Abstract

AIM: To compare the outcomes of concomitant cholangiocarcinoma (C-CCA) and subsequent cholangiocarcinoma (S-CCA) associated with hepatolithiasis.

METHODS: From December 1987 to December 2007, 276 patients underwent hepatic resection for hepatolithiasis in Changhua Christian Hospital. Sixty-five patients were excluded due to incomplete medical records and the remaining 211 patients constituted our study population base. Ten patients were diagnosed with C-CCA based on the preoperative biopsy or postoperative pathology. During the follow-up period, 12 patients developed S-CCA. The diagnosis of S-CCA was made by image-guided biopsy or by pathology if surgical intervention was carried out. Patient charts were reviewed to collect clinical information. Parameters such as CCA incidence, interval from operation to CCA diagnosis, interval from CCA diagnosis to disease-related death, follow-up time, and mortality rate were calculated for both the C-CCA and S-CCA groups. The outcomes of the C-CCA and S-CCA groups were mathematically compared and analysed.

RESULTS: Our study demonstrates the clinical implications and the survival outcomes of C-CCA and S-CCA. Among the patients with unilateral hepatolithiasis, the incidence rates of C-CCA and S-CCA were fairly similar (4.8% *vs* 4.5%, respectively, P = 0.906). However, for the patients with bilateral hepatolithiasis, the incidence rate of S-CCA (12.2%) was higher than that of C-CCA (4.7%), although the sample size was limited and the difference between two groups was not statistically significant (P = 0.211). The average follow-up time was 56 mo for the C-CCA group and 71 mo for the S-CCA group. Regard to the average time intervals from operation to CCA diagnosis, S-CCA was diagnosed after 67 mo from the initial hepatectomy. The average time intervals from the diagnoses of CCA to disease-related death was 41 mo for the C-CCA group and 4 mo for the S-CCA group, this difference approached statistical significance (P = 0.075). Regarding the rates of overall and disease-related mortality, the C-CCA group had significantly lower overall mortality (70% *vs* 100%, P = 0.041) and disease-related mortality (60% *vs* 100%, P = 0.015) than the S-CCA group. For the survival outcomes of two groups, the Kaplan-Meier curves corresponding to each group also demonstrated better survival outcomes for the C-CCA group (log rank P = 0.005). In the C-CCA group, three patients were still alive at the time of data analysis, all of them had free surgical margins and did not have pathologically proven lymph node metastasis at the time of the initial hepatectomy. In the S-CCA group, only one patient had chance to undergo a second hepatectomy, and all 12 S-CCA patients had died at the time of data analysis.

CONCLUSION: C-CCA has better outcomes than S-CCA.

The first hepatectomy is crucial because most patients with recurrent CCA or S-CCA are not eligible for repeated surgical intervention.

Comparison of concomitant and subsequent cholangiocarcinomas associated with hepatolithiasis: Clinical implications. *World J Gastroenterol* 2013; 19(3): 375-380 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/375.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.375

INTRODUCTION

Hepatolithiasis is the presence of stones in the intrahepatic duct (IHD) proximal to the confluence of the right and left main hepatic ducts. This disease is endemic in Southeast Asia and is also referred to as "IHD stones", "recurrent pyogenic cholangitis", "oriental cholangiohepatitis" and "Hong Kong disease" in the literature[1-3]. Since Sanes and MacCallum pointed out the possible association between hepatolithiasis and cholangiocarcinoma (CCA) in 1942, numerous studies have reported similar observations and formulated theories about CCA pathogenesis[4-7].

Currently, hepatic resection is frequently used for the definitive treatment of hepatolithiasis. Among patients who undergo hepatectomy for hepatolithiasis, approximately 5%-10% are incidentally found to have concomitant cholangiocarcinoma (C-CCA)[8-10]. On the other hand, subsequent cholangiocarcinoma (S-CCA) may appear mo to years after the initial hepatectomy. To the best of our knowledge, no previous study has reported on the clinical course and outcomes of S-CCA. During our daily practice, we observed that many patients with S-CCA progressed to death rather quickly. We wondered if patients with S-CCA really have worse outcomes than those with C-CCA. If this premise is true, it would be reasonable to treat hepatolithiasis more aggressively to minimize the deleterious consequences of S-CCA.

MATERIALS AND METHODS

Study design

From December 1987 to December 2007, a total of 276 patients underwent hepatic resection for hepatolithiasis in Changhua Christian Hospital. After excluding 65 patients with incomplete medical records, the remaining 211 patients constituted the base of our study. For each case, the diagnosis of hepatolithiasis was made by the means of image studies preoperatively (liver ultra-sonography, computed tomography, endoscopic retrograde cholangiopancreatography, or magnetic resonance cholangiopancreatography), which was then confirmed by postoperative pathologic examination. The C-CCA diagnosis was based on the preoperative biopsy or the postoperative pathologic examination. The S-CCA diagnosis was made by image-guided aspiration cytology, or by pathology if surgical intervention was carried out. By this assessment, 10 patients were diagnosed with C-CCA. During the follow-up period, 12 patients developed S-CCA (Figure 1).

Patient parameters evaluated

Patient charts were reviewed to collect clinical information. Parameters such as CCA incidence, interval from operation to CCA diagnosis, interval from CCA diagnosis to disease-related death, follow-up time, and mortality were calculated for both the C-CCA group and the S-CCA group. Finally, a mathematical comparison between the two groups was performed.

Statistical analysis

All data were recorded in a computerized database. Continuous variables are expressed as mean and range. A non-parametric test was used to examine the differences between the two groups. The Mann-Whitney *U* test was used for comparing continuous variables. Categorical variables were tested by the Person χ^2 test. Kaplan-Meier analysis with log rank test was used to compare survival between the two groups. *P* values less than 0.05 were considered statistically significant. The statistical analysis was performed with SPSS version 16.0 (Statistical Package for the Social Sciences; SPSS, Inc., Chicago, IL).

RESULTS

Patient clinical characteristics details are shown in Table 1. Among the patients with unilateral hepatolithiasis, the incidences of C-CCA and S-CCA were similar (4.8% *vs* 4.5%, respectively; $P = 0.906$). However, when we looked at bilateral hepatolithiasis, the C-CCA incidence (4.7%) was comparable with that for unilateral hepatolithiasis, but 12.2% of patients with bilateral hepatolithiasis developed S-CCA. However, the case number was too small to allow determination of a statistically significant difference ($P = 0.211$).

The average ages for the C-CCA group and the S-CCA group were 61 and 59 years old, respectively ($P = 0.742$). In both groups, the gender distribution were similar, and only approximately 10% of the patients were male ($P = 0.892$). After the patients were diagnosed with C-CCA, the average life span until disease-related death was 41 mo. On average, S-CCA is diagnosed after 67 mo from the initial hepatectomy. However, after the diagnosis is established, the average life span in these patients was only 4 mo. This difference between intervals from CCA to disease-related death approached statistical significance ($P = 0.075$).

The clinical outcomes of the C-CCA patients are summarized in Table 2. At the time of data analysis, 70% (7/10) of the C-CCA patients had died. Two of them

C-CCA: Concomitant cholangiocarcinoma; S-CCA: Subsequent cholangiocarcinoma; CCA: Cholangiocarcinoma.

(cases 89 and 142) had regional lymph node metastasis at the time of hepatectomy. Three C-CCA patients (cases 119, 212 and 217) had positive surgical margins reported by pathology. One patient (case 227) had a free surgical margin and negative regional lymph nodes; however, she suffered from CCA recurrence at the common bile duct 4 years following the initial hepatectomy. After excision of the common bile duct (free surgical margin), she lived for 5 more years. One patient (case 128) had a free surgical margin and negative regional lymph nodes. However, a hypopharyngeal tumor was diagnosed 3 mo after the initial hepatectomy, and the patient finally expired due to acute respiratory failure. After excluding this last patient, the disease-related mortality was only 60% (6/10). The three patients (cases 90, 253 and 143) who were still alive share some common characteristics. They all had free surgical margins and did not have pathologically-proven lymph node metastasis at the time of the initial hepatectomy. Patients 90 and 253 had been completely disease-free for 140 and 49 mo, respectively. Patient 143 was a victim of bilateral hepatolithiasis, and recurrent IHD stones were detected during the follow-up period. However, she refused treatment until recurrent CCA at the common bile duct was found 5 years following the initial hepatectomy. After excising the common bile duct (free surgical margin), she was disease-free for more than 43 mo. The C-CCA diagnosis was made pre-operatively in one patient (case 142), intra-operatively in four patients (cases 89, 128, 217 and 253), and post-operatively in five patients (cases 90, 119, 143, 212 and 227).

The clinical outcomes of S-CCA patients are summarized in Table 3. All 12 of the patients with S-CCA had died at the time of data analysis, resulting in a 100% overall, and disease-related, mortality. Among them, only one patient (case 11) had undergone a second hepatectomy. However, the surgical margin was positive for cancer and the patient expired 4 mo later.

Figure 2 shows the Kaplan-Meier curves corresponding to each group. The C-CCA group demonstrated clearly better survival outcomes than the S-CCA group ($P = 0.005$, log rank).

DISCUSSION

The S-CCA incidence in unilateral hepatolithiasis is 4.5%, which is comparable to that of C-CCA (4.8%). However, the S-CCA incidence in bilateral hepatolithiasis (12.2%) is more than double that of C-CCA incidence (4.7%). Our case number was too small for this difference to be reflected in statistical significance ($P = 0.211$). We believe, however, that this is quite possibly a true biological difference. This difference can be explained by recent studies that showed that hepatectomy for unilateral hepatolithiasis is associated with high stone clearance rates and low stone recurrence rates[8,11-13]. However, with bilateral hepatolithiasis, there are still very few reports in the literature discussing the best management and long-term outcomes[14]. According to a recent report and our unpublished data, treating bilateral hepatolithiasis with hepatic resection did

not show encouraging results as did resection in unilateral disease[15]. We speculate that hepatic resection seems to be less effective in stopping the disease progression toward S-CCA in patients with bilateral hepatolithiasis.

This study showed clearly that the C-CCA group had lower overall mortality (P = 0.041) and disease-related mortality (P = 0.015) than the S-CCA group. This better survival outcome is demonstrated by the Kaplan-Meier curves (Figure 2, P = 0.005, log rank). Considering that the complete removal of the malignancy with a free surgical margin is essential for achieving good survival outcomes[16-18], the role of the first hepatectomy is definitely crucial. Paradoxically, preoperative C-CCA diagnosis is sometimes difficult due to the presence of IHD stones[19-21]. Among our 10 C-CCA patients, only one patient was diagnosed pre-operatively. In order to solve this problem, making good use of intraoperatively-collected frozen sections is recommended. In the case of a strongly suspected C-CCA in the absence of conclusive tissue proof, carrying out the hepatectomy aggressively can increase the likelihood of creating a safe surgical margin.

For the five patients (cases 90, 119, 143, 212 and 227) whose C-CCA diagnoses were made incidentally by post-operative pathology, the survival outcomes were good if they had safe surgical margins (cases 90, 143 and 227). The lymph node status is also an important prognostic factor for these patients; however, these data were incomplete because regional lymph node dissection was not routinely performed on these patients.

All 12 S-CCA patients died shortly after definitive S-CCA diagnosis. A possible explanation is that most patients at the time of S-CCA diagnosis are not eligible for a second hepatectomy due to distant metastasis, locally advanced disease, peritoneal seeding, or insufficient remaining liver volume. Only one S-CCA patient in our series (case 11) had the opportunity to undergo a second hepatectomy. However, the tumor could not be removed completely, and the patient died 4 mo after the operation.

The interval from the initial hepatectomy to S-CCA development ranged from 7 to 138 mo (average 67 mo). After hepatic resection for hepatolithiasis, we observed that in patients who presented residual or recurrent IHD

stones, the S-CCA incidence (11.8%, 4/34) was higher than in S-CCA patients who had achieved complete stone clearance and disease-free status after hepatectomy (4.9%, 8/163). However, 67% of S-CCA patients (8/12) had neither residual nor recurrent IHD stones. We can presume that undiagnosed CCA might be left in the liver remnant, resulting in S-CCA, especially for patients who developed S-CCA relatively soon after the initial hepatectomy (e.g., cases 157, 159, 163 and 236). Interestingly, however, one patient (case 37) had neither residual nor recurrent IHD stones but ultimately developed S-CCA after a follow-up period of 138 mo. Beyond the presence of residual and recurrent IHD stones, we should also consider other predisposing factors for the development of S-CCA such as cancer-related genes, female gender, choledochoenterostomy, liver atrophy, smoking, family history, and viral hepatitis infection[22-26].

This retrospective study is the first published investigation that subdivided and compared hepatolithiasis-related cholangiocarcinoma in concomitant and subsequent groups. The study design included patients who underwent hepatic resection for hepatolithiasis during the past two decades (1987 to 2007) in Changhua Christian Hospital. Unexpectedly, incomplete information in 65 patient medical records was noticed during data collection, forcing us to exclude these patients. The majority of the excluded patients were treated in the first decade (1987 to 1997). However, all CCA patients in our study were operated on after 1997. We believe that these missing records should cause minimal effect on our results, although the data collected in our study were skewed towards the second decade (1997 to 2007). Another limitation of this study could be the relatively small number of enrolled CCA patients. However, considering that the C-CCA incidence is only 5%-10% in our patient population, the difficulty in obtaining very large patient numbers is appreciable.

We want to reemphasize the importance of a successful first hepatectomy, because most patients with recurrent CCA or that develop S-CCA are not candidates for repeated surgical intervention.

COMMENTS

Background

Hepatolithiasis is the presence of stones in the intrahepatic duct (IHD) proximal to the confluence of the right and left main hepatic ducts. This disease is endemic in Southeast Asia and is also referred to as "IHD stones", "recurrent pyogenic cholangitis", "oriental cholangiohepatitis" and "Hong Kong disease" in the literature.

Research frontiers

Concomitant cholangiocarcinoma (C-CCA) has better outcomes than subsequent cholangiocarcinoma (S-CCA). The first hepatectomy is crucial because most patients with recurrent CCA or S-CCA are not eligible for repeated surgical intervention.

Innovations and breakthroughs

Parameters such as cholangiocarcinoma (CCA) incidence, interval from operation to CCA diagnosis, interval from CCA diagnosis to disease-related death, follow-up time, and mortality rate were calculated for both the C-CCA and S-CCA groups. The outcomes of the C-CCA and S-CCA groups were mathematically compared and analysed.

Peer review

C-CCAs associated to hepatolithiasis is a crucial problem in hepatobiliary medicine. The authors can heal well unilateral hepatolithiasis today, but there are not effective methods in a treatment of bilateral hepatolithiasis. S-CCAs associated to hepatolithiasis is a larger problem than unilateral hepatolithiasis. The long-term outcomes are bed. The authors show the average life span only 4 mo. Literature's data are similar. The subject is very interesting, rarely discussed in the literature, and the period of observation and follow-up are commendable. Manuscript is well written. Data table are well-documented. Refferences is appropriately selected.

Abstract

AIM: To explore the effectiveness of acupuncture transcutaneous electrical nerve stimulation (Acu-TENS), a non-invasive modality in reduction of rectal discomfort during barostat-induced rectal distension.

METHODS: Forty healthy subjects were randomized to receive 45 min of either Acu-TENS or placebo-TENS (no electrical output) over acupuncture points *Hegu* (large-intestine 4), *Neiguan* (pericardium 6) and *Zusanli* (stomach 36). A balloon catheter attached to a dual-drive barostat machine was then inserted into the subjects' rectum. A step-wise (4 mmHg) increase in balloon pressure was induced until maximal tolerable or 48 mmHg. Visual analogue scale and a 5-point subjective discomfort scale (no perception, first perception of distension, urge to defecate, discomfort/pain and extreme pain) were used to assess rectal discomfort at each distension pressure. Blood beta-endorphin levels were measured before, immediately after intervention, at 24 mmHg and at maximal tolerable distension pressure.

RESULTS: There was no difference in the demographic data and baseline plasma beta-endorphin levels between the two groups. Perception threshold levels were higher in the Acu-TENS group when compared to the placebo group, but the difference reached statistical significance only at the sensations "urge to defecate" and "pain". The distension pressures recorded at the "urge to defecate" sensation for the Acu-TENS and placebo-TENS groups were 28.0 ± 4.5 mmHg and 24.6 ± 5.7 mmHg, respectively (P = 0.043); and the pressures recorded for the "pain" sensation for these two groups were 36.0 ± 4.2 mmHg and 30.5 ± 4.3 mmHg respectively (P = 0.002). Compared to the placebo group, a higher number of participants in the Acu-TENS group tolerated higher distension pressures (> 40 mmHg) (65% in Acu-TENS *vs* 25% in placebo, P = 0.02). The plasma beta-endorphin levels of the Acu-TENS group were significantly higher than that of the placebo group at barostat inflation pressure of 24 mmHg (1.31 ± 0.40 ng/mL *vs* 1.04 ± 0.43 ng/mL, P = 0.044) and at maximal inflation pressure (1.46 ± 0.53 ng/mL *vs* 0.95 ± 0.38 ng/mL, P = 0.003).

CONCLUSION: Acu-TENS reduced rectal discomfort during barostat-induced rectal distension and concurrently associated with a rise in beta-endorphin level.

Acupuncture transcutaneous electrical nerve stimulation reduces discomfort associated with barostat-induced rectal distension: A randomized-controlled study. *World J Gastroenterol* 2012; 19(3): 381-388 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/381.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.381

INTRODUCTION

Early colonoscopy screening is encouraged in prevention of development of colorectal cancer[1]. However, the procedure is often associated with abdominal pain and discomfort[2]. The unpleasant feeling during examination may affect the patient's overall tolerance and thereby jeopardizing the accuracy of outcome findings. A combination of narcotic analgesia and benzodiazepines is often used to decrease the discomfort during colonoscopy[3,4]. However these medications are also associated with gastrointestinal upset and although uncommon, respiratory and cardiac arrests during colonoscopy were reported[5,6]. Report of a European colorectal cancer screening project revealed that more than 50% of the subjects developed hypoxaemia and 6% had severe bradycardia after colonoscopy with sedation[7].

Electroacupuncture (EA) is widely accepted in China and is considered a possible treatment option for acute and chronic pain of various origins[8-10]. The role of acupuncture in managing pain and anxiety during colonoscopy however is unclear. A randomized sham-controlled study[11] suggested that patients receiving EA to acupoints *Zusanli* (stomach meridian ST-36) and *Hegu* (large intestine meridian LI-4) experienced lower pain level during colonoscopy than those receiving sham acupuncture (SA), but the difference was non-significant statistically. Recently we have shown that application of EA to *Hegu* (large-intestine 4), *Neiguan* (pericardium 6) and *Zusanli* (stomach 36) was able to effectively reduce rectal discomfort during Barostat-induced rectal distension[12]. Acupuncture however is invasive, and its application requires an experienced acupuncturist. Application of transcutaneous electrical nerve stimulation (TENS) over acupuncture points (Acu-TENS) is a non-invasive modality and a novel analgesic therapy that combines the advantages of acupuncture and TENS in management of painful conditions[13,14]. Acu-TENS has been shown to be effective in reducing postoperative analgesic requirement[14]. This pilot study aims to explore the potential of Acu-TENS in reduction of visceral pain. Prior to investigation of its role at the actual colonoscopy procedure, where the intraluminal pressures often varied in different subjects, it is necessary to first establish its role using a model which standardizes the intensity and duration of the stimulation. A dual drive barostat device was therefore used to mimic the discomfort caused by gaseous distension during colonoscopy, such model allows the nature of discomfort, distension pressure and duration of stimulation to be standardized.

MATERIALS AND METHODS

Subjects

Hong Kong Chinese subjects with age between 18 to 65 years registered for a screening colonoscopy examination (a free health care service provided by the Hong Kong Hospital Authority for all local permanent residents with family history of colorectal cancer) were invited to participate in the study prior to the actual colonoscopy screening procedure. Exclusion criteria included known cardiovascular dysfunction (American Society of Anaesthesiologists grade Ⅲ or above), irritable bowel syndrome (Rome Ⅱ classification[15]), renal impairment, previous abdominal surgery or experience of colonoscopy, gastrointestinal complaints, pregnancy or allergy to acupuncture needles. Subjects who met the inclusion criteria were randomized to either the Acu-TENS or placebo Acu-TENS (PA) group. The respective intervention code was generated randomly by a computer program (Random Allocation Software, Version 1.0, Isfahan University of Medical Sciences, Iran). The group allocation numbers were then placed in sealed opaque envelopes. An envelope was drawn and allocated to each subject by a secretary blinded to the groupings. The envelope was opened by the investigator who then applied the identified intervention accordingly. The subjects, surgeons and all other parties, including an independent outcome assessor, were blinded to the implementation of Acu-TENS or PA.

Bowel preparation

All subjects were instructed to have low fiber diet three days prior to the study. On the day before examination, all subjects underwent standard mechanical bowel preparation with 4 liters of polyethylene glycol (Klean-Prep, Norgine Ltd., Middlesex, United Kingdom) to induce bowel movement and to clear the bowel in preparation for the colonoscopy procedure. Participants were asked to empty their bowel at home before coming to the hospital for examination.

Equipment

A dual-lumen polyethylene catheter (Model CR3-0005, Mui Scientific, Mississauga, Ontario, Canada) was attached to a 10 cm long and 600 mL capacity polyethylene bag (Model CT-BP600R, Mui Scientific) using a sterile surgical silk suture (Ethicon, Mersilk Soie, Somerville, New Jersey, United States), with the surgical knots sealed by latex glue. One lumen of the catheter allowed passage of compressed air for bag inflation and the other was attached to a transducer for monitoring of the pressure inside the bag. The catheter was attached to the dual drive barostat (Distender Series Ⅱ; G and J Electronics, Inc., Toronto, Canada) which controlled the rate of inflation and deflation of the bag electronically. To ensure

the bag attachment was airtight, the bag was inflated to 60 mmHg for 5 min and placed in sterile warm water to ensure there was no leakage of air from the system.

Intervention protocols

Acupuncture points *Hegu* (large-intestine 4), *Neiguan* (pericardium 6) and *Zusanli* (stomach 36) were first identified by the investigator before the procedure. LI 4 is located on the dorsum of the hand, between the 1st and 2nd metacarpal bones; Pericardium 6 is located on the palmar aspect of the forearm, 2 "cuns" above the transverse crease of the wrist between the flexor carpi radialis and palmaris longus tendons; ST 36 is located on the anterior aspect of the leg, at 3 cuns below the knee cap and one finger-breadth from the anterior crest of the tibia. One "cun" is the distance between the interphalangeal creases of the subject's middle finger[16]. These points were chosen because large-intestine 4 and pericardium 6 are reportedly used to reduce abdominal pain[17,18] and ST36 was shown to regulate colorectal muscle contractility in conscious rats[19,20]. All of the selected acupuncture points were swabbed with alcohol following a standard antiseptic process before the TENS electrodes were applied. Six gel pads were cut into size of 5 mm × 5 mm and placed over the subject's acupuncture points (bilaterally). Each cleaned rubber electrode was placed over the small gel pad (HD-001, ITO Company Limited, Tokyo, Japan), this allowed electrical stimulation to be focused mainly over the acupuncture points. The electrodes were then attached to a dual channel TENS machine (Model 120Z, ITO Company Limited, Tokyo, Japan). Subjects in the Acu-TENS group received a constant mode of electrical stimulation at 2 Hz and pulse width at 200 μs for 45 min. Intensity was set to just initiate muscle contraction. This stimulation protocol has been shown to be effective in inducing endorphin production[21,22]. Electrode placements were similar for subjects in the PA group, except that the electrical output from the TENS unit was disconnected. The output light however remained active and subjects were told that they may or may not feel the current.

Experimental procedures

All subjects arrived at the laboratory at 9 am on the assessment day. They were instructed to rest in the supine position for 15 min and randomized to receive 45 min of either Acu-TENS or PA in the supine position. The subject then adopted a left side-lying position with both knees flexed to 90º. The polyethylene bag which attached to the barostat was slowly inserted into subject's rectum to a distance 10 cm from the anal verge. The tube was taped to the buttock with micropores and the subject then resumed the supine position. After rested in this position for 15 min the bag was inflated for 60 s and then completely deflated in 60 s, a resting period of 1 minute then followed, this constituted one complete cycle of inflation. An incremental stepwise increase in rectal pressure at 4 mmHg was instilled at subsequent cycles until a pressure of 48 mmHg or when the subject could not tolerate further discomfort. Acu-TENS or PA continued during the whole barostat procedure. When the maximal 48 mmHg or an intolerable pressure was reached, the stimulation was discontinued and all electrodes and gel pads removed.

Outcome measures

Subjective discomfort scale: During each 60-s phase of sustained incremental pressure, the subject was asked to rate their rectal sensation using an electronic panel attached to a computer. Ratings were "no perception", "first perception of distension", "urge to defecate", "discomfort or pain" and "extreme pain". Concurrently, each subject was also asked to rate the degree of rectal discomfort using a visual analogue scale (VAS)-a 10 cm ungraduated line, with words "no discomfort at all" anchored to "0" end and "discomfort cannot be tolerated" anchored to the number "10". The VAS and subjective discomfort scales were recorded by an independent research assistant who was blinded to the intervention allocation.

Beta-endorphin measurement: Venous blood (3 mL) was drawn (from a cannula inserted into the cubital vein of each subject under aseptic technique) before the randomization process, immediately after the 45 min intervention, at a distension pressure of 24 mmHg and at highest tolerable pressure. The blood samples were transferred to the biochemistry laboratory of the involved hospital in EDTA tubes stored in a 4 ºC ice box. The blood sample was then centrifuged and frozen until further assayed. Batch analyzed for beta-endorphin (Human) were analyzed using EIA kit (Phoenix Pharmaceuticals Inc, 330 Beach Road, Burlingame, CA94010, United States). All subjects then undertook the colonoscopy screening procedure in the same afternoon following the barostat study.

Sample size estimation

Sample size estimation was based on the assumption that Acu-TENS could increase the mean pain threshold by 8 mmHg (this was based on our previous work which explored the effect of acupuncture in relief of discomfort induced by the barostat[12]. To yield a power of 80% with a significant level of 0.05, a sample size of at least 17 subjects in each group was required (sample size estimation was determined by SPSS Version 15.0 for Windows, SPSS Inc., Chicago, IL, United States).

Ethical approval

This study was conducted at a local district hospital from September 2009 to May 2010. The protocol was approved by the Ethics Review Committees of the involved hospital and ClinicalTrials.gov prior to data collection (Approval numbers: NCT01551654 and CRE-2008.546-T). Written informed consent was obtained from each subject prior to commencement of the study.

Table 1 Demographic data of subjects in the transcutaneous electrical nerve stimulation over acupuncture points and placebo transcutaneous electrical nerve stimulation over acupuncture points groups (mean ± SD)

Item	Acu-TENS group (n = 20)	PA group (n = 20)	P value
Age (yr)	53.4 ± 3.8	53.9 ± 3.5	0.669
Gender (male/female)	8/12	8/12	1.000
Body weight (kg)	63.9 ± 14.4	63.0 ± 9.35	0.825
Body height (m)	1.62 ± 0.07	1.61 ± 0.07	0.692
BMI(kg/m^2)	23.9 ± 3.61	24.0 ± 2.53	0.899

Acu-TENS: Transcutaneous electrical nerve stimulation over acupuncture points; PA: Placebo transcutaneous electrical nerve stimulation over acupuncture points; BMI: Body mass index.

Table 2 Number of subjects in the transcutaneous electrical nerve stimulation over acupuncture points and placebo transcutaneous electrical nerve stimulation over acupuncture points groups identified with colonic polyps during the colonoscopy screening procedure

Location of polyps	Acu-TENS group (n = 20)	PA group (n = 20)
Right side (caecum, ascending colon, hepatic flexure, transverse colon)	4	3
Left side (splenic flexure, descending colon, sigmoid)	1	1
Rectosigmoid junction	0	0
Rectum	0	0
No abnormality	15	16

Acu-TENS: Transcutaneous electrical nerve stimulation over acupuncture points; PA: Placebo transcutaneous electrical nerve stimulation over acupuncture points.

Statistical analysis

All data were analyzed using the Statistical Package for the Social Sciences (SPSS Version 15.0 for Windows, SPSS Inc., Chicago, IL, United States). Repeated measures ANOVA were used to determine the change in sensation at different bag inflation pressures. Between-group sensation at each pressure was compared using independent sample t test for parametric data, and Pearson χ^2 test or Mann-Whitney U test for nonparametric data. A statistical significant level was set at $P < 0.05$.

RESULTS

A total of 40 healthy subjects (16 male, 24 female; mean age 53.7 ± 3.62 years) were recruited to the study with 20 subjects randomized to either the Acu-TENS or PA group (Figure 1). The demographic data of all subjects were similar between the two groups (Table 1). All subjects completed the procedure and no adverse effects were observed during the intervention. Results of the colonoscopy screening procedure for this subject cohort are displayed in Table 2. While colonic polyps were found in some subjects, none were identified with rectal polyps or lesions. The pressures at which the subjects reported "urge to defecate" and "discomfort or pain" sensations were significantly higher in the Acu-TENS group compared to the PA group (Table 3). Furthermore, there were more subjects in the Acu-TENS group who tolerated a higher rectal distension pressures (at 40 mmHg, 44 mmHg and 48 mmHg) ($P < 0.05$) (Table 3). At each recorded pressure, the VAS score reported by the Acu-TENS group was lower (Figure 2A) although the differences did not reach a statistical significant level. The mean maximal tolerable pressure recorded during Acu-TENS (45.6 ± 5.09 mmHg) was higher than that during PA (39.8 ± 7.62 mmHg) ($P = 0.007$). The beta-endorphin level raised after 45 min Acu-TENS and continued to rise with increased inflation pressure (Table 3). Changes in beta-endorphin level in the PA group were not apparent. At 24 mmHg and maximal tolerable pressure, the beta-endorphin levels measured were significantly higher in the Acu-TENS when compared with the PA group (Figure 2B and Table 3).

Table 3 Perception threshold, distension pressures, levels of blood beta-endorphin in transcutaneous electrical nerve stimulation over acupuncture points and placebo transcutaneous electrical nerve stimulation over acupuncture points groups (mean ± SD)

	Acu-TENS	PA	P value
Perception threshold (mmHg)			
First perception of distension	18.4 ± 4.2	16.8 ± 6.4	0.358
Urge to defecate	28.0 ± 4.5	24.6 ± 5.7	0.043
Discomfort or pain	36.0 ± 4.2	30.5 ± 4.3	0.002
Extreme pain	40.0 ± 6.7	35.4 ± 5.6	0.179
Pressure (n = 20)			
40 mmHg	17 (85)	10 (50)	0.020
44 mmHg	13 (65)	3 (15)	0.001
48 mmHg	11 (55)	2 (10)	0.022
Levels of blood beta-endorphin (ng/mL)			
Baseline	1.04 ± 0.35	1.22 ± 0.52	0.216
After 45 min of intervention	1.14 ± 0.41	1.13 ± 0.48	0.980
At 24 mmHg pressure	1.31 ± 0.40	1.04 ± 0.43	0.044
At maximal tolerable pressure or 48 mmHg	1.46 ± 0.53	0.95 ± 0.38	0.003

Acu-TENS: Transcutaneous electrical nerve stimulation over acupuncture points; PA: Placebo transcutaneous electrical nerve stimulation over acupuncture points.

DISCUSSION

To the best of the authors' knowledge, this is the first report on the effect of Acu-TENS in reduction of rectal discomfort in human subjects. This study demonstrated Acu-TENS to large-intestine 4, pericardium 6 and stomach 36 reduced discomfort associated with rectal distension induced by a barostat. TENS is a non-invasive physical therapeutic modality commonly used for pain relief in conditions such as osteoarthritis and low back pain[23]. Although widely used in clinical situations, the working mechanism of TENS remains unclear. The pain-gate hypothesis proposed by Melzack and Wall[24] is considered a possible mechanism of control of stimulation

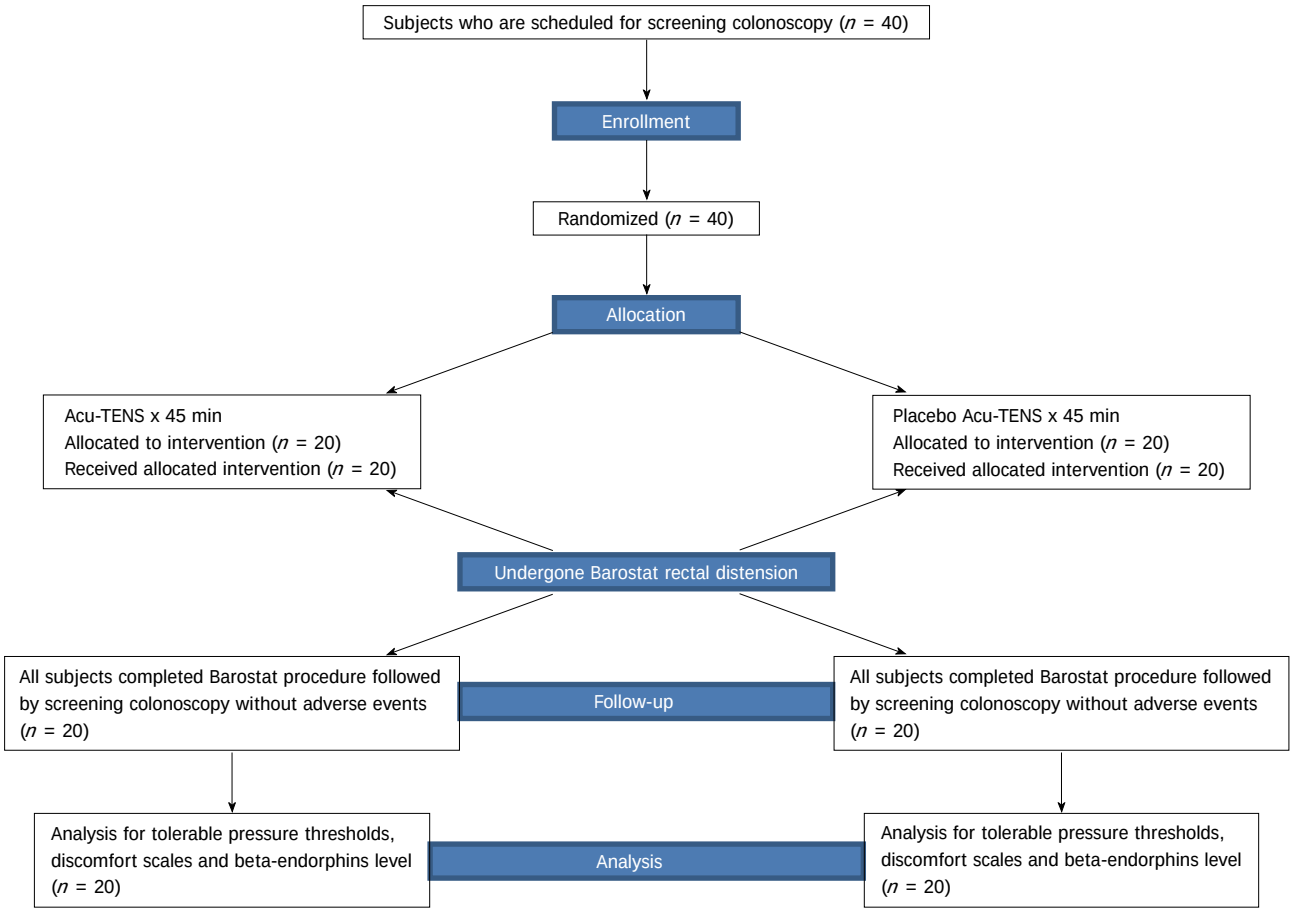

Figure 1 Flow diagram of the study. Acu-TENS: Transcutaneous electrical nerve stimulation over acupuncture points.

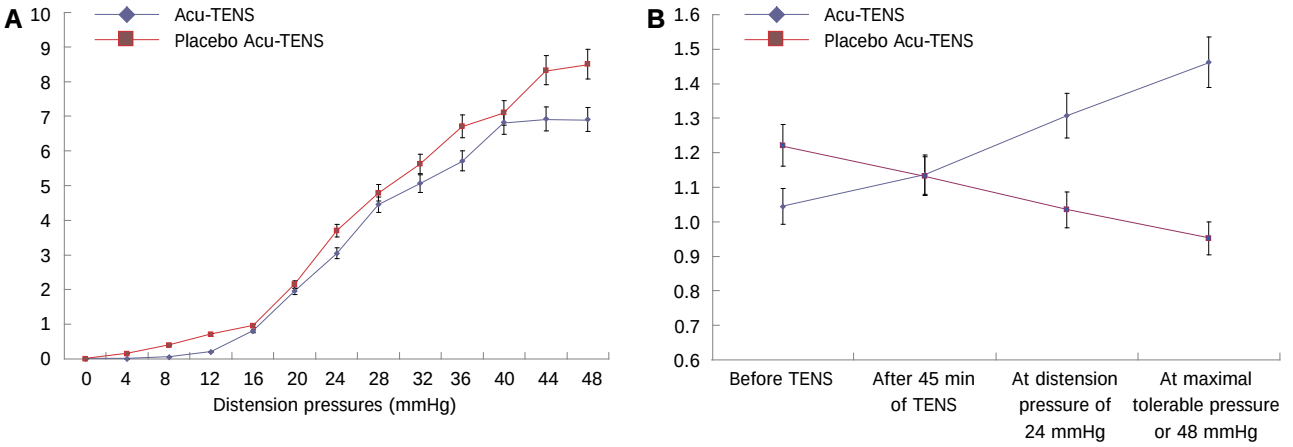

Figure 2 Visual analog discomfort score recorded at different distension pressures (A) and mean beta-endorphin levels recorded at different time-points (B). Acu-TENS: Transcutaneous electrical nerve stimulation over acupuncture points.

pathways during TENS. It was also believed that TENS inhibits pain signals via the descending pathway[25,26], the dorsal horn cell, and the spinothalamic tract[27]. Another prevalent theory discussed in literature is the release of endogenous opioids such as beta-endorphins, enkephalins and dynorphin after TENS[28-30]. Acu-TENS was previously shown to increase beta-endorphin levels in subjects with chronic respiratory disease[31]; finding of this current study further confirms that application of 45 min Acu-TENS induced the release of beta-endorphins in subjects with rectal discomfort. Our Acu-TENS protocol adopts a low stimulation frequency at 2 Hz. It was believed that low frequency TENS was able to trigger μ-and delta opioid receptors, the correspondents of beta-endorphin[29,31]. On the other hand, high frequency (100 Hz) stimulation was believed to trigger κ-opioid receptor and results in the release of dynorphin[29,31]. Irrespective of the working mechanisms, this study has shown that Acu-TENS

appears to be able to reduce the rectal distension pain induced by the barostat model and concurrently associated with an increase in beta-endorphin level. It was hypothesized that beta-endorphin possibly suppresses the action potential of neurons during neural transmission through the release of excess sodium molecules, consequently leading to inhibition of transmission of pain signals[32]. This is the first study which reports the effect of Acu-TENS on visceral pain in humans. We have previously demonstrated that acupuncture was an effective modality in reducing rectal discomfort associated with barostat induced rectal distension[12]. This study has shown that similar effect can be achieved non-invasively using Acu-TENS. The main difference in findings between our previous acupuncture study and this current one is that while the level of beta-endorphin increased immediately after 45 min of Acu-TENS, the increase reached a statistical significant level at 90 min after stimulation. However, in our previous study, the difference in change of beta-endorphin level between acupuncture and placebo acuptuncture was significant at immediately after 45 min of acupuncture stimulation. This probably is associated with the fact that one of the acupoints adopted in our studies, ST36, is situated in a much deeper anatomical position[33] and because Acu-TENS works in a "transcutaneous" manner, more time is therefore required for Acu-TENS to achieve the expected effect. Interestingly the level of beta-endorphin remained high for a longer period of time after Acu-TENS when compared with acupuncture stimulation. Acupuncture points large-intestine 4, pericardium 6 and stomach 36 were selected in this study because stimulation of *Hegu* (large-intestine 4) was associated with excitation of sensory nerve fibers in the pelvic complex and induced regulation of pelvic floor muscle contraction[34]. Stimulation of large-intestine 4 was also shown to be effective in management of labor pain and plantar fasciitis[34,35]. Stimulation of *Neiguan* (pericardium 6) and *Zusanli* (stomach 36) were reported to have significant clinical results in management of gastrointestinal symptoms[36,37]. Apart from being a non-invasive modality, another advantage of employing Acu-TENS over acupuncture is the low costing involved in Acu-TENS. The TENS machine is inexpensive, the Acu-TENS procedure is simple and experienced acupuncturists are not required for its application. Furthermore, apart from allergy to the gel used in a very minority of subjects, no side effects were reported with the use of Acu-TENS.

This study showed that while a higher distention pressure was tolerated during Acu-TENS, the difference at the VAS scores at any pressure level however did not reach a statistical difference. This could possibly be a consequence of both the slow release of endorphin during Acu-TENS, as well as the small sample size of this study. However convincing subjects who signed up for colonoscopy screening to pay an extra visit to the theatre for experimental recording of discomfort induced by a barostat machine was deemed demanding by many subjects. Another limitation of this study is that only Acu-TENS and placebo groups were included in the study, the strength of the placebo effect cannot be accurately evaluated without inclusion of a control group of no intervention. Inclusion of a control group however requires increasing the sample size, and as previously explained, this was difficult to comply. This study used the barostat model to mimic rectal discomfort. Previous reports on the use of the barostat model were mainly on patients with irritable bowel syndrome[38]. The barostat-induced rectal discomfort cannot accurately reproduce the same painful sensation as the stretching of mesenteric tissues during actual colonoscopy procedure. However, gaseous distension during colonoscopy also creates visceral pain and discomfort[39]. Our previous experience suggests that using the barostat model to mimic sensation of gaseous distension during colonoscopy appears to be a good model for evaluation of pain and distension discomfort under a standardized, controllable environment.

In conclusion, this study showed that 45 min of Acu-TENS over large-intestine 4, pericardium 6 and stomach 36, compared to placebo Acu-TENS, appeared to reduce the level of rectal discomfort induced by barostat distension and allowed the subjects to withstand a higher distension pressure. Subjective toleration of a higher inflation pressure was shown to be accompanied with a significant increase in beta-endorphin level. The role of Acu-TENS in application during clinical colonoscopy warrants further investigation.

COMMENTS

Background

Colonoscopy procedure is often associated with abdominal pain and discomfort. Application of transcutaneous electrical nerve stimulation over acupoints (Acu-TENS) is a non-invasive treatment modality for management of musculoskeletal pain, but its role for pain relief in endoscopic procedure has not been investigated.

Research frontiers

TENS has extensively been used as a physical modality for pain relief for musculoskeletal condition, however, the mechanism of action remains unclear. Beta-endorphin is a natural painkiller and largely found in the hypothalamus and pituitary gland. In this study, employing the barostat, an electronic device as an experimental pain model to standardize and mimic visceral pain caused by gaseous distension, the authors demonstrated that application of Acu-TENS is associated with the release of beta-endorphin effecting pain relief.

Innovations and breakthroughs

Endoscopic procedure is often associated with abdominal pain and discomfort, especially when there is increased gaseous distension. The unpleasant feeling during examination may affect the patient's overall tolerance and thereby jeopardizing the accuracy of outcome findings. Electroacupuncture is considered worldwide as a possible treatment option for acute and chronic pain of various origins, however, acupuncture is invasive and require an experienced acupuncturist. Acu-TENS, on the other hand, is a novel non-invasive modality that combines the advantage of TENS and acupuncture in the management of acute painful conditions.

Applications

Findings of this study suggest that Acu-TENS is potentially a therapeutic, non-invasive physical modality that could reduce rectal discomfort during an endoscopic procedure. The role of Acu-TENS during clinical colonoscopy warrants further investigation.

Terminology

Acu-TENS is the application of transcutaneous electrical nerve stimulation over acupuncture points. Visceral pain is an unpleasant sensation as a result of activation of nociceptors of the abdominal organs. Such type of pain is associated

with distension of the visceral tissue and often described as diffuse and difficult to localize. The electronic barostat served as an experimental pain model in this study to standardize and mimic visceral pain caused by gaseous distension.

Peer review

This is an interesting and well-designed study showing that Acu-TENS, a non-invasive analgesic therapy, reduced rectal discomfort during barostat-induced distensions. Moreover, reduction of pain was accompanied with a significant increase in beta-endorphin level, implying a key-role of endorphins in the mechanism of TENS.

Abstract

AIM: To identify the predictors of distant metastasis in pathologically T1 (pT1) colorectal cancer (CRC) after radical resection.

METHODS: Variables including age, gender, preoperative carcinoembryonic antibody (CEA) level, tumor location, tumor size, lymph node status, and histological grade were recorded. Patients with and without metastasis were compared with regard to age, gender, CEA level and pathologic tumor characteristics using the independent *t* test or χ^2 test, as appropriate. Risk factors were determined by logistic regression analysis.

RESULTS: Metastasis occurred in 6 (3.8%) of the 159 patients during a median follow-up of 67.0 (46.5%) mo. The rates of distant metastasis in patients with pT1 cancer of the colon and rectum were 6.7% and 2.9%, respectively ($P < 0.001$). The rates of distant metastasis between male and female patients with T1 CRC were 6.25% and 1.27%, respectively ($P < 0.001$). The most frequent site of distant metastasis was the liver. Age ($P = 0.522$), gender ($P = 0.980$), tumor location ($P = 0.330$), tumor size ($P = 0.786$), histological grade ($P = 0.509$), and high serum CEA level ($P = 0.262$) were not prognostic factors for lymph node metastasis. Univariate analysis revealed that age ($P = 0.231$), gender ($P = 0.137$), tumor location ($P = 0.386$), and tumor size ($P = 0.514$) were not risk factors for distant metastasis after radical resection for T1 colorectal cancer. Postoperative metastasis was only significantly correlated with high preoperative serum CEA level ($P = 0.001$). Using multivariate logistic regression analysis, high preoperative serum CEA level ($P = 0.004$; odds ratio 15.341; 95%CI 2.371-99.275) was an independent predictor for postoperative distant metastasis.

CONCLUSION: The preoperative increased serum CEA level is a predictive risk factor for distant metastasis in CRC patients after radical resection. Adjuvant chemotherapy may be necessary in such patients, even if they have pT1 colorectal cancer.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common ma-

lignancies and a leading cause of cancer-related deaths in Europe and the United States[1-3]. Similarly, it is the fifth leading cause of cancer deaths in China and the incidence of CRC is rapidly increasing[4,5].

The standard surgical treatment for CRC is radical resection. Recent advances in diagnostic methods have led to an increase in the detection of T1 CRC[6,7]. Local excision has been substituted for radical resection in some patients with early CRC. However, local excision may result in a higher rate of local recurrence than radical resection in patients with T1 CRC. Local excision leaves metastatic lymph nodes in 8%-15% of pathologically T1 (pT1) CRC patients without definitively retrieving regional lymph nodes[8], resulting in a recurrence rate of 4.1%-39%[9]. However, the recurrence rate has been reported to be 1.3%-2.8% after radical resection of early CRC[6,10]. To minimize recurrence, radical surgery has been performed in China for the treatment of most patients with pT1 CRC.

Previous studies have focused on evaluating the risk factors for lymph node metastasis[10-13], and there is little evidence with regard to the risk factors for postoperative distant metastasis in patients with pT1 CRC. The aim of the present study was to identify the predictive risk factors that may suggest postoperative distant metastasis in patients with pT1 CRC after radical resection.

MATERIALS AND METHODS

One hundred fifty-nine patients with pT1 CRC who had undergone radical resection with lymph node dissection between January 2005 and June 2011 were enrolled. All patients were followed up until December 2011. The study was performed after approval by the Ethics Committee at the Second Military Medical University in Shanghai, China. None of these patients had received preoperative radiotherapy or neoadjuvant chemotherapy. Patients with pT1 CRC who were treated by endoscopic mucosal resection or transanal resection were excluded. Other exclusion criteria were recurrent CRC or cancer associated with familial adenomatous polyposis and inflammatory bowel disease.

Preoperative investigations included colonoscopy, chest X-rays, ultrasonography, computed tomography (CT) of the liver, and blood tests for carcinoembryonic antigen (CEA). A 3-mL peripheral blood sample from each patient was obtained. Serum CEA levels were determined using an enzyme immunoassay test kit (Beckman Coulter, Inc., Fullerton, CA, United States) with the upper limit of 5 ng/mL being defined as normal according to the kit manufacturer.

We established a 5- to 10-year follow-up period which included serum CEA measurements every 3 mo for the first 2 years and every 6 mo for the next 3 years, hepatic imaging (ultrasonography or CT) and chest X-rays every 3 mo, pelvic CT for rectal cancer every 6 mo, and colonoscopy every year.

Continuous variables were presented as means (standard deviation) and dichotomous variables were presented as number and percentage values. Patients with and without metastasis were compared with regard to age, gender, and clinicopathologic characteristics using the independent *t* test or χ^2 test, as appropriate. Logistic regression analysis was used to identify risk factors for distant metastasis. Variables significant at $P < 0.10$ by univariate analysis were subjected to stepwise logistic regression analysis to identify independent risk factors ($P < 0.05$) for distant metastasis. All analysis were performed with SPSS version 17 statistical software package (SPSS, Inc., Chicago, IL, United States).

RESULTS

Demographic data of the 159 patients with pT1 CRC are shown in Table 1. Distant metastasis occurred in 6 (3.8%) of the 159 patients during a median follow-up of 67.0 (46.5%) mo. The rates of distant metastasis in patients with pT1 cancer of the colon and rectum were 6.7% and 2.9%, respectively ($P < 0.001$). The recurrence rates among male and female patients with pT1 CRC were 6.25% and 1.27%, respectively ($P < 0.001$). The most frequent site of metastasis was the liver in pT1 CRC. Preoperative serum CEA level was higher in patients with distant metastasis than in patients without distant metastasis (11.35 ng/mL *vs* 3.25 ng/mL). Comparisons of patients with and without distant metastasis are shown in Table 1. The distant metastasis negative and positive groups were similar with regard to patient demographics and clinicopathologic features.

Based on univariate analysis of the correlation between lymph node metastasis (LNM) and clinicopathologic features, we found that age ($P = 0.522$), gender ($P = 0.980$), tumor location ($P = 0.330$), tumor size ($P = 0.786$), histological grade ($P = 0.509$), and high serum CEA level ($P = 0.262$) were not predictive factors for LNM (Table 2).

Univariate analysis revealed that age ($P = 0.231$), gender ($P = 0.137$), tumor location ($P = 0.386$), and tumor size ($P = 0.514$) were not risk factors for distant metastasis after radical resection for pT1 CRC (Table 2). The patients with unfavorable histological grade [odds ratio (OR) 1.365] were more likely to have metastasis, although the difference did not reach statistical significance ($P = 0.086$). Postoperative metastasis was only significantly correlated with a high serum CEA level ($P = 0.001$, Table 2). Using multivariate logistic regression analysis, high serum CEA level (OR 15.341, 95%CI 2.371-99.275, $P = 0.004$) was an independent predictor for postoperative distant metastasis.

Details of patients with distant metastasis are shown in Table 3. All distant metastases were found less than 3 years after surgery. Two of the six patients died due to the metastases, and the remaining patients are still alive after hepatic resection.

Table 1 Characteristics of 159 patients *n* (%)

Characteristics	With T1 colorectal cancer	Without metastasis (*n* = 153)	With metastasis (*n* = 6)	*P* value

CEA: Carcinoembryonic antibody; LNM: Lymph node metastasis.

DISCUSSION

Patients with pT1 CRC have a favorable prognosis, however, some patients develop recurrence including local recurrence and distant metastasis after radical resection[14,15]. Total recurrence rates have been reported to be as low as 0%-4% and as high as 17%-31% in T1 CRC[16]. The rate of distant metastasis in the present study was 3.8% which was consistent with a previous report.

Various factors such as serum CEA level, histological grade, and LNM for distant metastasis in CRC have been identified in previous reports[17-20], but most of these reports included pT2-T4 patients, and there is a paucity of evidence on the risk factors for distant metastasis in pT1 CRC[21-25]. Following univariate analysis of our data, we found that preoperative serum CEA level (OR 18.400, 95%CI 3.106-109.006, $P = 0.001$) and histological grade (OR 1.365, 95%CI 0.957-1.945, $P = 0.086$) were risk factors for predicting postoperative distant metastasis in patients with pT1 CRC.

Previous studies have reported that the LNM rate is up to 21% for T1-T2 CRC[21,22]. LNM is considered a risk factor for distant metastasis after radical resection for CRC[22]. It is noteworthy that LNM did not reach statistical significance in our series, with a higher OR in univariate analysis (OR 2.154, 95%CI 0.234-19.850, $P = 0.498$). Although our results did not show the same conclusion as previous reports, it is difficult to confidently exclude a correlation between LNM and distant metastasis in T1 CRC, because most patients (5/6, 83.3%) had less than 12 lymph nodes investigated (mean 6.2 lymph nodes).

CEA has been proved to be important in the assessment of prognosis of advanced CRC. Koca *et al*[11] conducted a study on 221 individuals, comprised of 69 (31.2%) patients with clinical stage Ⅱ and 152 (68.8%) with clinical stage Ⅲ, to evaluate potential predictors of recurrence and survival. They found that high serum CEA level was one of the risk factors for recurrence. Kim *et al*[26] also found that elevation of serum CEA was an independent factor for pulmonary metastasis after curative resection in 105 patients with CRC. In multivariate analysis of our data, we found that preoperative serum CEA level was an independent risk factor (OR 15.341, 95%CI 2.371-99.275, $P = 0.004$) in the prediction of postoperative distant metastasis in patients with pT1 CRC. Adjuvant chemotherapy might be necessary for such patients. Regular surveillance after radical resection in CRC patients should be performed, even if they have pT1 CRC, especially in patients with an increased serum CEA level. To our knowledge, this is the first study demonstrating a predictive role for serum CEA level in distant metastasis after radical resection in patients with pT1 CRC.

Interestingly, in our study, with a median follow-up period of 67.0 mo, the rates of distant metastasis in patients with T1 cancer of the colon and rectum were 6.7% and 2.9%, respectively ($P < 0.001$). The rates of distant metastasis in male and female patients with T1 CRC were 6.25% and 1.27%, respectively ($P < 0.001$). It is necessary to accumulate evidence in further studies to confirm these differences, because there is a limit to the number of cases seen in a single institution.

On the basis of our study of 159 consecutive patients with pT1 CRC, we propose that the increased preoperative serum CEA level is the independent risk factor for distant metastasis after radical resection. Adjuvant chemotherapy and regular surveillance after radical resection

Table 3 Details of distant metastasis patients

No.	Age (yr)	Gender	Location	CEA (ng/mL)	Histological grade	LNM	DFS	Recurrent site	Prognosis

for such patients should be performed.

COMMENTS

Background

Colorectal cancer (CRC) is one of the most common malignancies and a leading cause of cancer-related deaths. Previous studies have focused on evaluating the risk factors for lymph node metastasis, and there is little evidence with regard to the risk factors for postoperative distant metastasis in patients with pathologically T1 (pT1) CRC.

Research frontiers

Patients with pT1 CRC have a favorable prognosis, but some patients develop recurrence including local recurrence and distant metastasis after radical resection. In this study, the authors demonstrate that the preoperative carcinoembryonic antibody (CEA) level could be predictive of distant metastasis in pT1 CRC after radical surgery.

Innovations and breakthroughs

The authors described the relationship between preoperative CEA levels and distant metastasis in pT1 CRC after surgery. This is the first study to demonstrate a predictive role for serum CEA level in distant metastasis after radical resection in patients with pT1 CRC.

Applications

Preoperative CEA level could be predictive of distant metastasis in pT1 CRC patients after radical surgery. This study suggests that adjuvant chemotherapy might be necessary for such patients.

Terminology

Preoperative serum CEA level is a risk factor in the prediction of postoperative distant metastasis in patients with pT1 CRC.

Peer review

The authors present an interesting study on risk factors for the occurrence of distant metastasis in early pT1 colorectal carcinomas. The manuscript is well structured and the cited literature is comprehensive and up-to-date. This is a clinically very interesting topic. Their results are very valuable.

Abstract

AIM: To compare the clinical outcome of single-incision laparoscopic cholecystectomy (SILC) with three-port laparoscopic cholecystectomy (TPLC).

METHODS: Between 2009 and 2011, one hundred and two patients with symptomatic benign gallbladder diseases were randomized to SILC (n = 49) or TPLC (n = 53). The primary end point was post operative pain score (at 6 h and 7 d). Secondary end points were blood loss, operation duration, overall complications, postoperative analgesic requirements, length of hospital stay, cosmetic result and total cost. Surgical techniques were standardized and all operations were performed by one experienced surgeon, who had performed more than 500 laparoscopic cholecystectomies.

RESULTS: One patient in the SILC group required conversion to two-port LC. There were no open conversions or major complications in either treatment groups. There were no differences in terms of estimated blood loss (mean ± SD, 14 ± 6.0 mL *vs* 15 ± 4.0 mL), operation duration (mean ± SD, 41.8 ± 17.0 min *vs* 38.5 ± 22.0 min), port-site complications (contusion at incision: 5 cases *vs* 4 cases and hematoma at incision: 2 cases *vs* 1 case), total cost (mean ± SD, 12 075 ± 1047 RMB *vs* 11 982 ± 1153 RMB) and hospital stay (mean ± SD, 1.0 ± 0.5 d *vs* 1.0 ± 0.2 d) , respectively. TPLC had a significantly worse visual analogue pain score at 8 h after surgery (mean ± SD, 3.5 ± 1.6 *vs* 2.0 ± 1.5), however, the scores were similar on day 7 (mean ± SD, 2.5 ± 1.4 *vs* 2.0 ± 1.3). Cosmetic satisfaction, as determined by a survey at 2 mo follow-up favored SILC (mean ± SD, 8 ± 0.4 *vs* 6 ± 0.2).

CONCLUSION: SILC is a safe and feasible approach in selected patients. The main advantages are a better cosmetic result and less pain.

INTRODUCTION

Laparoscopic cholecystectomy (LC) has become one of the most effective procedures for the treatment of benign gallbladder pathology since its introduction in 1985[1]. However, surgical standards of practice continue to evolve toward less invasive approaches, therefore many researchers have

attempted to minimize the invasiveness by reducing the number and size of the ports. In this context, single-port laparoscopic cholecystectomy (SILC) emerged in 1997[2]. The proposed advantages of SILC include fewer port sites with the potential for decreased pain, cosmetic benefit and faster recovery[3-10]. Some investigators have predicted that it may become a standard approach to LC[11,12]. However, it has also been suggested that SILC has many disadvantages, such as the technique is difficult to handle, prolonged operative time, cost of special instruments and increased risk of per-operative complications[9,13]. It is difficult to make an unbiased comparison between SILC and multi-port LC because of lack of prospective, randomized controlled trials (RCT). Therefore, we designed and conducted this RCT to evaluate the advantages and disadvantages of SILC and three-port laparoscopic cholecystectomy (TPLC).

MATERIALS AND METHODS

Inclusion criteria were as follows: (1) patients aged between 18 and 70 years; (2) body mass index less than 40 kg/m^2; (3) preoperative diagnosis of symptomatic gallstones or gallbladder polyps, and (4) willing to comply with the protocol requirements and signed written informed consent.

Exclusion criteria were as follows: (1) American Society of Anesthesiologists class Ⅳ and Ⅴ; (2) Patients with contraindication to laparoscopy; (3) Patients with suspected Mirizzi syndrome, common duct stones or malignancy; (4) Patients with previous upper abdominal surgery; (5) Patients on long-term anticoagulant treatment; (6) Acute cholecystitis or choledocholiathiasis; and (7) Gallstones > 3 cm in diameter.

Eligible patients were randomized into two groups (SILC and TPLC) using sealed opaque envelopes which contained a computer-generated random number. Before the trial, all patients underwent basic investigations such as blood tests, electrocardiogram, ultrasonography of the abdomen and radiologic imaging such as chest radiograph. All operations were performed by one experienced surgeon, who had performed more than 500 laparoscopic cholecystectomies.

Operative techniques

Surgical techniques were standardized. SILC was performed with the help of 2 slings of sutures, which included four steps: (1) Under general anesthesia, a 20 mm (approximately) bracket-shaped skin incision was made through the inner margin of the umbilicus and a pneumoperitoneum was set at 13 mmHg. One 10 mm trocar (Kanger, Tong Lu, China) to allow the insertion of a 30 degree laparoscope (Olympus, Tokyo, Japan) was inserted through the abdomen at the left side of the incision and a 5 mm trocar (Kanger, Tong Lu, China) was inserted at the right side for the harmonic scalpel. The tissues between the trocars were preserved to prevent air leakage; (2) The first suture using a straight needle was inserted through the right 7th intercostal space in the anterior axillary line, and the seromuscular layer of the gallbladder fundus was punctured and retracted toward the anterior abdominal wall. Hartmann's pouch was punctured and retracted using the second suture to expose Calot's triangle (Figure 1); (3) The harmonic scalpel (Ethicon Endo-Surgery, Cincinnati, OH, United States) was used to dissect Calot's triangle. Once the cystic artery and duct have been exposed, the cystic artery was cut using the harmonic scalpel, and the cystic duct was triple clipped and divided; and (4) The harmonic scalpel was used to dissect the gallbladder from the gallbladder fossa. When the gallbladder was free, the 5 mm trocar was exchanged for a 10 mm one, and through the 10 mm port, a specemen bag was inserted and the gallbladder was extracted after removal of the suspending sutures from the abdominal wall. The umbilical incision was closed and restored and no drainage tube was left in place (Figure 2).

Figure 1 A sketch of the suspension procedure.

Figure 2 The incision is reconstructed after single-incision laparoscopic cholecystectomy.

In TPLC, a sub-umbilical incision, sub-xiphoid incision and right sub-costal incision were made. A 10 mm trocar placed in the sub-umbilical incision allowed the introduction of laparoscope and the other two trocars, a 10 mm and a 5 mm, respectively, were placed for the grasp and harmonic scalpel. The operation was performed following the routine TPLC procedure[14], however, the cystic artery was divided and cut using the harmonic scalpel instead of being clipped and divided. The primary end-point of the

study was the postoperative pain score (at 6 h and 7 d). Secondary end-points included blood loss, operation duration, overall complications (intra- and post-operative complications), postoperative analgesic requirements, length of hospital stay, cosmetic result and total cost. A standard visual analog scale [range, 0 (no pain) to 10 (maximum pain)] was used for assessments at 8 h after surgery and on postoperative day 7. Cosmetic satisfaction of the surgical scar was rated on a scale [range, 0 (worst) to 10 (best)], and was evaluated at the 2-mo follow-up visit.

Statistical analysis

Statistical analysis was accomplished using the SPSS program for Windows 12.0 (SPSS, Chicago, IL, United States). The χ^2 test or the t test was used as indicated. All data were presented as mean ± SD. All P values were 2-sided. A P value of 0.05 was considered statistically significant.

RESULTS

From January 2009 to March 2011, 108 eligible patients were randomized to SILC (n = 51) or TPLC (n = 57). Two patients in the TPLC group and four patients in the SILC group refused to participate before surgery. In total, 102 patients (SILC, n = 49; TPLC, n = 53) were analyzed. Demographic variables in the two groups were similar (Table 1). All patients in the TPLC group successfully underwent three-port laparoscopic cholecystectomy without conversion to open surgery. Of 49 patients in the SILC group, one patient was converted to two-port LC due to anatomical difficulties and the operator felt it was unsafe to proceed with SILC. Overall, No major intra- or post-operative complications, such as biliary injury, abscess, bleeding, biliary collection or port-site hernia were observed in the two treatment groups. Several patients experienced port-site complications such as contusion and hematoma, however, all recovered a few days after surgery. There were no significant differences in estimated blood loss (14 ± 6.0 mL *vs* 15 ± 4.0 mL; P = 0.2643), operation duration (41.8 ± 17.0 min *vs* 38.5 ± 22.0 min; P = 0.4222), port-site complications (contusion at incision: 5 cases *vs* 4 cases; P = 0.7350 and hematoma at incision: 2 *vs* 1; P = 0.6070), hospital stay (1.0 ± 0.5 d *vs* 1.0 ± 0.2 d; P = 1.0000) and total cost (12 075 ± 1047 RMB *vs* 11 982 ± 1153 RMB; P = 0.6715) between the SILC and TPLC groups. However, the TPLC group had a significantly worse visual analogue pain score at 8 h after surgery (3.5 ± 1.6 *vs* 2.0 ± 1.5; P = 0.0000), but the score was similar on day 7 (2.5 ± 1.4 *vs* 2.0 ± 1.3; P = 0.0651). Cosmetic satisfaction as shown by the cosmetic score was significantly higher in the SILC group than in the TPLC group (8 ± 0.4 *vs* 6 ± 0.2; P = 0.0000) (Table 1).

DISCUSSION

SILC has attracted wide attention because of its potential cosmetic results. It may even be possible for this approach to become a gold standard for cholecystectomy[11,12]. However, there is still a long way to go before this approach is a gold standard, as standardization, safety, and the cosmetic results of SILC require validation[15]. Although recent reports have focused on comparisons between SILC and multi-port LC, the safety, better cosmetic results and faster recovery following SILC have been agreed, however, SILC has not been standardized and there is much technical variation. On the one hand, different surgeons have attempted SILC in different ways. For example, in exposing Calot's triangle, trials using sutures, Kirschner wires and loop retractors have been reported, in addition to different manipulative instruments, such as straight instruments and reticulating instruments[7]. On the other hand, devices used to prevent air leakage vary from one surgeon to another: some use common trocars[8], some tend to use SILS multi-port[7] and others favor self-designed devices such as sterile gloves[16]. In our center, we have tried many approaches in the initial stage. For example, to prevent air leakage, we have tried tri-port and gel-port, but due to their high cost in special ports and larger lesions of about 3 cm requiring a trans-umbilical incision these devices are no longer used. We decided to select routine trocars in our practice because they were sufficient to prevent air leakage and were more economical. With regard to the selection of surgical instruments, we use the suture suspension method in SILC, which requires only a 30 degree laparoscope and a manipulative instrument, eliminating the need for more instruments intra-operatively.

In practice, we focus on improving the auxiliary procedure with suspension sutures. To achieve ideal exposure of Calot's triangle, we select the puncture spot at the superior chest wall along the costal margin so that the suspension suture can draw the liver up a bit more than in other

places, different to Piskun *et al*[17] that the puncture spot should be selected at the inferior costal margin. In addition, the harmonic scalpel is effective for occluding 3 mm blood vessels and dissecting tissues[18]. In our experience, cystic arteries in the trial were cut using the harmonic scalpel, indicating the safety of this scalpel. Intra-operative management of the gallbladder is critical for the safety in SILC. Initially, we were perplexed as to how to handle intra-operative bile leakage. First, we placed the suspension sutures into the seromuscular layer to avoid perforation of the cyst wall, but this was inevitable sometimes. Subsequently, we found that this technique was useful as long as evacuating and repeated rinsing were conducted.

There have been a few comparisons between SILC and conventional multi-port LC[19-22]. These studies concluded that SILC is superior to multi-port LC in terms of cosmetic outcome, but not in terms of total cost, surgical time and postoperative pain. A similar cosmetic outcome in both treatment groups was observed in our study. However, there was no significant difference in the total cost between SILC and traditional LC when standard materials were selected. In addition, we found that SILC resulted in less postoperative pain than TPLC, and no significant difference in operation duration was observed between the two techniques. The higher pain score may be explained by the fact that there are more incisions in TPLC and the size of the incisions is larger than those in SILC. The different outcome of surgical time could be explained by difference in experience of the surgeon in SILC.

In conclusion, the results of this prospective trial demonstrate that SILC is a safe procedure when conducted by experienced surgeons, with some outcomes similar to that of TPLC, however, SILC was superior in terms of cosmetic outcome and postoperative pain. In the future, more high-powered randomized studies comparing SILC with conventional LC will be needed to validate its objective benefits and clinical role during the follow-up.

COMMENTS

Background

Laparoscopic cholecystectomy (LC) has been regarded as the "gold standard" for the management of benign gallbladder diseases since its introduction in 1985. However, surgical standards of practice continue to evolve toward less invasive approaches, therefore many researchers have attempted to minimize the invasiveness by reducing the number and size of the ports. In this context, single-incision laparoscopic cholecytectomy (SILC) emerged as a complement to standard LC. The proposed advantages of SILC include fewer port sites with the potential for decreased pain, cosmetic benefit and faster recovery. Some investigators have predicted that it may become a standard approach in LC. However, it has also been suggested that SILC has many disadvantages, such as the technique is difficult to handle, prolonged operative time, cost of special instruments and increased risk of per-operative complications. Therefore, it is difficult to make an unbiased comparison between SILC and multi-port LC due to the lack of prospective, randomized controlled trials.

Research frontiers

SILC has attracted wide attention because of its potential cosmetic results. However, it is unknown whether SILC could become a new standard preocedure, and therefore it is necessary to compare the clinical outcome of SILC and multiple-port laparoscopic cholecystectomy.

Innovations and breakthroughs

This prospective randomized study was performed to explore the safety and feasibility of SILC for the treatment of benign gallbladder diseases, and to compare the clinical outcomes with three-port laparoscopic cholecystectomy (TPLC).

Applications

In selected patients with benign gallbladder diseases, single-incision laparoscopic cholecystectomy is safe and feasible. The main advantages are that SILC result in a better cosmetic outcome and less pain compared with TPLC.

Terminology

SILC is a minimally invasive surgical procedure in which cholecystectomy is accomplished exclusively through a single 15-25 mm incision in the patient's navel. It is complementary to standard LC and an alternative to natural orifice transluminal endoscopic surgery. Unlike the traditional multi-port laparoscopic approach, SILC leaves only a single small scar in the navel.

Peer review

The authors have compared the clinical outcomes of SILC with TPLC and have concluded that SILC is a safe and feasible approach in selected patients. The main advantage is its better cosmetic result and less pain. The study is well organized and the content is adequately written, patient number is good and the authors have used good technique (harmonic for cystic artery).

Abstract

AIM: To study the effects of *Helicobacter pylori* (*H. pylori*) tumor necrosis factor-α (TNF) inducing protein (Tip-α) on cytokine expression and its mechanism.

METHODS: We cloned Tip-α from the *H. pylori* strain 26695, transformed *Escherichia coli* with an expression plasmid, and then confirmed the expression product by Western blotting. Using different concentrations of Tip-α that affected SGC7901 and GES-1 cells at different times, we assessed cytokine levels using enzyme-linked immunosorbent assay. We blocked SGC7901 cells with pyrrolidine dithiocarbamate (PDTC), a specific inhibitor of nuclear factor κB (NF-κB). We then detected interleukin (IL)-1β and TNF-α levels in SGC7901 cells.

RESULTS: Western blot analysis using an anti-Tip-α antibody revealed a 23-kDa protein, which indicated that recombinant Tip-α protein was recombined successfully. The levels of IL-1β, IL-8 and TNF-α were significantly higher following Tip-α interference, whether GES-1 cells or SGC-7901 cells were used ($P < 0.05$). However, the levels of cytokines (including IL-1β, IL-8 and TNF-α) secreted by SGC-7901 cells were greater than those secreted by GES-1 cells following treatment with Tip-α at the same concentration and for the same duration ($P < 0.05$). After blocking NF-κB with PDTC, the cells (GES-1 cells and SGC-7901 cells) underwent interference with Tip-α. We found that IL-1β and TNF-α levels were significantly decreased compared to cells that only underwent Tip-α interference ($P < 0.05$).

CONCLUSION: Tip-α plays an important role in cytokine expression through NF-κB.

INTRODUCTION

Infection with *Helicobacter pylori* (*H. pylori*) leads to chronic gastritis, peptic ulcer, and gastric lymphoma[1-3]. *H. pylori* has also been associated with gastric cancer[4], is classified as a class I carcinogen by the International Agency for Research on Cancer[5], and *H. pylori* exerts its pathogenesis by secreting toxins, including hemolysin, lipopolysaccharides, CagA and VacA[6-9]. CagA and VacA are the major virulence factors. Persistent infection by *H. pylori* enables these toxins to stimulate gastric epithelial cells to produce a large number of cytokines such as tumor necrosis factor (TNF-α) and interleukin 1, 6 and 8 (IL-1, IL-6 and

IL-8), thus generating an inflammatory reaction[10-14]. Tumor necrosis factor-α inducing protein (Tip-α) is a new toxin discovered recently, and likely accelerates the inflammation and cancers caused by *H. pylori*[15]. However, its function and the mechanism underlying these effects remain unclear. The present work was conducted to determine the effects of recombinant Tip-α (rTip-α) on human gastric epithelial cells and gastric cancer cytokine expression, as well as explore the mechanisms involved.

MATERIALS AND METHODS

Materials

H. pylori strain 26695 was obtained from the Shanghai Institute of Digestive Disease. The following reagents were used in this study: Dual Promoter TA Cloning® Kit pCR® II and pET28a vectors (Invitrogen); monoclonal rabbit anti-Tip-α antibody (Beijing Aviva Systems Biology); *Bam*H I , *Xho* I and Prestained Protein Molecular Weight Markers (Fermentas); DNA and gel extraction kit from Tiangen Biotech (Beijing) Co. Ltd.; DNA marker (TaKaRa); His Trap™ *H. pylori* affinity chromatography column (GE Healthcare); and enhanced chemiluminescence kit (Pierce Protein Biology Products). The polymerase chain reaction primer sequences were 5'-TTGGATCCATGCTGCAGGCTTG-3', which contained an *Xho* I restriction site, and 5'-GGCTCGAGCTACATGGCTATAG-3', which contained a *Bam*H I restriction site. The primers were synthesized by Invitrogen. The human gastric epithelial cell line GES-1 and gastric cancer SGC7901 cells were purchased from the Shanghai Cancer Institute. Enzyme-linked immunosorbent assay (ELISA) kits were obtained from MultiSciences Biotech (Shanghai) Co., Ltd., while pyrrolidine dithiocarbamate (PDTC) was purchased from Jingmei Biotech Co., Ltd.

Methods

Expression, purification, and identification of Tip-α: We cloned *Tip-α* from the genome of *H. pylori* strain 26695. The *Tip-α* gene and pET28a vector (His tag) were digested with *Bam*H I and *Xho* I , purified, and then ligated together to generate the ET28a-Tip-α plasmid expressing recombinant Tip-α. This plasmid was transformed into *Escherichia coli* and the resultant protein was purified by Ni-NTA affinity chromatography and verified by Western blotting.

Cell recovery, culture, and passage: Cryopreserved GES-1 and SGC-7901 cells were centrifuged at 1000 rpm for 5 min. After removal of the supernatant, these cells were cultured in 60 mm × 60 mm dishes containing Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum.

IL-1β, IL-8 and TNF-α levels at different times following interference by 12.5 μg/mL rTip-α in GES-1 and SGC7901 cells: GES-1 and SGC7901 cells during their logarithmic growth phase underwent interference with 12.5 μg/mL rTip-α after starvation in serum-free medium for 24 h. The levels of IL-1β, IL-8 and TNF-α cytokines were then assessed at 0, 1, 2, 4 and 8 h post-interference using ELISA.

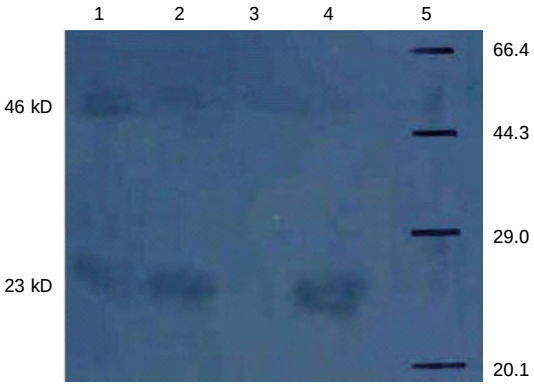

Figure 1 Western blotting identification of recombinant tumor necrosis factor-α inducing protein.

Levels of IL-1β, IL-8 and TNF-α in GES-1 and SGC7901 cells following incubation with different concentrations of rTip-α: We incubated GES-1 and SGC7901 cells with the following concentrations of rTip-α: 0, 12.5, 25 and 50 μg/mL. After 2 h, we examined the levels of IL-1β, IL-8 and TNF-α using ELISA.

Effects of rTip-α on IL-1β and TNF-α expression after PDTC-mediated inhibition of NF-κB: Four groups consisting of the same number of GES-1 and SGC7901 cells were starved in serum-free medium for 24 h before undergoing different treatments. Group A was treated with 12.5 μg/mL rTip-α for 2 h. Group B was treated similarly after PDTC blocking of NF-κB for 4 h. Groups C and D were incubated with serum-free medium and dimethyl sulfoxide (the vehicle with which PDTC was diluted), respectively. ELISA was performed to detect the levels of IL-1β and TNF-α in each group.

Statistical analysis

Data are presented as the mean ± SD and analyzed using SPSS 17.0. The Student's *t* test was used to compare two groups, while one-way analysis of variance was used to compare among several groups. A P value < 0.05 was considered statistically significant.

RESULTS

Identification by Western blotting after rTip-α expression and purification

Western blotting analysis demonstrated that the Tip-α recombinant protein and anti-human Tip-α monoclonal antibody could be specifically bound; specific bands were found (Figure 1). Western blotting analysis by non-denaturing gel electrophoresis showed active dimer bands (46 kDa).

[a]$P < 0.05$ *vs* group A. IL-1β: Interleukin-1β; TNF-α: Tumor necrosis factor-α.

IL-1β, IL-8 and TNF-α levels at different times following interference by 12.5 μg/mL rTip-α in GES-1 and SGC7901 cells

The levels of IL-1β, IL-8 and TNF-α were significantly higher after GES-1 and SGC7901 cells underwent interference by 12.5 μg/mL rTip-α for 1, 2, 4 and 8 h than those at 0 h. Cytokine secretion by GES-1 and SGC7901 cells peaked after rTip-α interference for 2 h, indicating no obvious dependence on time (Tables 1 and 2). However, after interference by rTip-α for 2 h, the levels of IL-8 (2.53 ± 0.50) and TNF-α (1.41 ± 0.10) in SGC7901 cells were significantly higher than those in GES-1 cells (0.84 ± 0.11 for IL-8 and 0.72 ± 0.08 for TNF-α). As shown in Table 1, the levels of IL-1β in GES-1 and SGC7901 cells (2.07 ± 0.10 and 2.07 ± 0.30, respectively) were not statistically different after rTip-α interference for 2 h.

Levels of IL-1β, IL-8 and TNF-α in GES-1 and SGC7901 cells following incubation with different concentrations of rTip-α

The levels of IL-1β, IL-8 and TNF-α were significantly higher than those in the blank control in GES-1 and SGC7901 cells after rTip-α interference for 2 h. Cytokine secretion of GES-1 and SGC7901 cells peaked at 12.5 μg/mL, suggesting that this effect was not concentration-dependent (Table 2).

Effects of rTip-α on IL-1β and TNF-α expression after PDTC-mediated inhibition of NF-κB

The levels of IL-1β and TNF-α in SGC7901 cells in Group B (treated with PDTC + rTip-α) were higher than those in Groups C and D (no rTip-α and PDTC), but markedly lower than those in Group A (only treated with rTip-α). As shown in Table 3, these differences were statistically significant ($P < 0.05$, $F = 40.15$).

DISCUSSION

Tip-α is a novel gene that was discovered recently in *H. pylori*. Located in the *H. pylori* 0596 open reading frame of the *H. pylori* 26695 strain, Tip-α is also called *H. pylori* 0596 protein. Its open reading frame is 519 bp in length and constitutes 173 amino acids. Tip-α has a molecular weight of 19 kDa and can form active homodimers with a molecular weight of 38 kDa through disulfide bonding[15]. Recent studies have found that Tip-α is associated with the adsorption and colonization of *H. pylori* in gastric mucosa[16]. Some studies have shown that the structure of Tip-α is different from penicillin binding proteins. Tip-α is composed of three closely linked domains that interact with other proteins and nucleic acids. In particular, the homodimer formed by cysteine C25 and C27 is essential for Tip-α to serve its role in the gastric mucosal acidic environment[17]. Detected by gene chip technology, expression of the chemokines Cc 12 Cc17, Cc120, Cx11 and Cx15 was enhanced after Tip-α treatment in gastric cancer cells and gastric epithelial cells[18]. These chemokines can induce chemotaxis of immune cells to local sites of infection, resulting in immune regulation and pathology, and ultimately the inflammatory response[19].

Because our pET28a-Tip-α vector also expresses a 3.74 kDa His tag, the recombinant Tip-α protein we produced possesses a molecular weight of about 23 kDa and can form active homodimers with a molecular weight of 46 kDa through disulfide bonding. Our work indicates that after affecting gastric epithelial and cancer

cells, rTip-α can promote the expression of IL-1β, IL-8 and TNF-α. These cytokines are important in promoting the inflammatory response, thus linking Tip-α to inflammation and the occurrence of *H. pylori*-related gastrointestinal diseases. After incubating the cells for 2 h with rTip-α, the levels of cytokine expression peaked at 12.5 μg/mL, which was the best concentration for interference. The levels of cytokine expression induced by rTip-α were not time- or concentration-dependent. These results suggest that Tip-α affects the host by inducing toxin secretion into the exterior environment of the bacteria through the type Ⅱ secretion system[20]. The toxins then enter host cells *via* receptor-mediated endocytosis instead of through injection *via* the Ⅳ secretion system[21-23]. Studies have shown that Tip-α possesses DNA binding activity. In particular, DNA affecting gastric mucosal cells can combine with some transcription factors to promote IL-1β, IL-8 and TNF-α expression, leading to the occurrence and development of *H. pylori*-related gastrointestinal diseases[24].

PDTC is a specific NF-κB inhibitor that works by blocking degradation of the NF-κB p65 subunit or IκB, thereby reducing NF-κB nuclear translocation[25]. Our data demonstrated no significant increase in IL-1β and TNF-α levels after pretreatment of SGC7901 cells with PDTC followed by rTip-α interference. This finding suggests that the promotion of cytokine expression by Tip-α may be regulated by NF-κB. However, further study is required to determine the underlying mechanism.

In addition, we found that when gastric epithelial and cancer cells were treated with the same concentration of Tip-α for the same duration, the level of cytokine expression in gastric cancer SGC7901 cells was significantly higher than that in gastric epithelial GES-1 cells. This difference may be due to differential effects of rTip-α on NF-κB expression in the cell types or may be related to variations in the DNA binding activity of Tip-α in the cells. Some studies suggest that the increased cytokine expression promoted by Tip-α may hasten the invasion and metastasis of gastric cancer[26]. Overall, Tip-α can activate cytokine expression in an NF-κB-dependent manner. Tip-α plays a major role in the pathogenesis of *H. pylori*, however, its mechanism requires further investigation.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) exerts its pathogenesis by secreting toxins. Tumor necrosis factor-α (TNF-α) inducing protein (Tip-α) is a new toxin discovered recently, however, its function and mechanism of pathogenesis remain unclear.

Research frontiers

The pathogenesis of *H. pylori* is partially clear, as *H. pylori* may secrete many types of toxins. With the exception of CagA and VacA, new *H. pylori* toxins have been discovered, such as Tip-α, mammalian, prokaryotic high-temperature requirement A, and the duodenal ulcer-promoting gene. Only the function of the toxins and their mechanism of pathogenesis are clear, as the mechanism of *H. pylori* pathogenesis is known.

Innovations and breakthroughs

Other studies discovered that Tip-α promoted the expression of cytokines, however, this article first showed the difference in the promotion of the expression of cytokines between gastric epithelial cells and cancer cells, and that Tip-α activates cytokine expression in a nuclear factor κB (NF-κB)-dependent manner.

Applications

Tip-α may become a marker of *H. pylori* virulence. The virulence of *H. pylori* may be determined by detecting Tip-α.

Terminology

Tip-α is the abbreviation for tumor necrosis factor-α inducing protein. It was first discovered that this new *H. pylori* toxin can promote the expression of TNF-α, therefore, it was called Tip-α.

Peer review

The authors certified that Tip-α-a new toxin of *H. pylori*, promoted the expression of cytokine, discovered the difference of this function between gastric epithelial cells and cancer cells, and in an NF-κB-dependent manner, further interpreted the mechanism of pathogenesis of *H. pylori*.

Abstract

AIM: To assess the diagnostic value of using magnifying chromoendoscopy combined with immunohistochemical staining of proliferating cell nuclear antigen (PCNA) and p53 in the detection of gastric precancerous lesions.

METHODS: Ninety-five patients who were treated for abdominal discomfort, abdominal pain, bloating, and acid reflux at our hospital from January 2010 to December 2011 were included in the study. An ordinary gastroscopic procedure was initially performed to select the lesions. All subjects underwent magnifying chromoendoscopy to observe morphological changes of gastric pits. Biopsies were then taken from each area of interest and sent for pathological examination and detection of PCNA and p53 expression by immunohistochemistry. An immunoreactivity score for each lesion was calculated. Based on immunoreactivity scores, immunohistochemical staining was then considered.

RESULTS: Compared to intestinal metaplasia, gastric pits were more diverse in size, more irregular in shape, and more disorderly in arrangement in moderate and severe dysplasia. PCNA and p53 expression was significantly higher in precancerous lesions (intestinal metaplasia and dysplasia) than in chronic gastritis. PCNA expression showed an upward trend in types A-F pits. The number of cases that showed strong PCNA positivity increased significantly with an increase in the severity of lesions. Rank sum test for independent samples showed that p53 expression was significantly higher in types E and F pits than in types A-D pits (H = 33.068, P = 0.000). Rank sum test for independent samples showed that PCNA expression was significantly higher in types E and F pits than in types A-D pits (H = 31.791, P = 0.001).

CONCLUSION: The presence of types E and F pits, in which p53 and PCNA are highly expressed, is highly suggestive of the occurrence of early cancer, and patients developing these changes should be closely followed.

ing for early diagnosis of gastric cancer. *World J Gastroenterol* 2013; 19(3): 404-410 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/404.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.404

INTRODUCTION

Gastric cancer is one of the most common human malignancies, ranking first in terms of both incidence and mortality among gastrointestinal malignancies in China. Although great technological progress has been made in the diagnosis and treatment of gastric cancer, there is no significant improvement in its prognosis, and the 5-year survival rate of gastric cancer is only about 20%[1]. This is because 67% of patients have already had local spread or distant metastasis at initial diagnosis[1]. Therefore, early diagnosis and treatment are important for improving the prognosis of gastric cancer.

Early gastric cancer only invades the mucosal layer and submucosal layer and has a 5-year survival rate as high as 90% to 95%. Gastroscopy has the advantages of easy operation and low false-negative detection rate and has long been considered the preferred and most reliable diagnostic modality for gastric cancer. It allows detection of minute lesions and flat lesions easily, estimation of the depth of invasion[2], and the performance of histological and molecular biological analysis of diseased tissue; it therefore has a higher detection rate of early cancer and precancerous lesions. Thus, it is important to carry out a regular follow-up of gastric precancerous lesions to increase the detection rate of early gastric cancer. However, the widespread use of gastroscopy does not significantly improve the detection rate of early gastric cancer. A recent study in Japan[3] indicates that endoscopy has a sensitivity of only 81% in detecting early gastric cancer, and this means that the false-negative rate is 19%. Therefore, worldwide efforts are being made to improve the sensitivity of endoscopy in the detection of early cancer and precancerous lesions so that the tumor can be detected at an early treatable stage.

The human genome is composed of about 100 000 genes, and the selective expression of these genes determines the whole human life course. Changes in gene expression play a central role in biological regulatory mechanisms. Tumorigenesis is the result of multiple genetic changes. Activation of oncogenes and inactivation or deletion of tumor suppressor genes are considered closely related to tumorigenesis. The tumor suppressor gene *p53* is well known as the guardian of the cell. To date, extensive and in-depth research on p53 has been conducted. Wild-type p53 is an important negative regulator of cell growth and can antagonize oncogenic functions *in vivo* to maintain the relative stability between positive and negative proliferation signals. Wild-type p53 is involved in many important biological processes such as cell cycle, DNA repair, cell differentiation, and apoptosis.

Proliferating cell nuclear antigen (PCNA) is an acidic nuclear protein that is involved in eukaryotic DNA synthesis and plays an important role in the regulation of the cell cycle. PCNA expression is significantly up-regulated in the process of malignant transformation of normal epithelium and is deemed a marker reflecting cell proliferation activity in most tumor types.

The aim of this study was to assess the diagnostic value of magnifying chromoendoscopy combined with detection of PCNA and p53 in the detection of gastric precancerous lesions.

MATERIALS AND METHODS

Patients

Ninety-five patients who were treated for abdominal discomfort, abdominal pain, bloating, and acid reflux at our hospital from January 2010 to December 2011 were selected. There were 60 males and 35 females. Their ages ranged from 17 to 78 years, with a median age of 52 years.

Methods

Endoscopic examination: The procedure was performed using a Fujinon (EG-590) gastroscope and EPX 4400 processor. An ordinary gastroscopic procedure was initially performed to select the lesions, and magnifying chromoendoscopy was then performed to observe morphological changes of gastric pits. Three to four biopsies were taken from each area of interest and sent for pathological examination and detection of PCNA and p53 expression.

Criteria for morphological classification: Based on morphological classification criteria proposed by Yang *et al*[4], gastric pits were divided into six fundamental types: A (round spot-like pits), B (short rod-like pits, arranged regularly and tightly, with elongations, branches and curvatures), C (linear pits, more sparse and thick compared to type B), D (patchy pits, elongated and tortuous pits connected to form a reticular appearance), E (villous pits, with finger-like tubers similar to enteral villus-like changes) and F (the pits have obscure or disappearing structures and extremely irregular arrangement). The boundaries between bowl-shaped defects on the erosion surface and neighboring structures are unclear. Defect areas may show granular protrusions and irregular thickened capillaries). When two or more types of gastric pits were present in a lesion, the lesion was defined as having the severe type of pits.

Immunohistochemical staining for PCNA and p53: Immunohistochemistry: Immunohistochemical analysis was performed using the streptavidin-peroxidase method to determine the expression of p53 and PCNA in the gastric mucosa. Briefly, tissue samples were fixed in 10% neutral buffered formalin, dehydrated in a graded series of ethanol, cleared, paraffinized, and cut into 4 μm sections. The sections were deparaffinized, hydrated

in a graded series of ethanol, incubated in a microwave to heat and high pressure cook for 10 min for antigen retrieval, and washed in tris-buffered saline (TBS) (3 × 5 min). After treatment with 3% H_2O_2 for 10 min, slides were washed again in TBS (3 × 5 min). The slides were then incubated with primary anti-PCNA (1:50; Maxim, Fuzhou, China) or anti-p53 (1:100; Maxim) antibody for 30 min at room temperature and washed in TBS (3 × 5 min). Immunolabeling was visualized by reaction with DAB for 10 min at room temperature. The sections were counterstained with hematoxylin, dehydrated and mounted. This experiment was performed by an experienced technician.

Evaluation of immunohistochemical staining: Scoring of immunohistochemical results was performed according to the semi-quantitative method. The percentage of immunopositive cells was scored using a four-point system as follows: 0 point, < 5% of positive cells; 1 point, 5%-25% of positive cells; 2 points, 26%-50% of positive cells; 3 points, 51%-75% of positive cells; 4 points, > 75% of positive cells. The staining intensity was scored similarly, with 0 point for negative staining, 1 point for weak staining (light yellow), 2 points for moderate staining (brown), and 3 points for strong staining (dark brown). Immunoreactivity score for each lesion was calculated as (the score for the percentage of immunopositivity cells + the score for the staining intensity)/2. Based on immunoreactivity scores, immunohistochemical staining was considered negative (< 0.5), weakly positive (0.5-1.5), or strongly positive (> 1.5). Estimation of scores for all lesions was performed by the same pathologist.

Statistical analysis

All statistical analysis were performed using SPSS 11.5 software. P values ⩽ 0.05 were considered statistically significant.

RESULTS

Magnifying chromoendoscopic findings

Relation between gastric pit patterns and histopathological phenotypes: A total of 248 biopsies were taken under a magnifying chromoendoscope. Of these biopsies, 9 had type A gastric pits, 38 had type B, 42 had type C, 67 had type D, 62 had type E, and 30 had type F (Table 1).

Under a magnifying chromoendoscope, intestinal metaplasia was characterized by the presence of type E gastric pits (villous pits). Dysplasia also showed changes similar to those of intestinal metaplasia (e.g., the presence of villous, linear or patchy pits); however, some characteristic changes were observed in some cases of dysplasia. Compared to intestinal metaplasia, gastric pits were more diverse in size, more irregular in shape, and more disorderly in arrangement in moderate and severe dysplasia. Type F gastric pits in the 30 cases of dysplasia showed varying degrees of these changes (Figure 1).

Immunohistochemical results

p53 expression: p53 expression was lowest in type A gastric pits and highest in type F pits, showing an upward trend from types A to F pits. p53 expression intensity also showed an upward trend (Figure 2A and B). Rank sum test for independent samples showed that p53 expression was significantly higher in types E and F pits than in types A-D pits ($H = 33.068$, $P = 0.000$). Between-group comparisons showed that p53 expression was significantly higher in types E and F pits than in type A pits (Table 2).

PCNA expression: PCNA expression was lowest in type A gastric pits and highest in type F pits, showing an upward trend from types A to F pits (Figure 2C and D). The number of cases that showed strong PCNA positivity increased significantly with an increase in the severity of lesions. Rank sum test for independent samples showed that PCNA expression was significantly higher in types E and F pits than in types A-D pits ($H = 31.791$, $P = 0.001$). Between-group comparisons showed that PCNA expression was significantly higher in types E and F pits than in type A pits (Table 2).

DISCUSSION

The normal gastric mucosa surface is divided by criss-cross small grooves into many lesser gastric areas, in

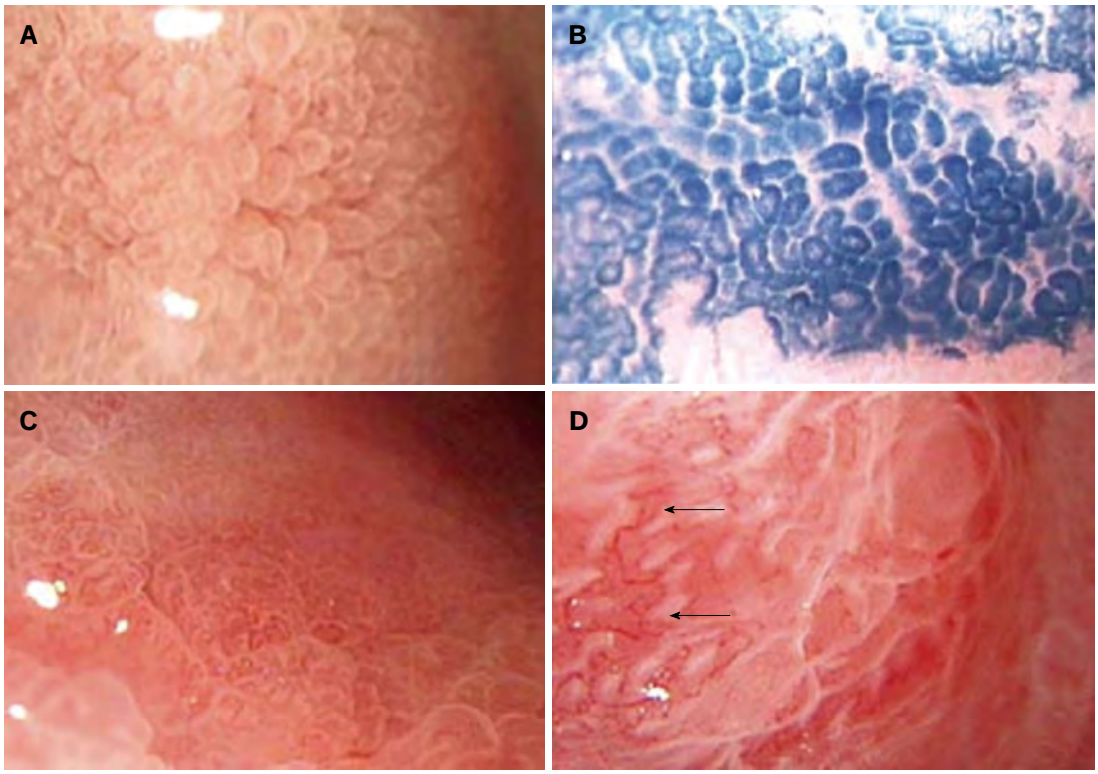

Figure 1 Magnifying chromoendoscopic findings. A: Type E pits; B: Type E pits after dye staining; C: Type F pits; D: Type F pits after dye staining, arrows show disorderly arranged thickened capillaries. Magnification, ×100. Type E: Villous pits, with finger-like tubers similar to enteral villus-like changes; Type F: The pits have obscure or disappearing structures and extremely irregular arrangement.

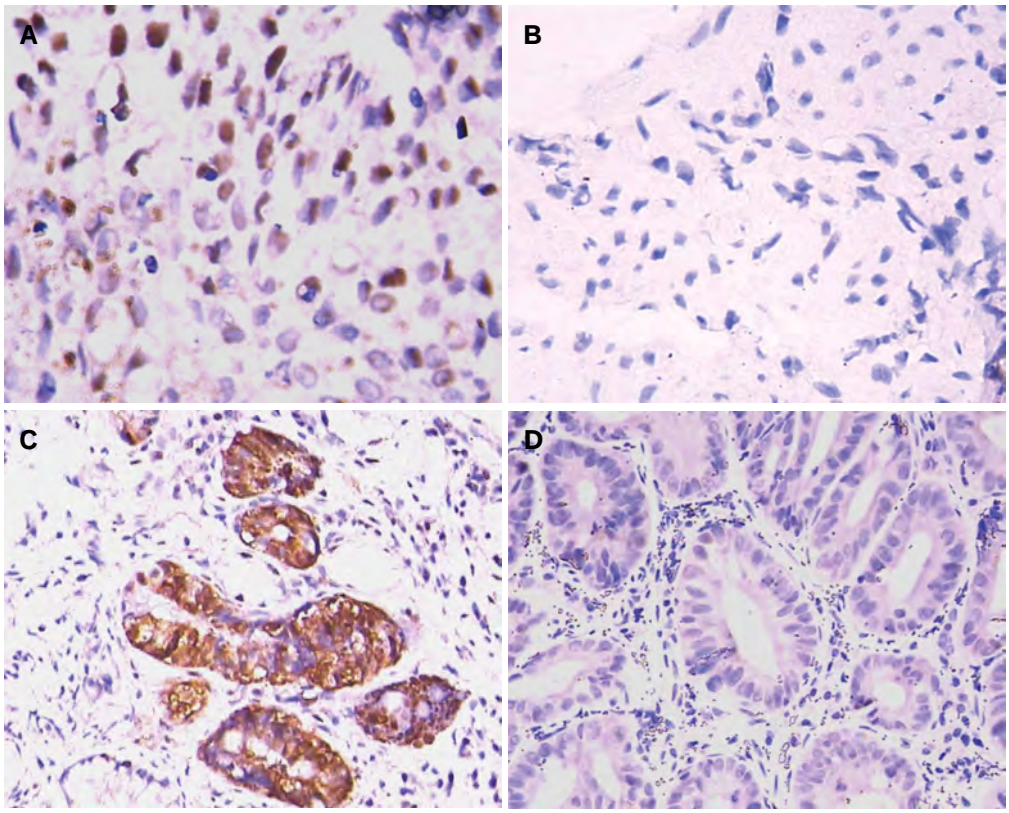

Figure 2 Immunohistochemical results. A: Expression of p53 in gastric pits in chronic atrophic gastritis, and nuclei were stained dark brown; B: p53 expression was undetectable in gastric pits in chronic superficial gastritis; C: Expression of proliferating cell nuclear antigen (PCNA) was detected in gastric pits in chronic atrophic gastritis, and nuclei were stained dark brown; D: PCNA expression was undetectable in gastric pits in chronic superficial gastritis.

which there are many spot- or rod-like gastric pits. When gastric mucosal lesions occur, morphological changes of gastric pits often appear first. Under an ordinary microscope, it is difficult to observe the morphological changes of gastric pits. In contrast, a magnifying endoscope has a magnification comparable to that of a stereomicroscope and allows observing gastric pit patterns clearly. Dye staining is an important auxiliary method for magnifying endoscopy. Magnifying chromoendoscopy can more clearly show the extent and surface conditions of lesions, which is conducive to clearer observation of lesions and more accurate biopsy. In recent years, domestic and foreign scholars have divided gastric mucosal pit patterns into four fundamental types: spot-like, reticular, granular, and villous[4,5]. Yang *et al*[4] and Huang *et al*[6] discovered that gastric pit morphology correlates with the severity of mucosal inflammation. They further divided gastric pits into five fundamental types: A (round spot-like pits), B (short rod-like pits), C (elongated and tortuous pits), D (reticular pits), and E (villus-like pits). This classification can more accurately reflect the evolution from the normal mucosa to superficial gastritis and atrophic gastritis. The presence of type E pits is a characteristic change of intestinal metaplasia. Wang *et al*[7] believe that epithelial and gland hyperplasia and intestinal metaplasia are main factors leading to morphological changes of gastric pits in atrophic gastritis. Endo *et al*[8] examined intestinal metaplasia of Barrett's esophagus and gastric cardia and found that villus-like pits are a characteristic change of intestinal metaplasia.

