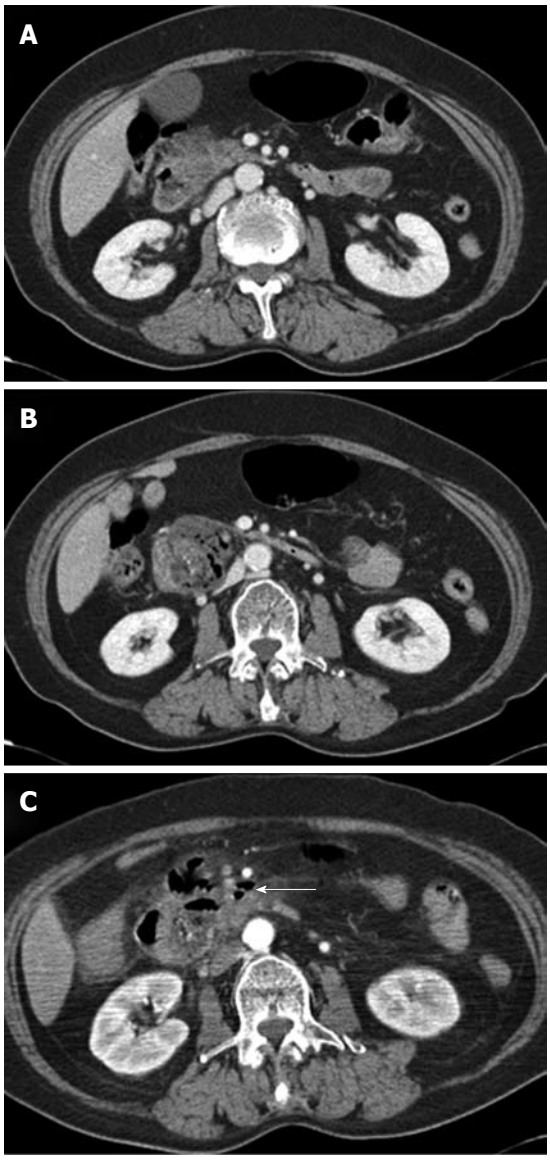

Figure 1 Abdominal computed tomography findings. A: The pancreas head showed swelling with irregular contour of the pancreatic margin and mild peripancreatic infiltration; B: There is a 5 cm size subtle rim enhancing mass with air bubbles, indicating acute diverticulitis in the second duodenal portion or air forming abscess of the pancreatic head; C: After nine days, a few extraluminal air bubbles (arrow) suspicious for microperforation were found.

to be originated from the large periampullary diverticulum and migrated toward the distal portion (Figure 2A). A large broad based inflamed diverticulum was observed, with small secondary diverticula corresponding to the extraluminal air bubbles seen on the follow-up abdominal CT. Endoscope was not able to pass through because of luminal obstruction. We tried to extract the bezoar with the help of a basket and a net, but it was unsuccessful as the bezoar was too hard and big (Figure 2B). On eighteenth hospital day, when the clinical symptoms and the laboratory findings of acute pancreatitis and septic shock had been improved, the patient was transferred to the department of general surgery for operation. A gastrotomy was performed and a huge bezoar (5 cm × 2.5 cm) was removed through the antrum by manually push-

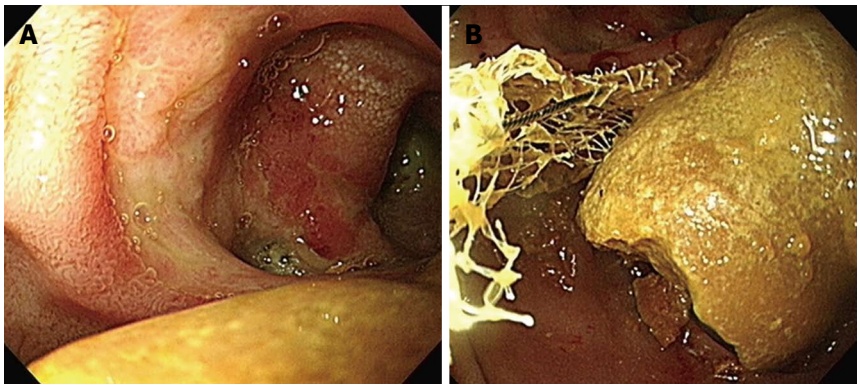

Figure 2 Endoscopic findings. A: There is a huge luminal obstructing bezoar near the duodenal diverticulum; B: The bezoar was too large to be captured and removed by an endoscopic basket or net.

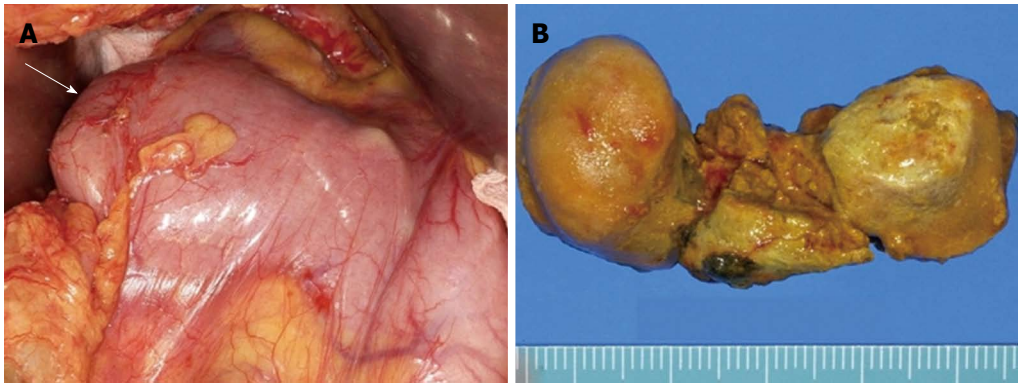

Figure 3 Surgical findings. A: Obstructed duodenum with impacted huge bezoar (arrow); B: Surgical specimen of the divided bezoar, 5 cm long, 2.5 cm in diameter.

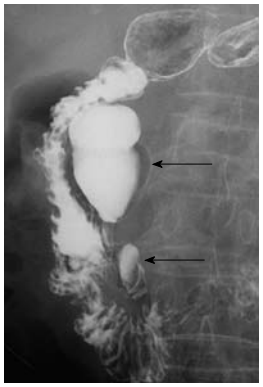

Figure 4 Upper gastrointestinal series show two periampullary diverticula (arrows) in the second duodenal portion.

ing the duodenal bezoar up into the stomach (Figure 3). The patient was discharged on the 6th postoperative day. During the 2-mo follow-up, the patient did not complain of any discomfort and two periampullary diverticula were seen in the upper gastrointestinal series (Figure 4).

DISCUSSION

Bezoars are composed of vegetable matter (phytobezoar), hair (trichobezoar), or more unusual materials[1]. They are usually related to previous gastric operations, such as vagotomy or partial gastrectomy, which reduce gastric motor activity and delay gastric emptying. In one report, 70% of patients with bezoar had undergone previous surgery[2]. Bezoars also can be induced by gastroparesis caused by hypothyroidism or diabetes mellitus, and poor mastication or ingestion of indigestible materials[3].

Most bezoars occur in the stomach, but may be encountered elsewhere, including the small bowel and even the esophagus and rectum. Clinical manifestations vary depending on the location of the bezoar from showing no symptom to acute abdominal syndrome, such as, epigastric distention, abdominal pain, and acid regurgitation. Major complications of bezoars include intestinal obstruction, gastric perforation, gastric ulcer, and gastritis[5]. Small bowel obstruction is a severe complication requiring surgery[6]. Small bowel obstructions were usually due to migration of gastric bezoars, but it could also be caused by primary bezoars formed in the small bowel in association with stricture, tumor or diverticulum[3]. Biliary obstruction or acute pancreatitis caused by bezoars has seldom been reported[4,7,8]. In our case, a large duodenal bezoar had originated from an inflamed periampullary diverticulum, causing acute pancreatitis. This was then followed by a spontaneous migration of the bezoar, resulting in a duodenal obstruction and septic shock. The duodenal obstruction due to large gallstone migrated through a cholecysto-enteric fistula can give a similar

radiological and endoscopic appearance as our case[9]. However, there was no cholecysto-duodenal fistula or air in the gallbladder in the present case.

Although duodenal bezoars are rare, they can develop in patients with previous gastric surgery[8], deformed duodenal bulb[10], superior mesenteric artery syndrome[11], and duodenal diverticulum[12] as in our case. Most cases of pancreatitis caused by duodenal bezoars are trichobezoars also known as the "Rapunzel syndrome"[4]. This was a case of having unusually long hairballs that extend from the stomach into the jejunum or ileum. It may cause extrinsic compression of the ampulla, common bile duct or pancreatic head. It is thought that bezoars in the periampullary diverticulum may also cause acute pancreatitis through similar mechanisms[13].

Several studies suggested that patients with periampullary diverticulum had higher frequencies of pancreatitis. It is still controversial whether or not pancreatitis is induced by periampullary diverticulum per se. Periampullary diverticulum is associated with choledocholithiasis, and it predispose to gallstone pancreatitis[14]. Our patient showed no evidence of stones in the common bile duct on abdominal CT and MRCP, thus acute pancreatitis did not result from bile duct stones. In fact, the large bezoar had caused compression of major ampulla leading to pancreatitis.

Contrast-enhanced abdominal CT is the most useful tool for diagnosis of duodenal diverticulitis, but it can be misinterpreted as acute pancreatitis or its complications (phlegmon, pseudocyst, abscess), cystic pancreatic head neoplasms, and peripancreatic lymphadenopathy[15]. In our case, the enhanced CT showed findings that were suspicious for pancreatic abscess or microperforation of duodenal diverticulum adjacent to the pancreatic head. After EGD, the condition was recognized as periampullary diverticulitis with secondary diverticula inside. Endoscopy is an important diagnostic modality for diagnosis of diverticular diseases. The side-viewing endoscopy can be beneficial compared to the forward-viewing endoscopy, because acute diverticulitis causes mucosal swelling and narrowing of the diverticular orifice that further hampers the diagnostic yield of a forward-viewing endoscopy[16].

Bezoars are treated by endoscopy or surgery. If the bezoar is large, fragmentation is tried with the use of overtube, baskets, lithotripsic equipment, paraffin, cellulose, acetylcysteine, Coca-Cola lavage, and even lasers. If the bezoar is accompanied by complications such as small bowel obstruction, gastric perforation or gastric hemorrhage, the patient needs urgent treatment, such as surgery[3].

In conclusion, we report a case of a large duodenal bezoar, which had originated from the periampullary diverticulum, causing acute pancreatitis, with subsequent duodenal obstruction by migration. Complications caused by duodenal bezoar, in particular, pancreatitis and subsequent duodenal obstructions are rare, but a high index of suspicion is required for the correct diagnosis and proper management.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

We acknowledge our sincere thanks to our reviewers. Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of our World Series Journals. Both the editors of the journals and authors of the manuscripts submitted to the journals are grateful to the following reviewers for reviewing the articles (either published or rejected) over the past period of time.