Gastric mucosal erosions are common lesions that show a special pattern during endoscopy, and some of them have malignant potential with the progression of inflammation. Therefore, it is particularly important to detect and determine the nature of mucosal erosions by endoscopy. By carefully observing gastric erosions, we found that the evolution of six fundamental types of gastric pits reflects the evolution from the normal mucosa to superficial gastritis, atrophic gastritis, intestinal metaplasia, and dysplasia. Type F pits evolve gradually from type E pits. They have obscure or disappearing structures and an extremely irregular arrangement. The boundaries between bowl-shaped defects on the erosion surface and neighboring structures are unclear. The erosive areas may show granular protrusions and irregular thickened capillaries. Histopathological analysis indicates that gastric mucosal lesions that have these subtle structural features are closely related to dysplasia or even early gastric cancer. Tajiri *et al*[9] observed the lesions of depressed early gastric cancer and divided the patterns of microvessels on the lesion surface into six types. They found that microvessels with branches of different calibers, spiral microvessels, and microvessels of different calibers were more commonly seen in undifferentiated carcinoma. Liu *et al*[10] applied magnifying endoscopy to the diagnosis of gastric mucosal erosions and found that there was an indirect or direct causal relationship between gastric mucosal erosions and gastric cancer. The presence of mucosal protrusions on the erosion surface is an endoscopic feature of malignant erosions, and this is initially caused by the replacement of cancerous tissue defects by regenerative non-cancerous mucosa. As time goes on, regenerative mucosa can be replaced by cancerous tissue to form pink mucosal protrusions[11]. In our study, about 80.6% of cases of type E mucosa showed intestinal metaplasia. Under a magnifying endoscope, type F mucosa usually contains no bowl-shaped defects on the erosion surface, which are commonly found in types C-E mucosa. However, the erosion surface has become rough, and the mucosa shows granular hyperplasia or irregular changes. The boundaries between the erosion surface and surrounding structures are unclear, and gastric pits in the periphery of the lesion are sparse, irregularly arranged type E pits. Type F mucosa often suggests varying degrees of dysplasia, which has a coincidence rate of 86.7% compared with pathological results. In addition, some cases of type F mucosa that is proved to have dysplasia by histopathology show varying degrees of capillary dysplasia, which manifests as the presence of irregular, thick, disordered capillaries on the erosive mucosal surface. This characteristic change is similar to tumor vascular change described by Otsuka *et al*[12] and Tajiri *et al*[9] in early gastric cancer. Thus, the presence of types E and F mucosa can be regarded as a subtle structural feature of gastric precancerous lesions. In this study, comparison of the findings of magnifying chromoendoscopy and histopathological analysis results indicates that the presence of types E and F mucosa suggests the emergence of intestinal metaplasia and dysplasia.

The *p53* gene is a tumor suppressor gene that is located on the short arm of human chromosome 17. It encodes a 53-kDa nuclear phosphoprotein that has transcription factor activity and plays an important role in the control of the cell cycle and apoptosis[13]. p53 mediates G1 arrest in response to DNA damage for DNA excision and repair to maintain the stability of the genome[14]. Wild-type p53 acts as not only a transcriptional activator but also a transcription suppressor[15]. Mutant-type p53 (mt-p53) can interfere with intracellular growth factor signaling to promote cell proliferation, suppress apoptosis, and eventually lead to cell transformation and tumor development and progression. In addition, mt-p53 can confer cell resistance to radiotherapy and chemotherapy by inhibiting apoptosis. Therefore, the biological behavior of tumors expressing mt-p53 is worse than that of tumors not expressing mt-p53[16].

Wild-type p53 induces cell differentiation. After transformed cells or cancer cells that do not express wild-type p53 were transfected with wild-type p53, the malignant phenotypes of cells were suppressed, cell growth and division were inhibited, cells were arrested at G1 phase, and *in vivo* tumorigenicity was decreased after inoculation into nude mice. On the other hand, introduction of p53 antisense RNA into the colon cancer cell line SW1116 significantly decreased proliferation rate and blocked cells in G0/1 phase, as revealed by flow cytometry[17].

Wild-type p53 induces apoptosis. After myeloid leukemia cell lines that do not express wild-type p53 were transfected with wild-type p53, typical apoptosis occurred, and cells lost viability. Treatment of tumors with radiation or anticancer agents not only induces DNA damage, blocks DNA metabolism, and leads to necrosis, but also induces apoptosis. The expression of transfected wild-type *p53* gene can increase anticancer treatment-induced apoptosis. In contrast, tumor cells transfected with the *mt-p53* gene or tumor cells not expressing wild-type *p53* gene are resistant to anticancer treatment-induced apoptosis. A study has proved that p53 induces apoptosis *via* the mitochondrial pathway in activated thymocytes[18].

The expression of p53 protein is detectable in almost all types of somatic cells. In normal cells, wild-type p53 protein has a half-life of about 20-30 min and shows little accumulation. Finlay *et al*[19] found that, in actively growing tumor cells, mt-p53 protein, but not wild-type p53 protein, can form a complex with heat shock protein 70. This complex extends the half-life of mt-p53 protein, which significantly increases the accumulation of mt-p53 protein in the nucleus[20]. The *p53* gene is an important tumor suppressor gene, and many human tumors, such as breast cancer, lung cancer, colorectal cancer, and gastric cancer, carry various *p53* gene mutations. High expression of the *mt-p53* gene is often detectable in many types of tumors and transformed cells. This study found that the expression of p53 protein in precancerous lesions (intestinal metaplasia and dysplasia) was higher than that in chronic gastritis.

PCNA was first discovered by Miyachi *et al*[21] in 1978 in the sera of patients with systemic lupus erythematosus. It was named as such because it is only expressed in normal proliferating cells and tumor cells. PCNA is a 36-kDa nuclear protein that is the auxiliary protein of DNA polymerase delta. Two types of nuclear PCNA exist, soluble and insoluble. Soluble PCNA is expressed in various phases of the cell cycle, and its quantity does not change significantly in the process of DNA synthesis. It is susceptible to detergent extraction and destruction by methanol. Insoluble PCNA is more stable and insusceptible to detergent elution and destruction by methanol. No obvious expression of soluble PCNA is detected in G0-Gl phase. However, its expression shows a significant increase in the late Gl phase, peaks in S phase, and decreases significantly in G2-M phase. Since the expression of soluble PCNA correlates well with DNA synthesis, it can be used as a marker for evaluation of cell proliferation. Given that cancer cells have a strong proliferative activity and that PCNA can be used as a cell proliferation marker, many domestic and foreign studies have investigated the relationship between PCNA expression and tumor development, grading, staging, radiation sensitivity, prognosis, recurrence and metastasis, death causes, and tumor markers in a variety of tumor types, and drawn many conclusions, although some of them are still controversial among different studies. In addition, some conclusions were drawn from analyses of one or several tumor types, and it remains to be studied whether they are applicable to all tumor types.

PCNA, as the auxiliary protein of DNA polymerase δ, plays an important role in the regulation of DNA replication and is closely related to the proliferative state of cells. Wu *et al*[22] examined the expression of PCNA in gastric cancer and precancerous lesions and found that the positive rate of PCNA in the cancer group was significantly higher than that in the control group (80.77% *vs* 55.36%, $P < 0.01$), suggesting that high PCNA expression correlates positively with cancerous transformation. These authors therefore believe that cell proliferation activity significantly increases in gastric dysplasia and intestinal metaplasia. In a study of 133 patients with early gastric cancer, Noda *et al*[23] found that high expression of PCNA was significantly associated with a higher rate of lymph node metastasis and a lower 5-year survival rate, indicating that PCNA expression correlates with the degree of tumor differentiation and distant metastasis. PCNA expression was significantly higher in poorly differentiated gastric cancer or gastric cancer with distant metastasis than in well differentiated gastric cancer or gastric cancer without distant metastasis. In this study, we found that PCNA expression showed an upward trend from types A to F pits. The number of cases that showed strong PCNA positivity increased significantly with the increase in the severity of lesions.

In conclusion, this study demonstrates that, compared with ordinary endoscopy, magnifying chromoendoscopy can provide more detailed information about fine mucosal morphology and has a significant advantage in the diagnosis of minute lesions. Magnifying chromoendoscopy in combination with p53 and PCNA detection is particularly helpful for the diagnosis of gastric precancerous lesions. The presence of types E and F pits, in which p53 and PCNA are highly expressed, is highly suggestive of the occurrence of early cancer, and patients developing these changes should be closely followed. If necessary, surgery or endoscopy can be considered.

COMMENTS

Background

Early diagnosis and treatment are important for improving the prognosis of gastric cancer. However, the widespread use of gastroscopy does not significantly improve the detection rate of early gastric cancer. Worldwide efforts are being made to improve the sensitivity of endoscopy in the detection of early cancer and precancerous lesions.

Research frontiers

This study assessed the diagnostic value of magnifying chromoendoscopy combined with detection of proliferating cell nuclear antigen (PCNA) and p53 in the detection of gastric precancerous lesions.

Innovations and breakthroughs

Compared with ordinary endoscopy, magnifying chromoendoscopy can provide more detailed information about fine mucosal morphology and has a significant advantage in the diagnosis of minute lesions.

Applications

Magnifying chromoendoscopy is better than ordinary endoscopy; it can provide more information about mucosal morphology and has a significant advantage in

the diagnosis of minute lesions. Magnifying chromoendoscopy in combination with p53 and PCNA detection is particularly helpful for the diagnosis of gastric precancerous lesions.

Peer review

An interesting manuscript assessing the diagnostic value of magnifying chromoendoscopy combined with detection of PCNA and p53 in gastric precancerous lesions to increase the detection rate of early gastric cancer.

Abstract

Endoscopic epinephrine injection is relatively easy, quick and inexpensive. Furthermore, it has a low rate of complications, and it is widely used for the management of nonvariceal upper gastrointestinal bleeding. There have been several case reports of gastric ischemia after endoscopic injection therapy. Inadvertent intra-arterial injection may result in either spasm or thrombosis, leading to subsequent tissue ischemia or necrosis, although the stomach has a rich vascular supply and the vascular reserve of the intramural anastomosis. In addition to endoscopic injection therapy, smoking, hypertension and atherosclerosis are risk factors of gastric ischemia. We report a case of gastric ischemia after submucosal epinephrine injection in a 51-year-old woman with hypertension and liver cirrhosis.

Gastric ischemia after epinephrine injection in a patient with liver cirrhosis. *World J Gastroenterol* 2013; 19(3): 411-414 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/411.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.411

INTRODUCTION

Acute gastric ischemia rarely occurs due to the rich vascular supply of the stomach and the vascular reserve of the intramural anastomosis[1]. Therefore, there have been few case reports of gastric ischemia worldwide[2,3]. In the rare cases that have been reported, the risk factors for gastric ischemia were smoking, hypertension, atherosclerosis and endoscopic injection therapy[3]. Endoscopic epinephrine injection is a widely used therapy for the management of nonvariceal gastrointestinal bleeding, and it promotes initial hemostasis to stop the bleeding[4].

We report a case of gastric ischemia and necrosis after endoscopic epinephrine injection at the site of the lesion of a biopsy in a patient with liver cirrhosis and hypertension

CASE REPORT

A 51-year-old woman with hypertension and liver cirrhosis was admitted with hematemesis and hematochezia. One day prior to admission, an upper gastrointestinal endoscopy was performed, revealing an elevated lesion with a central depression of the gastric antrum. A variceal lesion was not observed. She underwent an endoscopic biopsy of the lesion of the antrum (Figure 1A), and submucosal injection was performed with a 1:10 000 solution of epinephrine due to bleeding after the endoscopic biopsy. Injection boluses of 2 mL were used for a total of 6 mL. The patient returned home safely after hemostasis. However, she presented to the emergency

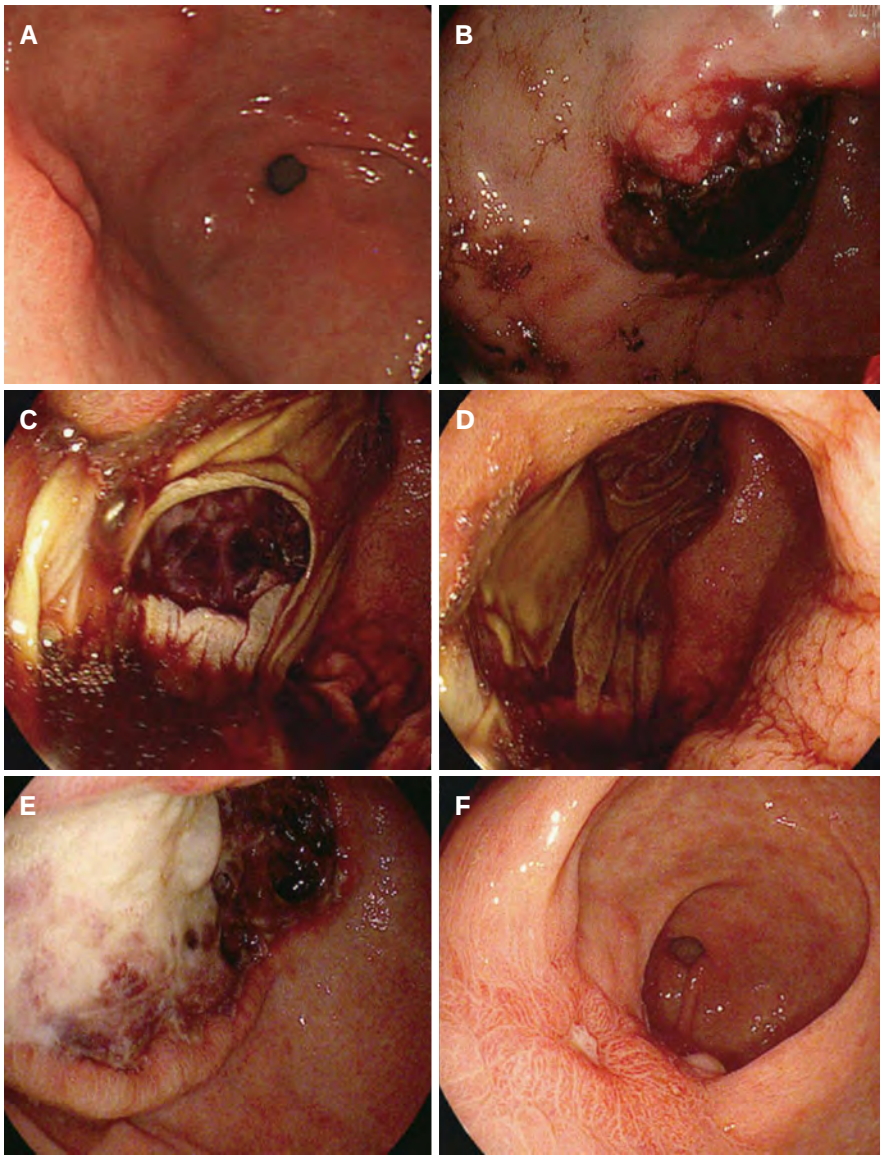

Figure 1 Upper gastrointestinal endoscopy. A: Mucosal elevated lesion with a central depression of the gastric antrum anterior wall. We took an endoscopic biopsy of the elevated lesion; B: Endoscopy revealed the oozing bleeding covered by a hemorrhagic clot in the distal antrum after the endoscopic biopsy. We tried the hemostasis by submucosal injection of a 1:10 000 solution of epinephrine; C: Mucosal dissection with extensive ulcerated; D: Necrotic areas from the distal to the proximal antrum. We did the conservative treatment with proton pump inhibitor, wide spectrum antibiotics and parenteral nutrition; E: Three days after the conservative treatment, a large extensive ulcer with fibrinous and hemorrhagic exudates surrounded by a clear elevated margin. The conservative care was continued; F: Two months later, the decreased size of the ulcer was surrounded by regenerative epithelia with a clear margin.

department reporting massive hematemesis and hematochezia the next day.

In the emergency room, she was in a severe distress with a heart rate of 90 beats/min, an arterial blood pressure of 100/70 mmHg and a respiratory rate of 20 breaths/min. Her abdomen was tender to palpation without guarding. A digital rectal examination was positive for bloody stools. The chest X-ray film and electrocardiogram were normal, as was the plain film of the abdomen. A complete blood count revealed anemia (hemoglobin level, 10.4 g/100 mL; hematocrit level, 29.7%) leukopenia (2360 cells/mm^3 with 56.3% polymorphonuclear cells) and thrombocytopenia (53 000 cells/mm^3). The Child-Pugh classification was A with a mildly prolonged prothrombin time of 14.4 s and hypoalbuminemia (3.0 g/dL). The upper endoscopy revealed oozing bleeding on the site of a previous biopsy, and the lesion was covered by a hemorrhagic clot (Figure 1B). We considered hemoclipping at first, but it was difficult to target the site of clipping because the hemorrhagic clot blocked our view, although vigorous irrigation and precise vessel exposure were not observed. Therefore, we again attempted hemostasis by submucosal injection of a 1:10 000 solution of epinephrine (a total dose of 8 mL). We were not concerned that epinephrine injection would result in gastric ischemia or necrosis at that time. Two days later, the patient presented with severe epigastric pain and melena. The hemoglobin level was 7.7 g/dL. An upper endoscopy

was performed. The endoscopy revealed a mucosal dissection with extensive ulcerated and necrotic areas from the distal to the proximal antrum (Figure 1C and D). We believed that this condition represented mucosal necrosis and severe ischemia. Emergency abdominal computed tomography ruled out arterial thrombosis and perforation, and it revealed an edematous mural thickening with mild mucosal enhancement in the antrum of the stomach. We decided to use conservative treatment because the signs of perforation or sepsis were not observed and the patient had underlying liver cirrhosis. The patient was treated with proton pump inhibitor perfusion, wide spectrum antibiotics and parenteral nutrition. Three days later, endoscopy was performed again to identify changes in the lesion. Endoscopy showed a large extensive ulcer with fibrinous and hemorrhagic exudates surrounded by a clear elevated margin (Figure 1E). We thought that the ischemic ulcer was in a healing state, and conservative care was continued. Her condition was gradually improved, and there was no sign of bleeding. A liquid diet was started, and the patient was discharged from the hospital after 2 wk. A follow-up endoscopy 2 mo later showed the decreased size of the ulcer surrounded by regenerative epithelia with a clear margin (Figure 1F).

DISCUSSION

The rich blood supply of the stomach protects the stomach from ischemia and necrosis[1]. Acute gastric ischemia, an emergency condition associated with high mortality, is rare[3]. Possible risk factors of gastric ischemia include smoking, hypertensive and atherosclerotic vascular disease, trauma, infection, and epinephrine injection[3]. We performed epinephrine injection to control the bleeding after a biopsy. Most cases of post-biopsy bleeding stop on their own without endoscopic therapy. However, we performed the injection therapy because of underlying cirrhosis and the strength of the injection procedure. Injection of epinephrine is effective for controlling upper gastrointestinal bleeding[5]. This technique is relatively easy, quick, and inexpensive. The complication rate associated with epinephrine injection was minimal[2].

However, a few cases have been reported of ischemic necrosis of the stomach and/or duodenum after injection of epinephrine (with or without a sclerosant) to control ulcer bleeding[2,4]. There are multiple mechanisms of action invoked to explain the efficacy of epinephrine, including vasoconstriction, a vascular tamponade effect, and enhanced platelet aggregation[5]. We postulated that gastric ischemia in this case resulted from the injection of a 1:10 000 solution of epinephrine as a vasoconstrictive drug. First, the epinephrine injection might have caused vascular contraction and opening of the intramural arteriovenous shunts, which could have contributed to gastric ischemia. Second, direct mechanical distress of the gastric artery caused by the needle followed by immediate obliteration of the arterial lumen was most likely the cause of the ischemia. The double injection of epinephrine most likely aggravated the gastric ischemia in this patient. Furthermore, morphological alterations in the gastric microcirculation in cirrhosis might be the cause of ischemia. One study reported that increased arteriovenous anastomoses in the gastric wall were related to the occurrence of acute gastric mucosal lesions in patients with liver cirrhosis[6]. Another study showed arteriovenous anastomoses of 50% in the gastric wall and a straight pattern of the arterioles with dilation of the precapillaries, capillaries, and submucosal and subserosal veins in cirrhotic patients, although the sample size was small[7]. In addition, the long-term history of hypertension, might have caused atherosclerotic vascular changes. Therefore, the abnormal mucosal structure resulting from liver cirrhosis and hypertension was an important risk factor, in addition to the injection of epinephrine, for gastric ischemia in this patient.

Clinically, gastric infarction presents as an acute abdominal emergency with diarrhea or hematemesis that rapidly progresses to acute peritonitis, irreversible septic shock, and death if untreated[8]. The treatment of acute necrotizing ischemic gastritis is emergency laparotomy with resection when necessary. In most cases, gastric ischemic necrosis has been treated with surgery[3,4,9]. In our case, the patient was only treated with conservative therapy with total parenteral nutrition, intravenous antibiotics, and a proton pump inhibitor. The results of this conservative treatment were favorable.

This is first report of the occurrence of gastric ischemia after epinephrine injection in a patient with liver cirrhosis. We report a case of fatal gastric ischemia and postulate that accidental intra-arterial injection may be responsible for this event. Inadvertent intra-arterial injection may result in either spasm or thrombosis and lead to subsequent tissue ischemia or necrosis, and underlying liver cirrhosis might influence this rare complication. Therefore, we should pay more attention to the risk of bleeding in underlying vascular disease or cirrhosis during endoscopic hemostasis.

Abstract

Primary abdominoaortic fistula is an extremely rare cause of upper gastrointestinal (GI) bleeding. The diagnosis is frequently delayed due to the rarity of the disease and low index of suspicion by physicians. A range of invasive and non-invasive diagnostic tools are available, but helical computer tomography (CT) remains the mainstay. Surgery offers the only hope for survival. This case report presents a 47-year-old male with massive upper GI bleeding. Various diagnostic tests and an exploratory laparotomy failed to identify the diagnosis. Later, a primary aortoduodenal fistula was confirmed by CT scan which necessitated surgical repair of the fistula and a Goretex graft for the abdominal aortic aneurysm. The patient made an uneventful recovery and remained well to the first postoperative visit in the clinic 2 wk after surgery.

INTRODUCTION

Primary aortoduodenal fistula (PADF) is a rare, challenging complication of abdominal aortic aneurysm (AAA). PADF is an abnormal communication between the infrarenal aorta and duodenum, whereas secondary aortoduodenal fistula usually results from a previously implanted endovascular stent-graft procedure[1]. Since their first description about 100 years ago, more than 200 PADFs have been reported in the world literature[2-4]. They are usually found between the 3rd part of the duodenum and infrarenal aorta, caused by evolutionary complication of an aortic aneurysm[5]. Although less frequent, this abnormal communication also occurs between the aorta and other parts of the gastrointestinal (GI) tract, namely the esophagus, jejunum, ileum, or colon. The rarity of PADFs poses major diagnostic and therapeutic difficulties to the treating physicians.

The present case report describes a PADF between the infrarenal AAA and fourth part of the duodenum, which was successfully managed at King Khalid Hospital, Najran, Saudi Arabia.

CASE REPORT

A 47-year-old Saudi male presented to the emergency room of King Khalid Hospital Najran, Saudi Arabia with a 6-h history of massive fresh upper GI bleeding. He was a heavy smoker with no notable medical history. On examination, he had normal sensorium, pulse 113 beats/min, blood pressure 90/70 mmHg, and a cold sweaty skin. The laboratory investigations showed hemoglobin (Hb) 9.3 g/dL, white cell count 7100/mm^3, while electrolytes, renal and coagulation profiles, serum amylase and liver function testes were normal. The abdominal examination was unremarkable except for tenderness in the epigastrium. After initial resuscitation,

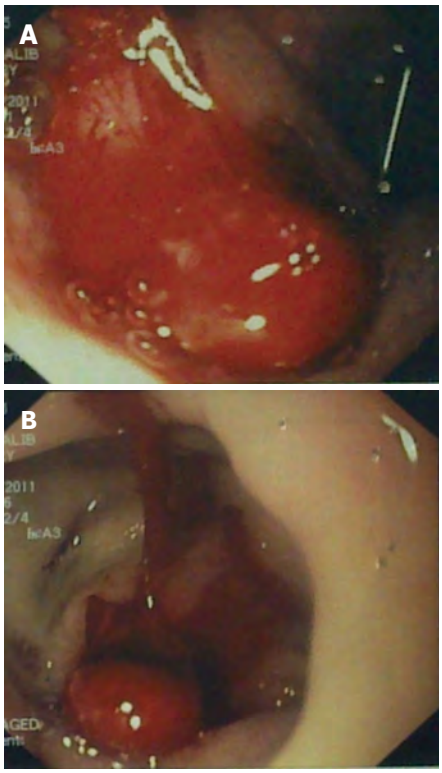

Figure 1 Endoscopic views of the stomach (A) and duodenum (B) showing a huge amount of fresh blood emerging from a concealed source.

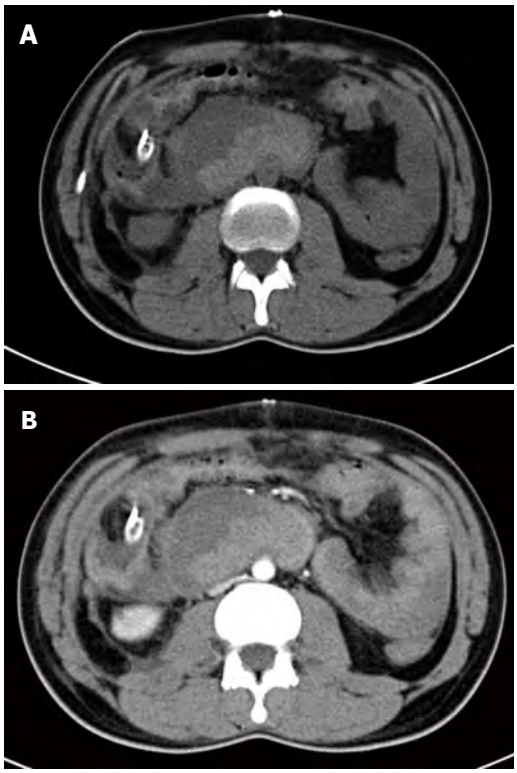

Figure 2 Computer tomography scan showing a primary aortoduodenal fistula between the infrarenal aorta and 4th part of the duodenum. A: Computer tomography (CT) scan without contrast showing a ruptured aortic aneurysm; B: Arterial phase of the CT scan showing the partially thrombosed abdominal aortic aneurysm.

upper GI endoscopy was performed and showed a huge amount of fresh blood emanating from the duodenum (Figure 1). No definite source of the bleeding could be identified. The patient was admitted in the intensive care unit, where, despite massive blood transfusion and active fluid resuscitation, the patient remained hemodynamically unstable, fresh bleeding continued in the nasogastric tube, and Hb dropped to 6.7 g/dL. On the 2nd post-admission day, the responsible consultant surgeon performed an exploratory laparotomy which revealed a distended duodenum and no blood in the peritoneum. A duodenotomy was performed which drained fresh and clotted blood, but no active source of the bleeding could be delineated. Perioperative upper GI endoscopy could not provide any additional information. Duodenotomy was closed over a tube drain followed by mass closure of the abdomen. Postoperatively, the patient continued to have fresh bleeding in the nasogastric tube. A computer tomography (CT) scan at that stage showed a PADF between the infrarenal aorta and fourth part of the duodenum (Figure 2). The vascular team was consulted and a second exploratory laparotomy was undertaken where the AAA was repaired with a prosthetic Goretex tube graft, and the duodenal fistula was closed in two layers. An omentopexy was performed between the aorta-graft anastomosis and duodenum. The culture and sensitivity report of the aortic wall reported the growth of *Klebsiella*. The patient made an uneventful recovery and was discharged home in a stable condition. His first follow-up visit in the surgical outpatient clinic, 2 wk after discharge, showed normal parameters.

DISCUSSION

The term PADF was first coined by Cooper[6], and the first case report was described by Salman[7]. The incidence of primary aorto-enteric fistulas is very low and, according to autopsy findings, ranges between 0.04% and 0.07%[8]. Up to December 2006, 366 cases of primary aorto-enteric fistulae have been reported[9]. Regarding the anatomical distribution, the 3rd part of the duodenum is involved in two-thirds of cases while the 4th part is affected in one-third of cases. Because of the close approximation and fixed nature of the duodenum, the expanding nature of the AAA causes irritation and inflammation, resulting in eventual fistulization over the passage of time.

The proposed mechanisms for the development of PADF are direct wear and inflammatory destruction triggered by infection, foreign bodies, or erosion[5]. Eighty percent of PADFs have been estimated to arise from an AAA. Gad reported 73% of PADFs developed from atherosclerotic aneurysms and 26% from traumatic or mycotic aneurysms[10]. The remaining 1% are caused by radiation, pancreatic carcinoma, metastases, ulcers, gallstones, diverticulitis, and appendicitis. The classical presentations

of PADFs are upper GI bleeding (64%), abdominal pain (32%), and a pulsatile abdominal mass (25%)[11,12]. Other rare symptoms include intermittent back pain, fever, and sepsis, melena, and syncope. Quite frequently an expansile abdominal mass and a bruit is noticed on abdominal examination.

The most valuable diagnostic tool for the diagnosis of PADF is considered to be helical CT scan with intravenous contrast[13]. Rapid scanning, high resolution, non-invasive procedure, image quality, and data processing are the outright benefits of CT scanning. Loss of the aneurysmal wall, air in the retroperitoneum or thrombus, or destruction of the fat plane between the aneurysm and duodenum strongly suggest a PADF. In addition, visualization of the contrast within the GI tract is a striking CT finding. Other diagnostic modalities include upper GI endoscopy and angiography. Endoscopy is useful in diagnosing upper GI bleeding, although a negative report does not exclude the possibility of a PADF. The visualization of the fistula below the 3rd part of the duodenum is quite difficult due to acute angulation between 3rd and 4th parts of the duodenum[12]. Angiography is not reliable in diagnosing PADF. In a retrospective study, 13 out of 36 aorto-enteric fistulas were diagnosed by angiography before surgery[14]. Magnetic resonance imaging, tagged white blood cell scans, colonoscopy, and ultrasound are of limited value[15].

The mortality from untreated PADF is almost 100%. The survival after surgery ranges from 18% to 93%[16]. The recommended surgical procedure consists of closure of the duodenal fistula, aortic ligation to exclude the aneurysm, and an extraluminal bypass. In the case of an infected AAA, antibiotics should be given for 4-6 wk after surgery, if a positive culture is obtained[17]. The most commonly encountered cultured organisms in primary mycotic PADF are *Salmonella* and *Klebsiella*. In our case, third generation cephalosporins were administered for 1 mo with promising results.

To conclude, PADF are an extremely uncommon cause of massive upper GI bleeding and abdominal mass. A CT scan is the gold standard for diagnosis of this entity, and surgical intervention offers the only treatment for survival.

Abstract

We report a case of metachronous multiple primary malignancies involving both rectum and liver with colonic metastasis from hepatocellular carcinoma (HCC) through hematogenous pathway. A 72-year-old woman was admitted to the emergency department with right upper abdominal pain for 4 h. Considering her surgical history of Mile's procedure plus liver resection for rectal cancer with liver metastasis three years ago and the finding of urgent computed tomography scan on admission, the preoperative diagnosis was spontaneous rupture of rectal liver metastasis located in caudate lobe and colonic metastasis from rectal cancer. The patient underwent an emergency isolated caudate lobectomy at a hemorrhagic shock status. Pathology reported a primary HCC in the caudate lobe and colonic metastasis of HCC with tumor embolus in the surrounding vessels of the intestine. No regional lymph node involvement was found. It is hypothesized that HCC may disseminate hematogenously to the ascending colon, thus making it a rare case.

INTRODUCTION

The caudate lobe of the liver is located deep in the hepatic parenchyma and surrounded by some major vessels. Because of its surgically difficult-to- approach anatomic location and perception of early involvement of the inferior vena cava (IVC) or portal vein by tumors, caudate lobectomy was once used infrequently. With more precise anatomical knowledge, development of surgical technique, and improvement in perioperative care, it has become more common recently. But in order to succeed in the procedure, the optimal operative approach should be planned and determined carefully before operation. Emergency isolated caudate lobectomy was rarely reported worldwide, especially for the ruptured primary hepatocellular carcinoma (HCC). The incidence of colorectal cancers has increased in recent years. As the overall survival rate has improved due to the development of multiple therapies, it is not surprising to see more patients with multiple primary malignancies involving the colorectum and other organs. For colorectal cancer, stomach was the most common extracolonic site of both the synchronous and metachronous multiple primary malignancies, but liver is very rarely involved. Extrahepatic metastasis of HCC occurs occasionally and increases with prolonged survival. However, HCC with gastrointestinal (GI) tract metastasis is seldom reported, and it is only found in less than 6% of the cases in autopsy series. GI metastasis through hematogenous pathway is especially rare.

CASE REPORT

A 72-year-old woman was admitted with right upper abdominal pain. The pain started in the epigastrium. A few hours before admission, the pain disseminated to the upper right abdominal quadrant and right back region and became severe.

The patient had a previous history of rectal adenocarcinoma with liver metastasis. Three years earlier she underwent the Miles procedure and partial hepatectomy. Following the operation, she received combined chemotherapy with 5-fluorouracil, folinic acid and oxaliplatin. Six months ago, computerized tomography (CT) scan of the abdomen showed a 5 cm × 5 cm × 5 cm, diverticulum like, exophytic mass located in the ascending colon near the ileocecus, without lymph node enlargement. It was considered a metastasis of rectal cancer. The mass showed no obvious response to systemic adjuvant chemotherapy.

On admission, her temperature was 36.9 ℃, pulse was 112 beats/min and blood pressure was 90/50 mmHg. The oxygen saturation was 95% while the patient was breathing ambient air. On physical examination, the patient was ill-looking, conscious with skin and conjunctival pallor. The abdomen was distended, and bowel sounds were absent. There was tenderness in the right upper abdominal quadrant, with guarding and rebound tenderness. Lungs and heart sounds were normal.

Her blood work-up on admission showed a hemoglobin level of 6.8 g/L, white cell count of 8.9 × 10^9/L and neutrophils of 72%. Coagulation tests, liver function, renal function and electrolytes were all within the normal range. Urgent CT scan of the abdomen showed multiple masses localized in the liver, a 6 cm × 6 cm × 6 cm mass in the caudate lobe of the liver (Couinaud's segment 1), and signs of abdominal haemorrhage (Figure 1). The preoperative diagnoses were hemorrhagic shock, spontaneous rupture of rectal liver metastasis, colonic metastasis of rectal cancer or multiple primary cancers.

Hemodynamic stability was achieved following rehydration with intravenous fluid and multiple blood transfusions. At the same time, the patient was promptly sent to the operating room. Open exploratory laparotomy was performed *via* a J-shaped skin incision, with more than 2 liters of blood and clots and intra-abdominal adhesions due to the last operation visualized in the peritoneum. Inspection of the liver revealed a ruptured mass of 6 cm × 6 cm × 6 cm in the hepatic segment I with active bleeding. A 5 cm × 5 cm × 5 cm erosive tumor lesion was localized in the beginning of the ascending colon and nearly occupied the whole lumen. Isolated caudate lobectomy was performed *via* bilateral approach, in addition to the resection of ileocecum. The operation time was 290 min and blood loss was 2000 mL. Ten units of packed red blood cells and 2000 mL of fresh frozen plasma were transfused during the perioperative period. Histological examination demonstrated a primary HCC located in the caudate lobe and a colonic metastasis of HCC with tumor embolus in the surrounding vessels of the intestine (Figure 2). No regional lymph node metastasis was found. Immunohistochemical findings revealed that polyclonal alpha fetoprotein and hepatocyte antigen were positive and carcinombryonic antigen was negative. The patient made a full recovery from the surgery and was subsequently discharged 10 d after admission. Eight months later, the patient died of cachexia.

DISCUSSION

The caudate lobe of the liver is located deep in the hepatic parenchyma behind both major lobes and between the confluence of the three main hepatic veins, IVC, and hepatic hilum. It is generally divided into three parts, as described by Kumon: the left Spiegel lobe (Couinaud's segment 1), the caudate process, and the paracaval portion (Couinaud's segment 9). Because of its surgically difficult-to-approach anatomic location and perception of early involvement of the IVC or portal vein by tumors, caudate lobectomy was once called a forbidden zone of hepatic surgery and not performed frequently until it was first described by Lerut. In the early days, patients underwent resection of the caudate lobe along with removal of adjacent portions of the liver, i.e., right or left lobectomy, in order to get a better exposure. But for patients who concurrently had chronic liver disease, removal of too much normal hepatic parenchyma would delay recovery or even cause liver failure. With more precise anatomical knowledge, development of surgical technique, and improvement in perioperative care, isolated caudate lobectomy[1] has become common recently. Nevertheless, clinical assessment should be conducted strictly before operative period[2]. Laboratory investigations, including tests of complete blood count, coagulation, liver function, renal function, electrolytes, indocyanine green retention rate at 15 min, and virology, should be carried out to evaluate the patient's surgical fitness; and radiological studies, including ultrasonography, CT scan, and three dimensional reconstructive CT, should be undertaken to evaluate the hepatic lobe size, extent and location of the tumor, vascular involvement, lymph node affection, and the severity

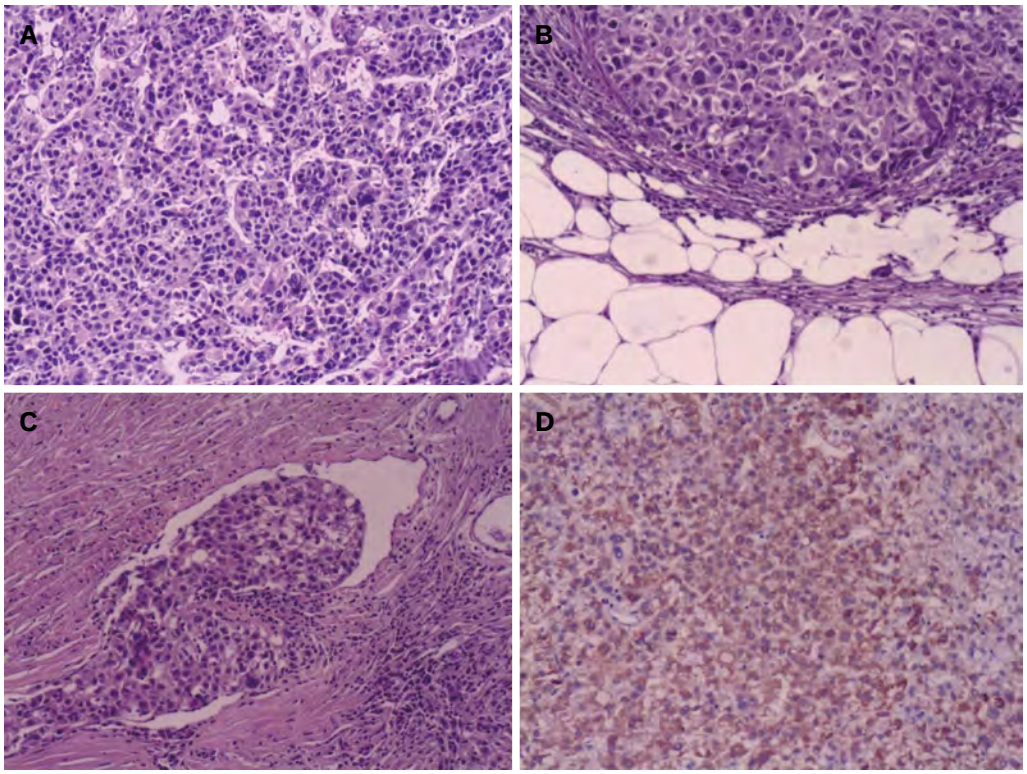

Figure 2 Histopathology. A: Hepatocellular carcinoma (HCC) located in the caudate lobe [hematoxylin and eosin (HE), ×100]; B: Colonic metastasis of HCC (HE, × 100); C: Cancer embolus in the vessels surrounding the intestine (HE, ×100); D: Polyclonal hepatocyte antigen was positive by immunohistochemistry, ×100.

of cirrhosis, and to rule out intra-abdominal metastasis. The most appropriate operative procedure should be planned and determined preoperatively[3]. Consequently, emergency isolated caudate lobectomy was rarely reported worldwide, especially for the ruptured primary HCC. For these patients, routine treatments included compression and packing hemostasis, transcatheter arterial chemoembolization (TACE), and partial hepatectomy. Because the caudate lobe requires the arterial blood supply from the two major lobes of the liver, TACE cannot achieve the goal of hemostasis. The necrotic tumor tissue and important vessels surrounding the caudate lobe also affect the compression and packing hemostasis. As a result, emergency isolated caudate lobectomy is considered to be the best choice for these patients. There are four approaches for the resection of the caudate lobe of the liver, left side approach, right side approach[4], bilateral approach, and anterior transhepatic approach by splitting parenchyma of the liver. The approach to the caudate lobe depends on the location of the tumor and the expertise of the surgeon. Hepatic surgery is a very bloody procedure, especially the caudate lobectomy, because of the unique anatomical relationship between the caudate lobe and IVC and the portal triad. Vascular control combined with positioning and central venous pressure control is recommended to minimize intraoperative blood loss. Full mobilization of liver is indicated before the dissection of the caudate lobe. Dividing the fibrous retrocaval ligament is extremely important in fully mobilizing the caudate lobe to expose the hepatic veins along the anterior surface of the IVC. Once the left lateral edge of the caudate lobe is free, ligation of the short hepatic veins draining directly into IVC is performed. Our patient underwent a partial hepatectomy three years ago for rectal liver metastasis resulting in complicated intra-abdominal adhesions, which further increased the difficulties of the operative procedure[5]. Likewise, the pathophysiological changes of hemorrhagic shock also make it more difficult to keep the stability of the haemodynamics of the patient.

Considering the history of rectal cancer three years ago in this case, the preoperative diagnosis was spontaneous rupture of rectal liver metastasis and colonic metastasis of rectal cancer. But histological examination demonstrated a primary HCC located in the caudate lobe and a colonic metastasis of HCC. Multiple primary cancers are relatively rare[6]. The overall incidence rate is between 0.73% and 11.7%. However, more multiple primary cancers have been encountered due to an increase in the number of elderly patients and advancement in diagnostic techniques. In addition, cancer patients are assumed to be at an increased risk of developing cancers in other organs due to genetic alterations or exposure to the same environmental carcinogens[7]. It is generally defined according to the criteria of Warren and Gates: (1) each tumor must be clearly malignant on histologic examination; (2) each tumor must be distinct; and (3) the possibility that the second tumor represents a metastasis must be excluded. Multiple primary cancers can be synchronous or metachronous depending on the interval between their diagnosis. Synchronous malignancies are secondary

cancers occurring simultaneously or within 6 mo after the diagnosis of primary cancers, while metachronous malignancies are secondary cancers that developed more than 6 mo after the diagnosis of primary cancers. The incidence of colorectal cancers has increased in recent years. As the overall survival rate has improved due to the development of multiple therapies, it is not surprising to see more patients with multiple primary malignancies involving the colorectum and other organs[8]. For colorectal cancer, stomach is the most common extracolonic site of the synchronous multiple primary cancers. The thyroid gland is the second organ involved. The stomach is also the most common extracolonic site of the metachronous multiple primary malignancies, followed by the cervix, lung, and skin. The metachronous multiple primary malignancies involving both rectum and liver are very rare. Although the mechanisms underlying the development of multiple primary cancers are not fully understood, some factors such as sustaining environmental carcinogens, susceptibility to carcinogen, cancer cell immunodeficiency, and immunosuppression caused by radiotherapy and chemotherapy have been implicated. Under these circumstances, it is expected that as people live longer, they have more chances to develop multiple primary malignancies. The prognosis of the patients with multiple primary cancers can be predicted independently by the stage of each tumor.

HCC is one of the most common malignancies worldwide[9]. Extrahepatic metastasis of HCC occurs occasionally and increases with prolonged survival. The most frequent sites of metastasis are lungs, bones, regional lymph nodes, and adrenal glands. However, HCC with GI tract metastasis is very rare, being found in only less than 6% of cases in autopsy series[10]. The metastasis sites only reported in some case reports included duodenum, stomach, colon and jejunum. The major pathway of the metastasis is direct invasion to the contiguous GI tract via adhesion to the serosal side by a bulky tumor mass. However, the frequency of metastatic colon cancer arising from HCC is low. In this case, the solitary metastasis from HCC appeared in ileocecus, separated from other liver tissues. The mode of the metastasis to the colon is still unclear. It is hypothesized that HCC may disseminate hematogenously to the distant GI tracts. Tumor embolus in the vessels surrounding the intestine may be the key evidence of hematogenous metastasis. Absence of regional lymph node metastasis may indicate low possibility of lymphatic metastasis. The prognosis of GI metastasis from HCC is known to be poor with a median survival period of seven months.

In conclusion, we report a rare case of metachronous multiple primary malignancies involving both rectum and liver with colonic metastasis through hematogenous pathway. This patient was manifested by spontaneous rupture of HCC located in the caudate lobe, and underwent an emergency isolated caudate lobectomy, with a full recovery after surgery.

Abstract

Histiocytic sarcoma (HS) is a rare malignant neoplasm that originates from a histiocytic hematopoietic lineage characterized by histiocytic differentiation and its corresponding immunophenotypic features. We herein reported a case of primary HS of the stomach which was confirmed through histopathologic examination and immunohistochemical staining. A 52-year-old woman presented with progressive difficulty in feeding and dull pain in the epigastric region. Gastroscopy, endoscopic ultrasonography, double contrast examination, and computed tomography revealed a mass located on the posterior wall of fundus and lesser curvature of the stomach. Microscopically, the cytoplasm of the tumor cells was abundant and eosinophilic. Immunohistochemical staining revealed that the tumor cells were positive for CD45RO and CD68. It is difficult to differentiate HS of stomach from other gastric malignancies by radiological evaluation alone. However, HS may be considered when a protruding and ulcerated mass in stomach shows heterogeneous hypervascular features. To the best of our knowledge, this is the first report in English language literature that emphasizes the imaging findings of human gastric HS.

INTRODUCTION

Histiocytic sarcoma (HS) is an exceedingly rare lymphohematopoietic malignant neoplasm composed of tumor cells showing morphologic and immunophenotypic features of mature histiocytes[1,2]. Most patients are adults (median age 46 years). Male predilection is found in some studies. About one-third of cases present in lymph nodes, about one-third in skin, and about one-third in a variety of other extranodal sites, most commonly the intestinal tract[3].

HS of the stomach is extremely rare and it has rarely been described in the English literature[3,4]. The imaging findings of gastric HS are not well known. Thus, it is still indistinguishable from other gastric neoplasms both clinically and radiographically[5]. To the best of our knowledge, only ten cases of gastric HS have been reported in the international medical literature[3-8].

We report herein a case of primary HS of the stomach with an emphasis on the imaging findings of endoscopic ultrasonography (EUS), gastroscope, double contrast examination, and computed tomography (CT).

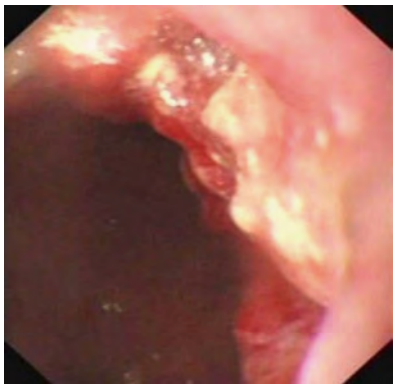

Figure 1 Gastroscopic examination revealed a large irregular ulcer with apophysis and erosive hemorrhage located on the posterior wall of fundus and lesser curvature.

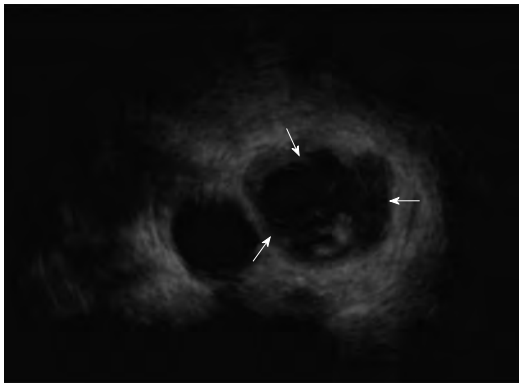

Figure 2 Endoscopic ultrasonography showed thickening about the semi-perimeter of the gastric fundal mucosa and a heterogenous hypoechoic mass, the whole layer of the local wall involved (arrows).

CASE REPORT

A 52-year-old woman presented with a one-month history of progressive difficulty in feeding and dull pain in the epigastric region for 3 d, without haematemesis or black dejection. At physical examination, she was slightly tender in the middle of the upper abdomen, without abdominal distension. There was no history of previous known stomach disease.

Gastroscopic examination revealed a large irregular ulcer with apophysis and erosive hemorrhage located on the posterior wall of fundus and lesser curvature of the stomach (Figure 1).

EUS detected thickening about the semi-perimeter of the gastric fundal mucosa, and a heterogenous hypoechoic mass, and the whole layer of the local gastric wall was infiltrated (Figure 2).

The upper digestive pneumobarium double imaging demonstrated a filling defect and a shadow of soft tissue mass around the cardia and lesser curvature of the stomach, and the abdominal part of esophagus was involved. There was destruction of the mucosa, rigidity of the gastric wall, and intracavitary niches in the lesion area (Figure 3).

Plain and contrast-enhanced CT scans of the abdomen showed a focal irregular thickened gastric wall and a poorly marginated, ulcerated soft tissue mass formation with heterogeneously obvious enhancement in the lesser gastric curvature and fundus area (Figure 4). Swelling of the adjacent regional lymph nodes was also found.

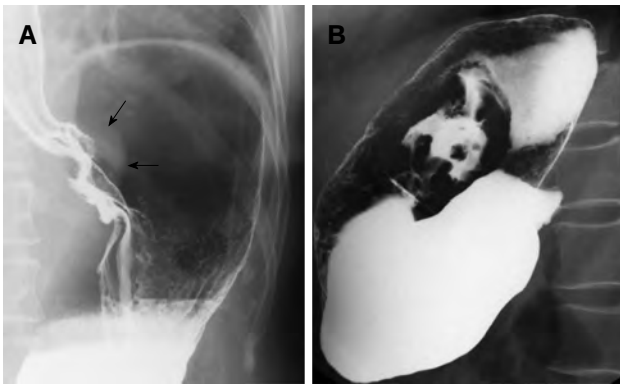

Figure 3 Double contrast examination demonstrated the shadow of soft tissue mass around the cardia and lesser curvature of stomach (arrows) (A), and **filling defect, intracavitary niches, destruction of mucosa, as well as rigidity of** the local wall were seen (B). The abdominal part of esophagus was involved.

Radical total gastrectomy was performed, and a 7 cm × 6 cm irregularly protruded tumor in the gastric curvature and fundus with the distal esophagus involved was found during the operation, associated with enlargement of the 9th and 11th groups of perigastric lymph nodes.

The surgical specimens were sent to histopathologic examination. The greater omentum did not show any tumor invasion, and tumor metastasis was not found in any of the 22 examined perigastric lymph nodes. The tumors showed infiltrative borders and areas of ulceration, with invasion into the serosa. The tumor cells were monomorphic to pleomorphic in shape. The cytoplasm was abundant and eosinophilic. The nuclei were large, and round to oval. Bizarre multinuclear giant cells were scattered. Immunohistochemical analysis indicated that the tumor cells expressed CD68, CD45RO, CD31 and Cyclin D1, and approximately 90% of the cells stained for Ki-67, but Bcl-2, Bcl-6, CD10, CD23, CD35, CD56, EMA, CK, Mum-1 and Pax-5 were negative (Figure 5). The histological and immunohistochemical diagnosis for the malignant tumor of the stomach was histiocytic sarcoma.

The patient received three cycles of chemotherapy after radical surgery. She has been free of recurrence or metastasis for 4 mo.

DISCUSSION

Histiocytic sarcoma, also known as true histiocytic lymphoma, is an exceedingly rare lymphohematopoietic malignant neoplasm composed of tumor cells showing morphologic and immunophenotypic features of mature histiocytes[2]. These malignant tumors most commonly present in lymph nodes or at extranodal sites, such as the gastrointestinal (GI) system, bone marrow and skin. The vast majority of GI HS are located in the intestinal tract; only few cases are found in the stomach. Hornick *et al*[3]

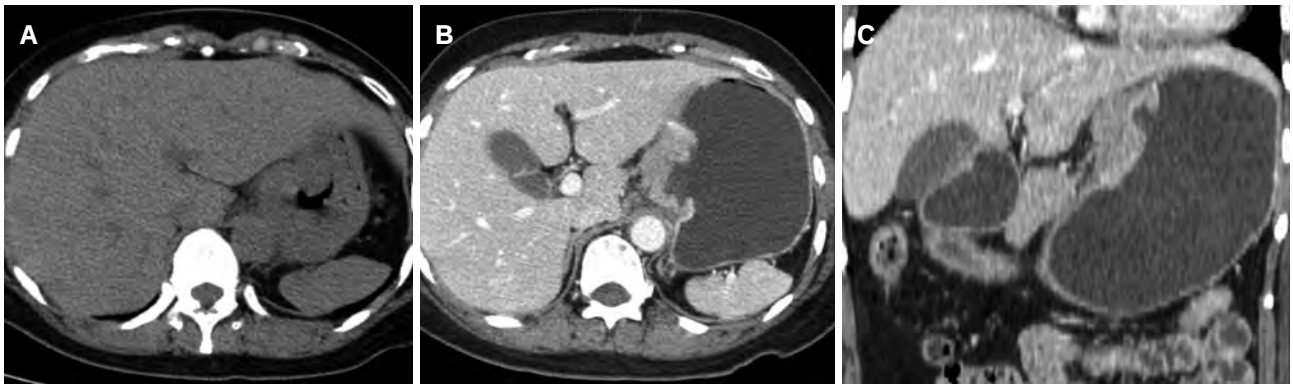

Figure 4 Abdominal computed tomography scan showed focal irregular thickened gastric wall and a ulcerated soft tissue mass formation with heterogeneously obvious enhancement in the lesser gastric curvature and fundus area. A: Plain scan; B: Contrast-enhanced scan; C: Coronal multiplanar reconstruction of enhancement scan.

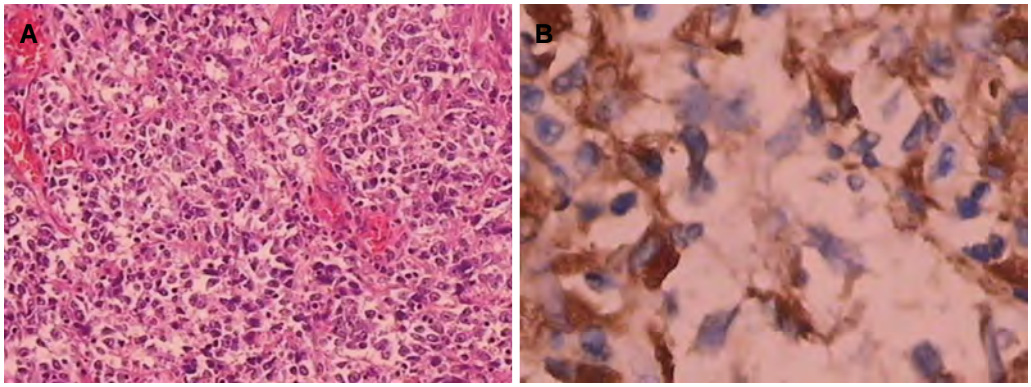

Figure 5 Histopathologic exam showed the tumor cells were marked inequality in the sizes, the cytoplasm was abundant and eosinophilic, the nuclei were large, round to oval, bizarre multinuclear giant cells were scattered. The tumor cells expressed CD68. A: Hematoxylin and eosin ×100; B: Immunohistochemical staining for CD68 ×400.

and Copie-Bergman *et al*[4] once described 14 cases of extranodal HS and 13 cases of true histiocytic lymphomas, respectively; among these cases, a total of 12 lesions in 11 patients were located in the GI tract, but only one lesion arose in the stomach. Gastric HS can be located anywhere in the stomach: the cardia, the fundus, the antrum, the lesser curvature, or the greater curvature, but most arise in the lesser curvature and involve the adjacent area. There were ulcers in almost all lesions, and perigastric regional lymphadenopathies were also the common associated findings in the patients with gastric HS[5-8].

Sundersingh *et al*[7] reported a multifocal HS of the gastrointestinal tract, and a CT scan revealed multifocal, circumferential gastrointestinal wall thickening involving the stomach and jejunal loops. Gastric HS can also exist together with HS of the colon[2]. In our case, the distal esophagus had also been infiltrated. Akiba *et al*[9] reported a case of HS arising in the parotid gland region; the patient had recurrent lesions in the pelvis and stomach 5 mo after parotidectomy.

On CT or magnetic resonance imaging enhanced scans, extranodal HS lesions often present with notably heterogeneous contrast enhancement, because generally the neoplasm has a plentiful blood supply[10,11]. Fant *et al*[12] reported one case of primary gastric HS in a dog, a large, protruding and ulcerated mass was observed on tomographic and endoscopic examinations, moreover, the lesion was also apparently strengthened on enhanced CT scan. The CT manifestations in our case were exceedingly similar with those of the above case.

The imaging features of gastric HS are nonspecific. Abdominal radiographs may show a soft tissue mass with an irregular ulcer and heterogeneous hypervascular features, mostly arising in the lesser curvature and involving the adjacent area.

In conclusion, HS of the stomach is extremely rare, and, to our knowledge, its imaging features have not been previously detailed and summarized in the English-language literature in humans[5-8]. The gastric HS can be primary or secondary, but the primary tumor seems to be more prevalent, and it can also coexist with other sites of HS. It is difficult to differentiate HS of the stomach from other gastric malignancies by radiological evaluation alone. However, HS may be considered when a protruding and ulcerated mass in the stomach shows heterogeneous hypervascular features, particularly when it arises in the lesser curvature.

Abstract

Following the international guidelines criteria an adequate "diagnostic conclusion" of inflammatory bowel disease (IBD) can be achieved only if clinical, endoscopic and laboratory findings, together with sample technical adequacy and unequivocal histomorphological signs of the disease are available. Thus, a conclusive diagnosis requires a complex combination of clinical, endoscopic and histological data. A considerable number of endoscopic biopsies obtained from IBD patients do not meet the above-mentioned requirements. The aim of the present proposal is to introduce a binary system of evaluation in the "diagnostic conclusion" of the histopathological report that will help to simplify the clinical decisions and consequent patient management. In patients with no history of disease, the pathologist should classify the biopsies in "Diagnostic", when the criteria established by the international guidelines are satisfied and "not diagnostic" when one or more of the above-mentioned criteria are not met. The term "not diagnostic" should replace "highly suggestive" and "probable". This new terminology could avoid ambiguous expressions that encourage the clinician to classify the patient as affected by IBD without fulfilling all of the requirements for an accurate diagnostic approach.

Inflammatory bowel disease: A proposal to facilitate the achievement of an unequivocal diagnosis. *World J Gastroenterol* 2013; 19(3): 426-428 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/426.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.426

TO THE EDITOR

Various guidelines have defined the criteria used for the diagnostic evaluation of endoscopic biopsies as chronic idiopathic inflammatory bowel disease (IBD)[1-5].

Most of these guidelines include a "preliminary section" of the histological report that includes the evaluation of the different morphological parameters of the

biopsy specimen and a final section with the "diagnostic conclusion" derived from the previous synoptic analyses. In practice, the adequate diagnosis of colon biopsy specimens for non-neoplastic disease requires the following parameters: (1) clinical, endoscopic, and laboratory findings; and (2) technical adequacy of endoscopic sampling and histological procedures, particularly a proper orientation of the biopsies[3]; and unequivocal evidence of specific morphological signs of the disease in histological analysis[5-7].

Thus, a conclusive diagnosis requires a complex combination of clinical, endoscopic and histological data. Consequently, a considerable number of endoscopic biopsies obtained from IBD patients do not meet the above-mentioned requirements and cannot receive a definite histological diagnosis. In the more recent guidelines, the categories "highly suggestive[1] and "probable"[6] in the final section of the diagnostic report encompass all of these cases. Although these terms are ambiguous, they are often interpreted as a definitive diagnosis for the clinical management of patients with endoscopy suggestive for IBD.

The aim of the present proposal is to introduce a binary system of evaluation in the "diagnostic conclusion" section that will help to simplify the clinical decisions and consequent patient management. For this purpose, patients without a previous histological diagnosis of IBD and patients with a previous unequivocal diagnosis of IBD should be approached differently.

In patients with no history of disease, the pathologist should use the following terms to classify the biopsies.

Diagnostic, when the criteria established by the international guidelines[1,2] for the diagnosis of IBD are satisfied: (1) complete or extensive mapping of ileo-colonic segments; (2) adequate specimens, correctly oriented; (3) adequate information, including clinical history, laboratory data, and previous histological and/or endoscopic reports; and (4) histological examination of specimens shows unequivocal microscopic signs of the disease (diagnostic for IBD) or definitely rules out the diagnosis of IBD (negative for IBD). If possible, the pathologist should specify the type of the non-IBD colitis (infective, drug-induced, lymphocytic, collagenous, *etc.*).

Not diagnostic, when one or more of the above-mentioned criteria are not met. The term "not diagnostic" should replace "highly suggestive"[1] and "probable"[6]. After discussion with the gastroenterologist and the endoscopist, these patients should be re-evaluated. In cases with persistent symptoms, the patient should be sent back to endoscopy with the goal of achieving diagnostic biopsies. IBD shows a distinctive microscopic morphology only after 2-3 wk[8], which should be considered in the timing of subsequent biopsies.

In cases of a previous unequivocal diagnosis of IBD performed in the same institution (or in a different center, if specimens are available for revision), the sampling requirements are less stringent and more dependent on endoscopy. The categories "diagnostic/not diagnostic" in the final section of the report are not required, but the report should include an evaluation of disease activity, the presence or absence of dysplasia, and the presence or absence of Cytomegalovirus (follow-up evaluation). Figure 1 provides an example of an algorithm used for this classification.

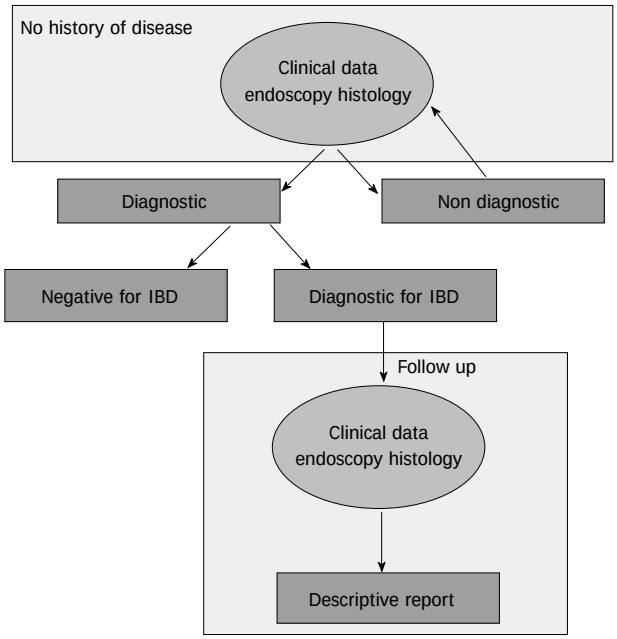

Figure 1 A graphic representation of the described terms (boxes) with suggestions for clinical management. IBD: Inflammatory bowel disease.

In our opinion, the advantages of using this binary system to approach endoscopic biopsies in IBD are the following: (1) this terminology could avoid ambiguous expressions that encourage the clinician to classify the patient as affected by IBD without fulfilling all of the requirements for an accurate diagnostic approach; (2) a second set of biopsies after a "not diagnostic" result should simplify the differential diagnosis from non-IBD colitis. Moreover, after the first set of biopsies, the clinician may be able to collect other data (laboratory data, response to therapy, *etc.*) that are useful for diagnosis; (3) this approach will reduce the use of inappropriate treatments that might cause mucosal changes, which can complicate the histological evaluation and compromise the correct assessment of the patient[8]; and (4) last, but not least, the quality of clinical and biological studies should be improved by including only case series with a definitive diagnosis.

The final goal of our proposal is to seek comments and suggestions about this topic and share this approach with other authors.

Abstract

Rafiei *et al* recently described an association between the presence of the C150T polymorphism of the inducible nitric oxide synthase (*iNOS*) gene and *Helicobacter pylori* (*H. pylori*) induced gastric cancer. When we used primer-BLAST to find the polymerase chain reaction (PCR) product that would be generated by the primers used by these authors no products against any of the sequences present in the GenBank database were found. Further analysis of the *iNOS* sequences present in the GenBank suggest that the result from their study might come from a faulty primer design and may thus represent an artifact. Alternatively they may be correct and have identified a truly interesting explanation for the mechanism whereby *H. pylori* induces gastric cancer but some additional experiments would be in order to exclude the possibility of a PCR artifact.

TO THE EDITOR

Rafiei *et al*[1] recently published an interesting article in the *World Journal of Gastroenterology* entitled "Inducible nitric oxide synthetase genotype and *Helicobacter pylori* infection affect gastric cancer risk". In this study, they investigated the possible association between inducible nitric oxide synthase (*iNOS*) genotype and gastric cancer among the 329 patients from northern Iran. They found a clear association between the presence of C150T polymorphism of the *iNOS* gene and the presence of gastric cancer in *Helicobacter pylori* (*H. pylori*) infected patients. Strikingly they found an overall frequency of the 150T allele of approximately 25% of the individuals (both controls and cases) tested[1], which came as a surprise to us for the original description by Shen *et al*[2] mentions a frequency of 13%. This discrepancy could obviously be explained by genetic differences in the ethnic populations but is not discussed by Rafiei *et al*[1] in their paper and this prompted us to carefully study the methods used to establish the C150T polymorphism. In order to establish the polymorphism the authors used the method that was described by Shen *et al*[3]. Briefly, a polymerase chain reaction (PCR) was used to produce a 255 bp amplicon of the *iNOS* gene that was subsequently digested with *Tsp* 509 I for determination of the C150T polymorphism. When we used primer-BLAST (http://www.ncbi.nlm.nih.gov/tools/primer-blast) to find the PCR product that would be generated by these primers this program was unable to find any products against

any of the sequences present in the GenBank database. Performing a manual search against the Assembled RefSeq human Genomes database (Build 37.3) did only result in two *iNOS* hit for the forward primer (database entry ref NT 010799.15 and NW 001838430.2) and no hits for the reverse primer. When we subsequently performed a basic BLAST search with the separate primers we only found hits with the forward primer in 7/9 *iNOS* sequences in the Genbank database version 25 September 2012 and no hits with the reverse primer. Further analysis of the 9 *iNOS* sequences present in the GenBank revealed that a *Tsp* 509 I site at the expected distance from the forward primer in all but one sequence (GenBank accession no DQ149843.1). This sequence (DQ149843.1) was submitted by Shen *et al*[3], the group who originally identified the C150T polymorphism. Interestingly the 3' end of this 288 bp sequence (supposedly containing the binding site for the reverse primer) differs considerably from all but one of the other *iNOS* sequences in the database; i.e., an 288 *iNOS* sequence with accession no X85772.1. This closely homologous sequence (X85772.1) differs only in the C150T position and was submitted to the database by Xu *et al*[4]. A possible explanation for the aberrant 3' end of this sequence is that the sequence from Xu *et al*[4] is assembled from two cosmid clones and as the sequence differences seem to be at the link region of these two cosmids it may represent a cloning artifact. Careful analysis of these two sequences in fact does show some similarity to the reverse primer at the expected position, but the two 3' bases clearly differ, making it almost impossible to produce a PCR product with this primer. Conclusively, it looks like the unique results of these two studies[1,2] might come from a faulty primer design and may thus represent an artifact. Alternatively they may be correct and present a truly interesting clue for the mechanism whereby *H. pylori* induces gastric cancer but we feel that some additional experiments would be in order to exclude the possible artifact as mentioned above.

Abstract

Colorectal cancer is the third most common cancer in men and the second most common cancer in women worldwide. Diagnosing colorectal has been increasingly successful due to advances in technology. Flexible endoscopy is considered to be an effective method for early diagnosis and treatment of gastrointestinal cancer, making it a popular choice for screening programs. However, millions of people who may benefit from endoscopic colorectal cancer screening fail to have the procedure performed. Main reasons include psychological barriers due to the indignity of the procedure, fear of procedure related pain, bowel preparation discomfort, and potential need for sedation. Therefore, an urgent need for new technologies addressing these issues clearly exists. In this review, we discuss a set of advanced endoscopic technologies for colorectal cancer screening that are either already available or close to clinical trial. In particular, we focus on visual-inspection-only advanced flexible colonoscopes, interventional colonoscopes with alternative propulsion mechanisms, wireless capsule colonoscopy, and technologies for intraprocedural bowel cleansing. Many of these devices have the potential to reduce exam related patient discomfort, obviate the need for sedation, increase diagnostic yield, reduce learning curves, improve access to screening, and possibly avert the need for a bowel preparation.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer in men and the second most common cancer in women worldwide with approximately 608 000 people dying each year[1]. In the United States alone there are approximately 1.14 million people alive who have a history of CRC and 1 in 20 will be diagnosed with cancer of the colon or rectum in their lifetime[2]. Unfortunately, this number is projected to increase by 62% by the year 2030[3].

Diagnosing CRC has been increasingly successful due to numerous advances in technology. One of the paramount technological advances has been the ability to directly visualize the gastrointestinal (GI) tract (and provide therapy) with the flexible endoscope. The earliest flexible endoscope, completely based on optical fibers, was

presented at the American Gastroscopy Society annual meeting in May 1957 by Hirschowitz[4]. This achievement was inspired by a paper published in 1954, entitled "a flexible fiberscope using static scanning", by Hopkins *et al*[5] at the Imperial College of Science and Technology in London. Building on this history of technological innovation, and driven by breakthroughs in electronics, material science, computational capabilities, sensing, and actuation strategies, many novel GI devices and diagnostic techniques have emerged. In this review, we will discuss a set of advanced endoscopic technologies for CRC screening that are either already available or close to clinical trial; and have the potential to reduce procedure related patient discomfort and increase diagnostic yield.

LIMITATION OF STANDARD GI ENOSCOPY

Flexible endoscopy is considered to be an effective method for early diagnosis and treatment of GI cancer, thus is a primary choice for screening programs. Few complications are associated with this technique, with cardiorespiratory problems related to sedation and analgesia being the most common (0.03%-20% incidence[6]). Less frequent complications include, infection (0.2% incidence[7]), bleeding (0.2%-2.1% incidence) or perforation (0.1% incidence[8]), which potentially require subsequent medications, transfusions, or endoscopic/surgical intervention to correct.

Based on the efficacy and low complication rate of flexible endoscopy, it is clear that the main clinical challenge facing GI endoscopy is one of distribution. Millions of people who may benefit from endoscopic CRC screening fail to have the procedure performed. The reasons cited include psychological barriers due to the indignity of the procedure, fear of procedure related pain, bowel preparation discomfort, and potential need for sedation[9].

How rational are these fears? From a mechanical perspective, the endoscope consists of a long and fairly stiff (compared to the compliant colon) tube with a steerable head. The colonoscope must easily navigate the colon curves and traverse the intestinal environment efficiently - meaning that a colonoscope must be simultaneously stiff and compliant. If the colonoscope is too stiff, it will deform the colon wall significantly at turns; yet, if it is too compliant there will be undesired buckling[10]. Since the colonoscope must be pushed from the back, while the tip is aimed along the lumen center, when the intestine bends, the shaft pushes against the colon wall until the lumen and its surroundings provide sufficient counter pressure to force the endoscope shaft to bend. This stretches the colon and often leads to "loop" formation, thus potentially causing substantial discomfort. In particular, looping occurs when the colonoscope continues to be advanced into the colon without a corresponding progression of the tip. This displaces the colon from its native configuration and stretches mesentery muscles. Looping of the endoscope has been shown to be responsible for 90% of the pain episodes in colonoscopy and increases the chance of tissue damage and perforation[11]. Special maneuvers can be performed to minimize this effect, making colonoscopy a procedure that requires a great degree of training, technical skill, and experience to safely perform[12,13]. Despite these techniques, even expert endoscopists can not always prevent all challenges or complications; partially because the flexible endoscope design is one of compromise and is not perfect for its intended purpose[10]. Additionally, the need for a bowel preparation acts as a potential deterrent due to the unpleasantness of ingesting powerful medications to clean the intestine. A detailed discussion on bowel preparation is beyond the scope of this review and will only be discussed briefly.

TOWARD MECHANISMS ENABLING PAINLESS COLONOSCOPY

Several colonoscope modifications have recently been presented with the common goal of preventing excessive force application to the colon wall and consequent looping. These devices can be categorized into two groups: those designed purely for visual inspection (visual inspection devices), and those that contain internal channels through which interventional devices (i.e., biopsy, snare, needle, *etc.*) can be passed (interventional devices). In addition to flexible colonoscope modifications, wireless capsule colonoscopy is emerging as a "patient-friendly" alternative technique for visual inspection of the colon. In this section we will provide an overview of recent advancements in these three device categories.

Visual-inspection-only advanced flexible colonoscopes

An example diagnostic-only device is the CathCam, whose development has been supported by Ethicon Endo Surgery, Inc., represented in Figure 1A. The CathCam is a nonsterile, disposable, multilumen catheter with a working length of 1.8 m and a diameter of 11 mm. Vision and illumination are provided by a 3-mm camera with six light-emitting diodes. The catheter is designed for single use, while the camera is reusable and is mounted into the catheter tip prior to the procedure. The channels of the CathCam accommodate the cables of the video camera and enable the system to provide suction, irrigation, and visualization. An accessory channel (2.8 mm in diameter) is provided for a looped guide wire (0.024-inch hinged lumen-seeking guide wire) that is advanced through the channel and into the lumen of the colon. The guide wire then serves to guide the catheter forward when the catheter is pushed[14]. This device has demonstrated 30%-40% peak force reduction in benchtop experiments and in live pigs, in comparison to standard colonoscopes[15] (Table 1).

Another advanced diagnostic flexible endoscope is the Aer-O-Scope™ (GI View Ltd., Ramat Gan, Israel), which is a pneumatic, skill-independent, self-propelling, and self-navigating disposable colonoscope[16], repre-

Figure 1 Figures of the devices. Table 1 Main characteristics of advanced flexible colonoscopes

Technology	Advantages	Disadvantages	Human studies
CathCam	Disposable; peak force reduction with respect to standard colonoscope	No instrument channel; no steering	No
Aer-O-Scope™	Disposable; "tip pulling" locomotion; computer-aided control	No instrument channel; no steering	Yes[18]
Endotics™	Disposable; Steerable head; "tip pulling" locomotion; computer-aided control; thin tail	No instrument channel; average procedure time longer than colonoscopy	Yes[20,21]
NeoGuide™	Instrument channel; shape retention; 3D map of the device; computer-aided control	Reusable (need for cleaning); large diameter	Yes[11]
Invendoscope™	Disposable; instrument channel; "tip pulling" locomotion; computer-aided control	Diameter similar to a colonoscope	Yes[24,25]
ColonoSight™	Disposable; instrument channel; "tip pulling" locomotion	Diameter similar to a colonoscope	Yes[26]
Magnetic endoscopic device	Instrument channel; "tip pulling" locomotion; computer-aided control; thin tail	Complexities related to magnetic control	No
Endo-Ease™	Facilitates cecal intubation	Large diameter	Yes[29]
ScopeGuide™	3D real-time visualization of the device	Standard colonoscope	Yes[32,33]

sented in Figure 1B. The device is composed of a rectal introducer, a supply cable, and an endoscope embedded within a scanning balloon that serves as its vehicle. The rectal introducer is a hollow silicon tube (1.7 m in length, 19 mm in diameter) with a silicone balloon (80 mm in diameter) attached to its outer surface. The introducer is inserted into the rectum with its outer balloon, and the endoscope and its vehicle balloon are passed through the hollow tube of the introducer. The silicone balloon on the introducer seals the anus to prevent gas leakage. CO_2 is insufflated between the two inflated balloons, and gas pressure advances the vehicle balloon, endoscope, and a trailing supply cable. The supply cable on the endoscope/scanning balloon is a flexible polyurethane multi-lumen catheter, 5.5 mm in diameter, coated with a hydrophilic material, which supplies the electro-optical capsule (the scope) and its vehicle balloon with electricity, air, water, and suction. The volume of the vehicle/scanning balloon is pressure-regulated. The balloon is designed to adapt to the shape of the colon as it travels forward. The balloon has a large predetermined maximal volume and thin wall (8 μm) that help it adapt to the shape of the colon in response to pressure exerted by the colonic walls. These features allow the balloon to maintain the seal with the colon wall, so that gas introduced on one side of the balloon does not escape to the other side. This allows a pressure gradient to develop from behind the balloon to in front of it during forward propulsion, and vice versa during withdrawal. Since the tip has no steering capabilities, an omnidirectional colonoscopic viewing system has been installed on the tip of the latest prototype[17]. The Aer-O-Scope™ is intended to be used for diagnostic purposes and therefore does not have a working channel for therapeutic instruments. In a preliminary pilot feasibility study[18], the Aer-O-Scope™ effectively intubated the cecum in 10 out of 12 subjects (83%) with an average time to cecum of 14 min ± 7 min.

Another approach, inspired by Geometer moths, is inchworm locomotion[19]. Inchworm locomotion is similar to the motion utilized in double balloon endoscopy where there is lengthening and shortening along two anchor points (distal anchor and proximal anchor). The Endotics™ system (Era Endoscopy s.r.l., Pisa, Italy) effectively utilized inchworm locomotion and consists of a disposable robotic probe as a head, a steerable tip, a flexible body (17 mm in diameter), a thin tail (7.5 mm in diameter), and a control box with an electro-pneumatic connector. The Endotics™ endoscopic device is represented in Figure 1C. The head hosts both a vision system, including camera, light emitting diode light source and channels for a water jet and air insufflation/suction. The operator can steer the head of the robotic colonoscope 180° in every direction, elongate the body of the probe in order to move it forward along the intestine, and can control rinsing, insufflation, and suction. A semiautomatic sequence of actions is implemented to move the probe like an inchworm, wherein two vacuum anchors located in the proximal and distal ends of the probe are sequentially actuated between extensions and retractions of the central body. Experiments in a phantom model with embedded force sensors demonstrated 90% lower force application than conventional colonoscopy[20]. A human study[21] with 71 unsedated patients demonstrated that this system has a comparable diagnostic accuracy to colonoscopy, and does not require sedation. The frequency of successful procedures (i.e., reaching the cecum), the total procedure time, and the need for sedation were recorded in this study. In 13 cases (18%), the device was unable to reach the cecum and the average procedure time was 45.1 ± 18.5 min for the Endotics™ system compared to 23.7 ± 7.2 min for traditional colonoscopy ($P < 0.0001$).

Currently, the lack of tissue interaction makes it improbable that diagnostic-only devices will completely replace traditional colonoscopes. Only prospective comparative outcome trials will be able to conclusively determine whether a diagnostic-only device (followed by conventional colonoscopy for potential therapeutic intervention) will be preferable to conventional colonoscopy with both diagnostic and therapeutic capabilities.

Interventional colonoscopes with alternative propulsion mechanisms

A first subset of this class of colonoscopes consists of shape retention devices, which are essentially tubes that

are initially flexible and can be stiffened when desired. While several examples of devices utilizing this principle are described in literature[10], only one has reached the clinical trial stage. This is the NeoGuide™ from NeoGuide Systems Inc. (a company based in San Jose, California, United States that was acquired in 2009 by Intuitive Surgical of Sunnyvale, CA, United States). The NeoGuide™, represented in Figure 1D, consists of a 173 cm-long endoscope composed of sixteen 8 cm-long independent vertebrae. Each segment can be directed to assume a right, left, up, down, circular curve, or a combination of these motions. During manual insertion of the device, the position and angle of the scope tip are encoded into a computer algorithm. As the colonoscope is advanced, the computer directs each successive vertebra to take the same shape that the tip had at a given insertion depth. The insertion tube thus changes its shape at different insertion depths in a "follow-the-leader" manner. By controlling the shape of the insertion tube, the NeoGuide™ does not rely on conventional pushing against the colon wall to maneuver. The cross-sectional diameter of the NeoGuide™ insertion tube is approximately 14 mm at the tip, increasing to approximately 20 mm at the proximal shaft of the scope (the working channel is 3.2 mm). The mechanical valves that control insufflation, suction, or water irrigation are the same as in conventional endoscopes. Biopsies and therapeutic maneuvers are conducted with the scope in passive mode; where the shape and stiffness of the endoscope is the same as that of a standard colonoscope. *In vitro* evaluation of the NeoGuide™ system[22] showed significantly less looping and lateral force required for advancement than procedures with a standard colonoscope. An initial clinical trial of 10 sedated patients demonstrated a looping rate of 40%. Although looping was defined as extensive in three of four cases, it was successfully straightened under computerized 3D imaging and the cecum was reached in all patients[11]. The 3D map images generated by the NeoGuide™ endoscopy system provide information regarding tip position, insertion tube position, and colonic looping[23]. These additional pieces of information may contribute to a safer and more comfortable procedure for the patient.

Another computer-aided colonoscope is the disposable Invendoscope™ (Invendo Medical GmbH, Kissing, Germany). The colonoscope, represented in Figure 1E, has a working length of 210 cm and the internal functional endoscope is covered by several layers, starting with a 10-mm diameter sheath. The sheath is covered by double layers of an "inverted sleeve" that provides the propulsion mechanism. Eight drive wheels in the driving unit grip the inner layer of the inverted sleeve and rotate, causing it to move forward. The "inverted sleeve" mechanism causes the colonoscope to "grow" at a position 10 cm below the distal end. Similarly, when the colonoscope is being retracted, the drive wheels rotate in the opposite direction and the endoscope "shrinks". This technology, combined with a small bending radius, was designed to reduce the forces exerted on the walls of the colon, with the goal of minimizing patient discomfort - even without sedation. Other than these mechanisms, the Invendoscope™ functions in a manner similar to conventional endoscopes, allowing for insufflation, rinsing, and suction. It also has a 3.2-mm working channel, allowing for therapeutic procedures to be performed.

A pilot study of 34 healthy volunteers (19 men; mean age 49.7 years) demonstrated that the Invendoscope was able to reach the cecum without any sedation in 80%-90% of cases[24]. This result was supported by a prospective single-arm study of 61 healthy volunteers (34 men and 27 women; mean age 57.5 years) undergoing screening colonoscopy, with a cecal intubation rate of 98.4% with less than 5% of patients requiring sedation[25].

The ColonoSight™, a disposable, self-propelling device based on IntraPull and ProtectiScope technologies by Stryker, Inc., has three working channels: a 3.7-mm-wide channel for suction and insertion of accessory tools, a channel for irrigation, and a channel for insufflation (Figure 1F). A disposable sleeve anchored at the proximal end of the device envelopes the endoscope, protecting it from contamination. The IntraPull mechanism generates a force close to the tip of the scope by pumping compressed air inside the sleeve controlled by depressing a foot pedal. The material of the sleeve does not allow expansion, and therefore the increased pressure inside the sleeve creates a force directed toward the tip of the colonoscope, thus pushing the tip forward as the folded part of the sleeve is deployed. The maximum force generated is 4.9 N (0.5 kgf) whereby the maximum force generated with a standard colonoscope is approximately 44 N (4.5 kgf). Once the endoscopist releases the foot pedal, the sleeve is deflated and the applied force is removed. A pilot prospective study of 178 participants (48 women and 130 men; age 51.8 ± 10.7 years) reported a success rate of 90% in reaching the cecum without complication of bleeding or perforation. All patients in the study were sedated using midazolam, mepiridine, or propofol; therefore, no data on patient discomfort was reported[26].

With the exception of the Endotics™ system, tip deflection of the above devices are accomplished by wires travelling the length of the device - effectively creating a minimum outer endoscope diameter (lower boundary) of approximately 10 mm. If however, one could "pull" rather than "push" the endoscope, the outer diameter lower boundary may be reduced further; limited by the space needed for the therapeutic channel and the electrical connections to the vision module[21]. Magnetic steering and control was applied to an endoscopic device containing a tip-mounted magnetic camera (diameter 11 mm, length 26 mm) connected to an external control box by a 5.4-mm diameter multi-lumen soft tether[27]. This connection was used for insufflation, passage of a therapeutic instrument, activation of a lens cleaning mechanism, and for operating the vision module. The external magnet was held by a 7 degree-of-freedom (DoF) robotic arm that was controlled in real-time by the endoscopist. The external magnet driving the endoscopic device is represented in Figure 1G.

A magnetic field sensor was also embedded in the device head to enable localization and closed loop control. The magnet capsule system allowed for "pulling" of the device throughout the colon thus eliminating the need for structural cables traveling the length of the device and the need for pushing the endoscope at the base in order to forward advance the scope. This approach would appear to prevent looping and reduce stretching of the colon wall. These advantageous characteristics are enhanced by dramatic reduction in both the bending stiffness of the shaft and in the mass of the proposed device (from 1240 g for a standard colonoscope to 34 g, including the soft tether), while retaining the therapeutic capabilities provided by a conventional colonoscope. The device has been tested in *ex-vivo* colon models and animal trials with encouraging results. Human trials are planned, but have not yet been conducted.

Another noteworthy mechanism for locomotion, designed to improve cecal intubation rate when standard colonoscopy fails, is the Spirus Endo-Ease™ system[28]. The Endo-Ease™ system, represented in Figure 1H, consists of a 90 cm disposable flexible plastic overtube with a 5-mm soft spiral thread at its tip. The overtube is designed with a 13-mm inner diameter to host a variable-stiffness pediatric colonoscope. Clockwise rotation of the overtube, which mimics the motion of a corkscrew, pleats the bowel onto the external surface of the tube. Bowel pleating is accomplished without apparent twisting of the lumen because the mesentery attachment resists the rotation. In a preliminarily clinical trial[29] of 22 patients (the median age 68 years, 58% men) with incomplete colonoscopy secondary to redundancy of their colon, the cecal intubation rate was reported in 22 patients (92%) with a median time to cecum of 14.2 min (range 6-30 min). No complications were reported.

The same principle was used in a computer-aided colonoscope[30] where two sections with a spiral thread rotate to achieve forward motion. While preliminary qualitative data about *in vivo* experience shows the feasibility of this approach (forward speed of 11 mm/min), clinical trials have not been reported to date.

A common theme in reducing discomfort associated with standard colonoscopy appears to be shifting the location of the propulsive force from the base of the device outside of the patient (i.e., "pushing", typical force profile available in literature[31]) to the tip of the colonoscope inside the patient (i.e., "pulling"). The latter can result in improved alignment of the direction of the applied force with the desired direction of forward tip motion. Several devices have demonstrated that this technique can reduce forces applied to the colon wall during insertion, which is believed to correlate with a reduction in patient discomfort and the risk of colon perforation. Diverse methods for reducing tip forces have been proposed, ranging from pneumatic pressure[22,25,26] to robotic locomotion[21] to magnetic fields[27]. While it remains to be seen which of these technologies will achieve market penetration and widespread clinical use; the thin tether of the last two devices described previously appears advantageous.

An alternative approach to minimize looping of the endoscope may lie in the endoscopists ability to "visualize" the shape of the endoscope as she or he advances it throughout the colon. A commercially available endoscopic system from Olympus, the ScopeGuide™ (CF-H180DL), integrates electromagnetic tracking into a standard colonoscope and provides a real-time rendering of the endoscope shape in free space on a display. A recent study[32] comparing this platform with standard colonoscopy reported reduced cecal intubation time (181 s *vs* 216 s; $P < 0.05$) and reduced patient discomfort on a 10-point visual analog scale (2.44 *vs* 1.85; $P < 0.05$). Unfortunately, other studies[33] of expert endoscopists utilizing this device have not reproduced these results; leading one to believe that the application of the system may be limited to novices.

In regard to reducing the learning curve, computer-aided devices or image guided techniques[18,21,23,25,27,32] have the potential to make colonoscopy less technically challenging for novices. Haptics has also been explored with promising results to facilitate colonoscopy[34]. In particular, lumen detection by real-time image analysis was used to provide a feedback force at the user interface that should aid the physician to steer the endoscope tip toward the lumen. Given the increasing role of technology in healthcare, one day it may be possible for examinations to be carried out remotely (i.e., patient and provider are not in the same physical location) by health care professionals in the community in order to meet the increased demand for screening colonoscopy.

Wireless capsule colonoscopy

Trends in consumer electronics such as miniaturization, low power operation, and wireless technologies have paved the way to the introduction of wireless capsule endoscopy (WCE) in 2000[35]. This technology has now become essential for small bowel inspection[36] and it is trying to expand its reach for use in the large intestine with purposely developed capsule devices, such as the PillCam™ Colon by Given Imaging (Yokneam, Israel). The effectiveness of the second generation of PillCam™ Colon[37] as an alternative to colonoscopy for CRC screening has been analyzed in a recent editorial[38] that appeared in this journal on the basis of recent clinical trials. Although the sensitivity for polyp detection for the PillCam™ Colon is close to 90%, specificity remains disappointingly low due to a substantial rate of false-positive results[39]. Therefore, despite clear patient comfort benefits provided by WCE, colonoscopy is still the gold-standard for CRC screening[40].

A main research stream for WCE toward the final goal of replacing flexible endoscopy consists in providing the capsule with the possibility to be remotely controlled and manipulated. Magnetic coupling is one of the few physical phenomena capable of transmitting actuation forces across a physical barrier. Remote magnetic ma-

nipulation has been adopted to steer capsule endoscopes by several research groups worldwide. Given imaging has investigated the use of a handheld external magnet to translate and orient a capsule in the upper GI tract using a modified version of PillCam™ Colon, which was half-filled with magnets[41]. This demonstrated the feasibility of magnetic steering, but revealed that more research was required to increase the reliability and accuracy of magnetic control[42]. An alternative technique for generating the external magnetic field, jointly developed by Olympus and Siemens, involved use of a magnetic resonance imaging scanner to create the field and field gradients[43]. In a recent nonrandomized blinded pilot study comparing a capsule device to traditional endoscopy for evaluation of the stomach, the overall diagnostic yield was similar for both methods[44].

A robotic navigation system - commonly used for cardiovascular clinical procedures (Niobe™, Stereotaxis, Inc, United States) - was used to control the orientation of a wireless capsule endoscope throughout the entire GI tract in several *ex-vivo* and *in-vivo* animal trials[45-47]. This technique was validated by equipping a PillCam™ with a custom-made coaxial magnetic shell[48] glued to its external surface. *In vivo* tests performed with 3D fluoroscopic localization demonstrated an accuracy of 1° in orientation[47]; however, the Niobe™ does not allow for field-gradient control, thus controlled translations of the capsule are not possible - this is an important limitation for this approach.

Magnetic control over position and orientation of a capsule inside the colon was demonstrated by coupling permanent magnets - one embedded inside the endoscopic capsule and the other connected as the end effector of a 6 DoF industrial robotic arm in an animal pilot study[49]. The same kind of magnetic coupling was used by the first ever reported wireless therapeutic endoscopic capsule[50]. This pilot study in a porcine model demonstrated the feasibility of wireless controlled deployment of a surgical clip to close an iatrogenic bleed in the colon. In a different study[51], the combined use of external static magnetic fields and internal actuation to move small embedded permanent magnets allowed for wirelessly controlled precise camera steering. This approach was used to obtain a full 360° view in the gastric cavity and a 45° span inside the colon.

Overall, this body of literature indicates that precise capsule manipulation can be achieved by means of magnetic coupling and that, if relevant clinical evidence will further support this approach, the next generation of wireless capsule endoscopes may eventually have a concrete potential to replace traditional colonoscopy, at least for CRC screening.

TOWARD MECHANISMS ENABLING UNPREPARED COLONOSCOPY

A significant common disadvantage of both conventional and novel colonoscopes is the need for bowel preparation. An innovative device addressing this challenge is the ClearPath™ system[52] that consists of a control cabinet and a disposable unit. The control cabinet includes a peristaltic pump, a controller, and a pinch valve that enables control of suction. The disposable element consists of a multi-lumen, custom-made, extruded tube. The tube has two channels: one that supplies water for irrigation and one that provides suction. When attached to the standard colonoscope, the ClearPath™ system adds an additional 6 mm to the outer diameter of the standard colonoscope. Water for irrigation flows through four 0.6 mm nozzles in the distal head and debris is evacuated through a single 18 mm^2 cross-sectional aperture. Preliminary animal trials on partially prepared domestic swine demonstrated effective intraprocedural colon cleaning with no immediate mucosal damage, acute complication (i.e., perforation), or delayed adverse consequence.

An alternative approach[53] for cleaning the colon during colonoscopy consists of a disposable soft-tipped catheter with a water jet spray that can be advanced, under direct vision, through the accessory channel of the standard colonoscope and into fecal matter. When the water jet is activated the solid stool can be broken apart for removal by suction. The water jet catheter tip has 4 radial nozzles through which the water is pumped. Feasibility studies in the unprepared colons of anesthetized pigs demonstrated effectiveness; however, mucosal trauma, bleeding, perforation, clogging of the colonoscope suction channel, and electrolyte imbalances may limit the overall impact.

A similar approach for intraprocedural bowel cleansing[54], still based on a disposable catheter, has been developed by Medjet Ltd., Tel Aviv, Israel. The MedJet digestive tract lumen cleaning device provides controlled delivery of a supersonic two-phase jet of micro-droplets consisting of minimal amounts of saline solution and CO_2. The solution is accelerated through the catheter, and enhances visibility by clearing away stool, secretions, or blood; and by disintegrating small particles for suctioning through the working channel of the endoscope during colonoscopy. In a recent clinical study[54], the MedJet was reported to be effective - offering significant improvement in bowel cleansing in 32 patients with no device-related adverse events.

In summary, there have been promising advances in the development of devices utilized for CRC screening with the devices designed to achieve a common goal to improve the way we directly view the colon (and possible intervene on any pathology present). The main principle that must be kept in mind with any new device is patient safety. Secondary principles that continue to be addressed include ease of use, reduction of the learning curve, improvement in colonic visualization, improvement in patient procedural comfort, better access to endoscopic screening, and possibly obviation of the need for a bowel preparation. With technology improving at a rapid pace, it may not be long before a disruptive innovation takes hold and we see the conventional colonoscope as an item on the shelf in a medical museum.

Abstract

A recent work of Iliopoulos *et al* published in *Cell* highlighted a circuit orchestrated by microRNAs (miRNAs) that results in liver tumorigenesis and inflammation. This feedback loop, governed by miR-24 and miR-629, promotes a hepatocyte nuclear factor-4α transient inhibition resulting in miR-124 induction and signal transducer and activator of transcription 3 activation. These promising data support the use of miRNA mimics or inhibitors as potent therapeutic approaches in liver cancer.

COMMENTARY ON HOT TOPICS

Hepatocyte nuclear factor-4α (HNF-4α) belongs to the nuclear receptor superfamily of ligand dependent transcription factors NR2A1[1]. It is expressed in the kidney, intestine and pancreas. HNF-4α is most highly expressed in the liver[2-5], where it binds to the promoter of 12% of genes expressed in the adult liver[6]. It plays a key role in liver development during gastrulation[7] and orchestrates the parenchyma formation in the adult liver[8]. It also guides hepatoblasts to hepatocyte differentiation[9]. The conditional disruption of HNF-4α in mouse liver showed that HNF-4α regulates a number of genes involved in lipid, glucose, amino acid and xenobiotic metabolisms[4]. Related to its central role in liver physiology, HNF-4α has been reported to be involved in liver oncogenesis; however, its role is still controversial. A study by Xu *et al*[10] suggested that HNF-4α expression was increased in human hepatocarcinoma (HCC), which contrasted with other studies that reported that the HNF-4α level was decreased in HCC[11-13]. HNF-4α has also been associated with cancer and inflammation in the colon: its intestinal disruption in mouse revealed that HNF-4α protects against colitis and inflammatory disease[14,15] and promotes tumorigenesis[15]. Liver cancer is a clear example of an inflammation-related cancer[16-19]; therefore, it does not seem surprising that HNF-4α could also orchestrate an inflammatory program in the liver, as was shown last year by Wang *et al*[20] in experiments performed on hepatocarcinoma cells exposed to interleukin (IL)-6.

In a recent paper published in *Cell*, D. Iliopoulos' Laboratory aimed to decipher the epigenetic circuit centered on HNF-4α, which promotes liver oncogenesis[21]. They particularly focused on microRNAs (miRNAs), which are small RNAs produced from non-coding DNA regions that control gene expression by binding to the 3' untranslated region (3' UTR) of target messenger RNAs (mRNAs). miRNA binding results in the degradation of the mRNA and/or the repression of its translation[22].

Since their discovery in 1994 in *Caenorhabditis elegans*[23], miRNAs have become an expanding area of research, and evidence supports the view that miRNAs are key regulators of many physiological processes, e.g., growth, proliferation and differentiation[24-27]. They are also implicated in the initiation and progression of various cancers[28-30]. Concerning HCC, microtranscriptomic analyses revealed a miRNA signature of liver cancer, i.e., miR-122 loss[31] or miR-221 upregulation[32], and a number of studies support the view that miRNAs direct HCC progression through the induction of cell proliferation or metastasis and the suppression of apoptosis[33]. Taken together, these data highlight miRNAs as promising diagnostic and therapeutic targets for HCC.

The work of Maria Hatziapostolou is a robust description of the molecular factors underlying HNF-4α loss-mediated hepatocarcinoma based on *in vitro* and *in vivo* experiments and confirmed on HCC human samples. Prior to the precise deciphering of hepatocarcinoma molecular origins, the authors confirmed that the silencing of HNF-4α was sufficient to increase cell colony formation and invasion of nontransformed immortalized human hepatocytes (IMH) and human liver cancer cell lines. On their own, the injection of IMH cells with a preliminary transient inhibition of HNF-4α in immunosuppressed mice resulted in tumor apparition. Interestingly, HNF-4α was maintained at a low level 55 d after cell xenografts, suggesting that transient silencing of HNF-4α initiated a feedback loop that stably maintained cell transformation and suppressed its own expression.

What are the factors involved in HNF-4α silencing? An miRNA screening was performed on a luciferase reporter gene containing the 3' UTR region of HNF-4α, which revealed that miR-24 and, to a lesser extent, miR-629, were HNF-4α repressors. The transient expression of both miRNAs, the equivalent of HNF-4α silencing, transformed IMH cells, increased their invasiveness *in vitro* and promoted the appearance of tumors in mice. Strikingly, both miRNAs were induced following HNF-4α silencing, supporting the involvement of these miRNAs in the HNF-4α- dependent feedback loop.

Interestingly, miR-24 and miR-629 possess a binding motif for signal transducer and activator of transcription 3 (STAT3) in their promoters, a well-known effector of IL-6-dependent cancer inflammation[34] (for a review), particularly in liver cancer[35] (for a review). In brief, the binding of IL-6 to its receptor, IL-6R, activates the Janus kinase family, which phosphorylates STAT3 on tyrosine residues. STAT3 could then form homodimers before translocation into the nucleus to promote the expression of an inflammatory program[36] (for a review). Here, the authors showed that in response to IL-6, STAT3 binding to miR-24 and miR-629 promoters increased, resulting in miRNA expression. In turn, miR-24 expression and HNF-4α silencing enhanced the phosphorylation status of STAT3, and thus its activation. STAT3 and IL-6 are two other members of the HNF-4α feedback circuit promoting liver oncogenesis; an antibody against IL-6 blocked all the HNF-4α silencing effects that they observed.

The next step consisted in screening of miRNAs possessing an HNF-4α binding site, which identified miR-124 as a preferential HNF-4α target. miR-124 was, in fact, an integral part of the feedback loop, because its inhibition by an antisense as-miR-124, or following HNF-4α silencing, enhanced STAT3 phosphorylation coupled to an induction of IL-6 secretion and expression of IL-6R, a direct target of miR-124.

The relevance of the loop miR-24/miR-629/HNF-4α/miR-124/STAT3 was confirmed *in vivo* with a mouse model of HCC induced by diethylnitrosamine. During tumor progression, the HNF-4α level was initially dropped off after four weeks, followed by miR-124 repression and inversely by miR-24 and IL-6R induction, which supports the essential role of the HNF-4α loop in tumor progression. One of the important finding of this study was that an injection of miR-124-mimic encapsulated into liposomes in this model was sufficient to limit tumor growth, even if this mimic was administered four weeks before analysis. miR-124 mimics were also able to prevent tumor development. Taken together, these results argue in favor of miR-124 delivery as a potent strategy for treating or preventing HCC. Although, to date, the efficacy of miRNA mimics have not been demonstrated *in vivo*, this approach could be attractive. The prerequisite for this approach is that the complementary passenger RNA in the double stranded miRNA mimic does not create a new miRNA that could induce off-target effects[37,38].

The second exciting idea from this study relies upon the need for an inflammatory context to optimally disrupt the HNF-4α epigenetic circuit and promote tumorigenesis. If the tumors developed in a mouse model lacked STAT-3 in the liver, the tumors were smaller when the HNF-4α loop was less inhibited. This supports the hypothesis that HNF-4α loss engages an anti-tumorigenic program and a STAT3-dependent anti-inflammatory program, both orchestrated by the trio miR-24/miR-629/miR-124, to induce hepatocyte transformation. Such an epigenetic loop has already been described by the same authors for breast cancers, in which cell transformation was dictated by an epigenetic switch achieved by IL-6, nuclear factor-κB and the miRNA let-7[39].

Finally, the authors demonstrated the relevance of their model for human liver oncogenesis: more than 50% of HCC samples from patients showed a loss of HNF-4α and of miR-124, accompanied by an increase in miR-24 and IL-6R expression; all these parameters were associated with a higher level of phospho-STAT3 status in relation with IL-6 and IL-6R expression. As a confirmation of the HNF-4α circuit's key role in HCC progression, the authors showed that the activity of the HNF-4α circuit becomes more deregulated as the HCC grade increased.

In summary, this work strongly argues for a tumor suppressor role of HNF-4α in liver, as was already sh-

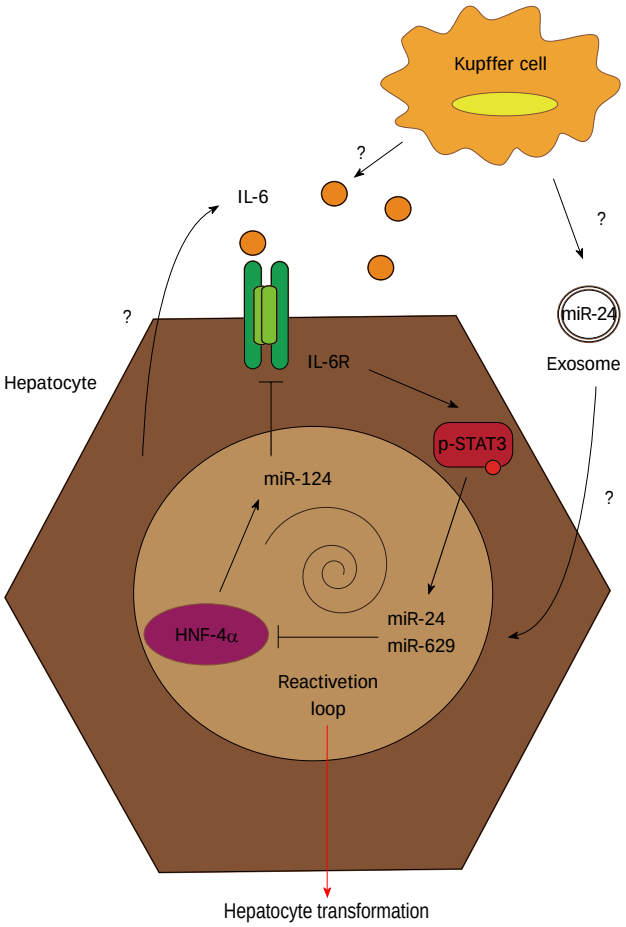

Figure 1 From transient hepatocyte nuclear factor-4α inhibition to stable hepatocyte transformation. The transient inhibition of hepatocyte nuclear factor-4α (HNF-4α) following miR-24 and miR-629 induction promotes stable repression of the pro-tumorigenic HNF-4α feedback circuit. This results in miR-124 inhibition, followed by an increase in interleukin (IL)-6 secretion and IL-6R expression. These two events lead to hyperphosphorylation of signal transducer and activator of transcription 3 (STAT3), which auto-amplifies the process through the re-induction of miR-24 and miR-629.

own[12], and supports the key role of this transcription factor in limiting the tumor inflammatory environment by inhibiting the IL-6/STAT3 pathway. The authors described the interconnection between the trio miR-24/miR-629/miR-124 and HNF-4α as a key regulator of HCC progression (Figure 1). In 2010, Takagi *et al*[40] described a crosstalk between HNF-4α and miR-24 in a liver metabolic loop for the control of bile acid synthesis. In brief, bile acids induce reactive oxygen species generation, resulting in the activation of the mitogen-activated protein (MAP) kinase pathway. In turn, miR-24, induced by the MAP kinases, downregulates HNF-4α, and, thus, the expression of bile acid-synthesizing enzymes. Hepatitis B virus (HBV) and alcohol abuse, two etiological agents associated with HCC development, contribute to oxidative stress in the liver. In consequence, miR-24 inhibition and, thus, reactivation of the HNF-4α feedback circuit in HCC could also be performed using antioxidants, a class of therapeutic agents currently used for HBV patients[41].

The take-home message of this study is that a transient signal at any level of the feedback circuit (HNF-4α or miR-124 silencing, miR-24 overexpression or IL-6 secretion) stably induces hepatocyte transformation, which could be auto-amplified by this feedback loop, and lead to chronic inflammation, predisposing a patient to liver cancer development and immune escape[19]. The activation of the IL-6/STAT3 axis is, at least in part, caused by a hepatocyte source, as shown by the *in vitro* experiments, but this could also be boosted by IL-6 secretion by non-parenchymal liver cells like Kupffer cells. Another possible scenario for the disruption of HNF-4α circuit by tumor environment could be the secretion of exosomes containing miRNA, in particular miR-24, by immune cells. Exosomes are small extracellular vesicles derived from the multivesicular body-sorting pathway, which are produced by various cells like epithelial cells, immune cells and tumor cells. Recently, it has been shown that some miRNAs, particularly those deregulated in cancer, are encapsulated into exosomes and play a role as cell-cell mediators[41]. In particular, miR-24 has been detected in exosomal structures, and a similar mechanism might exist in liver, permitting miR-24 to be delivered to hepatocytes by neighboring cells.

The most promising result of this study was that intravenous delivery of miR-124 mimic encapsulated into liposomes was able to prevent and reduce the growth of liver cancer. To date, few works have demonstrated the potency of an miRNA-based anticancer approach. However, the great advantage of HCC is that mimics or inhibitors against miRNAs are preferentially distributed to the liver[42]. For that reason, the first miRNA-based therapy authorized in clinical trials is the anti-miR-122 compound Miravirsen, indicated for the treatment of hepatitis C virus (HCV), which uses miR-122 in hepatocytes for its replication. This clinical trial follows promising results obtained in primates infected with HCV and treated with an anti-miR-122[43], which was well-tolerated[44]. Concerning the HNF-4α circuit, the authors showed the efficiency of a mimic of miR-124 to perturb HCC development, but we could also conceive the injection of inhibitors against miR-24 and miR-629 to avoid HNF-4α loss. Even if miRNA inhibitor delivery appeared as a promising therapeutic approach, the use of these modulators poses a number of challenges. The question of treatment specificity could be raised. In fact, an miRNA could target multiple mRNAs[45,46], and, thus, many cellular pathways, pro- or anti-tumorigenic. It could be difficult to restrict the effect of one miRNA to only one target of interest. However, this notion could be generalized to many other treatments currently used, such as proteasome[47] or histone deacetylase inhibitors[48], which have demonstrated efficacy. Another major disadvantage could be the inhibition of a non-identified target. Their delivery could also be an important challenge, although many improvements have appeared recently, with chemical modifications limiting their degradation by nucleases[49-51]. The other problem is that these inhibitors preferentially target the liver and other tissues are more difficult to enter[42]. Finally, these inhibitors could also

be toxic[52,53]. As suggested by the data of Hatziapostolou, mimics or inhibitors could be delivered in a free formulation, or protected into liposomes or even into exosomes, as was shown for siRNAs[54]. In conclusion, miR-124-based treatment could be a therapeutic strategy of choice for HCC, as an alternative to the anti-STAT3 approach[55]. This therapeutic option has the great advantage of targeting the inflammatory, as well as the metabolic initiators, of HCC, and its efficiency demonstrated in this work argue for an epigenetic switch as the major event underlying cancer initiation.

Abstract

Liver cirrhosis is a major cause of mortality worldwide, often with severe sepsis as the terminal event. Over the last two decades, several studies have reported that in septic patients the adrenal glands respond inappropriately to stimulation, and that the treatment with corticosteroids decreases mortality in such patients. Both cirrhosis and septic shock share many hemodynamic abnormalities such as hyperdynamic circulatory failure, decreased peripheral vascular resistance, increased cardiac output, hypo-responsiveness to vasopressors, increased levels of proinflammatory cytokines [interleukine(IL)-1, IL-6, tumor necrosis factor-alpha] and it has, consequently, been reported that adrenal insufficiency (AI) is common in critically ill cirrhotic patients. AI may also be present in patients with stable cirrhosis without sepsis and in those undergoing liver transplantation. The term hepato-adrenal syndrome defines AI in patients with advanced liver disease with sepsis and/or other complications, and it suggests that it could be a feature of liver disease *per se*, with a different pathogenesis from that of septic shock. Relative AI is the term given to inadequate cortisol response to stress. More recently, another term is used, namely "critical illness related corticosteroid insufficiency" to define "an inadequate cellular corticosteroid activity for the severity of the patient's illness". The mechanisms of AI in liver cirrhosis are not completely understood, although decreased levels of high-density lipoprotein cholesterol and high levels of proinflammatory cytokines and circulatory endotoxin have been suggested. The prevalence of AI in cirrhotic patients varies widely according to the stage of the liver disease (compensated or decompensated, with or without sepsis), the diagnostic criteria defining AI and the methodology used. The effects of corticosteroid therapy on cirrhotic patients with septic shock and AI are controversial. This review aims to summarize the existing published information regarding AI in patients with liver cirrhosis.

Key words: Liver cirrhosis; Adrenal insufficiency; Septic shock; Corticosteroid therapy

Trifan A, Chiriac S, Stanciu C. Update on adrenal insufficiency in patients with liver cirrhosis. *World J Gastroenterol* 2013; 19(4): 445-456 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/445.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.445

INTRODUCTION

Adrenocortical dysfunction in patients with liver cirrhosis has been described for over half a century[1], but was ignored until a decade ago when several studies reported that some septic patients had an inappropriately low response of adrenal glands to stimulation, and treatment with corticosteroids decreased mortality[2,3]. Relative adrenal insufficiency (RAI) is the term given to inadequate production of cortisol with respect to the severity of

illness[4,5]. More recently, another term, namely critical illness related corticosteroid insufficiency (CIRCI) defined as "inadequate cellular corticosteroid activity for the severity of the patient's illness"[6], has been used. Despite a large number of published studies during recent years, the concepts of RAI and CIRCI are still under debate.

Liver cirrhosis is a major cause of mortality worldwide[7], often with septic shock as the terminal event[8]. It is a well-established fact that cirrhotic patients have increased susceptibility to bacterial infections[9]. Both cirrhosis and septic shock share many hemodynamic abnormalities such as hyperdynamic circulatory failure, decreased peripheral vascular resistance, decreased mean arterial pressure, increased cardiac output, hyporesponsiveness to vasopressors, increased levels of proinflammatory cytokines [interleukine (IL)-1, IL-6, tumor necrosis factor-α (TNF-α)][5,10,11] and, consequently, several studies reported that adrenal insufficiency (AI) is common in critically ill cirrhotic patients[8,12-14]. Furthermore, AI may occur in compensated and decompensated cirrhosis without sepsis[14-20] or in early and late post-liver transplantation (LT)[12,21-23]. Nowadays, liver cirrhosis is considered to be among the major groups of high-risk diseases with a predisposition to AI[24]. The term hepatoadrenal syndrome is used to define AI in patients with advanced liver disease with sepsis and/or other complications[12,15], suggesting that adrenocortical insufficiency may be a feature of liver disease *per se*, with a different pathogenesis from that occurring in septic shock.

Mechanisms of AI in cirrhotic patients are not entirely known, but they may include impaired synthesis in total cholesterol, high-density lipoprotein (HDL) cholesterol and low-density lipoprotein (LDL) cholesterol, as well as increased levels of proinflammatory cytokines and circulating endotoxin (e.g., lipopolysaccharide)[25-27]. The effects of corticosteroid therapy on cirrhotic patients with septic shock and AI are controversial, some studies reporting favorable results[12-14,28], while a recent randomized control study[29] has shown no benefit.

This review aims to summarize the existing published data regarding all aspects of AI prevalence, diagnosis and treatment in patients with liver cirrhosis.

PHYSIOLOGY OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS: A SHORT REVIEW

Cortisol is the main glucocorticoid secreted by the adrenal cortex under the control of adrenocorticotropic hormone (ACTH) which is released from the pituitary gland. The stimulus for ACTH release is corticotropin-releasing hormone (CRH) secreted by the paraventricular nuclei of the hypothalamus. Among factors influencing cortisol synthesis and production (diurnal rhythm of ACTH secretion, negative feedback by cortisol), stress plays the most important role. During stress and severe illness, activation of the hypothalamic-pituitary-adrenal (HPA) axis by the action of cytokines and other factors results in increased secretion of CRH, which will stimulate the production of ACTH and, consequently, increased release of cortisol into the circulatory system[30]. Cortisol is an essential component of the global adaptation to stress, contributing to the maintenance of cellular and organ homeostasis. Adequate levels of cortisol are absolutely necessary to increase cardiac output and vascular tonus, and to decrease proinflammatory cytokines (IL-1, IL-6, TNF-α) released[31,32] in order to overcome critical illness.

Over 90% of circulating cortisol is bound to corticosteroid-binding-globulin (CBG) (also called transcortin) and albumin, with less than 10% in the free biologically active form[33]. CBG is the predominant binding site (85%), with albumin binding smaller amounts of circulating cortisol. During severe sepsis, CBG levels fall, determining a higher percentage of free cortisol[34]. Hypoalbuminemia, frequently present in cirrhotic patients, has also been suggested to increase the free cortisol fraction[35,36]. Approximately 80% of circulating cortisol is synthesized both at rest and during stress from plasma cholesterol (particularly in the form of HDL cholesterol) and this could be relevant in patients with liver cirrhosis where cholesterol is low and may limit the synthesis of cortisol[26]. In the liver, cortisol is converted to its inactive metabolite cortisone by the enzyme 11β - hidroxysteroid dehydrogenase. After diffusion across the cell membrane, cortisol binds to glucocorticoid receptor and translocates into the nucleus of the cell[37] where its effects are exerted (increased vascular tonus and cardiac output, protein catabolism, lipolysis, hyperglycemia, and decreased cytokine production)[38]. These effects of cortisol are beneficial in critical illness, and several studies have shown that corticosteroid therapy is beneficial in patients with severe sepsis or septic shock[12-14,39,40]. As adrenal glands do not store cortisol, this must urgently be synthesized from its precursor, cholesterol, under any conditions of stress. In cirrhotic patients there is a low substrate (HDL cholesterol) for the synthesis of cortisol, favoring AI in conditions of stress[26].

PATHOGENESIS

Mechanisms leading to AI in liver cirrhosis remain largely unknown, although some hypotheses such as endotoxemia, decreased levels of apolipoprotein A-1, HDL cholesterol and LDL cholesterol, increased levels of proinflammatory mediators, structural damage to the adrenal gland due to infarction or hemorrhage, bacterial translocation of enteric organisms, "exhaustion" of the adrenal cortex, and glucocorticoid resistance have been suggested[12,41-49]. Many (if not all) of these pathophysiologic mechanisms are also involved in the genesis of AI in critically ill patients with sepsis[50-56].

As we have mentioned, cholesterol is the main source of steroidogenic substrate in the adrenal gland[26,57]. Several studies reported a significant decrease in the level

of serum HDL in cirrhotic patients which was related to the severity of the disease[12,26,47]. Furthermore, increased levels of circulating endotoxin (lipopolysaccharide) and TNF-α inhibit cortisol synthesis, limiting the delivery of HDL cholesterol to the adrenal gland[58-60]. In addition to this, TNF-α, IL-1 and IL-6 decrease hepatocyte synthesis of apolipoprotein A-1[58], the major component of HDL cholesterol. The lack of substrate for steroidogenesis will eventually lead to the so-called "adrenal exhaustion syndrome"[42] which contributes to AI in cirrhotic patients.

Besides low levels of serum total cholesterol, HDL-cholesterol and LDL-cholesterol, other factors may play a definite role in the pathogenesis of AI in patients with liver cirrhosis. Thus, coagulopathy (frequent in liver cirrhosis) may cause adrenal hemorrhage and infarction leading to structural damage of the adrenal gland[5], resulting in AI. Systemic inflammation is common in cirrhotic patients[61]. Bacterial translocation of enteric organisms has been demonstrated in patients with advanced liver cirrhosis[41,62].

A high prevalence of AI reported in patients with stable cirrhosis[15-19,63], similar to that reported in cirrhosis complicated by sepsis/septic shock, suggests that AI may be a feature of liver disease *per se*, with a different pathogenesis from that occurring in septic shock. These findings are consistent with the observations of Marik *et al*[12] who put forward the term hepato-adrenal syndrome in order to define AI in patients with advanced liver disease.

DIAGNOSIS

Diagnosis of AI made on clinical grounds in critically ill cirrhotic patients is impossible because of the lack of typical addisonian features[5,13]. Hypotension refractory to vasopressors and fluid resuscitation is the most important clinical sign in such patients[52]. Therefore, the diagnosis of AI in patients with liver cirrhosis is based on the following laboratory tests.

Standard dose

Measurement of serum total cortisol, either at baseline or following stimulation by the standard dose-short synacthen test (SD-SST) or low dose-short synacthen test (LD-SST). Baseline serum total cortisol levels under 414 nmol/L[8,13,20,64-66], < 250 nmol/L[45] or < 138 nmol/L[67] have been used to define AI in different studies. The following thresholds were used to diagnose subnormal response to SD-SST or LD-SST: (1) a peak cortisol level (defined as the highest cortisol concentration after synacthen stimulation) < 690 nmol/L[16], < 552 nmol/L[12], < 500 nmol/L[14,15,18,45], < 442 nmol/L[17]; and (2) a delta cortisol (defined as the difference between peak and basal cortisol) less than 250 nmol/L[8,13,15-20,45,64-67].

As one can easily see, there are differences in the thresholds of serum total cortisol used to define AI in published studies, which may explain significant discrepancies in the prevalence of AI in cirrhotic patients. Moreover, the diagnosis of AI based on serum total cortisol in patients with cirrhosis may be inaccurate due to changes in serum concentrations of CBG and albumin (both synthesized in the liver) which are usually low[68-70]. It has been already shown that low levels of CBG and albumin lead to overestimation of the diagnosis of AI[45,67]. As we have mentioned before, over 90% of serum circulating cortisol is bound to CBG and albumin, with less than 10% in the free form. Standard laboratory assays of serum total cortisol measure the bound plus free fractions. This means that a decrease in the binding protein levels, as it often happens in cirrhosis, will reduce serum total cortisol, affecting the interpretation of SD-SST/LD-SST[35,44], and this may lead to the overestimation of AI in cirrhotic patients[45]. However, most of the studies evaluating adrenal function in critically ill patients with liver cirrhosis still rely on the measurement of serum total cortisol, both at baseline and after stimulation.

Serum free cortisol assays are considered the most reliable method to assess adrenal function in critically ill patients[71]. There are several methods used to measure serum free cortisol (gel filtration, ultrafiltration, equilibrium dialysis)[72], all of them expensive and inconvenient for routine clinical practice[73]. In patients with liver cirrhosis, the serum free cortisol level is not altered by a reduced concentration of CBG and albumin[74] and it therefore appears to be a more appropriate marker for assessing adrenal function in such patients[44,74]. Some studies reported significant differences in diagnosis of AI using serum total cortisol and free cortisol criteria in cirrhotic patients with septic shock[75] or in those with stable cirrhosis[15], while others found that assessing serum free cortisol had limited additive diagnostic value over serum total cortisol[76]. Serum free cortisol levels under 50 nmol/L at baseline or less than 86 nmol/L after synacthen stimulation are suggestive for the diagnosis of AI (in critically ill patients)[35], although the reference range for baseline values in healthy subjects varies from 8-25 nmol/L[71] to 12-70 nmol/L[44,77].

Due to the limitations of available assays to estimate serum free cortisol, surrogate markers may be used, such as Coolens equation "$U^2 \times K (1 + N) + U [1 + N + K (G - T)] - T = 0$", where T is total cortisol, G is CBG, U is unbound cortisol, K is the affinity of CBG for cortisol at 37 ℃ and N is the ratio of albumin-bound to unbound cortisol[68], free cortisol index (FCI) (serum total cortisol concentration divided by CBG level)[78], and salivary cortisol[71,79]. However, Coolens equation and FCI do not take into account the concentration of low serum albumin and CBG frequently present in cirrhotic patients and, therefore, both surrogates may not be suitable to estimate serum free cortisol in such patients[69-71]. By contrast, salivary cortisol, regardless of serum binding protein levels, correlates well with free cortisol levels[71,79]. Basal value of salivary cortisol < 1.8 ng/mL or a concentration after stimulation (SD-SST) < 12.7 ng/mL, an increment < 3 ng/mL[45] or a peak serum free cortisol < 33 nmol/L[15] are suggestive of AI. However, there are

significant variations in normal salivary cortisol values reported by different studies[74]. Other limits of salivary cortisol are represented by oral candidiasis, low salivary flow, and contaminated salivary samples from gingival bleeding, common in cirrhotic patients[44].

SD-SST

SD-SST measures total serum cortisol at baseline and 60 min after an intravenous injection of 250 μg of synthetic ACTH. Currently, there are two corticotropic analogues that can be used, namely tetracosactrin (synacthen, Novartis Pharma AG, Basel, Switzerland) and cosyntropin (Cortrosyn, Amphastar Pharmaceuticals, Rancho Cucamonga, CA, United States). Using a supraphysiological dose of 250 μg of corticotropin (which results in approximately 100 times higher than normal maximal stress ACTH levels)[17], SD-SST is not a "physiological test"[17,80]. In the context of critical illness, AI was defined by the International Task Force[6] as a delta cortisol of < 250 nmol/L (< 9 μg/dL) after SD-SST or a random serum total cortisol of < 276 nmol/L (< 10 μg/dL). There is no consensus on the diagnostic criteria of AI in cirrhotic patients, although a delta cortisol under 250 nmol/L has been used by most studies to define AI in such patients[81].

LD-SST

LD-SST uses 1 μg of synacthen given intravenously, and serum cortisol measured after 20 and 30 min (the latter time-point is mostly used). The normal response is a serum cortisol level > 500 nmol/L (> 18 μg/dL)[49]. In a meta-analysis[82] comprising the diagnostic value of SD-SST and LD-SST for diagnosing AI, LD-SST was found to be superior, contrary to another meta-analysis[83] which reported similar operative characteristics for both tests. LD-SST seems to be a more physiological and sensitive test than SD-SST for the diagnosis of AI, and appropriate for use in non-critically ill cirrhotic patients[49].

Insulin-induced hypoglycemia test

Insulin-induced hypoglycemia test (IIHT) has been considered to be the gold standard to evaluate the HPA axis. The test uses injection of 0.15 IU/kg regular insulin to achieve blood glucose less than 40 mg/dL or until symptoms of hypoglycemia develop. Blood samples are taken before and at 15, 30, 45, 60, 90 min post-stimulation. Peak cortisol cut points between 500 and 550 nmol/L (18-20 μg/dL) are used for the diagnosis of adrenal sufficiency. This test is contraindicated in patients with cardio- or cerebrovascular diseases and convulsive disorders. In addition, the IIHT is unpleasant for the patients and therefore it has been replaced by alternative tests (LS-SST, SD-SST) for evaluating the HPA axis[84].

Corticotrophin-releasing hormone test

Corticotrophin-releasing hormone test (CRHT) evaluates the entirety of the HPA axis. Blood samples for the measurement of ACTH and cortisol are taken at baseline and at 15, 30, 45 and 60 min after an intravenous injection of 1 μg/Kg of CRH. Although CRHT is free of serious side effects, it is both difficult and costly and therefore it has been used in few studies in liver disease.

To conclude, in the absence of a gold standard test, SD-SST remains the most used test to assess the adrenal function in critically ill cirrhotic patients, while LD-SST seems to be more appropriate in those with stable cirrhosis. At present, serum free cortisol and salivary cortisol are the most accurate methods for the diagnosis of AI in cirrhotic patients, but cannot be used in routine clinical practice. The use of salivary cortisol needs to be validated. As diagnosis of AI in cirrhotics is of major clinical importance, there is an urgent need for a consensus as to which is the most appropriate diagnostic test of AI in such category of patients.

PREVALENCE AND EXISTING EVIDENCE

Initial reports on AI in liver cirrhosis were followed by multiple studies (Tables 1 and 2) and, recently, by excellent systematic reviews[43,44,46,49,81]. There are significant discrepancies between studies on the prevalence of AI in patients with liver cirrhosis, mainly because of the different tests used for diagnosis of adrenal dysfunction and the criteria applied to define AI. Thus, the prevalence of AI varies between critically ill cirrhotic patients (10%-87%; Table 1), those with stable cirrhosis (7%-83%; Table 2), and patients with liver transplant (61%-92%; Table 1). Overall, several published studies have reported a high prevalence of AI both in critically and non-critically ill cirrhotic patients[17,29,63,64,69,85] as well as in those who had received liver transplant[12].

Critically ill patients with liver cirrhosis

Almost all studies that included critically ill patients with liver cirrhosis[8,13,20,29,64-66,74,85] used SD-SST for the diagnosis of AI and only two performed LD-SST[12,16]. With SD-SST, the reported prevalence of AI in critically ill cirrhotics varied between 10%[74] and 87%[85], while with LD-SST, the prevalence range was between 33%[12] and 60%[16].

Harry *et al*[14] reported a prevalence of AI (defined as peak cortisol levels less than 500 nmol/L) of 69% in critically ill cirrhotic patients requiring vasopressor support. In a prospective study including 25 cirrhotic patients with severe sepsis, Fernández *et al*[13] reported a very high incidence of AI (68%) using SD-SST and defining AI either as baseline serum total cortisol level less than 414 nmol/L or a delta cortisol lower than 250 nmol/L in those with a baseline concentration below 966 nmol/L. The AI prevalence rate was correlated with the severity of liver disease (76% Child-Pugh C *vs* 25% Child-Pugh B).

SD-SST was also used to evaluate adrenal function in a prospective study which included 101 critically ill patients with cirrhosis and severe sepsis[8]. Authors found that 51% of their patients met the criteria for AI (defined as baseline serum total cortisol values under 414 nmol/L

Table 1 Prevalence of adrenal insufficiency in critically ill patients with liver cirrhosis

Ref.	No. of patients (type of cirrhosis)	Diagnosis and definition of AI	Prevalence of AI
Harry *et al*[14]	20 (ALF/CLD)	SD-SST: Peak cortisol < 500 nmol/L[1]	69%
Marik *et al*[12]	340	LD-SST: Peak cortisol < 552 nmol/L or	72%
	(ALF: 24)	random cortisol level < 414 nmol/L in non-stressed patients or	33%
	(CLD: 146)	random cortisol level < 552 nmol/L in stressed patients	66%
	(recent LT: 119)		92%
	(remote LT: 51)		61%
Tsai *et al*[8]	101 (cirrhosis+ severe sepsis)	SD-SST: Baseline cortisol < 414 nmol/L or delta cortisol < 250 nmol/L if baseline cortisol between 414 and 938 nmol/L	51%
Fernandez *et al*[13]	25 (cirrhosis + septic shock)	SD-SST: Baseline cortisol < 414 nmol/L or delta cortisol < 250 nmol/L if baseline cortisol between 414 and 966 nmol/L	68%
Thierry *et al*[64]	14 (cirrhosis + septic shock)	SD-SST: Baseline cortisol < 414 nmol/L; delta cortisol < 250 nmol/L	77%
du Cheyron *et al*[65]	50 (critically ill cirrhosis)	SD-SST: Baseline cortisol < 414 nmol/L; delta cortisol < 250 nmol/L if baseline cortisol between 414 and 938 nmol/L	82%
Vasu *et al*[86]	24 (critically ill cirrhotics)	SD-SST: Definition of AI was not reported	62%
Arabi *et al*[29]	75 (cirrhosis + septic shock)	SD-SST: Delta cortisol < 250 nmol/L	76%
Mohamed *et al*[85]	15 (cirrhosis+septic shock)	SD-SST: Definition of AI was not reported	87%
Thevenot *et al*[74]	30 (cirrhosis + sepsis)	SD-SST: Peak serum total cortisol < 510 nmol/L	10%
Acevedo *et al*[89]	166 (decompensated cirrhosis)	SD-SST: Delta cortisol < 250 nmol/L	26%
Graupera *et al*[20]	37 (severe acute bleeding)	SD-SST: Baseline cortisol < 414 nmol/L and/or delta cortisol < 250 nmol/L	38%
Triantos *et al*[16]	20 (cirrhosis with variceal bleeding)	SD-SST: Baseline cortisol < 276 nmol/L or delta cortisol < 250 nmol/L	30%
		LD-SST: Peak serum cortisol < 690 nmol/L or a delta cortisol < 250 nmol/L	60%
El Damarawy *et al*[66]	45 (cirrhosis with septic shock or HRS, cirrhosis without septic shock or HRS)	SD-SST: Baseline cortisol < 414 nmol/L or delta cortisol < 250 nmol/L in patients with baseline cortisol < 966 nmol/L	73%

[1]To convert serum total cortisol concentrations from nanomoles per liter to micrograms per deciliter divide by 27.59[79]. ALF: Acute liver failure; CLD: Chronic liver disease; HRS: Hepatorenal syndrome; LT: Liver transplant; AI: Adrenal insufficiency; SD-SST: Standard dose short synacthen test; LD-SST: Low dose short synacthen test.

or delta cortisol lower than 250 nmol/L with a baseline value between 414 and 938 nmol/L) which was related to disease severity [Child-Pugh and model for end-stage liver disease (MELD) scores] and increased mortality. Recently, Arabi *et al*[29], using the same test (SD-SST) and definition for AI (delta cortisol < 250 nmol/L) in a similar group of critically ill patients (cirrhosis with septic shock) reported an even higher AI prevalence rate (76%).

The SD-SST test was also used in several other studies to assess adrenal function in critically ill cirrhotic patients[64-66,74,85,86].

Adrenal function has also been evaluated by SD-SST in cirrhotic patients with variceal bleeding[16,20]. Graupera *et al*[20] reported AI prevalence (defined as baseline serum cortisol < 414 nmol/L or delta cortisol < 250 nmol/L) in 38% of bleeding patients. AI was associated with increased risk of failure to control bleeding and lower survival rate at 6 wk. In a prospective observational study on 20 cirrhotic patients with variceal bleeding and 60 with stable cirrhosis, Triantos *et al*[16] reported an AI prevalence rate (defined as basal cortisol < 276 nmol/L or delta cortisol < 250 nmol/L following SD-SST) of 30% (similar to that in stable cirrhosis); with the use of LD-SST, AI prevalence (defined as a peak cortisol < 690 nmol/L or a delta cortisol < 250 nmol/L) was significantly higher in bleeders (60%) than in stable cirrhotics (48%).

LD-SST was also previously used by Marik *et al*[12] to evaluate adrenal function in 340 critically ill patients with liver disease (24 with fulminant hepatic failure, 146 critically ill cirrhotics, 51 with remote LT, and 119 having recently undergone LT). AI was defined as having a random cortisol level of < 552 nmol/L in highly stressed patients (hypotension, hepatic failure, respiratory failure) and a random cortisol level of < 414 nmol/L or a 30 min post LD-SST level of < 552 nmol/L in all other patients. Out of 340 patients studied, 245 (72%) met the criteria for AI (33% fulminant hepatic failure, 66% critically ill cirrhotics, 61% remote LT, 92% recent LT).

Non-critically ill cirrhotics

AI is also common in patients with stable liver cirrhosis (Table 2). However, as in critically ill cirrhotic patients, AI prevalence rate in those with stable liver cirrhosis varies significantly, depending on the diagnostic test used.

In a prospective study, Tan *et al*[15] evaluated adrenal function in 43 clinically stable cirrhotic patients. All patients underwent SD-SST, and AI was defined by delta cortisol < 250 nmol/L or a peak total cortisol < 500 nmol/L, or a peak serum free cortisol < 33 nmol/L. The prevalence of AI was 47% using delta cortisol < 250 nmol/L, 39% using peak total cortisol < 500 nmol/L, and 12% with serum free cortisol < 33 nmol/L. This study clearly shows that the reported prevalence of AI depends largely on the diagnostic test used and criteria for defining AI.

Galbois *et al*[45] have evaluated adrenal function in 88 patients hospitalized for complications of cirrhosis without bleeding and shock. Salivary and serum total cortisol were assessed 60 min before and after stimulation with SD-SST in all patients. Serum free cortisol was estimated

Table 2 Prevalence of adrenal insufficiency in patients with liver cirrhosis, not critically ill

Ref.	No. of patients (type of cirrhosis)	Diagnosis and definition of AI	Prevalence of AI
McDonald *et al*[69]	38 (stable cirrhosis)	IIHT: Reduction in maximal increments of plasma cortisol	64%
		SD-SST: Reduction in maximal increments of plasma cortisol	39%
Zietz *et al*[112]	52 (stable cirrhosis)	CRHT: Peak cortisol < 550 nmol/L or an increase < 250 nmol/L[1]	58%
		rise of plasma ACTH < twice the baseline	42%

		LD-SST: Peak serum cortisol < 500 nmol/L	48%
Mohamed *et al*[85]	15 (stable cirrhosis)	SD-SST: Definition of AI was not reported	53%
Risso *et al*[18]	85 (cirrhosis with ascites, without sepsis or shock)	SD-SST: Delta cortisol < 250 nmol/L and/or peak cortisol < 500 nmol/L	39%
Vincent *et al*[73]	26 (liver impairment)	SD-SST: Serum total cortisol < 550 nmol/L;	46%
		free cortisol index < 12	13%

[1]To convert serum total cortisol concentrations from nanomoles per liter to micrograms per deciliter divide by 27.59[79]. AI: Adrenal insufficiency; SD-SST: Standard dose short synacthen test; LD–SST: Low dose short synacthen test; CRHT: Corticotropin-releasing hormone test; IIHT: Insulin-induced hypoglycemia test; ACTH: Adrenocorticotropic hormone.

from serum total cortisol and CBG levels using Coolens' formula[68]. The following definitions of AI were used by the authors: (1) according to serum total cortisol assays: baseline < 250 nmol/L, or a peak total cortisol < 500 nmol/L, or delta cortisol < 250 nmol/L; (2) according to salivary cortisol assays: baseline < 1.8 ng/mL, or an increase < 3 ng/mL or a concentration < 12.7 ng/mL after stimulation. The results indicated a significant difference in AI prevalence depending on the test used: 33% when serum total cortisol was considered *vs* 9.1% using salivary cortisol.

Another study performed by Thevenot *et al*[74] has demonstrated that assessment of adrenal function with measurements of serum total cortisol overestimated AI prevalence in cirrhotic patients. In this study, baseline and post-synacthen serum total cortisol, serum free cortisol and salivary cortisol concentrations were measured in 125 cirrhotic patients (95 non-septic, 30 septic). AI was defined as serum total cortisol < 510.4 nmol/L after SD-SST. AI was found in nine patients (7.2%) (6 non-septic; 3 septic) and restricted to cirrhotics with Child-Pugh C. Serum total cortisol concentrations, CBG and albumin levels significantly decreased in non-septic patients as liver function deteriorated (from Child-Pugh A to C). Cirrhotic patients with or without AI had similar basal serum free cortisol and salivary cortisol levels. As the serum total cortisol level overestimated the prevalence of AI in cirrhotic patients, and serum free cortisol is not suitable for routine laboratory use, authors concluded that measurement of salivary cortisol is a useful approach in such patients. The same group of investigators[67] analyzed only the 95 hemodynamically stable cirrhotic patients from the previously mentioned study, who underwent a LD-SST. The serum total cortisol and serum free cortisol concentrations were measured 30 min before and after LD-SST. AI was defined as: (1) basal serum total cortisol < 138 nmol/L and < 440 nmol/L after stimulation; (2) serum total cortisol < 500 nmol/L after stimulation; and (3) cortisol increment < 250 nmol/L. AI prevalence rates varied significantly according to the threshold used: 7.4 % with basal serum total cortisol, 19% using serum cortisol < 440 nmol/L, 27.4 % with serum cortisol < 500 nmol/L, and 49.4% with delta cortisol. Serum free cortisol levels before and after LD-SST stimulation were higher in the more severe cirrhotic patients regardless of CBG and albumin concentrations, and directly associated with the risk of non-transplant-related mortality in hemodynamically stable patients with cirrhosis.

In opposition to the above mentioned studies, recently, in a prospective study, Molenaar *et al*[76], using SD-SST, assessed the value of free *vs* total cortisol levels while evaluating AI in 49 septic and 63 non-septic patients with treatment-insensitive hypotension and found that total cortisol correlated with free cortisol during critical illness. Moreover, in sepsis, hypoalbuminemia did not affect total and free cortisol, contrary to the findings of other published studies[45,67].

Others, using SD-SST or LD-SST to diagnose adrenal dysfunction in patients with stable liver cirrhosis reported high AI prevalence rates[16-19,63,69,73,85,87,88]. Fede *et al*[17] reported an AI prevalence of 38% in 101 patients with stable cirrhosis (absence of infections or hemodynamic instability). AI, defined as a peak serum total cortisol level < 500 nmol/L after LD-SST, was correlated with the severity of liver disease graded according to Child-Pugh or MELD scores.

Using SD-SST in 85 cirrhotics with ascites but without sepsis, Risso *et al*[18] reported AI (delta cortisol < 250 nmol/L and/or peak cortisol < 500 nmol/L) in 39% of patients.

Vincent *et al*[73] evaluated adrenal function by SD-SST in 26 patients with liver impairment. Authors defined AI as serum total cortisol < 550 nmol/L or FCI < 12. Three patients (13%) met both criteria, 12 patients (46%) had a serum total cortisol < 550 nmol/L but an FCI > 12. When serum total cortisol was used, 46% of patients had AI, while when using FCI only 13% fulfilled the criteria for AI. Authors suggested that FCI is better suited for the evaluation of AI in patients with liver impairment.

Acevedo *et al*[19], using SD-SST, evaluated the prevalence of AI in 198 patients with liver cirrhosis [10 with compensated, 188 with decompensated cirrhosis and complications (hepatic encephalopathy, spontaneous bacterial peritonitis, ascites, gastrointestinal bleeding, hepatorenal syndrome)]. AI defined as basal serum total cortisol < 414 nmol/L was found in 64% of patients, and only in 27% when delta cortisol < 250 nmol/L was used, with no differences between compensated and decompensated cirrhosis. The same group of researchers evaluated the prevalence and prognostic value of AI in 166 patients with advanced cirrhosis (no severe sepsis or septic shock)[89]. AI, defined as delta cortisol < 250 nmol/L after SD-SST, was found in 26% of patients. Those with AI had a higher degree of circulatory dysfunction, greater prevalence of systemic inflammatory response syndrome, increased probability to develop severe infections, and higher hospital mortality rates than patients without AI.

AI after LT

AI has been reported both early as well as late after LT[12,21-23,90].

With LD-SST, Marik *et al*[12] found that 92% of 119 patients undergoing recent LT and maintained on steroid-free immunosuppressive regimens had AI. The steroid-free immunosuppressive regimen may expose patients undergoing LT to an increased risk for AI, while the use of steroids intra and postoperatively in LT may reduce such a risk or mask an AI[46]. Furthermore, LD-SST is not recommended for the diagnosis of AI in high-stress conditions like LT[6] as it may lead to an overestimated AI prevalence in such patients.

Toniutto *et al*[21], using SD-SST, reported an AI prevalence rate of 26% in 87 patients having received LT for end-stage liver disease and maintained on prolonged immunosuppressive treatment.

Patel *et al*[90] reported significantly reduced requirements for fluid, vasopressors, invasive ventilation, and renal replacement therapy, and intensive care unit stay for patients undergoing LT who received 1000 mg methylprednisolone prior to the liver graft reperfusion.

TREATMENT

Cortisol has several beneficial effects such as an increase of the vascular tonus and cardiac output, enhancement of catecholamine responsiveness, inhibition of the production of nitric oxide, modulation of cytokine production in septic shock[32,91-97], but the effects of corticosteroid therapy in sepsis, severe sepsis and septic shock remain, however, controversial. Thus, a significant reduction in mortality rate with hydrocortisone therapy in patients with septic shock has been reported in several studies and meta-analyses[6,28,39,98-101], while others have shown no effect on the 28-d mortality rate[14,29,102]. Both doses and duration of corticosteroid therapy vary significantly in published studies[6,28,39,40,102,103]. Thus, some used a daily dose of hydrocortisone (or equivalent) of 200-300 mg ("low-dose", also called "physiologic-dose" or "stress-dose")[3,28,39,98,100-105] while others used a "supra-physiologic" dose (> 300 mg)[98,106-108].

None of the early studies using high doses of corticosteroids for short courses reported any benefit[98,106-108], while more recent studies using a "physiologic-dose" for longer durations have shown a significant reduction in vasopressor agents requirement and in intensive care unit length of stay, greater shock resolution, and decreased mortality[6,28,39,98,100,104,105,109-111]. A randomized, double-blind placebo controlled trial, CORTICUS (Corticosteroid Therapy of Septic Shock)[102] including 499 patients with septic shock randomized to hydrocortisone (50 mg intravenously every 6 h for 5 d, followed by 50 mg intravenously every 12 h for 3 d, and then by 50 mg daily for 3 d) or placebo, concluded that there was no benefit in terms of mortality, although steroid administration was associated with a greater shock reversal, but also with a higher incidence of episodes of new infections. On the other hand, Annane *et al*[28] in a randomized, double-blind controlled trial have found that the administration of hydrocortisone (50 mg intravenously every 6 h) and oral fludrocortisone (50 μg once daily) in patients with refractory septic shock and AI (delta cortisol < 250 nmol/L) resulted in a 30% decrease in 28-d mortality. It should be mentioned that consensus statements from an international task force[6] recommended corticosteroid therapy

Table 3 Published studies on corticosteroid therapy in patients with liver cirrhosis

Ref.	No. of patients (type of cirrhosis)	Study design	Steroid dose	Outcomes
Harry *et al*[14]	20 (ALF or ACLF)	Retrospective	Hydrocortisone 300 mg/d	Reduction in vasopressor doses, but higher incidence of infection and no survival benefit
Marik *et al*[12]	140 (ALF or CLD)	Not RCT	Hydrocortisone 300 mg/d	Reduction in the dose of norepinephrine at 24 h, and lower mortality rate increased survival
Fernandez *et al*[13]	17 (cirrhosis and septic shock)	Prospective but not RCT	Hydrocortisone 200 mg/d	Significant increase in shock resolution and high hospital survival rate
Arabi *et al*[29]	39 (cirrhosis and septic shock)	RCT	Hydrocortisone 200 mg/d	Reduction in vasopressor doses and higher rates of shock reversal, but no benefit in 28 d mortality, increase in gastrointestinal bleeding and shock relapse

ALF: Acute liver failure; ACLF: Acute-on-chronic liver failure; CLD: Chronic liver disease; RCT: Randomized controlled trial.

(intravenous hydrocortisone 200-300 mg/d in four divided doses for a week before tapering slowly) in patients with vasopressor-dependant septic shock.

Like in patients with severe sepsis/septic shock with other causes than liver cirrhosis, as mentioned above, the effects of steroid therapy in cirrhotic patients with AI remain controversial, some studies reporting beneficial results[12-14] while a recent randomized control study[29] has shown no benefit (Table 3).

Harry *et al*[14] evaluated the effects of stress doses of hydrocortisone in a retrospective comparative study including 40 patients. Twenty patients received hydrocortisone (300 mg/d) for 4-5 d. In patients with acute-on-chronic liver failure requiring norepinephrine support, the results showed a reduction in vasopressor doses, but no survival benefit; moreover, corticosteroid therapy was associated with a significant increase in infections.

Another study, carried out by Marik *et al*[12] evaluated the effect of 300 mg/d hydrocortisone given intravenously in vasopressor-dependant patients with acute or chronic liver disease. In patients with AI, treatment with hydrocortisone was associated with a significant reduction of the norepinephrine dosage at 24 h and with a lower mortality ($P = 0.02$), whereas in those patients without AI hydrocortisone did not affect the norepinephrine dose.

Fernández *et al*[13], in a prospective but non-randomized study have evaluated adrenal function by SD-SST and the effects of low-dose hydrocortisone in 25 patients with advanced cirrhosis and septic shock. Patients with AI received intravenous hydrocortisone (50 mg every 6 h) and results were compared with those obtained from a retrospective 50 cirrhotic patients with septic shock in whom adrenal function was not investigated and who did not receive corticosteroid therapy. Results showed that hydrocortisone therapy was associated with a significant increase in shock resolution and hospital survival rate. Authors suggested that all cirrhotic patients with AI should be treated with hydrocortisone.

Recently, Arabi *et al*[29] in a randomized controlled trial, have shown that low dose hydrocortisone therapy in cirrhotic patients with septic shock had a significant reduction in vasopressor doses and higher rates of shock reversal, but it did not reduce mortality and was associated with an increase in adverse effects (gastrointestinal bleeding) and shock relapse.

Based on the above mentioned studies, there are still several unsolved problems and questions awaiting answers. Thus, re-evaluation of both doses and duration of corticosteroid therapy is necessary. Obviously, further prospective randomized clinical studies are needed to assess the effect of corticosteroid therapy in critically ill cirrhotic patients with AI.

CONCLUSION

AI occurs frequently in patients with liver cirrhosis both during critical illness and in stable disease. Studies, however, do not agree on the prevalence of AI in cirrhotic patients, mostly because of the different criteria and the methodology used to define AI. Diagnosis of AI in patients with liver cirrhosis remains controversial (particularly in those critically ill) as all diagnostic tests proved their limitations. Pathogenesis of AI in liver cirrhosis is still unknown, although decreased levels of cholesterol (mainly HDL cholesterol) and increased levels of pro-inflammatory cytokines and circulating endotoxin have been put forward. Some data suggest that AI may be a feature of cirrhosis *per se*, with a pathogenesis subtly different from that occurring in septic shock from other causes. Yet, there is still controversy in what concerns treatment with corticosteroids, although some cirrhotic patients with vasopressor resistant shock may benefit. However, further prospective, randomized clinical trials are necessary to assess the effect of corticosteroid therapy in critically ill patients with cirrhosis.

Abstract

It is estimated that about half of the population in developed countries are either overweight or obese. In some developing nations obesity rates have increased to surpass those seen in Western countries. This rate increase in obesity has many implications as obesity has been associated with numerous negative health effects including increased risks of hypertension, diabetes, cardiovascular disease, stroke, liver disease, apnea, and some cancer types. Obesity is now considered to be one of the major public health concerns facing the society. Cholangiocarcinomas (bile duct cancers) are malignant tumors arising from cholangiocytes inside or outside of the liver. Although cholangiocarcinomas are relatively rare, they are highly lethal. The low survival rate associated with cholangiocarcinoma is due to the advanced stage of the disease at the time of diagnosis. Prevention is therefore especially important in this cancer type. Some data suggest that the incidence of cholangiocarcinoma in the western world is on the rise. Increasing rate of obesity may be one of the factors responsible for this increase. Determining whether obesity is a risk factor for cholangiocarcinoma has significant clinical and societal implications as obesity is both prevalent and modifiable. This paper seeks to provide a summary of the current knowledge linking obesity and cholangiocarcinoma, and encourage further research on this topic.

INTRODUCTION

Obesity is increasing worldwide and affects a large portion of the population in developed[1-5] and some developing nations[6-13]. In many countries obesity and its comorbidities have become a major public health concern[1,14-16]. Recently, obesity-associated cancer has attracted great attention. Epidemiological studies have provided strong evidence that obesity can increase the incidence of many cancer types[17] including colon[18,19], breast[20,21], liver[22], endometrium[23,24], kidney[25], esophagus[26], stomach[27] and pancreas[28].

Cholangiocarcinomas (bile duct cancers) are malignant tumors arising from cholangiocytes inside or outside of the liver. Traditionally cancers arising from the cholangiocytes inside the liver were grouped together with hepatic cancers and classified as primary liver tumors, while those arising from the cholangiocytes outside the liver were grouped together with cancers of the gallbladder and the ampulla of Vater and classified as biliary cancers[29]. More recently, the term cholangiocarcinoma has been used to refer to cancers arising from cholangiocytes irrespective of their location[29].

Intrahepatic cholangiocarcinomas originate from cholangiocytes lining the small intrahepatic ductules while extrahepatic cholangiocarcinomas arise from cholangiocytes lining the larger bile ducts (right and left hepatic ducts, common hepatic duct, and common bile duct)[30]. The distinction between intrahepatic and extrahepatic cholangiocarcinomas is important, as the incidence and risk factors associated with each may be different[31-33].

In Western countries established risk factors for cholangiocarcinoma are age, sex, primary sclerosing cholangitis, and bile duct cysts. Less-established potential risk factors include cirrhosis, diabetes, obesity, alcohol, and smoking. Some data suggest that the incidence of cholangiocarcinoma in the Western world is on the rise. Increasing rate of obesity may be one of the factors responsible for this increase.

Although cholangiocarcinomas are rare in Western countries, they are highly lethal[34]. Annual mortality associated with cholangiocarcinoma is virtually identical to its incidence throughout the world, underscoring the high case fatality rate of this cancer type[35]. The low survival rate associated with cholangiocarcinoma is due to the advanced stage of the disease at the time of diagnosis[36]. Prevention is therefore especially important in this cancer type. Determining whether obesity is a risk factor for cholangiocarcinoma has significant clinical and societal implications as obesity is both prevalent and modifiable.

EPIDEMIOLOGY

Obesity prevalence

Obesity is considered to be among the most alarming health concerns in the United States. It has been estimated that each year, more than 300 000 Americans die from illnesses related to overweight and obesity[37]. The Centers for Disease Control and Prevention (CDC) defines obesity based on the body mass index (BMI). BMI is the ratio of weight in kilograms (kg) to height in meters squared (m^2). Per CDC criteria, a BMI of 18.5-25 kg/m^2 is normal, 25-30 kg/m^2 is overweight and $\geqslant$ 30 kg/m^2 is obese[38]. The most recent statistics from the National Health and Nutrition Examination Surveys using BMI as a measure of overweight and obesity indicate that 35.7% of adults 20 years or older were obese in 2009-2010[39]. Compared with the statistics for 1976-1980 this reflects a 2-fold increase in the prevalence of adult obesity[40,41]. This rate increase in obesity has many implications as obesity has been associated with numerous negative health effects including increased risks of hypertension, diabetes, cardiovascular disease, stroke, liver disease, apnea, and some cancer types possibly also cholangiocarcinoma. Therefore, as a potentially modifiable risk factor, a reduction in the prevalence of obesity among adults could have a substantial impact on morbidity, mortality, and incidence of various cancers.

Cholangiocarcinoma incidence

The available epidemiologic data on incidence and prevalence of cholangiocarcinoma are difficult to interpret because of differing classifications and diagnostic criteria across studies[29,32,42]. For instance, some studies group intrahepatic cholangiocarcinomas with liver cancers while others group extrahepatic cholangiocarcinomas with gallbladder cancers and cancers of the ampulla of Vater. Furthermore, some studies misclassify types of cholangiocarcinomas. For example, Klatskin tumors (a type of extrahepatic cholangiocarcinoma), at times, have been misclassified as intrahepatic cholangiocarcinoma[29,30]. Finally, some studies use histology as the only diagnostic criterion while others accept other forms of diagnosis such as clinical evaluation or imaging studies.

Despite these shortcomings, the available data suggest a highly variable incidence in different parts of the world, with the highest incidence in Southeast Asia and lowest in Australia[43,44]. The incidence of cholangiocarcinoma has been reported to be as high as 96 cases per 100 000 in men and 38 per 100 000 in women in northeast Thailand[43]. In Australia, the reported incidence is 0.2 per 100 000 among Australian men and 0.1 per 100 000 among Australian women[43]. In other Western countries including the Unites States the incidence is close to 1 case per 100 000 population[43]. In Western countries, approximately 80% of cholangiocarcinomas are extrahepatic[45]. Differing exposure to risk factors is thought to account for the varying geographic incidences, with parasitic infections and hepatolithiasis being more prevalent in Asia[46-48].

Recent data show that the incidence of intrahepatic cholangiocarcinoma is increasing around the world, while the incidence of extrahepatic cholangiocarcinoma has been largely stable or even decreasing[32,43,49]. Although the exact underlying mechanism for this discrepancy is not known, it suggests that intrahepatic and extrahepatic cholangiocarcinomas may be biologically different[32,49,50].

Finally, there is evidence suggesting under-diagnosis of cholangiocarcinoma. For example among patients transplanted for liver cirrhosis of various etiologies, an incidental cholangiocarcinoma was found in approximately 12% of explanted livers[51]. This suggests that the true incidence of cholangiocarcinoma may be higher than previously reported.

Obesity as a risk factor for cholangiocarcinoma

Data assessing the association of obesity and cholangiocarcinoma are limited. So far, four epidemiologic studies have tried to assess the link between obesity and cholangiocarcinoma (Table 1). Three of these studies were specifically designed to identify risk factors for cholangiocarcinoma[52-54].

One of those studies using the Surveillance, Epidemiology, and End Results database that links cancer registry data and Medicare enrollment and claims files, reported a significant association between obesity and intrahepatic cholangiocarcinoma, but not between obesity and extrahepatic cholangiocarcinoma[52]. That study however, has several limitations. The study only included patients 65 years of age and older, therefore the findings might not be generalizable to a younger population. Furthermore, because Medicare data are collected for billing rather than research purposes, completeness and accuracy of the Medicare data on prevalence of obesity and cholangiocarcinoma can be questioned. Finally, the possibility of diagnostic bias cannot be excluded because obese people with different medical conditions are more likely to undergo testing and thus have more diagnoses than other people.

Another population-based study conducted in Denmark did not find any significant association between

Table 1 Epidemiologic studies assessing obesity as a potential risk factor for cholangiocarcinoma

Ref.	Study design	Type of CC	Study findings	Study limitations
Welzel *et al*[52]	Case-control	ICC and ECC	Positive association between obesity and ICC; no association between obesity and ECC	Only included age ⩾ 65 yr; database limitations; possible diagnostic bias
Welzel *et al*[53]	Case-control	ICC	No association between obesity and ICC	ECC not included
Grange *et al*[54]	Case-control	NS	Positive association between obesity and cholangiocarcinoma	Type of CC not specified; diagnosis subject to misclassification
Oh *et al*[55]	Cohort	NS	Positive association between obesity and cholangiocarcinoma	Does not distinguish ECC and ICC; included only males; database limitations

CC: Cholangiocarcinoma; ECC: Extrahepatic cholangiocarcinoma; ICC: Intrahepatic cholangiocarcinoma; NS: Not stated.

obesity and intrahepatic cholangiocarcinoma[53]. That study used a fairly accurate and complete national registry. Another strength of that study was histological confirmation of cholangiocarcinoma diagnosis in all cases. Extrahepatic cholangiocarcinoma, however, was not studied.

The third study, conducted in the United Kingdom by Grainge *et al*[54], found that obese patients (BMI ⩾ 30 kg/m^2) had 1.5 times the risk of cholangiocarcinoma compared with those with BMI < 25 kg/m^2. In that study the type of cholangiocarcinoma (intrahepatic versus extrahepatic) was not specified. Another limitation of that study was that the diagnosis was not based on histology and therefore subject to misclassification.

Aside from studies looking specifically to identify risk factors for cholangiocarcinoma, a South Korean population-based study tried to assess the effect of excess weight on incidence of various cancers including cholangiocarcinoma[55]. The study found that compared to the reference group (BMI 18.5-23 kg/m^2), increasing BMI was associated with an increase in the relative risk for development of cholangiocarcinoma[55]. That study, however, did not distinguish between intrahepatic and extrahepatic cholangiocarcinomas, included only males, and the database used was not inclusive of the entire population.

In summary, the epidemiologic data available on obesity as a risk factor for cholangiocarcinoma show conflicting results and are too limited to make any conclusions.

BIOLOGIC MECHANISMS FOR POSITIVE ASSOCIATION BETWEEN OBESITY AND CHOLANGIOCARCINOMA

Obesity is an excess of adipose tissue. Adipose tissue is a biologically active organ which in addition to adipocytes contains multiple other cell types such as pre-adipocytes, endothelial cells, macrophages and other immune cells[56]. Adipose tissue secretes molecules into the bloodstream, which signal to other metabolic organs or to the brain to coordinate responses to altered metabolic demands[57]. Some of these molecules, known as adipokines, have a role in modulating the risk of cancer development. Among adipokines, some of the most studied are leptin, adiponectin and pro-inflammatory molecules.

Leptin is a hormone that is primarily secreted by the adipose tissue[58]. It acts on the hypothalamus to regulate food consumption and caloric homeostasis[58,59]. Although the major physiological site of leptin action is in the central nervous system, leptin receptors are also expressed at lower levels in peripheral tissues[60]. Two studies have shown presence of leptin receptors on cholangiocytes[61,62]. Circulating serum leptin is increased in obesity, and has been suggested as a risk factor for cholangiocarcinoma[62]. A recent study showed that normal and malignant intrahepatic cholangiocytes express leptin and leptin receptors[62]. The investigators of that study also showed that leptin stimulates growth and migration, and prevents apoptosis of intrahepatic cholangiocarcinoma cells *in vitro*[62]. They also showed that genetic ablation of leptin-mediated signaling inhibits cancer development and growth in an animal model of cholangiocarcinoma[62].

Adiponectin is another adipokine that may be involved in cancer development[63]. It acts on a number of tissues to regulate glucose and lipid metabolism. Adiponectin levels are reduced in obesity. Several basic and epidemiological studies have suggested that adiponectin has antitumor effects[63,64]. Although the link between adiponectin and cholangiocarcinoma has not been studied, there is convincing evidence for an inverse association between adiponectin levels and cancer risk for several cancer types[59,63,65-67].

Several pro-inflammatory cytokines are secreted by monocytes and other immune cells that infiltrate adipose tissues in obesity[68,69]. Among these cytokines, interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) have been found to have a role in development of cholangiocarcinoma[70]. A growing body of evidence suggests that the inflammatory environment in the obese state is linked to the development of cancer through various mechanisms[71]. IL-6 seems to have an important role in the pathogenesis and growth of cholangiocarcinoma and has been shown to act by both an autocrine and paracrine manner stimulating several intracellular pathways involved in survival and growth of malignant cholangiocytes[36,72-74]. TNF-α is a mediator of inflammation with actions directed towards both tissue destruction and recovery[70]. Evidence suggests that TNF-α may act as an endogenous tumor promoter in addition to its role in immune responses[75,76]. Overexpression of TNF-α receptor genes has been observed in cholangiocarcinoma associated with hepatolithiasis[75-78].

Although not specifically linked to cholangiocarcino-

ma, there are multiple other substances that have directly or indirectly been linked to cancer in general[57]. Research on the role of different substances on development and progression of different cancers including cholangiocarcinoma is evolving.

DISCUSSION

It is estimated that about half of the population in developed countries are either overweight or obese[79]. In some regions of the world overweight and obesity affects more than two-thirds of the population[80]. By 2008, an estimated 1.5 billion adults globally were overweight and 500 million adults were obese[81]. Because of such high prevalence, establishing a clear link between excess body weight and cholangiocarcinoma can have significant effect on prevention of cholangiocarcinoma. Establishing a link may also encourage further research on identification of underlying pathophysiologic mechanisms that can potentially lead to discovery of better treatment options.

Research on obesity and cholangiocarcinoma risk should be encouraged through a variety of activities, including large cooperative initiatives, database resources, epidemiologic studies, basic science studies, and increase in funding resources.

If a link between excess weight and cholangiocarcinoma is established, multiple new questions will emerge that will need to be answered. Does reversal of obesity affect the risk for cholangiocarcinoma? Are there any differences between different modes of weight reduction (calorie restriction, exercise, drugs, bariatric surgery) in terms of cholangiocarcinoma risk reduction? Can the link between obesity and cholangiocarcinoma be somehow disrupted in the absence of weight loss (which for many individuals is a difficult task)?

Answers to these and other questions that will surely follow require well-designed studies that incorporate molecular, genetic, metabolic and nutritional factors.

Abstract

Diagnostic and therapeutic endoscopy can successfully be performed by applying moderate (conscious) sedation. Moderate sedation, using midazolam and an opioid, is the standard method of sedation, although propofol is increasingly being used in many countries because the satisfaction of endoscopists with propofol sedation is greater compared with their satisfaction with conventional sedation. Moreover, the use of propofol is currently preferred for the endoscopic sedation of patients with advanced liver disease due to its short biologic half-life and, consequently, its low risk of inducing hepatic encephalopathy. In the future, propofol could become the preferred sedation agent, especially for routine colonoscopy. Midazolam is the benzodiazepine of choice because of its shorter duration of action and better pharmacokinetic profile compared with diazepam. Among opioids, pethidine and fentanyl are the most popular. A number of other substances have been tested in several clinical trials with promising results. Among them, newer opioids, such as remifentanil, enable a faster recovery. The controversy regarding the administration of sedation by an endoscopist or an experienced nurse, as well as the optimal staffing of endoscopy units, continues to be a matter of discussion. Safe sedation in special clinical circumstances, such as in the cases of obese, pregnant, and elderly individuals, as well as patients with chronic lung, renal or liver disease, requires modification of the dose of the drugs used for sedation. In the great majority of patients, sedation under the supervision of a properly trained endoscopist remains the standard practice worldwide. In this review, an overview of the current knowledge concerning sedation during digestive endoscopy will be provided based on the data in the current literature.

INTRODUCTION

Today, both the number and complexity of endoscopic procedures have increased considerably due to the wide availability and application of sedation, which facilitates successful endoscopic procedures because it can relieve patients' anxiety and discomfort, concurrently allowing them to experience a rapid recovery with the use of antidotes. Consequently, the willingness of patients to undergo endoscopy, irrespective of the severity of their situation, is increasing.

The best methods for analgesia and sedation during digestive endoscopy are still debated. Intravenous sedation can be administered by the endoscopist who concurrently performs the procedure while a qualified nurse monitors the patient's state of consciousness and vital signs. Providing an adequate regimen of sedation/analgesia may be considered a form of art, which influences,

for example, the quality of the examination and the patient's and physician's satisfaction with the sedation[1]. It must be argued that the optimal level of sedation differs according to the procedure being performed. Deep sedation or even general anaesthesia may be preferred for therapeutic procedures in which it is important for a patient to remain immobile. It is obvious that endoscopists commencing sedation/analgesia should be able to rescue patients whose level of sedation has become deeper than initially intended.

However, even today, many significant issues, such as the benefits, risks, and costs of sedation; the selection of the most suitable drug and combination of drugs for use; and the person responsible for the administration of sedation and monitoring of the patient, especially during time-consuming procedures such as colonoscopies and endoscopic retrograde cholangiopancreatography (ERCPs), remain unanswered[2].

The aim of this review is to provide the reader with an overview of the current knowledge concerning sedation during digestive endoscopy (drugs currently used and drugs under investigation, sedation during upper and lower gastrointestinal (GI) endoscopy and ERCP, and endoscopy in special situations) based on the data available in the current literature.

SEDATION PRACTICES

Sedation practices vary in different countries depending on health system regulations and local circumstances. On the other hand, differences in the setting in which the practice of gastroenterology and endoscopy takes place, e.g., at university hospitals versus community hospitals or private endoscopy units, as well as other systematic practice differences, could influence the attitude of endoscopists concerning sedation practices.

Data concerning the incidence of sedation application in routine practice are rather limited. Among the members of the Canadian Association of Gastroenterology, more than 90% use sedation during colonoscopy[3]. The use of sedation has become a standard practice during GI endoscopy in Italy[4]. Among the members of the Hellenic Society of Gastroenterology, 64% use sedation regularly in cases of upper GI endoscopy, 78% use sedation in colonoscopies, and 100% use sedation during ERCP and endoscopic ultrasound (EUS)[5]. In the United States, more than 98% of colonoscopies are performed with intravenous sedation[6]. In Switzerland, the use of sedation in GI endoscopy has markedly increased, and the use of electronic monitoring has become a standard practice. In this country and during 2003, sedation was used in 78% of upper and lower GI endoscopic procedures, compared with 60% in 1990. In Germany, the majority of esophagogastroduodenoscopy (EGDs; 74%) and colonoscopies (87%) are carried out under sedation[7]. In Spain, sedation is used in 20% of EGDs and 20% of colonoscopies, while ERCP is almost always performed under sedation[8].

With regard to the most common sedation regimen used in different countries, it was reported that most Canadian endoscopists use a combination of midazolam and fentanyl for colonoscopy, while propofol, either alone or in combination with other drugs, is used in a small proportion of patients[3]. Interestingly, a significantly higher proportion of adult gastroenterologists who routinely used propofol are highly satisfied compared with those using other drugs. According to a recent survey among the members of the Italian Society of Digestive Endoscopy, the most commonly employed sedation patterns are benzodiazepines for upper GI endoscopy (50.8%), benzodiazepines plus opioids for colonoscopy (39.5%) and enteroscopy (35.3%), and propofol for ERCP (42.3%) and EUS (35.6%). Concerning the use of propofol, 66% of endoscopists stated that the drug was administered exclusively by anaesthesiologists[4]. In Greece, 62.1% of the endoscopists use synergistic sedation (benzodiazepines plus opioids), 35.3% use benzodiazepines alone and 33.8% use propofol-based sedation in selected cases. Propofol administration is directed by an anaesthesiologist in most cases[5]. In the United States, more than 75% of endoscopists use a benzodiazepine plus narcotic combination, with the combination of midazolam and fentanyl being the most common[6]. In Switzerland, midazolam is the most commonly used medication. The drug is administered by the endoscopy nurse *via* an intravenous cannula. A significant percentage of endoscopists (43%) also use propofol regularly, mainly in a hospital setting. Endoscopists reporting the use of propofol without the assistance of an anaesthesiologist had performed a total of 82 620 procedures. The morbidity in this group of patients was 0.19%, with no cases of mortality[9]. The doses of midazolam and fentanyl used by the Canadian endoscopists are similar to those recommended in the United States (< 6 mg of midazolam and < 200 μg of fentanyl) and in the United Kingdom (< 5 mg of midazolam and < 100 μg of fentanyl)[10]. In Spain, the most common drugs were midazolam for gastroscopy and midazolam and pethidine for colonoscopy and ERCP, while propofol is most frequently used by anaesthesiologists[8]. In Germany, the most frequently used agents for sedation are midazolam (82%) and propofol (74%), and the most common sedation regimens used are propofol plus benzodiazepines (38%) and benzodiazepines plus an opioid (35%)[7].

In Italy, pulse oximetry is the most common system for patient monitoring during endoscopy, while supplemental O_2 is routinely administered by 39.3% of endoscopists[4]. In Greece, pulse oximetry is used in 96% of endoscopic procedures[5]. Major endoscopy societies, including those of Canada and the United States, recommend the use of pulse oximetry, continuous electrocardiogram and blood pressure, and heart rate monitoring in patients receiving propofol[11,12]. In Switzerland, pulse oximetry monitoring is currently used in more than 95% of examinations, compared with 2.5% of examinations in 1990[9]. In Germany, all patients are routinely moni-

Table 1 Percentage of sedation use in different countries

Country	Sedation	Propofol use	Benzodia-zepines alone use	Benzodiaze-pines plus opioids use	No. of nurses present during endoscopy	Pulse oximetry use	Supplemental oxygen use
Canada	90%	12%		always	1		
Italy		42.30% for ERCP (by anaesthesiologists)	50.80%	39.50%		100%	By 39.3% of endoscopists
Greece	EGD: 64%; Colonoscopy: 78%; ERCP: 100%; EUS: 100%	33.80% (in selected cases and only by anaesthesiologists)	35.30%	62.10%		96%	
United States	98%	25.70%		74.30%		98.60%	By 72.7% of endoscopists (in all EGDs)
Switzerland	78%	43% (regular use with or without the help of an anaesthesiologist)	Midazolam for the majority of endoscopies		1	95%	
Spain	EGD: 20%; Colonoscopy: 20%; ERCP: 100%; EGD: 74%	Only by anaesthesiologists	Only for EFD	Only for colonoscopies	1	77%	
Germany	Colonoscopy: 87%	74%	82%	35%		97%	34%

ERCP: Endoscopic retrograde cholangiopancreatography; EGD: Esophagogastroduodenoscopy; EUS: Endoscopic ultrasound; EFD: Energy flux density.

tored by pulse oximetry, while automated blood pressure monitoring and/or electrocardiography are applied in 29 and 13% of cases, respectively. Supplemental oxygen is routinely administered to 34% of patients[7].

Data concerning endoscopy practices in developing nations are scarce. In a study comparing endoscopy practices between endoscopists practising in 46 developed and developing countries, no significant differences in the use of a benzodiazepine and opioid combination, propofol alone, or unsedated endoscopy were found. Sedation is used for most endoscopic procedures, leading to the conclusion that sedation practices do not significantly differ between developing and developed countries[13].

Table 1 provides a summary of sedation practices in some parts of the world.

DRUGS CURRENTLY USED FOR SEDATION IN GI ENDOSCOPY

Various types of sedation and analgesia techniques are used during GI endoscopy procedures. Currently, there is no standard sedation regimen, and even within individual institutions, the choice of sedation may depend on endoscopist preference and the procedure being performed. Benzodiazepines, such as alprazolam, bromazepam, brotizolam, clotiazepam, diazepam, etizolam, flunitrazepam, lorazepam, midazolam, oxazepam and triazolam, are among the most frequently prescribed drugs. These drugs act as anxiolytics, sedatives, hypnotics, amnesics, antiepileptics and muscle relaxants. Among them, midazolam is an important drug and is widely used in everyday endoscopy work. It is now considered to be the benzodiazepine of choice, as it has a shorter duration of action and a better pharmacokinetic profile than diazepam. Other drugs used for sedation include opioids (pethidine and fentanyl), propofol, ketamine and droperidol. Adequate knowledge of the pharmacokinetic properties of these agents is crucial when commencing sedation (Table 2)[14].

The special characteristics of the currently available drugs for digestive endoscopy, as well as the drugs under investigation, are shown in Table 3 and are subsequently summarised in the following sections.

Midazolam

Midazolam is most likely the most widely used drug for sedation in everyday endoscopic work. The action of midazolam is due to the potentiation of the neural inhibition mediated by gamma-aminobutyric acid. In addition to its action on the central nervous system, midazolam exhibits a dose-dependent ventilatory depressant effect and causes a reduction in arterial blood pressure and an increase in heart rate. Midazolam is metabolised by cytochrome P450 enzymes and glucuronide conjugation. CYP3A4 is important in the biotransformation of midazolam.

The duration of action of midazolam is dependent on the duration of its administration. It also has synergistic interactions with other hypnotics and opioids. Various factors, including age, compromised renal function, and liver dysfunction, affect the pharmacokinetics of the drug[15].

Clinical studies: A large number of prospective, randomised, placebo-controlled and non-controlled trials have been published in recent years concerning the efficacy and safety of midazolam alone or in combination with analgesics. The most recent of these trials are mentioned below.

In a study conducted to evaluate the prevalence of hypoxia related to midazolam sedation during upper GI endoscopy, 180 patients referred for selective endoscopy were randomised to either midazolam sedation or pla-

Table 2 Characteristics of the pharmacological agents used to achieve a moderate level of sedation in gastrointestinal endoscopy (*i.v.* administration)[1]

Agent	Chemical structure	Molecular weight (g/moL)	Onset of action (min)	Duration of action	Elimination half-life	Metabolism/excretion
Midazolam	$C_{18}H_{13}ClFN_3$	325.78	1.0-2.5	2-6 h	1.8-6.4 h	Hepatic and intestinal; excreted in urine
Propofol	$C_{12}H_{18}O$	178.27	< 1	3-10 min	Triphasic: 2.2 min, 20 min, 8 h	Hepatic; excreted in urine
Fentanyl	$C_{22}H_{28}N_2O$	336.471	⩽ 1.5	1-2 h	2-7 h	Hepatic; excreted in urine
Meperidine	$C_{15}H_{21}NO_2$	247.33	5	2-4 h	2-7 h	Hepatic; excreted in urine

cebo. The results revealed that no patients developed any serious episodes of hypoxia and that the incidence of mild hypoxia was not significantly different between the two groups. There was no significant difference in arterial oxygen saturation as recorded by the endoscopist staff[16].

In another study, haemodynamic responses during gastroscopy in healthy subjects were studied in two groups: midazolam alone *vs* midazolam in combination with meperidine. It was found that blood pressure and oxygen saturation significantly decreased with sedation in both groups during endoscopy, but no significant differences were found between the two groups. Heart rate increased significantly, whereas systolic arterial pressure, diastolic arterial pressure and O_2 saturation (SpO_2) decreased significantly, with both regimes. Patient compliance was significantly better with combined sedation[17].

Midazolam has been tested in combination with a variety of other drugs. In one study, the efficacy and safety of midazolam in combination were tested in 74 patients. The midazolam group received only midazolam, and the midazolam/meperidine group received midazolam plus meperidine. The results showed that there was no significant difference between the two groups with regard to the recovery time, procedure time and mean visual analogue scale scores[18].

In a randomised trial comparing the efficacy and recovery time of two sedation regimens consisting of midazolam in combination with either meperidine or fentanyl in patients submitted for colonoscopy, it was found that the use of fentanyl in combination with low-dose midazolam resulted in a significantly faster recovery from sedation compared with meperidine, without any apparent loss of analgesic effect[19].

The synergistic sedation with low-dose midazolam plus propofol *vs* the standard regimen of midazolam and pethidine for conscious sedation in colonoscopy was investigated in a group of patients that included a large number of elderly patients with comorbidities. The synergistic sedation with low-dose midazolam plus propofol was superior to a standard combination of midazolam and the opioid pethidine for colonoscopy in terms of patient comfort and recovery time[20].

In a prospective, randomised study, the standard regime of midazolam and pethidine *vs* a propofol-fentanyl mixture was tested. It was found that patient-controlled sedation/analgesia with propofol and fentanyl was a safe and effective combination, resulting in a high level of satisfaction for both the patient undergoing upper GI tract endoscopic ultrasonography and the endoscopist[21].

Barriga *et al*[22] evaluated the adequacy of conscious sedation during upper endoscopy using midazolam alone compared with midazolam plus fentanyl. Although, from the endoscopist's perspective, patients in the combination group had better tolerance, no significant differences were found in the patient assessments. These results suggest that an adequate level of sedation can be obtained safely by either midazolam or midazolam plus fentanyl.

Midazolam was also tested as an orally administered premedication in patients undergoing upper GI endoscopy. In a double-blind, placebo-controlled, randomised trial, 130 patients were randomised to receive either 7.5 mg of midazolam orally or a placebo as the premedication. The results showed that the median anxiety score during the procedure in the midazolam group was significantly lower than that in the control group. Moreover, a significantly greater number of patients in the midazolam group graded overall tolerance as "excellent or good" and reported partial or complete amnesia in greater degree compared with the control group. Finally, patients in the midazolam group were more willing to repeat the procedure if necessary. However, the median recovery time was significantly longer in the midazolam group than in the control group. No significant differences in the satisfaction score and haemodynamic changes between the two groups were observed[23].

In conclusion, midazolam must be considered as an excellent drug for achieving safe and effective sedation during upper and lower GI endoscopy, whether used alone or in combination with analgesics.

Propofol

The sedative-hypnotic drug propofol (2,6-diisopropylphenol) is a phenolic derivative with satisfactory sedative,

hypnotic, antiemetic and amnesic properties. Additionally, propofol the advantage of a rapid onset of action and a short recovery profile. The depth of sedation increases in a dose-dependent manner. Propofol is highly lipophilic and, therefore, can rapidly cross the blood-brain barrier, resulting in an early onset of action. Consequently, emergence from sedation is also quite rapid because of its fast redistribution into peripheral tissues. Sedation with propofol can be achieved both by bolus administration and continuous infusion. The drug can cause unconsciousness within 30 s. As an additional advantage, regardless of the length of the sedation period, recovery from propofol will occur within 10-20 min after discontinuation. Propofol also has an excellent amnesic effect and short half-life (4 min *vs* 30 min for midazolam). Currently, there is no dispute regarding propofol's superiority over benzodiazepines (with or without opioids) in terms of the abovementioned physiological effects. However, it must be strongly emphasised that titrating propofol to achieve conscious sedation without inducing general anaesthesia requires significant clinical expertise.

This drug is being increasingly used for sedation during painful diagnostic and therapeutic procedures because it increases the quality of upper GI endoscopy by increasing patients' acceptance of the procedure and improving the diagnostic accuracy of endoscopy[24].

With regard to side effects, propofol is generally associated with good haemodynamic stability, although it can induce a dose-dependent decrease in blood pressure and heart rate. Transient decreases in blood pressure are more prominent during bolus administration. Thus, slow initial infusions are recommended in most patients. Moreover, strict aseptic technique must be used during the handling of the product to prevent accidental extrinsic microbial contamination. There are also some other disadvantages of propofol, including the lack of a pharmacological antagonist. The combination of propofol and midazolam has synergistic effects and may have advantages over the use of propofol as a single agent[20]. Thus, a combined sedation regimen with a benzodiazepine retains the possibility for partial pharmacological reversibility using flumazenil.

However, data from a recent meta-analysis suggest that propofol sedation is not associated with an increased risk of complications. In fact, propofol sedation for colonoscopy was associated with lower complication rates than sedation with traditional agents[25]. Several prospective studies confirmed that lower doses were needed for combined sedation with midazolam/propofol compared with propofol alone during diagnostic or therapeutic endoscopy[26,27].

A large number of clinical trials and meta-analyses of these trials have been published, the main results of which are discussed below.

Clinical studies of propofol in upper GI tract endoscopy: A number of studies revealed that propofol offers significant advantages over benzodiazepines and opioids for sedation during endoscopic procedures. Other prospective studies indicated that propofol was safer and more effective than midazolam and meperidine for reaching and maintaining an adequate level of sedation during endoscopy, resulting in better titration of the level of sedation and a shorter recovery time[28].

A prospective study evaluated the safety and efficacy of nurse-administered, low-dose propofol sedation in 8431 adults submitted to upper GI endoscopy. Propofol was administered by bolus injection at a dose of 40 mg for patients < 70 years old, 30 mg for patients 70-89 years old, and 20 mg for patients 90 years old or older. Only 0.26% of the patients required a transient supplemental oxygen supply, and full recovery occurred in 99.9% of patients 60 min after the procedure. However, men and younger patients required significantly higher doses of propofol than women and older patients. A total of 99% of patients were willing to repeat the same procedure. This study showed that the use of only a low dose of nurse-administered propofol sedation is safe and effective for diagnostic esophagogastro-duodenoscopy[29].

Levitzky *et al*[30] showed that balanced propofol sedation targeted to induce moderate sedation in patients undergoing upper GI endoscopy results in better patient satisfaction and a shorter recovery time than standard sedation alone.

Propofol in lower GI tract endoscopy: The optimal regimen of propofol for colonoscopy sedation is still controversial. Both propofol alone and propofol in combination with opiates (meperidine) or benzodiazepines (midazolam) are frequently used during colonoscopy to achieve moderate levels of sedation. Hsieh *et al*[31] noticed that for sedated colonoscopy, propofol in combination with meperidine is better than propofol alone for improving patients' tolerance and recovery.

The combination of 1.0-2.0 mg of midazolam with either 50-100 mg of fentanyl or *i.v.* propofol of 0.5-2.5 mg/kg allowed patients to undergo colonoscopy under comparable sedative and analgesic conditions. The combination with fentanyl had a significantly smaller effect on pulse rate and blood pressure, while the combination with propofol produced more favourable results, especially in terms of superior amnestic effects[32].

In a study of 300 adults undergoing colonoscopy, the use of fentanyl in combination with low-dose midazolam was found to result in a faster recovery from sedation compared with meperidine without decreasing the analgesic effect[19].

Recently, patient-controlled sedation with propofol has been advocated as a method for dealing with the narrow therapeutic window for moderate sedation. In a relevant study, 50 patients undergoing elective colonoscopy were randomised to receive midazolam/fentanyl or propofol/remifentanil administered *via* patient-controlled sedation. Patients in the propofol/remifentanil group were sedated and recovered significantly more rapidly than patients in the midazolam/fentanyl group[33].

Propofor in therapeutic GI endoscopic procedures: In a prospective, randomised, single-blinded study of 222 patients, Lee *et al*[34] compared the safety and efficacy of balanced propofol sedation with conventional sedation (midazolam and meperidine) in patients undergoing therapeutic endoscopic procedures. They found no significant differences between the balanced propofol sedation and conventional groups with regard to the rates of cardiopulmonary complications and transient interruption of procedures, although balanced propofol sedation provided a significantly higher level of endoscopist satisfaction and better patient cooperation.

Meta-analyses of the use of propofol for sedation: To date, two meta-analyses have been published concerning the safety and efficacy of propofol for GI endoscopy.

The first meta-analysis, published in 2005, included 12 original studies with 1161 patients. Of these patients, 634 received propofol and 527 received midazolam, meperidine, and/or fentanyl. Most of the studies were randomised trials of moderate quality. It was found that the pooled odds ratio for developing hypoxia or hypotension for all of the procedures combined was 0.74 in patients using propofol. The pooled odds ratios were 0.85 for upper GI endoscopy, 0.4 for colonoscopy, and 1.07 for ERCP/EUS. Compared with traditional agents, it was noted that sedation with propofol during colonoscopy appears to result in a lower incidence of cardiopulmonary complications, although the risk of complications associated with upper GI endoscopy seems to be similar[25].

The second meta-analysis included 20 studies on the use of propofol for colonoscopy[35]. The analysis showed that recovery and discharge times were shorter with the use of propofol. There was also higher patient satisfaction with the use of propofol, although no significant differences in the procedure time, cecal intubation rate and number of complications were noticed. Finally, no difference in pain control with non-patient-controlled sedation with propofol compared with the traditional agents was noted. The only disadvantage was that pain control with propofol was inferior compared with the use of traditional agents. The general conclusion from these meta-analyses is that propofol for sedation during colonoscopy results in a faster recovery and discharge time, as well as increased patient satisfaction and acceptance rates of side effects.

In conclusion, propofol provides a faster onset of action and deeper sedation compared with standard doses of benzodiazepines and narcotics. More rapid cognitive and functional recovery should be expected when propofol is used as a single agent compared with benzodiazepines. The drug appears to have more advantages when used for prolonged and therapeutic endoscopic procedures, including ERCP and EUS. Although it can be safely and effectively used by a physician-supervised nurse, patients must be under continuous care, consistent with the care required for patients undergoing deep sedation. Personnel in the endoscopy room should be able to rescue the patient from severe respiratory depression.

Fentanyl

Fentanyl, a μ-opioid receptor agonist, is a synthetic narcotic analgesic characterised by a rapid onset and short duration of action. The action of the drug is related to its agonism of the opioid receptors. It is 100 times more potent than morphine, with 100 μg equivalent to 10 mg of morphine and 75 mg of meperidine (pethidine) in terms of analgesic activity. Its strong potency is largely due to its high lipophilicity, which also explains the rapid penetration of the drug into the central nervous system. Fentanyl binds μ-opioid G-protein-coupled receptors, which inhibits the release of pain neurotransmitters by decreasing intracellular Ca^{2+} levels. It has been used in combination with midazolam, mainly in patients undergoing lower GI endoscopy.

In a trial comparing meperidine with fentanyl, the authors noted that the total procedure time was shorter for those receiving fentanyl than for those receiving meperidine. Based on post-procedure pain scores, examinations performed using meperidine were less painful compared with those performed with fentanyl[36].

A meta-analysis compared the efficacy, safety, and efficiency of agents used for moderate sedation in upper GI endoscopy or colonoscopy in 36 studies involving a total of 3918 patients. Sedation improved patient satisfaction and the willingness of patients to repeat upper GI endoscopy compared with these measures in patients who received no sedation. Midazolam provided superior patient satisfaction and resulted in a less frequent memory of the upper GI endoscopy procedure compared with diazepam. Adverse events and patient/physician assessments were not different between midazolam (with or without narcotics) and propofol. The procedure time was similar, but sedation and recovery times were shorter with propofol than midazolam-based regimens. The results confirmed that moderate sedation provides a higher level of physician and patient satisfaction and a lower risk of serious adverse events compared with other currently available agents. Midazolam-based regimens have longer sedation and recovery times than propofol[37].

DRUGS UNDER INVESTIGATION FOR GI ENDOSCOPY

Various other drugs are also under investigation for GI endoscopy. Among them, prodrug formulations of propofol have been developed to overcome the disadvantages of the lipid-based formulations. So far, the results of the relevant studies appear promising. The most important clinical data are presented below.

Nitrous oxide gas

Nitrous oxide gas (N_2O) (molecular mass 44.013) has been proposed as an alternative to *i.v.* analgesia in patients undergoing lower GI endoscopy. N_2O/O_2 mixtures have a satisfactory analgesic effect and short half-lives, thus providing an alternative method of sedation for colonoscopy procedures.

A systematic review of 11 randomised studies including 623 patients was published in 2010[38]. In these studies, N_2O was compared with a lack of sedation in patients undergoing either flexible sigmoidoscopy or colonoscopy. The results revealed that patient-reported pain was similar for N_2O when undergoing flexible sigmoidoscopy *vs* no sedation and when undergoing colonoscopy *vs i.v.* sedation. No differences in duration, procedure difficulty or complications were identified. N_2O was associated with a more rapid recovery than *i.v.* sedation. This systematic review supports the assumption that N_2O provides comparable analgesia to *i.v.* sedation in patients undergoing colonoscopy. Rapid recovery enables quicker patient discharge and removes the need for a patient to be chaperoned.

In a more recent Cochrane review, 257 patients were randomised to receive a N_2O/O_2 mixture (7 studies), while 225 patients received some form of sedation with or without additional analgesia (6 studies) and 65 patients received placebo (3 studies). Four studies showed that N_2O/O_2 reduced pain/discomfort compared with conventional methods, whereas one study showed that sedation was better and another study showed that N_2O/O_2 was better. Six studies showed that N_2O/O_2 groups had a quicker recovery time and shorter length of hospital stay, whereas one study showed no difference between the two groups. Two studies showed that N_2O/O_2 was safer, whereas one showed that sedation was safer. The conclusion was that N_2O is as efficient as and safer than other pain relief methods used during colonoscopy[39].

A randomised clinical trial compared the efficacy of Entonox (50% N_2O and 50% O_2) with midazolam-fentanyl sedation in 131 patients undergoing elective colonoscopy. Sixty-five patients received Entonox, and 66 patients received midazolam-fentanyl. Patients receiving Entonox had a shorter time to discharge. They also reported significantly less pain and better recovery of psychomotor function immediately after the procedure and at discharge. Patients who received Entonox also reported a higher level of satisfaction. Again, this study concluded that Entonox provides better pain relief and faster recovery than midazolam-fentanyl in patients undergoing elective colonoscopy[40].

A double-blind, randomised, placebo-controlled trial showed that N_2O inhaled intermittently is not an effective substitution for *i.v.* on-demand sedation in the setting of colonoscopy without sedation. In this study, patients inhaled N_2O or placebo on demand. The median patient-reported pain level was 2 in both the N_2O and control groups. Additional sedatives and analgesics were given equally often and at similar doses in both groups. No side effects related to the administration of N_2O were noted[41].

In conclusion, the available data suggest that N_2O is an effective analgesic and sedative agent that must be further investigated in larger studies.

Remimazolam

Remimazolam ($C_{21}H_{19}B_rN_4O_2$; molecular weight 439.304) is a short-acting GABA(A) receptor agonist that exhibits organ-independent metabolism, which was developed as an *i.v.* sedative agent for use in day-case procedures and the induction and maintenance of anaesthesia.

Preclinical studies in animals demonstrated that remimazolam caused a more rapid onset and a shorter duration of action compared with midazolam.

In a phase Ⅱ a clinical trial evaluating remimazolam as a procedural sedative for upper GI endoscopy, the time to recovery from sedation was shorter and more consistent with remimazolam compared with midazolam. Because of its organ-independent metabolism and rapid and predictable onset and recovery profile, remimazolam appears to have potential advantages over other currently available short-acting benzodiazepines. However, its respiratory depressant effect has been reported in numerous studies[42].

Fospropofol

Various prodrug formulations of propofol have been developed to overcome the disadvantages of the lipid-based formulations, the complications of lipid infusion, and the risk of fluctuations in propofol plasma levels due to bolus injection.

Fospropofol ($C_{13}H_{19}Na_2O_5P$, molecular weight: 332.24) is a water-soluble prodrug of propofol, metabolised *in vivo* to produce liberated propofol (producing the sedative effect), phosphate and formaldehyde. After *i.v.* injection, propofol is released from fospropofol by tissue alkaline phosphatases with a pattern of plasma concentrations, resulting in lower peak concentrations and a more gradual decline in drug concentrations compared with standard propofol administration protocols. As a result, the drug has pharmacokinetic and pharmacodynamic properties that differ from those of propofol emulsion. The time of the peak sedative effect after a bolus injection fluctuates between 3 and 7.5 min, compared with 1 min 36 s for propofol[43]. Fospropofol was generally well tolerated in clinical trials. Adverse events are mostly of mild-to-moderate severity and are transient and self-limiting[44].

The 6.5-mg/kg dose of fospropofol provides the ideal balance of efficacy and safety for patients undergoing colonoscopy. In a double-blind trial evaluating 127 patients who received fospropofol (2, 5, 6.5 or 8 mg/kg) or midazolam 0.02 mg/kg following pre-treatment with fentanyl, fospropofol yielded a significant dose-dependent increase in sedation success from 24% (2 mg/kg), 35% (5 mg/kg) and 69% (6.5 mg/kg) to 96% (8 mg/kg; $P < 0.001$)[45].

The same group of authors evaluated the efficacy and safety of *i.v.* fospropofol administration in patients undergoing colonoscopy for moderate sedation. Patients were randomised to receive fospropofol 2 mg/kg, fospropofol 6.5 mg/kg, or midazolam 0.02 mg/kg after pretreatment with *i.v.* fentanyl 50 μg. The results showed that sedation success was higher in the fospropofol 6.5 mg/kg group compared with the 2 mg/kg group (87% *vs* 26%; $P < 0.001$) and was 69% in the midazolam group.

Most adverse events were mild to moderate in intensity, the most common being paraesthesias (68% *vs* 60%) and pruritus (16% *vs* 26%) in the fospropofol 6.5 and 2 mg/kg groups, respectively. Fospropofol 6.5 mg/kg was associated with higher rates of sedation success, memory retention, and physician satisfaction than fospropofol 2 mg/kg[46].

Together, these results suggest that fospropofol is a promising drug requiring further investigation.

Dexmedetomidine

Dexmedetomidine ($C_{13}H_{16}N_2$, molecular mass: 200.28), a pharmacologically active dextroisomer of medetomidine, is a selective α(2)-adrenergic receptor agonist. It is indicated for the sedation of mechanically ventilated adult patients in an intensive care setting and in non-intubated adult patients prior to and/or during surgical and other procedures[47]. The drug should be administered *i.v.* only by experienced individuals, and the patient must be continuously monitored. Additionally, the dose must be adjusted in patients with liver and renal failure, as well as in elderly patients.

Dexmedetomidine can be safely used as a sedoanalgesic agent in colonoscopies because it provides efficient haemodynamic stability, higher satisfaction scores and lower Numeric Rating Scale scores. A study comparing dexmedetomidine (1 μg/kg and as a continuous infusion dose of 0.5 μg/kg per hour) with midazolam (0.05 mg/kg) plus fentanyl citrate (1 μg/kg) with regard to perioperative haemodynamics, sedation, pain, satisfaction and recovery scores during colonoscopy showed that, although statistically significant differences in mean arterial pressure were not detected between the two groups, heart rates were higher and SpO_2 scores were lower in dexmedetomidine group. When the groups were compared using the Ramsay sedation scale, the scores of group I at the 10th and 15th minute were significantly lower than those of group II[48].

In a recent study, Takimoto *et al*[49] showed that sedation with dexmedetomidine is a safe and effective practice in patients with gastric tumours undergoing endoscopic mucosal resection. In their study, 90 patients with gastric tumours were sedated with either dexmedetomidine [*i.v.* infusion of 3.0 μg/kg per hour over 5 min, followed by continuous infusion at 0.4 μg/kg per hour (n = 30), propofol (n = 30), or midazolam (n = 30)]. In all groups, 1 mg of dexmedetomidine was added *i.v.* as needed. The results showed that none of the dexmedetomidine-sedated patients exhibited a significant reduction in oxygen saturation level. Fewer patients in the dexmedetomidine group showed body movement during endoscopy compared with the other groups. The rate of effective sedation was significantly higher in the dexmedetomidine group compared with the midazolam and propofol groups. The mean duration of endoscopic submucosal dissection in the dexmedetomidine group was significantly shorter than that in the other two groups. However, dexmedetomidine alone is most likely not as effective as propofol combined with fentanyl for providing conscious sedation during ERCP, exhibiting concurrently greater haemodynamic instability and prolonged recovery[50].

Alfentanyl

Alfentanyl ($C_{21}H_{32}N_6O_3$, molecular weight: 452.98) is a narcotic analgesic with a rapid onset of action, a very short duration of action, and a potency of approximately one-third that of fentanyl. Recently, it was shown that patient-controlled analgesia pumps and sedation with alfentanyl and fentanyl for colonoscopy are safe, feasible, and acceptable to most patients, although a shorter sedation time makes alfentanyl more attractive, as it reduces the postprocedural workload[51].

Remifentanil

Remifentanil ($C_{20}H_{28}N_2O_5$, molecular weight: 376.447) is a μ-opioid receptor agonist that has important neuroanaesthesia characteristics. It has been used in a small number of clinical trials in patients undergoing GI endoscopic procedures. There are many reports of the use of remifentanil in different settings, including GI endoscopy, with or without background infusion, and the quality of analgesia and patient satisfaction seem to be the same as with standard sedation/analgesia. It seems that remifentanil patient-controlled analgesia is safe and effective for inducing sedoanalgesia during colonoscopy.

In a randomised, double-blind clinical trial, 60 patients undergoing colonoscopy were randomly assigned to either the remifentanil or meperidine group. All of the patients received premedication with midazolam 0.03 mg/kg *i.v.* In the remifentanil group, a bolus dose of remifentanil was given, and a patient-controlled sedation/analgesia pump was set to inject further bolus doses, while patients in the meperidine group received a bolus of meperidine and a sham, patient-controlled sedation analgesia pump. The degree of pain, level of satisfaction with sedoanalgesia of patients and gastroenterologists, and degree of difficulty experienced by the endoscopist, as well as the discharge time and duration of colonoscopy, were not different between the two groups[52].

In another study, the safety and efficacy of remifentanil during colonoscopy compared with the standard combination of midazolam and pethidine were tested in 116 patients who received either midazolam and pethidine or remifentanil only. Recovery was found to be faster in the remifentanil group. There was also a significant difference with regard to the time of hospital discharge. In this study, remifentanil during colonoscopy provided sufficient pain relief with better haemodynamic stability, less respiratory depression, and significantly faster recovery and hospital discharge times than moderate sedation with midazolam and pethidine[53]. However, further studies are needed to confirm these interesting results.

Music

Among methods reported to minimise patient discomfort during GI endoscopy (especially colonoscopy), mu-

sic has been utilised as an important therapeutic tool for effectively relieving stress and inducing analgesia. During recent years, several papers investigating the efficacy of music on patients' stress and pain relief were published. The most important of these publications are discussed below.

Clinical trials concerning the role of music in sedation: More recent clinical trials not included in the abovementioned meta-analyses have revealed rather conflicting results.

In a single-blind, randomised, controlled trial, the authors showed that music significantly reduces discomfort and, consequently, should be routinely provided to patients undergoing colonoscopy. In this study, 109 patients were randomised to receive music-delivering or non-sound-emitting headphones before and during endoscopy. The results revealed that the mean pain score was significantly lower in the music group compared with the control group, while overall satisfaction and willingness to repeat the procedure were significantly improved and the difficulty perceived by physicians was significantly reduced. Interestingly, the total amount of midazolam and pethidine was significantly lower in the music group compared with the control group[54].

Music in the endoscopy room was also found to reduce the anxiety levels in patients undergoing endoscopic procedures. In a controlled trial of 180 patients, the effect of age and type of endoscopic procedure on anxiety levels upon arrival in the unit and immediately before the endoscopy procedure after listening to music or no music (control group) for the same period was investigated. Although anxiety levels were not influenced by age or procedure, it was found that listening to music resulted in a significant reduction in anxiety scores, which was maintained for all age groups, irrespective of the type of endoscopic procedure performed. The authors suggest that providing music in the endoscopy unit is a simple strategy that can improve the well-being of patients[55].

Another study, which was specifically designed to investigate whether listening to music reduced the pain experienced by patients during sigmoidoscopy without sedation or analgesia, concluded that listening to music did not reduce pain intensity. In this study, it was found that the mean pain intensity in the music group was not different from that in the control group, and the proportion of patients with at least moderate pain during sigmoidoscopy did not differ between the two groups[56].

Meta-analyses concerning the role of music in sedation: Three meta-analyses regarding the role of music in sedation have been published to date. At least two of them suggested that music can effectively relieve stress and improve the level of analgesia during GI endoscopy. In the first of these meta-analyses, the authors included six randomised, controlled trials with a total of 641 patients. They found that in studies that did not use pharmacotherapy, patients receiving music therapy exhibited significantly lower anxiety levels compared with controls. Additionally, in studies in which pharmacotherapy was used, patients receiving music therapy exhibited significant reductions in analgesia requirements and an almost significant reduction in sedation requirements compared with controls. Furthermore, the procedure time was significantly reduced in the music therapy group compared with the control group. The authors' conclusion was that music therapy is an effective tool for stress relief and analgesia in patients undergoing GI endoscopic procedures[57].

In the second meta-analysis, which was published in 2008 and focused on colonoscopy, the authors included 8 studies with a total of 722 patients. In four studies, music was transmitted through headphones/earphones (as background music in three studies, and one study did not specify the media method). The results showed that the combined mean time taken for the colonoscopy procedure was shorter in the music group compared with the control group. There was weak evidence of benefit regarding the pain score, blood pressure, and mean recovery time in the music group compared with the control group. No harmful effects from listening to music were reported in any of the studies in this meta-analysis. The only disadvantage found in allowing patients to listen to music through headphones/earphones was the isolation of patients from the medical staff during the procedure. The authors concluded that "listening to music is effective in reducing procedure time and amount of sedation during colonoscopy and should be promoted"[58].

Finally, in the third meta-analysis, which was published in 2009 and included 8 studies with a total of 712 patients, it was found that patients' overall experience scores were significantly improved when they were allowed to listen to music. However, no significant differences were noted in patients' pain scores, mean doses of midazolam and meperidine, procedure time, and willingness to repeat the same procedure in the future, indicating that music improves only patients' overall experience with colonoscopy[59].

One possible explanation for the reduction in the doses used for sedation sedation is that patients in the music group are more relaxed and have less anxiety, resulting in a faster completion of the procedure and the use of less sedation[60]. The reduction in procedure time implies a reduction in the time during which patients feel anxious, frightened, and uncomfortable while undergoing the procedure and may be useful in enhancing the compliance rate. The avoidance of sedation may obviously result in a quicker patient discharge, less need for monitoring, and overall cost savings. Two other advantages of music are its inexpensiveness and ease of implementation[61].