Dr. BS Anand, Professor, Digestive Diseases Section (111D), VA Medical Center, 2002 Holcombe Blvd., Houston, TX 77030, United States

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/esps/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of Gastroenterology

Contents

Weekly Volume 18 Number 39 October 21, 2012

EDITORIAL

5489 Peritoneal carcinomatosis of colorectal origin: Incidence, prognosis and treatment options
Klaver YLB, Lemmens VEPP, Nienhuijs SW, Luyer MDP, de Hingh IHJT

FIELD OF VISION

5495 Diagnosis of Zollinger-Ellison syndrome: Increasingly difficult
Ito T, Cadiot G, Jensen RT

GUIDELINES FOR BASIC SCIENCE

5504 Molecular targets in the treatment of alcoholic hepatitis
Dhanda AD, Lee RWL, Collins PL, McCune CA

GUIDELINES FOR CLINICAL PRACTICE

5514 Checkmate to liver biopsy in chronic hepatitis C?
Trifan A, Stanciu C

REVIEW

5521 Treatment of locally advanced rectal cancer: Controversies and questions
Trakarnsanga A, Ithimakin S, Weiser MR

5533 Experimental and clinical evidence of antioxidant therapy in acute pancreatitis
Esrefoglu M

ORIGINAL ARTICLE

5542 Dietary copper triggers onset of fulminant hepatitis in the Long-Evans cinnamon rat model
Siaj R, Sauer V, Stöppeler S, Spiegel HU, Köhler G, Zibert A, Schmidt HHJ

5551 MUC5AC/β-catenin expression and *KRAS* gene alteration in laterally spreading colorectal tumors
Nakae K, Mitomi H, Saito T, Takahashi M, Morimoto T, Hidaka Y, Sakamoto N, Yao T, Watanabe S

BRIEF ARTICLE

5560 Software for automated classification of probe-based confocal laser endomicroscopy videos of colorectal polyps
André B, Vercauteren T, Buchner AM, Krishna M, Ayache N, Wallace MB

5570 Quantitation of HBsAg predicts response to entecavir therapy in HBV genotype C patients
Orito E, Fujiwara K, Kanie H, Ban T, Yamada T, Hayashi K

5576 Inhibition of gastric perception of mild distention by omeprazole in volunteers
Iida A, Kaneko H, Konagaya T, Funaki Y, Tokudome K, Izawa S, Tamura Y, Mizuno M, Ogasawara N, Sasaki M, Kasugai K

5581 Thioredoxin and thioredoxin-interacting protein as prognostic markers for gastric cancer recurrence
Lim JY, Yoon SO, Hong SW, Kim JW, Choi SH, Cho JY

5589 Photodynamic therapy prolongs metal stent patency in patients with unresectable hilar cholangiocarcinoma
Lee TY, Cheon YK, Shim CS, Cho YD

5595 Surgical outcome of pancreatic cancer using radical antegrade modular pancreatosplenectomy procedure
Chang YR, Han SS, Park SJ, Lee SD, Yoo TS, Kim YK, Kim TH, Woo SM, Lee WJ, Hong EK

5601 Biochemical characteristics of neonatal cholestasis induced by citrin deficiency
Wang JS, Wang XH, Zheng YJ, Fu HY, Chen R, Lu Y, Fang LJ, Saheki T, Kobayashi K

5608 Colonic stenting *vs* emergent surgery for acute left-sided malignant colonic obstruction: A systematic review and meta-analysis
Ye GY, Cui Z, Chen L, Zhong M

5616 Comparison between different reconstruction routes in esophageal squamous cell carcinoma
Zheng YZ, Dai SQ, Li W, Cao X, Wang X, Fu JH, Lin P, Zhang LJ, Lu B, Wang JY

5622 Carbon dioxide insufflation for endoscopic retrograde cholangiopancreatography: A meta-analysis and systematic review
Cheng Y, Xiong XZ, Wu SJ, Lu J, Lin YX, Cheng NS, Wu TX

CASE REPORT

5632 Clostridium perfringens bacteremia caused by choledocholithiasis in the absence of gallbladder stones
Atia A, Raiyani T, Patel P, Patton R, Young M

5635 A *de novo* germline *MLH1* mutation in a Lynch syndrome patient with discordant immunohistochemical and molecular biology test results
Airaud F, Küry S, Valo I, Maury I, Bonneau D, Ingster O, Bezieau S

5640 Ischemic colitis and large bowel infarction: A case report
Georgescu EF, Carstea D, Dumitrescu D, Teodorescu R, Carstea A

5645 Gastrointestinal stromal tumor presenting with prominent calcification
Izawa N, Sawada T, Abiko R, Kumon D, Hirakawa M, Kobayashi M, Obinata N, Nomoto M, Maehata T, Yamauchi S, Kouro T, Tsuda T, Kitajima S, Yasuda H, Tanaka K, Tanaka I, Hoshikawa M, Takagi M, Itoh F

5649 Hepatothorax due to a right diaphragmatic rupture related to duodenal ulcer perforation
Baek SJ, Kim J, Lee SH

5653 Tracheobronchial nodules and pulmonary infiltrates in a patient with Crohn's disease
Lu DG, Ji XQ, Zhao Q, Zhang CQ, Li ZF

5658 Severe acute cholangitis after endoscopic sphincterotomy induced by barium examination: A case report
Zhang ZH, Wu YG, Qin CK, Su ZX, Xu J, Xian GZ, Wu SD

ACKNOWLEDGMENTS I Acknowledgments to reviewers of *World Journal of Gastroenterology*

APPENDIX I Meetings

I-VI Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Gastroenterology*, Zenichi Morise, MD, PhD, Professor and Chairman, Department of Surgery Banbuntane Houtokukai Hospital, Fujita Health University School of Medicine, 3-6-10 Otobashi Nakagawa-ku, Nagoya, Aichi 454-8509, Japan

FLYLEAF I-IX Editorial Board

EDITORS FOR THIS ISSUE

Abstract

Peritoneal carcinomatosis (PC) is one manifestation of metastatic colorectal cancer (CRC). Tumor growth on intestinal surfaces and associated fluid accumulation eventually result in bowel obstruction and incapacitating levels of ascites, which profoundly affect the quality of life for affected patients. PC appears resistant to traditional 5-fluorouracil-based chemotherapy, and surgery was formerly reserved for palliative purposes only. In the absence of effective treatment, the historical prognosis for these patients was extremely poor, with an invariably fatal outcome. These poor outcomes likely explain why PC secondary to CRC has received little attention from oncologic researchers. Thus, data are lacking regarding incidence, clinical disease course, and accurate treatment evaluation for patients with PC. Recently, population-based studies have revealed that PC occurs relatively frequently among patients with CRC. Risk factors for developing PC have been identified: right-sided tumor, advanced T-stage, advanced N-stage, poor differentiation grade, and younger age at diagnosis. During the past decade, both chemotherapeutical and surgical treatments have achieved promising results in these patients. A chance for long-term survival or even cure may now be offered to selected patients by combining radical surgical resection with intraperitoneal instillation of heated chemotherapy. This combined procedure has become known as hyperthermic intraperitoneal chemotherapy. This editorial outlines recent advancements in the medical and surgical treatment of PC and reviews the most recent information on incidence and prognosis of this disease. Given recent progress, treatment should now be considered in every patient presenting with PC.

INTRODUCTION

Peritoneal carcinomatosis (PC) secondary to colorectal

cancer (CRC) is characterized by the development of solid tumor deposits on the peritoneal surface[1]. Cell shedding from the primary tumor is thought to be responsible for these peritoneal deposits, which may occur spontaneously or as a result of spillage during surgical procedures. Attachment of tumor cells to peritoneal mesothelial cells involves neoangiogenesis and is mediated by several growth factors[2]. Tumor implantation and growth may lead to invasion of any organ or structure that is covered by peritoneum.

Common sites for peritoneal implants are the omentum, mesentery, bowel surface, pouch of Douglas, right paracolic gutter, and diaphragm[3,4]. Patients initially present with nonspecific symptoms such as abdominal discomfort, nausea, weight loss, cachexia, and fatigue; however, these symptoms are often indistinguishable from more general features of malignant disease. The tumor growth on intestinal surfaces and associated fluid accumulation eventually result in signs of bowel obstruction[5] and incapacitating volumes of ascites[6,7]. Previously, providers were reluctant to treat these patients because of their extremely poor prognosis and invariably fatal outcomes[8-10]. Therefore, PC resulting from CRC had received little attention from oncologic researchers. Hence, data was lacking regarding incidence, clinical disease course, and accurate treatment evaluation for patients with PC.

Since the 1980s, PC research has attracted renewed interest because of the observation that a subgroup of patients presents solely with peritoneal tumor implants without systemic metastases[11,12]. This finding spurred the development of aggressive surgical treatment modalities which combined radical cytoreductive surgery with intraperitoneal chemotherapy[13-17]. With this approach, prolonged overall survival and even disease cure have been reported[8,18-26]. Here, we will discuss the recent advances in the characterization and treatment of these patients.

INCIDENCE OF PC

The extent of peritoneal disease is frequently underestimated by imaging modalities[27], and the presence of peritoneal involvement often remains unknown until a laparotomy is performed. This uncertainty in preoperative diagnosis results from the low sensitivity and specificity of imaging techniques such as abdominopelvic ultrasound and computed tomography. The small size of tumor deposits (typically less than 1 cm) negatively affects sensitivity[27-30]. Furthermore, peritoneal spread of tumor cells characteristically follows the anatomic outline of normal abdominal structures, making radiologic detection more challenging.

Underestimation of PC due to poor preoperative imaging diagnostics, combined with the aforementioned lack of interest, likely explains the virtual absence of data on PC incidence. Most available data were retrieved from single hospital-based studies that reported incidence of PC encountered during laparotomy. In the largest study, which included 2756 patients with CRC, 214 (8%) patients were diagnosed with synchronous PC and 135 (5%) with metachronous disease[10]. Two older studies, also single hospital-based, reported that 10% to 15% of patients with colon cancer presented with PC[9,31]. Recently, two population-based studies reported the incidence of synchronous PC in The Netherlands (4.8%) and in Sweden (4.3%)[32,33]. Risk factors for developing PC include right-sided tumor, advanced T-stage, advanced N-stage, poor differentiation grade, and younger age at diagnosis.

In clinical studies, metachronous PC is reported in 4% to 12% of patients following curative resection for colon cancer and in 2% to 19% of patients following curative resection for rectal cancer[34]. In patients undergoing repeat procedures for CRC following primary curative resection, 21% to 44% of patients are diagnosed with peritoneal tumor deposits[35,36]. In autopsy studies, PC is found in up to 40% of patients who die from colorectal carcinoma[37,38]. On a population level, 4.2% of Swedish patients with CRC developed metachronous PC following initial treatment[33]. Risk factors for developing metachronous PC are similar to those for synchronous PC, but also include initial emergency procedures and non-radical initial tumor resection[33].

TREATMENT

Systemic treatment

Few studies have been published describing the effectiveness of systemic chemotherapy in patients with PC. Due to an inability to accurately measure tumor load and treatment response, patients with peritoneal tumors usually do not meet the inclusion criteria for randomized trials[39]. The few studies describing chemotherapeutic treatment response focus on systemic 5-fluorouracil (5-FU) and leucovorin using retrospective analysis. The results invariably show a disappointing response to systemic treatment and a poor prognosis compared to other metastatic sites. A French prospective multicenter study of 118 patients with PC of colorectal origin showed a median survival of only 5.2 mo[40]. In a large series of CRC patients, which included 392 patients with peritoneal involvement, Jayne *et al*[10] showed a median survival of 7 mo. Chu *et al*[9] reported a median survival of 6 mo in a series of 45 patients who were treated primarily with 5-FU and leucovorin. A sub-analysis by Köhne *et al*[41] of patients with PC treated with 5-FU-based therapy showed a median survival of 7.7 mo. Slightly better results were reported by Bloemendaal *et al*[8], who described 50 patients with PC but without hematogenous metastases who were treated with systemic chemotherapy and palliative surgery. Their overall median survival was 12.6 mo, with a 2-year survival rate of approximately 18%[8,24]. However, selection bias probably explains these findings, because these patients were initially referred for hyperthermic intraperitoneal chemoperfusion (HIPEC)-

treatment but eventually randomized to the study control group. It is conceivable that these patients were healthier and their PC disease was more limited compared to the average PC patient.

A few studies have aimed to describe the effect of newer chemotherapeutic combinations, such as oxaliplatin plus irinotecan[8,42,43]. Results are conflicting and require careful interpretation. Many of these studies were performed to compare systemic treatment with surgical treatment. Selection bias may play a role in these studies because only patients in good condition with limited disease and without systemic metastases were eligible. Nevertheless, the median survival of 23 mo, as described by Elias *et al*[18] and obtained with modern systemic chemotherapy, is remarkable and dispels the notion that PC is chemotherapy-resistant. A similar conclusion may be drawn from the only population-based study to investigate this topic thus far. From 1995 to 2008, the administration of chemotherapy to patients with PC gradually increased, from 16% to 46% ($P = 0.001$), with the treatment rate rising to 64% for younger patients[41]. However, a survival benefit was only apparent after 2005 when modern chemotherapy schedules were introduced[44].

Introduction of targeted therapies, including monoclonal antibodies specifically targeted to epidermal growth factor receptor and vascular endothelial growth factor, has resulted in a significantly increased survival among patients with metastasized CRC[41,45,46]. Although these agents are now routinely included in the treatment of patients with stage Ⅳ disease, only one small retrospective study has evaluated the effect of adding targeted therapies in patients with PC; a survival of 22.4 mo was observed when biologicals were added to first line of treatment in this patient group[47].

Cytoreductive surgery and intraperitoneal chemotherapy

The observation that some patients present with PC in the absence of systemic metastases has led to the hypothesis that PC results from locoregional spread rather than systemic metastasis. This belief has encouraged surgical oncologists to examine possibilities for locoregional therapies. In the 1980s and 1990s, physicians and researchers developed new treatment strategies consisting of aggressive cytoreductive surgery plus intraperitoneal chemotherapy, often combined with hyperthermia.