In conclusion, it seems that listening to music, especially during colonoscopy, could reduce the procedure time, anxiety, and amount of sedation needed, without producing any harmful events. As a result, music should be promoted because of its beneficial effect and negligi-

ble cost. However, several aspects of this method, such as the choice of music and the mode of transmission, are worth further investigation.

SEDATION FOR GI ENDOSCOPY IN SPECIAL CLINICAL SITUATIONS

A large number of situations require special attention not only at the beginning of the endoscopic procedure but also during the procedure and recovery. The drugs that must be used, along with the precautions that must be followed, are analysed below.

Obesity

Obesity is a significant health problem that has assumed epidemic proportions. As a result, the number of obese patients requiring endoscopy is increasing. Morbid obesity can result in pulmonary hypertension, obstructive sleep apnoea, and restrictive lung disease. It is relatively unknown how safe the current practices of sedation for endoscopic procedures are in bariatric patients[62]. Therefore, special consideration should be given to these patients, and endoscopists need to be aware of challenges that may be present while performing endoscopic procedures in obese patients[63].

There are limited data on the use of sedation in obese patients. Studies published to date refer mainly to the use of sedation in obese subjects undergoing advanced endoscopic procedures or upper GI endoscopy before bariatric surgery.

In a study involving 69 subjects with morbid obesity submitted to upper GI endoscopy before bariatric surgery, the authors administered sedation with propofol at a mean dose of 380 ± 150 mg (range 80-900 mg). Two patients developed severe hypoxemia, which required bronchoscopic intratracheal O_2 insufflation. Thus, although upper GI endoscopy can be performed safely in obese patients, careful monitoring and anesthesiological support are required, especially in patients with concomitant diseases[64].

In a study investigating the safety of anaesthesia-assisted endoscopy using propofol-mediated sedation in subjects undergoing advanced endoscopic procedures, the authors found that an increased body mass index was associated with an increased frequency of airway manoeuvres and hypoxemia. A multivariate analysis revealed that body mass index was an independent predictor of the appearance of sedation-related complications. Interestingly, in obese individuals, there was no difference in the frequency of sedation-related complications in patients receiving propofol alone or in combination with other drugs. Propofol sedation can be safely used in obese patients undergoing advanced endoscopic procedures when administered by trained professionals, despite the increased frequency of sedation-related complications[65].

Finally, it was found that patients who undergo upper GI endoscopy with either anaesthesiologist- or surgeon-monitored sedation seem to tolerate the procedure equally well. However, significantly fewer patients in the anaesthesiologist-monitored sedation group complained of throat pain after the procedure and/or remembered gagging during the procedure, thus leading to the conclusion that anaesthesiologist-monitored sedation should be considered in patients undergoing preoperative upper endoscopy before bariatric surgery[66].

In conclusion, although quite safe, moderate sedation during endoscopy may pose some risks to obese patients. In particular, the presence of obstructive sleep apnoea may identify a subset of patients at higher risk of complications. Further studies are required in this field, as the number of subjects undergoing bariatric surgery is constantly increasing worldwide.

Chronic liver disease

Endoscopy, either diagnostic and/or therapeutic, is often necessary in patients with chronic liver disease, sometimes on an emergency basis. It is well established that liver disease may impair the metabolism of drugs usually administered for sedation. The evaluation of patients with chronic liver disease before endoscopy should include a full assessment of hepatic function, as well as a complete physical examination to exclude the possibility of the presence of hepatic encephalopathy. As a general rule, sedation should be used especially in patients undergoing ligation of acutely bleeding varices, although in some cases sedation is not necessary[67].

Liver dysfunction could reduce both the clearance of the drugs eliminated by hepatic metabolism or biliary excretion and plasma protein binding. Chronic liver disease is also associated with a reduction in drug-metabolising activities, such as the activity of the CYP450 enzymes. In patients with advanced cirrhosis, it is necessary to adjust the dose of those drugs eliminated by renal excretion[68].

Concerning the drugs used in the sedation of cirrhotic patients, most authors prefer to use propofol instead of benzodiazepines and opioids because of its short biological half-life and lower risk of provoking hepatic encephalopathy.

In a recently performed study, the authors compared sedation with combinations of propofol plus fentanyl and midazolam plus fentanyl in 210 cirrhotic patients undergoing upper GI endoscopy. The doses of midazolam and propofol were 0.05 and 0.25 mg/kg, respectively, while the dose of fentanyl was 50 μg *i.v.* in both groups. It was found that sedation with propofol was more effective and yielded a shorter recovery time than sedation with midazolam, indicating that it is a safe and effective regimen[69].

Another study reported that the use of propofol in patients with cirrhosis does not precipitate minimal or overt hepatic encephalopathy during upper GI endoscopy[70]. The results of this study were recently confirmed in a study showing that sedation with propofol in patients with compensated liver cirrhosis resulted in a shorter time to both recovery and discharge than midazolam, thus not exacerbating sub-clinical hepatic encephalopathy[71].

These results are in accordance with those described in a previous study that demonstrated that propofol sedation does not cause deterioration of minimal hepatic encephalopathy concurrently associated with improved recovery in patients with liver cirrhosis[72].

In conclusion, propofol represents a safe and effective sedation drug that could be used as an alternative to midazolam in patients with liver cirrhosis[73].

Pregnancy

Despite the fact that endoscopy is rarely required during pregnancy and is generally considered to be safe, endoscopists must be aware of the potential risks concerning both the mother and the foetus. Before endoscopy, the endoscopist must calculate the potential foetal risks, mainly due to sedation, and try to correct any possible maternal pathological situation, including hypoxia and hypotension.

During endoscopy, pregnant women should be carefully monitored by continuous electrocardiography, pulse oximetry, and intermittent blood pressure estimation[74].

Sedative drugs comprise a significant foetal risk during endoscopy in pregnant women because of the risk of hypoxia. Additionally, the exposure of pregnant women to radiation during ERCP represents another important risk that should be reduced as much as possible.

Currently, there is no evidence that endoscopy precipitates premature labour. If possible, endoscopic procedures must be performed without any sedation or, alternatively, by administering the lowest effective dose of sedative medication.

Regarding the types of drugs used for sedation, the available literature suggests that midazolam appears to be safe if used carefully[75].

ERCP is rarely necessary during pregnancy, although it cannot be avoided in pregnant women with recurrent biliary colic, abnormal liver function tests, and a dilated bile duct. A relevant study showed that ERCP can be safely performed during pregnancy, leading to successful treatment in almost all patients. Sedation is uneventful for all pregnant women and their foetuses. However, it must be recognised that pregnancy may be associated with a higher rate of post-ERCP pancreatitis compared with the general population[76]. The same conclusion was reached in another study, the authors of which noted that ERCP is a safe procedure during pregnancy, even if the placement of a biliary stent is necessary[77].

In conclusion, upper GI endoscopy, including therapeutic interventions such as the banding of oesophageal varices, seems to be relatively safe for the foetus, although it should be performed only when strongly indicated. Similarly, flexible sigmoidoscopy also appears to be safe for the foetus and, again, should only be performed when strongly indicated. Colonoscopy data suggest that this procedure should be performed only during the second trimester and only if there is a strong indication. Finally, ERCP seems to be relatively safe but should only be performed if there is a strong indication for its use. Sedation is rather safe in ERCP, and midazolam is the preferred pharmaceutical agent by most endoscopists. As a general rule, it may be suggested that endoscopy in pregnant women should always be performed in a hospital by an expert endoscopist and only when strongly indicated[78].

Sedation in celiac disease

It has been suggested that patients with celiac disease exhibit increased rates of neuropsychiatric disturbances and visceral hypersensitivity. In a retrospective cohort study, Lebwohl *et al*[79] noted that 26% of patients with celiac disease required higher amounts of both opioids and midazolam compared with age- and gender-matched controls, possibly due to increased visceral hypersensitivity, chronic opioid/anxiolytic use, and/or underlying neuropsychiatric illness.

Sedation in the elderly

Although GI endoscopy with sedation is increasingly performed in elderly patients, data on the outcomes and side effects of sedation are limited. Age-related pharmacokinetic changes and the presence of comorbidities and polypharmacy complicate drug therapy. Aging results in impairment in the function of multiple organs, including the liver, which may also affect drug metabolism and pharmacokinetics. In addition, older people often have to consume a variety of drugs, the bioavailability of which could be increased. Additionally, lipophilic drugs may have a prolonged half-life. Combined with reduced hepatic and renal clearance mechanisms, this prolonged half-life can prolong the recovery of elderly patients after sedation. In the elderly, hepatic drug clearance of some drugs can be reduced by up to 30%. Midazolam is indicated because there are no major differences in CYP3A4 activity between young and old people. Finally, renal excretion is decreased in most elderly individuals because of the presence of hypertension and coronary heart disease[80].

In the geriatric population, conscious sedation practices are modified by the administration of fewer agents at a slower rate and lower cumulative dose. Midazolam has been widely used in elderly patients[81]. Under certain circumstances, it seems that the benefits, in terms of tolerance of low-dose midazolam for upper GI endoscopic sedation, outweigh the risks in older people. Christe *et al*[82], in a randomised, double-blind, placebo-controlled study, administered either midazolam (30 μg/kg *i.v.*) or saline (placebo) to 65 geriatric inpatients undergoing upper GI endoscopy. The results revealed that midazolam increased the probability of good tolerance. Midazolam resulted in a 10-mmHg reduction in the mean arterial pressure without inducing clinically significant hypotension. Finally, midazolam was associated with a higher risk of hypoxemia after endoscopy, but not of confusion.

In a recent study, it was found that elderly patients submitted for endoscopy required lower mean propofol doses for sedation compared with patients aged < 70

years. No major complications and no difference in the number of minor complications were noted. A favourable safety profile for combined sedation with midazolam/propofol and a higher sensitivity to propofol must be expected in patients older than 70 years of age who have various co-morbidities[83].

A study evaluating the safety of sedation with propofol in patients > 90 years of age showed that for upper GI endoscopy, percutaneous endoscopic gastrostomy, colonoscopy, and ERCP, the mean propofol doses used were 22, 24, 46 and 42 mg, respectively. In upper GI endoscopy, the level of sedation and propofol blood concentrations after administration of the drug in the group of patients > 90 years of age corresponded to those resulting from propofol use in middle-aged patients[84].

Finally, Martínez *et al*[85] found that continuous propofol sedation in patients > 80 years of age is generally as safe as in younger patients, although patients > 80 years showed a greater tendency to develop severe oxygen desaturation during the colonoscopy and endoscopic ultrasonography procedures. In general, there were no significant differences in sedation-related complications between the two groups.

Sedation in time-consuming endoscopic procedures

Time-consuming endoscopic procedures, such as ERCP, endoscopic ultrasonography and endoscopic mucosal resection, require sedation for a significantly longer period of time compared with routine upper and lower GI tract endoscopy. Moreover, endoscopic submucosal dissection for early gastric cancer generally lasts much longer than conventional endoscopy and usually requires moderate-to-deep sedation with close surveillance to ensure patient safety, thus increasing the risks related to sedation and analgesia. Therefore, the administration of safe sedation of a satisfactory degree for a longer period of time is necessary.

During recent years, a significant number of papers have been published examining the most suitable and effective drug or combination of drugs for these complex procedures. The data from these clinical studies are discussed below.

Concerning ERCP, a study comparing satisfaction, recovery scores, and safety profiles for ERCP sedation between continuous infusion of propofol and conventional sedation revealed that the continuous infusion of propofol for ERCP under the direction of a gastroenterologist yields no differences in the procedure completion rate and adverse profiles compared with intermittent meperidine and midazolam injection. However, the infusion of propofol does provide a better recovery profile[86].

It is well known that the dose requirements and complications of propofol are less when used in the diluted form than when used in the undiluted form. In a study investigating diluted and undiluted propofol requirements and recovery time in patients undergoing ERCP, it was shown that the requirements in both groups were comparable, although the incidence of sedation-related hypotension was lower in the diluted group[87].

An interesting study showed that patient-controlled sedation with propofol/remifentanil seems to be a well-accepted sedation regimen for ERCP. Additionally, the study showed that anaesthesiologist-managed propofol sedation using constant propofol infusion is associated with deep sedation without any impact on the degree of patient or gastroenterologist satisfaction[88].

EUS and ERCP can be safely performed under conscious sedation on the same day with minimal adverse events. However, combined procedures are associated with higher doses of sedatives and a slightly longer recovery time[89].

Finally, another interesting study suggested that synergistic sedation with an oral dose (7.5 mg) of midazolam 30 min before *i.v.* propofol is given combined with *i.v.* propofol could result in a significant reduction in the dosage of propofol required and in patient anxiety levels before ERCP[27].

With regard to endoscopic ultrasonography, a prospective, randomised study demonstrated that patient-controlled sedation/analgesia with propofol and fentanyl is a more effective and safe technique compared with midazolam and pethidine, resulting in a high level of satisfaction of both patients and endoscopists[21].

Concerning endoscopic mucosal dissection (ESD) for early gastric cancer, a recent study in Japan revealed that ESD performed under sedation using continuous propofol infusion for early gastric cancer was as safe as ESD performed using intermittent midazolam injection. Moreover, patients treated with continuous propofol administration experienced a quicker recovery time than those treated with midazolam[90].

A more recent study, also from Japan, confirmed the results of the study by Kiriyama *et al*[90] and suggested that propofol is as safe and effective as midazolam during ESD. Despite these promising results, sedation guidelines for the use of propofol in early gastric cancer are needed[91].

Among the newer drugs used for sedation and analgesia during GI endoscopy, dexmedetomidine has been used in patients with early gastric cancer undergoing ESD. In a randomised study of 90 patients who underwent ESD treatment, sedation was achieved with either dexmedetomidine (3.0 μg/kg *i.v.* per hour over 5 min, followed by continuous infusion at 0.4 μg/kg per hour), propofol, or midazolam. It was shown that none of the dexmedetomidine-sedated patients developed a significant reduction in the oxygen saturation level. The rate of effective sedation was significantly higher in the dexmedetomidine group compared with the other two groups. It seems, therefore, that sedation with dexmedetomidine is safe and effective in patients with gastric tumours who are undergoing ESD[49].

ADVERSE EVENTS DURING SEDATION FOR ENDOSCOPY

Sedation is usually safe; however, complications may occur, although in various proportions depending on a

number of factors, including the type, dose and mode of administration of sedative drugs, as well as the patient's age and underlying chronic disorders. A large number of side effects, including hypotension, desaturation, bradycardia, hypertension, arrhythmia, aspiration, respiratory depression, vomiting, cardiac arrest, respiratory arrest, angina, hypoglycaemia, and/or allergic reaction, have been reported.

A study in patients submitted to colonoscopic examination showed that midazolam combined with propofol appeared to influence the pulse rate and blood pressure at a significantly higher rate than a combination with fentanyl or midazolam alone. The combination with fentanyl had a significantly lower effect on pulse rate and blood pressure[32].

Prolonged hypoxemia (oxygen saturation of < 90% for ⩾ 15 s) and apnoea (lack of respiratory activity for ⩾ 15 s) are not uncommon during moderate sedation for endoscopy. In a related study, it was noted that hypoxemia usually occurs within 5 min of medication administration or endoscope intubation and that only 1/3 of all apnoea/abnormal ventilation events lead to hypoxemia. Additionally, the total dose of meperidine/fentanyl and the total dose of midazolam are predictors of apnoea[92].

Dreaming is commonly reported after propofol-based sedation. In a relevant study, the per cent of patients reporting dreaming was 19%. It seems that this phenomenon appeared more frequently in patients who received high doses of propofol and in patients who had lower bispectral index values during sedation[93].

In a study of 17 999 endoscopic procedures performed over 8 years, the authors concluded that deep sedation during endoscopic procedures is safe[94]. They noted that adverse events occurred in a small proportion of patients (4.5%) and that six complications, i.e., hypotension, desaturation, bradycardia, hypertension, arrhythmia, and aspiration, occurred in more than 0.1% of patients.

Conigliaro *et al*[95] found a percentage of 0.47% of complications related to endoscopy in patients undergoing colonoscopy when sedation was used as recommended by the guidelines.

The administration of propofol as a sedative agent in GI endoscopy resulted in a significant reduction in mean arterial pressure compared with pre-intervention values, although severe hypotension (systolic blood pressure < 60 mmHg) was noted in 0.5% of patients. Oxygen saturation decreased from 96.5% to 94.4%, although a critical decrease in oxygen saturation (< 90%) was documented in only 2.4% of patients[28].

In cirrhotic outpatients undergoing upper GI endoscopy, sedation with a combination of propofol plus fentanyl or midazolam plus fentanyl revealed no significant differences in the rate of complications between the two groups (14% *vs* 7.3%). In this study, both sedation schemes appeared to be safe[69].

Another study revealed no significant differences in complication rates between propofol deep sedation and meperidine/midazolam administered for moderate sedation. In this study, the complication rate with propofol was 0.60%, compared with 1% in the historical case-control (meperidine/midazolam moderate sedation) group[96]. Among the 324 737 unique procedures performed in patients under conscious sedation, unplanned events were reported in 1.4% of the procedures, 0.9% of which were associated with unplanned cardiopulmonary events[97]. Ljubicić *et al*[98] observed a decrease in oxygen saturation to < 85% and a temporary decrease in heart rate to < 50 beats/min in 5.5 and 11.8% of patients receiving propofol for endoscopy, respectively. Finally, Amornyotin *et al*[87] noted significantly different overall complication rates of 18.2% and 42.9%, respectively, between patients receiving diluted or undiluted propofol for ERCP. Significant differences were also noted in the overall rate of cardiovascular events.

In conclusion, sedation in GI endoscopic procedures, even in time-consuming procedures, seems to be safe. The rate of complications, either cardiovascular or respiratory, could be characterised as "acceptable", provided that all prevention measures have been adopted and the endoscopy staff is suitably equipped, properly trained in the handling of possible complications, and ready to immediately apply rescue measures. Table 4 lists the main sedation-related adverse events occurring during endoscopy in clinical trials, while Table 5 shows the main adverse effects related to the administration of drugs used for sedation in GI endoscopy.

LEGAL ISSUES RELATED TO SEDATION IN GI ENDOSCOPY

Important medical and legal issues regarding sedation have been raised during recent years. Such issues include informed consent of the patient, difficulties in assessing withdrawal of consent in a sedated patient, and the need for sedation monitoring that meets accepted standard of care guidelines[99]. Other controversies possibly related to medico-legal aspects include both the use of propofol and the administration of sedation by anaesthesia personnel. The former controversy is extremely important from a legal point of view if the continuously increasing use of propofol in GI endoscopy by non-anaesth esiologists is taken into account. In a related article, Axon emphasises the possible clinical negligence that could be associated with sedation administration. Interestingly, while the law recognises the desirability of sedation in endoscopy procedures, the facts of a particular case will be scrutinised to determine possible responsibilities of the endoscopist if an adverse outcome occurs[100]. Some questions related to the administration of sedation during GI endoscopy are discussed below.

Should sedation be administered by an endoscopist gastroenterologist or an endoscopist nurse?

The optimal drug for sedation administered by non-anaesthesiologists should have certain properties, such as a

Table 4 Main adverse events related to sedation occurring during endoscopy in clinical trials

Ref.	Drug regimen	Percentage of side effects	Severe hypotension (< 60 mmHg)	Severe desaturation (< 90%)
Ljubicić *et al*[98]	Propofol	17.3% (including bradycardia: 11.8%)		5.5%
Conigliaro *et al*[95]	Midazolam	0.47%		
Gasparović *et al*[28]	Propofol	2.9%	0.5%	2.4%
Sharma *et al*[97]	Cardiopulmonary events	EGD: 0.6%; Colonoscopy: 1.1%; ERCP: 2.1%; EUS: 0.9%		
Nayar *et al*[96]	Propofol deep sedation *vs* moderate sedation	0.6% *vs* 1.0%	0.1%	0.1% (apnoea: 0.3%)
Correia *et al*[69]	Midazolam plus propofol *vs* midazolam plus fentanyl	14% *vs* 7.3%		
Amornyotin *et al*[87]	Diluted *vs* undiluted propofol for deep sedation	18.2% *vs* 42.9%	11.4% *vs* 31.0%	0 *vs* 2.4%
Wang *et al*[32]	Midazolam *vs* midazolam combined with either fentanyl or propofol		Midazolam combined with propofol resulted in hypotension and bradycardia more significantly than a combination with fentanyl or midazolam alone	

EUS: Endoscopic Ultrasound; EGD: Esophagogastroduodenoscopy; ERCP: Endoscopic retrograde cholangiopancreatography.

Table 5 Side effects related to the administration of drugs used for sedation in gastrointestinal endoscopy

Side effect	Midazolam	Propofol	Fentanyl
Hypotension	Yes	Yes	
Hypertension		Yes	
Heart rate alterations	Arrhythmia	Decrease	Arrhythmia
Respiratorydepression	Yes	Yes	Yes (particularly in the elderly)
Apnoea	Yes (in combination with fentanyl)	Yes	Yes (in combination with Midazolam)
Dystonia		Yes	Yes
Priapism		Yes	Yes (very rarely)
Pain on injection		Yes	
Lactic acidosis		Yes	
Intraocular pressure changes		Decrease	
Myoclonic movements		Yes	
Nervous system side effects	Yes (especially in the elderly)	Rare	Yes
Unusual dreams		Yes	
Hypersensitivity	Yes	Yes	Yes (rarely)
Liver damage		Yes	
Amnesia	Yes		
Impairment of cognitive functions - inability to drive safely	Yes		
Paradoxical behaviour	Yes	Yes	
Gastrointestinal effects (nausea, vomiting, hiccups, diarrhoea)	Yes	Yes	Yes
Sexual disinhibition	Yes		
Potential for abuse			Yes
Haemolysis			Yes (slow injection rates and/or mixture in isotonic fluid)

predictable pharmacokinetic profile, rapid onset of action, analgesic and anxiolytic effects, short recovery time, and minimal associated risks, thus making the presence of an anaesthesiologist unnecessary.

There is evidence suggesting that non-anaesthetists can administer sedative drugs, including propofol, safely and effectively in most cases[101].

In the last decade, a number of studies addressed the safety and efficacy of the administration of propofol during GI endoscopy by either physicians or trained nurses[102,103].

With regard to the occurrence of major side effects in these studies, there were no cases of death among patients submitted to endotracheal intubation. In a prospective trial involving 36 743 cases of nurse-administered propofol sedation, the authors concluded that adequately trained nurses and endoscopists can safely administer propofol[104].

Rex *et al*[105], in a safety review of 646 080 (223 656 published and 422 424 unpublished) endoscopist-directed propofol sedation cases, noted that endotracheal intubation and death occurred in 11 and 4 cases, respectively. They concluded that the endoscopist-directed administration of propofol appears to result in a lower mortality

rate than that of traditional sedation with benzodiazepines and opioids and a comparable rate to that of general anaesthesia administered by anaesthesiologists.

Nurse-administered propofol sedation for endoscopic procedures is safe when performed by personnel properly trained in airway handling and sedation with propofol and has considerable advantages compared with conventional sedation for endoscopy[106].

Finally, in a very recent study assessing the current use of propofol during colonoscopy screening in 29 countries, it was found that non-anaesthesiologist-administered propofol was used by 29.9% of respondents in 9 countries. Approximately 2/3 of the other endoscopists reported that they would consider implementing non-anaesthesiologist-administered propofol in low-risk patients. It was also found that propofol, benzodiazepine plus opioids and benzodiazepine alone were used in 45%, 31% and 14% of cases, respectively. Importantly, the main reasons for not considering non-anaesthesiologist-administered propofol implementation were medico-legal issues and cost[107]. We suppose that these issues have not been solved and will continue to be discussed in the future.

Should sedation be administered only by a specialist anaesthesiologist?

It is well established that most of the complications occurring during GI endoscopy, such as hypoxemia, hypoventilation, airway obstruction, apnoea, arrhythmias, hypotension and vasovagal episodes, are not related to the procedure itself, but rather to sedation. A recent trial compared endoscopist-administered propofol sedation for colonoscopy with anaesthetist-administered deep sedation. It was found that endoscopist-administered propofol sedation for colonoscopy yielded a better level of satisfaction and patient willingness to undergo further colonoscopies under the same conditions, as well as fewer side effects than anaesthetist-administered deep sedation[108].

Guidelines concerning the use of propofol have been delivered by most major endoscopic associations worldwide. The guidelines of the Endoscopic Section of the German Society for Digestive and Metabolic Diseases suggest that "for simple endoscopic examinations and in low-risk patients, sedation with propofol should be induced by a properly qualified physician and can then be monitored by an experienced person with appropriate training. The person must not have any other tasks while monitoring the sedation". Furthermore, they suggest that an anaesthesiologist should be required only in patients with a high-risk profile.

Four major United States GI Societies, the American Association for the Study of Liver Disease, American College of Gastroenterology, American Gastroenterological Association and American Society for Gastrointestinal Endoscopy, suggest that the administration of propofol is comparable to that of standard sedation with benzodiazepines by non-anaesthesiologists with respect to their safety and efficacy profile.

The guidelines of the European Society of Gastrointestinal Endoscopy, the European Society of Gastroenterology and Endoscopy Nurses and Associates, and the European Society of Anaesthesiology (produced by 32 individuals from 12 countries, published in 2010) can be summarised as follows:[109] "The consensus suggested that endoscopists and nurses with appropriate training can safely and effectively administer propofol to low-risk patients undergoing endoscopic procedures".

Therefore, the safety profile of non-anaesthesiologist-administered propofol sedation for GI endoscopy seems to be equivalent to that of standard sedation with respect to the risks of hypoxemia, hypotension and bradycardia in ERCP and EUS. Concerning upper and lower GI endoscopy, ERCP and EUS, the time for sedation induction and the recovery time using non-anaesthesiologist-administered propofol sedation are shorter compared with those associated with standard sedation, while non-anaesthesiologist-administered propofol sedation is most likely more cost-effective than standard sedation for ERCP and EUS.

However, the opinion of almost all anaesthesiology societies concerning the use of propofol by non-anaesthesiologists is definitely negative. They emphasise the fact that the manufacturers of propofol restrict its use solely to personnel trained in general anaesthesia and that the United States Food and Drug Administration denied a petition by gastroenterologists seeking the removal of this particular restriction. In a recent consensus statement, the European Society of Anaesthesiology, together with 20 European national anaesthesiology societies in Europe, published new guidelines, entitled "Non-anaesthesiologist Administration of Propofol for Gastrointestinal Endoscopy". They stated that due to its significant risks, propofol should be administered only by those trained in the administration of general anaesthesia[110]. Again, this is a topic of continued debate. International consensus by the major endoscopy societies of the world is urgently needed.

CONCLUSION

Currently, both diagnostic and therapeutic endoscopy is well tolerated and accepted by both patients and endoscopists due to the application of sedation by most centres in the world. During the last 15 years, dramatic changes have occurred in endoscopic procedures, mainly with regard to the sedation techniques and the sophisticated endoscopic instruments and equipment utilised. Today, a large number of drugs are available for achieving successful moderate and deep sedation, and other substances are in the clinical evaluation stage. Moderate sedation using midazolame and an opioid represents the standard method of sedation, although propofol is being increasingly used in many countries. We suggest that the use of this drug will be accepted by an increasing number of endoscopists and that it could become the

preferred sedation agent in the near future. Today, midazolam remains the benzodiazepine of choice, while the most popular opioids are pethidine and fentanyl. Safe sedation in special clinical circumstances, such as in obese, pregnant, and elderly individuals, as well as in patients with chronic lung, renal or liver disease, requires modification of the drug doses used for sedation. It is also crucial for endoscopists to be very familiar with the drug or combination of drugs that they are using in everyday clinical practice. However, the controversy regarding the administration of sedation by an endoscopist, anaesthesiologist or an experienced nurse continues. We emphasise that sedation under the supervision of a properly trained endoscopist could become the standard practice. Due to the legal issues related to the occurrence of unwanted effects of sedation, an updated international consensus regarding the use of sedative agents, especially propofol, is urgently needed.

Abstract

AIM: To investigate retrograde tracer transport by gastric enteric neurons in insulin resistant mice with low or high glycosylated hemoglobin (Hb).

METHODS: Under anesthesia, the retrograde tracer fluorogold was superficially injected into the fundus or antrum using a microsyringe in KK Cg-Ay/J mice prior to onset of type 2 diabetes mellitus (T2DM; 4 wk of age), at onset of T2DM (8 wk of age), and after 8, 16, or 24 wk of untreated T2DM and in age-matched KK/HIJ mice. Six days later, mice were sacrificed by CO_2 narcosis followed by pneumothorax. Stomachs were removed and fixed. Sections from fundus, corpus and antrum were excised and mounted on a glass slide. Tracer-labeled neurons were viewed using a microscope and manually counted. Data were expressed as the number of neurons in short and long descending and ascending pathways and in local fundus and antrum pathways, and the number of neurons in all regions labeled after injection of tracer into either the fundus or the antrum.

RESULTS: By 8 wk of age, body weights of KKAy mice (n = 12, 34 ± 1 g) were heavier than KK mice (n = 17, 29 ± 1 g; F (4, 120) = 4.414, P = 0.002] and glycosylated Hb was higher [KK: (n = 7), 4.97% ± 0.04%; KKAy: (n = 6), 6.57% ± 0.47%; F (1, 26) = 24.748, P < 0.001]. The number of tracer labeled enteric neurons was similar in KK and KKAy mice of all ages in the short descending pathway [F (1, 57) = 2.374, P = 0.129], long descending pathway [F (1, 57) = 0.922, P = 0.341], local fundus pathway [F (1, 53) = 2.464, P = 0.122], local antrum pathway [F (1, 57) = 0.728, P = 0.397], and short ascending pathway [F (1, 53) = 2.940, P = 0.092]. In the long ascending pathway, fewer tracer-labeled neurons were present in KKAy as compared to KK mice [KK: (n = 34), 302 ± 17; KKAy: (n = 29), 230 ± 15; F (1, 53) = 8.136, P = 0.006]. The number of tracer-labeled neurons was decreased in all mice by 16 wk as compared to 8 wk of age in the short descending pathway [8 wk: (n = 15), 305 ± 26; 16 wk: (n = 13), 210 ± 30; F (4, 57) = 9.336, P < 0.001], local antrum pathway [8 wk: (n = 15), 349 ± 20; 16 wk: (n = 13), 220 ± 33; F (4, 57) = 8.920, P < 0.001], short ascending pathway [8 wk: (n = 14), 392 ± 15; 16 wk: (n = 14), 257 ± 33; F (4, 53) = 17.188, P < 0.001], and long ascending pathway [8 wk: (n = 14), 379 ± 39; 16 wk: (n = 14), 235 ± 26; F (4, 53) = 24.936, P < 0.001]. The number of tracer-labeled neurons decreased at 24 wk of age in the local fundus pathway [8 wk: (n = 14), 33 ± 11; 24 wk: (n = 12), 3 ± 2; F (4, 53) = 5.195, P = 0.001] and 32 wk of age in the long descending pathway [8 wk: (n = 15), 16 ± 3; 32 wk: (n = 12), 3 ± 2; F (4, 57) = 2.944, P = 0.028]. The number of tracer-labeled enteric neurons was correlated to final body weight for local fundus and ascending pathways [KK: (n = 34), r = -0.746, P < 0.001; KKAy: (n = 29), r = -0.842, P < 0.001] as well as local antrum and descending pathways [KK (n = 36), r = -0.660, P < 0.001; KKAy (n = 31), r = -0.622, P < 0.001]. In contrast, glycosylated Hb was not significantly correlated to number of tracer-labeled neurons [KK (n = 17), r = -0.164, P = 0.528; KKAy (n

= 16), r = -0.078, P = 0.774].

CONCLUSION: Since uncontrolled T2DM did not uniformly impair tracer transport in gastric neurons, long ascending neurons may be more susceptible to persistent hyperglycemia and low effective insulin.

INTRODUCTION

Diabetes mellitus (DM), characterized by persistent hyperglycemia and a deficiency of effective plasma insulin, can result in neuropathy of autonomic neurons. In rodent models of type 1 DM (T1DM) and type 2 DM (T2DM), neuropathies of the parasympathetic vagus nerve[1-3] and enteric neurons located within the wall of the gut[4,5] have been described. Many factors likely contribute to the development of autonomic neuropathy[6,7] including accumulation of sorbitol in nerves[8,9], oxidative stress[10,11], and somal deficiency of neurotrophins[7,12-14].

Neurotrophins, proteins that support the proper functioning of neurons, are retrogradely transported from the innervated organ to the soma by an axonal active transport mechanism. Active axonal transport of proteins in the vagus nerve was impaired in animal models of DM. Early studies using nerve ligation demonstrated reduced axonal transport of opiate receptors[15] and choline acetyltransferase[8] in the vagus nerve of streptozotocin (STZ) rats with partial reversal by immediate treatment with insulin[15] or an aldose reductase inhibitor[8]. Retrograde transport by the vagus nerve of endogenous neurotrophins[8] or experimental neuronal tracers injected into the stomach[16,17] was impaired after 16 or 24 wk of uncontrolled hypoinsulinemia and hyperglycemia in STZ rats. In a rodent model of T2DM, the db/db mouse, axonal transport of acetylcholinesterase[18,19] and choline acetyltransferase[20] in peripheral nerves was impaired, but only after at least 25 wk[18,19], approximately double the time observed in STZ models of T1DM[16,17,21]. To date, active axonal transport of proteins by enteric neurons located within the wall of the gut has not been evaluated in rodent models of DM. We hypothesized that retrograde transport of the neural tracer fluorogold (FG) would be impaired in enteric neurons, but only after prolonged insulin resistance and hyperglycemia.

Coordinated contraction and relaxation of fundus, corpus and antrum is required for normal storage and emptying of gastric contents[22,23]. Enteric neural control of contraction and relaxation of gastric smooth muscle varied by region in rodent models of DM[24,25]. Therefore, tracer transport in ascending and descending enteric neurons innervating the fundus and antrum, respectively, were evaluated.

These studies used an obese mouse model of T2DM, the KKAy mouse. As the result of an agouti mutation on a diabetes susceptible background (KK strain), the KKAy mouse overeats normal chow, accumulates adipose tissue, and develops overt hyperglycemia. Since both mouse groups are insulin resistant[26-28], but only the KKAy mouse group develops persistent hyperglycemia[26], the contribution of overt hyperglycemia to enteric retrograde axonal transport could be determined. We hypothesized that the combination of insulin resistance and overt hyperglycemia in KKAy mice would accelerate the onset of impaired FG transport by enteric neurons as compared to KK mice.

MATERIALS AND METHODS

Animals

Female KK Cg-Ay/J mice (KKAy, strain 2468, n = 60), an obese model of T2DM, and age-matched female KK/HIJ mice (KK, stock number 2106, n = 70), were obtained at 3-6 wk of age (Jackson Laboratories, Bar Harbor, ME, United States). Initially, KKAy mice were screened for onset of T2DM by urine glucose. Since most KKAy mice became diabetic at 8 wk of age, onset of T2DM was defined as 8 wk of age and T2DM was untreated for 8, 16, or 24 wk. Body weight was recorded weekly. At sacrifice, drops of whole blood were used to determine glycosylated hemoglobin (Hb) (A1C Now+® Multi Test A1C System; Bayer, Tarrytown, NY, United States) and stress-induced glucose (BD Logic blood glucose monitor; Becton, Dickinson, and Co., Franklin Lakes, NJ, United States). Urine was drained from the bladder using a syringe and tested for glucose using uristix (Bayer). Urine was considered positive for glucose if glucose was $\geqslant$ 500 mg/dL.

Injection of FG into stomach

Surgeries were performed prior to onset of T2DM (4 wk of age), at onset of T2DM (8 wk of age), and after 8, 16, or 24 wk of untreated T2DM (i.e., 16, 24, and 32 wk of age, respectively). The number of mice at each age is shown in Table 1. Both KKAy and age-matched KK mice surgeries were performed on the same day using the same tracer solution. Surgeries were performed under ketamine (100-150 mg/kg, *ip*; Fort Dodge Animal Health, Fort Dodge, IA, United States) and xylaxine (8 mg/kg, *ip*; Vedco, St. Joseph, MO, United States) anesthesia. The neural tracer FG was used to assess active axonal retrograde transport in enteric neural pathways.

The tracer solution containing 4% FG (hydroxystilbamidine methanesulfonate; Invitrogen Molecular Probes) in dimethyl sulfoxide was superficially injected into the

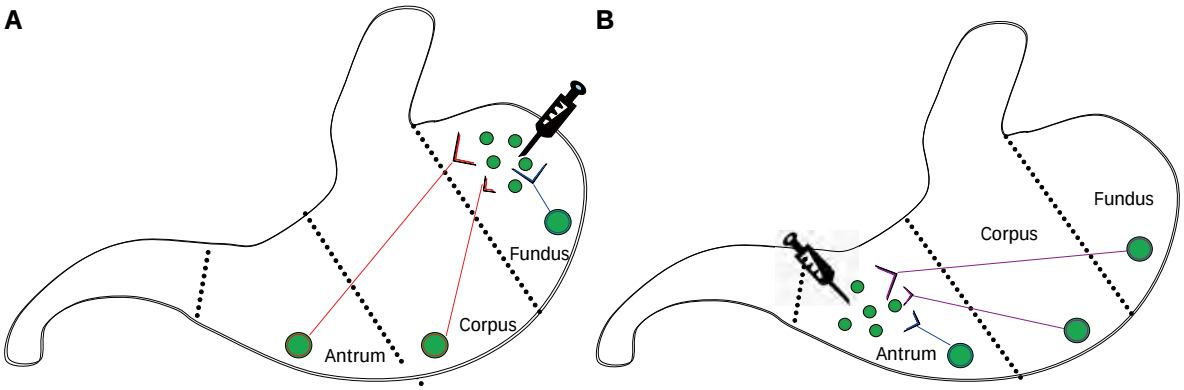

Figure 1 Cartoon of ascending, descending and local enteric pathways in the stomach. Enteric nerve terminals endocytosed the tracer fluorogold (small green circles) and it was transported back to cell bodies (large green circles) located in the fundus, corpus, or antrum. A: The retrograde tracer fluorogold was injected into the fundus. Red neurons were in the ascending pathway while blue neurons were in the local fundic pathway. The approximate distances from fundus injection sites were 0.6, 2.2, and 3.3 cm for fundus, corpus, and antrum sections, respectively; B: The retrograde tracer fluorogold was injected into the antrum. Purple neurons were in the descending pathway while blue neurons were in the local antral pathway. The approximate distances from antrum injection sites were 3.2, 1.1, and 0.4 cm for fundus, corpus, and antrum sections, respectively.

ventral fundus or ventral antrum at 5 sites, 2 μL each, using a microsyringe (702RN, 25 μL; Hamilton, Reno, NV, United States) with replaceable needle (3/8, point style 2, 33 G, Hamilton). An analgesic (buprenorphine, 0.05 mg/kg, *sc*; Hospira, Inc., Lake Forest, IL, United States) was administered immediately after surgery. Ketoprofen (5 mg/kg, *ip*; Fort Dodge Animal Health) was administered 6 h after surgery and the following day.

To promote selective labeling, care was taken to inject the tracer into the gastric wall and avoid leakage of the tracer into the abdominal cavity. Other experiments performed in the lab using the same injection technique have shown that ventral injection of tracer into the stomach wall resulted in unilateral FG labeling of efferent vagal neurons in the brainstem dorsal motor nucleus[29]. If tracer were not confined to the stomach wall, brainstem labeling would be bilateral.

Stomach removal

Six days after tracer injection, mice were sacrificed by CO_2 narcosis followed by pneumothorax. Stomachs were removed, placed in oxygenated Krebs solution, trimmed, opened along the lesser curvature, and emptied of contents. The fundus was cut away from the corpus/antrum. Tissues were stretched and pinned, mucosa side up, in a sylgard-lined Petri dish then fixed overnight at 37 ℃ in 4% paraformaldehyde in 0.1 mol/L PBS. The mucosa was removed. Using a razor blade, the center of each fundus, corpus, and antrum region along the greater curvature was cut out and mounted on a glass slide then coverslipped. The approximate distances of the excised sections from fundus injection sites were 0.6, 2.2, and 3.3 cm for fundus, corpus, and antrum sections, respectively. The approximate distances from antrum injection sites were 3.2, 1.1, and 0.4 cm for fundus, corpus sections, and antrum sections, respectively.

Counting FG-labeled neurons

Tracer-labeled neurons were viewed at 20× using a microscope (Leica DMIL with UV light source; Leica Microsystems Inc., Buffalo Grove, IL, United States) with attached digital camera (MagnaFire; Optronics, Goleta, CA, United States) using the Chroma filter for FG (11006V3 Gold: Ex. 300-390, Em. ≥ 515). Digital images (1280 by 1024 pixels) were 0.327 μm/pixel. Digital images were in 32 bit RGB color at an image resolution of 100 dpi and a computer screen resolution of 92 dpi. Labeled neurons were manually counted with the assistance of ImagePro Plus (version 4.5.0.29, Media Cybernetics, Silver Spring, MD, United States). The numbers of labeled neurons in 20 adjacent images (418.6 μm by 334.8 μm) of the fundus and in 12 adjacent images of the corpus and antrum (total area: 2.8, 1.7, and 1.7 mm^2, respectively) were counted and data were expressed as (1) total number of tracer-labeled neurons in that pathway; and (2) total number of neurons in all three regions labeled after tracer injection into the fundus or antrum.

Description of ascending, descending, and local enteric neural pathways

Six pathways in the stomach were assessed in this study (Figure 1). Enteric neurons in ascending pathways had cell bodies in the corpus (short ascending pathways) or antrum (long ascending pathways) and nerve terminals in the ventral fundus, while those in descending pathways had cell bodies in the fundus (long descending pathways) or corpus (short descending pathways) and nerve terminals in the ventral antrum. Enteric neurons in fundic local pathways had both cell bodies and nerve terminals in the ventral fundus, while those in antral local pathways had both cell bodies and nerve terminals in the ventral antrum.

Statistical analysis

All data were expressed as mean ± SE. Data were statistically analyzed using SPSS (version 18.0, Chicago, IL). Independent factors for analysis of variance included KK or KKAy, age (4, 8, 16, 24, or 32 wk) or pathway (ascending or descending). Both main effects of one

Table 1 Number of mice at each age with tracer injection into the fundus or antrum

independent factor and interactions of two independent factors were evaluated and Sidak correction was used for post-hoc analysis. The ratios of KK and KKAy mice with positive urine glucose were compared using χ^2. Correlations were performed using Pearson correlation (r), linear regression (r^2) was performed using SigmaPlot (version 12.0, Systat Software, Inc., San Jose, CA). The number inside the bar in the graphs indicates the number of animals in the group. A P value < 0.05 was considered statistically significant with $^aP < 0.05$, $^bP < 0.01$.

RESULTS

Animal characteristics

Body weights of KK and KKAy mice were similar at 4 wk of age (Table 2), then KKAy mice became heavier [interaction: KK/KKAy and age F (4, 120) = 4.414, P = 0.002]. Body weight plateaued in KK and KKAy mice at 24 and 16 wk of age, respectively.

Glucose control was impaired in KKAy mice (Table 2). Glycosylated Hb, an index of average plasma glucose over the previous 40 d for a mouse[30], was elevated in KKAy as compared to KK mice [main effect F (1, 26) = 24.748, P < 0.001] but did not change with age [main effect: F (3, 26) = 1.916, P = 0.152]. For all mice 8 wk of age and older, glycosylated Hb was higher in KKAy mice (6.53 ± 0.31, n = 17) than in KK mice (5.02 ± 0.04, n = 17). The ability to raise blood glucose in response to stress was greater in KKAy as compared to KK mice. Stress-induced hyperglycemia was highest at 16 wk in KKAy mice (535 ± 47, n = 7), but remained steady in KK mice (297 ± 20, n = 9) [interaction: KK/KKAy and age F (4, 67) = 2.609, P = 0.043]. Glucose was detected in the urine of some KKAy mice prior to onset of T2DM, but was not detected in any KK mice.

Tracer-labeled neurons in enteric pathways

Six days after injection of tracer into the fundus or antrum, FG accumulated in the cell bodies of enteric neurons of the fundus, corpus, and antrum. Tracer-labeled enteric neurons of the corpus are shown in Figure 2.

In the long ascending pathway (Figure 3A), significantly fewer FG-labeled enteric neurons were detected in KKAy as compared to KK mice. For both KK and KKAy mice, the number of FG-labeled neurons was reduced by 16 wk of age and reached its lowest value at 24 wk of age.

In the short ascending pathway (Figure 3B), there was a trend for fewer FG-labeled enteric neurons in KKAy as compared to KK mice. By 16 wk of age, the numbers of FG-labeled neurons were reduced as compared to 4 and 8 wk of age. The numbers of FG-labeled neurons remained low at 24 and 32 wk of age.

In the long (Figure 3D) and short (Figure 3E) descending pathways, similar numbers of FG-labeled enteric neurons were detected in KK as compared to KKA^y mice. The total number of FG-labeled enteric neurons reached its lowest value at 24 wk of age for the short descending pathway and 32 wk of age for the long descending pathway.

A similar dominance of ascending projections as compared to descending projections reported in guinea pig stomach[31,32] was observed in this mouse study. At 4 wk of age, more FG-labeled neurons were in the ascending pathways as compared to the descending pathways for KK and KKAy mice [main effect: F (1, 20) = 98.981, P < 0.001; KK: ascending (n = 6), 858 ± 45; descending (n = 6), 397 ± 55; KKAy: ascending (n = 6), 800 ± 37; descending (n = 6), 384 ± 37].

Similar numbers of FG-labeled fundic (Figure 3C) and antral (Figure 3F) enteric neurons were detected in KK as compared to KKAy mice. In the local fundic pathway, the

[1]Number of mice with urine glucose ⩾ 500 mg/dL out of the total number of mice tested for urine glucose. [b]P < 0.01 *vs* KK; [d]P < 0.01 *vs* 4 wk; [f]P < 0.01 *vs* 8 wk; [h]P < 0.01 *vs* 16 wk. HbA1c: Haemoglobin A1c.

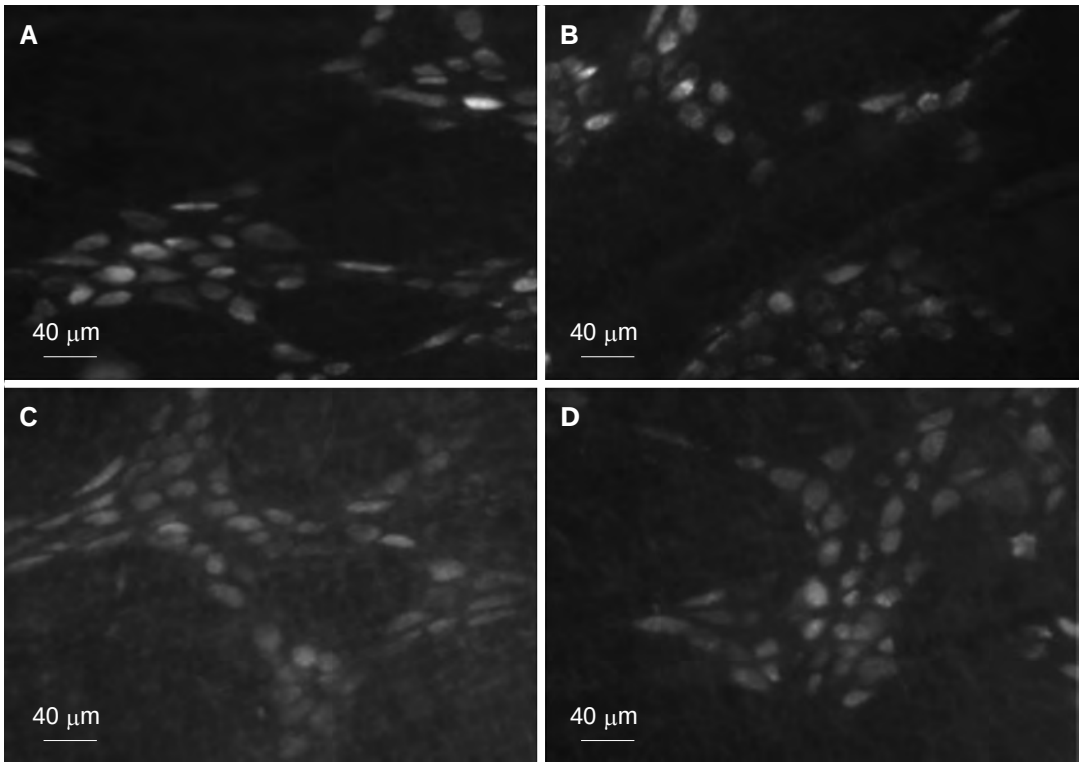

Figure 2 Fluorogold-labeled enteric neurons in gastric corpus. A: Fluorogold-labeled ascending enteric neurons in KK mice; B: Fluorogold-labeled ascending enteric neurons in KKAy mice; C: Fluorogold-labeled descending enteric neurons in KK mice; D: Fluorogold-labeled descending enteric neurons in KKAy mice. The brightness of neurons varied depending on the amount of fluorogold transported to the cell body, but most neurons in the ganglia were labeled with fluorogold.

total number of FG-labeled enteric neurons was variable, reaching its highest value at 8 wk and its lowest value at 24 wk of age. In contrast, in the antral pathway, the total number of FG-labeled enteric neurons was decreased by 16 wk in KK and KKA^{y} mice.

Correlation of FG-labeled neurons with body weight or blood glucose

The total number of FG-labeled neurons in all sections after injection into either the fundus or antrum was significantly correlated to mouse final body weight, but not stress-elevated blood glucose (Figure 4). As KK mice aged and body weight increased, the total number of enteric neurons labeled by fundus injection (Figure 4A) decreased (n = 34, r = -0.746, P < 0.001). In the heavier KKAy mice, the correlation was stronger (n = 29, r = -0.842, P < 0.001). As a result of injection into the antrum (Figure 4B), the total number of FG-labeled neurons similarly decreased with body weight in both groups of mice [KK (n = 36), r = -0.660, P < 0.001; KKAy (n = 31), r = -0.622, P < 0.001]. In contrast, stress-elevated blood glucose was not correlated with the number of FG-labeled neurons [fundus injection (Figure 4C): KK (n = 17), r = -0.097, P = 0.712; KKAy (n = 15), r = 0.328, P = 0.232; antrum injection (Figure 4D): KK (n = 25), r = 0.174, P = 0.407; KKAy (n = 20), r = 0.308, P = 0.187]. In addition, HbA1c was not correlated to number of FG-labeled neurons for antrum injection [KK (n = 17), r = -0.164, P = 0.528; KKAy (n = 16), r = -0.078, P = 0.774]. Data was not available for fundus injection.

DISCUSSION

The principal findings of these studies were that (1) insulin resistance, in the absence of persistent hyperglycemia, slowed retrograde FG transport in KK mice at 16 wk of age, the approximate age of onset of insulin resistance[26-28]; and (2) persistent hyperglycemia, as indicated by elevated HbA1c, significantly slowed tracer transport in long ascending pathways in KKAy as compared to KK mice, but the age of onset was unchanged. Persistent hyperglycemia did not significantly accelerate the age of onset of neuropathy in KKAy as compared to KK mice.

Reduced numbers of FG-labeled neurons may be due to many factors related to enteric neuropathy. Enteric neurons undergoing neuropathy may take up less tracer because of limited endocytosis[33]. Retrograde transport of tracer may be impaired due to glycosylation of axonal cytoskeletal proteins[34-36]. The density of nerve terminals in the tracer injection field may be reduced due to degeneration of nerve terminal processes[3,37,38] or to low rates of neuronal apoptosis[1,39] as a consequence of metabolic disturbances[40]. In addition, impaired active axonal transport of growth factors to the neuronal soma, including insulin and neurotrophins[11,14,41-44], may both promote and exacerbate neuropathy[6,7].

Specific mechanism(s) in distinct populations of neurons may contribute more significantly to neuropathy. Many factors play a role in the development of diabetic neuropathy[6,7,45], but treatments targeting a single mechanism do not prevent neuropathy of all autonomic neu-

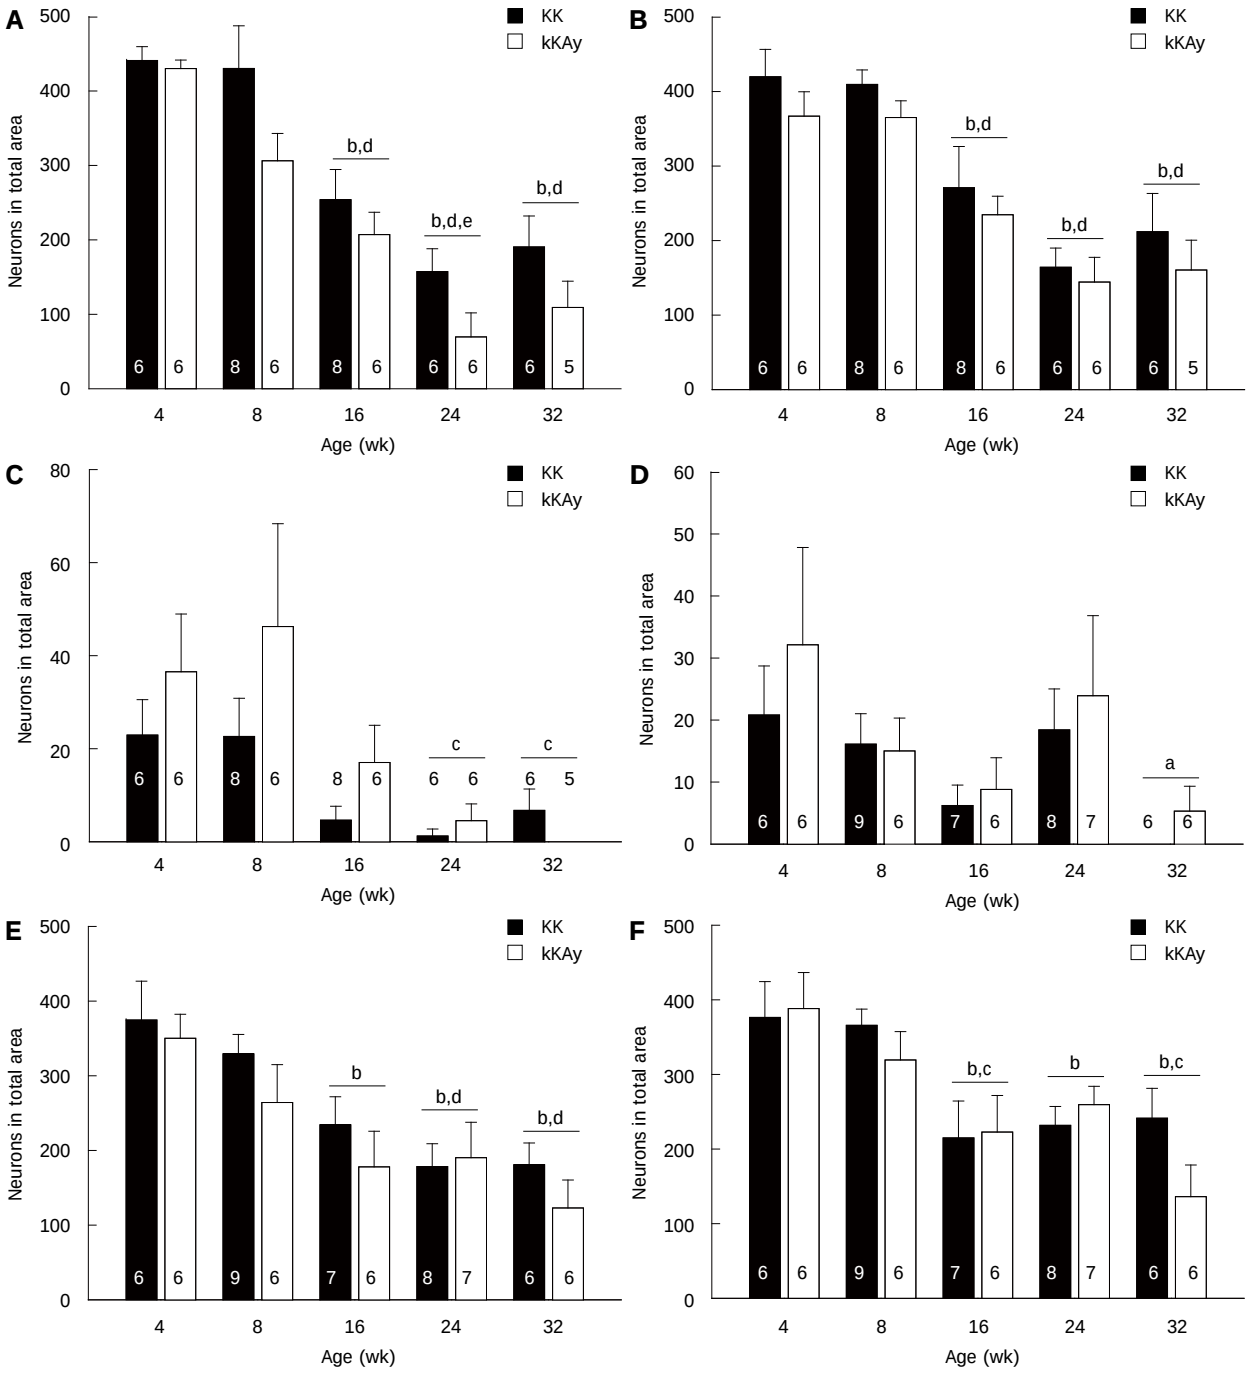

Figure 3 Number of fluorogold-labeled neurons in enteric neural pathways in 4-32 wk old KK and KKAy mice. A: Long ascending pathway: The number of fluorogold (FG)-labeled neurons was significantly decreased in KKAy as compared to KK mice [main effect: F (1, 53) = 8.136, P = 0.006]. The numbers of FG-labeled neurons began to decrease with age in KK and KKAy mice at 16 wk of age with the fewest neurons detected at 24 wk of age [main effect: F (4, 53) = 24.936, P < 0.001]; B: Short ascending pathway: There was a trend for the numbers of FG-labeled neurons to be reduced in KKAy as compared to KK mice [main effect: F (1, 53) = 2.940, P = 0.092]. The number of FG-labeled neurons decreased with age in KK and KKAy mice [main effect: F (4, 53) = 17.188, P < 0.001]. By 16 wk of age, the numbers of FG-labeled neurons were reduced and remained low; C: Fundus: Similar numbers of FG-labeled neurons were observed in KK and KKAy mice [main effect: F (1, 53) = 2.464, P = 0.122]. In KK and KKAy mice, the numbers of labeled FG neurons were highest at 8 wk and lowest at 24 and 32 wk [main effect: F (4, 53) = 5.195, P = 0.001]; D: Long descending pathway: Similar numbers of FG-labeled neurons were observed in KK and KKAy mice [main effect: F (1, 57) = 0.922, P = 0.341]. By 32 wk of age, the numbers of FG-labeled neurons were reduced as compared to younger ages [main effect: F (4, 57) = 2.944, P = 0.028]; E: Short descending pathway: Similar numbers of FG-labeled neurons were observed in KK and KKAy mice [main effect: F (1, 57) = 2.374, P = 0.129]. The numbers of FG-labeled neurons began to decrease in KK and KKAy mice at 16 wk of age with the fewest neurons detected at 24 wk of age [main effect: F (4, 57) = 9.336, P < 0.001]; F: Antrum: Similar numbers of FG-labeled neurons were observed in KK and KKAy mice [main effect: F (1, 57) = 0.728, P = 0.397]. By 16 wk of age, the numbers of FG-labeled neurons were reduced as compared to 4 and 8 wk of age [main effect: F (4, 57) = 8.920, P < 0.001]. ^{a}P < 0.05, ^{b}P < 0.01 *vs* 4 wk; ^{c}P < 0.05, ^{d}P < 0.01 *vs* 8 wk; ^{e}P < 0.05 *vs* 16 wk.

rons[46-48]. In this study, long ascending enteric neurons, but not long descending enteric neurons, displayed significantly slower tracer transport in KKAy as compared to KK mice despite similar axonal lengths. Ascending enteric neurons are predominantly cholinergic[31,49-51]. Impaired axonal transport has been reported for acetylcho-

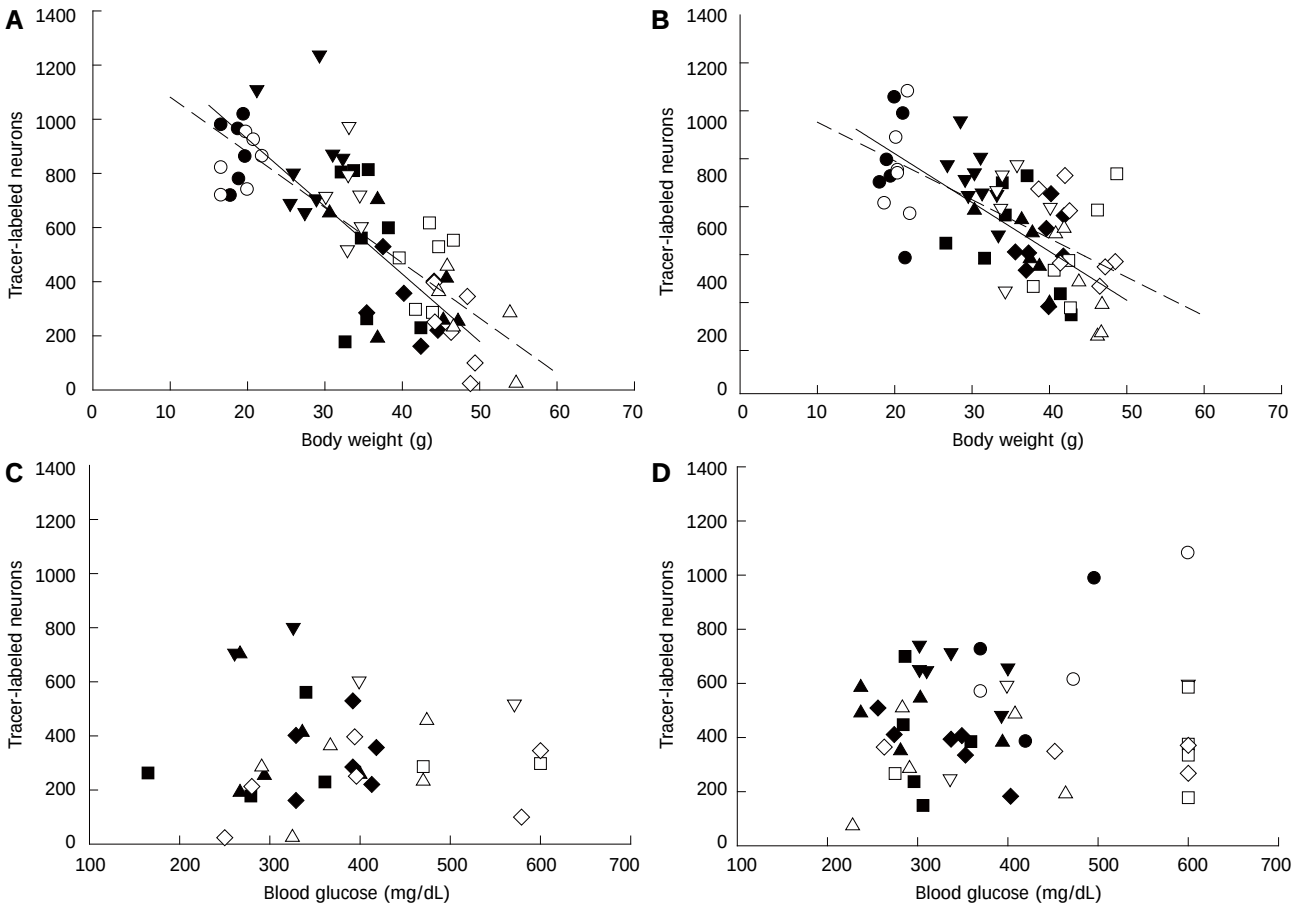

Figure 4 Correlation of body weight or stress-elevated blood glucose with number of tracer-labeled enteric neurons. A: Body weight was correlated with number of neurons labeled by fundus injection (KK mice, r^2 = 0.4362; KKAy mice, r^2 = 0.3868); B: Body weight was correlated with number of neurons labeled by antrum injection (KK mice, r^2 = 0.5565; KKAy mice, r^2 = 0.7087); C: Stress-elevated blood glucose was not correlated with number of neurons labeled by fundus injection (KK mice, r^2 = 0.0093; KKAy mice, r^2 = 0.108); D: Stress-elevated blood glucose was not correlated with number of neurons labeled by antrum injection (KK mice, r^2 = 0.0301; KKAy mice, r^2 = 0.0947). Legend: Black symbols and solid line, KK mice; white symbols and dashed line, KKAy mice; circle, 4 wk; inverted triangle, 8 wk; square, 16 wk; diamond, 24 wk; upright triangle, 32 wk.

linesterase[18,19] and muscarinic receptors[15] and debated for choline acetyltransferase[8,20,43,52] in rodent models of DM. Hence, active tracer transport in this subpopulation of autonomic neurons with a cholinergic phenotype may be more susceptible to combined persistent hyperglycemia and low effective insulin.

Age-related degeneration of axonal branches[37,40] may contribute to the reduction in the number of FG-labeled neurons observed in older as compared to younger mice. In young NMRI mice, the number of myenteric neurons per ganglion section did not change between 1 and 3 mo of age[53]. Similarly, in this study, neuron density was unchanged from 4 to 8 wk of age. In rats, gastric myenteric neurons have been reported to be less susceptible to age-related degeneration than intestinal myenteric neurons[54,55]. The density of gastric myenteric neurons was unchanged until 27 mo of age, when density was reduced in the forestomach, but not corpus or antrum[55]. In this study, the initial reduction in FG labeled neurons was observed at 16 wk of age in KK and KKA^y mice. Hence, in mice with insulin resistance, the reduced delivery of target organ trophic factors back to the cell soma may be associated with increased susceptibility of enteric neurons, especially those with cholinergic phenotype[54], to age-related degeneration[37,56].

A heavier body weight, reflecting a higher degree of adiposity and therefore insulin resistance, contributed more strongly to enteric neuropathy than severity of hyperglycemia. The correlation of total FG-labeled neurons with body weight was stronger for heavier KKAy as compared to lighter KK mice. In contrast, the severity of hyperglycemia was not correlated to total FG-labeled neurons. Other studies have also reported that insulin deficiency, but not hyperglycemia, was associated with severity of peripheral neuropathy[14,38,57-59].

An increase in stomach size may result in a lower density of nerve terminals in the injection field for FG endocytosis and subsequent reduction in FG labeling. The weights of stomachs from 16 wk old KK and KKAy mice were similar [personal observation, KK (n = 4), 277 ± 40 mg; KKAy (n = 4), 263 ± 33 mg, P = 0.80] suggesting that stomachs from KKAy mice were not hypertrophied.

Insulin resistance itself in the absence of persistent hyperglycemia slowed tracer transport in 16-wk-old KK mice. The addition of persistent hyperglycemia in KKAy mice further slowed tracer transport in only long ascend-

ing enteric neurons without accelerating the age of onset. Slowed active tracer transport in enteric neurons implies that retrograde transport of endogenous neurotrophins required for maintenance of normal nerve function may also be impaired[6,21,33,60]. Given the codependence of neurons and the target tissue on neurotrophins to preserve organ function[6], neuropathy resulting from impaired retrograde transport of neurotrophins may result in imprecise coordination of gastric regions by ascending and descending inhibitory and excitatory enteric reflexes[61,62], thereby contributing to asynchronous gastric motor function[63,64].

COMMENTS

Background

Diabetes mellitus (DM), characterized by persistent hyperglycemia and a deficiency of effective plasma insulin, can result in neuropathy of autonomic neurons. In rodent models of type 1 DM (T1DM) and type 2 DM (T2DM), neuropathies of the parasympathetic vagus nerve and enteric neurons located within the wall of the gut have been described. Many factors likely contribute to the development of autonomic neuropathy including accumulation of sorbitol in nerves, oxidative stress, and somal deficiency of neurotrophins.

Research frontiers

Under anesthesia, the retrograde tracer fluorogold was superficially injected into the fundus or antrum using a microsyringe in KK Cg-Ay/J mice prior to onset of T2DM (4 wk of age), at onset of T2DM (8 wk of age), and after 8, 16, or 24 wk of untreated T2DM and in age-matched KK/HlJ mice. Six days later, mice were sacrificed by CO_2 narcosis followed by pneumothorax. Data were expressed as the number of neurons in short and long descending and ascending pathways and in local fundus and antrum pathways, and the number of neurons in all regions labeled after injection of tracer into either the fundus or the antrum.

Innovations and breakthroughs

The principal findings of these studies were that (1) insulin resistance, in the absence of persistent hyperglycemia, slowed retrograde fluorogold transport in KK mice at 16 wk of age, the approximate age of onset of insulin resistance; and (2) persistent hyperglycemia, as indicated by elevated HbA1c, significantly slowed tracer transport in long ascending pathways in KKAy as compared to KK mice, but the age of onset was unchanged. Persistent hyperglycemia did not significantly accelerate the age of onset of neuropathy in KKAy as compared to KK mice.

Applications

Insulin resistance itself in the absence of persistent hyperglycemia slowed tracer transport in 16-wk-old KK mice. The addition of persistent hyperglycemia in KKAy mice further slowed tracer transport in only long ascending enteric neurons without accelerating the age of onset. Slowed active tracer transport in enteric neurons implies that retrograde transport of endogenous neurotrophins required for maintenance of normal nerve function may also be impaired.

Peer review

The manuscript is formally well written and figures are clear and understandable. Experimental design and methodology are suitable for publication.

Abstract

AIM: To study the effects of combined early fluid resuscitation and hydrogen inhalation on septic shock-induced lung and intestine injuries.

METHODS: Wistar male rats were randomly divided into four groups: control group (Group A, *n* = 15); septic shock group (Group B, *n* = 15); early fluid resuscitation-treated septic shock group (Group C, *n* = 15); and early fluid resuscitation and inhalation of 2% hydrogen-treated septic shock group (Group D, *n* = 15). The activity of hydroxyl radicals, myeloperoxidase (MPO), superoxide dismutase (SOD), diamine oxidase (DAO), and the concentration of malonaldehyde (MDA) in the lung and intestinal tissue were assessed according to the corresponding kits. Hematoxylin and eosin staining was carried out to detect the pathology of the lung and intestine. The expression levels of interleukin (IL)-6, IL-8, and tumor necrosis factor (TNF)-α in lung and intestine tissue were detected by enzyme-linked immunosorbent assay method. The expression levels of Fas and Bcl2 in lung tissues were determined by immunohistochemistry and Western blotting.

RESULTS: Septic shock elicited a significant increase in the levels of MDA (10.17 ± 1.12 nmol/mg protein *vs* 2.98 ± 0.64 nmol/mg protein) and MPO (6.79 ± 1.02 U/g wet tissue *vs* 1.69 ± 0.14 U/g wet tissue) in lung tissues. These effects were not significantly decreased by Group C pretreatment, but were significantly reduced by Group D pretreatment (MDA: 4.45 ± 1.13 nmol/mg protein *vs* 9.56 ± 1.37 nmol/mg protein; MPO: 2.58 ± 0.21 U/g wet tissue *vs* 6.02 ± 1.16 U/g wet tissue). The activity of SOD (250.32 ± 8.56 U/mg protein *vs* 365.78 ± 10.26 U/mg protein) in lung tissues was decreased after septic shock, and was not significantly increased by Group C pretreatment, but was significantly enhanced by Group D pretreatment (331.15 ± 9.64 U/mg protein *vs* 262.98 ± 5.47 U/mg protein). Histological evidence of lung hemorrhage, neutrophil infiltration and overexpression of IL-6, IL-8, and TNF-α was observed in lung tissues, all of which were attenuated by Group C and further alleviated by Group D pretreatment. Septic shock also elicited a significant increase in the levels of MDA, MPO and DAO (6.54 ± 0.68 kU/L *vs* 4.32 ± 0.33 kU/L) in intestinal tissues, all of which were further increased by Group C, but significantly reduced by Group D pretreatment. Increased Chiu scoring and overexpression of IL-6, IL-8 and TNF-α were observed in intestinal tissues, all of which were attenuated by Group C and further attenuated by Group D pretreatment.

CONCLUSION: Combined early fluid resuscitation and hydrogen inhalation may protect the lung and intestine of the septic shock rats from the damage induced by oxidative stress and the inflammatory reaction.

Liu W, Shan LP, Dong XS, Liu XW, Ma T, Liu Z. Combined early fluid resuscitation and hydrogen inhalation attenuates lung and intestine injury. *World J Gastroenterol* 2013; 19(4): 492-502 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/492.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.492

INTRODUCTION

Septic shock is a common complication of infection, severe trauma, and major operation in patients. Septic shock is an autoimmune injury of the body, and the pathogenesis is very complicated. The immunocyte is activated in patients with septic shock, and the respiratory burst creates massive amounts of reactive oxygen species (ROS) which cannot be cleaned by the antioxidant defense systems[1,2]. Oxidative stress induced by ROS can increase lipid peroxidation, and can also increase the permeability of the alveolar epithelial cells by destroying the cell membrane. Simultaneously, the aggregation of neutrophilic leukocytes in the lung further induces the respiratory burst. The imbalance of antioxidant defense systems against oxidative stress then further damages the alveolar epithelial cells.

In order to ensure the blood supply of major organs, including the heart and brain, in patients with septic shock, blood flow is redistributed. There is a significant decrease in blood flow of the gastrointestinal tract which induces severe ischemia, hypoxia, and reperfusion injury. Inflammatory factors are activated which induce further injury in the gastrointestinal tract, and may consequently produce multiple organ dysfunction syndrome (MODS)[3]. Despite recent advances in antibiotic therapy and intensive care, sepsis is still considered to be one of the most common causes of death in intensive care units. The main therapy for septic shock is hemostasis and fluid resuscitation which can prevent MODS by improving hemodynamics[4]. However, fluid resuscitation is not effective in microcirculation disturbance and hypoxia. So, new and effective therapies for septic shock should be developed to improve the patient outcomes.

Recently, it has been suggested that molecular hydrogen exerts a therapeutic antioxidant activity by selectively reducing hydroxyl radicals (•OH, the most cytotoxic ROS) and effectively protects against organ damage[5-7]. Xie *et al*[1,8,9] also report that hydrogen inhalation can significantly decrease levels of oxidative product, increase activities of antioxidant enzymes, and reduce levels of high-mobility group box 1 in serum and lung tissue, thus improving the survival rate of mice with sepsis. However, there are no reports combining fluid resuscitation and hydrogen inhalation as treatment for septic shock. Therefore, the present study was designed to investigate the protective effects of combined early fluid resuscitation and 2% hydrogen on the lung and intestine in a lipopolysaccharide (LPS)-induced septic shock rat model.

MATERIALS AND METHODS

Animals and chemicals

Male Wistar rats weighing 180-200 g were used for the study. They were obtained from the Laboratory Animal Center (China Medical University, Shenyang, China). LPS (L-2880 from *Escherichia coli* serotype 055:B5) was obtained from Sigma Chemical Co. (St. Louis, MO, United States). The •OH, myeloperoxidase (MPO), superoxidase dismutase (SOD), and malonaldehyde (MDA) assay kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). The interleukin (IL)-6, IL-8, and tumor necrosis factor (TNF)-α enzyme-linked immunosorbent assay (ELISA) kits, rabbit polyclonal anti-Bcl-2 and rabbit polyclonal anti-Fas were purchased from Wuhan Boster Bio-engineering Limited Company (Wuhan, China).

Experimental design

Sixty male Wistar rats were divided into four groups randomly, 15 rats in each: control group (Group A); septic shock group (Group B); early fluid resuscitation + septic shock group (Group C); and early fluid resuscitation + inhalation of 2% hydrogen + septic shock group (Group D). Rats were anesthetized by intraperitoneal injection of 10% chloral hydrate (300 mg/kg) and tracheally ventilated using a Colombus ventilator (HX-300, TaiMeng Technologies, China), with a respiratory frequency of 100 breaths/min and a tidal volume of 10 mL/kg. The inhaled gas used for Group D was a hydrogen-air mixture (2% hydrogen in air), and the inhaled gas for other groups was room air. Left common carotid artery was cannulated to monitor the heart rate and mean arterial pressure (MAP). The femoral vein was cannulated for drug administration and fluid resuscitation. An electric heater was used to maintain body temperature. Half an hour after the rats reached a stable status, except for the rats in Group A, LPS was administered at a dose of 15 mg/kg by slow intravenous injection (not less than 2 min) to establish the septic shock rat model. Then, 0.2 mL saline was used to ensure that the LPS remaining in the syringe was completely injected[10]. Group A rats received intravenous injections of the same volume of saline. Fluid challenge (10 mL/kg per 15 min) was performed when MAP or arterial blood flow decreased to 80% of baseline values. If the percent change in pulse pressure > 13% with a persistent decrease in MAP or arterial blood flow, the fluid challenge was repeated. Norepinephrine was introduced when MAP remained low despite a normal percent change in pulse pressure (< 13%). Norepinephrine concentration was either progressively increased or decreased between 0.5 and 6 μg/kg.min, as needed, to maintain the MAP at ± 10% of baseline value[10]. Vital signs, fluid volume and the amount of norepinephrine were also recorded.

Preparation of lung tissues

The rats were sacrificed 2 h after the septic shock rat model was established. Arterial blood (1 mL) was collected for assessing the arterial blood gases. The heart and lung were removed through a thoracotomy and the dorsal lobe of the right lung was cut into three blocks (0.1 cm × 0.1 cm × 0.1 cm). The excess liquid of the first block was drained by the filter paper, and wet weight (W) was recorded. Then the same block was dried in a drying oven at a temperature of 70 ℃ for 24 h to measure dry weight (D). The second block was fixed with 4% paraformaldehyde at a temperature of 4 ℃, and then, the block was embedded in paraffin and sliced for hematoxylin and eosin (HE) staining and immunohistochemical study. The other lung tissue block was frozen at -70 ℃ for Western blotting analysis. The right hilum was ligated, and 2 mL of saline solution was used for the left lung lavage, and about 3.0-3.6 mL of bronchial alveolar lavage fluid (BALF) was collected. The BALF was centrifuged at 1500 × *g* for 4 min, and the supernatant was collected and stored at -20 ℃ for inflammatory mediator analysis.

Preparation of small intestine tissues

The rats were sacrificed 2 h after the septic shock rat model was established. Arterial blood (1 mL) was collected for assessing the arterial blood gases. Another 4 mL arterial blood was centrifuged at 2000 rpm for 10 min, and the supernatant serum was collected and stored at -20 ℃. A laparotomy was performed, two small intestinal segments were resected from 10 cm distal to the ligament of Treitz, and the intestinal segments were gently washed using saline rinse cooled to 4 ℃. These two small intestine segments (cut to 1 cm × 1 cm) were fixed with 4% paraformaldehyde and 2.5% glutaraldehyde, respectively. The other small intestine segments used for assessing the oxidative stress were frozen at -70 ℃.

Determination of oxidative damage

Small intestinal tissues and lung tissues were homogenated, centrifuged at 12 000 × *g* for 20 min, and the supernatant serum was collected. The OH, MDA, SOD, and MPO activities were measured according to the manufacturer's instructions (Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

Measurement of serum diamine oxidase activity

The frozen serum was thawed on ice, and centrifuged at 1000 × *g* for 15 min at 4 ℃. The serum diamine oxidase (DAO) activity was detected with dianisidine developer, and the serum DAO activity assay was performed according to the manufacturer's instructions (Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

HE staining of tissues

Both the small intestinal tissue and lung tissues were fixed with 4% paraformaldehyde for more than 24 h. After dehydrating and embedding, the tissues were cut into 5 μm slices. The slices were stained with HE. The pathogenesis of lung injury and small intestinal mucosal injury was observed under microscope. The intestinal mucosal injury was evaluated by the Chiu scoring system. The Chiu's score was graded as: Grade 0: normal mucosa; Grade 1: formation of subepithelial detachments at the tip of the villi with capillary congestion; Grade 2: subepithelial detachments exert a moderate amount of upward push on the mucosal epithelium; Grade 3: large subepithelial detachments exert a massive amount of upward push on the mucosal epithelium along the villi and a few denuded villus tips are observed; Grade 4: the villi are denuded to the level of lamina propria and dilated capillaries; Grade 5: presence of ulceration, disintegration of lamina propria, and hemorrhage[11]. Ten fields for each sample were observed, and the average score was recorded as the pathology score of the small intestinal tissue.

Changes in the organelles of small intestine

The small intestine segments were fixed with 2.5% glutaraldehyde. After dehydration, the samples were embedded in epoxy resins, and then were cut into ultrathin sections. The changes in the organelles were observed under transmission electron microscope.

Measurement of serum inflammatory mediators

The frozen serum was thawed on ice, and centrifuged at 1000 × *g* for 15 min at 4 ℃. Levels of IL-6, IL-8 and TNF-α were detected by ELISA according to the manufacturer's instructions (Wuhan Boster Bio-engineering Limited Company, Wuhan, China).

Immunohistochemical study

Tissue sections (slice thickness 3 μm) were dried for 4 h at 60 ℃-65 ℃, and then were deparaffinized and rehydrated. Sections were immersed in phosphate buffered saline (PBS) three times (5 min/time). Then antigen retrieval was performed followed by cooling at room temperature. The slides were immersed in PBS three times (5 min/time). After that, the sections were incubated with methanol containing 3% hydrogen peroxide for 20 min, and then were left at room temperature for 10 min followed by washing with PBS three times (5 min/time). The slides were blocked with normal goat serum solution at room temperature for 10 min, and the superfluous serum surrounding slides was wiped off. After that, the slides were incubated with primary antibody (50 μL) at 4 ℃ overnight. After washing with PBS three times (5 min/time), sections were incubated in horseradish peroxidase-polymer goat anti-Ms/Rb immunoglobulin G at room temperature for 20 min followed by rinsing in PBS three times (5 min/time). The slides were developed with 3,3'-diaminobenzidine solution for about 3-5 min, rinsed with tap water, and then counterstained with hematoxylin. Acid alcohol solution (1%) was used for differentiation for 1 s, followed by rinsing with tap water for 10-15 min. Finally, specimens were dehydrated and mounted, and examined with a microscope equipped with an image analysis system. Yellow or brownish-yellow staining represents positive staining.

Table 1 Comparison of blood gas and fluid volume among four groups (mean ± SD)

Group	pH value	MAP (mmHg)	Heart rate	PaO_2 (mmHg)	$PaCO_2$ (mmHg)	Lactate (mmol/L)	Fluid volumes (mL)	Norepinephrine (μg/kg per minute)
A	7.38 ± 0.12	101 ± 8	240 ± 13	93.9 ± 2.23	38.65 ± 1.78	1.50 ± 0.34	0	0

[a]$P < 0.05$ *vs* Group A; [c]$P < 0.05$ *vs* Group C. •OH: Hydroxyl radical; MDA: Malonaldehyde; MPO: Mmyeloperoxidase; SOD: Superoxide dismutase.

Western blotting analysis

Levels of Fas and Bcl2 proteins in lung tissue were quantified by Western blotting as described previously with some minor modifications[12]. Briefly, about 10 mg frozen lung tissue were immersed in the tissue lysates at a ratio of 1:10 w/v, then submitted to ultrasound homogenation for 1 min followed by centrifugation at 13 000 rpm for 5 min at 4 ℃. The supernatant was collected, and total protein concentration was measured by the Bradford method. About 15 μg total proteins was loaded in each well and separated on 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis for 1 h. After running, the proteins were transferred onto the polyvinylidene difluoride membranes (Millipore, United States). The membranes were blocked with 5% fat-free milk, and then were incubated with Tris-buffered-daline Tween20-containing the primary antibodies (1:500 dilution) overnight at 4 ℃. After extensive washing, the second antibody was added, and the immunocomplexes were then detected using an enhanced chemiluminescence Western blotting detection kit (GE, Healthcare). The relative densities of the protein bands were analyzed using the Quantity One software from Bio-Rad. Data were represented in relative arbitrary units.

Statistical analysis

All the data analyses were carried out using the statistical analysis software SPSS 13.0 for Windows (SPSS Inc., Chicago, IL, United States). Data were presented as the mean ± SD. Significant differences between the groups were analyzed by analysis of variance, and differences were considered significant at $P < 0.05$.

RESULTS

Fluid volume and blood gas parameters

Compared with Group A, the pH, MAP, heart rate and oxygen partial pressure of Group B were significantly decreased; however, a significant increase in lactate value was observed ($P < 0.05$). The pH, MAP, heart rate and oxygen partial pressure were increased obviously, and the lactate value was clearly decreased in Group C as compared with Group B. Furthermore, a significant increase in pH value and oxygen partial pressure and decrease in lactate value were also observed in Group D compared with Group C ($P < 0.05$). There was no significant difference in MAP and heart rate between Group D and Group C. Total fluid volume and the amount of norepinephrine used in Group D were significantly less than in Group C ($P < 0.05$). There was no significant difference in partial pressure of carbon dioxide among the four groups ($P > 0.05$; Table 1).

OH, MDA, MPO and SOD levels and lung W/D values

In Group B, the levels of OH, MDA, and MPO were significantly increased, and the level of SOD was significantly decreased compared with Group A ($P < 0.05$). Compared with Group B, lower levels of OH, MDA and MPO, and a higher level of SOD in Group C were also observed, but there was no significant difference between the two groups ($P > 0.05$). However, compared with Group C, there were also significant decreases in the levels of OH, MDA and MPO, and a significant increase in the SOD level in Group D ($P < 0.05$). The lung W/D value in Group B was significantly increased compared with group A ($P > 0.05$), and a higher lung W/D value was observed in Group C compared with Group B, but there was no significant difference between the two groups ($P > 0.05$). However, there was a significant decrease in the lung W/D value in Group D compared with Group C ($P < 0.05$; Table 2).

HE staining of lung tissues

HE-stained lung tissue sections were observed under

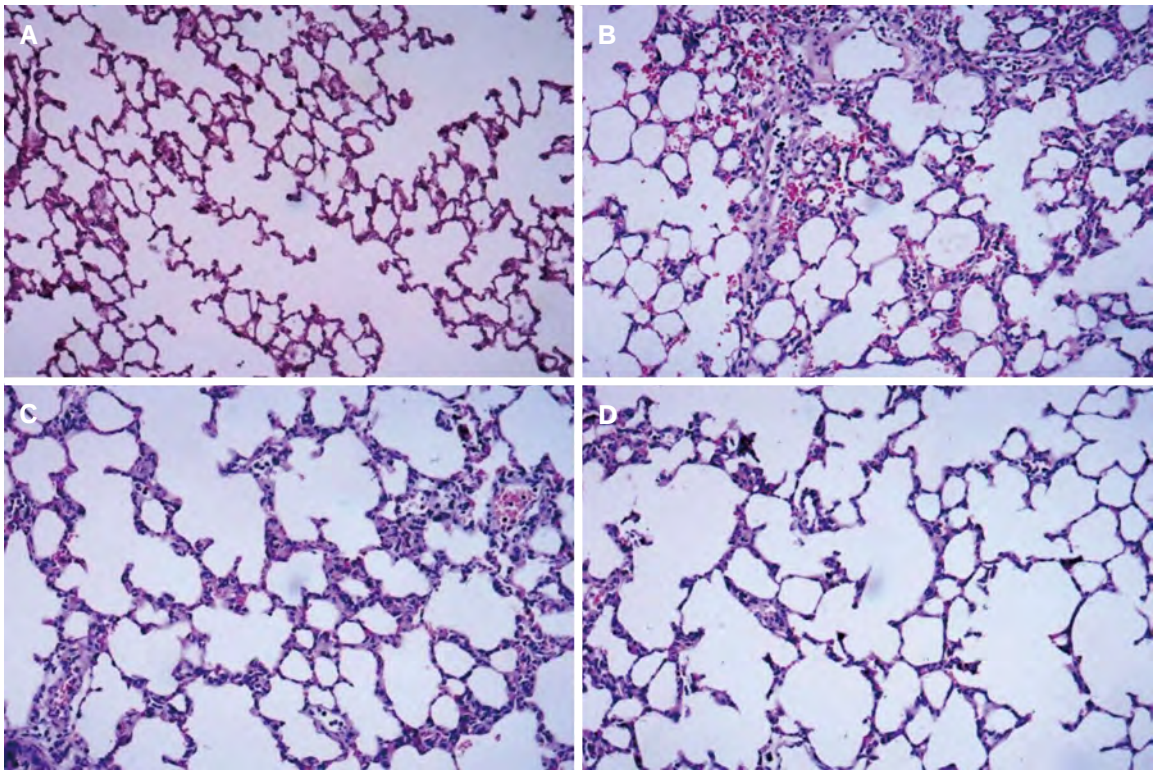

Figure 1 Hematoxylin and eosin staining of dorsal lobe of right lung tissue. A: Control group; B: Septic shock group; C: The early fluid resuscitation-treated group; D: Combined early fluid resuscitation and 2% hydrogen inhalation-treated group. Lung tissues were fixed with 4% paraformaldehyde for more than 24 h. After dehydrating and embedding, they were cut into 5 μm slices, and were stained with hematoxylin and eosin. The pathogenesis of lung injury was observed under a microscope (original magnification × 200). Normal alveolar structure was found in Group A. In Group B, disorders of the alveolar structures, severe neutrophil infiltration in the alveoli and alveolar capillary congestion were observed. In Group C, the extent of neutrophil accumulation and the alveolar-capillary exudate were reduced compared with Group B. However, significant decreases in alveolar damage were found in Group D, and there was significant improvement in alveolar edema compared with Group C.

Table 3 Level of inflammatory mediators in the bronchial alveolar lavage fluid of four groups (mean ± SD)

Group	IL-6 (pg/mL)	IL-8 (pg/mL)	TNF-α (pg/mL)
A	35.88 ± 3.12	24.29 ± 4.23	19.65 ± 1.78
B	446.89 ± 37.24[a]	411.19 ± 32.78[a]	158.54 ± 16.89[a]
C	387.79 ± 31.58[c]	347.34 ± 29.37[c]	104.09 ± 9.18[c]
D	118.32 ± 11.38[e]	96.45 ± 10.25[e]	47.58 ± 3.65[e]

[a]$P < 0.05$ *vs* Group A; [c]$P < 0.05$ *vs* Group B; [e]$P < 0.05$ *vs* Group C. TNF-α: Tumor necrosis factor-α; IL: Interleukin.

a light microscope. The normal alveolar structure was found in Group A, and no hyperemia, neutrophil infiltration, and interstitial edema in the interstitium were observed (Figure 1A). In Group B, disorders of the alveolar structures, the collapse of alveoli, loss of integrity of the alveolar wall, severe neutrophil infiltration in the alveoli, and alveolar capillary congestion were observed, and the alveolar walls were thickened by edema (Figure 1B). In Group C, the extent of neutrophil accumulation and the alveolar-capillary exudate were reduced compared with Group B, but there was no significant improvement in alveolar edema (Figure 1C). Compared with Group B, significant decreases in alveolar damage were found in Group D (Figure 1D), and there was significant improvement in alveolar edema compared with Group C.

Cytokine profiles in lung tissues

Compared with Group A, significant increases in levels of IL-6, IL-8 and TNF-α were found in Group B ($P < 0.05$). The expression of IL-6, IL-8 and TNF-α was significantly decreased in Group C as compared with Group B. In addition, the expression of IL-6, IL-8 and TNF-α was even lower in Group D than in Group C, and the difference was significant (Table 3).

Expression of Fas and Bcl2-immunoreactivity in lung tissues

The positive expression of Fas and Bcl2 protein in lung tissue was demonstrated by the presence of brown-yellow granules, mostly located in the nucleolus cytoplasm (Figure 2). Most bronchial epithelial cells, alveolar epithelial cells and inflammatory cells were Fas-positive and Bcl-positive cells, and Fas and Bcl2 were expressed at low levels in normal lung tissue (Figure 2A and E). The expression of Fas proteins was up-regulated, while the expression of Bcl2 proteins was down-regulated in Group B (Figure 2B and F) compared with Group A. In Group C, however, the expression of Fas proteins was down-regulated, and the expression of Bcl2 proteins was up-regulated (Figure 2C and G) compared with Group B ($P < 0.05$). In addition, the lower expression of Fas proteins and the higher expression of Bcl2 proteins were

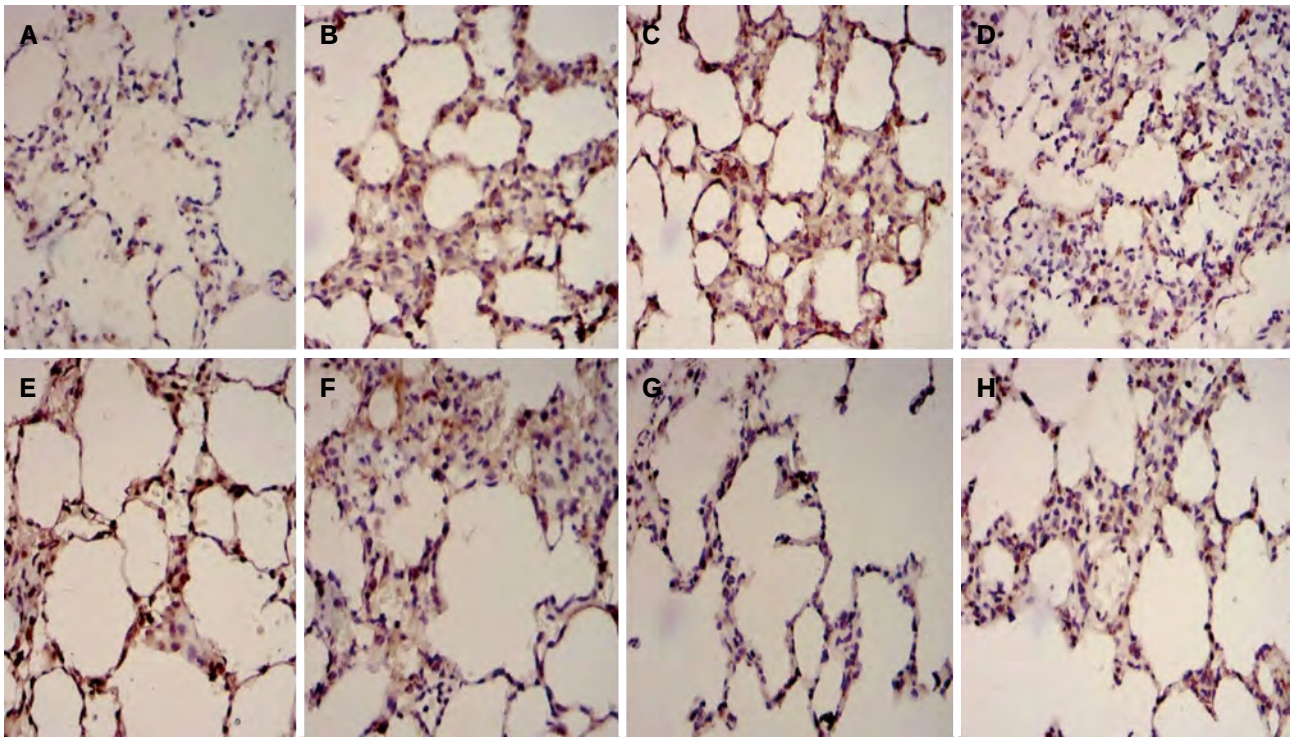

Figure 2 Immunohistochemical examples for Fas and Bcl2 in dorsal lobe of right lung tissue. A: Fas in control group; B: Fas in septic shock group; C: Fas in early fluid resuscitation-treated group; D: Fas in early fluid resuscitation + 2% hydrogen inhalation-treated group; E: Bcl2 in control group; F: Bcl2 in septic shock group; G: Bcl2 in early fluid resuscitation-treated group; H: Bcl2 in early fluid resuscitation + 2% hydrogen inhalation-treated group. Examples were examined under a light microscope equipped with an image analysis system. Yellow or brownish-yellow staining represents positive staining. The expression of Fas proteins was up-regulated, while the expression of Bcl2 proteins was down-regulated in Group B compared with Group A. In Group C, however, the expression of Fas proteins was down-regulated, and the expression of Bcl2 proteins was up-regulated compared with Group B. In addition, the lower expression of Fas proteins and the higher expression of Bcl2 proteins were observed in Group D compared with Group C.

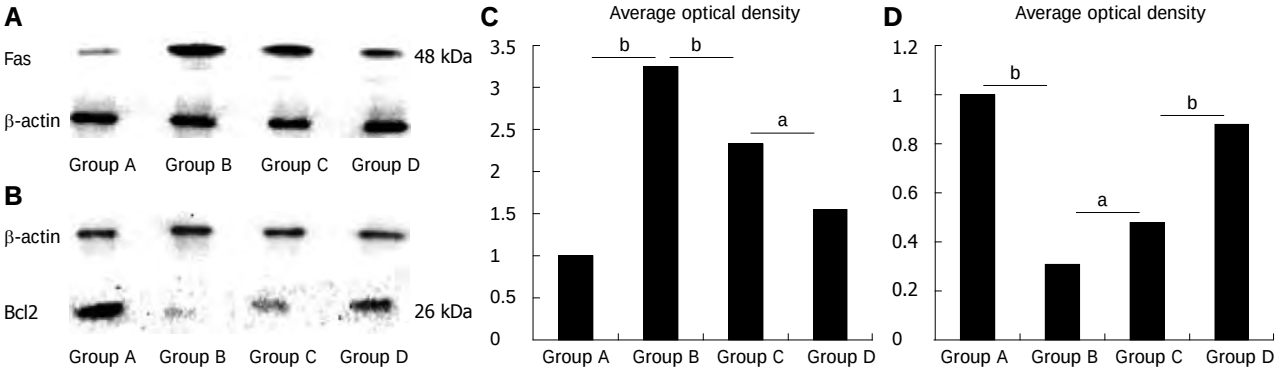

Figure 3 Levels of Fas and Bcl2 proteins in dorsal lobe of right lung tissues quantified by Western blotting. β-actin was used as a loading control. The relative Fas (A) and Bcl2 (B) protein levels of lung tissues from the four groups were expressed as arbitrary units after normalization with β-actin (C: Fas; D: Bcl2). Data were considered significant at $^{a}P < 0.05$ and highly significant at $^{b}P < 0.01$ *vs* the control group. The level of Fas protein was up-regulated, while the level of Bcl2 protein was down-regulated in Group B *vs* Group A. However, in Group C the level of Fas proteins was down-regulated, and the level of Bcl2 proteins was up-regulated *vs* Group B ($P < 0.01$). In addition, the lower level of Fas protein and the higher level of Bcl2 protein was found in Group D compared with Group C ($P < 0.05$).

observed in Group D (Figure 2D and H) compared with Group C ($P < 0.05$; Table 4).

Levels of Fas and Bcl2 protein in lung tissues

The level of Fas protein was up-regulated, while the level of Bcl2 protein was down-regulated in Group B compared with Group A ($P < 0.01$). However, in Group C, level of Fas protein was down-regulated, and the level of Bcl2 protein was up-regulated compared with Group B ($P < 0.01$; Figure 3). In addition, a lower level of Fas protein and a higher level of Bcl2 protein were found in Group D compared with Group C ($P < 0.05$; Figure 3).

Levels of DAO in intestinal tissues

The level of DAO in Group B was significantly increased compared with Group A ($P < 0.05$), and the level of DAO was even higher in Group C ($P < 0.05$). But the level of DAO in Group D was significantly decreased

Table 4 Comparison of average optical density and the positive area ratio of Fas and Bcl2 among the four groups (n = 15, mean ± SD)

Group	Average optical density (10^{-3})		Positive area ratio (%)	
	Fas	Bcl2	Fas	Bcl2

compared with both Group B and Group C (P < 0.05; Table 5).

HE staining of small intestinal tissues

In Group A, the structure of the small intestinal mucosa was intact, and normal intestinal mucosa was observed (Figure 4A). In Group B, glands of the small intestine were significantly damaged, and severe edema of mucosal villi, neutrophil infiltration, epithelial cell sloughing off, and structural changes in the epithelium of the small intestine and even small bowel ulceration were observed (Figure 4B). The damage mentioned above was far more severe in Group C (Figure 4C). But in Group D, the damage was significantly reduced (Figure 4D). The Chiu's score of Group B was significantly higher than Group A (P < 0.05), and the Chiu's score of Group C was even higher compared with Group B. But the Chiu's score of Group D was significantly decreased compared with Group B and Group C (Table 6).

Transmission electron microscopic analysis of small intestinal samples

In Group A, normal microvilli on the surface of epithelial cells of the intestine were observed. The mitochondria, lysosome and rough endoplasmic reticulum maintained normal morphology (Figure 5A). In Group B, disarrangement of the epithelial surface and intestinal microvillus reduction were observed. Mitochondria present in the cytoplasm also showed vacuolization, and the cristae of mitochondria were reduced. Heterochromatin nuclei showed margination phenomena, membrane rupture, and widened nuclear gap (Figure 5B). The microvilli on the surface of epithelial cells of the intestine were sparse in Group C; there was obvious reduction of the cristae of mitochondria, severe vacuolization of mitochondria and an abundance of marginated heterochromatin nuclei. The amount of rough endoplasmic reticulum was reduced, and more severe rough endoplasmic reticulum swelling and expansion were observed (Figure 5C). In Group D, the microvilli were missing to a small extent, and the heterochromatin nuclei showed only mild margination (Figure 5D).

Levels of MDA and SOD in small intestinal tissues

The levels of MDA and SOD in Group B were significantly increased compared with Group A (P < 0.05). Levels of MDA and SOD were higher in Group C than in Group B. In Group D, MDA and SOD were significantly decreased compared with both Group B and Group C (Table 6).

Cytokine profiles in small intestinal tissues

Levels of IL-6, IL-8 and TNF-α were significantly increased in Group B compared with Group A (P < 0.05). The expression of IL-6, IL-8 and TNF-α was significantly lower in Group C than in group B. In addition, the expression of IL-6, IL-8 and TNF-α in Group D was even lower compared with Group C, and the difference was significant (P < 0.05; Table 5).

DISCUSSION

In the present study, we investigated the effects of combined early fluid resuscitation and 2% hydrogen on the lung and small intestine in a LPS-induced septic shock rat model. Our study showed that early fluid resuscitation and inhalation of 2% hydrogen could decrease the oxidative damage and inhibit the over-expression of inflammatory factors (IL-6, IL-8 and TNF-α) in the lung tissue of the septic shock rats. This treatment could also down-regulate the expression of proapoptotic protein Fas, and up-regulate the expression of anti-apoptotic protein Bcl2 in the lung tissue. These data suggest that the application of combined early fluid resuscitation and inhalation of 2% hydrogen may protect the lung from septic shock damage by inhibiting the inflammatory reaction and apoptosis in comparison with traditional fluid resuscitation alone. Early fluid resuscitation and inhalation of 2% hydrogen not only decreased the oxidative damage and

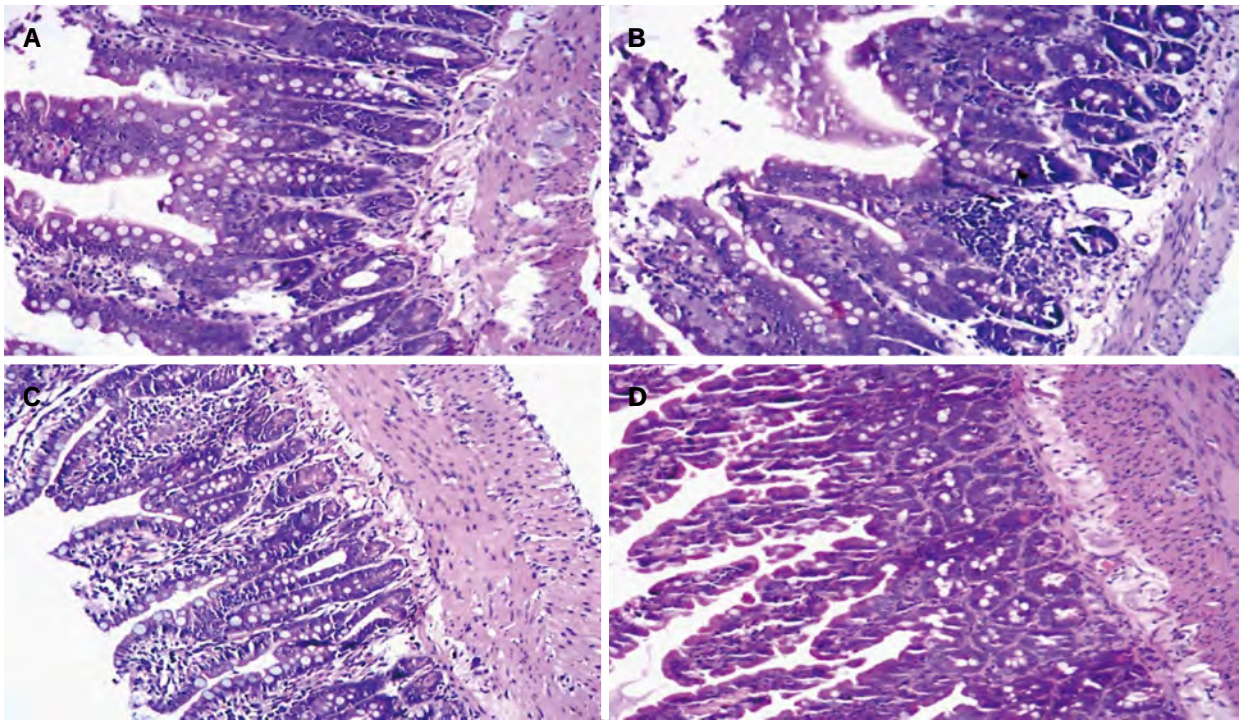

Figure 4 Hematoxylin and eosin staining of small intestine tissue. A: Control group; B: Septic shock group; C: Early fluid resuscitation-treated group; D: Early fluid resuscitation + 2% hydrogen inhalation-treated group. Small intestinal tissues were fixed with 4% paraformaldehyde for more than 24 h. After dehydrating and embedding, they were cut into 5 μm slices, and were stained with hematoxylin and eosin. The pathogenesis of small intestine injury was observed under a light microscope (original magnification × 200). In Group A, normal intestinal mucosa was observed. In Group B, glands of small intestine were significantly damaged, and severe edema of mucosal villi, neutrophil infiltration, epithelial cell sloughing off, and even small bowel ulceration were observed. The damage mentioned above was far more severe in Group C. But in Group D, the damage was significantly reduced.

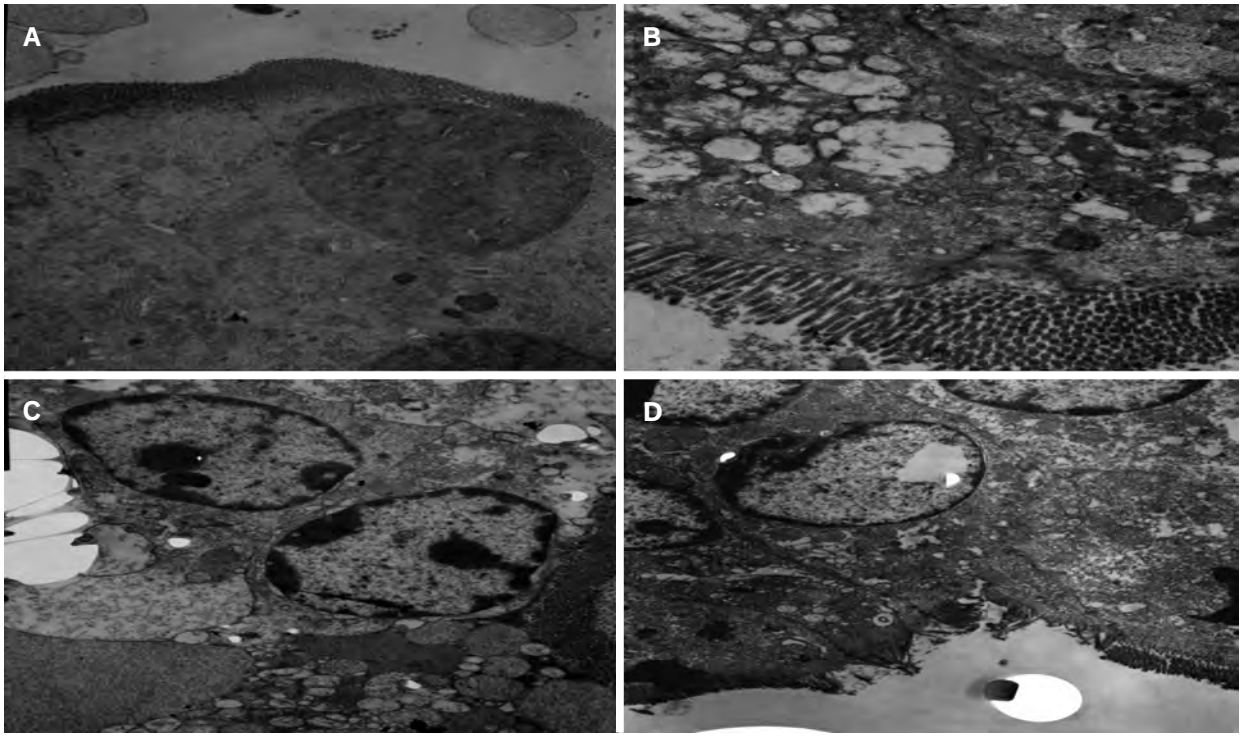

Figure 5 Changes in the organelles of small intestinal tissues under transmission electron microscope. A: Control group; B: Septic shock group; C: Early fluid resuscitation-treated group; D: Early fluid resuscitation + 2% hydrogen inhalation-treated group. The changes in the organelles were observed under transmission electron microscope. In Group A, normal microvilli on the surface of epithelial cells of the intestine were observed. In Group B, intestinal microvillus reduction was observed. Mitochondria showed vacuolization and heterochromatin nuclei showed margination phenomena. The microvilli on the surface of epithelial cells of the intestine were sparse in Group C, and reduction of the cristae of mitochondria, an abundance of marginated heterochromatin nuclei, and severe rough endoplasmic reticulum swelling and expansion were observed. In Group D, the microvilli were missing to a small extent, and the heterochromatin nuclei showed only mild margination.

the levels of IL-6, IL-8 and TNF-α in plasma, but also protected the intestinal mucosa from mechanical injury.

Effects of combined early fluid resuscitation and hydrogen inhalation on lung injury in a LPS-induced septic shock rat model

Previous studies have indicated that MPO is a peroxidase enzyme released by activated polymorphonuclear neutrophils, which can be used as an indicator of the level of tissue neutrophils. MDA is one of the toxic metabolites of ROS induced lipid peroxidation, and SOD is one of the most important free radical scavenging enzymes. Levels of MDA and SOD can reflect the extent of oxidative stress. In the present study, the levels of MDA, SOD and MPO were used as an indicator for oxidative stress[13-15]. The results showed that the levels of MDA and MPO were significantly increased, however, the level of SOD was significantly decreased in the septic shock rats, and severe neutrophil infiltrates were observed in the alveoli. These data suggest that changes in the lung oxidant-antioxidant status may be associated with lung injury in septic shock rats. There was no obvious improvement in oxidative stress in the traditional fluid resuscitation-treated group compared with the septic shock group, but there was significant improvement in the indicators above in the early fluid resuscitation and inhalation of 2% hydrogen treatment group. Early fluid resuscitation and inhalation of 2% hydrogen attenuated septic shock-induced organ injury, and decreased neutrophil infiltrate in the alveoli. Significant improvements in alveolar edema and reduced alveolar damage were also observed. Previous studies have indicated that hydrogen, as a selective antioxidant with a therapeutic antioxidant activity, can easily pass through the cell membrane and reach the organelles[16,17]. Hydrogen can effectively protect against organ damage induced by selectively clearing •OH. These findings indicate that 2% hydrogen may selectively reduce •OH and provide a beneficial effect on septic shock.

Amplification of inflammatory responses and cell apoptosis also play an important role in the pathogenesis of sepsis-induced acute lung injury (ALI)[18,19]. In the present study, the levels of IL-6, IL-8 and TNF-α in BALF were significantly increased in the LPS-induced ALI rats compared with the control group. Our data showed that the early fluid resuscitation and inhalation of 2% hydrogen treatment reduced the levels of IL-6, IL-8 and TNF-α in BALF in comparison with the traditional fluid resuscitation-treated group, and these results are consistent with the previous study[1]. In the process of sepsis-induced ALI, the expression of Fas protein in the lung epithelial cell was up-regulated, and blocking FAS-mediated apoptosis could reduce the LSP-induced lung injury[20]. As one of the most important anti-apoptotic factors, Bcl-2 plays an important role in regulating the progress of apoptosis, and it is considered as a cytoprotective factor[21]. In the present study, decreases in lung cell apoptosis were observed in the early fluid resuscitation-treated group, and further decreases in lung cell apoptosis were observed in the early fluid resuscitation and inhalation of 2% hydrogen treated group. These results demonstrated that co-treatment could down-regulate the levels of Fas protein and up-regulate the levels of Bcl2 protein, which may inhibit ALI by inducing apoptosis, and may protect lung function.

Effects of combined early fluid resuscitation and inhalation of 2% hydrogen on small intestine in a LPS-induced septic shock rat model

Clinical observations and animal experiments have shown that the gastrointestinal tract is one of the most important target organs during septic shock. In early shock, blood flow in the intestinal wall is significantly decreased because of the redistribution of blood, and intestinal mucosal barrier dysfunction is induced by hypoxia and ischemia. Previous studies show that intestinal mucosal edema and bacterial translocation are closely related to the occurrence of MODS[22]. In the present study, bowel mucosal structural changes were observed in the septic shock rats, including significant damage of the small intestine, severe edema of mucosal villi, sloughing off of epithelial cells, structural changes in the epithelium of the small intestine and even small bowel ulceration. Serum DAO activity, which was used as a marker of intestinal integrity, was significantly increased[23]. All these indicators suggest that the intestinal mucosal mechanical barrier is severely damaged during septic shock. Early fluid resuscitation treatment alone was not effective in reducing pathological changes of the small intestine; on the contrary, pathological changes were more severe, including more severe bowel wall edema, higher Chiu's score, and higher level of serum DAO activity in the early fluid resuscitation-treated group compared with the septic shock group. But 2% hydrogen gas treatment significantly reduced the pathological changes of the small intestine, indicating that early fluid resuscitation and inhalation of 2% hydrogen could protect the intestinal mucosal mechanical barrier, inhibit bacterial translocation, and then effectively prevent enterogenous sepsis, and protect the function of other organs in the body[24,25].

Increased endothelial cell ischemia and hypoxia were observed during septic shock. The endothelial cells could release large amounts of cytokine and chemokine, and induce large amounts of neutrophil aggregation. During the removal of harmful pathogens, large amounts of oxygen free radical, which increase the intestinal damage, were released[26]. After fluid resuscitation treatment, large amounts of oxygen free radical were generated in the course of ischemia and reperfusion injury. Thus, oxygen free radicals were considered as one of the major causes of intestinal damage during septic shock. Our data indicate that oxygen free radicals were involved in the severe intestinal mucosal damage, and pathological changes were more severe after fluid resuscitation treatment. Early fluid resuscitation and inhalation of 2% hydrogen could significantly decrease the level of MDA and MPO,

and mitigate the oxidative damage, indicating that 2% hydrogen may selectively reduce •OH, reducing ischemia/reperfusion-induced organ damage.

Intestinal mucosal injury can lead to the release of inflammatory mediators which play an important role in the process of shock-induced intestinal tissue injury[27]. The inflammatory mediators were one of the initiation factors of MODS, and could worsen organ dysfunction[28]. During the shock period, the intestinal tract is the main organ to produce TNF-α[29]. Release of TNF-α increases chemotaxis, aggregation and adhesion to endothelial cells of neutrophils. Then more inflammatory mediators such as IL-6 and IL-8 are also released, leading to aggravated intestinal mucosal injury[30]. In the present study, the levels of TNF-α, IL-6 and IL-8 in serum were significantly increased in septic shock rats, but the levels of TNF-α, IL-6 and IL-8 in serum were decreased after early fluid resuscitation treatment, while early fluid resuscitation and inhalation of 2% hydrogen gas further decreased the levels of TNF-α, IL-6 and IL-8 in serum compared with early fluid resuscitation only. These data demonstrated that the association of early fluid resuscitation and inhalation of 2% hydrogen gas may protect small intestine function by reducing inflammatory mediators.

In summary, combined early fluid resuscitation and inhalation of 2% hydrogen is beneficial for septic shock and septic shock-associated lung or small intestine injury, which is associated with a decrease of oxidative stress and inhibition of the inflammatory response. We conclude that combined early fluid resuscitation and inhalation of 2% hydrogen may be an effective therapeutic strategy for ALI and MODS in patients with septic shock.

COMMENTS

Background

Sepsis shock is a common complication of infection, severe trauma, and major operation in patients. However, the effective therapy method needs to be developed.

Research frontiers

Early fluid resuscitation has been demonstrated to have some protective effects on the sepsis shock -induced acute lung injury, but the effective is not significant. Recent studies indicate that hydrogen inhalation can significantly decrease the oxidative stress in septic animal model. The objective of this study is to explore the effects of combined early fluid resuscitation and hydrogen inhalation on septic shock induced lung and intestine injuries.

Innovations and breakthroughs

This is the first study to report that combined early fluid resuscitation and hydrogen inhalation exerts a potency to effectively attenuate lung and intestine injuries.

Applications

The paper provides the experiment basis for the clinical application of early fluid resuscitation and hydrogen inhalation to prevent sepsis induced lung and intestine injury.

Terminology

Sepsis shock is a common complication of infection, severe trauma, and major operation in patients. Sepsis shock leads to severe, hypoxia, and reperfusion injury of lung and intestine ischemia. The inflammatory factors in these tissues will be activated and may consequently develop the multiple organ dysfunction syndrome, which is associated with high morbidity and mortality rates. Early fluid resuscitation and hydrogen have the potential to clear these inflammatory factors.

Peer review

This study shows that combined early fluid resuscitation and hydrogen inhalation can significantly decrease septic shock induced lung and intestine injuries compared with early fluid resuscitation alone. The study is innovative and with potential therapeutic interest.

Abstract

AIM: To develop and validate a case definition of eosinophilic esophagitis (EoE) in the linked Danish health registries.

METHODS: For case definition development, we queried the Danish medical registries from 2006-2007 to identify candidate cases of EoE in Northern Denmark. All International Classification of Diseases-10 (ICD-10) and prescription codes were obtained, and archived pathology slides were obtained and re-reviewed to determine case status. We used an iterative process to select inclusion/exclusion codes, refine the case definition, and optimize sensitivity and specificity. We then re-queried the registries from 2008-2009 to yield a validation set. The case definition algorithm was applied, and sensitivity and specificity were calculated.

RESULTS: Of the 51 and 49 candidate cases identified in both the development and validation sets, 21 and 24 had EoE, respectively. Characteristics of EoE cases in the development set [mean age 35 years; 76% male; 86% dysphagia; 103 eosinophils per high-power field (eos/hpf)] were similar to those in the validation set (mean age 42 years; 83% male; 67% dysphagia; 77 eos/hpf). Re-review of archived slides confirmed that the pathology coding for esophageal eosinophilia was correct in greater than 90% of cases. Two registry-based case algorithms based on pathology, ICD-10, and pharmacy codes were successfully generated in the development set, one that was sensitive (90%) and one that was specific (97%). When these algorithms were applied to the validation set, they remained sensitive (88%) and specific (96%).

CONCLUSION: Two registry-based definitions, one highly sensitive and one highly specific, were developed and validated for the linked Danish national health databases, making future population-based studies feasible.

INTRODUCTION

Eosinophilic esophagitis (EoE) is a chronic immune-mediated disorder characterized by symptoms of esophageal dysfunction and infiltration of the esophageal mucosa by eosinophils[1]. While the first case was described in 1978[2], a set of case series in the early 1990s highlighted what are now viewed as the classic clinicopathologic features of EoE[3-5]. Since that time, there has been a remarkable increase in the incidence and prevalence of EoE[6-14], EoE has been detected in up to 16% of patients undergoing upper endoscopy for dysphagia[15-17], and EoE is now the leading cause of food impaction in patients presenting to emergency departments[18-20]. Most data regarding the evolving epidemiology of EoE originate from tertiary centers[7-13], and there have been few population-based studies of EoE across centers or at a national level.

The national population-based medical registries of Denmark, which link medical records, diagnostic codes, pathology findings, and prescription medications *via* an individual identifier assigned to every person in the country[21-24], offer a unique opportunity to systematically study the epidemiology of EoE. However, no validated registry-based case definitions of EoE exist, and this limitation hampers any attempt to accurately study EoE in Denmark and other countries where national health databases are maintained.

The aims of this study were to characterize candidate and definite EoE cases in Northern Denmark detected through a search of the health registries, and to develop and validate a registry-based case definition of EoE in the linked Danish clinical, pathology, and pharmacy databases that could be used for future epidemiologic study.

MATERIALS AND METHODS

Denmark health registries

This retrospective study of the Danish medical registries was approved by both the University of North Carolina IRB and the Danish Data Protection Agency (record number 2010-41-4986). Denmark, with its stable population of approximately 5.5 million people, is well-suited for epidemiological studies[21-24]. The establishment of the Civil Registration System in 1968 allows information about the same person to be linked across independent registries by using the Civilian Registration Number, a unique identifier assigned to every person in the country[23].

Three of the comprehensive national medical registries in Denmark were utilized to generate the necessary data for this study. These included: the Danish National Registry of Patients, which houses International Classification of Diseases-10 (ICD-10) codes dating from 1994, hospital admission and discharge codes, surgical procedure codes, and outpatient visit codes[25]; the National Pathology Registry, which contains Systematized Nomenclature of Medicine (SNOMED) codes for pathologic specimens dating from 1997[24]; and the Aarhus University Prescription Database, which has outpatient prescription data for Northern Denmark using Anatomical Therapeutic Chemical (ATC) classification system codes[26].

For the purposes of this study we limited our analysis to Northern Denmark. This geographic area contains 1.8 million inhabitants, approximately 1/3 of the Danish population, and allowed ready access to the required pathology specimens for case verification, as described below.

Case definition development

This study utilized two independent sets of patients, one set in which to develop the case definition and one set in which to validate it.

For case definition development, we queried the National Pathology Registry from 2006-2007 in Northern Denmark to identify candidate cases of EoE. These were patients with esophageal eosinophilia as defined by the combination of SNOMED codes for esophageal biopsies (T62xxx) and tissue eosinophilia (M47150). These codes were assigned by the clinical pathologist at the time of specimen examination and interpretation. Next, all ICD-10 diagnostic and ATC prescription codes for these patients were obtained from the National Registry of Patients and the Aarhus University Prescription Database, respectively. Finally, the original archived pathology slides were obtained and, using a previously validated protocol[27], were re-reviewed by the study pathologist (Vyberg M) to determine the maximum eosinophil count [eosinophils per high-power field (eos/hpf); hpf = 0.24 mm^2].

From this pool of subjects with esophageal eosinophilia, we identified the subset of patients with a confirmed diagnosis of EoE as per consensus diagnostic guidelines[1,28]. Specifically, these patients had symptoms of esophageal dysfunction, a maximum eosinophil count $\geqslant$ 15 eos/hpf on pathology re-review, and no other competing causes of esophageal eosinophilia identified. While the current consensus guidelines allow reflux and EoE to overlap[1], we attempted to minimize this overlap by ensuring that there was not a mixed inflammatory infiltrate on the re-reviewed esophageal biopsies and by assessing use of anti-acid mediations in the months preceding the diagnostic endoscopy (see below). These subjects with confirmed EoE comprised the reference standard for the case definition development set.

We used an iterative process to develop a case definition of EoE based on previously described methodology for gastrointestinal disorders used in the Danish and other administrative databases[29-31]. First, we empirically selected a combination of SNOMED, ICD-10 and ATC codes that were potentially pertinent to the diagnosis of EoE and could exclude disorders on the differential diagnosis for esophageal eosinophilia as well as patients with non-EoE conditions with similar symptom profiles. Next, the National Pathology Registry, National Registry of Pa-

tients, and Aarhus University Prescription Database were queried using this combination of codes to provide a set of possible EoE patients. Then, using the confirmed EoE cases previously identified as the reference standard, the sensitivity and specificity of this initial search strategy were determined within the population of patients with esophageal eosinophilia. Sensitivity was calculated by dividing the number of true positive EoE cases identified using the case definition by the total number of reference standard EoE cases. Specificity was calculated by dividing the number of true negative subjects identified using the case definition by the total number of subjects without EoE. By examining the coding and patient characteristics of those classified as false positive and false negative, the administration case definition was further refined, the databases were re-queried with the updated definition, and new operating characteristics were calculated. This process continued until sensitivity and specificity were optimized.

Case definition validation

Using the same methodology as described for case definition development, the case definition was validated in an independent population in Northern Denmark from 2008-2009. In brief, candidate cases of EoE were identified based on SNOMED codes, and a reference standard set of patients with confirmed EoE in the new time frame was created after re-review of original pathology slides and all coding data. The administrative case definition algorithm was then applied to the National Pathology Registry, National Registry of Patients, and Aarhus University Prescription Database, the set of possible EoE cases was generated, and sensitivity and specificity were calculated using the confirmed EoE cases as the reference standard.

RESULTS

Characteristics of the development set

There were 51 patients with esophageal eosinophilia identified in Northern Denmark from 2006-2007, and 21 (41%) had a confirmed diagnosis of EoE (Table 1). This group comprised the reference standard for the development set. Patients with esophageal eosinophilia had a mean age of 42 years, 75% were male, and almost half had dysphagia. While the EoE patients had a similar proportion of males (76%), they were somewhat younger (35 years), and 86% had dysphagia. The maximum eosinophil count was 71 eos/hpf in all patients with esophageal eosinophilia, and 103 eos/hpf in patients with confirmed EoE. The pathology re-review of slides confirmed that the SNOMED coding for esophageal eosinophilia was correct in the vast majority of cases, with 90% meeting criteria for histologic EoE (≥ 15 eos/hpf) (Figure 1).

Characteristics of the validation set

There were 49 patients with esophageal eosinophilia identified in Northern Denmark from 2008-2009, and 24 (49%) had a confirmed diagnosis of EoE (Table 1). This group comprised the reference standard for the validation set. Patients with esophageal eosinophilia had a mean age of 48 years, 73% were male, and 39% had dysphagia. While the EoE patients had a similar proportion of males (83%), they were also somewhat younger (42 years) and 67% had dysphagia. The maximum eosinophil count was 68 eos/hpf in all patients with esophageal eosinophilia, and 77 eos/hpf in patients with confirmed EoE. Overall, the clinical characteristics of the EoE cases in the development and validation sets were similar, and pathology re-review in the validation set also confirmed correct SNOMED coding in 90% of cases (Figure 1).

EoE case definition algorithms and operating characteristics

The iterative methodology for case definition development and validation yielded two registry-based case diagnostic algorithms, one that was highly sensitive and one that was highly specific. The highly sensitive case definition maximized the number of cases of EoE that were identified in the database search, while the highly specific definition accepted a lower sensitivity (i.e., not identifying all EoE cases) in exchange for ensuring that all cases were true EoE cases (i.e., minimizing false positives).

The final case definition algorithms are presented in Table 2. The "sensitive" algorithm has three steps. The

Table 2 Case definition algorithm

For both the sensitive and the specific case definitions:
(1) Include all patients with systematized nomenclature of medicine M47150 (finding of tissue eosinophil) and T62xxx (esophageal biopsy)
(2) Exclude patients if they have one of the following International Classification of Diseases-10 codes occurring at any time:
B20.x - human immunodeficiency virus
C15.x - malignant neoplasm of esophagus
C16.0 - malignant neoplasm of cardia
C92.x - myeloid leukemia
C94.x - other leukemias of specialized cell type
C96.x - other and unspecified lymph/heme malignancies
K22.0 - achalasia
K50.x - Crohn's disease
K52.8 - eosinophilic gastritis/duodenitis
T28.1 - burn of esophagus
T28.6 - corrosion of esophagus
(3) Include patients if one of the following International Classification of Diseases-10 codes is present at or before the date of the procedure:
K22.2 - esophageal obstruction
K30.9 - dyspepsia
P92.x - feeding problems of the newborn
R07.x - pain in throat and chest
R10.x - abdominal pain
R11.x - nausea/vomiting
R12.x - heartburn
R13.x - dysphagia
T18.0 - foreign body in mouth
T18.1 - foreign body in esophagus
T18.2 - foreign body in stomach
T18.9 - foreign body in genitourinary tract unspecified
T98.0 - sequelae of foreign body entering through a natural orifice
Additional requirement for the specific case definition:
(4) Include patients if there is a proton-pump inhibitor prescription (A02BCxx) or H2RA prescription (A02BAxx) within 2 mo of esophageal biopsy date, up to and including 2 d prior to the esophagogastroduodenoscopy

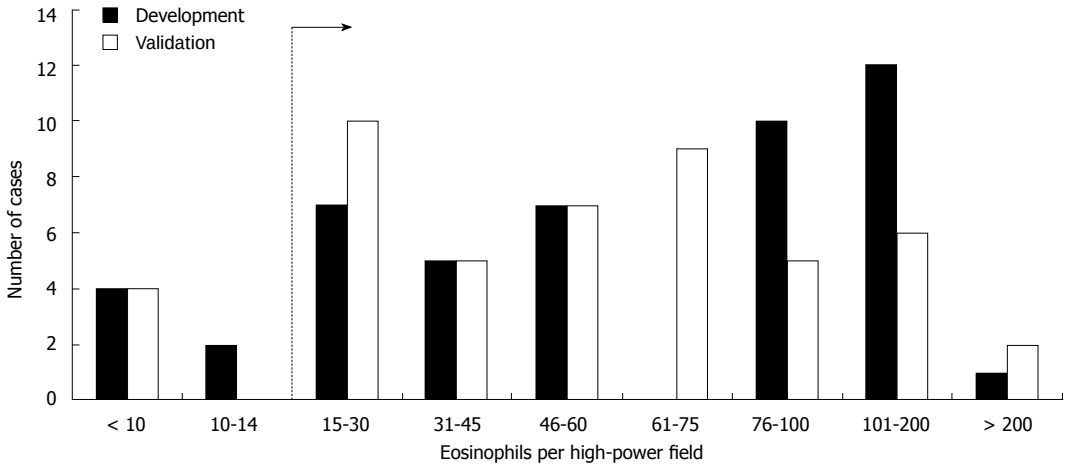

Figure 1 Distribution of levels of esophageal eosinophilia in the development and validation sets of candidate cases of eosinophilic esophagitis identified in the Denmark medical registries. Ranges of esophageal eosinophilia [in eosinophils per high-power field (eos/hpf)] determined after pathology re-review of archived slides are on the x axis. The typical histologic threshold for considering a diagnosis of eosinophilic esophagitis in the appropriate clinical context of 15 eos/hpf is indicated with a dotted line.

first uses SNOMED codes to include all patients with esophageal eosinophilia. The second excludes patients if they have any one of eleven ICD-10 codes that could cause non-EoE related esophageal eosinophilia or esophageal injury that could mimic EoE clinically. The third requires patients to have at least one of 13 ICD-10 codes for symptoms of esophageal dysfunction. The "specific" algorithm has an additional step to exclude false positives which requires a documented proton-pump inhibitor (PPI) or histamine-2 receptor antagonist prescription within 2 mo of the esophageal biopsy date.

When these algorithms were applied to the development set, the clinical characteristics of the cases identified for both the sensitive definition (n = 31; mean age 40 years; 71% male; 90% dysphagia; 84 eos/hpf) and the specific definition (n = 8; mean age 38 years; 78% male; 89% dysphagia; 93 eos/hpf) were similar to those for the reference standard EoE cases (Table 1).

Table 3 Sensitivity and specificity of the case definitions[1] *n* (%)

	Development set		Validation set	
	Sensitive definition	Specific definition	Sensitive definition	Specific definition
Sensitivity	90 (90)	38 (38)	88 (88)	21 (21)
Specificity	60 (60)	97 (97)	80 (80)	96 (96)

[1]Sensitivity: Number of true positive eosinophilic esophagitis (EoE) cases identified by the case definition divided by the total number of reference standard EoE cases; Specificity: Number of true negative subjects identified by the case definition divided by the total number of subjects without EoE.

When these algorithms were applied to the validation set, the clinical features for the sensitive definition (n = 26; mean age 49 years; 81% male; 69% dysphagia; 60 eos/hpf) and specific definition (n = 6; mean age 49 years; 67% male; 50% dysphagia; 43 eos/hpf) were also similar to those for the reference standard for EoE cases (Table 1).

In the development set, the "sensitive" algorithm had a sensitivity and specificity of 90% and 60%, and the "specific" algorithm had values of 38% and 97%, respectively (Table 3). When these algorithms were applied to the validation set, the operating characteristics were essentially unchanged, with a sensitivity and specificity of 88% and 80%, for the "sensitive" algorithm, and 21% and 96% for the "specific" algorithms.

DISCUSSION

The epidemiology of EoE has been rapidly evolving over the past two decades, with a marked increase in incidence and prevalence. The study of EoE in large national or administrative databases, however, has been hampered by the lack of a validated case definition of EoE and the difficulty of developing such a definition due to the clinicopathologic nature of the disorder. This study takes advantage of the fact that the health registries in Denmark can link pathologic data to diagnostic and prescription coding data, thus providing all of the needed components to identify cases of EoE.

There are two main results for this study. The first is that the confirmed EoE cases identified in Denmark *via* the health registries had similar features to those reported both in Denmark as well as elsewhere in the world[1,7-17,32-35]. The second is that two registry-based case definitions, one highly sensitive and one highly specific, were successfully developed and validated for use in the Danish national health databases. This is the first study to do so, and this result makes future large-scale population-based studies feasible in that country. This is important because the majority of investigations studying the epidemiology of EoE are either from selected counties within a country or region, from single centers but are not population-based, or from larger databases that have limitations.

For example, in the two counties studied in northern Sweden during the Kalixanda study, Ronkainen *et al*[36] found that 11 of 1000 (1.1%) subjects had prevalent esophageal eosinophilia ⩾ 15 eos/hpf. While this is the only published study with a true population-based sampling strategy, these individuals would not necessarily meet current EoE diagnostic guidelines because not all were symptomatic and competing causes of esophageal eosinophilia were not excluded[1,28]. In Olten County, Switzerland, a well-defined geographic region with a stable population and practitioners who are expert in EoE diagnosis, Hruz *et al*[14] have recently updated their estimates of the incidence (7/100 000) and prevalence (43/100 000) of EoE[12]. Prasad *et al*[9] reported similar estimates from Olmstead County, Minnesota (incidence 9/100 000; prevalence 55/100 000) in patients identified retrospectively, and Spergel *et al*[37] derived a similar prevalence estimate (52/100 000) from physician surveys. In all of these studies, however, the included patients and providers were not sampled in population-based frames. Additional retrospective single center studies, while providing important data, are subject to similar limitations[7,8,10,11,13,38,39]. Three prospective studies examining the prevalence of EoE in patients undergoing upper endoscopy for any symptom[17], or for dysphagia provide equally important data[15,16], but are also from single centers and enrolled patients who were actively undergoing evaluation and so cannot necessarily be generalized to an entire population. In a series of studies that utilized a large pathology database in the United States, the national distribution of esophageal eosinophilia and EoE has been confirmed, but the data are also not population based[40-42]. Most recently, abstract data from the national health system in the Netherlands has been presented showing a rapid rise in the incidence of esophageal eosinophilia, but this study did not employ a validated case definition of EoE[43]. The current study attempts to address the challenges encountered in the definition of EoE when using county- or national-level database or registry data, and to set the stage for conducting true population-level EoE research.

There are both limitations and strengths of this study that should be acknowledged. The first issue is whether there could be misclassification of cases of EoE in the reference standard groups. This appears to be unlikely given that histology, symptom coding, and prescription data were used to apply EoE consensus diagnostic guidelines to the study population. Nevertheless, because this is a retrospective analysis, we cannot completely exclude the possibility of overlap between gastroesophageal reflux disease and EoE, and are unable to fully address the issue of PPI-responsive esophageal eosinophilia (PPI-REE). It is interesting to observe, however that only 41% and 49% of subjects with esophageal eosinophilia were confirmed to have EoE in the development and validation sets, respectively, suggesting that half or more of subjects with esophageal eosinophilia do not have EoE. The proportion of subjects with esophageal eosinophilia who did not have EoE in our study is similar to the reported proportion of subjects with esophageal eosinophilia who have PPI-REE, ranging in various studies from approximately 30%-75%[44-48]. The poor specificity

of the presence of esophageal eosinophilia for the diagnosis of EoE, coupled with the high proportion of subjects with esophageal eosinophilia who have PPI-REE, emphasize that esophageal eosinophilia alone is not adequate for case-finding of EoE in pathology databases, and cannot be used in isolation to diagnose EoE[1,28,49,50]. A related point is that while it is a strength of this study to have obtained and re-reviewed the original pathology slides, it is important to acknowledge that the biopsies were originally taken for clinical purposes at the discretion of individual endoscopists, and the location and number of biopsies could vary.

It is a strength of the study that two case definitions, one sensitive and one specific, were developed. In instances where overlap or misclassification may be a concern, the "specific" algorithm could be used to ensure the most homogenous EoE population is generated. The two case definitions also allow for bounding and performing sensitivity analyses around epidemiologic estimates. Moreover, the use of the linked Denmark databases is another strength of this study, as there are relatively few data sources that are as rich and contain patient-level pathology information linked to administrative coding. This is illustrated by our ability to obtain and re-review the original glass pathology slides in order to validate the SNOMED codes for esophageal eosinophilia.

The case definitions developed in this study are derived from the Denmark databases and it is unknown whether these would be valid in other settings. However, the methodology presented here could be readily replicated in different databases to validate EoE case definitions, and our proposed algorithm could be used as a starting point in an iterative process to develop case definitions in other databases.

In conclusion, this study of the linked Danish national health registries successfully identified and confirmed cases of EoE in Denmark. Two administrative registry-based case definitions, one highly sensitive to maximize the number of cases of EoE identified, and one highly specific to minimize the number of false positive EoE cases included, were developed and validated. The operating characteristics of the case algorithms are sufficient to support future population-based studies of the epidemiology of EoE in Denmark, and may serve as a template for developing similar definitions in other databases.

COMMENTS

Background

Population-based data on eosinophilic esophagitis (EoE) are lacking. The national medical registries in Denmark offer a unique opportunity to systematically study EoE because these resources link pathology, clinical, and pharmacological data at the patient level. However, no validated registry-based case definitions of EoE exist, and these must be developed prior to conducting large-scale studies.

Research frontiers

EoE is a newly emerging chronic immune-mediated disorder characterized by symptoms of esophageal dysfunction and infiltration of the esophageal mucosa by eosinophils. The epidemiology of EoE is increasingly understood, but much of the data are from single referral centers, and there are few population-based studies published.

Innovations and breakthroughs

This is the first study to systematically develop and validate an administrative case definition of EoE in the Danish databases. The authors present two registry-based definitions, one highly sensitive and one highly specific for EoE.

Applications

These definitions can now be utilized in future population-based studies of EoE in Denmark.

Peer review

This is a well designed study about development and validation of a registry based case definition of EoE in Northern Denmark. It has to be pointed out that in the re-reviewed slides of pathology represents an advantage in methodology.

Abstract

AIM: To investigate endoscopic ultrasound (EUS) for predicting depth of mucosal invasion and to analyze outcomes following endoscopic and transduodenal resection.

METHODS: Records of 111 patients seen at our institution from November 1999 to July 2011 with the post-operative pathological diagnosis of benign ampullary and duodenal adenomas were reviewed. Records of patients who underwent preoperative EUS for diagnostic purposes were identified. The accuracy of EUS in predicting the absence of muscular invasion was assessed by comparing EUS reports to the final surgical pathological results. In addition, the incidence of the post-operative complications over a period of 30 d and the subsequent long-term outcome (recurrence) over a period of 30 mo associated with endoscopic and transduodenal surgical resection was recorded, compared and analyzed.

RESULTS: Among 111 patients with benign ampullary and duodenal adenomas, 47 underwent preoperative EUS for 29 peri-ampullary lesions and 18 duodenal lesions. In addition, computed tomography was performed in 18 patients, endoscopic retrograde cholangio-pancreatography in 10 patients and esophagogastroduodenoscopy in 22 patients. There were 43 patients with sporadic adenomas and 4 patients with familial adenomatous polyposis (FAP)/other polyposis syndromes. In 38 (81%, $P < 0.05$) patients, EUS reliably identified absence of submucosal and muscularis invasion. In 4 cases, EUS underestimated submucosal invasion that was proven by pathology. In the other 5 patients, EUS predicted muscularis invasion which could not be demonstrated in the resected specimen. EUS predicted tumor muscularis invasion with a specificity of 88% and negative predictive value of 90% ($P < 0.05$). Types of resection performed included endoscopic resection in 22 cases, partial duodenectomy in 9 cases, transduodenal ampullectomy with sphincteroplasty in 10 cases and pancreaticoduodenectomy in 6 cases. The main post-operative final pathological results included villous adenoma ($n = 5$), adenoma ($n = 8$), tubulovillous adenoma ($n = 10$), tubular adenoma ($n = 20$) and hyperplastic polyp ($n = 2$). Among the 47 patients who underwent resection, 8 (17%, 5 of which corresponded to surgical resection) developed post-procedural complications which included retroperitoneal hematoma,

intra-abdominal abscess, wound infection, delayed gastric emptying and prolonged ileus. After median follow-up of 20 mo there were 6 local recurrences (13%, median follow-up = 20 mo) 4 of which were in patients with FAP.

CONCLUSION: EUS accurately predicts the depth of mucosal invasion in suspected benign ampullary and duodenal adenomas. These patients can safely undergo endoscopic or local resection.

INTRODUCTION

Duodenal tumors often pose diagnostic and therapeutic challenges in their management as they arise in close proximity to biliary and pancreatic structures[1]. Villous tumors of the duodenum was first described by Perry in 1893 as a broad-based cauliflower-like mass that he referred to as a duodenal papilloma and in a 1981 review, only 73 cases had been reported by Komorowski *et al*[2]. Although tumors that arise in the duodenum are not typically common (only 1% of gastrointestinal tumors) a significant fraction of them (at least 25%) are adenomas at the time of presentation. Treatment of ampullary adenoma is complicated by difficult preoperative staging, malignant potential and a high recurrence rate[3]. Various techniques are advocated for their management ranging from simple excision to the ampullary tumor and the contiguous duodenal mucosa to wide resection of the mass including the papilla and adjacent duodenal, ductal and pancreatic tissue[4]. Despite their benign nature peri-ampullary and duodenal adenomas remain a therapeutic challenge because of their potential for malignant transformation. Surgical resection of duodenal tumors can be particularly difficult because of their location in the retroperitoneal space in contact with normal pancreatic gland entailing a high risk of postoperative morbidity and mortality[5]. The complex anatomy of the ampullary region and the difficulty of accurately diagnosing and staging *via* imaging and endoscopy makes the management of these tumors controversial and require multidisciplinary teams[6]. While these tumors can typically arise anywhere along the duodenum, they predominately appear in the first or second portion with tumors in the 3rd and 4th portions being less frequent but posing more difficulty in endoscopic detection[1]. Accurate preoperative histological diagnosis and staging of these tumors is therefore often difficult and inconclusive leading to controversy over the ideal management of treating these lesions. Transduodenal local excision (TDE), endoscopic snare excision or pancreatoduodenectomy (PD) are valid options for resection of these tumors[6]. Halstead first reported TDE of an ampullary mass in 1899[7]. In 1935 Whipple was the first to perform *en bloc* removal of the entire duodenum with the head of the pancreas in 1935 a procedure later refined to a one-stage procedure called PD in 1940 by Whipple[8]. Some studies have reported that the incidence of malignancy occurring in duodenal or ampullary tumors vary widely with some reports ranging from 35% to 60% and report that while the region of the ampulla can be accessible for endoscopic biopsy procedure, that there is a high incidence of false negative results for carcinoma, ranging from 25% to 60%[7]. In 1990, a collective series of 78 Japanese patients reported that the biopsy diagnosis of adenoma does not rule out the possibility of deeper carcinoma in ampullary tumors[9]. Another case report in 1992 found EUS as an emerging useful adjuvant to the preoperative evaluation of patients for potential local resection due to its ability to accurately diagnose duodenal adenomas and therefore usefulness in treatment planning[10]. Based on these earlier reported high incidence of malignancy and unreliability of preoperative endoscopic diagnosis, optimal operative management of these tumors remains controversial[7]. We performed a retrospective review of patients with suspected benign duodenal tumors who underwent preoperative EUS to determine the accuracy of this technique in predicting the absence of muscular invasion and also to analyze outcomes associated with endoscopic and transduodenal surgical resection at our institution.

MATERIALS AND METHODS

Patients

Records of 111 patients evaluated and treated at the University of Alabama Birmingham from November 1999 to July 2011 with the post-operative pathological diagnosis of benign ampullary and duodenal adenomas were identified and reviewed retrospectively. There were 43 patients with sporadic adenomas and 4 patients with familial adenomatous polyposis (FAP)/other polyposis syndromes. Patients were 55% women and average age was 63 years old (Table 1.)

Imaging diagnostic modality used

Among 111 patients examined, 47 underwent preoperative EUS for diagnostic purposes (Figure 1). In addition, computed tomography (CT) was performed in 18 patients, endoscopic retrograde cholangiopancreatography in 10 patients and esophagogastroduodenoscopy in 22 patients.

The accuracy of EUS in predicting duodenal adenoma absence of muscular invasion was assessed by com-

Table 1 Summary of clinical data of patients with benign duodenal and peri-ampullary adenomas who underwent endoscopic ultrasound pre-operatively

Age, yr, mean ± SD (range)	63.4 ± 12.63 (25-90)
Sex	45% male; 55% female
Types of resection	Endoscopic (22); pancreaticoduodenectomy (6); transduodenal (10); partial duodenectomy (9)
Tumor location	Periampullary (29); duodenal (18)
Post operative final path	Villous adenoma (5); tubulovillous adenoma (10); tubular adenoma (20); hyperplastic polyp (2); chronic inflammation (1); adenoma (8); Reactive epithelial changes of normal small bowel mucosa (1)
EUS prediction	Absence of muscularis invasion (n = 5, P < 0.05); underestimated submucosal invasion (n = 4, P < 0.05); Accurately predicted depth of tumor invasion (n = 38, P < 0.05)

EUS: Endoscopic ultrasound.

Table 2 2 × 2 Contingency table

	Absence of muscularis involvement path	
	Yes[1]	No
Muscularis involvement EUS		
No	36	4
Yes[1]	5	2

[1]Positive predictive value: 28%; Negative predictive value: 90%; Sensitivity: 33%; Specificity: 87.8% (P < 0.05). EUS: Endoscopic ultrasound.

paring EUS reports and comparing it to final surgical pathological results. In addition, the incidence of post-operative complications over a period of 30 d and subsequent long-term outcome (recurrence) over a period of 30 mo associated with endoscopic and transduodenal surgical resection was recorded, compared and analyzed.

RESULTS

Location of tumors

Twenty-nine patients had peri-ampullary tumors defined by immediate proximity (within 2 cm) to the major duodenal papilla. The remaining 18 patients had adenomas elsewhere in the duodenum as described in Table 1.

Type of resection performed

Resection of the analyzed adenomas was performed endoscopically in 22 cases. Partial duodenectomy was performed in 9 cases, TDE with ampullectomy with sphincteroplasty in 10 cases and pancreaticoduodenectomy in 6 cases.

Final pathologic results

Postoperative final pathology results included villous adenoma (n = 5), adenoma (n = 8), tubulovillous adenoma (n = 10), tubular adenoma (n = 20) and hyperplastic polyp (n = 2), chronic inflammation (n = 1), reactive changes of normal small bowel mucosa (n = 1).

Long-term follow-up

After median follow-up of 20 mo, there were 6 local recurrences (13%) 4 of which developed in patients with FAP (Table 2). Among the 47 patients who underwent resection, 8 (17%, 5 of which corresponded to surgical resection) developed post-procedural complications, which included retroperitoneal hematoma, intra-abdominal abscess, wound infection, delayed gastric emptying and prolonged ileus. EUS reliably identified absence of submucosal and muscularis invasion in 38 (81%) (P < 0.05) patients. There were 4 patients in whom EUS under-estimated invasion of the deep layers which was subsequently demonstrated in the final pathological analysis. In 5 cases (3 of which underwent pancreaticoduodenectomy, 1 underwent endoscopic resection, and 1 underwent transduodenal resection) EUS over-estimated submucosal invasion as this feature could not be proven in the resected specimen. Overall analysis therefore demonstrated that EUS predicted tumor muscularis invasion with a specificity of 88% and negative predictive value (NPV) of 90% (P < 0.05).

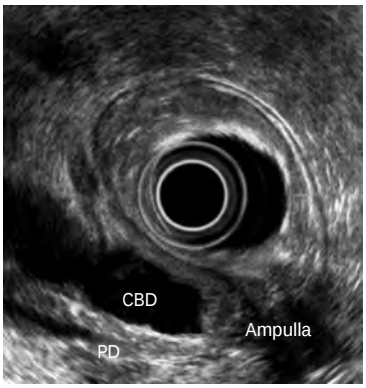

Figure 1 Endoscopic ultrasound showing absence of muscularis invasion in this lesion and as such amendable to local resection. PD: Pancreatoduodenectomy; CBD: Common bile duct.

DISCUSSION

The characterization of benign duodenal and peri-ampullary tumors, offers a diagnostic challenge to reliably distinguish adenomas from malignant lesions and render the possibility of transduodenal resection. While duodenal tumors are not common accounting for less than 1% of total gastrointestinal tumors and 25% of them are benign, the precise characterization continues to present a diagnostic challenge secondary to the complexity of the involved anatomical region. The surgical management of duodenal tumors is also challenging largely due

to their close relationship with the pancreatic and biliary ducts and their deep location[5].

The incidence of malignancy occurring in duodenal or ampullary tumors varies widely with false negative results for carcinoma as high as 60%[7] in the peri-ampullary region.

PD is the treatment of choice for invasive malignancies arising in the ampullary region and duodenum but its indication for treatment of benign peri-ampullary lesions is less clear. Several studies indicate that TDE exhibits less mortality and morbidity than PD[11]. Ampullectomy has been recommended as the procedure of choice to resect benign lesions smaller than 3 cm. TDE is therefore an organ-preserving operation with low morbidity but careful attention to the complex nature of the anatomy of the peri-ampullary region must be given to maximize its chances of success[11]. EUS is reportedly helpful in identifying non-invasive lesions suitable for local resection, but no preoperative test has been proven accurate enough to substitute for clinical judgment and intraoperative pathological confirmation[12]. In a study of local resection for ampullary tumors, the findings recommend local ampullary resection as an acceptable treatment in benign and selected premalignant and malignant ampullary lesions with a low threshold for conversion to PD when appropriate[13]. Another study of 63 patients proposed PD for even benign lesions because two patients in their series had to undergo repeat operations (PD) 4 and 22 years later for stage Ⅳ disease[14]. Local resection has been shown to be a viable alternative to PD in patients with benign tumors or as a palliative procedure in malignant cases with severe co morbidities where radical resection carries unacceptable surgical risk[15]. A review of 19 cases of villous tumors of the duodenum, suggests that some small benign ampullary villous adenomas or those with carcinoma in situ can be excised locally but prefer PD in the fit patient for better local control both of extensive benign lesions and cancers without distant metastases[16]. Other proponents of local resection confirm that benign duodenal villous tumors can be managed successfully by local submucosal excision[17]. In selected patients, endoscopic mucosal resection of superficial neoplastic lesions is associated with low morbidity when compared to surgery[18]. Pre-operative evaluation of these tumors to assess tumor depth is therefore paramount when planning the optimal therapeutic approach for resection of benign duodenal and peri-ampullary tumors. EUS has emerged as a useful technique in assessing the depth of invasion and is often employed when planning therapeutic approach. EUS images of tumors of the duodenal papilla correspond well to the final histological findings and report EUS as a reliable procedure for determining the extent of tumors in this location[19]. Comparison of EUS with other imaging modalities such as conventional sonography, CT, and angiography proved it to be the most effective method for local staging of pancreatic and ampullary cancers[20]. EUS can readily detect the presence of an ampullary or duodenal tumor in 96% of cases and reliably characterizes malignant lesions[21,22].

Consistent with prior publications, 16 of the 18 duodenal tumors in our study had tumors in the first or second portion of the duodenum (Table 1). Considering the above stated advantages, EUS is often employed at our institution when planning therapeutic approach to these tumors (Figure 1). Multiple studies have shown that EUS is superior to CT, magnetic resonance imaging, and transabdominal US in local peri-ampullary staging[23,24]. Previous studies evaluating the role of endoscopic resection of ampullary adenomas have presented it as a reasonable alternative to transduodenal surgical excision but long term follow-up data are needed to evaluate pre-operative staging accuracy and recurrence rates[25,26].

Our retrospective review shows that patients with peri-ampullary tumors and EUS showing absence of muscularis invasion can safely undergo transduodenal ampullectomy with sphincteroplasty and that this procedure results in satisfactory long-term outcomes. Muscularis invasion and pancreatic duct dilatation are features of malignant neoplasms that can be safely ruled out by EUS. Our findings further support endoscopic resection and TDE as safe treatment modalities for benign duodenal adenomas that avoid morbidity associated with PD and are associated with satisfactory long-term outcomes.

We conclude that EUS can accurately predict depth of mucosal invasion in the preoperative evaluation of suspected peri-ampullary and duodenal adenomas. These patients can safely undergo endoscopic or local resection with acceptable local control rates sparing the need for more extensive operations.

COMMENTS

Background

Management of benign duodenal and peri-ampullary adenomas is controversial as to the best management strategy. Some proponents of a more radical approach advocate a more aggressive pancreaticoduodenectomy while other proponents are in favor of a less invasive local resection.

Research frontiers

Endoscopic ultrasound (EUS) has emerged as a useful modality in the preoperative evaluation of these lesions and is used at our institution to guide management planning.

Innovations and breakthroughs

Duodenal tumors often pose diagnostic and therapeutic challenges in their management as they arise in close proximity to biliary and pancreatic structures and EUS has been shown to be a useful means of preoperative evaluation of these lesions to guide with the management planning. In one study, the sensitivity of EUS in the diagnosis of benign tumors was reported as 92%. The management of these benign tumors continues to be controversial posing a challenge to the surgeon, endoscopist and patients.

Applications

Based on their results, EUS can accurately predict depth of mucosal invasion in 81% ($P < 0.05$) of benign ampullary and duodenal adenomas with a specificity of 88% ($P < 0.05$) and negative predictive value of 90% ($P < 0.05$). These patients can safely undergo endoscopic or local resection with acceptable local control rates sparing the need for more extensive operations.

Terminology

Endoscopic ultrasound is an imaging modality that is used mostly in the upper digestive tract and in the respiratory system. It involves the insertion of a probe into a hollow organ and using ultrasound it is able to obtain images of internal organs that are in the chest, and abdomen and aids in visualizing these structures as well as blood vessels adjacent to them using the doppler imaging.

Gastroenterologists with advanced training typically perform the procedure. Transduodenal ampullectomy with sphincteroplasty is a local surgical excision procedure that is less invasive than the standard pancreaticoduodenectomy which is a radical resection typically used for more invasive lesions.

Peer review

This is a unique collection of cases establishing the value of endoscopic ultrasound in the management of duodenal and peri-ampullary adenomas and also reviewing the suitability and the results of the various possible operative procedures. With attention to minor details, it is an important paper and well worth publishing.

Abstract

AIM: To determine the evolution of transient elastography (TE) in patients with alcoholic liver disease according to alcohol cessation or continuation.

METHODS: We retrospectively selected in our local database all patients who had two TE between June 2005 and November 2010 with chronic alcohol excessive consumption and excluded those with associated cause of liver disease. TE was performed at least one week apart by senior operator. TE examinations with less than ten successful measures or with an interquartile range above 30% were excluded. We retrospectively reviewed file of all patients to include only patient followed up by trained addictologist and for which definite information on alcohol consumption was available. Concomitant biological parameters [aspartate amino transferase (AST), alanine amino transferase and gamma-glutamyl transpeptidase (GGT)] within 4 wk of initial and final TE were recorded. Putative fibrosis score according to initial and final TE were determined with available cut-off for alcoholic liver disease and hepatitis C. Initial and final putative fibrosis score were compared according to alcohol consumption during follow-up.

RESULTS: During the study period 572 patients had TE examination for alcoholic liver disease and 79 of them had at least two examinations. Thirty-seven patients met our criteria with a median follow-up of 32.5 wk. At the end of the study, 13 (35%) were abstinent, and 24 (65%) relapsers. Eight patients had liver biopsy during follow-up. TE decreased significantly during follow-up in 85% of abstinent patients [median (range): -4.9 (-6.1,-1.9)], leading to a modification of the putative fibrosis stage in 28%-71% of patient according to different cut-off value. In relapsers TE increased in 45% and decreased in 54% of patient. There was no statistical difference between initial and final TE in relapsers. In the overall population, using 22.6 kPa as cut-off for cirrhosis, 4 patients had cirrhosis at initial TE and 3 patients had cirrhosis at final TE. Using 19.5 kPa as cut-off for cirrhosis, 7 patients had cirrhosis at initial TE and 5 patients had cirrhosis at final TE. Using 12.5 kPa as cut-off for cirrhosis, 16 patients had cirrhosis at initial TE and 15 patients had cirrhosis at final TE. Evolution of biological data was in accordance with the relapse or abstinent status: abstinence ratio (duration of abstinence/duration follow-up) was correlated with AST ratio (r = -0.465, P = 0.007) and GGT ratio (r = -0.662, P < 0.0001). GGT was correlated with initial (r = 0.488, P = 0.002) and final TE (r = 0.49, P < 0.005). Final TE was correlated with AST (r = 0.362, P < 0.05). Correlation between TE ratio and AST ratio (r = 0.44, P = 0.01) revealed that TE varied proportionally to AST for all patients irrespective of their alcohol status. The same relationship was observed between TE ratio and

GGT ratio (r = 0.65, P < 0.0001). Evolution of TE was significantly correlated with the ratio of time of abstinence to observation time (r = -0.387, P = 0.016) and the evolution of liver enzymes.

CONCLUSION: TE significantly decreased with abstinence. Results of TE in alcoholic liver disease cannot be interpreted without taking into account alcohol consumption and liver enzymes.

INTRODUCTION

Alcohol excessive consumption is a major public health issue[1,2] as it may lead to liver fibrosis and cirrhosis with life threatening complications such as hepatocellular carcinoma[3], liver failure and death[4]. Early diagnosis of cirrhosis is an important goal as it may promote change in alcohol consumption by increasing motivation in patients and lead for specific screening of esophageal varices[5] or hepatocellular carcinoma[6]. Diagnosis of cirrhosis can be easy when patients have clinical[7] or biological signs of portal hypertension or liver failure. But at the early stage, these signs are for the most part absent, and liver biopsy is the only way to assess fibrosis[8]. Cost and complications of liver biopsy[9-11], leading to significant morbidity or mortality, urge the search for non invasive tools using clinical, biological or morphological finding to establish a probability of fibrosis[12-15].

Transient elastography (TE) is a reproducible and non-invasive test to assess liver fibrosis in chronic liver disease[16]. Initial studies in hepatitis C[17-19] had shown an accurate identification of patients with mild fibrosis or cirrhosis and TE is now part of the European Association for the Study of Liver (EASL) clinical guidelines for hepatitis C management[20].

Studies have also suggested correlation between TE and fibrosis in other chronic liver disease such as hepatitis B[21,22], primary biliary cirrhosis[23], primary sclerosing cholangitis[24], and non alcoholic steatohepatitis[25,26], but it then appears that disease-specific cut-off values for significant fibrosis or cirrhosis should be used[27,28].

Concerning alcoholic liver disease, two studies have shown that TE is correlated with fibrosis[27,28], but diagnosis of severe fibrosis or cirrhosis need the use of higher cut-off values than in other diseases, moreover there are some discrepancies between proposed cut-off values. Explanations offered are different spatial distribution of fibrosis and, that acute liver damage increases liver stiffness by different ways such as hepatocyte swelling, cholestasis, inflammation, and hepatocyte necrosis[29]. Thus excessive alcohol intake, with or without acute alcoholic hepatitis, could increase TE and lead to a false positive diagnosis of fibrosis. Of note, no information regarding patient alcohol consumption at time of fibrosis evaluation was available in the studies which proposed those cut-off values. Our hypothesis is that the alcohol consumption greatly influences TE and thus explains the difficulty to validate TE in alcoholic liver disease, but in the other hand it could make TE a useful tool in the follow-up of patient as an indicator of alcohol consumption beyond the sole fibrosis evaluation.

The aim of this study was to assess the evolution of TE during follow up of patients with alcohol excessive intake history in regards to alcohol withdrawal or continuation. Secondary objective was to determine correlation between biological parameters and TE modification.

MATERIALS AND METHODS

Patients and data

This is a retrospective study conducted in the department of Hepatology and Addictology, University Hospital, Rennes, France. In this unit, a measure of TE is routinely performed in patients hospitalized for alcohol withdrawal or compensated alcoholic liver disease. TE is measured with the Fibroscan® (Echosens, Paris) by a senior operator.

Internal memory of our Fibroscan® was screened for patients who had two TE between June 2005 and November 2010 for alcoholic liver disease. The two different TE examinations had to be performed at an interval of more than one week, ten successful measures were required with an interquartile range ⩽ 30% of the median value. Then we reviewed the patients files to collect information on their history, duration of alcohol withdrawal, and alanine aminotransferase (ALT), aspartate aminotransferase (AST) and gamma glutamyltranspeptidase (GGT) at the time (or up to 4 wk before or after) of the two TE.

Patients were excluded if (1) they presented other causes of chronic liver disease (hepatitis B or C, extrahepatic cholestasis, hemochromatosis); (2) information about alcohol consumption between the two TE were missing, or (3) liver tests at the time of the two TE were missing.

Patients' alcohol consumption during follow-up was assessed by self-declaration and corroborated by biochemistry evolution. Only patients followed by trained addictologists with definite information regarding alcohol consumption were included. We defined abstinence ratio as the duration of abstinence/duration of observation. In this study, patients were considered as abstinent if they were totally sober at least 90% of the time between the two TE.

TE initial (TEi) corresponds to the first TE, TE final

Table 1 Initial and final biological parameters and transient elastography and of patients according to their alcohol consumption status

	Abstinent (n = 13)		Relapser (n = 24)	
	Initial	Final	Initial	Final
Normal AST	8%	75%	8%	15%
AST (IU/L)	130 (39-374)	42 (15-118)	140 (16-472)	119 (17-749)
ALT (IU/L)	109 (34-387)	44 (13-163)	88 (18-266)	76 (9-329)

4	21.3	F4		14	F4	F3	Relapser
5	9.9	F3	F1	4.6	F ≤ 2		Relapser
6	5.3	F ≤ 2		16.9	F4	F3	Relapser
7	20.3	F4		14.3	F4	F4	Abstinent
8	11.7	F3		13.6	F4	F4	Abstinent

Data are shown in chronological order. EASL: European Association for the Study of Liver; TEi: Transient elastography initial; TEf: Transient elastography final.

(TEf) to the second TE and ΔTE to the difference between TEf and TEi. To determine variation of TE, we also defined TE ratio as (TEf-TEi)/TEi.

The liver fibrosis stages of the patients were calculated according to TE using cut-off values from different publications or guidelines: EASL recommendations for hepatitis C: 8 kPa for F ≥ 3 and 12.5 kPa for F = 4; Nahon[6]: 12.9 kPa for F ≥ 3 and 22.6 kPa for F = 4; and Nguyen[7]: 5.9 kPa for F ≥ 1, 7.8 kPa for F ≥ 2, 11 kPa for F ≥ 3 and 19.5 kPa for F = 4. Liver fibrosis stage referred to Metavir classification[9]: stage 0 corresponds to the absence of fibrosis, 1 to the presence of periportal fibrotic extension, 2 to periportal septa; severe fibrosis corresponds to stages 3 (porto-central septa) and 4 (cirrhosis). We defined Δstage as the difference between the fibrosis stages calculated at the first and the second TE, according to the different publications.

When liver biopsy had been performed, fibrosis was classified according to Metavir score[30].

We defined ASTi and GGTi as biological data related to the first TE, ASTf and GGTf to the second TE. The AST ratio [(ASTf-ASTi)/ASTi] and the GGT ratio [(GGTf-GGTi)/GGTi] were calculated to determine variation of biological markers.

Statistical analysis

Demographic data were expressed as median and inter quartile range. Qualitative variables were compared using the χ^2 test or Fischer exact test, when appropriate. Quantitative variables were compared using the Mann Whitney U test or Wilcoxon test for paired values. Correlation between variables was assessed using Spearman's rank correlation coefficient.

All tests were two sided with a significance of 5%. Tests were performed using JMP® software version 9.0 SAS, Cary, NC.

RESULTS

Characteristics of patients

During the period of the study, 6160 TE examinations were performed, of which 572 for patients with alcohol liver disease and 79 of them had 2 examinations. Forty-two patients were excluded because of missing data (lack of biological data or definite information on alcohol intake). Thus 37 patients corresponded to our criteria and were considered for analysis.

There were 7 women and 30 men with a median age of 44 years (39-53.5 years). Median follow up time was 32.5 wk (15-85 wk). At the end of the observation time, 13 (35%) were considered as abstinent, and 24 as relapsers.

Results of TE measures and biochemistry are shown in Table 1. Patients had marked increase in liver enzymes. TEi was significantly correlated with GGTi (r = 0.488, P = 0.002), and TEf with ASTf (r = 0.362, P < 0.05) and GGTf (r = 0.49, P < 0.05).

Repartition of patient according to putative liver fibrosis stage was different depending on TE cut-off used (EASL[2], Nahon[6] or Nguyen[7]). Results are shown in Figure 1. Overall, 16 patients had a TE indicating liver cirrhosis according to EASL, 7 according to Nguyen and 4 according Nahon cut-off values during initial evaluation.

Liver biopsy was performed in 8 patients. Results are shown in Table 2. According to EASL cut-off, 2 relapsers were misclassified. Patient 5 had stage 1 fibrosis, with TEi indicating severe fibrosis and normal TEf; and patient 6 had stage 3 fibrosis with TEf indicating severe fibrosis and normal TEi.

Evolution of TE according to alcohol consumption during observation period

During the observation period, 85% of abstinent patients had a decrease of TE, whereas among relapsers 45% had an increase and 54% a decrease of TE (P = 0.05, χ^2 test).

In the abstinent group, TE decreased significantly (Wilcoxon test for paired values, P = 0.0085) [median ΔTE = -4.9 kPa (-6.1, -1.9)] whereas TEf and TEi were not significantly different in relapsers [median ΔTE = -0.4 kPa (-4.8, +4)]. Δ TE were significantly different between abstinent and relapsers patients (P < 0.05).

There were variations in the putative staging of fibro-

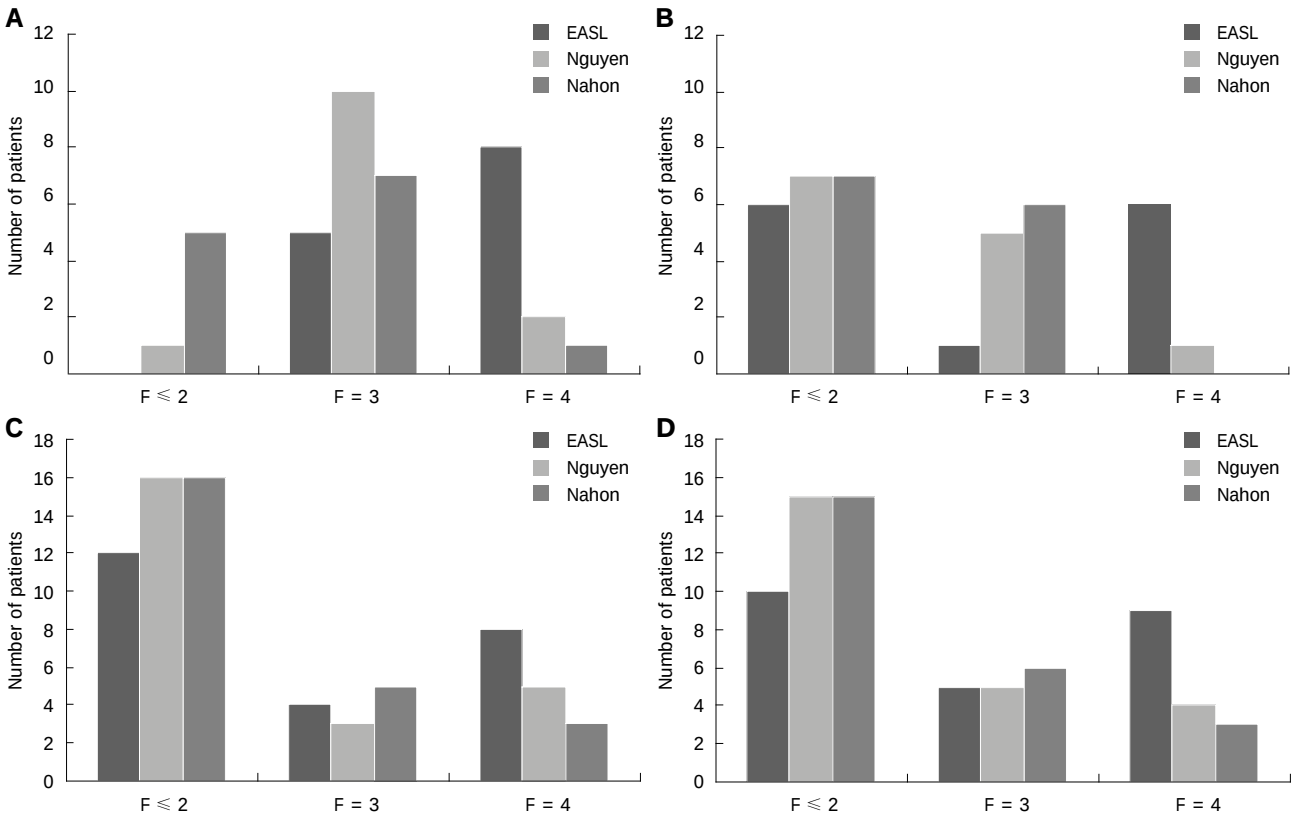

Figure 1 Initial and final repartition of liver fibrosis stage according to different cut-offs values of transient elastography (European Association for the Study of Liver, Nguyen and Nahon recommendations). A: Abstinent group [transient elastography initial (TEi)]; B: Abstinent group [transient elastography final (TEf)]; C: Relapser group (TEi); D: Relapser group (TEf). EASL: European Association for the Study of Liver.

sis according to TE during the observation time (Table 3). Putative fibrosis stage decreased in abstinent patients (in 28%-71% according to the cut-off used). In relapsers, stability, increase or decrease was observed. Δ stage according to EASL and Nguyen cut-offs were significantly different between relapsers and abstinent patients (P = 0.015 and P = 0.012 respectively).

TE decreased proportionally to abstinence, as demonstrated by the correlation between abstinence ratio and TE ratio (r = -0.47, P = 0.0029).

Variation of TE according to biological data

As expected abstinence ratio was correlated with AST ratio (r = -0.465, P = 0.007) and GGT ratio (r = -0.662, P < 0.0001).

Correlation between TE ratio and AST ratio (r = 0.44, P = 0.01) revealed that TE varied proportionally to AST for all patients irrespective of their alcohol status. The same relationship was observed between TE ratio and GGT ratio (r = 0.65, P < 0.0001).

DISCUSSION

TE is a useful tool which has been extensively validated in hepatitis C, but despite the incomparable more important frequency of alcoholic liver disease, few studies have been performed to assess TE in alcoholics. Moreover, despite of this active research, few studies evaluated TE regarding the current alcohol consumption of patients and only one studied the evolution of TE after alcohol detoxification. Our study is the first to assess TE evolution with a medium term follow up according to the alcohol consumption of patients.

Our results confirm the important variation of TE with alcohol withdrawal: 85% of abstinent patients showed a significant decrease of TE during a median follow up period of 32.5 wk. Moreover we showed a likely risk of overestimation of the fibrosis stage according to the different cut off values using TEi. TE evolution was correlated to AST and GGT evolution, which are usually used as marker of alcoholic hepatitis.

The results of our study may suffer from the retrospective data collection and the low number of patient. This is in part induced by the stringent inclusion criteria regarding missing data about alcohol consumption. Indeed, to avoid bias induced by poor quality of data and follow up bias we excluded all patients that were not followed by an addictologist and who lack definite information on alcohol consumption. Moreover, albeit alcoholic liver disease is an extremely frequent disease, patients are seldom compliant with follow up in the absence of severe disease, making rare those completing our inclusion criteria as shown by the number of TE performed for alcoholic liver disease (572) contrasting with the low number of patient who had a second TE (79).

In chronic hepatitis C, TE cut off associated with

Table 3 Percent of abstinent and relapser patient presenting a variation of Metavir score at the end of follow-up according to transient elastography using different cut off values

	Cut-off value	Increase in one or more stage of liver fibrosis (%)	Stable (%)	Decrease in one or more stage of liver fibrosis (%)
Abstinents	EASL	7	36	57
	Nguyen	7	22	71
	Nahon	7	65	28
Relapsers	EASL	29	55	16
	Nguyen	33	30	37
	Nahon	16	72	12

Results are expressed as percent of patient for each class. EASL: European Association for the Study of Liver.

fibrosis greater than stage 3 ranges from 8 to 9 kPa, and cirrhosis can be diagnosed with cut-off ranging from 14 to 15 kPa. Studies performed to assess TE diagnostic accuracy in other diseases than hepatitis C found higher cut off values for significant fibrosis or cirrhosis. Ganne-Carrié *et al*[31] studied 122 patients with non alcoholic or alcoholic steatohepatitis and found a cut off value for cirrhosis of 21.5 kPa. Nahon *et al*[27] studied 147 patients with alcoholic liver disease. Seventy-five percent of them had at least significant fibrosis, which is far more important than expected in alcoholic patients. They found a cut off value for significant fibrosis of 12.9 kPa and 22.6 kPa for cirrhosis. All the patients without cirrhosis and misclassified by TE had histological alcoholic hepatitis. In both studies, the patients were included if liver biopsy was indicated for chronic liver disease and there was no information regarding current alcohol consumption at the time of evaluation. Those data stressed the potential impact of alcohol induced liver modification beyond fibrosis on TE.

Coco *et al*[32] had reported that liver stiffness assessed by TE increased 1.3-to-3 fold during ALT flares in patients with viral hepatitis exacerbation. Studying 195 patients who had both liver biopsy and TE in acute liver damage, Fraquelli *et al*[33] showed that liver stiffness is increased in the acute phase with a correlation between TE and necroinflammatory activity. Recently Mueller *et al*[34] have showed that decrease of TE is correlated with the decrease of AST. Studying liver biopsies for alcoholic liver disease, they found that TE was constant if AST $\leqslant$ 100 UI/L and that accuracy of cirrhosis diagnosis by TE was improved in patient with AST $\leqslant$ 100 UI/L. Those data suggest that TE should be assessed differently regarding the current alcohol consumption and the presence or absence of acute liver modification or biochemical activity. In our study we used biochemical data gathered up to 4 wk from the date of TE, this is a long period which could have induced bias, however the rate of decrease or increase of TE in regard to the biochemical evolution remain to be determined in prospective study.

To date only one study assessed the evolution of TE with alcohol detoxification. Gelsi *et al*[35] studied in a population from an addictology unit the evolution of TE after alcohol weaning over a period of 60 d, and compared this evolution between relapser and abstinent patients. They found a rapid decrease of TE (-21% ± 27% at day 8) with detoxification in an increase proportion of patients if abstinence was sustained: 41% of patient had a decreased at day 8 and 66.7% at day 60. Relapsers were found to have a new increase in TE during follow up after alcohol relapse. As fibrosis is not likely to evolve during that short period of time, and albeit no liver biopsies were performed, one can assume that first TE measurement could have lead to overestimation of fibrosis.

Our results confirm those data, during a much longer follow up period (median 32.5 wk) with a precise addictologic follow up. TE decrease after alcohol cessation over a long period of time, and this was of particular importance in TEi ranging from 8 to 16 kPa, which could indicate significant fibrosis or cirrhosis in chronic hepatitis C, but should be interpreted with caution in alcoholic liver disease. However due to the retrospective design of the study which induced a variable timespan between TE examination, we could not assess the optimal time to perform TE after alcohol cessation.

Relapsers were found to have either an increase or a decrease of TE during follow up, this could be due to the level of alcohol consumption after relapse, as relapsers could have a lower alcohol consumption during follow up which could lead to a decrease of TE, as suggested by the correlation between Δ TE and GGT ratio. This point should be assessed in a prospective study with precise alcohol consumption amount, if confirmed TE could thus be a useful tool to monitor adherence during follow up and fluctuation in alcohol consumption.

TE was correlated with AST and GGT, and TE ratio was correlated with AST and GGT ratio, indicating that TE could be corrected by a calculated modifying factor based on liver enzymes value in order to increase the precision of this test in the diagnosis of fibrosis in alcoholic liver disease. This remains to be proven on large scale prospective studies of TE during alcohol withdrawal with liver biopsy as a gold standard. Such a study should also determine the optimal duration of alcohol cessation before initial increased TE could be controlled.

In conclusion our results show that TE decreased significantly after alcohol cessation over a long period of follow up. Thus TE in alcoholic liver disease should be interpreted with caution and assessed in regard to the current alcohol consumption. Variation of TE is correlated to AST and GGT suggesting that fibrosis could be more likely overestimated in patients with high biological perturbations. Large-scale prospective studies should be performed to determine the different optimal cut off values according to alcohol consumption and more data are required to determine the best delay of alcohol cessation for TE evaluation. TE examination could be a useful tool during the follow-up of alcoholic liver disease to assess actual alcohol consumption and maybe used as a prognosis tool as in chronic hepatitis C[36].

COMMENTS

Background

Excessive alcohol consumption is a major public health issue. Alcoholic liver disease can lead to liver fibrosis and cirrhosis with a risk of developing liver cancer or liver failure. Assessing the severity of liver fibrosis is thus an important landmark in alcoholic liver disease. Until recently the unique way to assess liver fibrosis was liver biopsy which is an invasive procedure with some risk of severe complication. Recently transient elastography (TE) was shown to be efficient in assessing liver fibrosis in chronic viral hepatitis C, it is now frequently used and acknowledged as a validated method by international hepatology society. Some studies have shown that TE could be used in alcoholic liver disease but with method differing from those in hepatitis C.

Research frontiers

TE (Fibroscan®) is an innovative non invasive method, measuring liver stiffness which is correlated to the severity of liver fibrosis. It has been widely validated in hepatitis C, but many studies have shown that results cannot be transposed "as this" to other type of liver disease because liver stiffness can be modified by other liver anomaly than fibrosis. In the area of alcoholic liver disease and liver fibrosis assessment, the research hotspot is how to use liver stiffness measured by TE and what are the parameter influencing liver stiffness.

Innovations and breakthroughs

This study showed that if performed in patient with alcoholic liver disease but without biological inflammation, performance of TE to assess fibrosis was good, which led the auhors to study the evolution of liver stiffness in patient with alcoholic liver disease in regard to their alcohol consumption.They compared the evolution of liver stiffness and biological data in patient with continued or stopped alcohol consumption. They showed that liver stiffness significantly decreases in patient after alcohol cessation and that this decrease is proportional to the severity of the biological inflammation.

Applications

The study results suggest that transient elastrography could be used in alcoholic liver disease by interpreting stiffness values in regard to the ongoing or not alcohol consumption. This hypothesis needs prospective confirmation before clinical application.

Terminology

Liver fibrosis is a "scar" that is developed in liver secondary to toxic (alcohol, iron overload) or viral (hepatitis C) damages. With increasing amount of fibrosis, cirrhosis appear thus leading to liver loss of function and an increased risk of liver cancer.

Peer review

The enclosed manuscript aims to the effect of alcohol consumption on liver stiffness measured by TE. The aim of the manuscript is sound.This is an interesting study.

Abstract

AIM: To investigate primarily the prognostic value of Ki-67, as well as other parameters, in gastrointestinal stromal tumors (GISTs).

METHODS: Ki-67, c-KIT, platelet-derived growth factor receptor-alpha (PDGFRα), smooth muscle actin (SMA), CD34, S100 were stained for immunohistochemistry which was performed on formalin-fixed, paraffin-embeded sections on representative block from each case. Proliferation index counted by Ki-67 antibody was calculated as a number of positive nuclear reaction over 100 cells. Immunoreactivity for c-KIT and PDGFRα was evaluated semiquantitatively (weak, intermediate, strong) and for c-KIT type of reactivity was analyzed (cytoplasmic, membrane and "dot-like" staining). Immunoreactivity for SMA, CD34 and S100 were was evaluated as positive or negative antigen expression. Pathologic parameters investigated in this study included tumor size, cell type (pure spindle, pured epitheloid mixed spindle and epitheloid), mitotic count, hemorrhage, necrosis, mucosal ulceration. Clinical data included age, gender, primary tumor location and spread of disease. χ^2 test and Student's *t*-test were used for comparisons of baseline characteristics. The Cox's proportional hazard model was used for univariable and multivariable analyses. Survival rates were calculated by Kaplan-Meier method and statistical significance was determined by the log-rank test.

RESULTS: According to the stage of disease, there were 36 patients with localized disease, 29 patients with initially localized disease but with its recurrence in the period of follow up, and finally, 35 patients had metastatic disease from the very beginning of disease. Tumor originated most commonly in the stomach (41%), small intestine was the second most common location (36%). The mean size of primary tumors was 6.5 cm. The mean duration of follow-up was 60 mo. Multiple parameters were analyzed for their effect on overall survival, but no one reached statistical significance (P = 0.06). Analysis of time to progression/relapse in initially localized disease (univariate analysis), tumor size, mitotic count, Ki-67 and type of d-KIT distribution (cytoplasmic *vs* membrane/"dot-like") showed statistically significant correlation. In multivariate analysis in the group of patients with localized disease, there were only 2 parameters that have impact on relapse, Ki-67 and SMA (P < 0.0001 and P < 0.034, respectively).

Furthermore, Ki-67 was analyzed in localized disease *vs* localized with recurrence and metastatic disease. It was shown that there is a strict difference between these 2 groups of patients (median value was 2.5 for localized disease *vs* 10.0 for recurrent/metastatic disease, $P < 0.0001$). It was also shown that the cut-off value which is still statistically significant in terms of relapse on the level of 6%. The curves for survival on that cut-off level are significantly different ($P < 0.04$, Cox F).

CONCLUSION: Ki-67 presents a significant prognostic factor for GIST recurrence which could be of great importance in evaluating malignant potential of disease.

Role of Ki-67 as a prognostic factor in gastrointestinal stromal tumors. *World J Gastroenterol* 2013; 19(4): 523-527 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/523.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.523

INTRODUCTION

Gastrointestinal stromal tumors (GIST) present a wide spectrum of tumors with variable malignant potential[1-3]. Although this entity has been defined rather recently, retrospectively it has been shown to be the most frequent mesenchymal neoplasm arising in the gastrointestinal tract[4]. Namely, in the last few decades, GISTs were sometimes wrongly diagnosed as leiomyoma, leiomyosarcoma and schwannoma. However, immunohistochemial staining and electron microscopic studies suggested difference comparing to other smooth muscle or Schwann cells. Finally, Hirota *et al*[5] demonstrated in 1998. mutation of c-KIT proto-oncogen as a paradigm of single-mutation tumorogenesis. It has also been shown that GIST originates from interstitial cells of Cajal[6].

Today we also know that both c-KIT and platelet-derived growth factor receptor-alpha (PDGFRα) oncoproteins are growth factor receptors that are normally activated by specific ligand stem cell factor. Their mutations lead to an independent activation of the receptor and constitutive activation and proliferation of cells[5]. Along with KIT-expression, very often is expressed CD34 and sometimes smooth muscle actin (SMA; focal of diffuse)[7].

The prediction of GIST behavior still remains controversial after all these years and, in many cases, non-conclusive. Many prognostic factors have been suggested and investigated in previous studies[8]. It is well known and established that the size of tumor (> 5 cm), mitotic rate > 5/50 HPF and site of the tumor play an important role. Nevertheless, it is not quite possible to predict the behavior of all GISTs. According to guidelines for the assessment of likely behavior, GISTs have been traditionally divided into probably benign, malignant and uncertain/low malignant potential (Fletcher)[9].

Imatinib mesylate, a selective tyrosine kinase inhibitor, has been known to have activity against such tumors. However, no patient had a complete response to the treatment so delineating prognostic factors for patients with GIST may be important even in post imatinib era[10]. It is not clear as well whether there is a role of adjuvant treatment in some GIST patients, although some current trials are still on going[11].

Ki-67 is a nuclear proliferation associated antigen. It is expressed in the growth and synthesis phases of the cell cycle but not in G0-phase (resting phase)[12]. It is a rather reliable marker of cell proliferation although there are differences between studies of Ki-67 labeling index, ranging from 4% to 22%[13,14].

The aim of this study was to investigate the role of Ki-67 among other parameters, as a prognostic factor of clinical behavior and prognosis, along with morphological and immunohistochemical profile in 100 GIST patients.

MATERIALS AND METHODS

All mesenchymal tumors of the gastrointestinal tract were retrieved from the files of the University Hospital Center Zagreb, in the period from 1997-2007. Since the immunohistochemistry has been developed on routine basis from the 2001, all specimens obtained before that time were retrospectively analyzed for c-KIT positivity. Inclusion criteria for the study were appropriate morphology and c-KIT positivity. Clinical data were retrieved from the files of the Clinic of Oncology and Surgical Oncology. Follow-up information was obtained from patients records or interviews. Clinical data included age, gender, tumor location (esophagus, stomach, small intestine, large bowel, retroperitoneum, mesentery) and spread of the disease. Spread of disease was classified into three groups: localized disease, localized disease with recurrence and metastatic disease. Pathological parameters that were assesed included tumor size, mitotic count, cell type (pure spindle, mixed spindle and epithelioid, pure epithelioid), necrosis, hemorrhagic areas and mucosal ulceration (invasion of lamina propria). Tumor size was measured in three dimensions and the largest dimension was taken into account. The mitoses were counted on 50 HPFx (400 ×). Immunohistochemistry was performed on formalin-fixed, paraffin-embedded sections on representative block from each case. Following antibodies were used: CD-117 (Dako, Glostrup, Denmark), CD34 (DAKO), PDGFRα (Novocastra, England), SMA (SMA-1, DAKO), S-100 (DAKO), Ki-67 (MIB-5, DAKO). Positive controls were included. All samples were evaluated by two experienced pathologists. Immunoreactivity for c-KIT and PDGFRα was evaluated semiquantitatively (weak, intermediate and strong), and c-KIT type of reactivity was analyzed (cytoplasmic, membrane or "dot-like" staining). Proliferating index counted by Ki-67 antibody was calculated as a number of positive nuclear reaction over 100 cells. Immunoreactivity for SMA, S100 and CD34 was evaluated as positive or negative antigen expression.

Table 1 Patient distribution according to sex and age in three different groups

Groups		Sex		Total
		Male	Female	
Localized disease	Number	19	17	36
	Average age (yr)	59.5	62.9	61.1
Recurrent disease	Number	17	12	29
	Average age (yr)	55.5	58.4	56.7
Metastatic disease	Number	20	15	35
	Average	60.7	48.7	55.5

Statistical analysis

χ^2 test or Student's t-test was used for statistical comparisons of baseline characteristics. In statistical analysis of our results we also used appropriate descriptive methods (median, range, minimum and maximum). The Cox's proportional hazard model was used in univariable and multivariable analyses. Survival rates were calculated by the Kaplan-Meier method, and statistical significance was determined by the log-rank test. The observed differences were assumed to be statistically significant if the probability of chance occurence was $P < 0.05$. All statistical analysis were performed by the statistical package statistica.

RESULTS

Our study comprised 100 GIST patients. Mean patients' age was 60.5 (range 20-78) years; 56% of patients were men. Patient distribution in three groups according to sex and age is shown in Table 1. There were 36 patients presenting initially with localized disease, 29 had localized disease further with recurrence and 35 had metastatic disease from the very beginning. Tumors originated most commonly in the stomach (41%), the small intestine was the second most common location (36%), in 8% colon and rectum and in 5% retroperitoneum was involved. In 10% of cases primary site of GIST was not clearly determined, because of the wide spread of the disease. The mean size of primary tumors (in patients without metastases) was 6.5 cm and 35 patients had distant metastases in the time of diagnosis. Metastases were most often localized in the liver, all other sites were rarely involved. The mean duration of follow-up was 60 (range 28-110) mo. Survival curve for all patients included in our study is shown in Figure 1. Further on, multiple parameters were analyzed for their effect on overall survival in all patients (Table 2). Most of them showed no effect, more precisely, only 2 parameters are close to statistically significant prediction of outcome and biological behavior, on the level of $P = 0.06$. These are Ki-67 and type of distribution of c-KIT. On the contrary, when we analyzed time to progression/relapse in localized disease, in univariate analysis tumor size, mitotic rate, Ki-67 and type of c-KIT distribution (cytoplasmic *vs* membrane/"dot-like") showed statistically significant correlation. In multivariate analysis in the group of patients with localized disease, there were only 2 parameters that have impact on relapse, Ki-67 and SMA expression (Table 3). Furthermore, when we compared Ki-67 in three different patients group it was obvious that there is a strict difference between mean value of Ki-67 in localized disease *vs* recurrent and metastatic disease together (median in localized disease was 2.5 *vs* 10.0 in recurrent and metastatic disease, $P < 0.0001$). It was shown that the cut-off value which is still statistically significant in terms of relapse on the level of 6% (Figure 2). Also, it has been shown that the curves for survival on that cut-off level are significantly different ($P = 0.04$, Cox F-test; Figure 3).

DISCUSSION

According to data obtained from our study, like age, sex distribution and primary localization, they are comparable to previous data in literature[8,15,16]. GISTs are rather rare tumors with very interesting biological behavior and sometimes unpredictable clinical course[17-19]. Although many reports indicated that the size and mitotic count are the most important and reliable prognostic factors[7], it has become obvious that the primary tumor localization was also very important issue[17]. Some 10 years ago, DeMatteo *et al*[20] showed that only tumor size is reliable predictor of survival in multivariate analysis. Some other

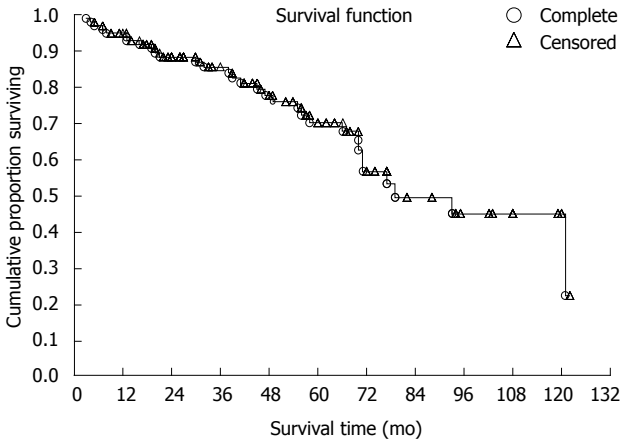

Figure 1 Survival curve for all patients with gastrointestinal stromal tumor (Cox regression analysis).

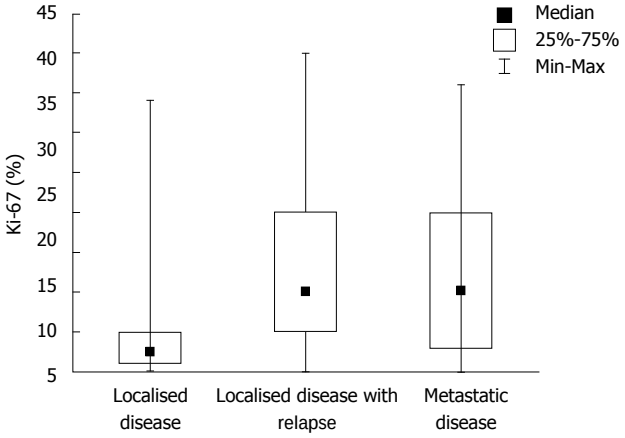

Figure 2 Value of Ki-67 in three different groups of patients.

authors found tumor size > 5 cm a poor prognostic factors[21]. However, there are only few reports of Ki-67 as a good indicator of the risk of metastases and as a prognostic factor[22]. Among other parameters, it was used for distinguishing leiomyoma and leiomyosarcoma[23]. Carrillo *et al*[13] stated that Ki-67 is one of the most accurate predictor of clinical behavior in GIST although it was not confirmed always and some other authors reported about Ki-67 with mitotic index as a prognostic factors in stomach GISTs[24]. In addition, we showed in our study, that there is no statistically significant difference in mean Ki-67 value between stomach- and small intestine-localization of GIST (52 patients together, 29 *vs* 23) (data not shown). That might support an idea of Ki-67 as a non-location-specific prognostic factor, what could be its advantage comparing to mitotic indeks which shows strong correlation to anatomic site of tumor.

One of the most important fact is observation that the level of Ki-67 is a prognostic factor for the relapse of initially localized disease ($P < 0.0001$), and the cut-off value is on 6%. Even in the survival setting this distinction remains statistically significant, no matter how these patients were treated ($P = 0.04$, Cox *F*-test). The expression of Ki-67 changes widely from one to another study, probably by the variety of cut-offs of various authors.

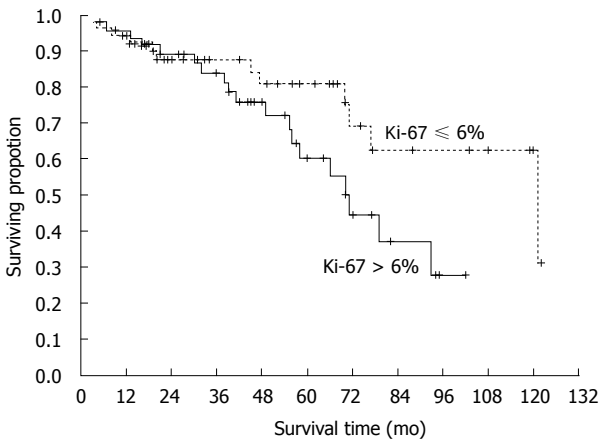

Figure 3 Survival curves with different values of Ki-67 (cut-off on 6%).

Toquet *et al*[25] and Nakamura *et al*[26] described cut-off of 10%, some others on the level of 5%. In that sense, our finding is important as additional indicator of importance of Ki-67 no matter the origin of GIST, and as well this might suggest, among other factors, which patient might have a greater risk of disease relaps. Maybe it might indicate the patients suitable for adjuvant treatment after surgical resection of localized GIST, in addition to contemporary concept of high-risk disease.

Considering other analyzed parameters, no one showed statistical power and impact on survival, as we expected. Just to mention that the meaning of statistical significance of SMA in DFI ($P < 0.034$) should be cautiously interpreted. It might be based on the fact that we assumed SMA-positive tumors generally better differentiated ones, thus it is to expect less aggressive course of disease which means fewer recurrences.

In conclusion, although there are some differences in numerical values of Ki-67 in various studies , that may be caused by different methodology in the assessment. But Ki-67 stays very important parameter of GIST-prognosis and should not be neglected when assessing malignant potential of the GIST.

COMMENTS

Background

Gastrointestinal stromal tumors (GIST) have a specific tumor biology with a wide spectrum of clinical behaviors. Thus, it is of great importance to define prognostic factors which could indicate risk of recurrence or spread of disease. Ki-67 is potentially good prognostic factor.

Research frontiers

So far, some of prognostic factors were rather well documented as the prognostic factors of further tumor behavior, for example mitotic count and tumor size, along with tumor primary localization. Ki-67 was unequivocally addressed as a prognostic factor.

Innovations and breakthroughs

This is the first study showing so clearly the significance of Ki-67 as a prognostic factor. Of importance is, that the patients included in the study were in different stage of disease, and also that comparison to other parameters have been done. It was shown that the cut-off value of Ki-67 of 6%, present the borderline value for recurrence of initially localized disease.

Applications

By understanding the meaning of Ki-67, it could be used as a parameter predicting tumor recurrence and suggest adjuvant treatment after surgery of localized disease.

Terminology

Ki-67 or MKI-67 is a protein that is in humans encoded by *MKI-67* gene. Ki-67 antigen is associated, and probably necessary, for cellular proliferation, it is associated with ribosomal RNA transcription. It is to assume that higher Ki-67 reveals tumor cell activity and thus predicts further behavior.

Peer review

This study is a contribution to the knowledge of GIST. It has a great value in better understanding of the biology of the disease, since some other parameters have already been recognized important as prognostic factors.

Abstract

AIM: To investigate whether endoscopic submucosal dissection (ESD) can be safely performed at small clinics, such as the Shirakawa Clinic.

METHODS: One thousand forty-seven ESDs to treat gastrointestinal tumors were performed at the Shirakawa Clinic from April 2006 to March 2011. The efficacy, technical feasibility and associated complications of the procedures were assessed. The ESD procedures were performed by five endoscopists. Sedation was induced with propofol for esophagogastorduodenal ESD.

RESULTS: One thousand forty-seven ESDs were performed to treat 64 patients with esophageal cancer (E), 850 patients with gastric tumors (G: 764 patients with cancer, 82 patients with adenomas and four others), four patients with duodenal cancer (D) and 129 patients with colorectal tumors (C: 94 patients with cancer, 21 patients with adenomas and 14 others). The *en bloc* resection rate was 94.3% (E: 96.9%, G: 95.8%, D: 100%, C: 79.8%). The median operation time was 46 min (range: 4-360 min) and the mean size of the resected specimens was 18 mm (range: 2-150 mm). No mortal complications were observed in association with the ESD procedures. Perforation occurred in 12 cases (1.1%, E: 1 case, G: 9 cases, D: 1 case, C: 1 case) and postoperative bleeding occurred in 53 cases (5.1%, G: 51 cases, D: 1 case, C: 1 case); however, no case required either emergency surgery or blood transfusion. All of the perforations and postperative bleedings were resolved by endoscopic clipping or hemostasis. The other problematic complication observed was pneumonia, which was treated with conservative therapy.

CONCLUSION: ESD can be safely performed in a clinic with established therapeutic methods and medical services to address potential complications.

INTRODUCTION

One-piece resection is considered the gold standard for endoscopic mucosal resection (EMR) because it provides an accurate histological assessment and reduces the risk of recurrence[1-5]. However, it is difficult to resect large and ulcerative lesions *en bloc* using conventional EMR techniques. Therefore, a new technique, endoscopic submu-

cosal dissection (ESD), has been developed[6-8]. ESD is a minimally invasive treatment for gastrointestinal cancer. It is usually performed in general hospitals because of the high frequency of complications and the need for a high level of technical skill[9-12]. The occurrence of complications negatively affects the quality life of patients and sometimes requires surgical treatment. Bleeding is one of the most common complications of ESD[13]. The use of hemostatic devices or endoscopic clipping prevents the occurrence of bleeding after ESD procedures[13]. Therefore, cases that require surgical treatment for bleeding after therapeutic procedures are quite rare. Perforation is also one of the most common complications of ESD[13]. Surgical treatment for iatrogenic perforation should be avoided at local clinics because most of these clinics do not have appropriate equipment for such surgeries.

The Shirakawa Clinic, a 19 bed inpatient clinic, was founded as a special clinic for endoscopic surgery. The main procedures performed at this clinic include endoscopy and endoscopic treatments. This clinic does not have surgeons or appropriate equipment for surgery. When surgical treatment is required, patients are transferred to a related tertiary hospital.

This study investigated whether ESD can be safely performed at small clinics such as the Shirakawa Clinic. The efficacy, technical feasibility and associated complications of ESD were assessed in the Shirakawa Clinic.

MATERIALS AND METHODS

Patients

We reviewed all cases of endoscopy and ESD to treat gastrointestinal tumors performed at the Shirakawa Clinic from April 2006 to March 2011. ESD was performed not only for treatment purposes, but also to make accurate histological diagnoses. Indications for ESD primarily included mucosal types of gastrointestinal cancers, excepting poorly differentiated cancers. A detailed description of the indications has been previously reported[9-12]. Depending on the procedure, we followed the guidelines of either the Japan Esophageal Society[14], the Japanese Gastric Cancer Association[15] or the Japanese Society for Cancer of the Colon and Rectum[16].

Clinic and ESD procedure

The Shirakawa Clinic includes 19 inpatient beds, 5 endoscopists and 5 endoscopical technicians certified by the Japan Gastroenterological Endoscopy Society. The endoscopic treatment room and treatment procedures are shown in Figure 1. The treatment teams included two doctors (one operator and one doctor who administered propofol sedation), two nurses and two endoscopical technicians. The years of experience of the endoscopists who performed the endoscopic treatment, including EMR, were as follows: 24 (Onozato Y), 20 (Sohara N), 16 (Hagiwara S), 14 (Iizuka H), and 11 (Arai R) years. The number of years of experience with ESD treatment were 10 (Onozato Y), 5 (Sohara N), 4 (Hagiwara S), 8 (Iizuka H), and 2 (Arai R) years. The numbers of ESD treatments performed were about 1000 (Onozato Y), 250 (Sohara N), 150 (Hagiwara S), 300 (Iizuka H), and 50 (Arai R) cases, respectively. All ESD procedures were supervised by Onozato Y, who had most experience performing ESD among the five endoscopists. As a result, all ESD cases were similarly treated because of the careful supervision.