Surgical procedures invariably start with a careful and systematic abdominal exploration and registration of the extent of peritoneal disease. The abdomen is divided in 13 regions and for each region, the number and size of tumor deposits are assessed and recorded. The sum of these scores represents the peritoneal cancer index (PCI), which ranges from 0 to 39. For PC resulting from CRC, a PCI score of 15 or more is generally accepted as exclusion criterion for HIPEC. In The Netherlands, the simplified PCI (sPCI) is commonly used to describe the PC involvement of 9 regions of the abdomen[24]. The PCI and sPCI are well-known predictive outcome indices for patients undergoing cytoreductive surgery and perioperative chemotherapy[48,49].

During cytoreductive surgery, surgeons attempt to remove all visible tumor deposits from the peritoneal surface. To achieve a radical resection, resection of grossly involved organs may be required. Additionally, peritonectomy may be performed[15]. Resection completeness is recorded using the completeness of cytoreduction score (CCR). A CCR-0 score indicates that no macroscopic peritoneal tumor remains following cytoreduction. A CCR-1 score occurs when tumor nodules less than 2.5 mm persist following cytoreduction. Residual disease measuring 2.5 mm to 2.5 cm is scored as CCR-2. A CCR-3 score indicates the presence of tumor nodules greater than 2.5 cm, or a confluence of unresectable tumor nodules at any site within the abdomen or pelvis[50]. Alternatively, the R1-R2a-R2b scoring system classifies R1 as no macroscopic residual tumor, R2a as macroscopic residual disease less than 2.5 mm, and R2b as tumor deposits greater than 2.5 mm[24]. Treatment outcomes are poorer in the presence of residual tumor following optimal cytoreduction, particularly for residual tumor diameters exceeding 2.5 mm. It is hypothesized that 2.5 mm is the maximum penetration depth of chemotherapeutic agents[48].

After macroscopically complete cytoreduction, intraperitoneal chemotherapy is administered to eradicate microscopic disease. This chemotherapy can be administrated immediately following surgery in the operating room, usually in combination with HIPEC or on postoperative days 1 to 5 (early postoperative intraperitoneal chemotherapy). HIPEC perfusion may be performed with a closed abdomen, or with an open "coliseum technique". Chemotherapeutic agents and doses vary widely between centers worldwide, with mitomycin C and oxaliplatin being the most frequently used agents.

Only one completed phase Ⅲ randomized trial investigating the outcome of surgical intraperitoneal treatment has been published to date. Verwaal *et al*[24,25,51] reported a significant increase in median overall survival among patients treated with cytoreductive surgery and HIPEC, as compared to patients receiving standard palliative care using systemic 5-FU and leucovorin. The promising outcomes observed in this study have convinced many surgeons to accept this technique as standard of care for selected patients with PC, and HIPEC treatment is now offered in specialized centers all over the world. However, this study was heavily criticized for not including a control group of patients receiving cytoreductive surgery only. Therefore, it remains unclear whether cytoreductive surgery and HIPEC are both required to improve survival, or if the observed benefit was due to a single component[52]. Ideally, these questions should be addressed in randomized trials. However, this type of study has proven difficult to implement, as demonstrated by a phase Ⅲ trial in France that failed to enroll enough patients due to patient dissatisfaction

with randomization[53]. Recently, investigations of cytoreductive surgery and HIPEC in PC animal models have provided a sound scientific rationale for the application of intraperitoneal chemotherapy in conjunction with cytoreductive surgery[54-56], although the additional value of hyperthermia is questionable[54].

The best available clinical evidence now comes from multi-institutional registries[18-23]. These data require careful interpretation, as surgeon experience, technique and perioperative care differs widely between institutions[57]. However, reported median survival rates of up to 63 mo following cytoreductive surgery and HIPEC with limited postoperative morbidity and mortality[58,59] suggest that treatment should be considered in all patients with PC secondary to CRC.

In conclusion, PC of colorectal origin was formerly considered untreatable, with an extremely poor prognosis. Recent treatment advances using modern systemic chemotherapy or cytoreductive surgery combined with HIPEC have improved patient outcomes. In our opinion, treatment should be considered for every patient presenting with PC due to CRC. However, further understanding of PC pathogenesis, optimal diagnostics and treatment requires ongoing experimental and clinical research.

Abstract

In the present paper the increasing difficulty of diagnosis of Zollinger-Ellison syndrome (ZES) due to issues raised in two recent papers is discussed. These issues involve the difficulty and need to withdraw patients suspected of ZES from treatment with Proton Pump Inhibitors (omeprazole, esomeprazole, lansoprazole, rabeprazole, pantoprazole) and the unreliability of many gastrin radioimmunoassays. The clinical context of each of these important issues is reviewed and the conclusions in these articles commented from the perspective of clinical management.

INVITED COMMENTARY ON HOT ARTICLES

Two recent papers by Poitras *et al*[1] and Rehfeld *et al*[2] call attention to two areas that are making it more difficult to diagnosis Zollinger-Ellison syndrome (ZES). In this short review after listing the papers and their abstracts, the importance of these two issues will be briefly commented on.

Background: General

ZES is a clinical syndrome due to the ectopic secretion of gastrin by a neuroendocrine tumor (gastrinoma), located primarily in the duodenum (60%-80%) or pancreas (10%-40%), resulting in gastric acid hypersecretion, which if left untreated results in refractory peptic ulcer disease, severe gastroesophageal reflux disease, diarrhea and finally death, primarily due to the complications of the refractory peptic ulcer disease[3-6]. The diagnosis of ZES, like the diagnosis of other ectopic hormonal pancreatic endocrine syndromes, historically requires the demonstration of inappropriate release of the hor-

mone and evidence of hormonal hypersecretion[3,6-8]. In the case of ZES this requires the demonstration of inappropriate gastrin release by demonstrating fasting hypergastrinemia in the presence of gastric acid hypersecretion[3,6-10]. This is clinically most frequently accomplished by demonstrating the inappropriate presence of fasting hypergastrinemia when gastric fluid is acidic with a pH $\leqslant$ 2 is present or gastric hypersecretion is present [> 15 mEq/h basal acid output (no previous gastric acid reducing surgery), > 5 mEq/h (if gastric acid reducing surgery)][7,8,11-14]. The combination of fasting hypergastrinemia and elevated gastric acid secretion are required for ZES diagnosis because numerous unrelated conditions can cause one or the other of these alone[5,6,8,10,14]. The most frequent cause of fasting hypergastrinemia is physiological hypergastrinemia (also called appropriate hypergastrinemia) due to the presence of hypo/achlorhydric, which in normal individuals results in a reciprocal increase in gastrin release from the G cells of the gastric antrum causing hypergastrinemia[7,8,10,14,15]. This is most frequently due to chronic atrophic gastritis, commonly due to the presence of a *Helicobacter pylori* (*H. pylori*) infection that spares the antrum or due to pernicious anemia[7,8,10,14,15]. A second very frequent cause is the use of potent gastric acid anti-suppressant drugs such as proton-pump inhibitors (PPIs) (omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole), which is discussed in the next paragraph. Other less common causes of hypochlorhydric/achlorhydria include chronic renal failure and vagotomy, which can be distinguished by appropriate other laboratory/clinical investigations[5,8,10,13]. Similarly, the presence of gastric acid hypersecretion without hypergastrinemia can be seen in patients with idiopathic gastric acid hypersecretion and a few other uncommon conditions (mastocytosis, basophilic granulocytic leukemia)[8,16,17].

While the diagnosis of ZES sounds simple enough, in recent years it is becoming increasingly more difficult, due to a number of developments, and now, as pointed out in the above two papers, it is even further complicated. Let's first consider the issues that were complicating the diagnosis of ZES prior to these two papers. First, acid secretion is now rarely measured and therefore generally not available, so alternatives to the classical basal acid output assessment were proposed. These include, in addition to the presence of fasting hypergastrinemia, an endoscopic measurement of gastric acid output[18], the use of either pH paper or a pH meter to establish the presence of an acidic pH in gastric fluid, assessment for the presence of other features of ZES such as the presence of a tumor on imaging or pathologic studies and the development of gastric fluid pH criteria , that when coupled with the presence of hypergastrinemia, support the diagnosis of ZES[1,11,14]. Second, the widespread use of PPIs is markedly complicating the ability to diagnosis ZES, because their use interferes with both needed assessments to establish the diagnosis of ZES: the measurement of fasting gastrin levels and the assessment of acid secretion[5,10,12,14,19]. This occurs because PPIs have a very long duration of action, with their gastric acid suppressive action lasting up to one week[13,20,21] which not only contributes to their marked effectiveness, but also makes it difficult to withdraw patients from these drugs to assess gastric secretion[1,5,14]. Furthermore, their potent antisecretory activity can lead to fasting hypergastrinemia due to the PPIs and thus mislead one into suspecting ZES[14,19,22]. The result of the PPIs is that they both mask the diagnosis of ZES, leading to delays in diagnosis, because they effectively control all presenting clinical symptoms, but also they can lead to a false diagnosis[3,5,14,19,23]. False diagnoses occur because long-term use of PPIs can cause fasting hypergastrinemia in 80%-100% of patients without ZES[24-27] with fasting gastrin values > 4 fold increased in 20%-25% of patients[24-27] and in some cases the gastrin levels are > 10-fold elevated into ranges that are frequently thought to reflect ZES[25,26].

Commentary paper

In Poitras *et al*[1] two patients are reported in whom ZES was suspected (later proven) after presenting with severe symptoms of gastroesophageal disease, subsequently treated with PPIs with symptom improvement and when the PPIs were withdrawn, both patients developed severe complications of peptic disease (patient No. 1, esophageal stricture requiring repeated dilatations; patient No. 2, intestinal perforation). It was proposed that PPI therapy should always be maintained and diagnostic evaluations be performed while taking PPIs[1]. This is a novel recommendation and would have a marked effect on the diagnostic approach to patients suspected of having ZES. This recommended approach differs from the approach recommended in recent consensus guidelines and by most authorities in recent reviews, wherein, it is recommended that acid antisecretory drugs have to be stopped at some point to establish the diagnosis of ZES. Specifically, both the North American Neuroendocrine Tumor Network guidelines[9] and the European Neuroendocrine Tumor Network's guidelines[3,12], as well as a recent reviews of the diagnosis of ZES by a number of authorities[7,10,14,22,28], all recommend that PPIs need to be generally stopped to establish the diagnosis of ZES.

Is there any additional evidence to support this novel recommended diagnostic approach for ZES in paper 1[1]? Others have reported severe esophageal strictures in patients with ZES, since the time that antisecretory drugs were available, whose acid hypersecretion was not controlled[29-31] and in one large study[32], 8% (10/122) patients with ZES required repeated esophageal dilations, because of previous poor control of the acid hypersecretion. We don't find additional cases in the literature to patient No. 1 described in this report[1], however, we have seen one patient with ZES who developed a severe long, esophageal stricture requiring a stent, because antisecretory medications were withdrawn at an outside hos-

pital for diagnosis (unreported case). Similarly intestinal perforations have been reported in a number of patients with ZES since antisecretory drugs became available. Intestinal perforations were reported in 7% of patients with ZES in one large series (11/160 cases)[33] and in a number of other case reports[34,35], with the perforations occurring prior to the diagnosis in most cases. However, we have seen three cases of ZES patients who developed intestinal perforations when taken off of antisecretory drugs for diagnostic reasons[33,34] (unpublished 2 cases). One case occurred after a patient with suspected ZES reduced the PPI dose they were taking on their own because they developed constipation while taking the PPI and then presented with a duodenal perforation after 5 d of stopping the PPI in preparation for a secretin test[34]. Two other cases occurred prior to the use of PPIs early in our experience and we have seen no additional cases at National Institutes of Health (NIH) in the last 20 years in acid studies of more than 300 patients with ZES, the majority of who were taking PPIs prior to diagnosis. These latter results demonstrate that acid secretory studies can be safely carried out if proper precautions are taken, even if patients are taking PPIs, although it requires a center well versed in performing these studies, and a proven approach, one of which is discussed below, However, the query raised by Poitras *et al*[1] still remains, as to whether it is necessary to withdraw antisecretory medications in most patients with ZES to establish the diagnosis.