The intravenous administration of pethidine hydrochloride and propofol was used for sedation, except in colorectal ESDs. The tumors were treated using standard ESD procedures as previously described[9-12]. For each patient, a data collection sheet was used to obtain relevant clinical information about the patient, tumor, procedure and complications. The data sheets were reviewed retrospectively. Findings from abdominal X-P, physical examinations and blood tests were assessed using a clinical pathway as a basis. Patients without complications were permitted to eat soft foods two days after ESD and then were discharged after endoscopic follow-up on the seventh day. The efficacy and complications of ESD were assessed.

One-piece resection was defined as *en bloc* resection. The resections were considered to be curative when tumor-free vertical and horizontal margins were achieved, *en bloc* resection was performed and resection criteria were met[14-16]. The operation time was calculated from the data of digital versatile disc recording systems for endoscopic procedures. Time from the start of the mucosal incision to the completion of the dissection was defined as the operation time. The time for marking or hemostasis after dissection was excluded from the operation time.

Procedure-related bleeding was subdivided into intra- and postoperative groups. Intraoperative bleeding was defined as large amounts of bleeding during the procedure and difficult cases of hemostasis. Postoperative bleeding was defined as clinical evidence of bleeding as evidenced by hematemesis or melena at 0-30 d after ESD and requiring endoscopic treatment. Furthermore, postoperative bleeding was subdivided into early postoperative (within three days of ESD) and delayed postoperative (more than three days after ESD) groups. We also recorded the incidence of perforation during endoscopy and after the procedures based on clinical evidence.

Endoscopic follow-up examinations were performed routinely one week, three months, nine months and every six months after ESD. To exclude distant metastases, abdominal ultrasonography (and/or computed tomography) was performed before ESD and three months and every six months after ESD on the same day as endoscopy.

Statistical analysis

The continuous variables are presented as the mean ± SD. The data were analyzed using the Fisher's exact probability test, and Mann-Whitney's *U*-test. A P value < 0.05 was considered to be significant.

ESD: Endoscopic submucosal dissection.

RESULTS

Total patients

From April 2006 to March 2011, a total of 35 540 endoscopies were performed at the Shirakawa Clinic. A total of 1047 lesions in 873 patients were resected with ESD (Table 1). Sixty-four patients with esophageal cancer (E), 850 patients with gastric tumors (G: 764 patients with cancer, 82 patients with adenomas and four others), four patients with duodenal cancer (D) and 129 patients with colorectal tumors (C: 94 patients with cancer, 21 patients with adenomas and 14 others) were treated. The *en bloc* resection rate was 94.3% (E: 96.9%, G: 95.8%, D: 100%, C: 79.8%). The median operation time was 46 min (range: 4-360 min) and the mean size of the resected specimens was 18 mm (range: 2-150 mm). No mortal complications were observed in association with the ESD procedures. Perforation occurred in 12 cases (1.1%, E: 1 case, G: 9 cases, D: 1 case, C: 1 case) and postoperative bleeding occurred in 53 cases (5.1%, G: 51 cases, D: 1 case, C: 1 case); however, no cases required emergency surgery or blood transfusion. All of the perforations were resolved using endoscopic clipping or hemostasis. The other problematic complication observed was pneumonia, which was treated with conservative therapy.

Esophageal cancers

The follow-up results of the 64 patients with esophageal cancer are shown in Figure 2A. The median follow-up period was 24 mo (range: 12-62 mo). Forty-six patients met the absolute indication criteria of the guidelines issued by the Japan Esophageal Society in 2007[14]. Twelve patients with lesions did not meet the conventional absolute criteria and instead met expanded indication criteria. Four patients did not meet the indication criteria. The *en bloc* resection rate was 96.9%. One of the 12 patients who met the expanded indication criteria and two of the four patients who did not meet the indication criteria received additional treatment. No local recurrences were observed in the patients who met the indication criteria.

Gastric cancers and adenomas

The follow-up results of the 850 patients with gastric tumors (764 patients with cancer, 82 patients with adenomas and 4 others) are shown in Figure 2B. The median follow-up period was 26 mo (range: 12-62 mo). Four

ESD: Endoscopic submucosal dissection; EP: Epithelium; MM: Muscularis mucosae; LPM: Lamina propria mucosae; Well diff.: Well differentiated adenocarcinoma.

hundred and thirty-three of the 764 patients with gastric cancer met the absolute indication criteria of the guidelines issued by the Japanese Gastric Cancer Association in 2010[15]. Two hundred and thirty-nine patients with lesions did not meet the conventional absolute indication criteria and instead met expanded indication criteria. Ninety-two patients with lesions exceeded the indication criteria. The *en bloc* resection rate was 95.8%. Curative

Table 2 Operation times and tumor sizes in the cases with and those without complications (mean ± SD)

	Number of lesions	Size of treated lesions (mm)	Operation time (min)
Esophagus			
All lesions	64	23.0 ± 11.0	76.4 ± 45.4
No complication	58	23.0 ± 11.1	76.4 ± 45.7

resection was achieved in 653 of the 764 patients with gastric cancer (85.5%). Nineteen patients with lesions underwent non-curative resection (non *en bloc* resection was performed, *etc*.) but were diagnosed curative clinically. No local recurrences were observed in the patients who met the indication criteria or in those who underwent clinically curative resection.

Duodenal cancers

The follow-up results of the four patients with duodenal cancer are shown in Figure 2C. The median follow-up period was 16 mo (range: 14-36 mo). All four patients underwent curative resection, and the *en bloc* resection rate was 100%.

Colorectal cancers and adenomas

The follow-up results of the 129 patients with colorectal tumors (C: 94 patients with cancer, 21 patients with adenomas and 14 others) are shown in Figure 2D. The median follow-up period was 32 mo (range: 12-62 mo). Twenty-eight of the 94 patients with colorectal cancer met the absolute indication criteria of the guidelines issued by the Japanese Society for Cancer of the Colon and Rectum in 2010[16]. Sixty-one patients with lesions did not meet the conventional absolute indication criteria and instead met expanded indication criteria. Five patients with lesions exceeded the indication criteria. The *en bloc* resection rate was 79.8%. Curative resection was achieved in 74 of the 94 patients with colorectal cancer (78.7%). Six patients with lesions underwent non-curative resection (because non *en bloc* resection was performed, *etc*.) but were diagnosed curative clinically. No local recurrences were observed in the patients who met the indication criteria or in those who underwent clinically curative resection.

Complications and endoscopic treatment

No mortal complications were observed in association with the ESD procedures. Perforations occurred in 12 cases (1.1%, E: 1 case, G: 9 cases, D: 1 case, C: 1 case) and postoperative bleeding occurred in 53 cases (5.1%, G: 51 cases, D: 1 case, C: 1 case) (Table 1). No problematic complications related to sedation were observed. One patient who experienced postoperative pneumonia was treated with an infusion of antibiotics and recovered in one week.

Operation times and tumor size for the cases with and without complications are shown in Table 2. Because the number of esophageal, duodenal and colorectal cases complicated by perforation or bleeding was small, it was not possible to make a statistical comparison between a no complication group and a complication group. It was possible to analyze the cases of gastric lesions statistically. Tumor size and operation times in the gastric cases with perforations were significantly larger than those observed in the cases without complications ($P < 0.05$).

All perforations were managed endoscopically using endoclips, a patch of omentum or conservative therapy. None of the patients with perforations required further surgery, and each of these patients were hospitalized for an additional zero to two days. A representative case of perforation is shown in Figure 3. Briefly, after detecting a perforation hole, the air was removed using an endoscopic fiber. Next, endoscopic clipping was performed. When the omentum became visible through the perforation hole, we attempted to aspirate the omentum through the perforation hole and clip the omentum to the hole.

All cases of intraoperative bleeding were controlled with endoscopic procedures such as soft coagulation with hemostatic forceps (Coagrasper; FD-410LR or FD-410-QR, Olympus, Tokyo). No case of intraoperative bleeding required surgical intervention or blood transfusion. Postoperative bleeding occurred in 53 cases. Early postoperative bleeding (within three days of ESD) occurred in 25/53 cases and delayed postoperative bleeding (more than three days after ESD) occurred in 28/53 lesions. All cases of postoperative bleeding were controlled with endoscopic treatment (clipping and/or electrocoagulation). No case of postoperative bleeding required surgical intervention or blood transfusion. A representative case of bleeding treated endoscopically is shown in Figure 3. Briefly, bleeding from a post-ESD ulcer was detected. After removing the coagulation, the bleeding point was detected. Clips were used to achieve hemostasis endoscopically.

DISCUSSION

ESD allows for the treatment of large and ulcerative

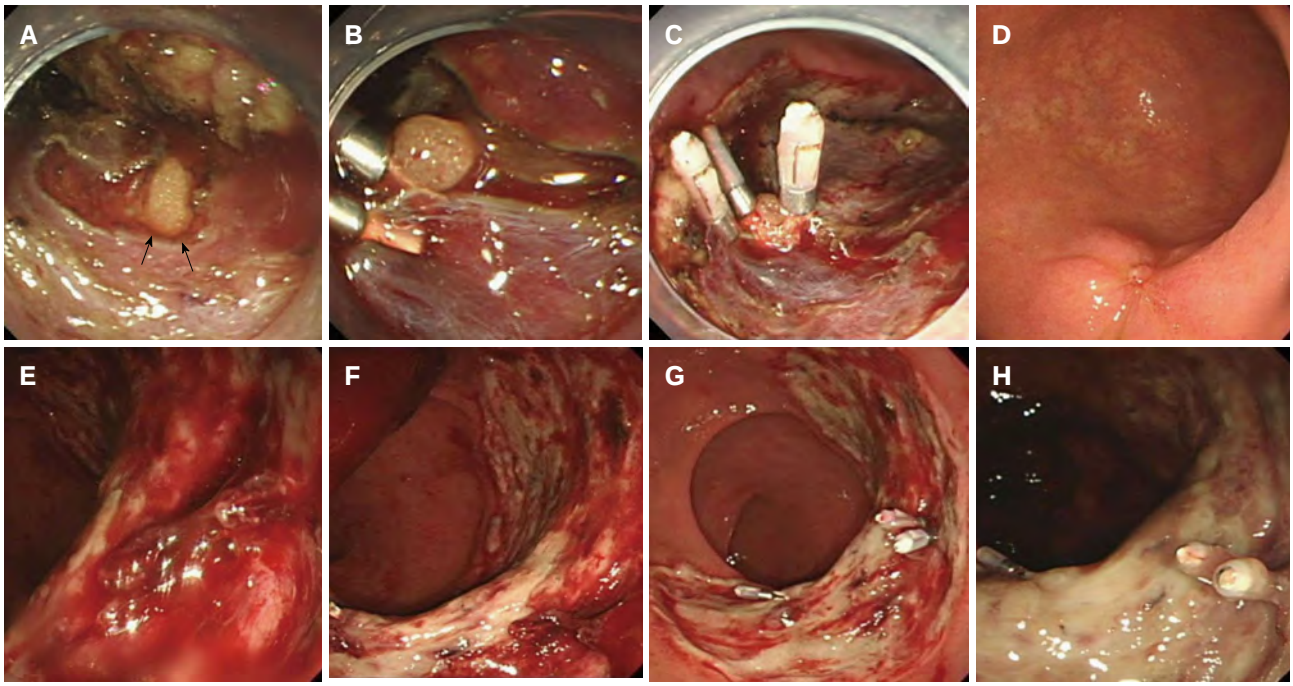

Figure 3 Representative cases of perforation and bleeding treated endoscopically. A: A perforation was detected (arrows); B: When the omentum became visible through the perforation hole, we attempted to aspirate the omentum through the perforation hole, then clipped the gastric wall and omentum together; C: Several clips were used to seal the hole completely; D: The appearance three months after clipping; E: Bleeding from a post-endoscopic submucosal dissection ulcer was detected; F: After removing the coagulation, the bleeding point was detected; G: Clips were used to achieve hemostasis endoscopically; H: The appearance 1 wk after clipping.

lesions and has revolutionized the management of gastrointestinal tumors[6,7,17,18]. ESD is a minimally invasive treatment for gastrointestinal cancer. However, ESD requires a high level of expertise and experience[19,20]. It is usually performed in general hospitals because of the high frequency of complications and the need for a high level of technical skill. Hemostatic devices and/or endoscopic clipping prevents the occurrence of complications after ESD. In this study, all complications of ESD were resolved using non-surgical therapies. Therefore, ESD can be safely performed in clinics with established therapeutic methods and medical services to address potential complications. This study showed that ESD can be safely performed in small clinics.

Since ESD is an endoscopic surgical procedure, the risk of complications is unavoidable[13]. Bleeding and perforation are most common complications of ESD procedures[13]. The incidence of complications[13] associated with ESD are reported to be: 0% for bleeding in the esophagus, 4.0%-6.0% for perforation of the esophagus[21,22], 1.8%-15.6% for bleeding in the stomach, 1.2%-4.7% for perforation of the stomach[23-26], 0.3%-1.5% for bleeding in the colon and 2.2%-5.5% for perforation of the colon[27-29]. Except in cases of esophageal ESD, bleeding is a common complication. It can be treated endoscopically using soft coagulation with hemostatic forceps or hemoclips[13]. In most reports, the incidence of bleeding is less than 10%[13]. In this study, the incidence of complications was 0% for bleeding in the esophagus, 1.7% for perforation of the esophagus, 6.0% for bleeding in the stomach, 1.1% for perforation of the stomach, 0.8% for bleeding in the colon and 0.8% for perforation of the colon. These complication rates are acceptable in comparison to those seen at other institutes[13].

Perforation is another common complication of ESD. Since mediastinitis and peritonitis occuring consequent to esophageal perforation and colon perforation, respectively, have high mortality rates, surgery was previously the method of choice for treating gastrointestinal perforations. Currently, conservative or endoscopic treatment tends to be selected to treat smaller perforations when the lesions are clean[30,31]. Most perforations resulting from ESD are smaller and tend to be treated in a non-surgical manner[32,33]. It is very important to recognize the occurrence of a perforation immediately. Endoscopic closure should be considered if the lesion is clean (i.e. without feces and so on). Matsui *et al*[13] have suggested the indications for endoscopic clipping of perforations to include (1) a small defect size (less than 10 mm); (2) the ability to prepare the bowel adequately; and (3) a stable patient condition immediate following perforation. After successful endoscopic closure is completed, the patient should be fasted and treated with antibiotics. Formal guidelines for fasting periods have not been established; however, one report regarding colonic perforations indicates a mean fasting period of 4.2 d and a mean duration of intravenous antibiotics of 5.5 d[34]. Surgical treatment should be considered when the perforated lesion cannot be closed with endoclips, abdominal pain has exacerbated or severe peritonitis is suspected. Of course, if there is any concern regarding the patient's condition, the patient should be transferred to surgery without hesitation. In

this study, all perforations were managed endoscopically using endoclips, patches of the omentum or conservative therapy. No patient required additional surgery due to perforation in this study.

Because ESD requires a high level of technical skill, an endoscopist's skill level[9-12], rather than the size of a clinic or hospital, may be more strongly related to the results of ESD, such as the success of *en bloc* resections, the length of operations and the rate of complications. In this study, all five endoscopists had more than 10 years of experience with endoscopic treatment, including EMR. Furthermore, all ESD procedures were supervised by the most experienced endoscopist in our clinic. As a result, all ESD cases received similar levels of treatment. This is one of the important reasons why ESD can be safely performed in small clinics. The patient volume may also strongly affect the ESD results. In this study, a total of 1047 lesions in 873 patients were treated during the five-year period, averaging approximately 210 ESDs each year. This is considered to be a moderate to high patient volume. Many experiences with cases and a relatively high patient volume are also needed for the improvement of ESD skills and were found to be important for safely performing ESD.

Two patients with cancer of the esophagus, 62 patients with cancer of the stomach and two patients with cancer of the colon refused additional treatment/surgery in spite of a non-curative resection in this study. The reasons for refusing additional treatment/surgery were varied, including advanced age, complicated diseases, *etc*. The long-term outcomes for such non-curative ESD patients who refused additional treatment/surgery may be of interest. It also may be important data for deciding on the indications for the treatment of elderly patients. However, we did not analyze the overall data in terms of the long-term outcomes for such non-curative ESD patients in this study, so a future study will be needed to clarify these issues.

In conclusion, ESD is associated with a few problematic complications. However, in this study, all complications were resolved using non-surgical therapies such as endoscopic clipping. ESD can be safely performed in clinics with established therapeutic methods and medical services to address potential complications.

COMMENTS

Background

Endoscopic submucosal dissection (ESD) is a minimally invasive treatment for gastrointestinal cancer. It is usually performed in general hospitals because of the high frequency of complications and the need for a high level of technical skill. The aim of this study was to determine whether ESD can be safely performed at small clinics. The efficacy, technical feasibility and associated complications of the procedures were assessed.

Research frontiers

ESD is usually performed in general hospitals. Treatment data and outcome of ESD at general hospitals were reported. However, such reports from clinics were rare. The efficacy, technical feasibility and associated complications of the ESD procedures at a local clinic were assessed.

Innovations and breakthroughs

This study showed that ESD can be safely performed in clinics with established therapeutic methods and medical services to address potential complications. ESD is associated with a few problematic complications. However, in this study, all complications were resolved using non-surgical therapies such as endoscopic clipping.

Applications

ESD can be safely performed in clinics with established therapeutic methods and medical services to address potential complications.

Terminology

ESD is a minimally invasive treatment for gastrointestinal cancer. One-piece resection is considered the gold standard for endoscopic treatment because it provides an accurate histological assessment and reduces the risk of recurrence. ESD enable us to resect large and ulcerative lesions *en bloc*.

Peer review

This study investigated whether ESD can be safely performed at small clinics. The authors indicated ESD can be safely performed in their small 19-bed clinic with similar ESD results as previously published from general hospitals. This is an interesting topic.

Abstract

AIM: To examine how the expression of caudal type homebox transcription factor 2 (Cdx2) is regulated in the development of malignancy in Barrett's esophagus.

METHODS: Cdx2, mucin (MUC) series (MUC2, MUC5AC and MUC6), p53 and E-cadherin expression in Barrett's esophagus and adenocarcinoma specimens were examined by immunostaining. Isolated clusters of cells from (1) MUC2 and Cdx2-positive intestinal metaplastic mucosa; (2) MUC5AC and MUC6-positive, and MUC2 and Cdx2-negative high-grade dysplasia (HD), or intramucosal adenocarcinoma (IMC); and (3) MUC5AC, MUC6 and Cdx2-positive poorly-differentiated invasive adenocarcinoma (PDA) were analyzed by methylation-specific polymerase chain reaction using sets of primers for detecting methylation status of the *Cdx2* gene.

RESULTS: Most of the non-neoplastic Barrett's esophageal mucosa showing intestinal-type metaplasia with or without low-grade dysplasia was positive for E-cadherin, MUC series and Cdx2, but negative for p53. A portion of the low-grade to HD was positive for E-cadherin, MUC5AC, MUC6 and p53, but negative for MUC2 and Cdx2. The definite IMC area was strongly positive for MUC5AC, MUC6 and p53, but negative for MUC2 and Cdx2. Methylation of the Cdx2 promoter was not observed in intestinal metaplasia, while hypermethylation of part of its promoter was observed in hot dipped and IMC. Hypermethylation of a large fraction of the Cdx2 promoter was observed in PDA.

CONCLUSION: Cdx2 expression is restored irrespective of the methylation status of its promoter. Apparent positive immunohistochemical results can be a molecular mark for gene silencing memory.

Cdx2 expression and its promoter methylation during metaplasia-dysplasia-carcinoma sequence in Barrett's esophagus. *World J Gastroenterol* 2013; 19(4): 536-541 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/536.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.536

INTRODUCTION

Barrett's esophagus, first described in 1950 and refined in 1957, is a condition whereby the distal esophageal squamous epithelium is replaced by metaplastic columnar epithelium[1]. Three types of morphologically distinct

metaplastic columnar epithelia are recognized in Barrett's esophagus: gastric-fundic, gastric-cardiac (junctional type), and intestinal (specialized type) metaplasia[2]. Reflecting a finding that patients with intestinal-type epithelium are at increased risk of developing adenocarcinoma, the American College of Gastroenterology has recently proposed a restricted definition of Barrett's esophagus: "a change in the esophageal epithelium of any length that can be recognized at endoscopy and is confirmed to have intestinal metaplasia at biopsy"[3]. Although a recent cohort study has demonstrated that the frequency of cancer development in Barrett's esophagus is not related to the presence of intestinal metaplasia, metaplastic columnar epithelium, *per se*, is generally accepted as a precancerous process predisposed to develop discrete neoplastic lesions such as the gastric or foveolar type, the adenomatous or intestinal type, hybrid type dysplasia, and intramucosal [high-grade dysplasia (HD) or intramucosal adenocarcinoma (IMC)] and invasive cancers[4]. Cancers derived from Barrett's esophagus are histopathologically classified into two major categories: gastric and intestinal[5]. Since most Barrett-related IMC cases are either gastric or intestinal with distinct phenotypic stability during progression, two separate (gastric and intestinal) pathways of carcinogenesis have been proposed[5]. Importantly, during the progression of the intestinal pathway, a gradual decrease in transcription factor caudal type homebox transcription factor 2 (Cdx2, a caudal-related homeobox gene essential for skeletal and intestinal development has been noted, suggesting its tumor suppressor role in Barrett's esophagus[5].

We encountered a case of invasive esophageal adenocarcinoma developing into intestinal-type dysplasia and IMC, and examined Cdx2 expression and its promoter methylation status in close histopatho- logical relation to the progression stages with the use of microdissection and methylation-specific polymerase chain reaction (MSP).

MATERIALS AND METHODS

Patient

An 81-year-old Japanese man was admitted to our hospital complaining of heartburn especially after eating sweet fare. The patient had undergone stomach surgery (distal partial gastrectomy) due to gastric ulcer nearly forty years earlier. Because of gastric regurgitation, he had undergone endoscopic examination of the upper digestive tract, which revealed severe reflux esophagitis with widespread Barrett's esophagus. A biopsy was taken from irregularly elevated lesions inside the Barrett's esophagus, and a histological examination confirmed esophageal adenocarcinoma in the lesions. An esophagectomy was carried out, and the right hemicolon was rebuilt. The patient has been free of recurrence for two years since the operation.

Immunohistochemistry

The specimens of Barrett's esophagus were subjected to immunohistochemistry using diaminobenzidine as the chromogen. Deparaffinized sections of formalin-fixed tissue were stained with mucin (MUC) series (Novocastra Laboratories Ltd., Newcastle upon Tyne, United Kingdom), p53 (Lab Vision, Kalamazoo, United States) and E-cadherin (Dako, Denmark) antibody diluted at 1:100 after heat-induced antigen retrieval and with Cdx2 (Dako, Denmark) antibody diluted at 1:50. Anti-rabbit immunoglobulin G (IgG) was used as the secondary antibody for p53 and anti-mouse IgG was used for MUC series, Cdx2 and E-cadherin.

Agarose-bead mediated template preparation

Paraffin-embedded samples were deparaffinized in xylene and subjected to microdissection under light microscopic observation (Leica Microsystems, LMD7000) with the aid of both E-cadherin immunostaining and Cdx2 immunostaining. The microdissected samples were liquefied in low-melting agarose (3.2%) at 1:1, and agarose beads were made by chilling on ice. Beads were treated with proteinase K, followed by bisulfite conversion, as previously described[6].

Polymerase chain reaction amplification and sequencing

Bead fragments were analyzed by MSP using sets of primers for accessing the methylation status of the *Cdx2* gene. The promoter region of the human *Cdx2* genomic sequence (GenBank accession no. AL591024) was searched for CpG islands with an online search engine (www.ebi.ac.uk/emboss/cpgplot). One of the CpG islands (AL591024 nt 28391-28683) was further analyzed for methylation status by MSP. In the first-step polymerase chain reaction (PCR) amplification, a 183-bp amplicon containing 71-bp CpG sites, was amplified with two primers, (forward) 5'-GCCAAGGGGCCTAGGGCTGGA-3', and (reverse) 5'-GTTCACCTCCTAATACAAGCCTTTG-3' (Table 1), under the following conditions: 98°C 2 min, 30 cycles (98 ℃ 10 s, 50 ℃ 15 s, 68 ℃ 39 s). The primers used for second-step PCR were, (forward) 5'-GGAGCTGCCCCGACAGGAGCG-3', and (reverse) 5'-CGCGCCCAGCTCGGn TTTCAGCAA-3' (Table 1), under the following conditions: 98 ℃ 2 min, 25 cycles (98 ℃ 10 s, 60 ℃ 15 s, 68 ℃ 30 s). The PCR mixture contained Mighty AMP® DNA polymerase (Takara, Tokyo, Japan) and bead fragments in a final volume of 25 μL. The PCR products were electrophoresed in a 3% agarose gel, stained with ethidium bromide and visualized under ultraviolet light.

Ethics

Written informed consent was obtained from this patient, and this study was reviewed and approved by the local ethics committee at Ehime University.

RESULTS

Pathological findings

Grossly, a superficial spreading IMC surrounded by low-

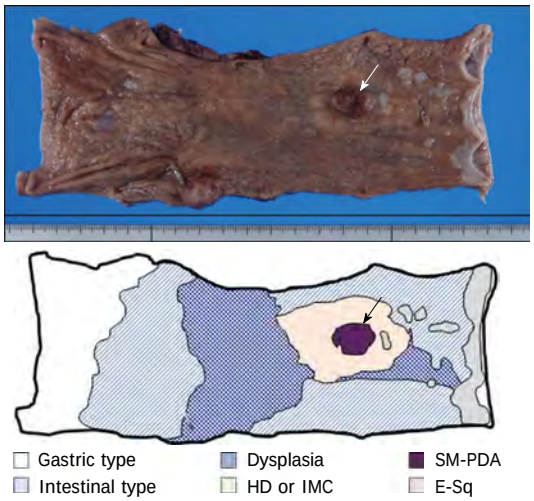

Figure 1 Macroscopic findings of excised esophagus. Surgical specimen shows the presence of superficial spreading carcinoma, extending between 30 mm from the oral and 105 mm from the anal surgical margins. The superficial spreading region is mostly composed of high-grade dysplasia (HD), or intramucosal adenocarcinoma (IMC), surrounded by dysplastic change (E-sq low-grade dysplasia). Inside this superficial spreading region, one observable elevated nodule (arrow) is composed of solid and submucosal invasive poorly-differentiated invasive adenocarcinoma (SM-PDA) with lymphatic invasion. The background non-neoplastic esophageal mucosa is extensively replaced by glandular mucosa with and without intestinal metaplasia.

Table 1 Primer sequences used in polymerase chain-based assays, product size and annealing temperature

Table 2 Summary of immunohistochemical findings

	G-type	I-type (IM)	HD or IMC	PDA
MUC2	-	+	-	-
MUC5AC	+	-	++	+
MUC6	+	-	++	+
p53	-	-	++	++
E-cadherin	++	++	++	+
Cdx2	-	+	-	+

G-type: Gastric metaplasia; IM: Intestinal metaplasia; HD or IMC: High-grade dysplasia or intramucosal adenocarcinoma; PDA: Poorly-differentiated invasive adenocarcinoma; MUC: Mucin.

grade dysplasia and intestinal-type metaplasia extended between 30 mm from the oral and 105 mm from the anal surgical margins (Figure 1). One elevated nodule was noted inside this superficial spreading region (Figure 1). Microscopically, the background non-neoplastic esophageal mucosa was replaced, very extensively, by gastric foveolar type mucosa with (Figure 1) and without intestinal metaplasia (Figure 1). The superficial spreading IMC region was mostly composed of definite well-differentiated tubular adenocarcinoma or HD, surrounded by dysplastic change (low-grade dysplasia). The oral elevated nodular ridge was a solid, poorly-differentiated, invasive adenocarcinoma with lymphatic invasion, but no venous invasion or metastasis within the esophageal mucosa was observed. Immunohistochemically, the original esophageal squamous epithelium was positive for E-cadherin, but negative for all the MUC series (MUC2, MUC5AC and MUC6), Cdx2 and p53. Most of the non-neoplastic Barrett's esophageal mucosa showing intestinal-type metaplasia with or without low-grade dysplasia was positive for E-cadherin, MUC2, MUC5AC, MUC6 and Cdx2, but negative for p53. A portion of the low-grade to high-grade dysplasia was positive for E-cadherin, MUC5AC, MUC6 and p53, but negative for MUC2 and Cdx2. The definite IMC area was strongly positive for MUC5AC, MUC6 and p53, but negative for MUC2 and Cdx2. Figure 2 shows the transitional area between the intestinal metaplasia with low-grade dysplasia and the definite IMC area. A portion of the poorly-differentiated adenocarcinoma was positive for MUC5AC, MUC6, Cdx2 and p53, but negative for MUC2 (Figure 3). Table 2 shows a summary of the immunohistochemical findings.

Microdissection and MSP of the Cdx2 promoter

MSP revealed no methylation in Cdx2-positive Barrett's mucosa with intestinal metaplasia (Figure 4, intestinal type). Microdissected samples from the Cdx2-negative IMC area showed that a fraction of the cells was hypermethylated (Figure 4, IMC). Although Cdx2 expression was found by immunohistochemical analysis, samples from the poorly-differentiated invasive (PDA) area showed a hypermethylation pattern (Figure 4, submucosal invasive PDA).

DISCUSSION

Cdx2 is an intestine-specific transcription factor expressed in cells constituting the mucosal epithelium from the duodenum to the rectum[7]. While Cdx2 is negative for the normal foveolar mucosa of the stomach and the squamous epithelium in the esophagus stemming from the foregut, its heterotopic expression in Barrett's esophagus is observed especially in cases with intestinal-type metaplasia[8]. Among most of the terminal differentiation-specific transcription factors, Cdx2 is known to play a tumor suppressor role in cancer progression in the distal colon, a role, which in adults, is functionally and geographically distinct from the homeotic role of Cdx2 during gut development[9]. In our present case, and in confirming its tumor suppressor role, Cdx2 expression diminished during the progression from intestinal-type metaplasia to distinct IMC. Mirroring Cdx2 expression at the protein level by immunohistochemistry, the hypermethylation of the *Cdx2* gene promoter was revealed (Figure 4, IMC). Since primers used for MSP are set to amplify the *Cdx2* gene promoter with hypermethylation,

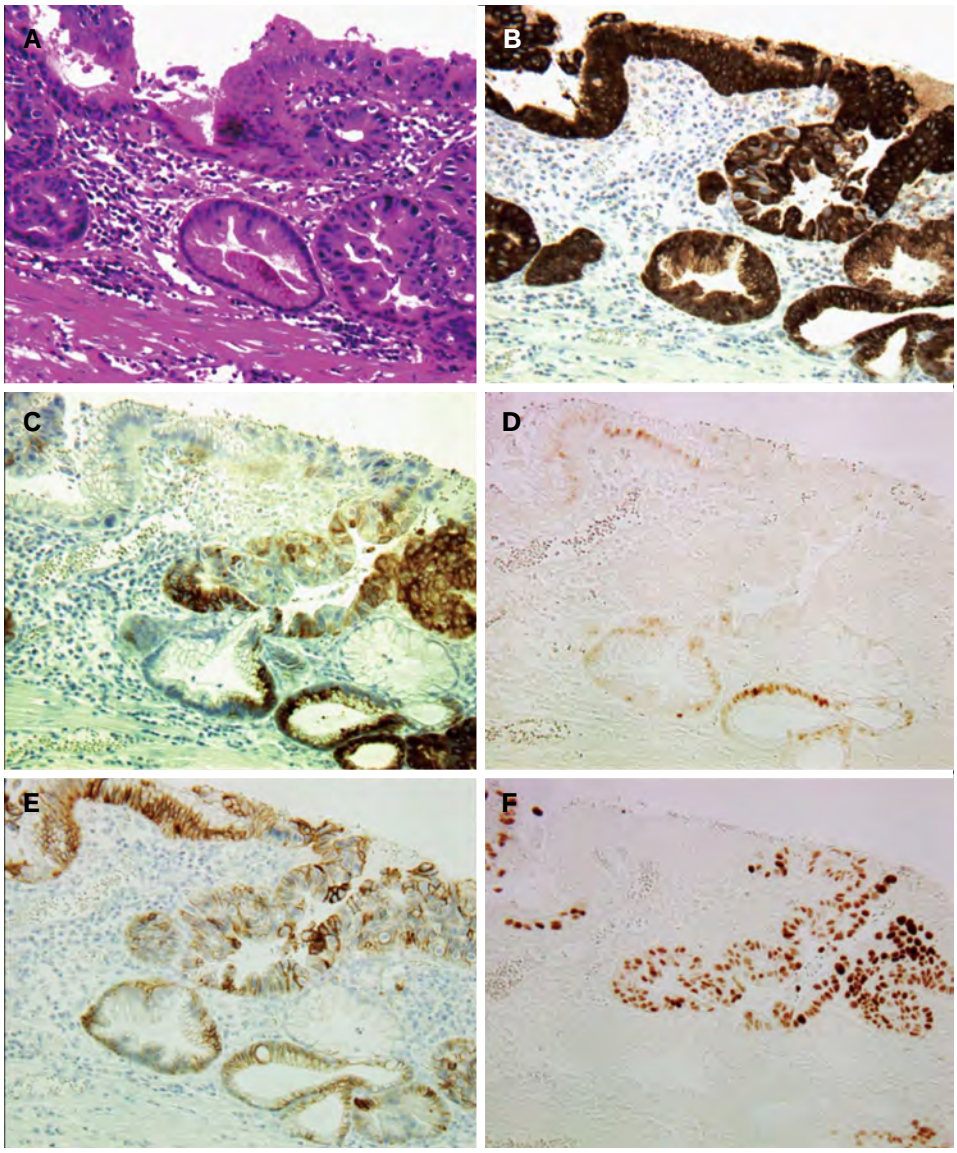

Figure 2 Histological findings of transitional area between intestinal metaplasia and high-grade dysplasia or intramucosal adenocarcinoma (× 200). A: Hematoxylin and eosin staining of transitional area. Intestinal metaplasia (IM) stretches from the upper left to the lower right corner; B: Mucin (MUC) 5AC immunostaining. Strong MUC5AC expression is observed in both IM and high-grade dysplasia (HD), or intramucosal adenocarcinoma (IMC) areas; C: MUC6 immunostaining. MUC6 expression is observed mostly in parts of the HD or IMC areas; D: Caudal type homebox transcription factor 2 (Cdx2) immunostaining. Cdx2 expression is observed only in the nuclei of the cells in the IM area; E: E-cad immunostaining. E-cad expression is observed on the membranes of cells in both IM and HD or IMC areas; F: p53 immunostaining. Strong p53 expression is observed in the nuclei of the cells in the HD or IMC area.

i.e., when all CpGs are methylated, a large fraction of the cells may acquire partial or scatter-type CpG methylation and, therefore, the *Cdx2* gene promoter may have been underestimated in our MSP. In support of our current study, Khor *et al*[5] also demonstrated the gradual down-regulation of Cdx2 expression during progression in adenomatous dysplasia, at least in the intestinal pathway of the Barrett esophageal cancers. These data suggest that Cdx2 also plays a tumor-suppressor role in the metaplasia-dysplasia-carcinoma sequence in Barrett's esophagus. In our present case, irrespective of the hypermethylation status of the *Cdx2* gene promoter, Cdx2 expression was restored in PDA as analyzed by immunohistochemistry (Figure 3F). To achieve final gene-silencing, chromatin condensation followed by modifications of histone proteins are essential[10], we therefore hypothesize that epigenetic alterations other than demethylation may lead to *Cdx2* gene reactivation during the progression phase. Indeed, our previous study showed that hypermethylation of the *E-cadherin* gene promoter and MeCP2, a methyl-CpG binding domain protein, synergistically silenced gene expression in colorectal cancers[6]. Therefore, it is evident that hypermethylation of the gene promoter, *per se*, is essential for establishing gene silencing, but not sufficient for blocking gene expression. Since in our present case, Cdx2 reactivation did not correlate with differentiated intestinal phenotype, but was observed in invasive or aggressive phenotypes, the tumor suppressive effect of Cdx2 on these invasive cancer cells might be lost. These somewhat complicated epigenetical events may partly explain the dispersion of Cdx2 expression. Therefore, when characterizing cancer cells by immunophe-

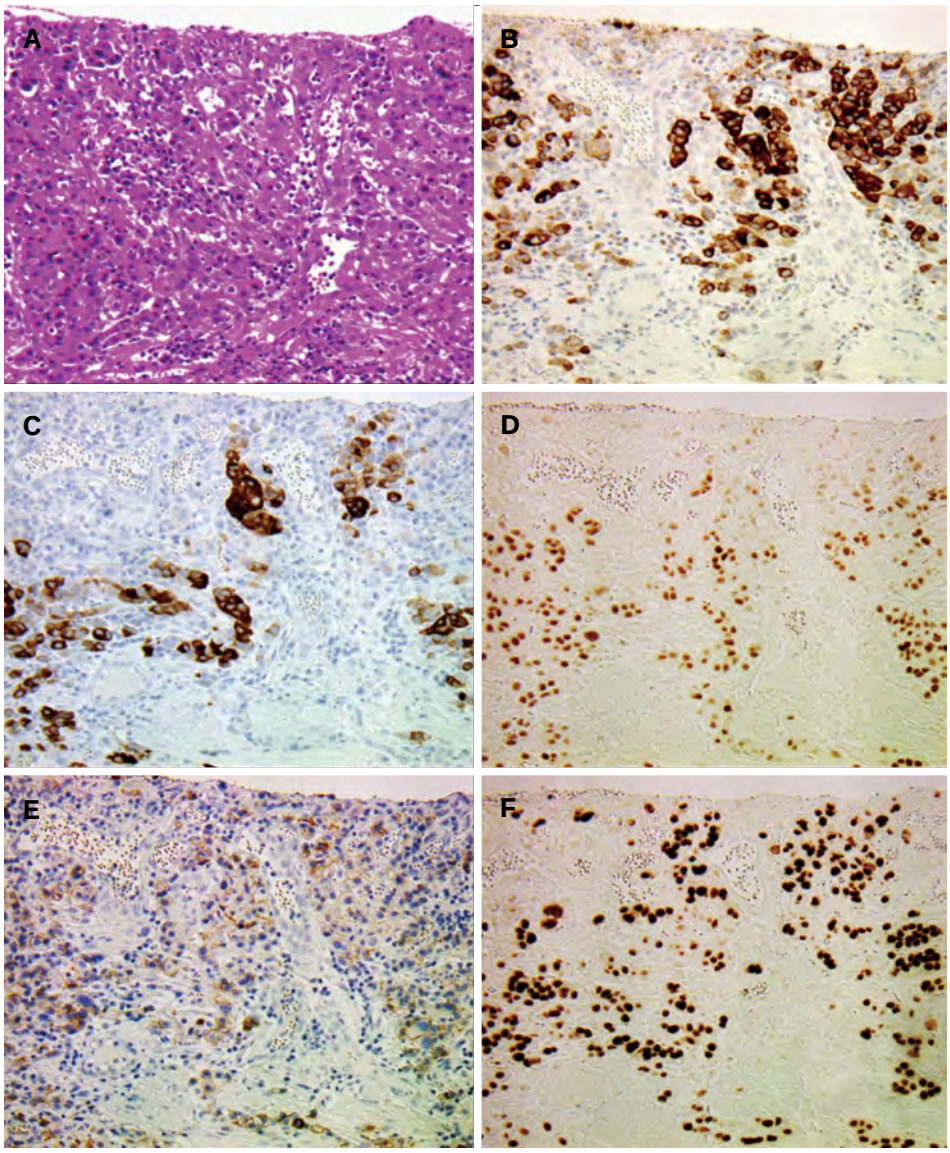

Figure 3 Histological findings of diffuse poorly-differentiated invasive adenocarcinoma (× 200). A: Hematoxylin and eosin staining of poorly-differentiated invasive adenocarcinoma (PDA). Cancer cells are diffusely scattered with prominent stromal reaction; B: Mucin (MUC) 5AC; C: MUC6; D: Caudal type homebox transcription factor 2 expression is positive in the PDA area; E: E-cad expression is markedly reduced in the PDA area; F: Strong p53 expression is observed in the nuclei of the cells in the PDA area.

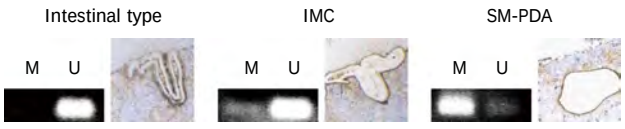

Figure 4 Detection of methylated cytosine by methylation-specific polymerase chain reaction analysis of caudal type homebox transcription factor 2 CpG-island region. Tissue samples were stained with E-cadherin and caudal type homebox transcription factor 2 (Cdx2) to assist cell identification. Cells, either isolated from intestinal metaplasia, intramucosal adenocarcinoma (IMC) or submucosal invasive poorly-differentiated adenocarcinoma (SM-PDA) by laser-assisted microdissection, were subjected to bisulfite conversion and subsequent methylation-specific polymerase chain reaction (MSP). MSP products using primers that specifically amplify only unmethylated DNA are indicated by visible polymerase chain reaction products in line unmethylated pattern (U), while visible polymerase chain reaction products in line methylated pattern (M) indicate those amplified by primers specific for methylated DNA. In intestinal-type metaplasia sections, MSP shows a U pattern, while MSP shows U patterns with partial M patterns in high-grade dysplasia or IMC sections. MSP shows a mostly M pattern in PDA where strong Cdx2 expression is observed (Figure 3D).

notyping, any apparent positive immunohistochemical results should be interpreted carefully with the help of the hypermethylation status as a molecular mark for gene silencing memory[10,11].

We thank Ms. Yuki Takaoka for technical assistance.

COMMENTS

Background

Barrett's esophagus, a pathological condition in which the esophageal squamous epithelium is replaced by metaplastic columnar mucosa, is known to predispose to the development of dysplasia and subsequent cancers.

Research frontiers

Caudal type homebox transcription factor 2 (Cdx2) has recently been shown to play a tumor-suppressor role in the 'metaplasia-dysplasia-carcinoma sequence'

in Barrett's esophagus.

Innovations and breakthroughs

Recent reports have evaluated the phenotypic stability and role of Cdx2 in the neoplastic progression of different types of dysplasias. This suggests that non-intestinalized columnar metaplasia may be an unstable intermediate state at risk for neoplastic progression.

Applications

When characterizing cancer cells by immunophenotyping, any apparent positive immunohistochemical results should be interpreted carefully with the help of the hypermethylation status as a molecular mark for gene silencing memory.

Peer review

The authors examined the expression of Cdx2 and its methylation in Barrett metaplasia and esophageal adenocarcinoma. It revealed that irrespective of the hypermethylation status of the *Cdx2* gene promoter, Cdx2 expression was restored in poorly-differentiated invasive adenocarcinoma. The results are interesting and when characterizing cancer cells by immunophenotyping, any apparent positive immunohistochemical result should be interpreted carefully.

Abstract

AIM: To investigated the incidence of diversion colitis (DC) and impact of DC symptoms on quality of life (QoL) after ileostomy reversal in rectal cancer.

METHODS: We performed a prospective study with 30 patients who underwent low anterior resection and the creation of a temporary ileostomy for the rectal cancer between January 2008 and July 2009 at the Department of Surgery, Korea University Anam Hospital. The participants totally underwent two rounds of the examinations. At first examination, endoscopies, tissue biopsies, and questionnaire survey about the symptom were performed 3-4 mo after the ileostomy creations. At second examination, endoscopies, tissue biopsies, and questionnaire survey about the symptom and QoL were performed 5-6 mo after the ileostomy reversals. Clinicopathological data were based on the histopathological reports and clinical records of the patients.

RESULTS: At the first examination, all of the patients presented with inflammation, which was mild in 15 (50%) patients, moderate in 11 (36.7%) and severe in 4 (13.3%) by endoscopy and mild in 14 (46.7%) and moderate in 16 (53.3%) by histology. At the second examination, only 11 (36.7%) and 17 (56.7%) patients had mild inflammation by endoscopy and histology, respectively. There was no significant difference in DC grade between the endoscopic and the histological findings at first or second examination. The symptoms detected on the first and second questionnaires were mucous discharge in 12 (40%) and 5 (17%) patients, bloody discharge in 5 (17%) and 3 (10%) patients, abdominal pain in 4 (13%) and 2 (7%) patients and tenesmus in 9 (30%) and 5 (17%) patients, respectively. We found no correlation between the endoscopic or histological findings and the symptoms such as mucous discharge, bleeding, abdominal pain and tenesmus in both time points. Diarrhea was detected in 9 patients at the second examination; this number correlated with the severity of DC (0%, 0%, 66.7%, 33.3% *vs* 0%, 71.4%, 23.8%, 4.8%, $P = 0.001$) and the symptom-related QoL ($r = -0.791$, $P < 0.001$).

CONCLUSION: The severity of DC is related to diarrhea after an ileostomy reversal and may adversely affect QoL.

Son DN, Choi DJ, Woo SU, Kim J, Keom BR, Kim CH, Baek SJ, Kim SH. Relationship between diversion colitis and quality of life in rectal cancer. *World J Gastroenterol* 2013; 19(4): 542-549 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/542.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.542

INTRODUCTION

The surgical interruption of fecal flow may induce inflammation in the non-functional region of the distal colon[1]. This condition, diversion colitis (DC), is particularly common after an ileostomy or a colostomy. Theoretically, the inflammation typically resolves when the fecal passage resumes[2]. In Western countries, the estimated incidence of DC ranges from 70% to 100%[1,3], but the incidence in Asian countries is unknown. Glotzer *et al*[4] first described the clinical symptom related to defunctioned colon. DC symptoms include abdominal pain, bleeding, mucous discharge, and tenesmus; however, many patients do not present with definitive symptoms[5]. Retrospective and prospective studies report abnormal endoscopic and histological findings in most DC patients[3,6-8]. For patients having rectal surgery for cancer, the functional outcome and quality of life (QoL) are related to the length of the remnant rectum, the radiation therapy parameters and the extent of anastomotic leakage[9-11]. After ileostomy reversal, DC may also influence QoL, but the significance of this influence has not been reported. We hypothesized that the endoscopic and histological incidence of DC before and after ileostomy reversal in rectal cancer patients will correspond with patient's symptoms and impact QoL. Thus, the aims of this study are to determine the incidence of DC and its impact on QoL after ileostomy reversal.

MATERIALS AND METHODS

Forty-eight consecutive patients had surgery for rectal cancer and the creation of a temporary ileostomy at our institution between January 2008 and July 2009. Rectal cancer was defined as tumor 16 cm or less from the anal verge measured with a rigid rectosigmoidoscope (lower third, < 6 cm; middle third, 6-12 cm; upper third, 12-16 cm). The eligible patients were aged 18 years or older with, an American Society of Anesthesiologists class 1 to 3 and diagnosed with rectal cancer within 16 cm from the anal verge. The initial exclusion criteria included inflammatory bowel disease, such as Crohn's disease or ulcerative colitis, preoperative or postoperative radiation therapy and anastomotic leakage after rectal cancer surgery. The indications for chemoradiation prior to surgery were as follows: T4 lesion involvement below the peritoneal reflection, bulky tumor mass or lateral pelvic lymph node metastasis. The surgical indications for rectal cancer included clinical T1-3 lesions based on a pelvic computed tomography and an magnetic resonance imaging, irrespective of any locally lymph node metastasis the within mesorectal fascia. For the enrolled patients, the stoma closure was performed 3-4 mo after the first surgery to allow for 8 patients with stage Ⅲ or Ⅳ disease to complete intravenous chemotherapy. Each patient was hospitalized on 1 d before the ileostomy reversal. At this time, they underwent the first round of endoscopy, tissue biopsy and completed a questionnaire. A single endoscopist conducted the colonoscopies without an enema to ensure the collection of abnormal tissues. Random biopsies were also performed on the descending or transverse colon, even in case of normal colonoscopic findings. A single pathologist examined the tissues. Both the endoscopist and the pathologist were blinded to the patient's symptoms. The first DC symptom questionnaire was also performed during these 3 to 4 mo. Five to six months after the ileostomy reversal, the same endoscopist and pathologist conducted endoscopic and histological examinations to evaluate for complete resolution of DC. In the second questionnaire, we investigated symptom changes and related QoL changes. The endoscopic findings were scored according to edema, mucosal hemorrhage and contact bleeding. These features were scored individually from 0 to 3, 0 to 3, and 0 to 1, respectively, for a total score of 0 to 7. The total score was defined as mild (1 to 2), moderate (3 to 5), or severe (6 to 7). The histological findings were scored according to acute inflammation, chronic inflammation, eosinophilic infiltration, crypt architecture distortion, follicular lymphoid hyperplasia and crypt abscess. These features were scored from 0 to 1; 0 to 2; 0 to 2; 0 to 1; 0 to 1; and 0 to 1, respectively, for a total score of 0 to 8. The total score was further defined as mild (1 to 3), moderate (4 to 6), or severe (7 to 8). Both of the questionnaires investigated DC symptoms such as mucous discharge, bleeding, abdominal pain and tenesmus. However, we excluded fecal frequency, incontinence and the symptoms that are associated with intestinal obstruction (abdominal distension and pain, and emesis). We also excluded the bleeding from hemorrhoids and anal fissures. The QoL section of the questionnaire assessed symptomatic changes from before to after ileostomy reversal as follows: "much worse", "slightly worse", "similar", "slightly better", or "much better". The institutional review board of our institution approved this study and all of the subjects provided informed consent.

Statistical analysis

The data were represented as the median (minimum-maximum), as appropriate for quantitative variables and frequency (percentage) for qualitative variables. The χ^2 test and Fisher's exact test were used to compare between the endoscopic and histological findings about incidence rates of DC, and to test difference or relation with symptoms according to severity of DC and QoL. *P* values less than 0.05 were considered statistically significant. The calculations were performed using SPSS version 12.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Between January 2008 and July 2009, 48 patients were enrolled in the study. However, preceding the study, 18 patients were excluded from the analysis because they underwent a bowel enema procedure (7 patients) that could alter mucosal findings or symptoms, had excessive bowel content that hindered a clear colonoscopic view (9 patients), or had an anastomotic stricture observed during colonoscopy that prevented the visualization of the proximal portion of the colon (2 patients). The final prospective analysis included 30 patients.

The patients' characteristics are listed in Table 1. The median age was 59 years (range: 31-73 years) and the male: female ratio was 7:3. The tumor was located in the upper rectum for 6 patients (20%), the mid-rectum for 5 patients (16.7%) and the lower rectum for 19 patients (63.3%). Only 8 patients received intravenous chemotherapy. Using the endoscopic and histological criteria, all of the patients (100%) developed DC after their ileostomy creation (Table 2). There was no significant difference between the endoscopic and the histological findings in terms of the DC grade prior to ileostomy reversal ($P = 0.084$) or 5-6 mo after reversal ($P = 0.195$), and the endoscopic and histological features decreased after the ileostomy reversal. The incidence of symptomatic DC was 63.3% after ileostomy creation, and 46.6% 5-6 mo after ileostomy reversal. Figure 1 shows the endoscopic findings by the mucosal hemorrhage and edema severity. Figure 2 shows histological findings by the eosinophilic infiltration and chronic inflammation severity. Of the endoscopic findings, edema and mucosal hemorrhage were most common, and contact bleeding was rare. The most common histological finding was chronic inflammation (100%), followed by eosinophilic infiltration (Table 3). The endoscopic and histological abnormalities disappeared or decreased after the ileostomy reversal (Table 3).

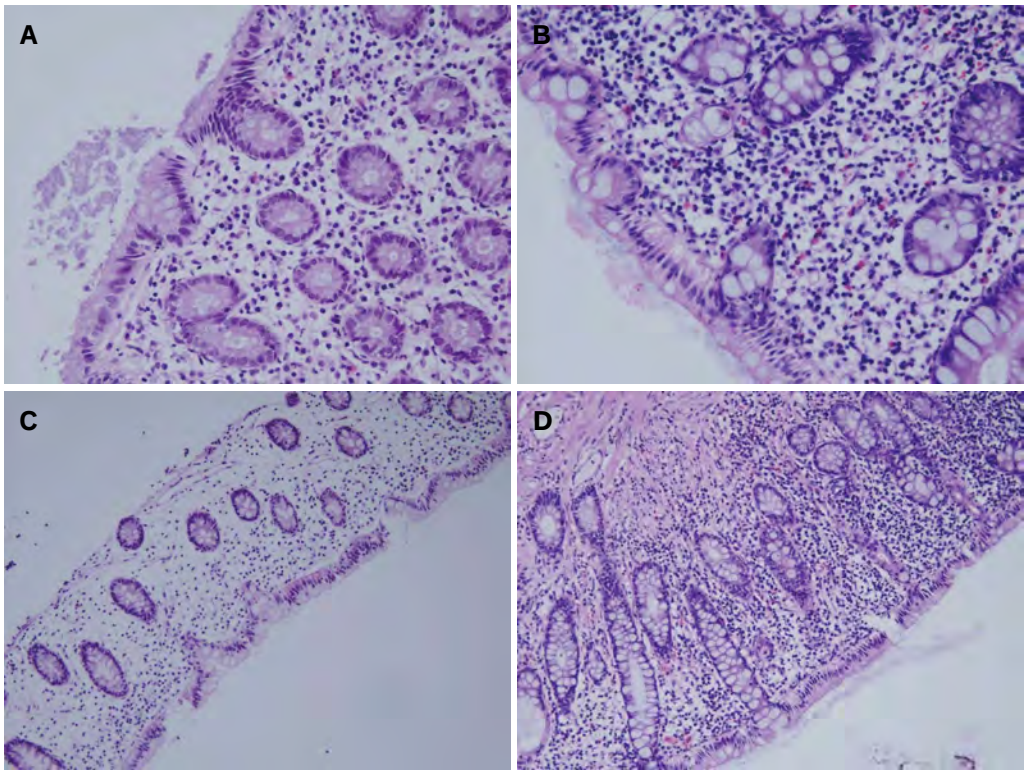

Figure 2 Example of major histological findings in diversion colitis according to relative severity. A, B: Eosinophilic infiltration including numerous cytoplasmic granules and bilobed nucleus (A: Score 1; B: Score 2; hematoxylin and eosin stain × 400); C, D: Chronic inflammation with mononuclear cell such as macrophage,lymaphocytes and plasma cells (C: Score 1; D: Score 2; hematoxylin and eosin stain × 200).

Before the ileostomy reversal, the most frequent initial symptom, according to the questionnaires, was mucous discharge, followed by tenesmus, bleeding and abdominal pain (Table 4). There were no reports of anal defecation caused by an ileostomy with incomplete diversion prior to the ileostomy reversal. The answers to the questionnaire conducted 5-6 mo after the ileostomy reversal showed that the symptoms had generally decreased since the first survey (Table 4). However, nine patients developed diarrhea as a new symptom (Table 4). We found no correlation between the endoscopic or histological findings and the symptoms before ileostomy reversal.

For example, there were mucous discharge ($P = 0.073$; $P = 0.284$), bleeding ($P = 0.338$; $P = 1.000$), abdominal pain ($P = 0.529$; $P = 0.602$), and tenesmus ($P = 0.075$; $P = 0.440$) (Table 4). Of the symptoms reported after the ileostomy reversal, only diarrhea correlated with the endoscopic and histological findings before the ileostomy reversal ($P = 0.001$; Table 4). In the second questionnaires, 4 patients indicated that they felt 'much worse', 8

[1]Spearman's correlation coefficient = -0.791.

patients felt 'slightly worse', 15 patients felt "similar" and 3 patients felt "slightly better" (Table 5). Finally, diarrhea showed a significant effect in the QoL relevance analysis of symptoms (r = -0.791, P < 0.001; Table 5).

DISCUSSION

Both the endoscopic and histological findings showed that 100% of the patients developed DC following the ileostomy creation. This figure exceeds the rates reported in Western populations (91% and 76%)[5,8]. The symptoms previously associated with DC include mucous discharge, rectal bleeding, abdominal pain and tenesmus[5]. We can check for diarrhea in patients with normal bowel continuity of bowel, but in patients with an ileostomy, we cannot. We expected that diarrhea would occur in DC after the ileostomy reversal as it commonly occurs in other forms of colitis (ulcerative colitis, Crohn's colitis and ischemic colitis). We tested this hypothesis using a questionnaire concerning symptoms, including diarrhea, with a study group that excluded the patients with inflammatory bowel disease and ischemic colitis.

DC symptom rates vary from 6% to 48%, although the overall occurrence is low[5,12,13]. Nineteen patients (63.3%) in our study had at least one symptom after ileostomy creation, and the incidence of symptoms after the ileostomy reversal was 46.6%. Thus, the incidence appears to have decreased slightly; however, these rates represent a dynamic situation. The current analysis showed that mucous discharge, bleeding, abdominal pain and tenesmus resolved, in 11 of 12 patients, 4 of 5 patients, all of 4 patients and 6 of 9 patients, respectively, after the

ileostomy reversal. Most of the symptoms disappeared; however, the symptoms experienced after the ileostomy reversal were either were continued or new but likely not caused by DC. For example, after the ileostomy reversal, 6 patients reported tenesmus; it was a new symptom in 3 patients and continued in 3 patients. Tenesmus can occur as the result of the rectal resection itself. Some authors have suggested that tenesmus resulted from altered motility and the reservoir function of the neorectum[14]. Considering the lack of a relationship between the DC symptoms (except diarrhea), and DC severity in this study, we assume that it is difficult to judge DC severity by these symptoms, particularly in patients with a temporary ileostomy. The endoscopic and histological findings, indicate that the inflammatory changes in DC resolve quickly after intestinal continuity is reestablished[5]. Some authors report normal sigmoidoscopy within 2 mo after restoring colonic continuity[4]. The patients in our study still had mild DC 5-6 mo after the ileostomy reversal. Therefore, the time to complete resolution of DC may vary and may not be predictable. To confirm this hypothesis, further evaluation is needed.

We must consider more active treatment selectively in symptomatic patients who have severe endoscopic/histological findings. There are two options for treating of symptomatic DC. DC symptoms may persist in patients with a permanent stoma. One patient with hemiplegia, for whom stoma reversal was not feasible, underwent rectal resection for severe DC[15]. Surgical treatment may have been appropriate here, but other studies show that medical treatment may also be effective. Early studies suggested that a deficiency of short chain fatty acids (SCFAs) in the excluded colon would contributes to DC[1]. Bacteria produce SCFAs as byproducts of carbohydrate fermentation in the colonic lumen, and SCFAs provide the primary energy source for colonic mucosal cells[15]. Some authors even argue that SCFAs enema may improve the symptoms and endoscopic findings[1]. In human neutrophils, SCFAs reduce the production of reactive oxygen species, which are the agents of oxidative tissue damage[16]. Therefore, SCFAs may be applicable to symptomatic DC patients who have temporary ileostomies.

The current study showed that there were no severe DC symptoms in the patients who had temporary ileostomies. This finding explains why the patients easily endured the ileostomy or, even though they were developed, and were able to wait for timing of ileostomy reversal after clinician's explanation. Most clinicians can predict which symptoms, may not merit treatment clinically.

Patients may not demand active treatment for other symptoms, but they will for diarrhea. The diarrhea appeared soon after the ileostomy reversal, and continued for a minimum of 3 wk and a maximum of 8 wk in this study. Most clinicians previously thought of diarrhea as low anterior resection syndrome (LARS) and others mistook it for a symptom of general enterocolitis. Most of the patients complained of anal skin irritation, lethargy and nervousness. Some went so far as to continue with a stoma rather than have their ileostomy reversed. In the present study, the patients who had diarrheal symptoms and no signs of obstruction could obtain some degree of control with anti-diarrheal agents such as loperamide.

Several factors may affect functional outcome and in QoL of rectal cancer. Hoerske *et al*[11] reported that patients diagnosed with lower rectal cancer have lower QoL score than those with upper and middle rectal cancer because of the smaller reservoir volume. Low anterior resection (LAR) for rectal cancer can leads to severe bowel dysfunction with fecal frequency, urgency and incontinence[17-19]. Other evidence suggests that patients who receive preoperative radiotherapy have a higher rate of urgency, diarrhea and fecal incontinence[20,21]. Therefore, we excluded the patients who received preoperative radiotherapy to limit the confusion with DC symptoms. Generally, radiation therapy can be used as local treatment for rectal cancer. Simunovic *et al*[22] reported that the local recurrence rate of rectal cancer was 6% in a preoperative radiation group *vs* 3% in a non-radiation group. This rate may indicate that radiation therapy can be omitted if surgery is performed on the proper surgical plane with exact preoperative evaluation of the mesorectal fascia. In this study, most of the patients with locally advanced cancer already had lymph node metastases within the mesorectal fascia in the preoperative evaluation. In the United States, however, postoperative chemoradiation therapy has been the standard treatment because of improved local control, without any effect on the overall survival rate[23]. In this study, the patients an advanced cancer stage, underwent chemotherapy only. Hypoxia in the post-surgical bed requires more radiation dose than preoperative state. Postoperative radiation can increase the possibility of acute and chronic gastrointestinal toxicities, such as radiation enterocolitis (including proctitis) and adhesions affecting the small bowel[24]. These events can negatively affect a patient's QoL. Postoperative complications such as anastomotic leakage after LAR can also result in poor long-term functional outcomes[9].

Although some important factors in functional outcome or QoL in this context are known, the role of DC after restoration of fecal movement is unknown. We conducted this study for this reason. The nine patients who developed diarrhea after the ileostomy reversal subsequently reported a moderate to large decrease in QoL. Most of the other symptoms did not correlate with the QoL. Diarrhea was also the only symptom that showed a significant correlation with the severity of DC; hence, we suggest that severe DC can be predicted by the occurrence of diarrhea alone after an ileostomy reversal. In the clinical environment, we propose that clinicians continue treatment with SCFA enemas instead of ileostomy reversal in patients with severe DC.

There are a few limitations in this study. First, the small sample size limited the statistical significance of our findings. Second, we did not use a validated questionnaire,

such as the Fecal Incontinence Quality of Life score analyzing multidimensional aspects that can indirectly reflect QoL. However, considering that the effectiveness of a questionnaire as a data collection tool depends on the nature of the study and the age of patients, we believe that modification of the questionnaire is needed. Third, 25 patients developed LARS with fecal frequency, urgency or incontinence after rectal cancer surgery. During the survey, most patients mistook fecal frequency or urgency for diarrheal symptom. Diarrhea is generally defined as the passage of abnormally liquid stool at an increased frequency, exceeding 200 g/d[25]. Although we tried to survey using an accurate definition, it was difficult to measure the total amount of stool per day. Future studies with a larger sample size, such as a multi-variate analysis of risk factors will be required to ascertain the relationship between LARS and diarrheal symptom. Finally, the pathogenesis of DC has been little reported until now. Some authors suggested that nitrate-reducing bacteria was found to be increased in the colon that is not receiving fecal flow[26]. We are investigating this issue at our hospital based on the hypothesis that differences in the colonic bacterial spectra may play a role in this variation.

In conclusion, in this study of South Korean patients diagnosed with rectal cancer, we observed a higher incidence of DC after temporary ileostomy than that reported for patients in Western countries. This is also the first study to indicate that DC after a temporary ileostomy may adversely affect patient QoL. The severity of DC after the closure of a diverting stoma appeared to influence patient QoL, primarily by causing diarrhea.

COMMENTS

Background

Up to now, the incidence of diversion colitis (DC) in western countries has been published in English literature, but not yet in eastern. Theorectically, DC can happen to patients with ileostomy after low anterior resection (LAR) in rectal cancer, in which patient's quality of life (QoL) after rectal resection is not only related to the remnant rectal length, but can be hypothesized to related to DC.

Research frontiers

Studies regarding the DC have mainly been limited to analyze clinicopathologic finding after surgical situation of the benign disease. Therefore, in patients with temporary ileostomy after LAR in rectal cancer, it would be great interest to examine the DC incidence in Asia and to evaluate if the severity of DC is related to patient's QoL after the ileostomy reversal.

Innovations and breakthroughs

The results of this study showed that DC developed in all patients with ileostomy after LAR and the symptoms in the period of diverting stoma were not correlated with severity of DC. But, diarrhea after the ileostomy reversal was related to the severity of DC.

Applications

There is a need to take notice of DC effect on the patient's QoL in rectal cancer. Severity of DC before an ileostomy reversal in rectal cancer can predict the patient's QoL after an ileostomy reversal and lead the patients into proper education and more intensive management. Also, on the base of this result, clinicians need to proceed the further study to clarify why the severity of DC is variable between the individual with patient's symptoms and impact QoL.

Terminology

DC is defined as the surgical interruption of fecal flow induce inflammation in the non-functional region of the distal colon and this is characterized that the inflammation typically can resolve when the fecal passage resumes.

Peer review

This paper is very well written in spite of a small sample size and has a possible message that the severity of DC seems to have an influence on patient's QoL, particularly on diarrhea, after reversal of a diverting stoma.

Abstract

AIM: To investigate factors contributing to the colon transit time (CTT), physical activity and characteristics were examined.

METHODS: Forty-seven Korean adults (males, *n* = 23; females, *n* = 24) took a capsule containing 20 radio-opaque markers to measure the CTT. The subjects used an accelerometer to measure the physical activity and underwent a bioelectrical impedance analysis to determine the physical characteristics. Macro-nutrient was also surveyed.

RESULTS: The mean total CTTs (TCTT) in the males and females were 8.8 and 24.7 h (*P* = 0.002), respectively. In the male subjects, the right CTT (3.5 ± 4.9 h *vs* 10.0 ± 11.6 h, *P* = 0.023) and recto-sigmoid CTT (4.4 ± 4.7 *vs* 13.6 ± 12.5 h, *P* = 0.004) were significantly shorter and the total energy expenditure (637.6 ± 44.3 kcal *vs* 464.3 ± 64.9 kcal, *P* = 0.003), total activity count (247 017 ± 75 022 count *vs* 178 014 ± 75 998 count, *P* = 0.003), energy expenditure of light intensity (148.5 ± 6.9 kcal *vs* 120.0 ± 16.8 kcal, *P* = 0.006), energy expenditure of moderate intensity (472.0 ± 36.2 kcal *vs* 281.4 ± 22.2 kcal, *P* < 0.001), fat intake (65.5 ± 23.3 g *vs* 51.2 ± 17.4 g, *P* = 0.010), and water consumption (1714.3 ± 329.4 g *vs* 1164.7 ± 263.6 g, *P* = 0.009) were significantly higher than in the female subjects. Regarding correlations, when adjusted for gender, fiber (*r* = -0.545, *P* < 0.001) and water intake (*r* = -0.257, *P* < 0.05) correlated significantly with the TCTT in all subjects. In addition, the body mass index (*r* = -0.424, *P* < 0.05) and fiber intake (*r* = -0.417, *P* < 0.05) in the males as well as the fiber intake (*r* = -0.655, *P* < 0.001) in the females showed significant correlations with the TCTT.

CONCLUSION: The subjects showed significant gender differences in the TCTT, right CTT, and recto-sigmoid CTT. Furthermore, the intake of the fiber and water contributed to the CTT.

INTRODUCTION

Colorectal cancer is the third most prevalent human cancer worldwide, with 1 million estimated new case annually, of which, about 50% lead to death[1]. The recog-

nized risk factors include westernized eating habits, obesity, insufficient physical activity and genetic factors[2,3]. However, the effects of gender and individual behavior on the colon transit time (CTT) remain controversial. In some studies, some factors affecting the CTT include age, gender, body mass index (BMI), dietary fiber, water intake, and living habits[4-6]. On the other hand, in a literature review of factors affecting the CTT, age[7], gender[2,3,7], BMI[8], and dietary fiber[9] were not found to be statistically significant.

The impact of exercise and physical activity (PA) on the gastrointestinal and colonic tracts is an area of emerging interest, with recent research focusing on the potential benefits of PA[3,4]. PA is known to be associated with colonic function and constipation[9,10]. In addition, walking, running, and strength training are known to reduce the CTT[10,11]. Also, a period of physical inactivity in subjects who had been engaged in regular PA for several years significantly increased the CTT[12,13]. At present, leisure time activities and transport activities constitute the majority of one's daily physical over all activity[14-16]. Increasing PA is an important health goal for everyone, but doing this requires an accurate method of measuring daily PA. To solve this problem, accelerometers are now being utilized in studies of PA. Accelerometers measure the acceleration of movement and can quantify the intensity, frequency and duration of movement. Lightweight, small and very durable, accelerometers are practical for all ages and activities and can be used indoors or outdoors. Several studies to date have supported the use of accelerometers to assess energy expenditure during locomotion and have confirmed a validity range of 0.77-0.89[11,12,16,17]. For this reason, to measure PA, we analyzed total energy expenditure and energy expenditure of low-, moderate-, and vigorous intensity physical activities using an accelerometer.

Measuring the CTT by the radio-opaque marker method is simple, widely available and important for the diagnosis of slow transit constipation[18-20]. Although there are several reports which sought to measure the CTT using Kolomark™, a radio-opaque marker, normative data on South Koreans are still lacking. Thus, to understand colonic motor function in Koran adults, the CTT was analyzed using Kolomark™ in the present study. To investigate the factors which influence the CTT in South Korean adults, we examined the effects of gender, physical characteristics, physical activity, and macro-nutrient and water intake on the CTT.

MATERIALS AND METHODS

Participants

The study subjects were 47 adults, 23 of whom were male and 24 female. The mean age was 36.0 years with a range of 25-59 years, and all voluntarily gave written informed consent. Of all potential subjects, those with any possible restriction on their normal PA or diet, those with cardiovascular or orthopedic disease which may affect the CTT, menstruating woman those who cannot ingest drugs due to functional stomach diseases, and those on any prescription of anti-constipation drugs or for diabetes mellitus or hypertension were excluded from the current analysis.

Measurement of physical characteristics

A bioelectrical impedance analysis (Inbody, Biospace, Seoul, South Korea) was used to measure the height, weight, BMI, lean body mass (LBM), and percentage of body fat (BF) at the beginning of the study in a fasted state.

Measurement of physical activity

PA was measured over a 1-wk period using an accelerometer (Actical, Mini Mitter, Chicago, IL, United States). To measure PA accurately, the study subjects were advised to perform their daily PA as they normally would. The accelerometer was attached to the iliac crest using a belt. Prior to measurement, the age, sex, height and weight of each participant were entered into the device. The total energy expenditure, activity energy expenditure, and time of activity depending on the PA intensity and frequency were individually measured according to the time. The results were automatically stored. Using the recorded data, the energy expenditure was calculated based on Muffin's formula to calculate the basal metabolic rate[11,17].

Analysis of macro-nutrient intake

To determine the average daily energy, carbohydrate, protein, fat, fiber and water intake, all participants recorded their daily dietary information using the dietary recall method over a 1 wk period during the accelerometer phase. Foods that could not fit into a standard measure were described by the dimensions of their shape, with a grid measured in centimeters to allow these measurements to be done accurately. The dietary records were analyzed using the nutrient analysis program.

Measurement of the CTT

To measure the colonic motor function, the CTT was measured using a multiple marker technique with a radio-opaque marker (Kolomark™, MI Tech, Pyeongtaek, South Korea). The subjects took one capsule containing 20 radio-opaque markers at the same time every day for three consecutive days. On the fourth day, following the first administration, a supine abdominal radiograph was performed. The mean CTT (hours) was calculated by counting the number of radio-opaque markers that were left in the total colon and in each segment of the colon and then multiplying this number by 1.2[18-20].

Ethics

This work was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. This study was approved ethically by the Institutional Review Board of Seoul National University (IRB No. 2011/1006). All patients provided informed written consent.

Table 1 Physical characteristic of the participants

Variable	Male (n = 23)	Female (n = 24)	Total (n = 47)	P value
Age (yr)	37.3 ± 5.8	35.9 ± 5.6	36.0 ± 5.9	0.108
Height (cm)	172.1 ± 5.1	159.6 ± 6.3	165.2 ± 8.5	< 0.001
Weight (kg)	75.6 ± 12.5	55.2 ± 6.8	64.4 ± 14.1	< 0.001
BMI (kg/m^2)	24.5 ± 3.5	21.7 ± 2.5	23.4 ± 3.5	< 0.001
LBM (kg)	57.1 ± 15.3	41.1 ± 5.0	48.3 ± 13.5	< 0.001
BF (%)	21.1 ± 8.7	25.5 ± 3.5	23.5 ± 6.7	0.009

Data are presented as mean ± SD. BMI: Body mass index; LBM: Lean body mass; BF: Body fat.

Table 2 Physical activity amount and intensity of the subjects

Variable	Male	Female	Total	P value
TEE (kcal)	637.6 ± 44.3	464.3 ± 64.9	542.4 ± 54.9	0.003
TAC (count)	247 017 ± 75 022	178 014 ± 75 998	212 515.5 ± 75 501	0.003
EEL (kcal)	148.5 ± 6.9	120.0 ± 16.8	133.1 ± 16.8	0.006
EEM (kcal)	472.0 ± 36.2	281.4 ± 22.2	367.4 ± 22.2	< 0.001
EEV (kcal)	24.5 ± 6.7	11.1 ± 47.8	17.8 ± 13.8	0.214

Data are presented as mean ± SD. TEE: Total energy expenditure; TAC: Total activity count; EEL: Energy expenditure of light intense activity; EEM: Energy expenditure of moderate intense activity; EEV: Energy expenditure of vigorous intense activity.

Table 3 Daily macro-nutrients intake of the subjects

Variable	Male	Female	Total	P value
Totalenergy (kcal)	2193.1 ± 259.2	2091.5 ± 229.2	2147.2 ± 233.6	0.292
Protein (g)	85.0 ± 18.6	82.5 ± 20.9	83.6 ± 19.6	0.493
Fat (g)	65.5 ± 23.3	51.2 ± 17.4	59.0 ± 21.9	0.010
Carbohydrate (g)	338.8 ± 71.7	298.5 ± 42.4	305.8 ± 61.2	0.054
Fiber(g)	8.1 ± 4.5	9.9 ± 4.7	8.9 ± 4.6	0.133
Water (g)	1714.3 ± 329.4	1164.7 ± 263.6	1227.0 ± 286.8	0.009

Data are presented as mean ± SD.

Table 4 Segmental colon transit time of the subjects

Variable	Male	Female	Total	P value
LCTT (h)	0.9 ± 2.2	1.1 ± 3.0	1.0 ± 2.6	0.592
RCTT (h)	3.5 ± 4.9	10.0 ± 11.6	6.8 ± 9.6	0.023
RSCTT (h)	4.4 ± 4.7	13.6 ± 12.5	9.0 ± 8.6	0.004
TCTT (h)	8.8 ± 9.4	24.7 ± 23.6	16.8 ± 16.2	0.002

Data are presented as mean ± SD. RCTT: Right colon transit time; LCTT: Left colon transit time; RSCTT: Recto-sigmoid colon transit time; TCTT: Total colon transit time.

Statistical analysis

Data analysis was conducted using the SPSS software package (version 18.0, SPSS Inc., Chicago, IL, United States), and descriptive statistics were presented using mean ± SD. The differences in the variables between the males and females were verified by an independent samples t-test. To assess the correlation between the total CTT and all of the experiment variables, Partial's correlation coefficient (r) was determined. An adjustment was made for gender. The level of significance (P) was 0.05 for all statistical analyses.

RESULTS

Physical characteristics

The physical characteristics of all subjects are presented in Table 1. The mean age was 37.3 and 35.9 years in the male and female subjects, respectively. The variables associated with the physical characteristics of the height, body weight, BMI and LBM were significantly higher in the males than in the females (P < 0.001). On the other hand, the BF was significantly lower in the male subjects than in the female subjects (P = 0.009).

Physical activity amount and intensity

The amounts and intensities of the PA of the male and female subjects are shown in Table 2. The total energy expenditure (173.3 kcal, P = 0.003), total activity count (69 003 count, P = 0.003), energy expenditure of light intensity (EEL) (28.5 kcal, P = 0.006), and energy expenditure of moderate intensity (EEM) (190.6 kcal, P < 0.001) were significantly higher in the male subjects than in the female subjects.

Macro-nutrient intake

Daily macro-nutrient and water intake by the subjects are presented in Table 3. The intake levels of fat (14.3 g, P = 0.010) and water (549.6 g, P = 0.009) were significantly higher in the males than in the females.

Segmental CTT and total CTT

The mean total CTT (TCTT) was 8.8 h and 24.7 h in the male and female subjects, respectively. This gender difference was statistically significant (P = 0.002). Although there was no significant difference in the left CTT, the right CTT (P = 0.023) and recto-sigmoid CTT (P = 0.004) showed significant gender difference (Table 4).

Correlation between the TCTT and parameters

Correlations between the TCTT and related parameters for the male and female subjects are shown in Table 5. In the male subjects, the BMI (r = -424, P < 0.05) and fiber intake levels (r = -417, P < 0.05) showed significant correlations with the TCTT. On the other hand, only the fiber intake (r = -655, P < 0.001) showed a significant correlation with the TCTT in the female subjects. Moreover, when adjusted for gender, the fiber (r = -545, P < 0.001) and water (r = -257, P < 0.05) intake levels showed significant correlations with the TCTT in all subjects.

DISCUSSION

All physical characteristics were higher in the male subjects, except for the BF, but even those values were within the normal range. These values indicate that the South Korean adults who participated in this study were relatively healthy.

[1]Adjusted for gender. BMI: Body mass index; LBM: Lean body mass; BF: Body fat; TEE: Total energy expenditure; TAC: Total activity count; EEL: Energy expenditure of light intense activity; EEM: Energy expenditure of moderate intense activity; EEV: Energy expenditure of vigorous intense activity.

Despite longstanding disputes, it is uncertain as to whether or not there is any difference in the CTT between males and females. In our study, the comparison of the TCTTs according to gender showed that the mean TCTTs of the males and females were 8.8 and 24.7 h, respectively. Drossman *et al*[21] and Heaton *et al*[22] reported that the prevalence of constipation is higher in women in than in man, and that it becomes more prominent in woman of childbearing age, suggesting a role of the female sex hormone. Jung *et al*[6] reported that the mean TCTT of healthy South Korean subjects was 22.3 h in male subjects and 30.1 h in female subjects and that was no significant difference in the TCTT between male and female subjects. In our study, however, a significant difference was noted in the TCTT according to gender. Moreover, the RCTT and RSCTT in females showed were significantly longer than they were in males. A radio-opaque marker study can provide us with information about the segmental CTT. Our study showed that gender and the LCTT were unrelated. Jung *et al*[6] showed that the RSCTT was significant longer in the female subjects, whereas TCTT, RCTT, and LCTT differences in terms of gender were not significant. Rao *et al*[23] in a study that used ambulatory 24 h colonic manometry revealed that women showed less pressure activity than men and that this difference was particularly significant in the transverse descending colon. Therefore, a gender difference may contribute to the prevalence of constipation in women. However, more studies of variables and sample sizes regarding this mechanism are required.

Because a sedentary lifestyle is a risk factor for chronic disease, promoting PA is very important[24,25]. Some studies reported that factors that can influence the CTT are regular PA and regular physical exercise, both of which are considered to be useful in the management of chronic constipation[26,27]. This is based partly on the assumption that exercise shortens the CTT through the gastrointestinal tract. However, studies testing the influence of exercise on the CTT in healthy young subjects show conflicting results. Some studies showed a decrease in the CTT after physical training[11-13], whereas other studies did not show a reduction partly owing to large intra-individual differences[28-30]. In our study, although South Korean male adults engaged in more PA with or without an adjustment for gender, the CTT did not correlate with the PA levels.

Regarding the intake of dietary fiber and water, several studies have shown that the CTT was shortened and the stool frequency increased when the amounts of dietary fiber and water increased[31-34]. In our study, the mean CTT also showed a significant correlation with the amount of dietary fiber intake in all subjects. This result is similar to those of previous studies, which found that the CTT is significantly correlated with dietary fiber intake. We observed an inverse association between the TCTT and fiber intake in males, females, and in all subjects with or without an adjustment for gender. This result indicates that fiber intake is a strong contributing factor which affects the CTT in South Korean adults. For water intake, although all subjects showed significant correlation between this and the TCTT, the discrepancy in water consumption may be due to the limitation of the measurement methods based on the subjects' food diaries. The Can-pro program by the Korean Nutrition Society does not analyze the moisture content of food. Thus, the surveyed amounts of consumed water were used for the water intake amounts. As a result, the amounts of water contained in the subject's food intake level were excluded from total water consumption in our study. However, although our ability to analyze water consumption was limited, water consumption was shown to help the CTT in all subjects in the present study. The current study was also limited by the small sample size, which prevents any generalization of the study results. Therefore, further studies should be conducted with more subjects.

Other factors that can influence the CTT include physical characteristics such as weight, and height and age[4,5]. In our study, the average BMI of the subjects was 24.5 kg/m^2 for the men and 21.7 kg/m^2 for the women. Considering that the normal range of BMI reported by the World Health Organization was 18.5-25.0 kg/m^2 for adults, these values indicate that the South Korean adults who participated in this study were relatively healthy. The finding of a correlation between the TCTT and BMI in the male subjects, but not in the female subjects, showed that the BMI increased the CTT, as in previous studies. The precise mechanism between the BMI and CTT could not be explained, although possible reasons include differences in eating habits and living patterns.

In our study, the BMI was a factor contributing to the CTT in only males. Martelli *et al*[4] showed that the CTT of healthy older subjects (age 55-74 years) was longer on average than that of healthy young subjects (age 21-27 years). However, in our study, age did not correlate with the CTT for those aged 25-59 years.

Based on these results, significant gender differences were noted in the TCTT, RCTT and RSCTT. The BMI and fiber intake in males and fiber intake in females were shown to assist the CTT. Moreover, the intake of the fiber and water intake was shown to help the CTT in all subjects.

COMMENTS

Background

The recognized risk factors of colorectal cancer include westernized eating habits, obesity, insufficient physical activity and genetic factors. However, the effects of gender and individual behavior on the colon transit time (CTT) remain controversial.

Research frontiers

The impact of exercise and physical activity (PA) on the gastrointestinal and colonic tracts is an area of emerging interest, with recent research focusing on the potential benefits of PA.

Innovations and breakthroughs

The authors measured physical activity by accelerometer, colon transit time by radio-opaque marker method and food intake by the nutrient analysis program that are all very good and relevant. Colon transit time in South Korean general population showed gender difference and modulation of CTT by the intake of fiber and water.

Applications

CTT has a gender difference which are involved total calories, energy expenditure, physical activity, and water consumption. Regardless the gender, the intake of fiber and water modulated to reduce colon transit time. It can help the general advise for life habit with patients of constipation. A further study that including larger sample size and physical activity intervention may assist to elucidate the precise relationship between physical activity and colon movement.

Peer review

The authors have studied CTT according to physical activity and characteristics in South Korean, finding that significant gender differences in the total CTT, right CTT, and recto-sigmoid CTT adults. The manuscript is a good study and should be acceptable.

Abstract

AIM: To propose a new endoscopic classification of achalasia for selecting patients appropriate for undergoing peroral endoscopic myotomy (POEM).

METHODS: We screened out the data of patients with achalasia examined from October 2000 to September 2011 at our Digestive Endoscopic Center with endoscopic pictures clear enough to reveal the morphology of middle and lower esophagus. After analyzing the correlation between the endoscopic morphology of the esophageal lumen and POEM, we proposed a new endoscopic classification (Ling classification) of achalasia according to three kinds of endoscopically viewed structures: multi-ring structure, crescent-like structure and diverticulum structure. There were three types based on the criteria of Ling classification: type Ⅰ, smooth without multi-ring, crescent-like structure or diverticulum structure; type Ⅱ, with multi-ring or crescent-like structure but without diverticulum structure; and type Ⅲ, with diverticulum structure. Type Ⅱ was classified into three subtypes: Ling Ⅱa, Ling Ⅱb and Ling Ⅱc; and type Ⅲ also had three subtypes: Ling Ⅲl, Ling Ⅲr and Ling Ⅲlr. Two endoscopists made a final decision upon mutual agreement through discussion if their separately recorded characteristics were different.

RESULTS: Among the 976 screened patients with achalasia, 636 patients with qualified endoscopic pictures were selected for the analysis, including 405 males and 231 females. The average age was 42.7 years, ranging from 6 to 93 years. Type Ⅰ was the most commonly observed type of achalasia, accounting for 64.5% (410/636), and type Ⅲ was the least commonly observed type of achalasia, accounting for 2.8% (18/636). And type Ⅱ accounted for 32.7% (208/636) and subtype of Ling Ⅱa, Ling Ⅱb and Ling Ⅱc accounted for 14.6% (93/636), 9.9% (63/636) and 8.2% (52/636), respectively. And subtype of Ling Ⅲl, Ling Ⅲr and Ling Ⅲlr accounted for 0.8% (5/636), 0.3% (2/636) and 1.7% (11/636), respectively.

CONCLUSION: A new endoscopic classification of achalasia is proposed that might help in determining the proper candidates for POEM.

INTRODUCTION

Treatments for achalasia include pharmacological therapy, endoscopic injection of botulinum toxin, endoscopic dilation, and laparoscopic or open surgery[1-5], among which laparoscopic surgery with fundoplication has been widely accepted as the primary therapy because of its low complication rate, durable symptom relief, and low incidence of postoperative gastroesophageal reflux[6-10]. However, a new alternative therapy named peroral endoscopic myot-

omy (POEM) has recently been reported to be effective clinically for esophageal achalasia without serious complications at least in a short term[11-13]. We have performed POEM since 2010, and found that not all the patients with achalasia were eligible to undergo POEM. If the esophageal lumen was too tortuous or if a diverticulum was formed in the middle or the lower part of the esophagus, to establish an appropriate submucosal tunnel would, to a great extent, cause a penetrative damage to the mucosa or the muscularis propria, which obviously destroyed the completeness of the submucosal tunnel, leading to a serious outcome such as mediastinitis if not successfully treated in time. Mucosal penetration at the gastric cardia has been firstly reported to occur respectively in 2 out of 5 and 2 out of 17 patients in two studies, although it did not cause serious consequences[12-14]. The occurrence of mucosal penetration at the cardia was also confirmed by several other studies[15-19]. Therefore, it is very important and necessary to make a precise judgment whether or not a patient with achalasia is a proper candidate for POEM. Inoune *et al*[12] suggested that a patient was not fit for a POEM therapy if a double-lumen sign was detected in the esophageal computed tomography (CT). However, no other studies have, to our best knowledge, reported the correlation between the morphology of the esophageal lumen and the indications of POEM. To better judge if a patient was suitable for POEM, we analyzed the correlation between the endoscopic morphology of the esophageal lumen and POEM, and proposed a new endoscopic classification of achalasia (Ling classification), hoping to assist in determining the indications of POEM.

MATERIALS AND METHODS

We reviewed the data of endoscopic examinations of patients diagnosed with achalasia from October 2000 to September 2011 at our Digestive Endoscopic Center and screened out the data of patients with endoscopic pictures clear enough to reveal the morphology of the middle and the lower parts of the esophagus. Two endoscopists (Li HK and Linghu EQ) independently recorded the characteristics of the morphology of the middle and the lower parts of the esophagus, which included three endoscopically detected intraluminal structures: multi-ring structure, crescent-like structure and diverticulum structure. There were three types according to the Ling classification[20]: type Ⅰ, smooth without multi-ring, crescent-like structure or diverticulum structure; type Ⅱ, with multi-ring or crescent-like structure but without diverticulum structure; and type Ⅲ, with diverticulum structure (Figure 1). Type Ⅱ was further divided into three subtypes: Ling Ⅱ$_a$, Ling Ⅱ$_b$ and Ling Ⅱ$_c$, and type Ⅲ also had three subtypes: Ling Ⅲ$_l$, Ling Ⅲ$_r$ and Ling Ⅲ$_{lr}$. The criteria for classifying subtypes Ⅱ and III were as follows: Ling Ⅱ$_a$, with multi-ring structure; Ling Ⅱ$_b$, with crescent-like structure and the midpoint of its inner edge not larger than 1/3 of the esophageal lumen; Ling Ⅱ$_c$, with crescent-like structure and the midpoint of its inner edge over 1/3 of the esophageal lumen; Ling Ⅲ$_l$, diverticulum structure in the left wall of esophagus; Ling Ⅲ$_r$, diverticulum structure in the right wall of esophagus; and Ling Ⅲ$_{lr}$, diverticulum structure in both the left and right walls of esophagus. If the two endoscopists recorded different characteristics, they would discuss together and made a final decision upon mutual agreement.

RESULTS

Data of 976 patients with achalasia were collected and analyzed, and 636 of them were screened out with clear endoscopic pictures revealing the morphology of middle and lower esophagus, while 340 were excluded for unqualified pictures. Among the 636 patients, 405 were male and 231 were female. The average age was 42.7 years, ranging from 6 to 93 years.

We named our proposed classification Ling classification since Ling is short for Linghu, which is the family name of the corresponding author. As shown in Table 1, 64.5% (410/636) of the patients were classified as type Ⅰ, which was the most common type of achalasia based on the Ling classification; 32.7% (208/636) of the patients were classified as type Ⅱ; and only 2.8% (18/636) as type Ⅲ. The typical pictures of each type or subtype are shown in Figure 1. The proportion of each type or subtype is described in Table 1 according to the Ling classification.

DISCUSSION

As early as in 1980, Ortega *et al*[21] for the first time performed cutting esophageal muscles using the needle knife through the peroral endoscope, but few doctors followed them due to the possible mediastinal contamination. Until 2007, Pasricha *et al*[22] reported the possibility of POEM through a submucosal tunnel in a porcine model. In 2010, Inoue *et al*[12] started to use POEM to treat patients with achalasia after several refinements, including applications of endoscopic submucosal dissection technique, the triangle-tip knife, positive pressure ventilation and CO_2 insufflations through the endoscope during POEM, and they reported a satisfactory short-term effects. Swanström *et al*[13] also reported their experience of POEM in patients with achalasia and esophageal motility disorders. Both of the above-mentioned clinical trials demonstrated that small mucosal penetration at the gastric cardia occurred respectively in 2 out of 5 and 2 out of 17 patients, but were treated differently. Inoue observed the penetrations without special treatment, while Swanström used traditional hemostatic clips to seal the penetrations. Even though no serious clinical outcomes were observed, we should keep alert about the incompleteness of the submucosal tunnel caused by mucosal penetration at the cardia, and we used fibrin sealant to treat this mucosal penetration[15]. If the penetrations were *in situ*, fluids from the stomach or the esophagus might flow into the tunnel, which might affect the healing of the incised inner circular muscles and further influence the effects of POEM.

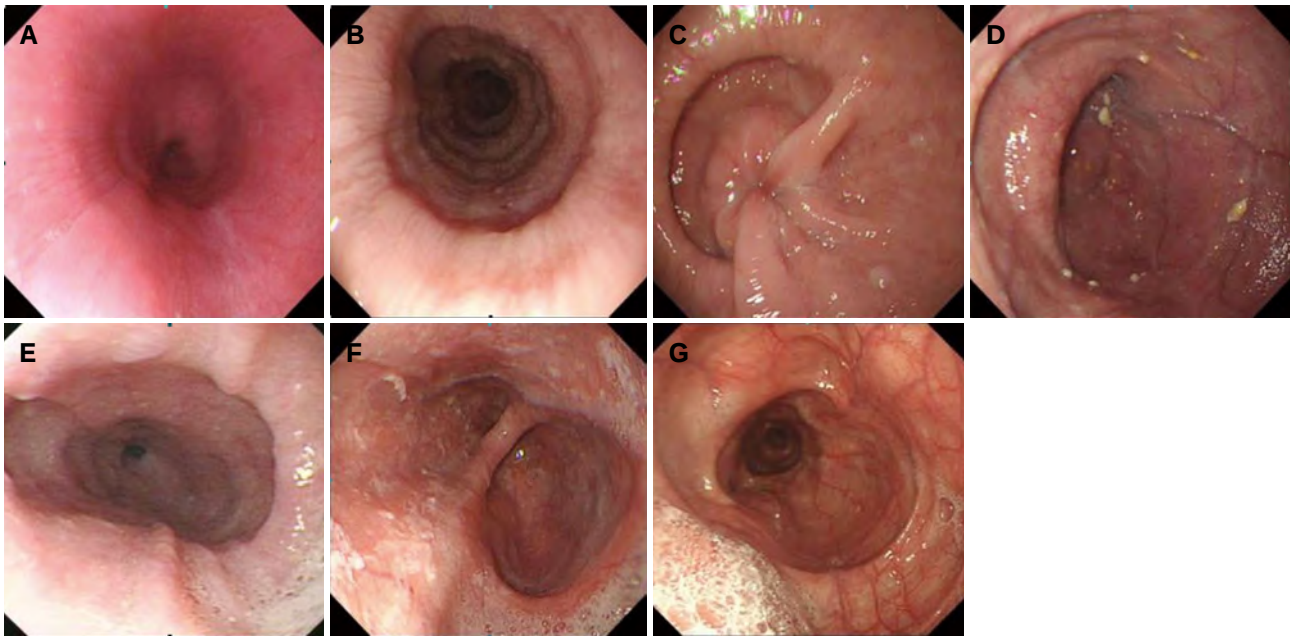

Figure 1 Typical pictures of each type or subtype in Ling classification. A: Type Ⅰ; B: Type Ⅱa; C: Type Ⅱb; D: Type Ⅱc; E: Type Ⅲl; F: Type Ⅲr; G: Type Ⅲlr.

Table 1 Proportion of each type or subtype according to Ling classification *n* (%)

Type	Proportion
Ling Ⅰ	410 (64.5)
Ling Ⅱ	208 (32.7)
Ling Ⅱa	93 (14.6)
Ling Ⅱb	63 (9.9)
Ling Ⅱc	52 (8.2)
Ling Ⅲ	18 (2.8)
Ling Ⅲl	5 (0.8)
Ling Ⅲr	2 (0.3)
Ling Ⅲlr	11 (1.7)

We think that the reason why mucosal penetrations are more likely to occur in the cardia is that the working space in the submucosal tunnel near the cardia is narrower than in other parts, which makes a precise electrocautery without damaging the cardiac mucosa very difficult. Similarly, if POEM was performed in patients with a very tortuous esophagus, penetrations of mucosa or muscularis propria could happen where the working space is confined by the tortuousness of the esophagus. So, from the point of minimizing complications like penetrations of mucosa or muscularis propria, it is very important to make a precise judgment whether a patient with achalasia is or not a proper candidate for POEM. Inoune mentioned that a patient was not fit for a POEM therapy if a double-lumen sign was detected in the CT scan[12], however, no other studies on POEM have reported the correlation between the morphology of esophageal lumen and the indications of POEM[13-14,16-18]. We, therefore, proposed the endoscopic Ling classification of achalasia, hoping to assist in determining the indications of POEM after analyzing the correlation between the endoscopic morphology of the esophageal lumen and POEM.

After reviewing the endoscopic pictures of nearly 1000 patients, we screened out 636 patients with pictures clear enough to reveal the middle and lower esophagus and analyzed the characteristics of the morphology of esophagus. Because the submucosal tunnel established during POEM generally starts from the middle esophagus and ends at about 3 cm distal to the cardia[12,13], we focused on the morphology of the middle and lower esophagus. Based on the Ling classification, the esophagus of type Ⅰ is very smooth and without multi-ring structure, crescent-like structure or diverticulum structure, so type Ⅰ patients are the most safe type to undergo POEM. The esophagus of type Ling Ⅱa with multi-ring structure was not so smooth as type Ⅰ, but not much difficulties were encountered during establishment of the submucosal tunnel in our practice of POEM. The crescent-like structure present in type Ling Ⅱb or Ling Ⅱc actually reflexes the tortuousness of the esophageal lumen, and the degree of tortuousness is more severe in Ling Ⅱc than in Ling Ⅱb, and therefore to establish a submucosal tunnel across the tortuous point of the esophagus is more difficult and more likely to cause a penetration in Ling Ⅱc than in Ling Ⅱb. Diverticulum structure occurred in type Ⅲ, making it the most challenging type to establish a submucosal tunnel across the diverticulum.

Location of the crescent-like structure or the diverticulum structure can greatly affect the success of a POEM therapy. Since we and other operators[12,13] preferred the establishment of submucosal tunnel in the right wall of the esophagus leading to the lesser curvature of stomach, the submucosal tunnel would be very difficult to be established if a crescent-like structure or diverticulum structure was located in the right wall of the esophagus. Otherwise, if a crescent-like structure or diverticulum

structure was located in the left wall of the esophagus, the submucosal tunnel would be established with much less difficulty.

Based on our experiences, we suggest that type Ling I and Ling II$_a$ patients are safe for POEM, and that Ling II$_b$ patients can also be considered for POEM, but more cautions should be used to avoid damaging the mucosa or the muscularis propria when the submucosal tunnel is being established across the crescent-like structure. For Ling II$_c$ and Ling III patients, POEM can be performed when the crescent-like structure is on the left side of the esophageal lumen, but it is not recommended when the crescent-like structure is on the right side. These suggestions may be modified in the future with improvement of technology. For example, when a new and safe technique to establish a tunnel across a crescent-like structure is available, a POEM therapy would be recommended for all the Ling II patients free of concerns of penetrations irrespective of the location of the crescent-like structures.

One classification of achalasia categorized by high-resolution manometry has been reported to be promising in predicting the efficacy of treatment of achalasia, such as balloon dilation[23-25]. But up to now, there has been no report about its usefulness for selecting candidates for POEM. And the relationship between the proposed endoscopic classification and manometric classification remains an interesting point worth further studying.

Since not all patients were eligible for undergoing POEM, we analyzed the characteristics of the esophageal lumen and proposed the Ling classification, hoping that Ling classification might help in determining the proper candidates for POEM, thus minimizing the complications such as penetration of mucosa or muscularis propria because other therapies such as endoscopic injection of botulinum toxin, endoscopic dilation or surgery would be recommended instead of POEM in patients with a severely tortuous esophagus. However, further prospective studies are needed to determine the usefulness of Ling classification for selecting candidates for POEM.

COMMENTS

Background

Peroral endoscopic myotomy (POEM) has been primarily confirmed to be effective for patients with achalasia in the short term by several studies since it was first clinically reported in 2010, but not all the patients with achalasia were eligible for a POEM therapy. If the esophageal lumen was too tortuous or a diverticulum was formed in the middle or the lower part of the esophagus, it would be quite challenging to establish a submucosal tunnel.

Research frontiers

Although no serious clinical outcomes of complications like mucosal perforation in the cardia has been reported, it is still of vital importance to select proper candidates for POEM so as to minimize those complications.

Innovations and breakthroughs

The authors proposed a new endoscopic classification of achalasia after analyzing the endoscopic pictures which clearly revealed the morphology of middle and lower esophagus and this new Ling classification of achalasia might assist in determining the indications of POEM.

Applications

The authors suggest the followings for choosing the candidates for POEM: Ling I and Ling II$_a$ patients are safe for POEM, and Ling II$_b$ patients can also be considered for POEM but more cautions should be used to avoid damaging the mucosa or the muscularis propria when the submucosal tunnel is being established across the crescent-like structure. For Ling II$_c$ and Ling III patients, POEM can be performed when the crescent-like structure is on the left side of the esophageal lumen, but it is not recommended when the crescent-like structure is on the right side.

Terminology

POEM is a newly developed endoscopic therapy for achalasia by myotomy of the inner circular muscle of the lower esophagus, thus reducing the lower esophageal sphincter pressure and relieving symptoms of the patients.

Peer review

This study proposed a new endoscopic classification of achalasia based on the morphology of the middle and lower part of the esophagus, and role of the new classification in determining proper candidates for POEM was explored, and the authors suggested indications based on this new classification,which is very interesting. However, further prospective studies are needed to determine the validity of this Ling classification for selecting candidates for POEM.

Abstract

AIM: To evaluate the efficacy of reduced cathartic bowel preparation with 2 L polyethylene glycol (PEG)-4000 electrolyte solution and 10 mg bisacodyl enteric-coated tablets for computed tomographic colonography (CTC).