Unfortunately, the evidence suggests, as concluded in the accompanying editorial[14] to paper No. 1[1], that to clearly establish the diagnosis of ZES, some appropriate assessment of gastric acid acidity/secretion is required after withdraw of PPIs in almost every patient. What is the evidence? First, it is both fortunate and unfortunate that PPIs are so effective in patients with ZES as well as patients with idiopathic peptic disease. It is fortunate because PPIs are very effective at controlling gastric acid secretion in these patients[5,7,36,37]. However, it is unfortunate for diagnostic purposes, because their effectiveness results in that fact that with PPIs, the usual doses used in idiopathic peptic disease are often effective also in ZES and result in hypo/achlorhydria in both ZES patients and in patients without ZES. In contrast with Histamine H_2-receptor antagonists, frequently 10-fold greater doses than used in treating patients with idiopathic peptic disease are required in ZES patients, with more frequent dosing to control the hypersecretion, however these high doses in ZES and the usual doses in patients without ZES, rarely result in hypo/achlorhydria[5,7,36,37]. Therefore, in most patients taking PPIs where ZES is suspected, the gastric pH will not be < 2 (the range required for diagnosis of ZES)[7,11], and therefore physiological and pathological hypergastrinemia can not be distinguished on the drug. Second, there is no feature of the clinical course that unequivocally allows one to establish the presence of ZES, with most patients currently presenting with idiopathic peptic ulcer disease or gastroesophageal reflux disease which is indistinguishable from that seen in non-ZES patients[7,14,35,38]. Third, when ZES is suspected, a fasting gastrin level is almost invariably the first diagnostic study performed[7-10,12,14,39]. Unfortunately, there is no absolute level of fasting hypergastrinemia alone that can distinguish a patient with ZES from a patient without ZES[6,39]. This will be covered in more detail below in the discussion of Rehfeld *et al*[2], however a few additional points will be made here. In the most common cause of fasting hypergastrinemia, chronic atrophic gastritis, fasting gastrin levels > 70 fold elevated have been reported and levels > 1000 or > 2000 ng/L are not uncommon[40-43], which is a similar finding in patients with pernicious anemia[44]. These values overlap with 80%-100% of patients with ZES in various series[39]. Similarly, in patients taking PPIs without ZES, which is the also one of the most common causes of hypergastrinemia, the PPIs can lead to various degrees of hypergastrinemia in different patients. Although, as pointed out in a number of studies, PPIs frequently lead to < 3 fold increase in fasting gastrin and in some studies do not increase the value out of a normal range[22,45,46], this finding can not be relied on in an individual patient. This conclusion is firmly supported by various studies which report 80%-100% of the patients without ZES in their studies treated with PPIs develop hypergastrinemia, 20%-25% > 4 fold elevated, and values > 1000 pg/mL are not uncommon[24-27,47]. These levels of PPI induced increases in fasting gastrin overlap with that seen in more than 60% of patients with ZES[6,39,48,49]. Fourth, alone, no absolute level of any other tumor marker such as a serum chromogranin A (CgA) level, can establish the diagnosis of ZES. CgA levels are elevated in 90%-100% of patients with ZES, which can be contributed to by both the gastrinoma and the gastrin induced enterochromaffin-like (ECL) cell hyperplasia which is almost always present[50-55]. However, the main problem is that PPIs or high doses of other antisecretory drugs, can increase CgA levels in patients without ZES, within a few days of use, which is thought secondary to the PPI-induced hypergastrinemia causing gastric ECL proliferative effects[27,56,57]. The PPI induced increases in CgA can are usually < 4 fold, but can be up to 40-fold, which overlaps with values seen in > 90% of patients with ZES, as well as seen in numerous, non-ZES conditions[24,27,53,54,57-59]. Fifth, the recommended establishment of a diagnosis of ZES in a hypergastrinemic patient by other methods, as proposed in paper No. 1[1], such as by attempting to establish the presence of a neuroendocrine tumor (primarily by imaging studies) or by establishing the presence of a gastrinoma, is unlikely to be successful in many patients and may lead, in fact, to false diagnoses. It is likely to be unsuccessful in many patients because < 30% of patients with ZES at presentation at the current time, have liver metastases that possibly could be biopsied and the diagnosis of a gastrinoma established by immunohistochemistry[13,60,61]. Even this does not secure the di-

agnosis, because other pancreatic neuroendocrine tumors [non-ZES primitive neuroectodermal tumors (pNETs)] can stain occasionally positively for gastrin but not be associated with ZES or the portion of the neuroendocrine tumor biopsied may not show gastrin staining[62-69]. Furthermore, localization of a primary gastrinoma, even with the use of increasingly sensitive methods such as somatostatin receptor imaging or endoscopic ultrasound studies, misses most small duodenal tumors, which are present in 60%-80% of patients with ZES[70-75]. Furthermore, cross-sectional imaging studies (computed tomographic scanning, magnetic resonance imaging, trans-abdominal ultrasound) will be negative in > 60% of all patients with duodenal tumors and thus not be able to assist in suggesting the presence of a pNET in the majority of suspected cases, especially those patients being examined early in their course[71,72,76,77]. Lastly, sensitive methods such as somatostatin receptor scintigraphy can lead to false positive localization results and in one prospective study[78,79], 12% of all possible pancreatic endocrine tumor localizations were false positive. These include the presence of an accessory spleen, gallbladder retention, an abscess, various inflammatory processes, inadequate bowel cleansing, thyroid disease, various granulomatous lung diseases, and other neuroendocrine tumors/proliferations such as gastric ECL proliferation or other gastrointestinal-neuroendocrine tumors like gastric carcinoids tumors[78-81]. Therefore, one cannot conclude that localization on a somatostatin receptor scintigraphy study in a patient with hypergastrinemia necessarily equates to localization of a gastrinoma and establishment of the diagnosis of ZES. Fifth, besides the assessment of fasting gastrin levels and gastric fluid pH, various gastrin provocative tests (primarily after secretin, occasionally after glucagon)[14,48,49,82,83] are widely used in the diagnosis of ZES. The secretin test in particular has been well studied and in one recent detailed analysis of 537 patients with ZES in the literature as well as 293 NIH patients with ZES prospectively studied, the secretin test was shown to have a sensitivity of 94% with a specificity of 100% using a criterion of ⩾ 120 ng/L increase post secretin[49]. Couldn't the secretin provocative test be used while the patient is taking PPIs to circumvent the need to stop the PPI? Unfortunately, the answer is no, because a recent study[84] reports a false positive secretin test in a patient without ZES taking PPIs. Furthermore, another study demonstrated if patients are achlorhydric, false secretin positive tests can occur[85].

Commentary on paper

In the study by Rehfeld *et al*[2], Seven of 12 tested commercial kits inaccurately measure plasma concentrations of gastrin; these assays used antibodies with inappropriate specificity that were insufficiently validated. Misdiagnosis of gastrinoma based on lack of specificity of assays for gastrin results in ineffective or inappropriate therapy for patients with ZES.

Background: An accurate assessment of fasting serum gastrin levels (FSG) is central to the diagnosis of ZES and the diagnosis cannot be made without it. This is especially true, because this is the initial study that leads to the suspicion of ZES, in most cases[2,7,9,12,83]. An assessment of FSG is generally used as the initial study not only because of its convenience and widespread availability, but also because it is elevated in almost all patients with ZES, except for a few specific situations. In a review of 2229 cases of ZES from the literature[39], FSG levels were elevated in 97% of patients and in 309 patients with ZES seen at the NIH it was elevated in 99.3% of patients[39]. These results and others[6,86,87] demonstrate that normal FSG levels are uncommon overall in patients with ZES however, in a few small subgroups with active disease, normal values are not uncommon. This includes patients with active ZES who had had unsuccessful curative resection of a gastrinoma previously, who have ZES with multiple endocrine neoplasia type 1 (MEN1) post successful parathyroidectomy for hyperparathyroidism, in patients being treated with somatostatin analogues or occasionally in patients after various anti-tumor treatments (chemotherapy, chemo-embolization, *etc*.)[86-96]. Although many physicians think FSG levels are massively elevated in ZES and easy to distinguish from other disorders, unfortunately, as pointed out above, this is not the case. Chronic atrophic gastritis, other hypo/achlorhydric conditions, chronic renal failure and the use of PPIs can cause FSG levels that overlap with those seen in most patients with ZES. Furthermore, in 60%-65% of ZES patients when initially diagnosed, the FSG levels are < 10-fold elevated and these levels overlap with a number of other conditions, some of which are much more frequent than ZES, which can also be associated with gastric acid hypersecretion, such as seen in ZES[5,13,39,48,97]. This FSG level (i.e., > or < 10 × increased) is pointed out because the existing criteria used for the diagnosis of ZES in most guidelines and reviews is divided on the basis of the elevation of FSG[3,12,14,38,39]. If the FSG is > 10-fold elevated (usually > 1000 ng/L) and the gastric fluid pH < 2, a diagnosis of ZES is established after ruling out a possible retained antrum syndrome by history[12,14,38,39,98]. On the other had if the FSG is < 10-fold increased and the gastric fold pH < 2, other conditions need to be excluded including *H. pylori* infection, antral G cell syndromes, gastric outlet obstruction and renal failure[3,7,9,38,39]. In these cases a gastric analysis with determination of basal acid output, and a secretin provocative test is recommend, or if secretin is not available, a glucagon provocative test has been recommended[7,12,49,82,87]. These latter provocative tests involve the assessment of serum gastrin before and after a secretin or glucagon injection, so an accurate assessment of serum gastrin is essential to their correct interpretation.

Specific comments: Rehfeld *et al*[2] report that in many cases that the gastrin laboratory assays being used to assess FSG levels are not giving accurate results. Only 5 of the 12 commercial assays examined accurately assessed

FSG levels with the others giving FSG values either too high or too low and thus their results could lead to an over- or under-diagnosis of ZES, based on the FSG levels reported[2]. While gastrin provocative test results (secretin, glucagon) were not assessed, a similar result would be expected with these and thus the result would not be dependable in most cases. This report raises a number of problems for physicians trying to diagnose and treat patients with ZES. First, it demonstrates that FSG levels should not be compared from different laboratories using different assays unless some validation is performed. Second and more important, this report raises a real dilemma for the practicing clinician, because it raises the question of whether he can rely on FSG values reported to him by the laboratory he uses. There is no simple solution to this dilemma. The lists of laboratories assessed in this paper[2] can be consulted to see if the one used for the blood samples sent by for the clinician's patients(s) are on this list. Because the diagnosis of ZES has such significance for any patient and alternative approach as discussed in a section below is to refer the patient to center with known expertise, or to contact them and find out which laboratory in their area they recommend to assess FSG, and confirm the results using this laboratory.

Recommended approach to diagnosis of ZES (based on points raised in papers 1, 2)

First, it is essential to realize that patients with untreated gastric acid hypersecretion with ZES can develop complications rapidly and that this needs to be adequately treated before trying to establish a diagnosis, especially by stopping PPIs. There is no urgency in establishing the diagnosis. Therefore if the patient has active peptic ulcer disease or symptoms and the diagnosis of ZES is suspected, a FSG should be drawn and the acid hypersecretion adequately controlled [our initial starting dose is equivalent to omeprazole 60 *qd*[99,100], or if complicated disease (presence of MEN1, Billroth 2 surgery, or severe gastroesophageal reflux symptoms), we start with the equivalent of omeprazole 40 *bid*][37,101-103] and the patient should undergo an upper gastrointestinal endoscopy. We start with a higher PPI dose to make sure the acid hypersecretion is initially well controlled and then later it can be reduced in many patients[37,101]. During this endoscopy, gastric pH can be measured and also the size of gastric mucosal folds noted because 92% of ZES patients have prominent gastric folds[35]. Most patients can be satisfactorily treated by this PPI dose initially, however some require higher doses and therefore it is best to assess the control of acid hypersecretion on PPI[37,99,104], however, only a few specialty centers have this capability, and thus most use control of symptoms to monitor effectiveness of treatment. If the patient has symptoms of gastroesophageal peptic disease or active disease on endoscopy they should be treated for 8-12 wk until symptom free and then the upper gastrointestinal endoscopy repeated to make sure any peptic disease is resolved before attempting to establish the diagnosis by stopping PPIs. During this time the reliability of the FSG assay used needs to be explored both by reviewing the laboratories in paper No. 2[2] and contacting some group well versed in your area with the diagnosis of ZES that uses gastrin assays regularly. If the FSG is elevated it, of course this could be due to the PPI the patient was taking when the blood sample was drawn, which is the situation in most cases, so that the diagnosis remains unclear at this point, particularly if the gastric pH was > 2. At this point many authorities recommend that consideration be given to referring the patient to a group in your area well versed in the diagnosis of ZES[7,9,12,14]. If not possible, then after the repeat endoscopy shows healing of mucosal disease and the patient is asymptomatic, one can consider PPI withdrawal for diagnosis. Our approach is similar to outlined recently[14] and briefly, is to carefully consult with the patient about the need to keep in close contact, then to substitute an H_2 receptor antagonist (usually ranitidine 450-600 every 4 to 6 h) for the PPI for 3-5 d and then stop the ranitidine for 24 h allowing liberal use of antacids. Then on the day of the test we measure FSG × 2, and measure gastric pH and acid output. We usually perform a secretin test at the same time if our index of suspicion is high[49]. This circumvents the need to take the patient off of PPIs again at a later time if the secretin test is deemed necessary. If a gastric/esophageal pH probe is available the assessment of gastric pH and FSG at early times can be done with an attempt to document a pH < 2 with an elevated FSG.