METHODS: Sixty subjects who gave informed consent were randomly assigned to study group A, study group B or the control group. On the day prior to CTC, subjects in study group A were given 20 mL 40% wt/vol barium sulfate suspension before 3 mealtimes, 60 mL 60% diatrizoate meglumine diluted in 250 mL water after supper, and 10 mg bisacodyl enteric-coated tablets 1 h before oral administration of 2 L PEG-4000 electrolyte solution. Subjects in study group B were treated identically to those in study group A, with the exception of bisacodyl which was given 1 h after oral PEG-4000. Subjects in the control group were managed using the same strategy as the subjects in study group A, but without administration of bisacodyl. Residual stool and fluid scores, the attenuation value of residual fluid, and discomfort during bowel preparation in the three groups were analyzed statistically.

RESULTS: The mean scores for residual stool and fluid in study group A were lower than those in study group B, but the differences were not statistically significant. Subjects in study group A showed greater stool and fluid cleansing ability than the subjects in study group B. The mean scores for residual stool and fluid in study groups A and B were lower than those in the control group, and were significantly different. There was no significant difference in the mean attenuation value of residual fluid between study group A, study group B and the control group. The total discomfort index during bowel preparation was 46, 45 and 45 in the three groups, respectively, with no significant difference.

CONCLUSION: Administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution enhances stool and fluid cleansing ability, and has no impact on the attenuation value of residual fluid or the discomfort index. The former is an excellent alternative for CTC colorectum cleansing

Pilot study on efficacy of reduced cathartic bowel preparation with polyethylene glycol and bisacodyl. *World J Gastroenterol* 2013; 19(4): 561-568 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/561.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.561

INTRODUCTION

Computed tomographic colonography (CTC) has been shown to be an effective tool for colorectal cancer screening, due to its non-invasiveness and high sensitivity for polyp and neoplasia detection[1-6]. This sensitivity is comparable to that obtained using optical colonoscopy[7,8]. However, this examination still requires bowel cleansing similar to that used prior to optical colonoscopy[9]. The need for thorough colorectal cleansing using cathartics remains a major barrier limiting subject acceptance[10]. Reduced cathartic bowel preparation will increase subject compliance to CTC screening[11-13]. To date, there is no general consensus on reduced cathartic bowel preparation, which combines easy preparation and good acceptance[14-18].

Polyethylene glycol (PEG) electrolyte solution is an isosmotic laxative which does not cause electrolyte imbalance[19]. To date, a little research has been conducted on reduced cathartic bowel preparation with PEG-3350 and 10 mg bisacodyl for CTC; however, there are no studies on reduced cathartic bowel preparation combining PEG-4000 with 10 mg bisacodyl[9,12]. Hence, the purpose of this pilot study was to prospectively evaluate the efficacy of reduced cathartic bowel preparation with 2 L PEG-4000 electrolyte solution and 10 mg bisacodyl enteric-coated tablets for CTC.

MATERIALS AND METHODS

Study subjects

Our randomized, prospective and investigator-blinded study group was composed of 60 subjects (34 men and 26 women; age range 22-76 years, mean age 43.6 years). Indications for participation were as follows: asymptomatic subjects with increased colorectal cancer risk due to family or personal history; subjects with recent onset of alarm symptoms, i.e., positive fecal occult blood test, blood in feces, abdominal pain, alternating bowel, refractory iron-deficient anemia, constipation or diarrhea. Subjects with age younger than 18 years, inflammatory bowel disease, end-stage renal disease, and women of child-bearing age were excluded.

After a subject was enrolled in the study, he or she was assigned either to study group A, study group B or the control group on the basis of random numbers. The study protocol was approved by the institutional review board, and informed consent was obtained from each subject.

Bowel preparation

Subjects were instructed to avoid solid food on the day prior to the colorectal examinations. Subjects in study group A were given 20 mL 40% wt/vol barium sulfate suspension (Qingdao Dongfeng Chemical Co. Ltd., Shandong, China) before 3 mealtimes (breakfast, 7:00; lunch, 12:00; supper, 19:00) to achieve fecal tagging; for fluid tagging, 60 mL 60% diatrizoate meglumine (Hunan Hansen Pharmacy Co. Ltd, Hunan, China) diluted in 250 mL water was taken orally after supper; and then two 5 mg bisacodyl enteric-coated tablets (Shaanxi Chuanlong Pharmacy Co. Ltd, Shaanxi, China) were administered at 19:00; and finally, at 20:00, 2 L PEG-4000 electrolyte solution (Jiangxi Hengkang Pharmacy Co. Ltd, Jiangxi, China; each liter solution consisted of 15 mEq PEG-4000, 125 mEq Na^+, 10 mEq K^+, 20 mEq HCO_3^-, 80 mEq SO_4^{2-}, and 35 mEq Cl^-) was administered orally with the first dose of 750 mL, and the remainder was divided into five 250 mL aliquots separated by 15 min. Bowel preparation of the subjects in study group B was identical to that in study group A, with the exception of bisacodyl administration at 21:00. Bowel preparation in subjects in the control group was the same as that in study group A, without administration of bisacodyl.

CTC protocol

Anisodamine hydrochloride (10 mg) was injected intramuscularly 10 min before helical computed tomography (CT) scanning to allow optimal colonic distention, minimize peristalsis and alleviate spasms. Subjects were placed in the right lateral decubitus position on the CT table and a rectal catheter with a retention cuff was inserted. After inflation of the retention cuff, the cuff was gently pulled back until its proximal end rested on the anal sphincter. To distend the colorectum as fully as possible, subjects were then moved into the supine position and room air was gently insufflated into the colorectum to maximal subject tolerance using an automated delivery (JS-628, Guangzhou Jinjian Co. Ltd, Guangdong, China). The delivery was stopped if the rectal pressure was consistently over 3.5 kPa.

Scanning was performed with a 128-slice CT scanner (Somatom Definition AS 128, Siemens AG, Erlangen, Germany) or a 4-slice CT scanner (Aquilion 4, Toshiba Co., Japan) using the following parameters: collimation, 0.625; thickness, 1 mm; pitch, 1.2; electric current, 60 mA; voltage, 120 kV; matrix, 512 × 512; field of view, 3500-4000 mm. Subjects were instructed to hold their breath during data acquisition. A standard CT scout image of the abdomen and pelvis was acquired to assess the degree of colorectal distention, and more room air was insufflated if required. With the scout image, each examination was tailored to encompass the entire colorectum. Scanning was then performed in the prone position, using the same parameters as those in the supine position.

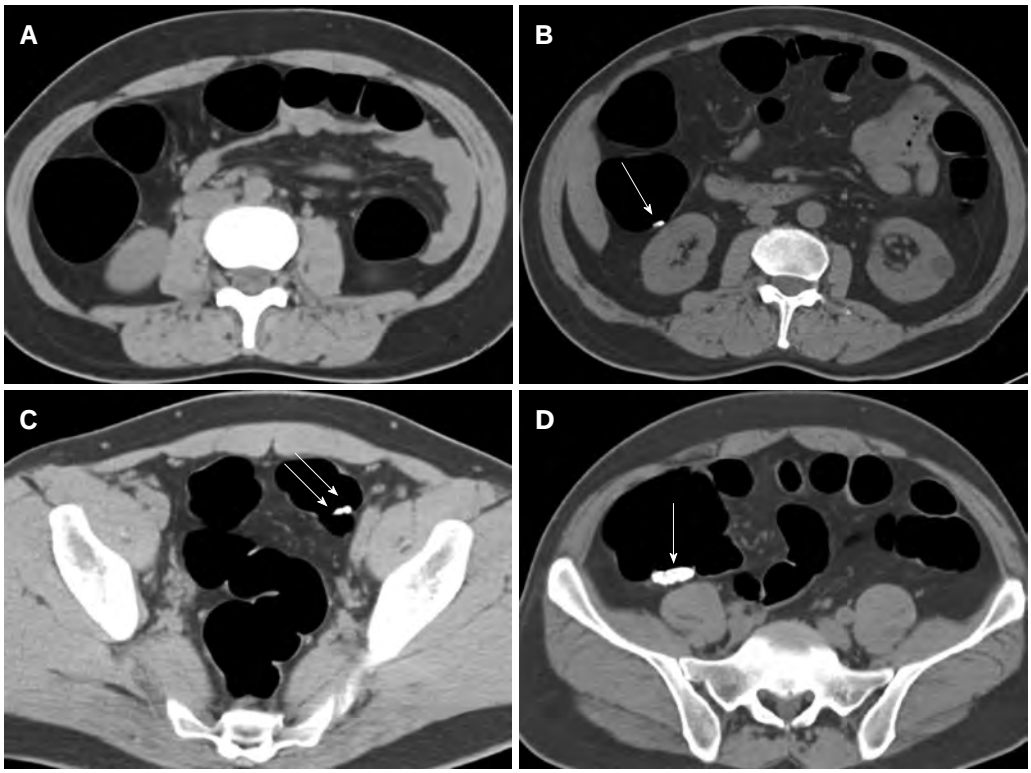

Figure 1 Four-point scoring system of residual stool. A: Stool score of 1: no residual stool; B: Stool score of 2: one stool particle (arrow) smaller than 5 mm in diameter; C: Stool score of 3: two stool particles (arrows) smaller than 5 mm in diameter; D: Stool score of 4: stool particle (arrow) larger than 5 mm in diameter.

Discomfort during bowel preparation

Subjects were invited to complete a questionnaire to describe their discomfort during bowel preparation. Possible discomfort included thirst, hunger, bloating, abdominal pain, sleep disturbance, malaise, nausea, vomiting, cramping, anal discomfort, dizziness and others.

Image evaluation

Axial two-dimensional images in the supine position were evaluated. Axial two-dimensional images in the prone position and multiplanar reformation images were also evaluated when necessary. All images were evaluated by two independent experienced readers, who were blind to histories, clinical symptoms and signs, and reduced cathartic regimens in the subjects, in random order on a picture archiving and communication system workstation with regard to residual stool, residual fluid and attenuation value of the residual fluid. If their evaluations differed, the two readers reached a consensus after reviewing and discussing the controversial images with another senior radiologist. The scores from the two readers were averaged to give an overall score for each segment in each subject. The entire colorectum was divided into six anatomic segments: cecum, ascending colon, transverse colon, descending colon, sigmoid colon and rectum.

Residual stool evaluation

A previously established four-point scoring system was used to evaluate residual stool in each of the six colorectum segments with lower scores corresponding to decreased residual stool[18]. A colorectum segment with no stool was given a score of 1; a segment with a single residual stool particle smaller than 5 mm in diameter, a score of 2; a segment with two or three particles of stool all smaller than 5 mm in diameter, a score of 3; and a segment with stool particles larger than 5 mm or more numerous than three, a score of 4 (Figure 1). A score of 1 or 2, indicated good stool cleansing; and a score of 3 or 4, indicated poor stool cleansing.

Residual fluid evaluation

A similar four-point scale was used to assess residual fluid with lower scores corresponding to a decreased percentage of the distended colorectum segment occupied by residual fluid[18]. The score reflected the percentage of the colorectum lumen filled with fluid. A segment with no fluid was given a score of 1; a segment with less than 25% of the lumen filled, a score of 2; a segment with 25%-50% of the lumen filled, a score of 3; and a segment with more than 50% of the lumen filled, a score of 4 (Figure 2). A score of 1 or 2, indicated good fluid cleansing; and a score of 3 or 4, indicated poor fluid cleansing.

Measurement of the attenuation value of residual fluid

The attenuation value of residual fluid was obtained by placing a single region of interest which was approximately 2 cm in diameter in the largest fluid collection. The mean of these measurements was calculated to establish the fluid attenuation value for each fluid collection.

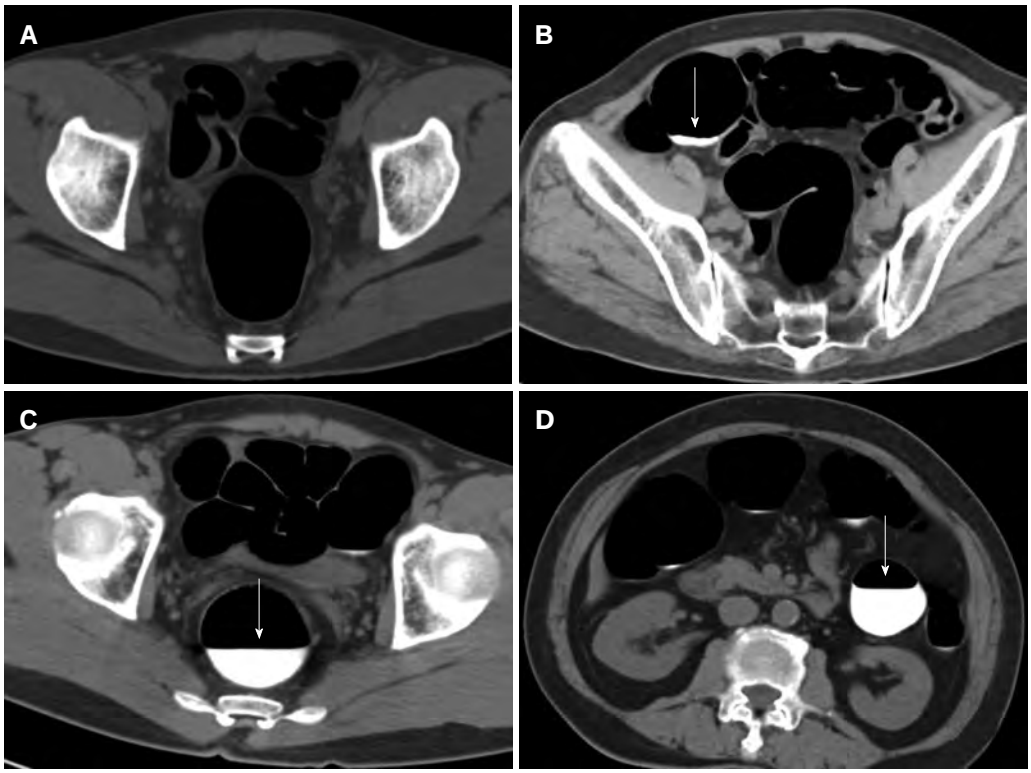

Figure 2 Four-point scoring system of residual fluid. A: Fluid score of 1: no residual fluid; B: Fluid score of 2: less than 25% of the lumen filled with fluid (arrow); C: Fluid score of 3: 25%-50% of the lumen filled with fluid (arrow); D: Fluid score of 4: more than 50% of the lumen filled with fluid (arrow).

Statistical analysis

Continuous data were expressed as means with standard deviations unless otherwise specified. Unpaired Student's *t* tests with the Welch correction were used to compare residual stool and fluid scores, attenuation value of residual fluid, and discomfort during bowel preparation among the three groups using SPSS version 13.0 for Windows. A P value < 0.05 was considered statistically significant.

RESULTS

Residual stool score

In study group A, a residual stool score of 1 was observed in 66 colorectum segments, 2 in 21 colorectum segments, 3 in 5 colorectum segments, 4 in 28 colorectum segments, with a mean score of 1.96 ± 0.11. In study group B, a residual stool score of 1 was observed in 68 colorectum segments, 2 in 15 colorectum segments, 3 in 5 colorectum segments, 4 in 32 colorectum segments, with a mean score of 2.01 ± 0.12. In the control group, a residual stool score of 1 was observed in 37 colorectum segments, 2 in 15 colorectum segments, 3 in 23 colorectum segments, 4 in 45 colorectum segments, with a mean score of 2.63 ± 0.12. There were no significant differences when study group A was compared with study group B ($P > 0.05$); however, when study group A was compared with the control group ($P < 0.001$), and study group B was compared with the control group ($P < 0.002$) significant differences were observed (Table 1).

Good and poor stool cleansing was 72.5% (87/120) and 27.5% (33/120), respectively, in study group A; 69.2% (83/120) and 30.8% (37/120), respectively, in study group B; and 43.3% (52/120) and 56.7% (68/120), respectively, in the control group.

Residual fluid score

In study group A, a residual fluid score of 1 was observed in 67 colorectum segments, 2 in 46 colorectum segments, 3 in 7 colorectum segments, 4 in 0 colorectum segments, with a mean score of 1.50 ± 0.06. In study group B, a residual fluid score of 1 was observed in 66 colorectum segments, 2 in 45 colorectum segments, 3 in 8 colorectum segments, 4 in 1 colorectum segment, with a mean score of 1.53 ± 0.06. In the control group, a residual fluid score of 1 was observed in 58 colorectum segments, 2 in 37 colorectum segments, 3 in 18 colorectum segments, 4 in 7 colorectum segments, with a mean score of 1.78 ± 0.08. There were no significant differences when study group A was compared with study group B ($P > 0.05$); however, when study group A was compared with the control group ($P < 0.05$), and study group B was compared with the control group ($P < 0.05$) significant differences were observed (Table 1).

Good and poor fluid cleansing was 94.2% (113/120) and 5.8% (7/120), respectively, in study group A; 92.5% (111/120) and 7.5% (9/120), respectively, in study group B; and 79.2% (95/120) and 20.8% (25/120), respectively, in the control group.

Attenuation value of residual fluid

In study group A, the attenuation value of residual fluid

Table 1 Residual stool and fluid score in the three groups *n* (%)

Group	Residual stool stool and fluid score				mean ± SD
	1	2	3	4	
Residual stool stool					
Study group A	66 (50.0)	21 (17.5)	5 (4.2)	28 (23.3)	1.96 ± 0.11
Study group B	68 (56.7)	15 (12.5)	5 (4.2)	32 (26.6)	2.01 ± 0.12
Control group	37 (30.8)	15 (12.5)	23 (19.2)	45 (37.5)	2.63 ± 0.12
Residual fluid score					
Study group A	67 (55.9)	46 (38.3)	7 (5.8)	0 (0.0)	1.50 ± 0.06
Study group B	66 (55.0)	45 (37.5)	8 (6.7)	1 (0.8)	1.53 ± 0.06
Control group	58 (48.4)	37 (30.8)	18 (15.0)	7 (5.8)	1.78 ± 0.08

in the cecum was 718 HU, ascending colon was 840 HU, transverse colon was 704 HU, descending colon was 761 HU, sigmoid colon was 694 HU and rectum was 655 HU, with a mean attenuation value of residual fluid of 729 HU. In study group B, the attenuation value of residual fluid in the cecum was 713 HU, ascending colon was 795 HU, transverse colon was 692 HU, descending colon was 665 HU, sigmoid colon was 532 HU, and rectum was 521 HU, with a mean attenuation value of residual fluid of 653 HU. In the control group, the attenuation value of residual fluid in the cecum was 647 HU, ascending colon was 662 HU, transverse colon was 593 HU, descending colon was 643 HU, sigmoid colon was 534 HU, and rectum was 503 HU, with a mean attenuation value of residual fluid of 597 HU. The *P* values in study group A, study group B and the control group were all > 0.05 and not statistically significant (Table 2).

Discomfort during bowel preparation

The three most common complaints related to bowel preparation were hunger (n = 43), bloating (n = 37), and thirst (n = 23). Other discomfort experienced during bowel preparation included nausea (n = 10), abdominal pain (n = 9), dizziness (n = 7), sleep disturbance (n = 6), and vomiting (n = 1). There were no serious adverse events during bowel preparation in the three groups. Total discomfort index during bowel preparation in study group A, study group B, and the control group were 46, 45 and 45, respectively, and the differences were not significant (P > 0.05, Table 3).

DISCUSSION

Despite being a preventable neoplasm, colorectal cancer is the fourth leading cause of cancer death in China[20]. Early detection and removal of the precursor lesion significantly reduces the incidence and mortality associated with this neoplasm[21,22]. CTC has been demonstrated to be a feasible and promising new technique in colorectal cancer screening[23-25]. However, with the current methods of CTC, it is necessary to undertake adequate colorectal cleansing to achieve acceptable CTC sensitivity and specificity, as excess stool creates pseudopolyps and obscures true soft-tissue polyp visualization[26,27]. Full bowel preparation with cathartics is the major barrier to screening, due to the discomfort and inconvenience of

the associated diarrhea, and negatively affects examination compliance[28]. Reduced cathartic bowel preparation will increase subject compliance, and is under extensive study at present[29-32]. There is no general consensus as to which reduced cathartic bowel preparation to use[33,34]. However, the prospect of replacing conventional preparation with reduced cathartics has driven researchers to identify a new method which combines diagnostic reliability, ease of preparation and subject acceptance[35].

PEG electrolyte solution is an isosmotic laxative which does not cause electrolyte imbalance, and results in improved tagging of residual stool. However, the use of PEG preparations often results in excess residual fluid within the colorectum[19]. As a stimulant laxative, bisacodyl decreases residual fluid. Hence, bowel preparation combining PEG electrolyte solution with bisacodyl enteric-coated tablet may have an ameliorative effect on colorectal cleansing. The standard volume of PEG-3350 is 4 L; each liter of PEG-3350 solution consists of 100 g PEG-3350, 7.5 g sodium sulfate, 2.7 g sodium chloride, 1.0 g potassium chloride, 5.9 g sodium ascorbate, and 4.7 g ascorbic acid. The common dosage of bisacodyl is 20 mg or 10 mg. In our study, a reduced volume of 2 L PEG-4000 electrolyte solution and 10 mg bisacodyl enteric-coated tablets were administered orally; each liter of PEG-4000 electrolyte solution consisted of 15 mEq PEG-4000, 125 mEq Na^+, 10 mEq K^+, 20 mEq HCO_3^-, 80 mEq SO_4^{2-}, and 35 mEq Cl^-. The molecular weight of PEG-4000 is greater than that of PEG-3350 and has higher viscosity and greater ability to form solids than PEG-3350, and their chemical performance is different.

In our series, the residual stool score in study group A (1.96 ± 0.11) was lower than that in study group B (2.01 ± 0.12) and the difference was not significant, which suggests that the cleansing stool ability was not affected by administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution. The residual stool score in study group A (1.96 ± 0.11) was lower than that in the control group (2.63 ± 0.12) and the difference was significant, which suggests that the stool cleansing ability was enhanced by administration of 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution. The residual stool score in study group B (2.01 ± 0.12) was lower than that in the control group (2.63 ± 0.12) and the difference was significant, which suggests that oral administration of 10 mg bisacodyl enteric-coated tablets after oral administration of 2 L PEG-4000 electrolyte solution increases

Table 3 Discomfort during bowel preparation

Group	Hunger	Bloating	Thirst	Nausea	Abd p	Diz	Sle d	Vom	Total
Study group A	15	12	7	3	3	3	2	1	46
Study group B	14	13	8	3	3	2	2	0	45
Control group	14	12	8	4	3	2	2	0	45

Abd p: Abdominal pain; Diz: Dizziness; Sle d: Sleep disturbance; Vom: Vomiting.

stool cleansing ability. Therefore, oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution improves stool cleansing ability.

Although the residual fluid score in study group A (1.50 ± 0.06) was lower than that in study group B (1.53 ± 0.06) and the difference was not significant, which suggests that the fluid cleansing ability was not influenced by oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution. The residual stool score in study group A (1.50 ± 0.06) was lower than that in the control group (1.78 ± 0.08) and the difference was significant, which suggests that oral administration of 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution heightened the fluid cleansing ability. The residual fluid score in study group B (1.53 ± 0.06) was lower than that in the control group (1.78 ± 0.08) and the difference was significant, which suggests that the fluid cleansing ability was improved by oral administration of 10 mg bisacodyl enteric-coated tablets after oral administration of 2 L PEG-4000 electrolyte solution. Hence, oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution increases the fluid cleansing ability. Borden *et al*[18] established a four-point scoring system to evaluate residual fluid in each of the six colorectum segments when comparing magnesium citrate and sodium phosphate. Using the same four-point scoring system, good and poor fluid cleansing was 52% and 48%, respectively, in the study by Hara *et al*[9] following the ingestion of 10 mg bisacodyl tablets after administration of 4 L PEG-3350. Good and poor fluid cleansing was 92.2% and 7.8%, respectively, in our study after oral administration of 10 mg bisacodyl enteric-coated tablets 1 h after oral administration of 2 L PEG-4000 electrolyte solution.

The mean attenuation value of residual fluid in study group A, study group B, and the control group was 729 HU, 653 HU and 597 HU, respectively, with no significant differences. This suggested that oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution did not affect the mean attenuation value of residual fluid. The attenuation value of residual fluid has been shown to have a significant effect on polyp conspicuity. Previous research has suggested that optimal viewing conditions in the two-dimensional format are met with an attenuation value of residual fluid of approximately 700 HU, due to high conspicuity of all polyps at this level. Such an increase in polyp conspicuity could lead to increased sensitivity and specificity of CTC. With a mean attenuation value of residual fluid of 729 HU, study group A was closer to this optimal level than study group B and the control group.

Total discomfort index during bowel preparation in study group A, study group B, and the control group was 46, 45 and 45, respectively; however, these differences were not significant. There were no serious adverse events during bowel preparation in the three groups. These results suggest that oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution does not influence subject discomfort during bowel preparation for CTC.

No significant differences were observed between study group A and B with regard to residual stool and fluid scores. However, the residual stool score in study group A (1.96 ± 0.11) was lower than that in study group B (2.01 ± 0.12), and the residual fluid score in study group A (1.50 ± 0.06) was also lower than that in study group B (1.53 ± 0.06), which indicated that oral administration of 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution resulted in a trend toward greater stool and fluid cleansing ability than when given after PEG-4000 electrolyte solution. It would be preferable to administer 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution for CTC bowel preparation.

There were two limitations in our pilot study. First, the number of subjects was relatively small and the study was likely underpowered to detect subtle differences in preparation adequacy. Second, we compared bowel preparation outcomes obtained with these three bowel preparation regimens, but did not assess the possible diagnostic performance of these regimens. Our study was not designed to address diagnostic performance, which will be studied at a later date.

In conclusion, oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution not only enhances the stool and fluid cleansing ability, but also has no impact on the attenuation value of residual fluid or discomfort during bowel preparation. Oral administration of 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution is an excellent alternative for CTC colorectum cleansing.

COMMENTS

Background

Computed tomographic colonography (CTC) has been shown to be an effective tool for colorectal cancer screening. At present, this examination still requires bowel cleansing similar to that used prior to optical colonoscopy. The need for thorough colorectal cleansing using cathartics remains a major barrier limiting subject acceptance. Reduced cathartic bowel preparation will increase subject compliance in CTC screening. There is no general consensus on reduced cathartic bowel preparation.

Research frontiers

Reduced cathartic bowel preparation is under extensive study at present. The prospect of replacing conventional preparation with reduced cathartics has driven researchers to identify a new method which combines ease of preparation and subject acceptance.

Innovations and breakthroughs

Polyethylene glycol (PEG)-4000 electrolyte solution is an isosmotic laxative that does not cause electrolyte imbalance, and results in improved tagging of residual stool and excess residual fluid. Bisacodyl enteric-coated tablet, a stimulant laxative, decreases the residual fluid. Bowel preparation with combined PEG-4000 electrolyte solution and bisacodyl enteric-coated tablets has an ameliorative effect on colorectum cleansing.

Applications

Oral administration of 10 mg bisacodyl enteric-coated tablets prior to or after oral administration of 2 L PEG-4000 electrolyte solution enhances stool and fluid cleansing ability, and has no impact on the attenuation value of residual fluid or discomfort during bowel preparation. Oral administration of 10 mg bisacodyl enteric-coated tablets prior to oral administration of 2 L PEG-4000 electrolyte solution is an excellent alternative for CTC colorectum cleansing.

Terminology

CTC uses 2D computed tomographic (CT) images of the colorectum, rendered into 3D images and is used to screen for polyps and other abnormalities. The examination consists of non-invasive CT scans, obtained in a few minutes. At the workstation, the images are reconstructed into a 3D model of the colorectum, and the physician may begin clinical analysis of the images.

Peer review

It is a good reason for physician to find a convenient and effective method for patients to carry bowel preparation. But the cost and benefit and the discomfort score of the patient need to be considered.

Abstract

AIM: To explore the optimal steroid therapeutic strategy for autoimmune pancreatitis (AIP).

METHODS: This study was conducted retrospectively in two large institutions in China. Patients with clinically, radiologically and biochemically diagnosed AIP were enrolled. The performed radiological investigations and biochemical tests, the regimen of the given steroid treatment, remission and relapse whether with and without steroid therapy were analyzed.

RESULTS: Twenty-eight patients with AIP received steroid treatment, while 40 patients were treated surgically by pancreatoduodenectomy, distal pancreatectomy and choledochojejunostomy, radiofrequency ablation for the enlarged pancreatic head, percutaneous transhepatic biliary drainage and endoscopic biliary drainage. The starting oral prednisolone dose was 30 mg/d in 18 (64.3%) patients and 40 mg/d in 10 (35.7%) patients administered for 3 wk. The remission rate of AIP patients with steroid treatment (96.4%) was significantly higher than in those without steroid treatment (75%). Maintenance therapy (oral prednisolone dose 5 mg/d) was performed after remission for at least 6-12 mo to complete the treatment course. Similarly, the relapse rate was significantly lower in AIP patients with steroid treatment (28.6%) than in those without steroid treatment (42.5%). Steroid re-treatment was effective in all relapsed patients with or without steroid therapy.

CONCLUSION: Steroid therapy should be considered in all patients with active inflammatory phase of AIP. However, the optimal regimen still should be trailed in larger numbers of patients with AIP.

Liu B, Li J, Yan LN, Sun HR, Liu T, Zhang ZX. Retrospective study of steroid therapy for patients with autoimmune pancreatitis in a Chinese population. *World J Gastroenterol* 2013; 19(4): 569-574 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/569.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.569

INTRODUCTION

Autoimmune pancreatitis (AIP) has recently been described as a type of chronic pancreatitis characterized by an autoimmune inflammatory process with prominent lymphocyte infiltration[1]. Since the concept of autoimmune pancreatitis was firstly introduced by Yoshida *et al*[2]

in 1995, the number of AIP reports has been recently increased in the medical literature.

AIP is characterized by diffuse or focal enlargement of the pancreas, irregular narrowing of the main pancreatic duct, elevated serum immunoglobulin G4 (IgG4) and presence of autoantibodies, and/or IgG4-positive plasma cells and/or dense lymphocyte infiltration with fibrosis[3]. Before the availability of the diagnostic criteria of AIP proposed by the Japan Pancreas Society[4], AIP was frequently misdiagnosed as pancreatic cancer, which consequently imposed the patients a superfluous pancreatic resection[5].

Since the fibroinflammatory process of AIP has a favorable response to steroids, steroid therapy has been accepted as a standard treatment for AIP[6]. Treatment protocols for AIP are still evolving. Although the initial and maintenance dose of oral steroids are clearly recommend by the Japanese literature[7], there is little consensus worldwide on a steroid treatment regimen for patients with AIP[8]. Hence, to explore the optimal steroid therapeutic strategy for AIP, we conducted a retrospective study on AIP treatment in two large institutions in China.

MATERIALS AND METHODS

Subjects

This retrospective study was done to evaluate steroid therapeutic strategy for patients with AIP. The study was conducted in the General Hospital of Tianjin Medical University and West China Hospital of Sichuan University. A total of 68 patients with clinically, radiologically and biochemically diagnosed AIP were enrolled.

Diagnostic criteria

AIP was diagnosed according to the Asian diagnostic criteria for AIP[9]. Consequently, the diagnosis was based on the following clinicopathological findings: (1) the imaging criteria including diffuse/segmental/focal enlargement of the pancreas and diffuse/segmental/focal pancreatic ductal narrowing, often with the stenosis of the bile duct; (2) the serological criteria including elevated serum IgG or IgG4 levels, or detection of autoantibodies; and (3) and/or the histopathological criteria including lymphoplasmacytic infiltration and fibrosis, with abundant IgG4-positive cell infiltration. Thus, AIP was diagnosed when the imaging criteria and one of the other two criteria, the serological and histopathological, were satisfied. Optionally, AIP can also be diagnosed with fulfillment of both the imaging criteria and a good response to steroid treatment.

Assessment of the investigations and therapeutic strategy

We assessed the performed radiological investigations and biochemical tests for all AIP patients. We analyzed remission and relapse whether with or without steroid treatment as well as the given steroid treatment regimen in the patients who received steroid treatment. Remission was defined as the disappearance of clinical symptoms and resolution of the pancreatic and/or extrapancreatic manifestations on radiological investigations[10-12]. All the patients underwent periodic laboratory tests and imaging studies every 3 mo in the first year after remission resulting from steroid treatment. Relapse was defined as reappearance of symptoms with the development of pancreatic and/or extrapancreatic abnormalities on imaging studies and/or marked elevation of serum IgG or IgG4 levels[11,12]. Relapse also included re-elevation of serological levels alone exclusive of clinical symptoms or abnormal imaging[7].

Statistical analysis

Statistical analysis was performed using Fisher's exact test and Mann-Whitney's *U* test (with commercially available software SPSS version 13.0; SPSS, Inc, Chicago, IL). Data were expressed as mean ± SD or median (range). The period from the start of steroid treatment to relapse was evaluated using the Kaplan-Meier method. Differences with P values < 0.05 were considered significant.

RESULTS

Patient profile

Sixty-eight patients with AIP fulfilling the Asian diagnostic criteria for AIP were included in this study. There were 50 men and 18 women with an average age of 62.5 years [patients with steroid 62 (43-78) years, patients without steroid 64 (47-72) years]. Forty patients underwent various surgical procedures (30 males, 10 females), while the remaining 28 patients received steroid treatment (20 males, 8 females). The surgical procedures included pancreatoduodenectomy, distal pancreatectomy and choledochojejunostomy, radiofrequency ablation for the enlarged pancreatic head, percutaneous transhepatic biliary drainage and endoscopic biliary drainage. The numbers of patients undergoing various surgical procedures are as follow: (1) thirteen underwent pancreatoduodenectomy; (2) nineteen underwent distal pancreatectomy and choledochojejunostomy; (3) three underwent radiofrequency ablation for the enlarged pancreatic head; (4) three underwent percutaneous transhepatic biliary drainage; and (5) two underwent endoscopic biliary drainage. In the current study, no patient received any other immunosuppressive treatments such as azathioprine or ursodeoxycholic acid or mycophenolate mofetil.

Given steroid therapy

Steroid therapy was administered in 28 of the 68 AIP patients who were initially presented with obstructive jaundice, abdominal pain, rapid weight loss (> 5 kg in the past 3 mo), diffuse enlargement of the pancreas, associated extrapancreatic abnormalities such as cholangitis and retroperitoneal fibrosis. The clinical presentations in the 28 patients are shown in Table 1.

Table 1 Clinical presentation of patients with steroid treatment *n* (%)

Clinical presentation	Patients (*n* = 28)
Obstructive jaundice	17 (60.7)
Abdominal pain	9 (32.1)
Rapid weight loss	6 (21.4)
Diffuse enlargement of the pancreas	17 (60.7)
Associated extrapancreatic abnormalities	
Cholangitis	18 (64.3)
Retroperitoneal fibrosis	3 (10.7)

Before steroid therapy, blood glucose levels were controlled using insulin in 6 (21.4%) patients and oral hypoglycemics in AIP patients with diabetes mellitus. Alternatively, for patients showing hyperbilirubinemia > 3 mg/dL, percutaneous transhepatic biliary drainage and endoscopic biliary drainage were performed in 4 and 3 patients, respectively.

Regimens of steroid therapy

Among the 28 AIP patients who received steroid therapy, 18 (64.3%) patients started on oral prednisolone at 30 mg/d, while 10 (35.7%) patients began oral prednisolone at 40 mg/d. The therapy monitoring 3 wk after starting steroid treatment was achieved based on the patient's clinical presentation as well as the biochemical results and the imaging findings. When steroid treatment was effective, the dose was tapered by 5 mg every 1-2 wk until the dose reached a maintenance dose of 5 mg/d. Then, maintenance steroids for at least 6-12 mo were given to complete the treatment course. The maintenance steroid treatment was withdrawn whenever complete radiological and serological improvement was obtained.

Remission rate with and without steroid therapy

Steroid therapy used in this study was very effective in alleviating the clinical presentation of AIP (such as obstructive jaundice and abdominal pain) and induced remission more quickly than other treatments without steroids. Likewise, clinical and radiological responses to steroid therapy were seen in 2-3 wk in this study. We also found that response to steroid therapy was typically rapid with significant radiological improvement at 2-3 wk.

The remission rate of AIP patients with steroid treatment (27/28 patients, 96.4%) was significantly higher ($P < 0.001$) than in those without steroid treatment (30/40 patients, 75%). Furthermore, the period to yield a remission in the patients treated with an initial prednisolone dose of 30 mg/d was not significantly different ($P = 0.273$) from the period in those treated with an initial prednisolone dose of 40 mg/d (6.4 ± 5.72 mo and 6.1 ± 6.05 mo, respectively). At remission, the enlarged pancreas returned to near-normal size in 22 (78.6%) patients. Pancreatic atrophy occurred in 6 (21.4%) patients and persistent focal enlargement was found in 1 (3.6%) patient. Irregularity of the pancreatic ducts and/or some degree of bile duct stenosis remained in 15 (53.6%) patients. Although the elevated serum IgG level declined in all patients after the start of steroid treatment, it failed to normalize (< 751 mg/dL) in 17 (60.7%) patients. Likewise, 15 (53.6%) patients with persistently elevated serum IgG levels showed irregular pancreatic ducts and/or some degree of bile duct stenosis.

Relapse rate with and without steroid therapy

The relapse rate was significantly lower ($P = 0.004$) in AIP patients with steroid treatment than in those without steroid treatment (8/28 patients, 28.6% and 17/40 patients, 42.5%, respectively). The relapse period after starting steroid treatment differed in the 8 patients: within 6 mo in 1 (12.5%) patient, within 1 year in 4 (50%) patients, within 2 years in 6 (75%) patients and within 3 years in all 8 (100%) patients. Multivariate analysis showed that there was no correlation ($P = 0.573$) between the relapse rate and the initial prednisolone dose (20% with prednisolone dose of 40 mg/d and 22.2% with prednisolone dose of 30 mg/d). Furthermore, the relapse occurred in 2 of the 10 patients who received prednisolone at 40 mg/d and in 4 of the 18 patients who received prednisolone at 30 mg/d. The relapse rate of AIP was significantly higher ($P = 0.003$) in patients with persistently elevated serum IgG levels (6/17 patients, 35.3%) than in those with normalized serum IgG levels (1/7 patients, 10%). Relapse occurred in 3 of the 8 (37.5%) patients during the maintenance treatment, whereas it occurred in the rest of the 5 (62.5%) patients when the maintenance treatment was stopped. Steroid re-treatment was effective in all relapsed patients with or without steroid therapy.

Maintenance dose of oral steroids after remission

The maintenance steroid therapy was administered after remission in all 28 AIP patients treated with steroids. After remission, the starting oral prednisolone dose was gradually tapered by 5 mg every 1-2 wk to reach a maintenance dose of 5 mg/d. The maintenance steroids were continued for at least 6-12 mo to complete the treatment course. The maintenance dose of steroid was withdrawn in 7 (25%) patients in whom complete radiological and serological improvement was obtained.

Complications of steroid treatment

There was no death attributable to steroid treatment related complications. As AIP patients were typically elder patients, they were at a high risk of developing steroid related complications. Steroid treatment related complications occurred in 7 of the 28 patients, including pneumonia in 3 patients, avascular necrosis of the femoral head in 1 patient, lumbar vertebral fracture in 1 patient and diabetes mellitus in 2 patients. In these patients, the steroid medication dose was reduced or completely ceased. In addition, the 3 patients with pneumonia were treated with antibiotics.

DISCUSSION

It has been reported that the overall prevalence of AIP was 0.82/100 000 in Japan. Moreover, on the basis of clinical presentation, biochemical results or histological findings, AIP constitutes 5%-11% of all patients with chronic pancreatitis[13,14]. Likewise, Song *et al*[15] stated that AIP patients accounted for 5% of chronic pancreatitis population in China.

In this study, AIP was found predominantly in elderly males. This coincides with the feature that although AIP occurs in both sexes, it is at least twice as common in men as in women. In addition, in spite that AIP varies widely in age, most AIP patients are older than 50 years[16]. The clinical presentation of AIP in the current study was in agreement with the studies by Kim *et al*[12] and Nishimori *et al*[17]. AIP was presented with obstructive jaundice in 49 (72.1%) patients, abdominal pain in 30 (44.1%) patients and rapid body weight loss in 21 (30.9%) patients. Alternatively, diabetes mellitus was present in 40 (58.8%) patients.

Moreover, AIP has frequently been diagnosed or suspected as pancreaticobiliary malignancy, which consequently imposed the patients an unnecessary pancreatic resection[18,19]. This study also showed that 40 (58.8%) patients with AIP underwent unnecessary surgical procedures.

Alternatively, Refaat *et al*[20] showed in their case report of AIP that although the imaging findings were suggestive of AIP, pancreatic biopsy was necessary to differentiate AIP from pancreatic cancer as the management differs significantly. Consequently, clinicians should be conversant with the clinical, radiographic, serologic and histologic evidence of AIP to improve the diagnostic accuracy for AIP.

Although steroid therapy is generally considered to be very effective in the initial inflammatory phase of AIP, its facile use for patients whose diagnosis of AIP is questionable should be prohibited[21]. In this study, steroid therapy was very effective in improving patient's clinical presentation such as obstructive jaundice and abdominal pain. Additionally, it induced remission more quickly than surgical treatments as the clinical presentation, the imaging findings and the laboratory results were improved in all cases in four week after steroid treatment. This result concurs with Hirano *et al*[22]. Therefore, we think that steroid therapy should be considered in all patients with AIP with active disease. This is in agreement with the study by Pannala *et al*[8].

There has been no consensus to date on steroid regimen and duration of treatment in AIP. Mayo Clinic recommended the initial oral prednisolone dose of 40 mg/d for 4 wk. Afterward, laboratory tests and radiological investigation should be performed 4-6 wk after initiating treatment. If there are biochemical and radiological responses, the dose is gradually tapered by 5 mg every week to complete the treatment course of 11 wk[10]. Considering that many complications are related to steroid treatment, maintenance low-dose oral prednisolone treatment was not routinely performed for patients with AIP[8]. In a Japanese consensus statement, Kamisawa *et al*[7] suggested that initiating treatment with prednisolone at 0.6 mg/kg daily should be tapered gradually to reach a maintenance dose of 5 mg/d over 3-6 mo. Finally, maintenance steroids are continued for at least 6 mo and possibly up to 3 years. Although the remission can be achieved in most AIP patients after steroid treatment[9], relapses still occur in 24%-40% of the patients and the starting doses of steroid (typically given for 3-4 wk) are often continued for varying periods of time[8].

In our practice, the starting oral prednisolone dose was 30-40 mg/d for 3 wk. Then, we monitored the patient's clinical presentation, the biochemical and serological results as well as the imaging findings in 3 wk after starting steroid treatment. Consequently, when steroid treatment was effective, we tapered the dose by 5 mg every 1-2 wk to reach a maintenance dose of 5 mg/d. Lastly, maintenance steroids were continued for at least 6-12 mo to complete the given treatment course. The maintenance steroid treatment was withdrawn once complete radiological and serological improvement was achieved. In this study, the response was typically rapid through significant radiological improvement at 2-3 wk in 96.4% of the patients. This coincides with Kamisawa *et al*[23].

Future studies should help to establish an optimal steroid therapy regimen to effectively alleviate the clinical presentation of AIP patients and reduce the risk of steroid-induced complications.

Similar to the previous studies[6,7], we also found that AIP patients were typically elder patients and are at a high risk of developing steroid related complications (diabetes, pneumonia and so forth). Instead of using long-term low-dose steroids, azathioprine, mycophenolate mofetil and other immunosuppresive drugs are used for maintenance of remission in AIP patients who relapse after steroid withdrawal[10]. But, similar to steroids, azathioprine or mycophenolate mofetil also have significant side effects such as increased risk of infection, headache, peripheral edema, hypertension, leucopoenia and lymphoma[8,24]. Thus, the option of long-term treatment for maintenance of AIP remission needs prospective and controlled trials in larger numbers of patients to assess the risk to benefit ratio of each approach.

In conclusion, steroid therapy, usually in a dose range of 30-40 mg/d, is effective in AIP patients and should be considered for all AIP patients in the acute inflammatory phase. The optimal regimen of steroid therapy remains to be determined.

ACKNOWLEDGMENTS

The authors are grateful to the staff of Department of General Surgery, General Hospital of Tianjin Medical University and the staff of Department of General Surgery, West China Hospital, Sichuan University for collecting the clinical materials, and to the staff of De-

partment of Endocrine, General Hospital of Tianjin Medical University for their skillful technical assistance. Special thanks are extended to the staff of Department of Radiology, General Hospital of Tianjin Medical University for collecting the imaging materials and the staff of Department of Clinical Laboratory of General Hospital of Tianjin Medical University for processing the blood samples.

COMMENTS

Background

There is no consensus so far on steroid regimen for patients with autoimmune pancreatitis (AIP).

Research frontiers

Steroid therapy has been accepted as a standard treatment for AIP. But, there is little consensus worldwide on a steroid treatment regimen for patients with AIP.

Innovations and breakthroughs

This is a retrospective study exploring the optimal steroid therapeutic strategy for AIP. The performed radiological investigations and biochemical tests, the regimen of the given steroid treatment, remission and relapse whether with and without steroid therapy were analyzed.

Applications

The study results suggest that steroid therapy should be considered in all patients with active inflammatory phase of AIP.

Terminology

Remission: the disappearance of clinical symptoms and resolution of the pancreatic and/or extrapancreatic manifestations on radiological investigations. Relapse: reappearance of symptoms with the development of pancreatic and/or extrapancreatic abnormalities on imaging studies and/or marked elevation of serum immunoglobulin G (IgG) or IgG4 levels

Peer review

This is a good retrospective study in which authors analyzed the optimal steroid therapeutic strategy for AIP. The results are interesting and suggest that steroid therapy should be considered in all patients with active inflammatory phase of AIP.

Abstract

AIM: To explore the alteration of tyrosine phosphatase SHP-2 protein expression in gastric cancer and to assess its prognostic values.

METHODS: Three hundred and five consecutive cases of gastric cancer were enrolled into this study. SHP-2 expression was carried out in 305 gastric cancer specimens, of which 83 were paired adjacent normal gastric mucus samples, using a tissue microarray immunohistochemical method. Correlations were analyzed between expression levels of SHP-2 protein and tumor parameters or clinical outcomes. Serum anti-*Helicobacter pylori* (*H. pylori*) immunoglobulin G was detected with enzyme-linked immunosorbent assay. Cox proportional hazards model was used to evaluate prognostic values by compassion of the expression levels of SHP-2 and disease-specific survivals in patients.

RESULTS: SHP-2 staining was found diffuse mainly in the cytoplasm and the weak staining was also observed in the nucleus in gastric mucosa cells. Thirty-two point five percent of normal epithelial specimen and 62.6% of gastric cancer specimen were identified to stain with SHP-2 antibody positively ($P < 0.001$). Though SHP-2 staining intensities were stronger in the *H. pylori* (+) group than in the *H. pylori* (-) group, no statistically significant difference was found in the expression levels of SHP-2 between *H. pylori* (+) and *H. pylori* (-) gastric cancer ($P = 0.40$). The SHP-2 expression in gastric cancer was not significantly associated with cancer stages, lymph node metastases, and distant metastasis of the tumors ($P = 0.34$, $P = 0.17$, $P = 0.52$). Multivariate analysis demonstrated no correlation between SHP-2 expression and disease-free survival ($P = 0.86$).

CONCLUSION: Increased expression of SHP-2 protein in gastric cancer specimen suggesting the aberrant up-regulation of SHP-2 protein might play an important role in the gastric carcinogenesis.

Increased expression of tyrosine phosphatase SHP-2 in *Helicobacter pylori*-infected gastric cancer. *World J Gastroenterol* 2013; 19(4): 575-580 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/575.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.575

INTRODUCTION

Gastric cancer remains the fourth most commonly diagnosed cancer and is the second leading cause of cancer related deaths worldwide[1]. The SHP-2 tyrosine posphatase encoded by tyrosine phosphatase SHP-2 (PTPN11) is an evolutionarily conserved protein, containing two Src homology domains at the N terminus, a central catalytic domain, and a C-terminal tail[2,3]. SHP-2 positively regulates many signaling pathways, such as insulin, epidermal growth factor, platelet-derived growth factor, fibroblast growth factor, interleukin (IL)-1, and IL-6[4-6]. SHP-2 has been identified as an essential component in several oncogenic signaling pathways. Elucidation of the events underlying SHP-2-evoked transformation may provide new insights into oncogenic mechanisms and novel targets for anti-cancer therapy[7-11]. Meanwhile, infection with *Helicobacter pylori* (*H. pylori*) is the leading cause for developing atrophic gastritis and gastric cancer worldwide. Many studies reveal that strains of *H. pylori* carrying the major protein virulence factor, cytotoxin-associated antigen A (CagA), are associated with increased risks of gastric cancer compared to strains of *H. pylori* lacking CagA[12]. *H. pylori* inject CagA protein into gastric epithelial cells *via* the bacterial type Ⅳ secretion system and then CagA localizes to the cell membrane and aberrantly activates SHP-2 and its downstream effectors. However, little effort has been devoted to assess an association of the expression level of SHP-2 with gastric cancer risk[13-15]. To investigate the relationship between *H. pylori* infection and SHP-2 protein production in gastric cancer, the SHP-2 protein expression was investigated in 305 patients with gastric cancer, and paired adjacent normal tissue samples were collected in 83 patients. Associations of the protein expression with patient clinical characteristics and prognostic values were also explored in this study.

MATERIALS AND METHODS

Patients and tissue specimens

Three hundred and five consecutive cases of gastric cancer were enrolled in the study. The patient did not receive any treatment before the surgical operation. Gastric cancers were removed by surgical excisions. Adjacent normal gastric epithelial samples were also collected from 83 patients for comparison. Patient ages ranged from 32 to 87 years, with a median age of 64 years. The diagnosis of gastric cancer was confirmed by two pathologists (Jin MS, Wang YP) independently at First Hospital of Jilin University. Written informed consent was obtained from each patient and the study protocol was approved by the Ethics Committee of the First Hospital of Jilin University.

Immunohistochemistry

The section (4 μm in width) of the archival paraffin-embedded block was excised, deparaffinized and stained using a streptavidin-biotin immunoperoxidase technique. The primary antibody, anti-SHP-2 monoclonal antibody (Santa Cruz Biotec, United States), was used in 1:500 dilution; and 3, 3-diaminobenzidine was employed as a chromogen. The section was counterstained with hematoxylin. The stained slides were evaluated by two independent pathologists (Jin MS, Wang YP), who were blinded to the clinical data. The widely accepted H-score system was used to assess staining intensity and percentage of the cells stained with a specific magnitude of intensity. The H-score was calculated with the following equation: H-score = $\sum$Pi (i) (i = 0, 1, 2, 3, Pi = 0%-100%), where i means the intensity of staining, 0 = no staining, 1 = weak staining, 2 = moderate staining and 3 = strong staining. and Pi represents percentages of stained cells with intensities varying from 0% to 100%. Therefore, the H-score ranged from 0 to 300. The H-score $\geqslant$ 100 is considered as positive staining and < 100 is considered as negative staining.

Determination of H.pylori infection

Among 305 gastric cancer patients, blood samples were collected from 100 patients for the examination of *H. pylori* infection before the surgical operation. Four mL of fasting blood samples were left at room temperature for 30 min and the centrifuged. The serum was drawn and stored at a -80 ℃ freezer. Serum immunoglobulin G (IgG) antibodies to *H. pylori* were detected by *H. pylori*-IgG enzyme-linked immunosorbent assay kit (Biohit, Helsink, Finland). The antibody titers were defined by optical density values according to the manufacturer's protocol, and titers higher than the cut off value of 30EIU were considered as positive for *H. pylori* infection. The kit quality control samples showed CVs of 4.5% for *H. pylori* infection examination.

Statistical analysis

As SHP-2 H-scores and their difference values were not normally distributed, these continuous variables were presented as median (interquartile). The Wilcoxon matched-pairs signed-rank test and Wilcoxon signed-rank test were used when comparing paired groups and two independent groups, respectively. Disease-specific survival analysis was performed using the Kaplan-Meier method with log rank test. Risk ratios and corresponding 95% CIs were calculated by the Cox proportional hazards model after adjusted by age (scale variable), sex (nominal variable), differentiation (nominal variable), lymph-vascular invasion (nominal variable) and tumor node metastasis (TNM) staging (scale variable). All statistical tests were two-tailed and *P* values < 0.05 were considered statistically significant. All analyses were performed using the SPSS software package 18.0 (SPSS Inc., United States).

RESULTS

Expression of SHP-2 in gastric cancer specimen and normal gastric epithelial tissues

SHP-2 staining was found diffuse mainly in the cytoplasm and the weak staining was also observed in the nucleus (Figure 1). SHP-2 positive staining was found in

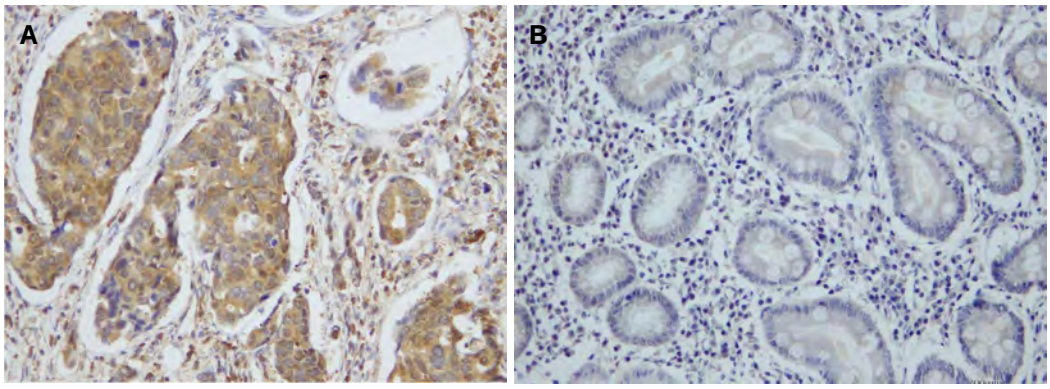

Figure 1 Visualization of SHP-2 expression in malignant gastric epithelial cells and normal mucosal cells by immunohistochemistry (× 200). A: SHP-2 positive immunostaining (2+) in the cytoplasm of gastric carcinoma cells; B: SHP-2 negative immunostaining in glandular cells of normal gastric mucosa.

Table 1 SHP-2 expression in 83 paired gastric cancers and adjacent normal mucus and SHP-2 by *Helicobacter pylori* infection in gastric cancer groups *n* (%)

	H-score				Median H-score (quartile)	*P* value
	0	1-99	100-200	201-300		
Cancer (n = 83)	10 (12.0)	21 (25.3)	27 (32.5)	25 (30.1)	160 (40-210)	< 0.001
Control (n = 83)	41 (49.4)	15 (18.1)	21 (25.3)	6 (7.2)	20 (0-160)	
Positive (n = 67)	8 (11.9)	8 (11.9)	24 (35.8)	27 (40.3)	180 (120-270)	0.401
Negative (n = 33)	1 (3.0)	10 (30.3)	11 (33.3)	11 (33.3)	160 (85-240)	

62/83 (62.6%) gastric cancer samples and in basal cells of 27/83 (32.5%) normal mucosal samples, respectively. There was a significantly increased rate of SHP-2 positive expression in gastric cancer compared to the normal mucosa ($P < 0.001$). In addition, the results showed statistically significant difference in the median H-score of SHP-2 expression between the cancer lesion and normal mucosa (160 *vs* 20, $P < 0.001$; Table 1).

SHP-2 levels and H. pylori infection

Among 100 gastric cancer patients tested for *H. pylori* antibodies, the positive rate of *H. pylori* infection was 67.0%. In the age subgroup analysis, the *H. pylori* infection rate was higher in the group aged between 45-65 years compared to the groups aged younger than 45 years, or older than 65 years. The results showed no correlation between *H. pylori* infection and the positive staining rate of SHP-2 expression ($P = 0.40$). Though SHP-2 staining intensities were stronger in the *H. pylori* (+) group than in the *H. pylori* (-) group, no statistical difference was observed between the two groups (76.1% *vs* 66.6%, $P = 0.09$; Table 1).

SHP-2 expression and clinical characteristics

Statistically, the SHP-2 expression in gastric cancer was not associated with the tumor stage, lymph node metastasis and distant metastasis of the tumors ($P = 0.34$, $P = 0.17$, $P = 0.52$). Kaplan-Meier survival curve was plotted for the 305 patients according to H-score of SHP-2, the overall survival rates of the four groups was not significantly different (log rank test, $P = 0.86$; Figure 2). In addition, the multivariate analysis did not demonstrate an association between SHP-2 expression and disease specific death. There were no differences of SHP-2 levels, age, sex, tumor differentiation, lymph-vascular invasion, TNM staging and survival time between subgroups (83 and 100 cases) and total subjects. The clinical characteristics of subjects are summarized in Tables 2 and 3.

DISCUSSION

Tyrosine phosphorylation and dephosphorylation are coordinated by tyrosine kinases and phosphatases. Recently, SHP-2 has been identified to play a vital role in the pathogenesis of human cancers[10,16,17]. Over-expressions of SHP-2 were reported in infiltrating ductal carcinomas of breast and in gastric cancers as well,[16,18] suggesting that the up-regulation of SHP-2 protein is involved in developing these cancers. In addition, the SHP-2 expression in breast cancers was positively correlated with lymph node metastases and tumor grades, implying that SHP-2 expression is associated with the progression of breast cancers[16]. By contrast, SHP-2 expression in gastric cancers was not found to be associated with lymph node metastases, neither tumor grades in our study (Table 2). The down-regulation in SHP-2 expression was identified to be a better prognostic marker in patients with hepatocellular carcinoma, indicating that SHP-2 plays a role in the tissue specific manner[10].

In general, SHP2 plays multiple roles in tumorigenesis and immune responses[7,8,12]. Activated glycogen synthase kinase-3β, bioactive lipids and their enzymatic generators have been reported to synergistically facilitate inter-

Table 2 SHP-2 expressions and clinical characteristics of 305 gastric cancer patients

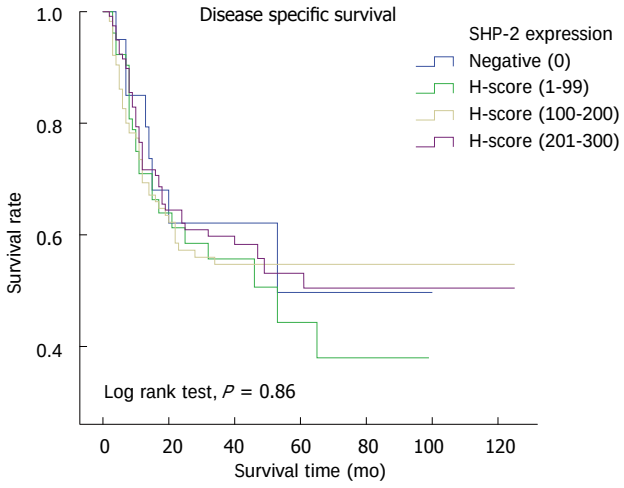

Figure 2 SHP-2 expression and disease specific survival.

ferons (IFN)-γ-induced STAT1 activation by inhibiting SHP-2[19]. Increasing evidences demonstrate that SHP-2 regulates immune responses through its effects on cytokine signaling pathways or inhibits receptor signaling

pathways, such as IFN, tumor necrosis factor-alpha, and JAK/STAT pathways[20-22]. These results support a hypothesis that increased SHP-2 expression would lead to changes in immune responses, eventually resulting in malignant transformation.

H. pylori is a group I carcinogen according to the World Health Organization and International Agency for Research on Cancer[23]. It has been generally accepted that gastric cancer is a multistep process involving a series of events such as atrophic gastritis, intestinal metaplasia, dysplasia and carcinoma. Several studies demonstrated that CagA molecules tethered to the inner surface of plasma membrane of gastric epithelial cells, where they are tyrosine phosphorylated[14,24-26]. SHP-2 is specifically bound by tyrosine phosphorylated CagA, which provokes RAS- and extracellular signal-regulated kinase-dependent signaling cascades. The deregulation of SHP-2 signal transductions leads to loss of epithelial cell polarity, manifested by cell elongation and increased motility, that has been considered to be an important mechanism by which CagA-positive *H. pylori* promotes gastric carcinogenesis[14]. Recently, we reported that rs12423190 polymorphism of the *PTPN11* gene (encoding SHP-2 protein) is significantly associated with an increased risk of gastric atrophy in *H. pylori* infection[27]. To the best of our knowledge, the present study is the first clinical evaluation of SHP-2 expression levels and *H. pylori* infection in gastric cancer. Although SHP-2 expression level was higher in the *H. pylori* (+) group of gastric cancer compared to the *H. pylori* (-) group, no statistical difference was found (76.1% *vs* 66.6%, $P = 0.40$).

In conclusion, we demonstrated that SHP-2 is overexpressed in gastric cancer. However, the level of SHP2 expression was associated with neither *H. pylori* infection nor prognosis of the tumor. Targeting SHP-2 might lead to development of a novel treatment for gastric cancer. The precise mechanisms underlying the effect of SHP-2 on gastric carcinogenesis remains to be further investigated[28-31].

ACKNOWLEDGMENTS

The authors would like to thank those who participated in this study, and particularly thank Mr. Chang-Song Guo and Ms. Ying Song for their technical supports.

COMMENTS

Background

Gastric cancer remains the second leading cause of cancer-related deaths worldwide. Recently, SHP-2 has been identified to play a vital role in the pathogenesis of human cancers.

Research frontiers

SHP-2 has been identified as an essential component of several oncogenic signaling pathways. Mutation in SHP-2 has been confirmed in several types of solid tumors. Elucidation of the events underlying SHP-2-evoked transformation may provide new insights into the novel targets for anti-cancer therapy.

Innovations and breakthroughs

The present study is the first clinical evaluation of SHP-2 expression levels and *Helicobacter pylori* infection in gastric cancer patients.

Applications

Targeting SHP-2 might lead to development of a novel treatment for gastric cancer in the future, such as SHP-2 inhibitors.

Terminology

SHP-2 tyrosine posphatase encoded by tyrosine phosphatase SHP-2 is an evolutionarily conserved protein, containing two Src homology domains at the N terminus, a central catalytic domain, and a C-terminal tail. SHP-2 positively regulates many signaling pathways.

Peer review

The authors showed that SHP-2 expression was higher in cancer specimen compared with normal specimen. However, no association was found between SHP-2 and other clinical parameters.

Abstract

Hepatitis C virus (HCV) infection after biological accident (needlestick injury) is a rare event. This report describes the first case of acute HCV infection after a needlestick injury in a female nursing student at Padua University Hospital. The student nurse was injured on the second finger of the right hand when recapping a 23-gauge needle after taking a blood sample. The patient who was the source was a 72-year-old female with weakly positive anti-HCV test results. Three months after the injury, at the second step of follow-up, a relevant increase in transaminases with a low viral replication activity (350 IU/mL) was observed in the student, indicating HCV infection. The patient tested positive for the same genotype (1b) of HCV as the injured student. A rapid decline in transaminases, which was not accompanied by viral clearance, and persistently positive HCV-RNA was described 1 mo later. Six months after testing positive for HCV, the student was treated with pegylated interferon plus ribavirin for 24 wk. A rapid virological response was observed after 4 wk of treatment, and a sustained virological response (SVR) was evident 6 mo after therapy withdrawal, confirming that the patient was definitively cured. Despite the favourable *IL28B* gene (rs12979860) CC- polymorphism observed in the patient, which is usually predictive of a spontaneous clearance and SVR, spontaneous viral clearance did not take place; however, infection with this genotype was promising for a sustained virological response after therapy.

Acute hepatitis C virus infection in a nurse trainee following a needlestick injury. *World J Gastroenterol* 2013; 19(4): 581-585 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/581.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.581

INTRODUCTION

The incidence rate of acute hepatitis C virus (HCV) infection has been dramatically reduced since the advent of blood products screening and the introduction of single-use medical equipment. However, acute hepatitis C is still present in Western countries. In Italy, the incidence ranges from 1 to 14 cases per 100 000 according to the National Surveillance Agency[1], the Italian Blood Program[2] and by evaluation in the general population[3].

Currently, intravenous (IV) drug use is the most common exposure leading to HCV infection, with HCV prevalence rates of 50%-80% in long-term IV drug abusers. Other possible modes of acquisition are medical procedures, sexual intercourse and needlestick injuries, particularly in health care professionals[4-7]. The average rate of HCV transmission after a single needlestick exposure depends on the amount of inoculated blood, increasing to 0.9% with a hollow needle full of blood and decreas-

ing to 0.3% for conjunctival exposure[8]. In our previous experience at the Padua University Teaching Hospital no cases resulted in seroconversion[9].

In the present report, the first case of HCV seroconversion in our hospital following a needlestick injury is reported. Even though the spontaneous rate of viral clearance after acute hepatitis C ranges from 20% to 50%[5,10] and it can be predicted by measurement of serum viral load[11], which should become negative within 12-14 wk after the exposure, the injured patient developed acute hepatitis without spontaneous viral clearance. The student nurse was treated with pegylated interferon and ribavirin.

CASE REPORT

A 19-year-old female student nurse was injured on the second finger of the right hand when recapping a 23-gauge needle after taking a blood sample. The patient who was the source was a 72-year-old female, weakly positive for anti-HCV by chemiluminescence (CIA) (VITROS, anti-HCV assay, Ortho Clinical Diagnostic, Abbott Laboratories, IL, United States) with an undetermined pattern (only C1+ and C2+) at confirmatory test by immunoblot assay (HCV-RIBA 3.0 assay, Chiron Corporation, United States). Moreover, the patient had a quantitative HCV-RNA level of 14 491 571 IU/mL (COBAS TaqMan, Roche, Basel) and viral genotyping showed HCV-1b (VERSANT® HCV genotype 2.0, INNOLiPA, Innogenetics, Belgium).

The student nurse was checked and followed according to the SIROH recommendations and procedures, which consist of the assessment of hepatitis B surface antigen (HBsAg), hepatitis C antibody and human immunodeficiency virus (HIV) antibody at the time of injury (step 1), 3 mo after the injury (step 2), and 6 mo after the injury (step 3). At the time of the injury she was anti-HBsAg positive (recently vaccinated) and HIV and HCV negative. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were within the reference range.

At the second step (3 mo after injury), a high increase in transaminases with a HCV seroconversion (CIA: anti-HCV positive and RIBA: NS4+, NS3+, C1+++, C2+++, GST-) was detected in the student nurse. The student had a quantitative HCV-RNA level of 330 IU/mL and the HCV genotype was also 1b, as was that of the patient source. Despite the fact that the injured student nurse had no symptoms, she was diagnosed with acute HCV infection. Transaminases were frequently analysed, decreasing until normalization at 4 mo after the injury (Figure 1). HCV-RNA was detectable, but below the lower limit of the linearity range (< 43 IU/mL) and was negative 5 mo after injury. At this time, AST and ALT persisted within the reference range. Unfortunately, 6 mo after injury a recurrence of viraemia (HCV-RNA positive, < 43 IU/mL) together with a slight ALT spike were observed. One month later, further analysis confirmed low viral load and an increase in transaminases.

Due to the chronic profile of the infection, antiviral therapy was prescribed and the subject received a regimen consisting of 180 μg pegylated interferon α-2a subcutaneously once a week and 400 mg ribavirin (adjusted for weight), by mouth twice a day.

During this treatment (Figure 1), a persistent transaminasemia and a slight neutrophilic leukopenia were evident. HCV-RNA analysis showed that the patient remained persistently negative beginning at week 4 of therapy. The patient suffered profound fatigue and musculoskeletal pain, which showed a good response to acetaminophen. During the last month of therapy, she had severe knee pain that was resistant to acetaminophen and only partially mitigated by other non-steroidal anti-inflammatory drugs (NSAID). Therapy lasted 24 wk without any adjustment to the drug dose.

At one month after therapy withdrawal the patient had increasing asthenia and unexplained anaemia (Hb 82 g/L, reference values 123-153 g/L) that resolved with vitamins and iron supplementation, and was probably due to NSAID-induced gastrointestinal bleeding. At 6 mo, HCV-RNA analysis remained negative, transaminases remained within the reference values, the patient felt well and her blood cell counts were restored.

Annual monitoring of HCV-RNA and liver function tests confirmed viral eradication and resolution of the liver disease up to 36 mo from the onset of the infection, thus the patient was defined as "cured".

DISCUSSION

Needle recapping is an unsuitable operation, which is usually performed only by expert physicians[12]. Student nurses should only use standard precautions and procedures and the subject of this case report has been re-educated according to the protocol following her professional exposure.

Because the student had no history of blood transfusion, sexual behaviour or IV drug abuse between the time of injury and the onset of acute HCV, it was highly probable that the lesion with the contaminated source was the cause of seroconversion. Furthermore, the student nurse had the same HCV-1b genotype as the patient; however, sequence analysis comparing the source and student nurse HCV-RNA would be required to eliminate all doubt.

The average rate of HCV transmission after a single needlestick exposure is low[13], and the transmission rate in Italy is as low as 0.4%[8]. The higher seroprevalence in health care workers[2] is probably related to the fact that health care workers are submitted to follow-up after biological contamination, therefore, there is a greater rate of discovery of seroconversions than in other workers not submitted to surveillance for biological risk. The adherence to procedures after biological exposure is important, because patients with acute HCV infection are often asymptomatic and this makes diagnosis difficult and cases remain underestimated[14].

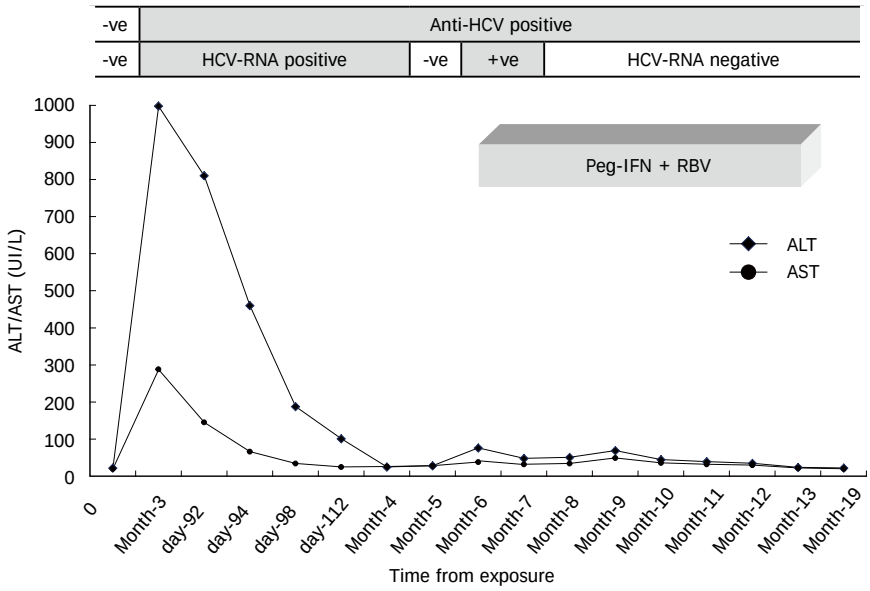

Figure 1 Behaviour of transaminases and hepatitis C virus-RNA after a needle stick injury and during the treatment with pegylated interferon α-2a at 180 μg *s.c.* once a week and ribavirin weight adjusted at 400 mg *p.o.* twice a day are shown. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; HCV: Hepatitis C virus; PEG-IFN RBV: Pegylated interferon plus ribavirin.

Table 1 Immunologic mechanisms involved in acute phase of hepatitis C virus infection and predictive of viral clearance or persistence and chronicity of infection

	Immunologic marker	Mechanism involved	Ref.
Acute phase of HCV infection and predictive of viral clearance	IFN-α/-β	Vigorous IFN-stimulated genes; inhibition of IL12 expression	[21]
	IFN-γ	HCV core induced generation of reactive oxygen species with stimulation of monocytes and NKs	[22]
	IFN-λ	Host *IL28B* gene polymorphism (CC allele favorable)	[23]
	CD4/CD8	Multispecific intrahepatic Th1 T cells activation	[26]
	HLA-B27/-B57/-A3	Protective HLA alleles on T cell epitopes	[29]
HCV persistence and chronicity of infection	TGF-β/IL10	Inhibition of anti-HCV core/NS2 Th1 response	[24,25]
	CD161	HCV-specific Th17 T cells regulated by TGF-β and IL10	[27]
	HCV HVR-1 specific Abs	Viral escape from Abs mediated neutralization	[28]
	PD1/2B4/CD160	Inhibitory T cell receptors on CD8+ cells	[30]

HCV: Hepatitis C virus; HVR: Hypervariable region; IFN: Interferon; TGF-β: Transforming growth factor-β; IL: Interleukin; HLA: Human leukocyte antigen; NK: Natural killer.

The expectation of a spontaneous viral clearance was initially high in our subject due to the normalization of transaminases and the transient HCV-RNA negativity. Some factors have been proposed as being associated with spontaneous viral clearance including ethnicity[15,16], short incubation period[17], rapid decline in HCV-RNA level[11], and female gender[18]. Unfortunately, despite the age, gender, absence of additional risk factors, rapid normalization of transaminases[19], low viral load (330 IU/mL, approximately 7000 copies/mL) and favourable *IL28B* gene (rs12979860) CC-polymorphism[20] no spontaneous viral clearance was observed in our subject. This was probably due to persistence of the virus (> 3 mo from onset), and particularly to the host complex immunological mechanisms that are associated with spontaneous clearance or to chronic infection (Table 1)[21-30].

In general, following injury with a HCV source, no post-exposure prophylaxis is indicated; on the other hand, whether and how to treat acute HCV infection is still up for debate. The use of α-interferon may be effective in preventing progression from acute to chronic disease[31], but there are no data to indicate that early treatment during the course of chronic infection is less effective than immediate treatment during the acute phase. Certainly, we must consider that in 20%-30% of cases, after an acute infection, spontaneous clearance of HCV occurs and that antiviral therapy is expensive and not well tolerated in the majority of cases[32]. Delaying treatment for 12-16 wk after disease onset permits the identification of cases whose infections spontaneously resolve and whether early initiation of treatment is more appropriate in cases with genotype 1b and/or with asymptomatic disease is still an open question.

The aim of therapy is to achieve a sustained virological response (SVR), defined as the absence of HCV-RNA in serum 6 mo after therapy withdrawal[33]. In acute infection, which has the favourable features of low pretreatment HCV-RNA levels and HCV-genotype non-1 correlate,

SVR varies between 71% and 94%[34-37] and is certainly higher than the rate obtained in cases with long time chronic infection[38].

During therapy, the student nurse showed a rapid virological response (RVR), defined as the absence of HCV-RNA at 4 wk after therapy withdrawal[39], which was maintained at 6 mo after therapy withdrawal, thus, she was defined as having a SVR. These findings confirm that the earlier the virus disappears from serum the higher the probability of achieving a sustained response to treatment.

This case report supports the vigorous application of measures to increase adherence to protocols after biological contamination. We believe that all cases, if there are no contraindications, should be evaluated promptly to prescribe a standard full antiviral schedule of pegylated interferon and weight-based ribavirin, especially in cases like this one in which there is a viral kinetic showing a transient or slow resolution of the active infection. Currently, response-guided therapy helps to determine the duration of treatment, which is cost saving and more advantageous for patients[40]. In this case report, the RVR allowed for the use of a shorter schedule, 24 wk of therapy, which is approximately 12.000 € less than the standard of 48 wk.

In conclusion, the lessons from this case are as follows: (1) health care workers must be counselled and trained to avoid occupational exposure; (2) all injured cases must report the exposure immediately and undergo standard procedures; and (3) a weight-adjusted full schedule of the standard regimen with pegylated interferon and ribavirin should be proposed in all cases with acute HCV infection showing an active and longer viral replication, in particular for cases with more than 6 mo of acquisition. These suggestions might help to avoid the unaware HCV-carrier status, and thus some chronic infections with the potential progression to cirrhosis and to major complications, such as hepatocellular carcinoma.

Abstract

Tubular duplication of the colon is very rare especially in adulthood, because it is frequently symptomatic earlier in newborn life, so only few cases are reported in literature. Several theories are proposed to explain the onset and the evolution of gut malformations as the aberrant lumen recanalization or the diverticular theory, the alteration of the lateral closure of the embryonal disk or finally the dorsal protrusion of the yolk-sac for herniation or adhesion to the ectoderm for an abnormality of the longitudinal line, but none clarifies the exact genesis of duplication. We present a case of "Y-shaped" tubular duplication of the transverse colon in a 21-year-old adult, with a history of chronic pain and constipation, referred to our department for abdominal pain with retrosternal irradiation, treated with the resection of the aberrant bowel.

INTRODUCTION

Duplications of gastrointestinal tract are infrequent in general population with an incidence of two or three cases per year in referred pediatric center[1]. The most frequent localization is the ileum 30% and the ileocecal valve 30%, followed by the jejunum with 8%, the colon 6%-7% and the rectum 5%[2,3]. Since 1950, less than 50 colonic duplication have been reported in literature[4] and they were more often discovered in the first two years of life (80%)[5]. If no associated malformation is present, they remain frequently hidden for several years until a complication occurs[6]. The symptoms are unspecific and depend on the type of duplication and on the associated abnormality. More often they are abdominal mass, chronic pain, constipation, occlusion, and less frequently volvulus[7] intussusception, bleeding[8] or perforation (especially in sigmoid colon mimicking diverticulitis). Also the arising of carcinoma is observed: the most frequent is adenocarcinoma[9-13] followed by squamous carcinoma and carcinoid tumors[14-16]. The carcinoembryonic antigen expression can be observed in association with the arising of adenocarcinoma[17], but the presence of the carbohydrate antigen 19-9 is not well defined yet.

CASE REPORT

A 21-year-old man with a history of chronic constipation was referred to our department for abdominal pain with retrosternal irradiation. During childhood he was hospitalized for the same symptoms without a clear diagnosis:

Figure 1 Computed tomography scan. The arrows indicate the duplication.

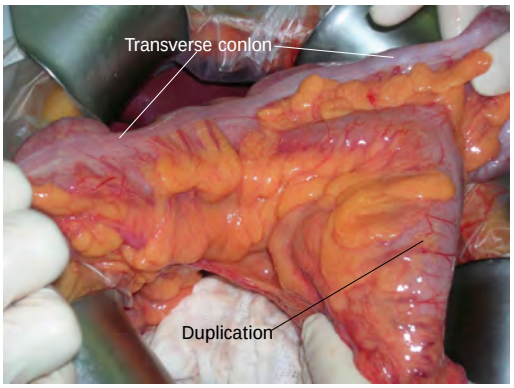

Figure 2 Intraoperative dissection.

alimentary intolerance or celiac disease were excluded, and all the abdominal ultrasounds were always negative. The mother had no particular problems during pregnancy and labour, she had no exposition to pollution, but the patient was an eight months premature birth. At the hospitalization the blood samples showed mild leukocytosis and the abdominal Rx plane was normal. Abdominal sonography was performed but it was not diagnostic, because of air hiding; an abdominal computed tomography (CT) scan (Figure 1) revealed an oval mass with wall enhancement and similar stool material inside, suggestive for intestinal duplication. A small-bowel contrast study was performed but no alteration could be demonstrated. The patient was treated with antibiotics and was discharged asymptomatic with a planned intervention for the following week. At the explorative laparotomy a transverse colon Y-type duplication was shown (Figure 2); the duplication was bent down at the origin of the transverse mesocolon and an own mesocolon was seen. After dissection from the mesocolic stamp, the duplication was unbent revealing that the blood supply origin from a distal division of the middle colic artery with a trifurcation for right and left transverse colon and one branch for the duplication. The upper part of the common mesocolon presented a crabbed fusion of small vessels. To preserve the left marginal arcade, we dissected the artery for the duplication with conservation of the two branches for the native transverse colon and with resection of the duplicated bowel and 5 cm of the native transverse colon. A colo-colic anastomosis was performed. The post operative period was uneventful and the patient was discharged; at the moment he lies symptoms free. Histopathology confirmed the tubular duplication with multiple mucosal ulceration.

DISCUSSION

Digestive duplication is defined by the three Rowling's criteria[18]: (1) the wall of the duplication is in continuity with one of the duplicated organ; (2) the cyst is surrounded by a smooth muscular layer; and (3) a layer of digestive mucosa is present, more often typical or heterotopic as gastric mucosa, colonic mucosa, bronchial or pancreatic structure[19,20]. Smith[21] well defined the term of duplication as "these formations, either tubular or spherical, which lie in contiguity with normal bowel and which share with it a common blood supply and usually a common muscle coat. There may or may not be a communication between the normal and anomalous lumina and the dividing septum may be muscular or merely a double layer of epithelium". Gross *et al*[22] described four variations in the shape of duplications: (1) a tubular structure that branches out from the intestine and extends for some distance between the mesenteric leaves; (2) a double-barreled structure communicating with the intestinal lumen at one or both ends; (3) a cystic structure lying in the peritoneal cavity, attached by a mesenteric stalk; and (4) a spherical lesion contiguous with some part of the bowel, particularly along the ileum. Cystic types are the most frequent with 90%-95% of the cases and the tubular type 5%-10%; the latter can be distinguished in double barreled (80%) or Y-shaped form (20%)[23-26]. For colonic duplication McPherson makes another classification as type I (simple cysts), type II (diverticula) or the most common type III (tubular colonic duplication)[27]. Several theories have been proposed to describe this abnormality in which environmental factors, such as trauma or hypoxia, can play a role[28]. The aberrant lumen recanalization theory exposed by Bremer[29] seems to be the most comprehensive. As described by Johnson[30] in 1910 the gut grows and obliterates the lumen at the sixth week with subsequent internal vacuolization and coalescence of vacuoles with the formation of the single lumen. The aberrant vacuolization well explains that vacuoles can remain separated and create one or more duplication that can be separated or communicating with the original gut. This theory can be easily associated to the double barrel duplication. Another theory is the diverticular one, described by Lewis *et al*[31], criticized by some authors[1] because it doesn't explain the forms of entire duplication of the colon (for example) with the presence of circular and longitudinal muscle coats. Blinder describes more simply that the tubular forms can be caused by an alteration of the lateral closure of the embryonal disk at the stage 9 of Steeter for an abnormality of the longitudinal line, instead of

cystic forms that originate from diverticulation later in the evolution[32,33]. Another explanation, well described by Smith[21], is the dorsal protrusion of the yolk-sac caused by its herniation or adhesion to the ectoderm in same phase of presomite development taking to a "dorsal remnants" structure, that can be divided into: congenital dorsal enteric fistula, congenital dorsal enteric sinus, congenital dorsal enteric cyst, congenital dorsal enteric divericulum[34]. This last theory can also explain the association with other abnormalities, especially the vertebral alteration. The association of other malformations, as vertebral or genitourinary alterations, can be classified in the notochordodysraphies: duplication or alteration of the hindgut is associated with genitourinary problem in 60% of cases[35,36] and high malformation with vertebral problems[37-40]. In particular the hindgut duplication can be explained by an insult to the caudal cell mass at the days 23-25 resulting in the "split notochord syndrome[41,42]. Until 2011 only 18 cases of transverse colon duplication have been reported. The particular localisation sometimes can give problems in diagnosis, like mismatching with pancreatic cyst[5,43]. In tubular type, CT scan, contrast enema and colonoscopy, could be the best diagnostic tools: in fact the presence of air and stool can facilitate the diagnosis; in ultrasonography the presence of air doesn't actually allow a good vision. Probably sonography, instead of CT scan, can be more performant in the cystic type, where the diagnosis is more difficult as described above. In fact in the cystic type of the transverse colon, the lesion have fluid inside and it could be adherent to the mesocolon or the pancreas, mimicking other alterations. The small-bowel contrast study, as in our case, is not so performant also in tubular type. The management of colonic duplication consists in the resection of the duplicated bowel with an extension of 2 cm in the normal bowel, due to the common blood supply at the two organs, the presence of fibrosis in the conjunction area[6,44] and the probability of arising tumor in the duplication. Our report shows that the symptomatology could be hidden for a long time, especially in absence of other anatomical alterations; probably for the presence of a big communication with the native bowel. The presence of stool inside the duplication helped us in the diagnosis, but it remains not easy to do, as reported by some authors[43]. In conclusion the colon duplication is not frequent especially in adulthood; the differential diagnosis is not easy; it must be resected even if asymptomatic, because of the risk of arising tumor.

Abstract

Primary sclerosing cholangitis is an infrequent extraintestinal manifestation of ulcerative colitis. Damage to bile ducts is irreversible and medical therapies to prevent progression of the disease are usually ineffective. We describe a patient with long-standing ulcerative colitis, which was refractory to corticosteroid therapy who developed primary sclerosing cholangitis (biochemical stage Ⅱ/Ⅳ) in the course of his pancolitis. Treatment with infliximab (5 mg/kg as an induction dose followed by maintenance doses every two months) was indicated because of steroid-dependent disease associated to primary sclerosing cholangitis as well as sacroiliitis and uveitis and previous episode of severe azathioprine-related hepatic toxicity. At present, after two years of follow-up, the patient is asymptomatic with normal liver tests and complete resumption of daily life activities. This case draws attention to the usefulness of anti-tumor necrosis factor-alpha therapy for the management of primary sclerosing cholangitis as extraintestinal manifestation of inflammatory bowel disease.

INTRODUCTION

Inflammatory bowel diseases are associated with extraintestinal manifestations involving almost every organ system in the body, including the musculoskeletal, dermatologic, hepatic, pancreatic, biliary, ocular, renal and pulmonary systems and can cause a significant challenge to physicians managing patients with Crohn's disease and ulcerative colitis[1-3]. Primary sclerosing cholangitis, a chronic, progressive disorder of unknown etiology that manifests as inflammation, stricturing, and fibrosis of medium and large intra- and extrahepatic bile ducts, is one of the most serious complications of inflammatory bowel disease, with an established strong relationship with ulcerative colitis[4]. At least 75% of patients with primary sclerosing

cholangitis have coexisting ulcerative colitis[2]. However, only 5% of patients with ulcerative colitis develop primary sclerosing cholangitis. The clinical course of sclerosing cholangitis bears no relationship with the underlying inflammatory bowel disease but damage to bile ducts is irreversible, no medical therapies have been shown to be effective at preventing the progression of the disease, and orthotopic liver transplantation is the only curative treatment.

The advent of biologic response modifiers, e.g., tumor necrosis factor-alpha (TNF-α) inhibitors, has improved the treatment of inflammatory bowel disease and its associated extraintestinal manifestations[5], such as arthritis and uveitis[6,7]. Current data suggest that infliximab is an effective alternative treatment option for patients with moderate to severe ulcerative colitis with an inadequate response to conventional glucocorticoid treatment[8]. However, the efficacy of infliximab in primary sclerosing cholangitis in patients with ulcerative colitis has not been previously assessed.

We report the case of a patient with steroid-refractory ulcerative colitis with intolerance to thiopurines and various extraintestinal manifestations, including ankylosing spondylitis and primary sclerosing cholangitis with favorable response to infliximab therapy.

CASE REPORT

We report here on a 68-year-old man in whom positive HLA B27 spondyloarthropathy and uveitis in the left eye were diagnosed at the age of 54. He was referred to the hospital because of an episode of subacute diarrhea with blood and mucous associated with mild iron-deficiency anemia. Also, he was diagnosed endoscopically and histologically of mild to moderate ulcerative rectosigmoiditis. He received oral and topical 5-aminosalicylic acid with good initial response. During the course of the disease, he presented multiple episodes of steroid-dependent ulcerative colitis and treatment with azathioprine was started 6 years after diagnosis. After 4 mo, azathioprine was discontinued due to severe hepatic cytolysis. Four years later, he was readmitted to the hospital because of bloody diarrhea and mucus (12-14 bowel movements daily, with generalized abdominal pain, proctalgia, fecal urgency and tenesmus without fever, and weight loss of 6 kg. Physical examination showed marked impairment of the patient's general condition, diffuse abdominal pain on palpation and functional limitation secondary to ankylosing spondylitis. Blood tests showed serum hemoglobin 10.5 g/dL, C-reactive protein 154 mg/dL and cholestasis hepatitis with bilirubin 1.2 mg/dL, aspartate aminotransferase (AST) 112 IU/L, alanine aminotransferase (ALT) 162 IU/L, alkaline phosphatase 281 IU/L, gamma-glutamyl transpeptidase (γ-GGT) 913 IU/L, and positive p-antinuclear antibodies 1/80. A diagnosis of moderate to severe episode of pancolitis was established. A cholangio-magnetic resonance imaging (MRI) study disclosed stenosis of the proximal common bile duct probably related to cholangitis. Causes of secondary sclerosing cholangitis were excluded as shown by the lack of abnormally elevated immunoglobulin G4 (IgG4) levels as shown in autoimmune pancreatitis or IgG4-related sclerosing cholangitis (IgG4 levels were < 100 mg/dL). Also, the patient showed increased values serum bilirubin and alkaline phosphatase of a lower magnitude that those suggestive of autoimmune pancreatitis, and radioimaging findings for enlargement of the pancreatic gland were absent. Also, the patient did not complain of abdominal symptoms suggestive of pancreatitis. All these data together with the presence of ulcerative pancolitis directed us to confirm the diagnosis of primary sclerosing cholangitis associated to inflammatory bowel disease and to exclude the diagnosis of autoimmune pancreatitis.

The patient was diagnosed of primary sclerosing cholangitis (biochemical stage Ⅱ/Ⅳ). He was treated with full doses of *i.v.* corticosteroids and urodesoxycholic acid 15 mg/kg body weight, without improvement. The patient received full doses of methylprednisolone, 1 mg/kg per day, with subsequent dose reductions at least on seven occasions over the course of 6 years. The situation of the patient was re-assessed and decided to start treatment with infliximab (5 mg/kg as an induction dose followed by maintenance doses every two months) because of steroid-dependent disease associated to primary sclerosing cholangitis, sacroiliitis and uveitis and previous history of an episode of severe azathioprine-related hepatic toxicity. At present, after two years of follow-up, the patient is still on treatment with infliximab and has remained asymptomatic, with improvement of anemia (hemoglobin 13.8 mg/dL) and biochemical evidence of cholestasis (bilirubin 0.4 mg/dL, AST 16 IU/L, ALT 20 IU/L, alkaline phosphatase 59 IU/L, γ-GGT 149 IU/L) and complete restoration of the quality of life. Annual endoscopic assessment did not show signs of dysplasia. Repeated cholangio-MRI performed during the follow-up was also unrevealing.

DISCUSSION

The incidence of primary sclerosing cholangitis varies between 0.9 to 1.6 per 100 000 persons/year[9]. More than two-thirds of patients are males and the most commonly associated condition is an inflammatory bowel disease which occurs in up to 70% of affected subjects. Inflammatory bowel disease in primary sclerosing cholangitis patients represents a distinct phenotype in that pancolitis is observed in 94% of patients with ulcerative colitis and in 96% of patients with Chron's disease[10]. It has been shown large differences between primary sclerosing cholangitis patients with and without concurrent inflammatory bowel disease. Patients with inflammatory bowel disease showed earlier appearance of primary sclerosing cholangitis than those without inflammatory bowel disease and are more likely to develop serious malignant complications and more likely to require liver transplantation[11].

In our patient, distal colitis was the initial manifestation of inflammatory bowel disease and later evolving to pancolitis, the time at which primary sclerosing cholangitis developed. Primary sclerosing cholangitis has been shown to be associated with greater anatomic extent of colitis[12-14]. It has been reported that development of primary sclerosing cholangitis in patients with ulcerative colitis may have a positive effect on colonic disease[15,16] with reduced disease activity and less use of steroids, azathioprine and surgery[17]. In other studies, ulcerative colitis associated with primary sclerosing cholangitis showed unique colonoscopic features (pancolitis, rectal sparing and backwash ileitis) with more frequent colorectal neoplasia development and worse prognosis than ulcerative colitis patients without primary sclerosing cholangitis[18]. In our patient the clinical course was characterized by severe ulcerative colitis refractory to steroid therapy. For this reason and taking into account the presence of other concomitant manifestations (uveitis, sacroiliitis) treatment with infliximab was started. However, indications of anti-TNF-α in well established primary sclerosing cholangitis should be carefully balanced due to immunosuppression and the risk of potentially fatal cholangitis.

The use of infliximab was followed by marked improvement in the patient's clinical condition, including the extraintestinal manifestations of ulcerative colitis and a favorable clinical and biochemical remission of primary sclerosing cholangitis. This suggests a direct effect of infliximab on hepatic inflammation. However, in a double-blind, placebo-controlled study of 24 patients with primary sclerosing cholangitis, no significant treatment benefit of infliximab was demonstrated[19], although in patients with primary sclerosing cholangitis and Crohn's disease treatment with infliximab was associated with improvement of liver function tests[20].

Currently, the use of anti-TNF-α treatment in primary sclerosing cholangitis is not well established. The observation that reduced T cell reactivity in liver infiltrating cells obtained from patients with primary sclerosing cholangitis was due to high local production of TNF-α provides support for the use of anti-TNF antibodies as an alternative treatment for these patients[21]. Contrarily, in the experience of Epstein *et al*[22] etanercept was well tolerated but not effective in a clinical series of 10 patients with clinically active primary sclerosing cholangitis. It is unknown whether early treatment with anti-TNF-α drugs may change the natural history of primary sclerosing cholangitis. Also, the use of this medication over years may raise financial concerns and secondary effects of this prolonged use. In the case here presented, although treatment with infliximab is expensive, the patient did not present recurrent episodes of colitis, uveitis, sacroiliitis or new episodes of cholangitis, allowing prompt resumption of work and social activities with an excellent quality of life and without further admissions to the hospital or the need of surgical operations, as a result of which direct and indirect costs have been markedly reduced in this particular case.

In conclusion, our report on a patient with steroid-refractory ulcerative colitis developing primary sclerosing cholangitis with favorable and maintained response to infliximab therapy draws attention to the usefulness of anti-TNF-α therapy for management of primary sclerosing cholangitis as extraintestinal manifestation of inflammatory bowel disease.

Abstract

Esophageo-tracheal fistula is a rare condition, and in most cases such fistulas are caused by malignant disease or emergency endotracheal intubation. A case where a wrapped tablet produced a fistula between the esophagus and trachea is described. The patient is a male born in 1938 who swallowed a tablet without unwrapping it. The patient was treated with self-expanding metal stents (SEMS), but closure of the fistula was not achieved. Different examinations and treatment options are discussed. Surgical treatment for this condition has demonstrated considerable mortality and morbidity. In some cases closure of the fistula can be achieved by use of SEMS. Although we advise treatment of such cases with SEMS, in some cases treatment with stents will prove troublesome and the risk/benefit analysis will have to be reevaluated.

INTRODUCTION

Esophagotracheal fistula is a rare condition, and in most cases such fistulas are caused by malignant disease or emergency endotracheal intubation. We describe a case with a unique etiology where a wrapped tablet produced a fistula between the esophagus and trachea. Challenges in diagnosis and treatment are described.

CASE REPORT

The patient is a male born in 1938. In 1997 he had prosthetic hip surgery, for which he was re-operated in 2008. Parkinsons disease was diagnosed in 2009, and he suffers from benign prostatic hyperplasia.

In 2008, during hospitalization for the hip-reoperation, he was given four tablets by a staff nurse as ordinated by a physician. Upon swallowing the tablets, the patient felt intense chest discomfort, and it was speculated whether he had swallowed one of the tablets without unwrapping it. No further investigation was done at this point.

In 2010 the patient was referred to the Department

Figure 1 Foreign body measured 2 cm x 2 cm and the tablet remained intact inside the wrapping.

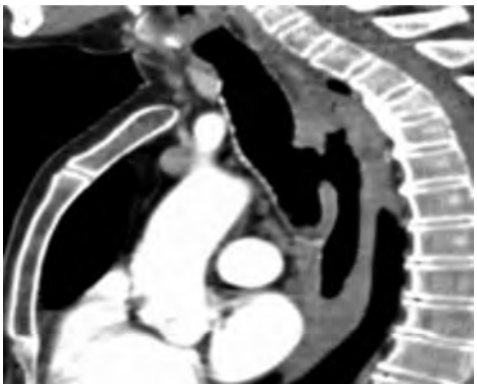

Figure 2 Computed tomography confirmed a fistula, 20 mm x 6-7 mm, at aortic arch level.

of Gastroenterology because of dysphagia.

An upper endoscopy was performed and at 25 cm from the teeth the endoscopist discovered a stenosing process with mucosal "irritation" and signs of ulceration. Biopsies from the area revealed ulceration, but no signs of malignancy. Distally, the esophagus was normal. He had signs of gastritis with a positive *Helicobacter pylori*-test. The duodenum was normal.

The initial computer tomography (CT) raised suspicion of malignancy, as it described a 4-5 cm tumor of the esophageal wall and adjacent pathological lymph nodes in the mediastinum.

Three weeks later a new endoscopy was performed, and the suspicion of a foreign body was raised. The structure in the esophagus had a blueish discoloration, and the consistency was "hard as a rock".

The patient was referred to a tertiary centre for possible endoscopic removal of a foreign body but, due to the risk for perforation, instead of trying to remove the foreign body a self-expanding, fully covered esophageal stent was placed. The patient now was able to eat.

Five months later the patient came back after having coughed up a foreign body. He brought the item to the outpatient clinic. Upon inspection it measured 2 cm × 2 cm and the tablet remained intact inside the wrapping (Figure 1). The patient reported chest discomfort, but no respiratory symptoms. Another endoscopy was performed. The stent was in place, and there was no visible fistula. Biopsies showed inflammation and proton pump inhibitor treatment was initiated.

Again a CT was performed, describing fibrotic changes in the right lung, and low-grade brochiectasia. No contrast leakage between the esophagus and the respiratory tract was seen.

The patient was in good health, but felt some discomfort having a stented esophagus. An informed decision was made to attempt stent removal under anaesthesia.

The stent was removed endoscopically, and 15 min after the procedure bleeding from the endotracheal tube was noticed. There was no subcutaneous emphysema. The patient was extubated and was able to breathe normally. The suspicion of a esophago-tracheal fistula was raised and antibiotic therapy was initiated. CT confirmed a fistula, 20 mm × 6-7 mm, at aortic arch level (Figure 2).

In order to - as far as possible - prevent aspiration from the esophagus to trachea, and to see if a spontanous closure of the fistula was achievable, a percutaneous endoscopic gastrostomy (PEG) was placed. This also ensured nutritional adequacy.

The patient was observed as an outpatient, and attended two control CTs. The fistula persisted unchanged.

After another three months it was decided to place a new esophageal stent. Upon esophagoscopy the fistula still measured 20 mm × 7 mm, and there was direct visability into the carina and the left and right main bronchus. The PEG was removed, and a fully covered, self-expanding stent was placed to cover the fistula. We chose a stent with a diameter of 28 mm at the two ends in an attempt to avoid food/liquids from getting access from the esophagus to the trachea. The length of the stent was 12.5 cm and the diameter in the center of the stent was 23 mm. A bronchoscopy was performed, during which the stent was directly visible from the tracheal side (Figure 3). A CT was performed, showing the stent in place (Figure 4).

Two months after the last stent placement the patient is asymptomatic, and is obtaining natural nutrition. A follow-up CT is scheduled.

DISCUSSION

A report on surgical correction in two cases of iatrogenic esophago-tracheal fistulas is available[1]. These fistulas were secondary to traumatic emergency endotracheal intubation. Another report on four patients with iatrogenic fistulas demonstrated considerable mortality and morbidity in relation to emergent surgery[2]. Two patients were under long term treatment in the ICU, one suffered a stroke, and one died. A study on four patients with esophago-tracheal fistula being treated with self-expanding oesophageal stents reported fistula closure in two patients[3]. A review on surgical techniques is available[4], outlining the invasiveness of the procedures. Management of an iatrogenic tracheo-esophageal fistula

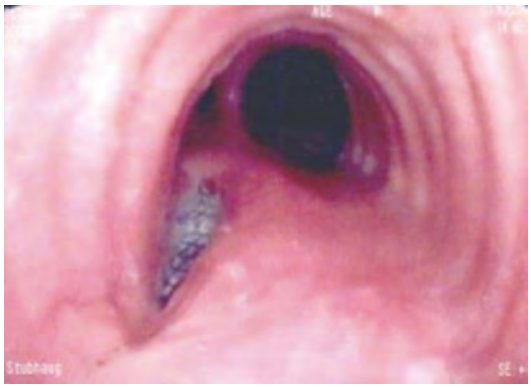

Figure 3 Bronchoscopy was performed, during which the stent was directly visible from the tracheal side.