One could ask at this point why go through all of this and why is it so important to establish the diagnosis of ZES correctly in most patients. The primary reason is that the diagnosis of ZES requires special treatment and the treatment must be continued life-long if the patient is not cured[7,9,105]. If the patient is not cured, life-long PPI treatment will be required, the doses may be different than that usually used in patients with idiopathic peptic disease, periodic assessment for the presence of MEN1 will be needed because 20%-30% of ZES patients have this and its diagnosis may not be initially evident and treatment directed at the gastrinoma, which are malignant in 60%-90% of cases, must be considered[13,35,38,106,107]. The latter include periodic assessment of tumor location/extent with imaging studies, consideration of surgical resection which is recommended in ZES patients in whom MEN1 is not present, life expectancy is good and no serious surgical contra-indications are present[7,71,108-110]. Therefore a diagnosis of ZES markedly effects clinical management and thus needs to be well established.

Abstract

Alcohol related costs to health and society are high. One of the most serious complications of alcohol misuse to the individual is the development of alcoholic hepatitis (AH), a clinical syndrome of jaundice and progressive inflammatory liver injury in patients with a history of recent heavy alcohol use. It has a poor outcome and few existing successful therapies. The use of glucocorticoids in patients with severe AH is still controversial and there remains a group of patients with glucocorticoid-resistant disease. However, as our understanding of the pathogenesis of the condition improves there are opportunities to develop new targeted therapies with specific actions to control liver inflammation without having a detrimental effect on the immune system as a whole. In this article we review the molecular mechanisms of AH concentrating on the activation of the innate and adaptive immune response. We consider existing treatments including glucocorticoids, anti-tumor necrosis factor therapy and pentoxifylline and their limitations. Using our knowledge of the disease pathogenesis we discuss possible novel therapeutic approaches. New targets include pro-inflammatory cytokines such as interleukin (IL)-17, chemokines and their receptors (for example IL-8, CXCL9 and CXCR3) and augmentation of anti-inflammatory molecules such as IL-10 and IL-22. And there is also future potential to consider combination therapy to selectively modulate the immune response and gain control of disease.

INTRODUCTION

Alcohol related morbidity in developed countries is second only to tobacco use and is responsible for 2.5 million deaths globally each year[1]. It costs 1% of the GDP of middle to high income countries[2]. In the United Kingdom, deaths from alcohol related liver disease have increased by 36% between 2001 and 2008[3]. Alcoholic hepatitis (AH) is a clinical syndrome characterised by jaundice and progressive inflammatory liver injury in patients with a history of recent heavy alcohol misuse. Severe cases are associated with a high mortality of around 30%-50% at 28 d[4,5]. However, the pathogenesis of the

condition is incompletely understood and there is a lack of targeted therapy.

It is clear that alcohol acts both directly on the liver, causing cell death by toxic mediators, and *via* activation of the immune system. Over the past 2 decades considerable headway has been made into understanding the immune basis of the disease with studies on pro- and anti-inflammatory cytokines, cell trafficking to the liver and mechanisms of hepatocyte death. This work has been hampered by the absence of a suitable animal model of the disease and much of the relevant work has been inferred from other models of acute hepatic injury or through chronic ethanol feeding. Although these models share several important similarities with human AH, such as neutrophil accumulation in the hepatic ischaemia model or hepatocyte ballooning in the ethanol-fed rat model, they still have significant differences. Neither the acute hepatic ischaemia model nor the carbon tetrachloride model involves alcohol metabolism and alcohol related liver damage. The chronic ethanol feeding model does not mirror the acute phase of inflammation in AH and instead is more similar to alcoholic steatohepatitis[6]. Therefore, at present we must interpret results from these studies with caution and focus attention on studies on human tissue.

In this review, we consider the pathogenesis of AH, focussing on the contribution of immunity (Figure 1), and relate this to the use of targeted molecular therapies. We briefly discuss the evidence for anti- tumor necrosis factor-α (TNFα) therapies and pentoxifylline, both of which have been extensively studied in AH, but do not intend this to be a definitive systematic review. For further discussion on these 2 treatments we refer the readers to recent comprehensive reviews[7-9]. We have emphasised the molecules that we believe have the greatest future therapeutic potential.

PATHOGENESIS

Within the liver alcohol can be metabolised to acetaldehyde by three enzyme systems: alcohol dehydrogenase in the cytosol, the microsomal ethanol-oxidising system and peroxisomal catalase. These metabolic pathways lead to the production of reactive oxygen species and cause lipid peroxidation. There is a reduction in the hepatoprotective methyl donor S-adenosylmethionine and mitochondrial glutathione. Acetaldehyde forms adducts with proteins, lipids and DNA, impairing their function and promoting DNA damage (see Setshedi *et al*[10] for a detailed review on this subject). However, it is not only the direct toxic effect of alcohol on the liver that causes damage but also activation of the immune response.

Activation of the innate immune system

Alcohol is known to change the gut microbiota[11] and can increase numbers of both aerobic and anaerobic organisms[12]. In addition, metabolism of alcohol by gut bacteria results in production of acetaldehyde which has a direct effect on the gut epithelium, opening up tight junctions, increasing its permeability[13,14]. This allows the presentation of bacteria or microbial cellular components to cells of the innate immune system. These pathogen-associated molecular patterns are recognised by toll-like receptors (TLRs) which are expressed on a wide variety of immune and stromal cells, in particular on monocytes and macrophages. Gut-derived endotoxin [or lipopolysaccharide (LPS)] crosses into the portal venous system and activates TLR4 on $CD14^+$ cells. Higher levels of LPS have been demonstrated in the portal veins of patients with alcohol related cirrhosis compared to non-alcohol related cirrhosis controls[15]. *Via* adaptor molecules MyD88 and toll/interleukin (IL)-1 receptor domain-containing adaptor inducing interferon-β, the signalling pathway converges on a few transcription regulators [nuclear factor κB (NF-κB), activator protein 1 (AP-1) and interferon regulatory factors], which lead to a pro-inflammatory immune response. Signalling through TLR4 plays an important role in the development of alcohol related liver damage as evidenced by TLR-mutant mice which are resistant to alcohol and have lower levels of circulating TNFα despite having higher circulating LPS[16]. Modulation of the gut microbiota with pro- or antibiotics reduces circulating levels of LPS in mouse models[17,18]. Activation of TLR4 on macrophages and kupffer cells (liver resident macrophages) leads to secretion of pro-inflammatory cytokines such as IL-1, IL-6 and TNFα, which act on surrounding hepatocytes and stromal cells as well as activating the adaptive immune response.

Activation of the adaptive immune system

It is clear that T-lymphocytes play a role in the development of AH with increased levels of $CD4^+$ and $CD8^+$ T-lymphocytes found in liver biopsy material from patients with AH compared to healthy controls[19]. The liver has a unique dual blood supply with both portal venous and hepatic arterial blood draining into the hepatic sinusoids. Hepatic sinusoid endothelial cells (HSEC) are therefore exposed to large numbers of leukocytes and HSEC expression of adhesion molecules and chemokine receptors enables adherence of lymphocytes and transmigration into the hepatic parenchyma to the site of inflammation. Unlike other endothelial cells HSEC express low levels of selectins[20] but high levels of intercellular adhesion molecule-1 (ICAM-1), vascular adhesion protein-1 (VAP-1) and vascular cell adhesion molecule-1 (VCAM-1)[21]. Inhibition of ICAM-1 and VCAM-1 reduce lymphocyte adhesion in *in vitro* flow-based adhesion experiments[21].

Liver infiltrating lymphocytes express high levels of CXCR3 and migrate towards its ligands CXCL9 and CXCL10[22], which are produced by a variety of liver cells including hepatic stellate cells and activated myofibroblasts[23]. High levels of TNFα found in AH stimulate production of CXCL10 from hepatocytes and HSECs increasing T cell recruitment to the liver[24]. Data from

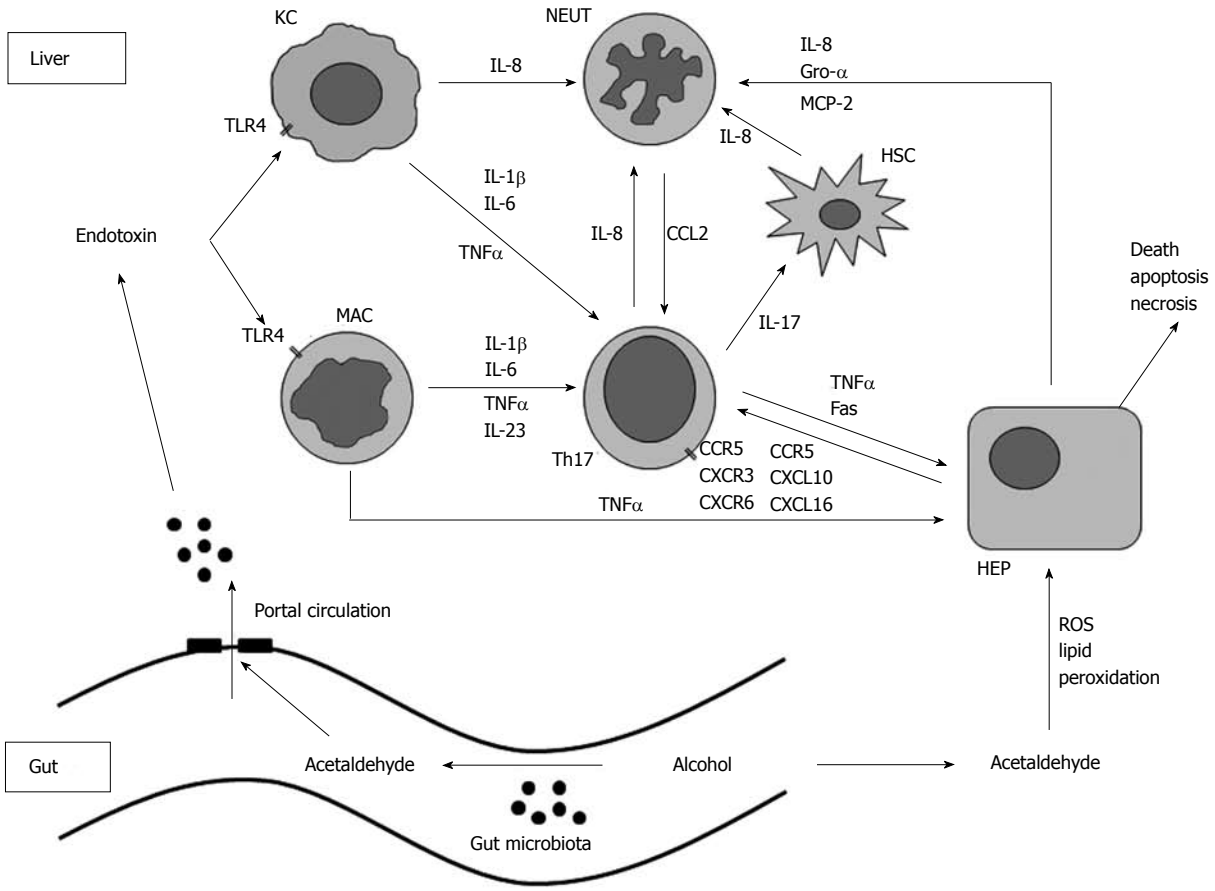

Figure 1 The effects of alcohol on the innate and adaptive immune system. Alcohol is metabolised by gut microbiota to acetaldehyde which has a direct effect on the epithelial tight junctions, making them more leaky. Endotoxin and other pathogen-associated molecular patterns enter the portal circulation and act *via* toll-like receptor (TLR) 4 receptors on kupffer cells (KCs) and macrophages (MAC), activating them to produce pro-inflammatory cytokines and chemokines, which act on hepatocytes, neutrophils (NEUT) and T cells. Both $CD4^+$ and $CD8^+$ T cells are recruited into the liver but there is a significant proportion of interleukin (IL)-17 secreting $CD4^+$ Th17 cells, which in turn activate stellate cells to produce IL-8. T cells also act directly on hepatocytes *via* the tumor necrosis factor (TNF) receptor 1 or Fas pathways leading to apoptosis. Alcohol also has a direct effect on hepatocytes (HEP) through metabolism by alcohol dehydrogenase, the microsomal ethanol-oxidising system and peroxisomal catalase to acetaldehyde, which damages cells by the formation of reactive oxygen species (ROS) and increased lipid peroxidation. HSC: Hepatic stellate cell; MCP: Monocyte chemotactic protein.

patients with chronic hepatitis C infection also demonstrate that liver infiltrating lymphocytes express high levels of chemokine receptor CXCR3 as well as others such as CCR5 and CXCR6[24,25].

Once T-lymphocytes have been recruited to the site of inflammation there is evidence that the $CD4^+$ subset mediates hepatocyte death. Adoptively transferred liver associated $CD4^+$ T cells from ethanol-fed rats demonstrated greater hepatocyte apoptosis in recipient rats compared to those transferred from non-ethanol-fed rats[26].

Hepatocyte death can occur by necrosis or apoptosis. Necrosis is characterised by ballooning and is clearly described in cases of AH. However, apoptosis has also been identified as an important mechanism of AH. There is greater hepatocyte apoptosis in the livers of patients with AH compared to controls[27] and the degree of apoptosis correlates with clinical measures of severity[28]. Apoptosis may be caused by direct cytotoxic T cell activation of the Fas apoptosis pathway, which in turn can induce IL-8, a neutrophil chemotaxin. Alternatively, TNFα binding to TNF-R1, a member of the death receptor family, can initiate apoptosis. As discussed above, TNFα is significantly elevated in severe AH suggesting it can mediate hepatocyte death by this mechanism as well as by direct toxic effects leading to necrosis.

Neutrophil recruitment

The degree of intrahepatic neutrophil infiltration correlates with severity of AH[29] although their exact role in the pathogenesis of the disease is less well understood. Data from animal models of other acute liver injury such as ischaemia suggest that neutrophils are activated by cytokines including TNFα, IL-1β and IL-17 and are recruited to the hepatic parenchyma by CXC chemokines such as Gro-α[29], IL-8 and monocyte chemoattractant protein 2[30]. CXC chemokines are particularly important for neutrophil infiltration in AH[31]. These neutrophils migrate into the parenchyma and cause hepatocyte necrosis by release of reactive oxygen species and proteases[32].

With this understanding of the molecular mechanisms of the pathogenesis of AH, we can more effectively target therapy.

Existing therapy for severe AH

Glucocorticoids: Glucocorticoid therapy was first demonstrated to be beneficial in the treatment of patients with severe AH in 1978[4]. Glucocorticoids are potent immunosuppressants which have wide ranging effects on a large number of cell types. Key among their actions is suppression of the pro-inflammatory transcription factors NF-κB and AP-1[33] resulting in lower levels of circulating TNFα and IL-8[34].

Glucocorticoid treatment has been evaluated in many clinical trials and debate continues whether they are beneficial with conflicting results of meta-analysis[35-37]. The largest placebo-controlled trial recruited a heterogeneous group of 90 patients (including those with moderate and severe disease as well as end stage alcoholic liver disease) and failed to show a survival benefit at 30 d[38]. Another trial recruiting only patients with histologically proven AH showed a survival benefit with glucocorticoid treatment at 2 mo[39] but no difference at long term follow-up at 2 years[40]. More recent meta-analysis of individual patient data demonstrated a survival benefit with glucocorticoid treatment in patients with severe AH[5]. However, they identify a proportion of glucocorticoid non-responders, with a significantly worse outcome, by applying the Lille model[41] at day 7 of treatment. This highlights the fact that as in other inflammatory diseases such as asthma and rheumatoid arthritis there is a proportion of patients resistant to steroid treatment[42]. In addition, the non-specific effect of glucocorticoids means that there is a risk of infective complications. Other therapeutic options are therefore essential.

Pentoxifylline: Pentoxifylline, a phosphodiesterase inhibitor, has a moderate effect on TNFα levels[43-45] although circulating TNFα levels in patients on active treatment did not show any difference from those on placebo in a randomised controlled trial[46]. The effects of pentoxifylline are likely to be less specific than inhibition of a single cytokine. In animal models of liver injury it has shown a reduction in pro-fibrogenic cytokines such as pro-collagen I and transforming growth factor beta 1[47]. Although the exact mechanism of action of pentoxifylline in AH is not clear several trials have shown a survival benefit, predominantly through a significant reduction in mortality due to hepatorenal syndrome[46,48]. However, a recent Cochrane systematic review was unable to draw firm conclusions about its beneficial effect due to probable bias in the design of a number of trials[49]. A large United Kingdom multi-centre randomised placebo-controlled trial of pentoxifylline, prednisolone or combination is currently underway, which hopes to provide a definitive answer as to whether these treatments are beneficial in patients with severe AH.

Anti-oxidant therapy: Oxidative stress plays an important role in the pathogenesis of AH (Dey *et al*[50]). In an attempt to reduce its toxic effects, several clinical trials of anti-oxidant agents have been undertaken either in combination with glucocorticoids or as a monotherapy. A recent randomized controlled trial (RCT) of 5 d of intravenous N-acetylcysteine (NAC) or placebo with 4 wk of glucocorticoids[51] demonstrated a reduction in mortality at 1 mo in the NAC arm but failed to reach significance at 2 mo and 6 mo (the primary outcome of the trial). A lower incidence of infections was noted in the NAC treated group.

A further RCT has been reported using an anti-oxidant cocktail (including NAC and vitamin E) with or without concomitant glucocorticoids, which failed to show an improvement in 6 mo survival[52]. A different anti-oxidant cocktail was tested against glucocorticoid therapy but a higher number of deaths at 30 d was reported in the anti-oxidant treatment arm[53]. Vitamin E versus placebo also failed to demonstrate any benefit in outcome[54].

Anti-TNFα therapy: Anti-TNF therapy with chimeric monoclonal antibody (infliximab) or fusion proteins (etanercept) have proved successful in other inflammatory conditions such as rheumatoid arthritis[55] and Crohn's disease[56]. With high levels of TNFα demonstrated in patients with severe AH[57] and since TNFα predicts short-[58] and long-term survival[59], it is an appropriate target for effective therapy.

In ethanol-fed rats treated with anti-TNF antibody, there was a significant improvement in hepatic inflammation, although serum levels of TNFα remained unchanged[60] supporting a role for this drug in human AH. An open label pilot study of a single dose of 5 mg/kg infliximab in combination with glucocorticoids found a significant reduction in Maddrey Discriminant Function[61]. An RCT of 3 infusions of infliximab 10 mg/kg or placebo at weeks 0, 2 and 4 in combination with prednisolone was stopped early due an excess of deaths in the active treatment group due to infection[62]. An RCT of etanercept also found that there was a significantly poorer outcome for patients on active treatment due to infection[63]. Lower doses of infliximab or less aggressive loading regimes may reduce the incidence of infection. Alternatively, combination therapy with an anti-inflammatory treatment such as recombinant IL-10 or IL-22 (see below) may boost the immune response to infections.

Alteration of the gut microbiota

Alcohol alters the gut microbiota and together with increased intestinal permeability there is activation of the innate immune system to produce an inflammatory response in AH. No clinical trial of probiotics has yet been reported in patients with AH. However, there is evidence that changing the bowel microbiota with probiotics in patients with alcohol related cirrhosis reduces the production of pro-inflammatory cytokines[64] and improves liver function tests in patients with alcoholic psychosis[65]. Further investigation is required to determine whether probiotic therapy is beneficial in AH. Alteration of the gut microbiota with non-absorbable antibiotics

such as rifaximin may also be beneficial and has recently been proven effective for the prevention of hepatic encephalopathy in patients with cirrhosis[66].

The treatments for AH discussed so far have wide-ranging effects on the immune system. These non-targeted therapies have failed to demonstrate a clear benefit in outcome. Both anti-TNFα therapy and glucocorticoids suppress the appropriate immune response to infection, resulting in a higher incidence of serious infections. Over the last decade the emphasis in treatment of inflammatory conditions has shifted to a more targeted approach to lessen the impact of inflammatory mediators, while reducing the systemic complications of treatment.

Future molecular targets

IL-10: IL-10 is a potent anti-inflammatory cytokine, suppressing the production of inflammatory cytokines (including TNFα) by T helper cells, monocytes and kupffer cells. IL-10 can also inhibit production of reactive oxygen species by neutrophils[67]. IL-10 is upregulated in surviving patients that had a response to glucocorticoid therapy[34]. This is consistent with studies of glucocorticoid effects on T cells in other inflammatory conditions such as asthma[68]. Therefore increasing the levels of IL-10 in patients with significant inflammation may prove to be a useful therapeutic target.

Unfortunately, treatment with recombinant human IL-10 (rhuIL-10) in patients with Crohn's disease has proved disappointing. Although well tolerated, it failed to induce clinical remission or response in patients with mild to moderately active Crohn's disease[69,70] and a recent systematic review suggested a lack of effect of rhuIL-10 in patients with Crohn's[71]. One study found that administration of rhuIL-10 lead to an increased capacity of leucocytes to produce interferon-gamma (IFNγ), a potent Th1 secreted pro-inflammatory cytokine[72], which may explain its lack of anti-inflammatory effect.

In the context of liver disease, rhuIL-10 has been trialled in chronic hepatitis C. Thirty patients with advanced fibrosis who failed treatment with antiviral therapy were treated with rhuIL-10 administered subcutaneously daily or 3 times weekly for 1 year[73]. There was a significant improvement in serum transaminase and a reduction in inflammation scores in 13 of 28 patients and fibrosis scores in 11 of 28 patients and a 2 fold reduction in the number of hepatitis C virus (HCV) specific $CD4^+$ IFNγ secreting T cells. However, there was a significant increase in HCV RNA levels which returned to baseline 6 mo after end of treatment.

A pilot open label study of rhuIL-10 in combination with glucocorticoids in 8 patients with severe AH failed to show any changes to neutrophil-derived or serum IL-8 and TNFα production[74]. No significant differences in mortality or MDF were observed in comparison to the control group. This may be explained by the fact that although in patients with severe AH IL-10 is upregulated, it is not sufficient to reduce the levels of TNFα[75]. Therefore a combination of cytokine targets to inhibit TNFα while augmenting IL-10 may be a useful approach.

IL-22, a member of the IL-10 family, shares its anti-inflammatory effects and potentiation of this molecule may be more beneficial than the use of rhuIL-10 since the IL-22 receptor is only expressed on epithelial cells such as hepatocytes. A study in a chronic ethanol-fed mouse model showed that treatment with recombinant IL-22 ameliorates liver injury and hepatic oxidative stress[76]. In a murine model of acute hepatitis IL-22 receptor is upregulated on hepatocytes and blockade of IL-22 exacerbates disease while administration of IL-22 ameliorates it[77]. Interestingly IL-22 is produced by Th17 cells, thought to be pathogenic (see below). Perhaps the strategy of blocking IL-17 in conjunction with augmenting IL-22 will have a more synergistic effect.

IL-8: Inhibition of neutrophil mediated hepatic damage may also prove to be an important therapy. Levels of *IL-8* gene expression and serum protein are elevated in patients with AH and higher levels are associated with a poorer outcome[31]. *IL-8* gene expression is also related to neutrophil hepatic infiltration as well as increased portal pressure[31]. IL-8 antagonism may reduce neutrophil recruitment into the liver without impairing the neutrophils' function in host defence and elimination of pathogens.

Hepatocyte growth factor: Hepatocyte growth factor (HGF) is thought to play an important role in the regeneration of the liver after an injury such as AH. It reduces hepatocyte apoptosis[78] as well as reducing ethanol-related oxidative damage[79]. Higher levels of HGF correlate with greater hepatocyte proliferation in AH[80] and are associated with better outcome[81]. Treatment of alcohol fed mice with recombinant HGF reduced the development of fatty liver[82]. Interestingly, HGF is produced by neutrophils and the degree of neutrophil infiltration in the liver correlates with levels of HGF[83]. Therefore a strategy of blocking neutrophil trafficking to the liver by IL-8 antagonism may also have a detrimental effect by reducing the liver's regenerative capacity. Combination of IL-8 antibodies with recombinant HGF or *HGF* gene therapy may reduce the inflammatory effects of neutrophils while maintaining the beneficial effects on hepatocyte proliferation.

T cells: T cells play a role in the recruitment of neutrophils and the perpetuation of inflammation in AH. Reduction in T cell proliferation through targeting IL-2, a T cell proliferation and survival factor, may reduce the number of pro-inflammatory cells within the inflamed liver. Inhibition of IL-2 receptor alpha (CD25) with a chimeric monoclonal antibody reverses glucocorticoid resistance *in vitro* in peripheral blood mononuclear cells from patients with AH[42]. This monoclonal antibody (basiliximab) is licensed for use in acute cellular rejection of cadaveric renal transplants. Promising results

Table 1 Summary of mechanism of action and existing evidence about potential future molecular targets for the treatment of severe alcoholic hepatitis

Treatment	Mechanism of action	Clinical evidence
rhu IL-10	Suppression of pro-inflammatory cytokines, e.g., TNFα Suppression of reactive oxygen species	Phase 2 study in severe AH with concomitant glucocorticoids showed no significant difference in mortality or levels of IL-8 and TNFα[74]
rhu IL-22	Increased levels of anti-inflammatory IL-22 Reduced oxidative stress	Reduced liver injury in ethanol-fed rat model[76] and acute hepatitis mouse model[77]. No studies in human liver disease yet reported
Anti-IL-8 antibody	Reduced neutrophil recruitment to liver	Phase 2 studies in COPD demonstrated reduced dyspnea[103]. No studies in human liver disease have yet been reported
rhu hepatocyte growth factor	Reduced hepatocyte apoptosis	HGF levels correlate with outcome in severe AH[81]. Well tolerated in a small phase 1/2 trial in fulminant hepatitis but no clear clinical benefit was seen[104]
Basiliximab (anti-CD25 antibody)	Reduced T cell proliferation and subsequent pro-inflammatory cytokine production	Reverses *in vitro* glucocorticoid resistance in patients with severe AH[42]. No clinical trials yet conducted in liver disease
Secukinumab (anti-IL-17A antibody)	Reduced pro-inflammatory IL-17A	Well tolerated in patients with rheumatoid arthritis, psoriasis or uveitis[93]. No clinical benefit in crohn's disease[94]. No clinical trial yet reported in liver disease
Anti-CXCL10 antibody	Reduced Th1 cell recruitment to liver	CXCR3 (receptor for CXCL10) is elevated in patients with chronic hepatitis C infection[95]. Phase 2 clinical trial is underway in patients with PBC

rhu: Recombinant human; AH: Alcoholic hepatitis; TNFα: Tumor necrosis factor-α; HGF: Hepatocyte growth factor; PBC: Primary biliary cirrhosis; IL: Interleukin; COPD: Chronic obstructive pulmonary disease.

from an open label study in patients with glucocorticoid resistant ulcerative colitis showed a benefit[84] but has not been borne out in a double-blind randomised controlled trial[85]. The immunogenicity of the drug together with a high achievement of clinical response and remission in the placebo arm, may have contributed to the lack of benefit over placebo in this study. However, given in a single dose (shown to be less immunogenic in renal transplant patients[86]) basiliximab may prove to be a useful adjunct to glucocorticoid therapy in patients who do not respond to this therapy.

Th17 cells: Recently, T cells producing IL-17 (known as Th17 cells) have been ascribed a central role in the pathogenesis of many inflammatory and autoimmune conditions[87] and are present in chronically inflamed tissues[88]. The generation of Th17 cells in humans requires IL-1β and IL-6 with IL-23 as a survival factor[89]. IL-17 can itself act as a neutrophil chemotaxin but can also stimulate production of other chemotaxins such as IL-8 and CXCL1[90]. To date, 6 Th17 cytokines have been described (known as IL-17A-F)[91], the most studied being IL-17A.

Serum levels of IL-17 are higher in patients with AH compared to healthy and HCV controls[92]. From the same study liver biopsy material from patients with AH showed significantly higher numbers of infiltrating IL-17$^+$ cells compared with alcohol related cirrhosis samples and the number of infiltrating cells correlated with the Maddrey Discriminant Function. The increased levels of IL-17 within the liver are likely to act on hepatic stellate cells, which when stimulated with IL-17 increase chemotaxis of neutrophils[92].

Phase 1 trials of humanised anti-IL-17A monoclonal antibody (secukinumab) have proved successful in the treatment of rheumatoid arthritis, psoriasis and uveitis[93] with phase 2 and 3 trials in rheumatoid arthritis ongoing. Disappointingly, small benefit was seen over placebo in patients with active Crohn's disease[94], which may be due to low concentration of the drug at the site of inflammation or presence of other Th17 produced cytokines such as IL-17F. To date no studies of secukinumab have been reported in patients with liver disease.

Lymphocyte trafficking to the liver

A number of chemokines and receptors have been identified as playing a role in neutrophil, macrophage or lymphocyte trafficking to the liver. Targeting these receptors or blocking their ligands could limit liver infiltration and subsequent damage leaving cells to perform other functions such as clearance of infection in the periphery. Several possible targets are appealing: CXCR3 and its ligand CXCL10 appears to be important in liver disease. CXCR3 is expressed on Th1 cells and intrahepatic CXCR3 is upregulated in patients with chronic hepatitis C infection[24,95]. Although no studies have yet been performed in AH, a monoclonal antibody to CXCL10 is currently under evaluation in patients with primary biliary cirrhosis, Crohn's disease and ulcerative colitis. However, this approach may have its limitations; a murine model of IFNγ mediated hepatitis [by Concanavalin A (ConA) challenge] demonstrated that CXCR3$^{-/-}$ mice developed a more severe hepatitis and failed to induce tolerance *via* conversion to an IL-10 secreting regulatory T cell (Treg) phenotype on re-challenge with ConA[96]. This suggests that CXCR3 is required for liver homing of lymphocytes in inflammation with subsequent development of an anti-inflammatory IL-10 secreting

Treg phenotype to limit hepatic inflammation. Therefore inhibition of the initial accumulation of T cells may lead to alteration of hepatoprotective downstream events. Combination therapy with anti-CXCL10 and rhuIL-10 or IL-22 may be an option to maintain the protective effects of IL-10 secreting Tregs.

VAP-1 is another potential target; VAP-1 is elevated in patients with inflammatory liver conditions[97] but also correlates with disease severity in AH[98]. Blockade of this molecule reduces peripheral blood and liver derived lymphocyte migration across HSECs[99].

Selective inhibition of T cell subsets, such as Th17 cells, from infiltrating the liver may reduce the most pro-inflammatory cell population from reaching the liver and causing more damage. However, the migratory fate of Th17 cells in humans is still poorly understood. Two chemokines, CCR4 and CCR6, have been identified as playing a role of Th17 migration in inflammatory disease[100,101] but these are also expressed on a variety of other T cell subsets[102]. Ongoing work is hoping to elucidate this pathway.

In conclusion, broad spectrum therapy for the treatment of severe AH has not been demonstrated to be clearly beneficial mainly due to development of infective complications. With our increasing understanding of the pathophysiology of the disease together with its immunological mechanisms, we have the opportunity to develop targeted molecular approaches (Table 1). However, work on AH remains challenging in the absence of an appropriate animal model. Many of the pre-clinical studies use chronic ethanol feeding murine models or we must infer results from non-alcoholic models of acute liver injury such as ischaemic or carbon tetrachloride induced hepatitis. This deficit must be addressed so we can further our understanding of the pathogenesis of this disease. Furthermore, clinical studies in AH lag far behind other inflammatory and autoimmune conditions such as rheumatoid arthritis and Crohn's disease. Learning from these studies we have seen that selected cytokine inhibition has rarely been successful (with TNFα being a notable exception). We therefore would strongly endorse future assessment of combination therapy such as recombinant IL-10 or IL-22 with anti-IL-17, HGF with anti-IL-8, glucocorticoids with IL-10, IL-22 or anti-CD25 or selective inhibition of chemokines and cytokines within the liver.

Abstract

Liver biopsy (LB) has traditionally been considered the gold standard for pretreatment evaluation of liver fibrosis in patients with chronic hepatitis C (CHC). However, LB is an invasive procedure with several shortcomings (intra- and interobserver variability of histopathological interpretation, sampling errors, high cost) and the risk of rare but potentially life-threatening complications. In addition, LB is poorly accepted by patients and it is not suitable for repeated evaluation. Furthermore, the prevalence of CHC makes LB unrealistic to be performed in all patients with this disease who are candidates for antiviral therapy. The above-mentioned drawbacks of LB have led to the development of noninvasive methods for the assessment of liver fibrosis. Several noninvasive methods, ranging from serum marker assays to advanced imaging techniques, have proved to be excellent tools for the evaluation of liver fibrosis in patients with CHC, whereas the value of LB as a gold standard for staging fibrosis prior to antiviral therapy has become questionable for clinicians. Despite significant resistance from those in favor of LB, noninvasive methods for pretreatment assessment of liver fibrosis in patients with CHC have become part of routine clinical practice. With protease inhibitors-based triple therapy already available and substantial improvement in sustained virological response, the time has come to move forward to noninvasiveness, with no risks for the patient and, thus, no need for LB in the assessment of liver fibrosis in the decision making for antiviral therapy in CHC.

INTRODUCTION

Chronic hepatitis C (CHC) is a major public health concern, with around 180 million individuals affected worldwide[1]. Liver fibrosis and its end-point cirrhosis are the main causes of morbidity and mortality in patients with CHC[2]. Information on the stage of liver fibrosis is useful in patients with CHC not only for estimation of prognosis, but also for indication of antiviral therapy. Early international guidelines, consensus statements and expert panel opinions on the management of CHC unanimously recommended that decisions on treatment should be made only after performing a liver biopsy (LB) for pretreatment evaluation of the disease[3-5]. Consequently, antiviral treatment for patients with CHC has been indicated only for those with moderate to severe

stages of fibrosis (Metavir F2, F3 or F4), while patients with no or minimal fibrosis (Metavir F0, F1) have not been treated[6]. The rationale of such a strategy was to treat all patients with advanced fibrosis to halt disease progression and prevent complications, rather than those with no or minimal fibrosis who may await better treatments considering the slowly progressing natural history of CHC[7]. The recommendations mentioned above led to the routine performance of LB in nearly all patients who were newly diagnosed with CHC and potential candidates for antiviral therapy. More recent guidelines[8] still recommend LB in making treatment decisions, although it has been recognized that it is not necessary in patients with genotype 2 or 3, who can have as high as a 80% sustained virological response (SVR) rate.

For several decades, LB has been widely regarded as the gold standard for the staging of liver fibrosis[9]. However, LB is an invasive procedure and it is sometimes associated with rare but severe complications[10]. In addition, LB has several drawbacks (intra- and interobserver variability in histopathological interpretation, sampling errors, variable accessibility, high cost) which raises questions about its value for pretreatment assessment of liver fibrosis in patients with CHC[11,12]. Nowadays, many clinicians no longer cite LB as the gold standard but, at best, it can only be considered an imperfect standard for the staging of liver fibrosis[13]. It was this context that, in recent years, triggered a huge interest in the noninvasive assessment of liver fibrosis in patients with CHC. The introduction of a noninvasive methodology for the assessment of liver fibrosis as an alternative to LB in patients with CHC represents a major advancement in clinical hepatology[14]. Many of the noninvasive methods demonstrated accuracy to a considerable degree in identifying significant fibrosis, particularly cirrhosis, and consequently, noninvasive assessment of fibrosis is already a reality in patients with CHC[15]. Obviously, with the recent therapeutic development in CHC and reliable noninvasive diagnostic procedures available, LB has lost both its monopoly in the pretreatment assessment of fibrosis and the influence on decision making for antiviral therapy in patients with CHC.

CASE AGAINST LB

For the last 50 years, LB has been considered the gold standard for the staging of liver fibrosis in spite of its several shortcomings: intra- and interobserver variability in histopathological interpretation[16,17], sampling errors[18,19], and potentially life-threatening complications[20,21]. In clinical practice, we frequently encounter the intra- and interobserver variability in the staging of liver fibrosis[16,17]. Diagnostic errors made by nonspecialist pathologists were reported in > 25% of patients undergoing LB in academic centers[22,23]. According to a recent study[24], community pathologists understaged liver fibrosis in > 70% of cases with CHC. Several studies have shown that sampling errors occur when the LB specimen size is too small for an accurate estimation of fibrosis[18,19]. Both the length and the diameter of the biopsy core may affect the accuracy of fibrosis stage evaluation in patients with CHC[25,26]. Obviously, the shorter and thinner the samples are, the greater is the number of misclassifications of liver fibrosis. There is some controversy among pathologists in defining an adequate LB sample for an accurate staging of liver fibrosis. Some investigators[27] suggest that a sample of at least 15 mm in length and containing more than five portal tracts is adequate, while others recommend biopsy samples of 20 mm containing at least 11 portal tracts[26] or even larger samples, up to 25 mm[18]. Bigger is better[28], but at the price of an increased risk of severe complications[10,18]. However, it should be noted that, in clinical practice, few LB specimens reach an adequate length of 20 mm[29]. Furthermore, LB only samples an extremely small part of the whole organ (1/50 000) and therefore, there is a risk in the evaluation of lesions that are heterogeneously distributed throughout the entire liver[21]. LB may underestimate the amount of fibrosis, and cirrhosis could be missed in 10%-30% of cases[30]. Studies concerning fibrosis staging have also shown differences in one third of cases with CHC between LB samples obtained from the right and left lobes of the liver during laparoscopy[19]. Data on LB complications are heterogenous and contain wide variations in reported rate from one study to another[10,20,21,31-34]. Major complications include bleeding and bile peritonitis, with a reported mortality rate ranging from 0.03% to 0.1%[10,20,31,32,34]. It is worthwhile mentioning that both the transjugular route and ultrasound guidance approaches to LB do not significantly reduce the rate of major complications[35,36]. Complication rates are higher when LB is performed by less-experienced physicians[31,37]. In addition, LB is costly, variably available, poorly accepted by patients, and not suitable for repeated evaluation. The cost of an LB in the United States, United Kingdom and Australia varies between 1000 and 2000 USD, and it could go over 3000 USD if complications occur[12,38-40]. LB is not welcomed by patients and it may be refused by more than half of those with CHC[41]. LB is inappropriate for a dynamic evaluation of liver fibrosis over time, and recommendation to repeat biopsy every 3-5 years to follow up disease progression is certainly unrealistic, mainly due to patient nonadherence[40]. LB is contraindicated in the presence of coagulopathy and thrombocytopenia. Last but not least, the prevalence of CHC makes LB impossible in all patients with CHC who are candidates for antiviral therapy. It is these drawbacks of LB that have led to the development of noninvasive methods for the assessment of liver fibrosis in patients with CHC and, hopefully, to a major change in hepatology practice.

Nevertheless, LB has some well-recognized advantages for assessing fibrosis in CHC, such as direct measuring of liver fibrosis, well-established staging system, and evaluation of associated lesions (steatosis, iron deposition, inflammation, alcoholic liver disease, nonalcoholic fatty liver disease, metabolic syndrome), although these diagnostic advantages are counterbalanced by the aforementioned disadvantages.

CASE IN FAVOR OF NONINVASIVE METHODS

Noninvasive methods for detecting liver fibrosis may be divided in two main groups: serum markers of fibrosis and transient elastography (Fibroscan).

Serum markers for liver fibrosis are commonly divided into direct serum markers, which are directly linked to the modifications in extracellular matrix turnover produced by hepatic stellate cells during the process of fibrogenesis in the liver, and indirect serum markers which reflect alterations of the hepatic functions. The direct markers include glycoproteins (hyaluronate, laminin, YKL-40), collagen family (procollagen Ⅲ, type Ⅳ collagen), collagenases and their inhibitors (matrix metalloproteases, tissue inhibitory metalloprotease-1), and they are not routinely available in most clinical laboratories. The indirect markers are biochemical parameters determined in routine blood tests [platelet count, prothrombin time, aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio]. Serum markers for liver fibrosis may be used singly[42-45] or combining panels of direct or indirect serum markers and demographic parameters[46-55], with the aim of increasing the accuracy of single parameters. Some of them are patent-protected and commercially available: FibroTest® (Biopredictive, Paris, France) licensed under the name of Fibrosure® in the United States (LabCorp, Burlington, NC, United States)[51], Fibrometer® (BioLiveScale, Angers, France)[52], Hepascore (PathWest, University of Western Australia, Australia)[53], ELF® (Enhanced Liver Fibrosis Test, iQur Ltd, Southampton, United Kingdom)[54], and FibroSpect Ⅱ® (Promotheus Laboratory Inc. San Diego, Ca, United States)[55]. Among these, Fibrotest [α-2-macroglobulin, γ-glutamyl transpeptidase (GT), apolipoprotein A1, haptoglobin, total bilirubin, age, sex] is the most widely used and was validated by several studies on patients with CHC[56-63]. The reported accuracy of Fibrotest for significant fibrosis/cirrhosis expressed as area under receiving operating characteristic curve (AUROC) ranges from 0.74% to 0.87%[46,51]. To improve the performance of Fibrotest, its combination with Fibroscan has been suggested; with such a combination, one study reported AUROC of 0.88 for at least F2 (stage in the Metavir scoring system) and 0.95 for F3 or F4[56]. The sensitivity and specificity of serum-marker-based tests could also be improved by combining them using sequential algorithms. Thus, Sebastiani *et al*[64] combined AST/platelets ratio (APRI) with Fibrotest - a combination known as sequential algorithm for fibrosis evaluation biopsy - and found it to have an accuracy of 92.5% in the detection of fibrosis in CHC, obviating 81.5% of liver biopsies. APRI has a slightly lower performance than Fibrotest, with an accuracy between 60% and 82% for significant fibrosis and 60% and 88% for cirrhosis[46,64], but it is a simple cost-free readily available test in all hospital settings. Both Fibrometer (platelet count, hyaluronate, AST, α-2-macroglobulin, international normalized ratio, urea, age) and Hepascore (bilirubin, γGT, α-2-macroglobulin, hyaluronic acid, age, sex) showed good performance for detection of significant fibrosis[52,53,65].

There are several advantages of serum markers such as high applicability, with no risk for the patient and no contraindication; they can be performed and repeated in outpatient clinics; widespread availability; and inter-laboratory reproducibility[66]. However, there are some limitations of serum markers: none is liver specific; results are unreliable in comorbidities (hemolysis, Gilbert syndrome, rheumatoid arthritis); and they have poor performance in the diagnosis of intermediate stages of liver fibrosis[66]. Nevertheless, it is important to note that the performance of each noninvasive marker is evaluated against LB which is an imperfect gold standard, and the apparent failure of noninvasive markers to make an accurate distinction between different stages of intermediate fibrosis could be the consequence of misclassifications from biopsy[67,68].

Transient elastography (Fibroscan®, Echosens, Paris, France) measures liver stiffness in a volume at least 100 times greater than a standard LB sample, and therefore, may be more representative of the entire liver. Fibroscan is composed of an ultrasound transducer probe mounted on the axis of a vibrator; vibration is transmitted to induce an elastic shear wave that propagates through the liver. Pulse-echo ultrasound acquisition is used to measure the velocity of the shear wave, which is directly related to liver stiffness: the stiffer the liver, the faster the shear wave propagates. Results are expressed in kPa, and values range from 2.5 kPa to 75 kPa, with normal values < 5.5 kPa[69]. According to several studies, a cutoff value of 7.2-8.7 kPa defines significant fibrosis, and cirrhosis is diagnosed by a cutoff value of 12.5-14.5 kPa[70,71]. Fibroscan seems to be a reliable method for the diagnosis of significant fibrosis (AUROC 0.84) and cirrhosis (AUROC 0.95)[72,73]. Its combination with serum-based tests (Fibrotest, Fibrometer) increases the performance (but also the costs) for the diagnosis of significant fibrosis[56,71,72]. Among noninvasive methods for diagnosis of cirrhosis, Fibroscan has the highest level of performance[62,72,73], and its combination with serum markers does not increase accuracy[63,72].

Fibroscan has several advantages: it is painless; quick (< 5 min); highly reproducible, with results immediately available; inexpensive; and easy to perform in the outpatient clinic and at the bedside[66]. In addition, Fibroscan can be repeated for longitudinal disease monitoring, which is difficult, if not impossible, with LB. In cirrhotic patients, Fibroscan values correlate with portal pressure (based on the hepatic venous pressure gradient measurement), which is a reliable predictor of clinical outcomes[74-77], disease severity[78], and the risk of hepatocellular carcinoma[79]. Finally, Fibroscan and serum markers are well accepted by patients, therefore, they could be used as screening methods for the detection of liver fibrosis/cirrhosis in at-risk groups[80] and even in general population[81], while LB is unacceptable for screening purposes. Fibroscan measurement failure and unreliable results are due to limited operator experience[82], narrowed intercostal spaces[82], and obesity[82,83], although

this last problem seems to be overcome by a new specially designed probe[84-86]. Results are influenced by ALT flares[87,88], extrahepatic cholestasis[89,90], and congestive heart failure[91].

DISCUSSION

In the past, expert consensus guidelines on the management of CHC unanimously recommended routine LB before initiation of antiviral therapy[3-5,92,93]. Based on LB findings, treatment has often been advocated only for patients with at least moderate to severe stages of fibrosis (Metavir F2, F3 or F4), and withheld for those with no or minimal fibrosis (F0, F1)[6,93]. As a consequence, tens of thousands of patients were most likely denied proper antiviral therapy. More recent guidelines[8,94] recommend LB only in patients with CHC genotype 1 (SVR rate < 50%) in treatment decision making, and consider it unnecessary in those with genotype 2 or 3 who may have an SVR rate as high as 80%. The primary endpoint of antiviral therapy for CHC is achieving SVR - defined as undetectable serum HCV RNA at 24 wk after discontinuation of therapy. Viral eradication prevents disease progression, improves survival, and reduces health care costs associated with the management of complications. Thus, if viral clearance is the aim of antiviral therapy in CHC, then to what degree does an exact histopathological fibrosis stage established through biopsy still matter? With the new protease inhibitor (PI)-based triple therapy (addition of telaprevir or boceprevir to pegylated interferon and ribavirin) available and SVR rates approaching 75% in patients with CHC genotype 1[95,96], it is clear that LB has lost its importance in the recommendation of antiviral therapy.

During the past 10 years, an intensive debate has taken place between those in favor of LB and those who promote noninvasive methods for pretreatment assessment of liver fibrosis in patients with CHC. There is extensive literature showing the pros and cons of LB or noninvasive methods. As in chess, winning does not come easy for a supporter of noninvasive methods against a supporter of LB with a firmly rooted preference. Step by step, those in favor of non-invasive methods have gained ground, waiting for the final move: checkmate! Today, several noninvasive methods, ranging from serum marker assays to advanced imaging techniques, have proved to be excellent tools for the evaluation of liver fibrosis in patients with CHC. According to the latest European Association of the Study of the Liver clinical practice guidelines[97] and United Kingdom consensus guidelines[98] recommendations, noninvasive methods can be used instead of LB in patients with CHC to assess liver disease severity prior to antiviral therapy. It is therefore surprising that many experts in the field of hepatology and the most recent American Association for the Study of Liver Diseases 2011 practice guidelines[99] favor LB before therapy initiation, despite substantial improvement in treatment success rate for genotype 1 patients with PI-based triple therapy. The main reason against noninvasive methods for evaluation of liver fibrosis is their apparent failure to make an accurate distinction between different stages of intermediate fibrosis. It is important to note that the performance of each noninvasive method was evaluated in all studies by calculating the AUROC using LB as a reference standard. As LB is an imperfect standard, a perfect noninvasive method will never reach the maximum value (1.0)[100], and therefore, noninvasive methods are as inaccurate as LB for the assessment of fibrosis stage. Thus, the failure of noninvasive methods to discriminate between different stages of intermediate fibrosis could be the consequence of classification errors from histopathological findings of biopsy[67,68]. For clinicians, it is more important to know if their patients have no/mild or advanced fibrosis/cirrhosis, rather than the exact pathological scoring system through LB, and this could be easily achieved by means of noninvasive methods. Taking into account that all recent international guidelines[97-99] recommend treatment with PI-based triple therapy in all patients with CHC genotype 1, provided that they have no contraindications to peg-interferon and ribavirin, the need to stage liver fibrosis accurately is decreasing in treatment decisions.

The final move - checkmate to LB - is, therefore, possible once the rate of SVR has reached 75% with PI-based triple therapy for patients with CHC genotype 1. Consequently, it is clear that in the era of PI-based triple therapy and other new potent direct-acting agents in the pipeline, the information obtainable from LB has little, if any, influence on treatment decisions. It should be underlined that in this article, checkmate to LB in patients with CHC refers strictly to cases with no need for this invasive and risky procedure in therapeutic decision making. With PI-based triple therapy already available in many countries, and an allocation system probably based mainly on medical need (therapy for those likely to develop complications in the next few years), noninvasive methods with the highest accuracy for detecting severe fibrosis/cirrhosis used as an alternative to LB for pretreatment assessment of liver fibrosis in patients with CHC are now part of routine clinical practice. Fibroscan or any patented biomarkers (Fibrotest, Fibrometer and Hepascore) have recently been recommended for first-line staging of liver fibrosis[101] before deciding on antiviral therapy. However, the adoption rates of noninvasive methods by hepatologists differ from country to country. In France, a survey of 546 hepatologists revealed that 81% of them used noninvasive methods[102], while in the United States, despite the aforementioned shortcomings of LB, there is still significant resistance to accepting noninvasive methods as an alternative to biopsy. We believe that sooner or later this will change, and the requirement of LB prior to starting antiviral therapy in patients with CHC will be reassessed.

In conclusion, in the era of PI-based triple therapy and other new potent direct-acting agents on the horizon that can achieve SVR rates approaching 100%, the time has come to move forward to risk-free noninvasive

methods for the patient, leaving LB behind in the evaluation of liver fibrosis in decision making for CHC antiviral therapy. In other words, checkmate to LB?