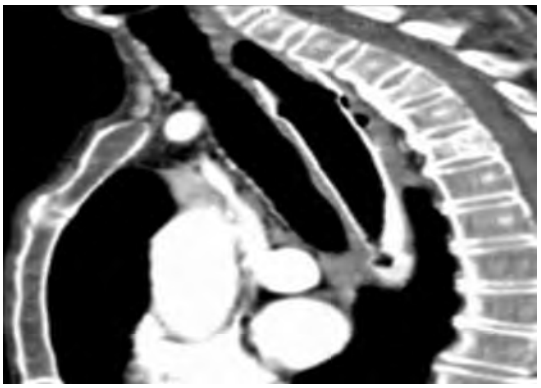

Figure 4 Computed tomography was performed, showing the stent in place.

using a Y-stent on the tracheal side is described[5]. A self-expanding metal stent is, according to one study, safe and effective in palliation of malignant fistulae in selected patients[6]. However, this study was conducted on 90 patients with malignant changes in the esophagus, of which only 5 patients had a fistula.

Our case illustrates a unique etiology of an esophago-tracheal fistula. The patient presents a continuous challenge in treatment. Discussions and considerations with thoracic surgeons have so far concluded with stenting as the treatment of choice. The patient's age and comorbidity is being taken into account in this decision. However, if the management with esophageal stents proves troublesome, the risk/benefit analysis will have to be re-evaluated.

The wrapped tablet was forced from the esophageal wall to the trachea, probably powered by the self-expanding stent. Long-term stenting has so far given no reduction in the size of the defect.

Abstract

Here, we report a case of fulminant gastrointestinal graft-versus-host disease (GI-GVHD) with cytomegalovirus (CMV) infection in 44-year-old woman. Despite the difficulties associated with the treatment of GI-GVHD and GI-CMV disease, the mucosal findings and the clinical course showed marked improvements during long-term clinical observation. The endoscopic findings were remarkable, with diffuse sloughing mucosa in the stomach and highly active inflammation and deep discrete ulcers throughout the colon. Changes in the CMV quantitative polymerase chain reaction results were correlated with the endoscopic mucosal findings and were useful for assessing the efficacy of the treatment. Although a definite diagnosis of GI-GVHD is generally made by endoscopy with biopsy, the gross appearance of this disease can vary depending on the endoscopy. In this paper, we also conduct a literature review of patients with GI-GVHD.

Fulminant gastrointestinal graft-versus-host disease concomitant with cytomegalovirus infection: Case report and literature review. *World J Gastroenterol* 2013; 19(4): 597-603 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i4/597.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i4.597

INTRODUCTION

Graft-versus-host disease (GVHD) is a serious complication of allogeneic hematopoietic stem cell transplantation (HSCT) and mainly attacks the skin, gastrointestinal (GI) tract and liver[1-5]. GI-GVHD, in particular, can cause life-threatening complications, such as massive diarrhea, hemorrhage, paralytic ileus, and perforation[6,7]; therefore, the accurate diagnosis of GI-GVHD is essential. Although endoscopic observation is an indispensable diagnostic tool, various mucosal patterns are observed on endoscopy[8]. In addition, testing for cytomegalovirus (CMV) infection is necessary because the complication of GI-GVHD with CMV infection will reduce the quality of life (QoL) of the patients[9]. This reduction in the QoL occurs because CMV-related GI disease is exacerbated by the administration of steroids for the treatment of GI-GVHD when antiviral drugs are not administered[10]. Here, we report a rare case of fulminant GI-GVHD detected by endoscopy and its clinical course, and we review related literature on the endoscopic findings of GI-GVHD.

CASE REPORT

The patient, a 44-year-old woman with acute myeloid leukemia who was diagnosed 18 mo earlier, underwent

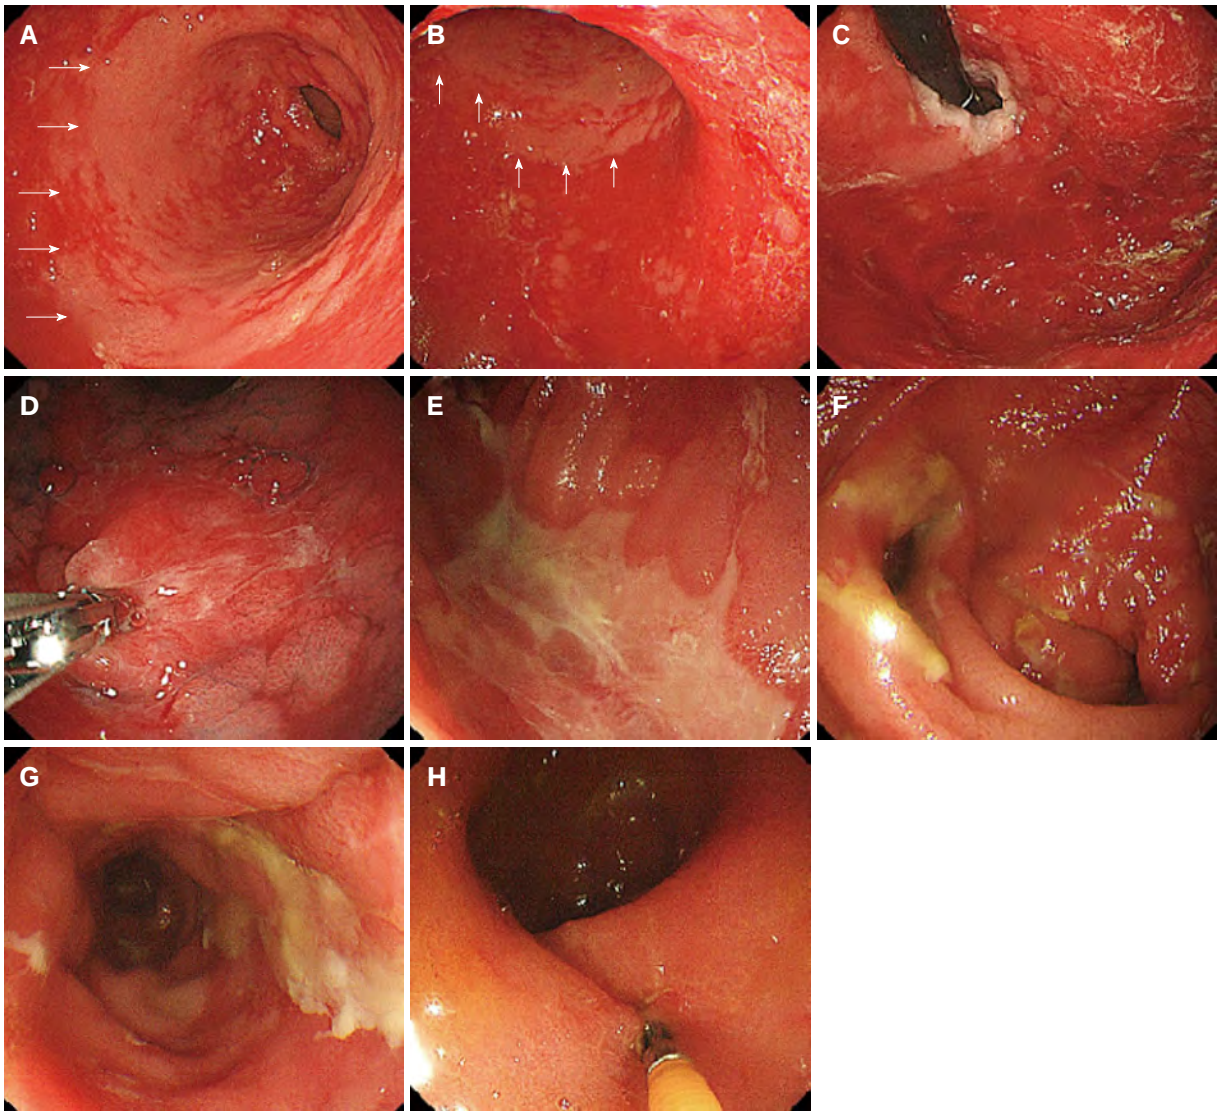

Figure 1 Upper and lower gastrointestinal endoscopic findings. A: The gastric mucosa in the antrum of the stomach. The antrum is the only segment exhibiting normal mucosa (arrows); B: The gastric mucosa in the lower segments of the corpus of the stomach. This mucosa demonstrates diffuse sloughing, whereas the antrum is the only segment exhibiting normal mucosa (arrows); C: The gastric mucosa in the upper segments of the corpus of the stomach; D: The greater curvature of the stomach near the center. A biopsy was taken from the edematous and sloughing mucosa of the greater curvature of the upper corpus; E: Shallow ulcer with fur at the cecal valve and cecum; F: Discrete longitudinal ulcer in the terminal ileum; G: Longitudinal ulcer with fur surrounded by the inflamed edematous mucosa of the sigmoid colon; H: Edematous mucosa of the rectum.

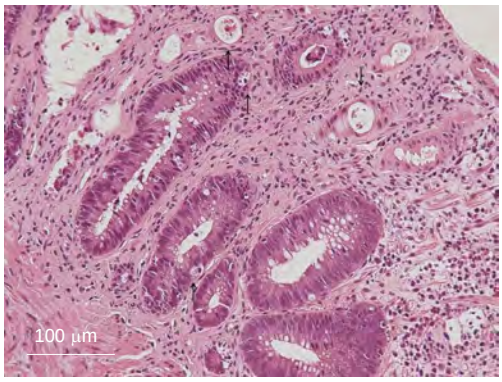

Figure 2 Histological findings. Biopsy specimen from the sigmoid colon revealing a crypt with multiple apoptotic cells (arrows) with severe lymphocytes corresponding to acute gastrointestinal graft-versus-host disease (GVHD). The presence of gland apoptosis is histological evidence of acute GVHD (hematoxylin and eosin stain, × 40).

allogeneic bone marrow transplantation 3 mo prior to the examination. A full-body skin rash appeared on day 26 after the transplantation. On day 85 after the transplantation, she experienced watery diarrhea more than 10 times per day and developed abdominal pain. Upper GI endoscopy showed diffuse sloughing of the mucosa with diffuse erythema and hemorrhage in the antrum and corpus of the stomach (Figure 1A-D). Lower GI endoscopy revealed multiple deep discrete ulcers with exudative and mucosal oozing in the terminal ileum end and throughout the entire colon (Figure 1E and F). Biopsy specimens from the upper and lower GI tract revealed diffuse erythema, erosions, and sloughing mucosa with active bleeding in the stomach, as well as multiple erosions and a small discrete ulcer with active bleeding in the lower GI tract. Gland apoptosis showed histological evidence of acute GVHD (Figure 2). Moreover, the

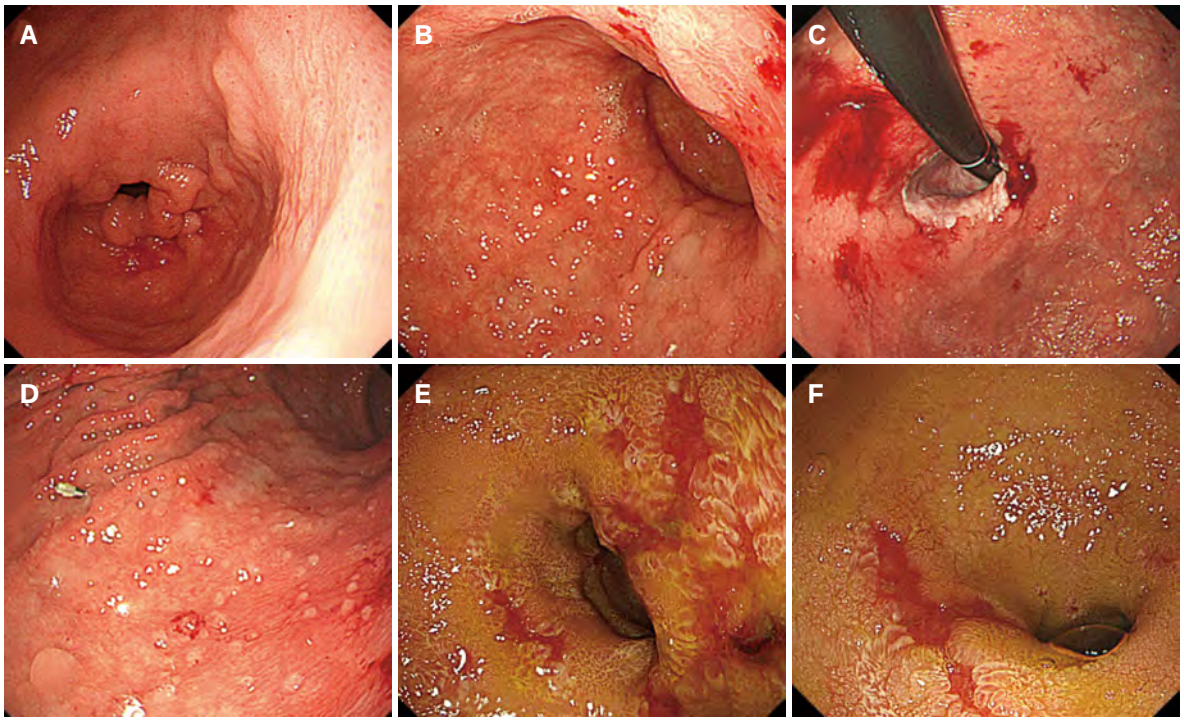

Figure 3 Upper and lower gastrointestinal endoscopic findings 70 d after the steroid therapy. A: The gastric mucosa in the antrum of the stomach. The mucosa is normal but somewhat edematous; B: The gastric mucosa in the lower segments of the corpus of the stomach, which has improved even though the rough gastric mucosal patterns and edematous changes remained; C: The gastric mucosa in the upper segments of the corpus of the stomach, which has also improved; D: The greater curvature of the stomach near the center. The endoscopic clipping has remained; E: Sigmoidoscopy revealing multiple discrete ulcers in the sigmoid colon; F: Disappearance of the visible vascular pattern in the sigmoid colon.

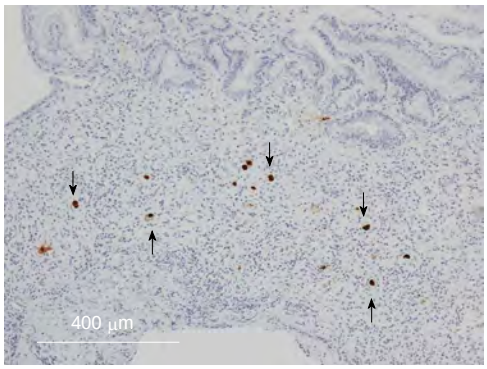

Figure 4 Immunostaining of the biopsy specimen. Immunohistochemically stained biopsy specimen from an ulcer of the sigmoid colon showing multiple cytomegalovirus-positive cells (arrows) (immunohistochemical stain, × 40).

biopsy specimens showed CMV infection detected by polymerase chain reaction (PCR) at remarkably elevated concentrations of 4.0×10^4 copies/μg DNA, but immunochemical staining for the CMV antibody was negative. Finally, the patient was diagnosed with severe GI-GVHD concomitant with a CMV infection. Other organ involvement included a whole-body skin rash and slight liver dysfunction.

The treatment for acute GVHD was started with an initial dose of prednisolone 1 mg/kg per day (50 mg/d) and for CMV infection with an initial dose of ganciclovir (GCV) 10 mg/kg per day. After 40 d of treatment, the patient improved clinically. Then, GCV was discontinued because of thrombocytopenia that appeared 60 d after the treatment. After 64 d, however, CMV was detected in the blood by a CMV-antigenemia assay, and the maintenance dose of GCV (5 mg/kg per day) was resumed. After 70 d, upper and lower endoscopy showed that the endoscopic findings of mucosal sloughing had improved (Figure 3A-D) but that the colonic mucosa remained ulcerative and inflamed (Figure 3E and F). Both upper and lower GI tract biopsies revealed CMV-infected cells in immunohistochemically stained tissue specimens (Figure 4), and the CMV-PCR from the GI tract biopsy was 2.0×10^5 copies/μg DNA. Intravenous GCV at 5 mg/kg every 12 h as the induction therapy was re-started and then changed to the maintenance therapy, and the prednisolone dose was tapered. Although the treatment continued for an additional 102 d, the CMV-PCR from the GI tract biopsy was 1.0×10^3 copies/μg DNA. Oral valganciclovir at 900 mg/d was started, with oral prednisolone 10 mg administered every other day. After 162 d, the upper and lower endoscopy showed notable improvements in the mucosal findings (Figure 5), and the CMV-PCR count from a GI tract biopsy was within the normal range of $< 4.0 \times 10$ copies/μg DNA.

DISCUSSION

Nausea and vomiting, appetite loss, abdominal pain, and watery diarrhea are common symptoms of GI-GVHD. Watery diarrhea appears in almost all cases of GI-GVHD and occasionally becomes chronic or causes bleeding. Therefore, this symptom is a major factor that reduces

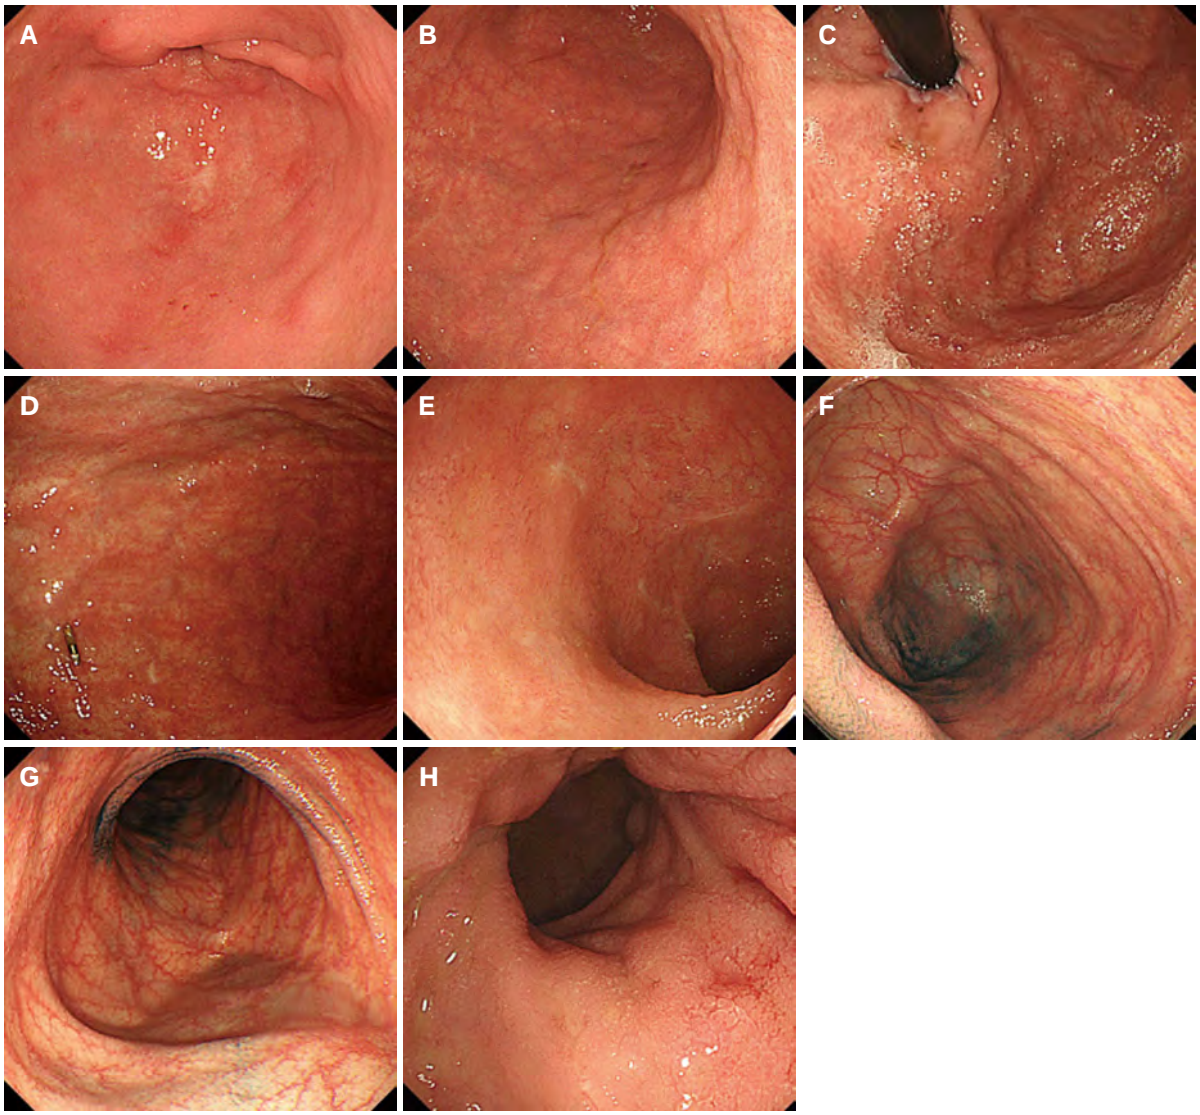

Figure 5 Upper and lower gastrointestinal endoscopic findings 162 d after the steroid and anti-cytomegalovirus therapies. A: The gastric mucosa in the antrum of the stomach; B: The gastric mucosa in the lower segments of the corpus of the stomach; C: The gastric mucosa in the upper segments of the corpus of the stomach; D: The greater curvature of the stomach near the center. The endoscopic clipping has remained, and nearly the entire mucosa of the stomach has improved to a normal state; E: Normal mucosa in the cecal valve and cecum; F: Normal mucosa in the terminal ileum; G: Marked improvement of the inflammation of the colonic mucosa, and healed ulcers in the sigmoid colon; H: The vascular patterns are now visible, indicating that the normal mucosa has returned in the rectum.

patient QoL[11]. Moreover, after HSCT, CMV infection of the GI mucosa and GI-GVHD can both cause diarrhea[12,13].

Diseases characterized by the development of GI symptoms after HSCT include not only CMV and GI-GVHD infection but also virus infections caused by enterovirus, adenovirus, rotavirus, and Epstein-Barr virus, complications with bacterial and fungus infections, and colitis associated with thrombotic microangiopathy and regimen-related toxicity. In routine clinical examination, differentiating among these diseases is difficult[14], particularly because GI-GVHD is frequently associated with CMV infection[15,16]. In this case, because of the severe GI-GVHD accompanied by CMV infection, the patient developed frequent and long-term bloody diarrhea and abdominal pain, which appeared to have led to serious symptoms such as anemia, malnutrition, and dehydration.

The endoscopic findings reflected the severity of the clinical symptoms. The lower GI tract exhibited severe signs of multiple deep ulcers, edema, and erythema, with no normal mucosa observed. The upper GI endoscopy revealed diffuse sloughing of the mucosa in the stomach, except for the antrum. Although the endoscopic findings of chronic GI-GVHD may include the characteristic esophageal web and strictures[2], various endoscopic findings are associated with acute GI-GVHD depending on the severity of the inflammation. We reviewed the English literature in the MEDLINE database by searching with "gastrointestinal", "GVHD", and "endoscopy" as key words (Table 1). Although there are some reports of normal mucosal findings, a large number of studies reported findings of erythema, erosions, and edema. Because the symptoms were generally mild in the upper GI tract, the lower GI tract often had relatively severe inflammatory symptoms, with occasional actively bleeding ulcers. In addition, although tortoise shell-like mu-

GI-GVHD: Gastrointestinal graft-versus-host disease; HSCT: Hematopoietic stem cell transplantation.

cosa and pseudomembrane formation are occasionally observed, no particular findings are reportedly associated with the colorectal mucosa. Moreover, even though some papers report mucosal sloughing and ulceration[8], a wide area of sloughing mucosa along with ulcers and inflamed mucosa, as observed in the present case, has never been reported. We believe that a combination of severe GVHD and CMV infection is the pathogenesis responsible for these symptoms[13]. According to He *et al*[17], GI-GVHD accompanied by CMV infection causes deep, discrete ulcers. The ischemic consequences of occluded blood vessels caused by enlarged vascular endothelial cells due to CMV infection are thought to be the mechanism underlying the GI mucosal damage[18]. Similarly, ischemic alteration, in addition to the cytotoxicity caused by GVHD[19], is a likely cause of the severe symptoms in our patient.

The early and accurate diagnosis of CMV infection in the GI tract is the key to preventing severe symptoms, such as perforation and bleeding[20]. In this case, even though immunostaining with an anti-CMV antibody was negative, the quantitative PCR results of the biopsy specimens were positive, with a high value of 1.0×10^4 copies/μg DNA, which enabled the diagnosis of CMV-GID. The diagnostic accuracy of the quantitative PCR method using biopsy samples is reportedly superior to that of immunostaining to determine the involvement of CMV in the GI symptoms[21]. This case showed that the results of the CMV quantitative PCR were closely correlated with the post-treatment improvement of the mucosa, suggesting the usefulness of the technique for evaluating the effects of CMV treatment.

In conclusion, when endoscopic observation is performed on HSCT patients with postoperative GI symptoms, it is necessary to look for signs of mucosal sloughing and ulcers. In addition to a detailed endoscopic observation, biopsy samples should be examined for the characteristic pathological features of GVHD[22] and for signs of CMV infection. The course of this case suggests that the quantitative PCR of biopsy samples is useful for revealing CMV infection in the GI tract.

Abstract

Emphysematous cholecystitis is a rare variant of acute cholecystitis with a high mortality rate. The combination of emphysematous cholecystitis and pneumoperitoneum is also rare. We herein describe a case of emphysematous cholecystitis with massive gas in the abdominal cavity. A 77-year-old male presented with epigastric pain and lassitude lasting for one week. A computed tomography scan demonstrated massive gas in the abdominal cavity. Gas was also detectable inside the gallbladder. Massive ascites as well as a pleural effusion were also detected. Under the diagnosis of perforation of the digestive tract, we performed emergency surgery. Beyond our expectations, the perforation site was not in the alimentary tract, but rather in the gallbladder. We then diagnosed the patient with emphysematous cholecystitis with perforation, and performed cholecystectomy. A pathological examination of the resected gallbladder revealed necrosis in the mucosa and thinning of the wall. Cultures of the ascites detected *Clostridium perfringens*, a gas-producing microorganism.

INTRODUCTION

Emphysematous cholecystitis is a type of acute cholecystitis characterized by the presence of intramural and/or intraluminal gas that may develop into gangrene or perforation of the gallbladder. The morbidity and mortality rates of emphysematous cholecystitis are considerable[1]. The disease begins with acute cholecystitis followed by ischemia or gangrene of the gallbladder wall and an infection caused by gas-producing bacteria.

Emphysematous cholecystitis is an uncommon variant of acute cholecystitis. Emphysematous cholecystitis occurring in association with a pneumoperitoneum is very rare. Modini *et al*[2] reported the 16th case of emphysematous cholecystitis with a pneumoperitoneum in the English-language literature in 2008. Thereafter, only one case was reported[3]. We herein report the 18th known case. What is of much note is that, among these cases, the finding of macroscopic perforation of the gallbladder was made in only eight patients[4].

This report presents a case of emphysematous cholecystitis causing a pneumoperitoneum with the finding of macroscopic perforation of the gallbladder.

CASE REPORT

A 77-year-old male was transported to our hospital in September 2011 because he was found falling down in his home with epigastric pain and lassitude lasting for one week. There was nothing particular in the patient's

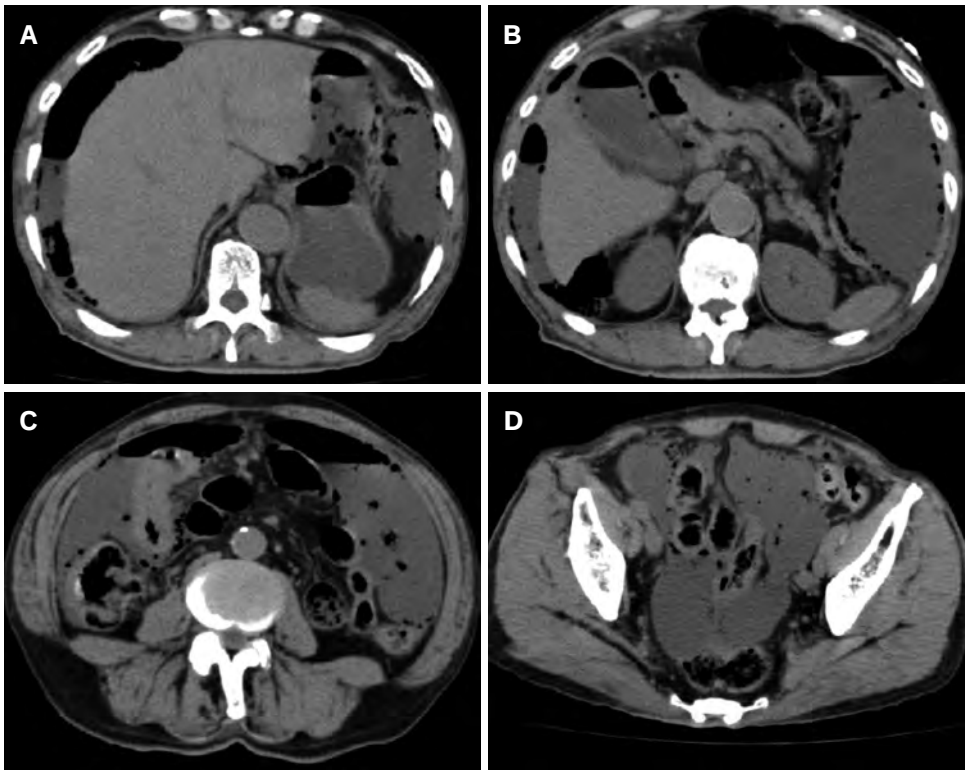

Figure 1 Computed tomography scan (axial axis). A: Demonstrating massive gas in the abdominal cavity; B: Demonstrating gas inside the gallbladder; C, D: Demonstrating massive ascites as well as a pleural effusion.

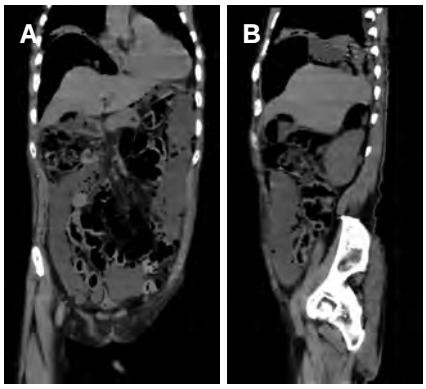

Figure 2 Computed tomography scan clearly demonstrated a massive collection of gas inside the gallbladder. A: The coronal axis; B: Sagittal axis.

history. His vital signs were as follows: pulse: 115 beats/min, blood pressure: 151/86 mmHg, respirations: 36 breaths/min, saturation: 92% on room air, and temperature: 37.7 ℃. The patient's abdomen was distended, and there was local tenderness in the upper abdomen without muscular defense. A laboratory examination showed the following values: leukocyte count: 16.6 × 10^3/μL, hemoglobin: 14.4 g/dL, hematocrit: 42.4%, platelet count: 16.5 ×10^4/μL; serum values: sodium: 130 mEq/L, potassium: 3.8 mEq/L, blood urea nitrogen: 88 mg/dL, creatinine: 3.6 mg/dL, alkaline phosphatase: 251 U/L, lactic dehydrogenase: 371 U/L, aspirate aminotransferase: 32 U/L, alanine aminotransferase: 25 U/L, total bilirubin: 0.4 mg/dL, γ-glutamyl trans ferase: 28 U/L, glucose: 207 mg/dL. Plain abdominal radiography showed the presence of intestinal gas. A computed tomography (CT) scan demonstrated massive gas in the abdominal cavity (Figure 1). Gas was also detectable inside the gallbladder (Figures 1B and 2). Massive ascites as well as a pleural effusion were also detected (Figure 1C and D). Under the diagnosis of perforation of the digestive tract, emergency surgery was performed. In the abdominal cavity, there was massive yellow-brown purulent ascites that did not include any saburra. Contrary to our expectations, the perforation site was not in the alimentary tract, but rather in the gallbladder (Figure 3). We therefore diagnosed the patient to have emphysematous cholecystitis with perforation, and performed cholecystectomy. No gallstones were detected in the gallbladder. Tazobactam/piperacillin was given pre- and post-operation. The patient's postoperative course was uneventful, and he was discharged healthy 28 d after undergoing surgery. Cultures of the ascites detected *Clostridium perfringens*. A pathological examination of the resected gallbladder revealed necrosis in the mucosa and thinning of the wall.

DISCUSSION

Emphysematous cholecystitis is a type of acute cholecystitis characterized by the presence of gas in the gallbladder wall. The disease begins with acute cholecystitis followed by ischemia or gangrene of the gallbladder wall and infection caused by gas-producing bacteria. Whereas the mortality rate of uncomplicated acute cholecystitis is

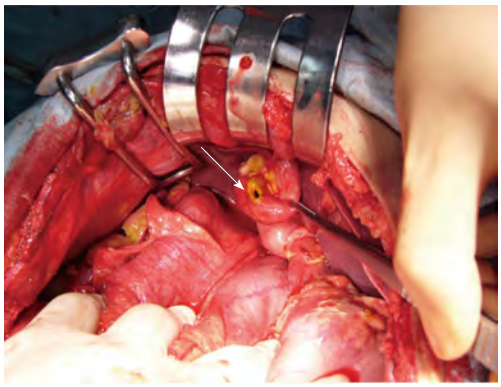

Figure 3 An 8 mm hole in the gallbladder was detected (arrow).

approximately 1.4%, that of acute emphysematous cholecystitis is 15%-20% due to the increased incidence of gallbladder wall gangrene and perforation[5]. Therefore, prompt diagnosis and treatment are essential. The most common symptoms are right upper quadrant pain, low-grade fever, nausea and vomiting. Peritoneal signs may be present, and masses in the right upper quadrant may be palpated in as many as half of patients. CT scanning is the most sensitive test for detecting emphysematous cholecystitis. The presence of gas within the gallbladder wall and lumen is easily confirmed on CT scans.

Emphysematous cholecystitis is more common in males than females (7:3), and 40% of affected patients have diabetes mellitus. In our case, there was no history of diabetes mellitus. After the operation, his blood sugar was decreased down to a normal level, and HbA1c was within normal range.

The presence of a concomitant pneumoperitoneum, which may occur following gallbladder perforation, is rarely found. Most patients with a concomitant pneumoperitoneum are in unstable condition. Therefore, the first choice of treatment in such cases is emergency exploratory laparotomy, followed by cholecystectomy, under a correct intraoperative diagnosis. Another method of treatment, involves initial percutaneous cholecystostomy with a strict intravenous antibiotics regimen, followed by subsequent cholecystectomy during a second stage[4]. In severely ill patients in particular, percutaneous cholecystostomy with broad-spectrum antibiotics may be an alternative choice of treatment[5]. In our case, we did not diagnose the patient with emphysematous cholecystitis preoperatively due to the huge amounts of gas in the abdominal cavity. Compared with previous cases, the amount of gas in our case was very large, thus suggesting not an acute stage, but a sub-acute stage and continuous infection with gas-producing bacteria. If the correct diagnosis could be done preoperatively, laparoscopic surgery may be the alternative treatment.

The bacteria most frequently cultured in this setting include anaerobes, such as *Clostridia welchii* or *Clostridia perfringens*. The bacteria second most frequently cultured include aerobes, such as *Escherichia coli*[5]. In our case, cultures of the ascites detected *Clostridium perfringens*. Zeebregts *et al*[4] reported that, in six of 14 cases, *Clostridium perfringens* was detected on cultures.

In conclusion, we herein reported a case presenting with a very large amount of gas in the abdominal cavity due to gallbladder perforation. We first suspected the possibility of upper gastrointestinal perforation and performed emergency surgery. However, we found a perforation not in the gastrointestinal tract, but rather in the gallbladder. Pneumoperitoneums are nearly always due to perforation of the gastrointestinal tract, however, although unusual, they may also be caused by emphysematous cholecystitis.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Serrated polyps have been an area of intense focus for gastroenterologists over the past several years. Contrary to what was thought before, a growing body of literature indicates that these polyps can be precursors of colorectal cancer (CRC). Most of these lesions, particularly those in the proximal colon, have so far been under-recognized and missed during colonoscopy, qualifying these lesions to be the main cause of interval cancers. It is estimated that 10%-20% of CRCs evolve through this alternative, serrated pathway, with a distinct genetic and epigenetic profile. Aberrant DNA methylation plays a central role in the development of this CRC subtype. This characteristic molecular background is reflected in a unique pathological and clinical manifestation different from cancers arising *via* the traditional pathway. In this review we would like to highlight morphological, molecular and clinical features of this emerging pathway that are essential for gastroenterologists and may influence their everyday practice.

INTRODUCTION

It is being increasingly recognized that colorectal cancer (CRC) is not a single disease, but rather a heterogeneous disorder including a collection of many distinct diseases with diverse molecular background and clinicopathological manifestations. According to the adenoma-carcinoma sequence proposed by Vogelstein *et al*[1] adenomatous polyps have long been considered as the sole preneoplastic lesions leading to CRC. On the other hand, hyperplastic polyps (HP) often found in the distal colon, until recently have been considered innocuous lesions, despite some contradictory opinions[2,3]. This common view has recently been challenged, as it turned out that these polyps along with other similar lesions commonly termed "serrated polyps" can be precursors to CRC[4,5].

The aim of this article is to provide a thorough clinicopathologic overview of this emerging pathway in colorectal carcinogenesis and help to understand how this accumulating data can be translated into clinical management strategies and better clinical outcomes.

CLASSIFICATION OF SERRATED POLYPS

General features of serrated polyps

The term "serrated polyp" contains a wide variety of colonic lesions and broadly refers to HP and different serrated adenomas. The main histological feature of serrated polyps is the infolding of the crypt epithelium[5], that is represented as a serrated or saw-toothed appearance in longitudinal section and a stellate or starlike appearance on cross section (Figure 1). The molecular basis for this histological feature has been attributed to decreased apoptosis[6-8] that is caused by the activated

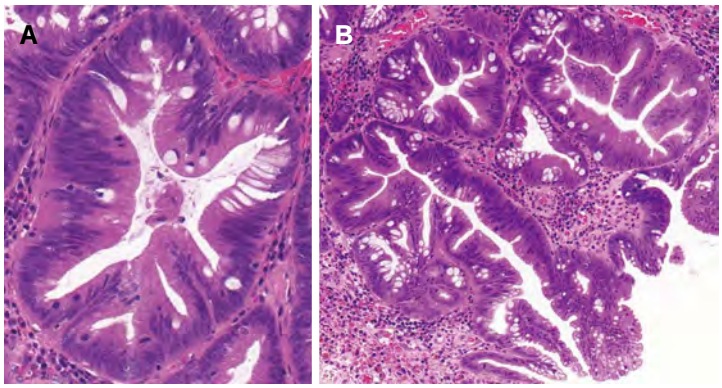

Figure 1 Microscopic features of serrated polyps. A: On cross section serrated crypt shows a stellate or starlike appearance; B: In longitudinal section a characteristic serrated or saw-toothed appearance can be seen.

mitogen activated protein kinase (MAPK)-ERK pathway that is induced by either *BRAF* or *KRAS* mutation (Figure 2). Inhibited apoptosis leads to the accumulation of non-proliferating cells. Serration is a general characteristics of this pathway from HP all the way to serrated adenocarcinoma (SAC)[9].

Hyperplastic (non-dysplastic) aberrant crypt foci

The earliest known microscopical precursors to CRC are mucosal abnormalities termed aberrant crypt foci (ACF). ACF can be further subclassified into two categories: dysplastic and hyperplastic[10,11] (also called as heteroplastic or non-dysplastic). Dysplastic ACFs, often termed as microadenomas, have been associated with sporadic adenomas arising *via* the traditional pathway[12,13]. Hyperplastic ACF may be serrated or non-serrated[11]. They are very frequent; almost every individual over 50 has at least one ACF in the distal colorectum[14]. Serrated hyperplastic ACF has a higher frequency of *BRAF* mutations, than non-serrated ACF, whereas non-serrated ACF has a higher frequency of *KRAS* mutations, than serrated ACF[11,15]. This finding supports the idea that these lesions are potentially initiating step on the serrated pathway to CRC[15], however their high frequency imply that only a small fragment progresses to HP or more advanced lesions of the serrated pathway[9]. *BRAF* and *KRAS* (mutually exclusive) mutations induce the activation of the MAPK-ERK pathway leading to decreased apoptosis and an initial burst of MAPK-ERK-dependent proliferation, leading to the formation of hyperplastic crypts. This uncontrolled proliferation is counteracted by a protective phenomenon called oncogene-induced senescence that is driven by telomere attrition, that triggers the induction of tumor suppressors including *p16*[16] or *IGFBP7*[17] (insulin-like growth factor binding protein 7), similarly as it was described in melanocytes. Hyperplastic crypts may remain dormant for prolonged periods due to the induction of crypt senescence[8] (Figure 2).

HP

HPs are the most common (80%-90%) and the best described serrated polyps. They occur most frequently in the distal colon and the rectum; they are usually slightly elevated, diminutive polyps, less than 5 mm in size. Key morphological features include elongated crypts with serration limited to the upper half of the crypt, with lack of cytologic or architectural dysplasia. These alterations can be seen only in the upper third or only on the surface of the crypts[18]. The proliferative zone may be expanded, but usually confined to the crypt base. The nuclei are small, uniform and basally placed[18], the cytoplasm is eosinophilic. If surface epithelium is not present for histological evaluation, a thickened basal membrane and muscularis mucosae with short smooth muscle extensions into the basal part of the mucosa ("comb-like" appearance) can be helpful hints to identify HP[19] (Table 1).

HPs usually occur a decade earlier (in the fifth and the sixth decade) than adenomatous polyps[20]. Several risk factors have been linked with the prevalence of serrated polyps including cigarette smoking, alcohol consumption, obesity and low-folate intake[20,21], whereas regular nonsteroidal anti-inflammatory drug use, hormone replacement therapy, and high calcium intake have been associated with reduced risk[20]. It is of note that besides smoking, all other factors have also been linked to adenoma formation *via* the traditional pathway[9,20]. This observation gained further importance when it was discovered that smoking is only a strong risk factor for those CRCs that exhibit a unique molecular phenotype [CpG island methylator phenotype (CIMP)] linked to sessile serrated pathway[22,23].

Subclassification of HP

Based on the epithelial mucin content, Torlakovic *et al*[19] histologically subclassified HPs into three categories: goblet cell-rich, microvesicular, and mucin-poor.

Microvesicular hyperplastic polyp (MVHP), also called type 2 HP, is the most common type and the typical representation of HPs encountered in the distal colon. It is characterized by large microvesicular mucin-containing epithelial cells in the upper half of the crypt, reduced goblet cells compared to normal colonic mucosa, and goblet cell abnormalities. MVHP shows prominent serration mostly in the upper half of the crypt and it has a large proliferative zone, which may take up the basal half of the mucosa. Nuclear stratification is present, but it is not prominent. The overall architecture is slightly distorted and minimal to mild crypt dilatation is present. Almost all MVHPs are slightly thicker than surrounding normal colonic mucosa. At the molecular level, MVHPs

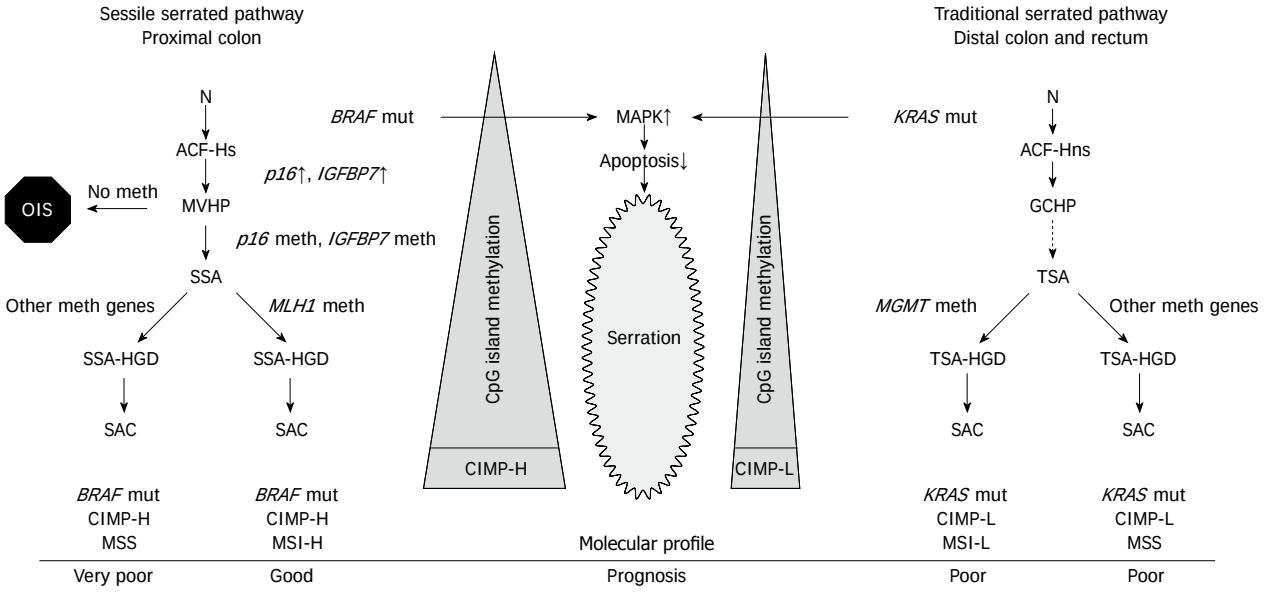

Figure 2 Schematic representation of the sessile and traditional serrated pathways. N: Normal mucosa; ACF-Hs: Serrated hyperplastic-type aberrant crypt focus; ACF-Hns: Non-serrated hyperplastic-type aberrant crypt focus; MVHP: Microvesicular hyperplastic polyp; OIS: Oncogene-induced senescence; GCHP: Goblet cell-rich hyperplastic polyp; SSA: Sessile serrated adenoma; TSA: Traditional serrated adenoma; SSA-HGD: Sessile serrated adenoma with high grade dysplasia; TSA-HGD: Traditional serrated adenoma with high grade dysplasia; SAC: Serrated adenocarcinoma; *IGFBP7*: Insulin-like growth factor-binding protein 7; MAPK: Mitogen activated protein kinase-ERK pathway; *MLH1*: MutL homolog 1; *MGMT*: O-6-methylguanine-DNA methyltransferase; CIMP-H: CpG island methylator phenotype-high; CIMP-L: CpG island methylator phenotype-low; MSI-H: High-level microsatellite instability; MSI-L: Low-level microsatellite instability; MSS: Microsatellite stable.

commonly (80%) exhibit *BRAF* V600E mutation[24], where valine is substituted for glutamic acid. As it was discussed above, this induces MAPK-ERK pathway that is followed by oncogene-induced senescence that includes overexpression of growth control genes *p16* and *IGFBP7* holding the cells in a dormant state. Aberrant CpG island methylation of the promoter region of *p16* and *IGFBP7* bypasses this dormant state[8] and drives MVHPs further to the next stage of serrated polyp progression, namely sessile serrated adenoma[9]. CpG island methylation is more pronounced in proximal MVHPs than in those located distally[25,26] (Figure 2).

Goblet cell-rich hyperplastic polyp (GCHP), also known as type 1 HP, is most commonly found in the distal colon, and is probably the most under-recognized variant. As its name implies this subtype is abundant of large, mature, distended goblet cells in the upper half of enlarged crypts and surface epithelial cells. Surface serrations are less prominent than in MVHP. Nuclear atypia is generally not present, but nuclei are slightly enlarged. *KRAS* mutations (in codon 12 and 13) were detected in almost half of these lesions[24,27], whereas *BRAF* mutations were rarely detected[27]. Successor lesions of GCHPs were rarely observed and it is open question whether they are self-limiting[9,24] or progress to advanced *KRAS*-mutated serrated polyps, presumably traditional serrated adenomas (TSA)[28] (Figure 2).

The mucin-poor hyperplastic polyp is the rarest form, almost absent of goblet cells. It has prominent nuclear atypia, hyperchromatic nuclei, lack of mucin, therefore it is considered to be a reactive version of MVHP with unknown clinical significance[29].

This distinction among these HP variants is primarily of theoretical importance, and an area of academic interest with little or no clinical importance at the moment. However, the distinction between HPs and more advanced lesions is of cardinal clinical importance[28] (Table 1).

PRECURSOR LESIONS TO SERRATED ADENOCARCINOMA

Serrated adenomas

In their landmark paper from 1990, Longacre and Fenoglio-Preiser[30] retrospectively overviewed 18 000 colorectal polyps and identified 110 (0.6%) as serrated adenomas. In 2003, Torlakovic *et al*[19] further divided serrated adenomas into two categories, TSA (those originally described by Longacre and Fenoglio-Preiser) and a new group identified as sessile serrated adenomas (SSAs), lesions with a serrated morphology without cytologic dysplasia.

Sessile serrated adenoma

SSAs are thought to be the second most common form of serrated polyps representing about 20% of all serrated polyps[18,19,31], however more recent studies have shown decreased prevalence (3%-8%)[32,33]. As mentioned above, before 2003 SSAs were labeled as "HP"[34]. It was demonstrated in a recent case series that according to the new WHO classification for serrated colonic polyps[35] a considerable proportion of HPs (especially those greater than 5 mm) were reclassified as SSAs[36].

Still today it is hard to distinguish SSAs from HPs, as

there are only subtle differences, and SSAs lack the typical features (such as cytologic dysplasia) of traditional adenomas. SSAs tend to locate in the proximal colon, but they can also be encountered in the distal colon (Table 1).

The microscopical features of SSAs were first described by Torlakovic and Snover[37] in their landmark paper in 1996, then the term was reintroduced in 2003[19,31]. Microscopically, most characteristic features include horizontal crypt extensions (inverted T- or L- shape) at the crypt bases, crypt branching, crypt invaginations and inverted crypts beneath the mucosal muscle layer (pseudoinvasion), mature goblet cells at the crypt bases, dilation in the lower crypts, serration throughout the crypt length, extending into the lower third of the crypt as well[18,38]. The proliferation zone can extend to the basis of the crypt. SSAs can exhibit mild nuclear atypia, but always lack cytologic dysplasia.

Endoscopically, SSAs are flat or slightly elevated, malleable lesions with irregular borders and may be covered with a thin layer of yellowish mucus giving them a pale appearance[28,38]. They are usually larger than 5 mm in diameter. Their surface is smooth or granular[28], sometimes resembling a prominent mucosal fold. These features altogether make it difficult to detect and remove completely with conventional white-light endoscope, therefore advanced, image-enhanced endoscopy techniques including traditional or virtual magnifying chromoendoscopy are needed. Chromoendoscopy is an image-enhanced endoscopic technique that highlights differences in colonic mucosa based on structural patterns, so-called "pit patterns". In a recent magnifying endoscopy study a new Type Ⅱ open-shape pit pattern (Type Ⅱ-O) was described and shown highly predictive of SSAs (with a sensitivity of 65.5% and a specificity of 97.3%). Progression of SSAs to more advanced lesions was associated with additional morphological changes, including the Type Ⅲ, Ⅳ and Ⅴ pit patterns[39] (Table 1).

On a molecular level, SSAs exhibit *BRAF* mutation and high level of CpG island methylation, supporting the hypothesis that they represent an intermediate stage between MVHPs and sporadic CIMP-H cancers. It was shown that SSAs can progress to dysplasia (SSA with high grade dysplasia, SSA-HGD) and then to CIMP-H cancers. Methylation and consequential loss of expression of *MLH1* (a major DNA mismatch repair gene) is thought to drive this transformation. Impaired mismatch repair leads to high level of microsatellite instability (MSI-H) (Figure 2). It was hypothesized that this malignant progression can occur at faster rate than that observed in the lesions emerging *via* the traditional pathway[40]. This is based on the observation that SACs are more prevalent than SSA-HGD[31,32,38]. The exact time of progression from SSA to SAC is unknown. In a recent case report an untreated SSA was described to transform into an early submucosal invasive cancer in a period of 8 months[41]. These data further underline the need for improved detection of these lesions.

Traditional serrated adenoma

TSAs were first described by Longacre and Fenoglio-Presier[30] in 1990. As mentioned above, until 2003 they were termed serrated adenomas when Torlakovic *et al*[19] divided serrated adenomas to SSA and TSA. In 2008 the same group further characterized these lesions[42]. TSAs represent the rarest subtype of serrated lesions, with a frequency of 1%-6%[18]. Similar to the majority of serrated lesions (unlike SSAs), TSAs have a predilection for the distal colon and the rectum. Macroscopically they resemble traditional adenomas, as having a pedunculated, polypoid appearance. Cytologic dysplasia (90% low-grade and 10% high-grade[18]), as their name implies, is a major feature of TSAs (Table 1).

In 2008, Torlakovic *et al*[42] proposed ectopic crypt formation as decisive morphological criterion for diagnosing TSAs. Ectopic crypts are newly formed aberrant crypts that lost their anchoring to the underlying muscular layer of mucosa[18]. Other characteristics include diffuse eosinophilic cytoplasm, mucosal bridges and protrusions resembling tennis-racquets[42]. On a molecular level, TSAs are frequently *KRAS* mutants; however they can exhibit *BRAF* mutation, and also lack both mutations.

Filiform serrated adenoma is an unusual, less aggressive variant of traditional serrated adenoma, with morphological features similar to TSA[43]. Unlike TSA, filiform SA is composed predominantly of prominent, thin, elongated filiform projections lined by neoplastic epithelium with a serrated contour[44].

Mixed polyps

Mixed polyps are combinations of traditional adenomas and serrated lesions. They are postulated to be the result of collision tumors[45] and successors of SSAs. It is not encouraged to use this term as it does not disclose the preinvasive nature of these lesions[18]. Still, "mixed polyp" is a widely used term and when used it is recommended to describe the components of these lesions (*e.g.*, TSA and traditional adenoma *etc.*)[18].

SERRATED ADENOCARCINOMA

Morphologic features

SAC, a special subtype of colorectal adenocarcinomas morphologically and histochemically resembling serrated polyps, was first described by Jass and Smith in 1992[46]. The relationship between serrated adenomas and SAC were further confirmed by Mäkinen *et al*[47], then histological characteristics of SAC were described[48] and reviewed by the same group[38]. Based on these seminal reports, most important diagnostic criteria of SAC include epithelial serrations, eosinophilic and abundant cytoplasm with vesicular nuclei, chromatin condensation and lack of necrosis. SAC was further classified into three major growth patterns. The most common (70%) serrated pattern contains mature, abundant, mucus-producing epithelium with well-preserved polarity, very similar to serrated

polyps[38]. The mucinous pattern (43%) strongly overlaps with the first group, and is characterized by eosinophilic papillary rods (93%) and eosinophilic cell balls floating in the mucus[38]. The least common (7%) trabecular pattern is a feature of poorly differentiated SACs, where serrated structures are absent and cancer cells grow in a trabecular pattern, but still these cases show eosinophilic epithelium with vesicular nuclei, uncharacteristic of poorly differentiated traditional CRCs[38].

Molecular features

Gene expression profiling study by Laiho *et al*[49] provided molecular evidence that SAC is a biologically distinct subclass of CRC. Comparison of SAC and conventional CRCs revealed 201 differentially expressed genes. Three potential candidates were identified that can be involved in the oncogenesis of SAC: Ephrin receptor B2 (*EPHB2*), hypoxia-inducible factor 1-alpha (*HIF1a*) and patched (*PTCH*) appeared as genes important for the oncogenesis of serrated CRC. *EPHB2* and *PTCH* expression are decreased in SAC compared to conventional CRC. On the other hand, constitutive overexpression of *HIF1a*, a major proangiogenic factor, can be the cause of infrequent necrosis seen in SAC[50]. Activating mutations of oncogenic *BRAF* and *KRAS* are common findings in SAC[26]. As mentioned above, these mutually exclusive mutations induce MAPK-ERK pathway that leads to the inhibition of apoptosis resulting in serrated appearance. Accumulation of CpG island methylation in the promoter regions and consequential silencing in key proapoptotic and tumor suppressor genes, such as *p16* or *IGFBP7* sets up a vicious circle. It is well established that methylation of *MLH1* leading to MSI-H phenotype (closely linked with the sessile serrated pathway) and methylation of *MGMT* leading to MSI-L are the main inducing factors in the malignant progression of serrated adenomas (Figure 2).

It is generally thought that CpG island hypermethylation is confined to the serrated pathway (CIMP)[51,52], however a recent study showed that sporadic CRCs and precursors arising *via* the traditional adenoma-carcinoma pathway also have a characteristic DNA methylation pattern different from those evolving through the serrated pathway[53].

Clinical characteristics

SAC predominantly locates to cecum (52%) and rectum (33%)[47]. It is estimated that 16% of proximal CRCs are SACs, whereas this proportion in the distal colon is only 6%[48]. It is hypothesized that proximal SACs (mostly MSI-H) arise from SSAs and distal SACs (MSI-L and MSS) originate from TSAs[38] (Figure 2). While serrated adenomas are more common in males, SACs are almost twice (1.9 : 1) as common in females, than in males[48]. The higher risk of malignant progression of serrated adenomas to SAC in (elderly) women was explained with postmenopausal estrogen deficiency and decreased folate level, however this needs to be further investigated[38].

The prognosis of SAC seems to be defined by its molecular profile (Figure 2). *BRAF*-mutated, microsatellite-stable cancers in the proximal colon confer a very poor survival[54] with adverse histological features such as lymphatic and perineural invasion and high tumor budding[55]. On the other hand, *BRAF*-mutated cancers with MSI-H phenotype (sporadic MSI-H CRCs) have a favorable prognosis[56].

SERRATED POLYPOSIS: A GENETIC PREDISPOSITION SYNDROME

Serrated polyposis, formerly called hyperplastic polyposis, is a rare form of intestinal polyposis, initially described in 1970 by Goldman *et al*[2]. Current diagnostic criteria, manifested in 2010[35], include (1) at least five serrated polyps proximal to the sigmoid colon with two or more of these being > 10 mm; (2) any number of serrated polyps proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis; and (3) > 20 serrated polyps of any size distributed throughout the colon (not all in the rectum).

Although serrated polyposis provided the first evidences for the malignant potential of serrated polyps, it is still one of the most under-recognized and poorly understood intestinal polyposis syndrome. This is probably due to its rarity (1 in 3000)[57], but also to the phenotypic plasticity[58] and overlapping clinical phenotypes within this disorder[59]. However, based on clinical observations including earlier onset of CRC, multiple cancers, increased individual and familial risk, accumulating evidence indicates that serrated polyposis is a genetic predisposition syndrome to CRC and probably confers also an increased risk for some extracolonic cancers[60].

IMPLICATIONS FOR MANAGEMENT OF SERRATED POLYPS

It is imperative to detect and completely remove serrated lesions, as majority of these lesions tend to progress, and contribute to the development of interval cancers. Data on the natural history of serrated polyps is limited, only retrospective studies with small sample size[61] are currently available. High risk serrated polyps are frequently flat and associated with synchronous advanced colorectal neoplasms[62]. Magnifying chromoendoscopy can facilitate to differentiate between serrated polyps, but it is still difficult to distinguish between SSA and typical HP[63]. Both endoscopists and pathologists should know the most important features in order to detect and diagnose these lesions (Table 1).

To date, no consensus guidelines exist on the management of serrated polyps, but new guidelines including recommendations for management and follow-up of serrated polyps are expected to be available in the near future. With the exception of small and diminutive HPs in the rectosigmoid, that confer no malignant potential,

Table 1 Most important features of serrated polyps[18,19,38,39,62]

	Sessile serrated adenoma	Traditional serrated adenoma	Hyperplastic polyps
Location	Proximal	Distal	Distal
Macroscopic characteristics	Sessile, flat, covered with mucus, poorly defined borders	Protruding, pedunculated	Flat
Color	Normochromatic, pale	Reddish	Pale
Size	> 5 mm	> 5 mm	< 5 mm
Molecular features	*BRAF* mt	*KRAS* mt	
Histological characteristics	Dilated, branched serrated crypts at the bottom	Prominent crypt serration, ectopic crypt formation	Serrations at the top
Pit pattern	Open-shape (type II-O)	Fern or pinecone-like	Starlike (type II)
Precursor	MVHP	GCHP	ACF
Malignant potential	+++	++	-
CIMP status	CIMP-H	CIMP-L	
MSI status	MSI-H or MSS	MSI-L or MSS	MSS
Gender predominance	Female	Male	Male
Dysplasia	Absent	Present	Absent
Ectopic crypt formation	Absent	Present	Absent

MVHP: Microvesicular hyperplastic polyp; GCHP: Goblet cell-rich hyperplastic polyp; ACF: Aberrant crypt focus; CIMP-H: CpG island methylator phenotype-high; CIMP-L: CpG island methylator phenotype-low; MSI-H: High-level microsatellite instability; MSI-L: Low-level microsatellite instability; MSS: Microsatellite stable.

Table 2 Colonoscopic management and surveillance strategies for serrated polyps based on experts' opinion and current literature[28,34,51,63]

Serrated polyp	Intervention	Surveillance interval
Hyperplastic polyp in the rectosigmoid	No surveillance recommended	Screening colonoscopy at 10 yr
SSA without dysplasia	Endoscopic resection (EMR)	< 3 lesions, < 1 cm: 5 yr ⩾ 3 lesions, ⩾ 1 cm: 3 yr
SSA with dysplasia	Endoscopic resection (EMR)	Complete: 2-6 mo Incomplete: Segmental colectomy
TSA	Endoscopic resection (cold-snare)	Complete: 3 yr Incomplete: Segmental colectomy
Serrated polyposis	Endoscopic resection	Follow-up colonoscopy at 6-12 mo Children: screening at an age 10 yr younger than index case
Serrated polyposis in first-degree relative	Screening at an age 10 yr younger	Follow-up colonoscopy at 12 mo

SSA: Sessile serrated adenoma; TSA: Traditional serrated adenoma; EMR: Endoscopic mucosal resection.

all other serrated polyps should be endoscopically removed. If endoscopic resection cannot be implemented, then segmental colectomy is advised[51]. There is no consensus among experts on the optimal post-polypectomy surveillance intervals, however because of lack of data and presumed faster progression rate a more intensive surveillance is recommended (Table 2).

Due to their sessile nature, SSAs are difficult to detect and remove endoscopically. For the removal of flat SSAs endoscopic mucosal resection (EMR) is the method of choice[34]. It is recommended to use a chromoendoscopy contrast dye (either onto the surface or injected submucosally) to define the border of the lesion, lifting it, then snare removing *in toto* or in multiple sessions[28,34]. It is important to note that because of the thin wall of proximal colon (where SSAs typically locate[65]), this difficult technique is even more challenging, as one has take the complications of EMR (bleeding, perforation, incomplete resection) into account and it is advised to use argon plasma coagulation to reduce the risk of complications and recurrence[34,66].

CONCLUSION

It is getting generally accepted that CRC is a heterogeneous disease. Serrated pathway is serrated pathway is a rapidly evolving concept in colorectal carcinogenesis and it is postulated that 10%-20% of CRCs arise *via* this alternative pathway. In the past two decades since its original description our knowledge of morphologic and molecular alterations of serrated lesions has greatly expanded and these lesions are getting increasingly recognized. A major challenge is how to translate these new findings into clinical practice and how to determine appropriate surveillance intervals in order to avoid interval cancers. Further investigation is needed to better characterize natural history, optimize management and improve clinical outcomes.

Abstract

Acute pancreatitis (AP) is a common clinical condition with an incidence of about 300 or more patients per million annually. About 10%-15% of patients will develop severe acute pancreatitis (SAP) and of those, 10%-30% may die due to SAP-associated complications. Despite the improvements done in the diagnosis and management of AP, the mortality rate has not significantly declined during the last decades. Toll-like receptors (TLRs) are pattern-recognition receptors that seem to play a major role in the development of numerous diseases, which make these molecules attractive as potential therapeutic targets. TLRs are involved in the development of the systemic inflammatory response syndrome, a potentially lethal complication in SAP. In the present review, we explore the current knowledge about the role of different TLRs that have been described associated with AP. The main candidate for targeting seems to be TLR4, which recognizes numerous damage-associated molecular patterns related to AP. TLR2 has also been linked with AP, but there are only limited studies that exclusively studied its role in AP. There is also data suggesting that TLR9 may play a role in AP.

INTRODUCTION

A central characteristic of the innate immune system is its capability to identify constitutive and conserved products of microbial metabolism. Several metabolic pathways are unique for invading microorganisms and absent in host cells. Being essential for survival, they are even highly conserved among a given class of microorganisms. A classical example is lipopolysaccharide (LPS), a molecule made by *Gram-negative bacteria*, but not by eukaryotic cells.

Molecules found in microorganisms, but not in host cells, can serve as molecular signatures that can be recognised by the innate immune system, starting an immunological response against the invasion and if necessary, assisting in the activation of the adaptive immune system[1]. As these molecules are conserved molecular patterns, they are called pathogen-associated molecular patterns (PAMPs) and interact with pattern-recognition receptors (PRRs), which are receptors of the innate immune system.

PAMPs are marvellous targets for innate immune recognition, as they are only produced by microbes, are invariant between microorganisms of a given class and are essential for microbial survival. Therefore, PRRs represents a vital component of the immune system, which probably developed early during evolution, as PRRs are found in all mammals, invertebrates and even in plants. PRRs are expressed on the cell surface or in intracellular

compartments, but they can be secreted into the blood stream and tissue fluids as well[2]. However, the role of PRRs in immune recognition is not solely associated to PAMPs, since PRRs in addition can recognize alarmins[3]. Alarmins are endogenous molecules released into the extracellular compartment by activated or necrotic cells in response to stress or tissue damage[4]. Even extracellular matrix molecules are alarmins when up-regulated upon injury or degraded following tissue damage[5]. Alarmins and PAMPs constitute damage-associated molecular patterns (DAMPs), which are the main targets of PRRs[3,4].

The relative recent discovery of a main PRR family, toll-like receptors (TLRs), has vastly increased our comprehension of the physiological and pathophysiological role of the innate immune system. While mice have twelve TLRs (TLR1 to TLR9 and TLR11 to TLR13), humans express only ten functional TLRs (TLR1 to TLR10) and ligands have been identified for all human TLRs, except for TLR10[3]. A selection of PAMPs and alarmins recognized by human TLRs are shown in Tables 1 and 2.

TLRs are type I transmembrane glycoproteins composed of an extracellular N-terminal that contains leucine-rich repeats, a single transmembrane domain and an intracellular C-terminal tail known as the Toll/IL-1 receptor (TIR)[6]. When TLRs form heterodimers or homodimers, an activating signal is started and TIR-TIR dimers are involved in the recruitment of five known signalling adaptor molecules: Myeloid differentiation primary response protein 88 (MyD88), TIR domain-containing adaptor protein (TIRAP), TIRAP inducing interferon β (TRIF), TRIF-related adaptor molecule (TRAM) and sterile-alpha and Armadillo containing motif protein[7-9].

Once the adaptor molecules are recruited, TLRs can activate two major intracellular signalling pathways. All TLRs except TLR3 can activate a MyD88-dependent pathway, in which IL-1R-associated kinases (IRAK), TNF receptor-associated factor 6 (TRAF-6) and mitogen-activated kinases are involved[5]. This pathway results in the transcription of pro-inflammatory genes through the activation of nuclear factor κβ (NFκB) and/or the activation of activating protein 1[9]. An alternative, non MyD88-dependent pathway can be activated by TLR3 and TLR4. In the TRIF pathway, the activation of interferon-regulated factors (IRF) *via* TRIF leads to the synthesis of interferon (IFN)[5].

As TLRs recognize several PAMPs and DAMPs, their involvement in the pathophysiology of several diseases has become a major research field[8,10]. Moreover, recent studies have reported the importance of NFκB pathways in the development of the systemic inflammatory response syndrome (SIRS) and the multiple organ dysfunction syndrome (MODS)[11,12]. However, NFκB pathways are not restricted to TLRs, which converts the elucidation of the role of TLRs in SIRS and MODS into a tremendous challenging task.

SIRS is a nonspecific condition that can be caused by infection, ischemia, trauma, and inflammation, or by the combination of several insults. Considered by many as a self-defense mechanism, SIRS results in a complex inflammatory cascade that involve humoral and cellular responses, complement, and cytokines cascades. Severe complications depend on the underlying etiology and the magnitude of the inflammatory response, and may include *e.g.*, single or multiple organ failure[13].

Table 1 Human Toll-like receptors: Localization, known pathogen-associated molecular patterns and their producing microorganisms

	Localization	PAMP	Origin of PAMP
TLR1	Plasma membrane	Soluble factors	*N. meningitidis*
		Triacyl lipopeptides	*Bacteria, mycobacteria*
TLR2	Plasma membrane	Glycoinositolphospholipids	*Trypanosoma cruzi*
		Glycolipids	*Treponema maltophilum*
		Haemagglutinin	*Virus*
		Lipoarabinomannan	*Mycobacteria*
		Lipoprotein/lipopeptides	*Various pathogens*
		Lipoteichoic acid	*Gram-positive bacteria*
		Peptidoglycan	*Gram-positive bacteria*
		Phenol-soluble modulin	*S. epidermidis*
		Porins	*Neisseria*
		Zymosan	*Fungi*
TLR3	Endosome	Double-stranded RNA	*Virus*
TLR4	Plasma membrane	Envelope protein	*Mouse-mammary tumour virus*
		Fusion protein	*Respiratory syncytial virus*
		Heat-shock protein 60	*Chlamydia pneumoniae*
		Lipopolysaccharide	*Gram-negative bacteria*
		Taxol	*Plants*
TLR5	Plasma membrane	Flagellin	*Bacteria*
TLR6	Plasma membrane	Diacyl lipopeptides	*Mycoplasma*
		Lipoteichoic acid	*Gram-positive bacteria*
		Zymosan	*Fungi*
TLR7	Endosome	Single-stranded RNA	*Virus*
TLR8	Endosome	Single-stranded RNA	*Virus*
TLR9	Endosome	DNA (CpG)	*Bacteria, virus*
		Haemozoin	*Plasmodium spp.*
			Rhodnius spp.
			Schistosoma spp.
TLR10	Endosome	Not determined	Not determined

Modified after Akira *et al*[7]. TLR: Toll-like receptor; PAMP: Pathogen-associated molecular patterns.

Acute pancreatitis (AP) is one common cause of SIRS and MODS. AP occurs with an incidence of about 300 or more patients per million annually[14,15], reported to have increased during the last decades[16,17]. Since the principal risk factors for AP are gallstones and excessive alcohol intake[18,19], plausible the augmented incidence reflecting the overweight epidemic observed in the Western World[20-22].

Most cases of AP are mild and self-limiting, with only brief need of clinical support[14,15]. However, about 10%-15% of patients will develop severe acute pancreatitis (SAP) and of those, 10%-30% may die due to SAP-associated complications (Table 3)[23]. Complications may be local or extrapancreatic and in up to one third, the pancreatic injury leads to pancreatic necrosis, acute fluid collections and pseudocyst formation. SIRS may develop early during the course of SAP and cause *e.g.*, adult respiratory dysfunction syndrome,

acute renal and liver failure[24]. SIRS in association with SAP may also result in MODS, which carries a 40% mortality rate[15]. A model for the course of AP is shown (Figure 1).

Despite the improvements done in the diagnosis and management of SAP, the rate of mortality has only marginally declined during the last decades[24]. This is of particular concern, considering that AP patient numbers has been persistently increasing. In order to decrease the mortality rates, it is imperative to find new therapeutic strategies that target the underlying pathophysiological mechanism of SAP.

TLRs seem to play a major role in the development of numerous diseases[5,10], which make these molecules attractive as potential therapeutic targets. Since SIRS is a potentially lethal complication in AP, and TLRs are involved in the development of SIRS[25]; it is plausible that TLRs play a major role in severe acute pancreatitis.

In the present paper, we aim to explore the current knowledge about the role of different TLRs that have been reported associated with AP. In addition, future therapeutic strategies will be discussed.

TLR2-FAR AWAY FROM THE ANSWER

TLR2 is expressed on the plasma membrane of a large diversity of cells, including monocytes and macrophages, dendritic cells, polymorphonuclear leukocytes, B cells, T cells and microglia. This PRR recognises a wide range of DAMPs (Tables 1 and 2) and forms heterodimers with TLR1, TLR6 or TLR10[10]. Usually associated to the innate immune response against *Gram-positive bacteria* (several of its ligands origin in these microorganisms), TLR2 signals through a MyD88-dependent pathway (Figure 2A). CD14 is a protein found either in soluble form or anchored into the plasma membrane by a glycosylphosphatidylinositol tail. It has been reported that CD14 is required for the activation of TLR2-TLR6 dimers, since it facilitates the transport of specific ligands, such as peptidoglycan or lipoteichoic acid. Additionally, CD36, a membrane protein found in lipids rafts, seems to be important in the activation of TLR2-TLR6 pathways. However, it is unknown how CD36 enhances the formation of TL2-TLR6 dimers. CD44 is another membrane protein that has been associated to TLR2 and appears to enhance TLR2-mediated pro-inflammatory response[26]. However, the mechanisms are still unknown. There are also reports suggesting that CD44 may interact with TLR2, down-regulating TLR2-mediated inflammation[27,28].

Upon dimerization with TLR1, TLR6 or TLR10, TIR-TIR dimers recruit TIRAP, which is needed for the further recruitment of MyD88. MyD88 interacts with IRAK-4, which phosphorylates IRAK-1 and IRAK-2. IRAK-1 and IRAK-2 then activate TRAF-6, which in turn activates TGF-β activated kinase-1 (TAK-1). TAK-1 phosphorylates I-κ-β kinase β (IKKβ), which together with IKKα phosphorylate I-κ-β kinase α (IKKα). Upon phosphorylation IκBα becomes inactive, allowing the nuclear translocation of NFκB, with subsequent production of several cytokines and molecules involved in immune responses (Table 4)[29].

Besides its role in infectious diseases, TLR2 has also been reported involved in several non-infectious disorders, including atherosclerosis, asthma, renal disease, systemic lupus erythematosus and even sporadic colorectal cancer[30-34]. Though, the role of TLR2 in AP has only been evaluated in a limited number of studies.

Pancreatic damage

The TLR2mRNA expression was found to be increased

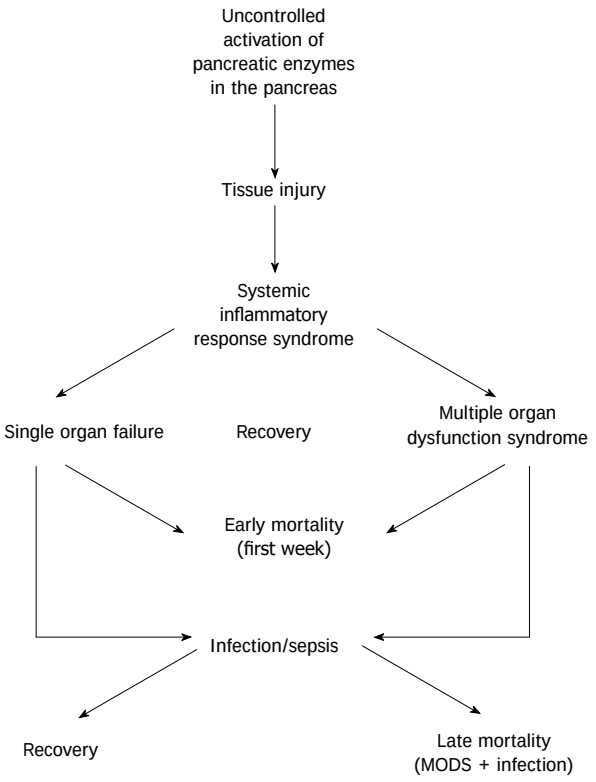

Figure 1 Systemic inflammatory response syndrome in acute pancreatitis.

in the pancreas in cerulein-induced AP in rats[35]. Furthermore, TLR2 levels in the gland were also increased, as well as TNF-α, intracellular adhesion molecule 1 and IL-6. TLR2mRNA overexpression seemed to be caused by peroxisome proliferator-activated receptor-α (PPAR-α), since WY14643, a synthetic PPAR-α antagonist, decreased TLR2 levels in treated animals. Even if the observed TLR2mRNA overexpression was associated with PPAR-α, it is uncertain how important TLR2 was in the development of inflammation and tissue damage. Possibly, hyaluronic acid fragments found in the injured pancreas could be a major source of TLR2 upregulation[36]. Small molecular weight hyaluronic acid fragments seem to need TLR2 in order to stimulate the pro-inflammatory state in mouse macrophages[37]. Heat shock proteins may leak into the extracellular compartment after necrotic cell death in AP, interact with CD14/TLR2 and induce the production of inflammatory cytokines (especially TNF-α)[38].

Lung injury

Acute lung injury (ALI) is possibly the most serious complication associated to SAP, since it accounts for most deaths in untreated patients and in hospitalised patients that die during the first week after the onset of AP[39].

In 2005, Wu *et al*[40] described that TLR2mRNA overexpression in the lungs in a sodium taurocholate-based AP rat model was coupled to elevated TNF-α levels and lower nitric oxide (NO) levels, when compared to controls. Moreover, L-Arg administration decreased TLR2mRNA expression and pulmonary TNF-α levels. Since L-Arg stimulates the production of NO, it is difficult to evaluate if the anti-inflammatory response was caused by NO itself or by a L-Arg-mediated TLR2 down-regulation. Chloroquine showed similar effects (both TLR2mRNA and TNF-α were decreased) but the lung injury was not significantly ameliorated. Chloroquine is a well-known anti-malaria drug that prevents against endosomal acidification[41] and is used to study the role of intracellular TLRs[42].

The authors concluded that SAP-associated ALI was coupled to higher TLR2 levels in the lungs and that reduced NO levels were in part responsible for the grade of inflammation, since NO has known anti-inflammatory properties. However, how NO levels are associated with TLR2 and its potential therapeutic use in AP, is still unknown.

Matsumura *et al*[43] reported that the expression of TLR2mRNA decreased in pulmonary macrophages in deoxycholate-induced AP in rats. Macrophages were obtained through bronchoalveolar lavage fluid (6 h after induction) and the cells were exposed to lipoteichoic acid. No change in TLR2mRNA was initially observed, but after six hours TLR2mRNA expression significantly decreased in macrophages. Additionally, the production of TNF-α after lipoteichoic acid stimulation was reduced. An important observation made was the increment of bacterial translocation (cultured from mesenteric lymph nodes) 18 h after AP-induction, indicating that impaired TLR2mRNA expression in pulmonary macrophages could partially be responsible for the development of ALI in SAP complicated by sepsis. It is widely accepted that $TLR2^{-/-}$ mice are vulnerable to infections[44,45]. Pulmonary macrophages have been pointed out as major players in ALI in SAP, as monocyte chemoattractant protein-1 and TNF-α are released by these cells[46]. Hence, diminished TLR2mRNA expression in pulmonary macrophages under AP is doubtfully important for the development of ALI when TLR2-related PAMPs are absent.

Liver involvement

Liver failure is a major complication in AP. Besides, there is increasing data suggesting that activated Kupffer cells mediates the inflammatory response and pulmonary damage seen in SAP[47].

Xiong *et al*[48] showed that hepatic TLR2mRNA expression was increased in AP-induced mice. The incremented TL2mRNA expression was observed 3 h after the induction, peaking at 12 h. Likewise, severe damage in the liver and SIRS ensued in the animals. However, in order to strengthen the immunological reaction, LPS was injected as well, leading to a TLR4mRNA expression increment in the liver. Thus, it is difficult to establish if SAP-related SIRS is associated with an increase in TLR2 or TLR4. Possibly, a combined increment of both TLRs account for the observed severity. Zhang *et al*[49] obtained similar results in a taurocholate-based rat model. Besides, decreased hepatic TLR2mRNA expression, chloroquine

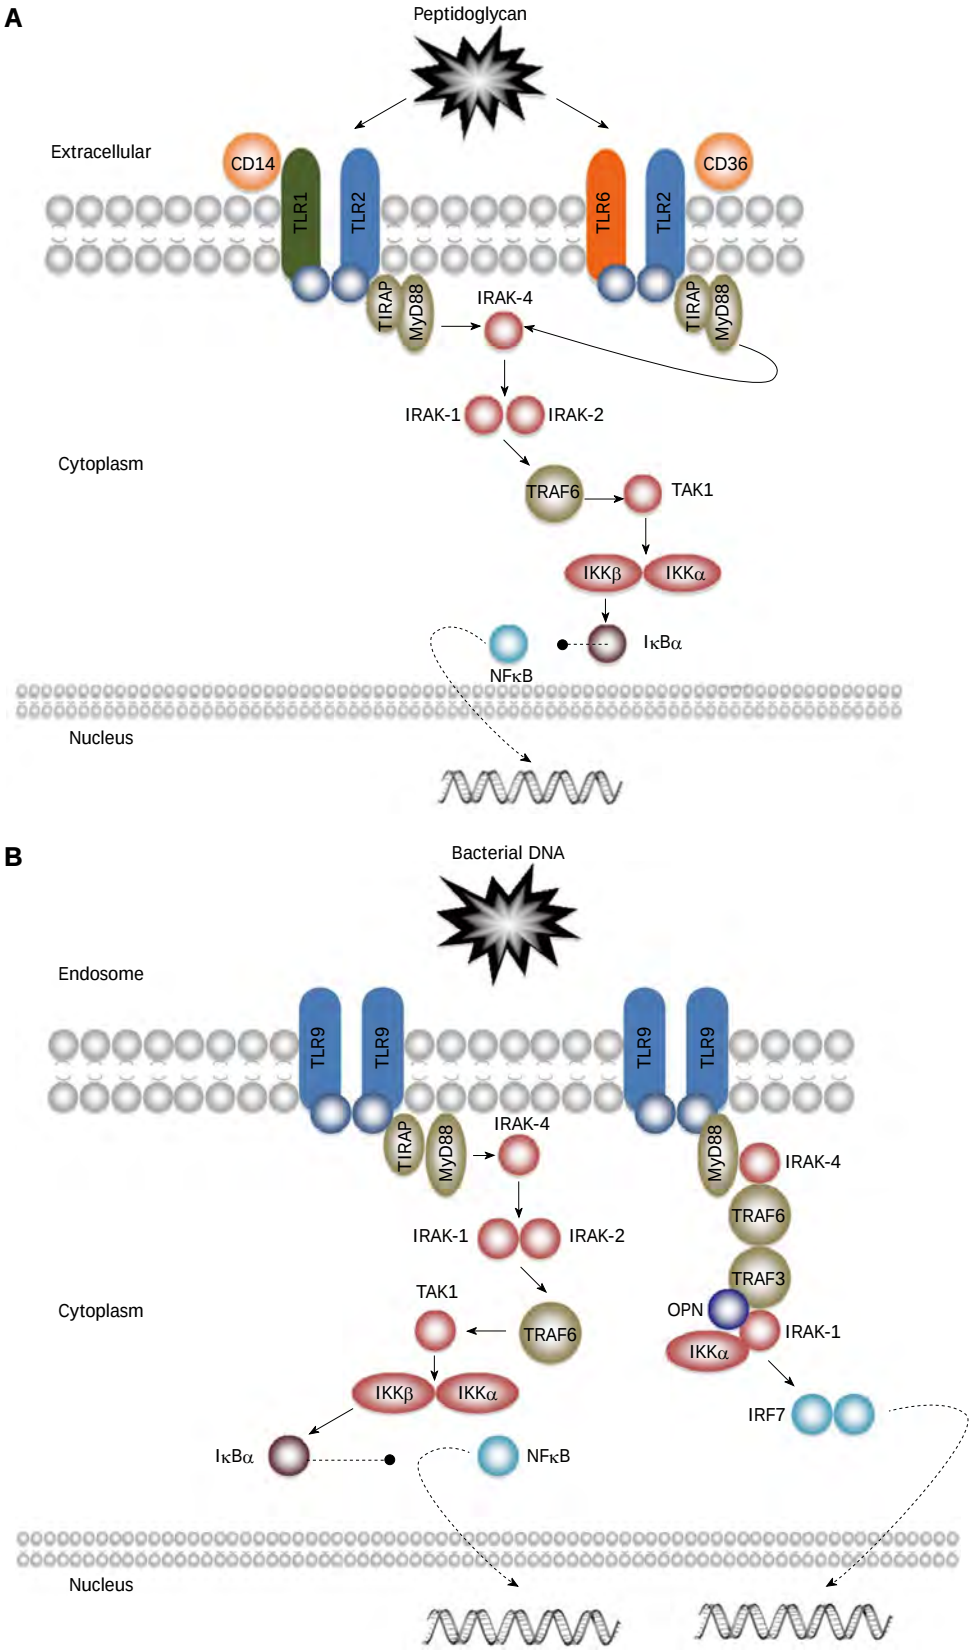

Figure 2 Toll-like receptor 2 and receptor 9 signalling pathways. A: Receptor 2; B: Receptor 9.

or L-Arg administration attenuated the liver injury and decreased TNF-α levels. Increased pro-inflammatory cytokines and chemokines are released following over-expression of TLR2mRNA in the liver of untreated animals. As previously shown in the lungs[40], NO levels also decreased in the liver. This is of special interest since reduced NO levels correlated with diminished secretion of anti-inflammatory mediators.

Even if several studies associate TLR2 to AP, it is still debated if TLR2 plays a pathophysiological role. Awla *et al*[50] reported that the progression of SAP was not significantly different in TLR2$^{-/-}$ mice when compared with wild-type mice. No significant differences were observed concerning pancreatic tissue damage, chemokine formation and neutrophil recruitment in taurocholate-induced AP.

TLR2 and AP in humans

In humans, microsatellite polymorphism in intron 2 in the human *TLR2* gene was associated with an increased risk for AP in Japan[51]. For this experiment, DNA was harvested from 202 patients of which 80 were diagnosed with SAP. When compared to healthy Japanese controls, AP patients showed significantly increased polymorphism rates in *TLR2* genes. Since the same polymorphism has been associated with susceptibility to colorectal cancer, tuberculosis, rheumatoid arthritis and sarcoidosis[34,52-54]; it is conceivable that TLR2 signalling is altered if intron 2 is changed. However, it remains to be elucidated if the relationship between changed *TLR2* genes and the risk for AP is just limited to Japanese subjects, or if the results can be extrapolated to other populations. Other studies have shown that gene-related vulnerability for AP in a country could not be demonstrated in other populations[55,56].

A very interesting observation was made by Szabo *et al*[57]. Monocytes were harvested from healthy volunteers before alcohol consumption and 24 h thereafter. The cells showed a decreased pro-inflammatory profile. Furthermore, *in vitro* acute alcohol stimulation of monocytes activated the pro-inflammatory state and decreased IL-production when TLR2 and TLR4 ligands were added. However, if only TLR2 ligands were added, no significant changes were observed. Therefore, acute alcohol stimulation appears to inhibit TLR2 expression in monocytes, worsening by this way the innate immune response against microorganisms that produce TLR2 specific ligands. Acute alcohol stimulation seems to be a double edged sword, since it could induce both anti and pro-inflammatory responses depending on which TLRs are involved.

In summary, TLR2 seems to be up regulated in the pancreas, lungs and liver in experimental AP animals. Moreover, TLR2-deficiency or inhibition (chloroquine or L-Arg) seems to ameliorate ALI in SAP.

How the increased TLR2 levels in vital organs are associated with SAP is still unknown. It is plausible that the overexpression of TLR2 in the pancreas, lungs and liver, amplifies the inflammatory response observed in SIRS when DAMPs released in SAP are recognised.

Despite an association found in Japan, the relationship between modified human *TLR2* genes and AP has not been reported in other populations. Even if TLR2 seems to be relevant for the development of ALI in SAP, further research has to be done before this important PRR can be considered as a potential therapeutic target in AP.

TLR4-THE MAIN CANDIDATE?

TLR4 was the first TLR identified and is widely expressed on the plasma membrane of various immune cells, including macrophages and dendritic cells[58]. TLR4 recognises several DAMPs, including LPS, fibrinogen, and various heat shock proteins (Tables 1 and 2). Upon activation, TLR4 forms homodimers or heterodimers with TLR6. The TLR4 recognition of many DAMPs demands several accessory molecules. As for TLR2, CD14 is needed for binding LPS to TLR4 dimers. Another vital protein for LPS recognition is myeloid differentiation protein-2[3].

In the same matter as other TLRs, except TLR3, TLR4 signals through a MyD88-dependent pathway, leading to the activation of NFκB (see previous section). Besides, TLR4 can signal *via* a TRIF-dependent pathway. Once activated, TIR-TIR dimers recruit TRIF and TRAM. TRIF then activates I-κ-β kinase epsilon (IKKε), which binds to TANK-binding kinase 1 (TBK1). Finally, IKKε-TBK1 phosphorylates and activates IRF3, culminating in the transcription of IFN-α and IFN-β (Figure 3)[26].

TLR4 was initially mainly studied because of its involvement in Gram-negative bacterial infection, but has in recent years also been associated with an increasing number of diseases. Many reports suggest its involvement in atherosclerosis, liver disease, obesity, cardiac disease, and renal disease, among others[59-63].

Bacteria are important microorganisms in AP. In acute haemorrhagic-necrotizing pancreatitis, intestinal bacterial translocation into the injured/necrotic pancreas or the systemic circulation, may lead to SIRS, ALI and MODS[16-19]. As TLR4 is related to LPS and a wide range of alarmins released during inflammation and tissue damage, its role in AP appears to be highly possible.

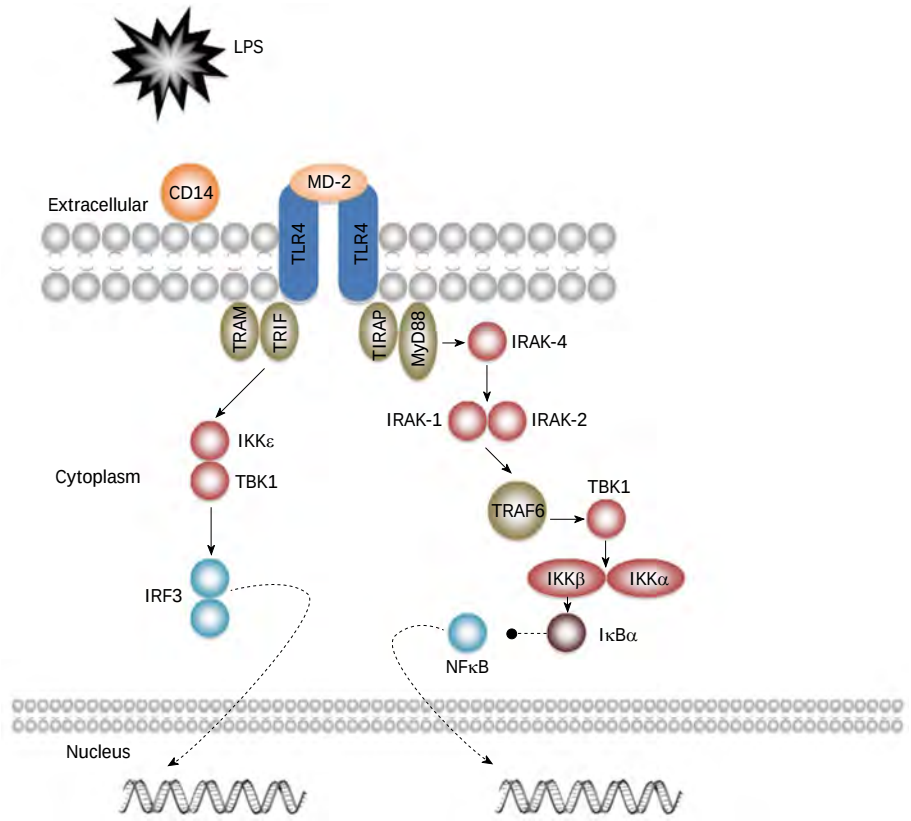

Figure 3 Toll-like receptor 4 signalling pathways.

Pancreatic damage

As for TLR2, overexpressed TLR4mRNA was also found in the pancreas in rats with cerulein-induced AP[35]. Li *et al*[64,65] reported (in the same animal model) that in both healthy and AP-induced animals, TLR4 was expressed mainly in the epithelium of the pancreatic duct and the pancreatic microcirculation. Even if some staining was observed in endocrine islets, no TLR4 protein was detected in the acinar cells. Likewise, TLR4 mRNA overexpression was observed, peaking after 1 h and returning to base levels after 4 h. In taurocholate-induced AP in TLR4$^{-/-}$ mice[50], serum amylase and myeloperoxidase levels in the pancreas decreased as compared to wild-type induced mice. Additionally, acinar cell necrosis, oedema, and haemorrhage significantly reduced. Interestingly, pancreas and serum levels of CXCL2, a chemokine, released by monocytes and macrophages, recruiting neutrophils, were strongly diminished.

Opposite results were presented by Ding *et al*[66] using the same AP model. No significant changes in serum amylase levels and pancreatic histological scores were observed between TLR4$^{-/-}$ and the controls. Curiously, TLR4$^{-/-}$ mice showed decreased levels of pro-apoptotic proteins in the pancreas 2 h after induction, but not after 4 h. TLR4 can increase the apoptotic rate in different cells[67]. As some studies suggest that apoptosis is favourable in AP[68,69], it is feasible that TLR4 is involved both in the beginning and in the resolution of AP.

Wang *et al*[70] showed that the administration of anti-CD14 antibody prior to cerulein-induction and LPS challenge in mice, reduced the severity of pancreatic injury, decreased pancreatic myeloperoxidase activity and down-regulated the secretion of pro-inflammatory cytokines.

TLR4 signalling pathways have been investigated in AP. Ding *et al*[71] showed in TLR4$^{-/-}$ mice that IRAK-4 could play a role in AP, independently of TLR4. In this experiment, lacking TLR4-mediated response did not result in increased IRAK-4 levels as was expected. This suggest that TLRs other than TLR4 may also play a role in AP, as the activation of TLR2 and TLR9 also results in decreased IRAK-4 in macrophages[72]. The hypothesis is supported by a report in which TRAF6 mediated inflammation in AP in TLR4$^{-/-}$ mice[73]. The author concluded that TLR4 may not be exclusively required for initiating AP, but its signal pathway may be of importance.

However, the association between alarmins released and TLR4-mediated inflammation in AP appears to be robust. In mononuclear inflammatory cells, the enzyme pancreatic elastase seems to activate NFκB, inducing TNF-α secretion[74,75]. Hietaranta *et al*[76] found that when human myeloid cells were exposed to porcine elastase, increased expression of NFκB and AP1 was achieved. The effects of elastase seem to be mediated by TLR4, since the blocking of TLR4 with a specific neutralizing antibody strongly prevented the expression of pro-inflammatory factors in elastase-exposed cells. Premature elastase activation has been reported in AP, implying its role in the disease[77]. Hence, TLR4-mediated inflammation may be important in AP. Blocking elastase might attenuate the severity of AP.

The degradation of matrix components appears to be connected with the pathophysiology of AP. Reports indicate that low molecular weight polysaccharides from degraded hyaluronan activates dendritic cells through TLR4[78]. Besides, dendritic cells might protect the pancreas against cell stress in AP[79]. Blycans and oligosaccharides of hyaluronan seem to signal *via* TLR4 and induce the production and secretion of great quantities of TNF-α and macrophage inflammatory protein-2 in macrophages[80]. Elastase and trypsin, both involved in the initiation of AP, cleaves heparin sulphate (HS) from cell surfaces and extra cellular matrix *in vitro*[81]. This, probably may in turn lead to free endogenous HS in damaged tissues in AP. Johnson *et al*[25] demonstrated that the rapid degradation of HS in mice causes a TLR4-mediated SIRS-like reaction in mice. When soluble HS was injected intraperitoneally, almost all wild type, but no TLR4-deficient mice, perish. This reaction was HS specific since molecules structurally similar to HS did not stimulate TLR4 and HS was not contaminated with LPS. Moreover, wild type, but not TLR4-deficient, mice had increased TNF-α serum levels 1 h after administration. Continuing in this line, Axelsson *et al*[82] confirmed that HS is involved in the initiation of AP in the rat.

Akbarshahi *et al*[83] later showed that the HS-induced TLR4-dependent immune response in the murine pancreas is IRF3-mediated. When TLR4$^{-/-}$ or MyD88$^{-/-}$ mice were challenged with HS or LPS, myeloperoxidase activity was annulled in the pancreas. The same pattern with HS was observed in IRF3$^{-/-}$ mice. However, LPS administration initiated a strong immune response in these animals. This outcome could explain preceding reports about discrepancies between TLR4-deficiency and decreased TRAF6 and IRAK-4 levels in AP[71,73]. Additionally, in this experiment, pre-treatment with the TLR4 antagonist eritoran inhibited the otherwise occurring increase in myeloperoxidase production in HS-treated wild type mouse pancreas. Eritoran is a synthetic Lipid A analogue that bind to TLR4/myeloid differentiation protein-2, thereby competing with Lipid A, resulting in inhibited LPS-mediated immune response[84].

Possibly, the inhibition of TLR4, elastase or HS, alone or in combination, could ameliorate pancreatic damage in AP, thus considerably reducing the risk for developing SAP.

Lung injury

As the role of TLR4 in AP has been investigated previously together with TLR2, similar results have been reported (see TLR2 section). Briefly, TLR4mRNA expression was increased in the lungs of AP-induced rats; leading to increased TNF-α levels combined with decreased NO levels. Chloroquine and L-Arg decreased TLR4mRNA expression and attenuated the lung injury[40]. Moreover, pulmonary macrophages decreased the TLR4mRNA expression, which caused decreased LPS-induced TNF-α levels and predisposition for intestinal bacterial translocation[41].

Pastor *et al*[85] concluded that TLR4 may not play a role in AP-associated ALI, but it may participate in pulmonary injury mediated by endotoxemia. In a cerulein-induced pancreatitis model in TLR4$^{-/-}$ mice there were no significant changes in serum amylase levels, pancreatic myeloperoxidase activity, and pancreatic oedema and acinar necrosis when compared to wild type mice. Additionally, cerulein-related pulmonary damage did not decrease in TLR4$^{-/-}$. Although, when cerulein was combined with LPS, a significant decrease in pulmonary damage was reported. Thus, TLR4 would only be of importance in AP-related ALI when the disease is worsened by sepsis.

Sharif *et al*[86] obtained pole opposed results. TLR4$^{-/-}$ mice showed decreased serum amylase activity and pancreatic damage (oedema, myeloperoxidase activity, necrosis). Importantly, myeloperoxidase activity in the lungs also decreased, indicating reduced neutrophil sequestration. Furthermore, when AP was induced in CD14$^{-/-}$ mice, pancreatic and pulmonary damage were reduced as previously observed in TLR4$^{-/-}$ animals. Since TLR4/CD14 are very important for LPS-mediated TLR4 activation, TLR4 appears to be involved in the development of ALI in AP, even when endotoxemia is absent. Still, the subject is controversial, since ALI can ensure LPS-mediated TLR4/CD11b activation in CD14$^{-/-}$ mice[87].

Matsuda *et al*[88] proposed that the TLR4-associated inflammatory response in AP complicated by endotoxemia is mediated by macrophage migration inhibitory protein (MIF). Increased MIF expression in the lungs was observed after cerulein/LPS administration in mice. MIF levels were coupled to ALI and increased TLR4 expression in the lungs. Moreover, AP-induced MIF$^{-/-}$ mice showed lower TLR4 expression than in wild type mice; and anti-MIF antibody administration greatly suppressed the pulmonary expression of TLR4. It is important to stress that MIF can mediate inflammation independently of TLR4. For instance, the induction of cytosolic phospholipase A_2, an enzyme that has been linked to ALI, may be MIF-mediated[89,90].

The role of TLR4 in AP-associated ALI is debated. While it is generally accepted that TLR4 plays a role in the course of ALI when endotoxemia ensues in AP; most reports are divided between those that suggests TLR4 as an important player (even in the absence of endotoxemia) and those that minimize its role. Fortunately, this discrepancy may lead to new experiments that focuses not only in LPS but also in the wide range of alarmins related to AP, ALI and TLR4. For instance, neuropeptide substance P, which has pro-inflammatory properties that increase vascular permeability and is correlated to AP and ALI[91]; has also been associated to the up regulation of TLR4 in AP[92]. Moreover, extracellular heat shock protein 70 can induce SIRS-like immune responses in cerulein-challenged mice[93]. The action of this protein appears to be mediated by TLR4, as TLR4$^{-/-}$ mice did not showed the same outcome.

Liver, kidneys and intestine

Similarly to TLR2, TLR4mRNA expression is increased

in the liver during AP-associated SIRS[48,49]. Briefly, after AP-induction, higher levels of liver enzymes and TNF-α were observed. Hepatic NO levels decreased. All these changes appeared to be related to the TLR4mRNA overexpression in the liver. The administration of chloroquine and L-Arg decreased TLR4mRNA expression, thus reducing the liver damage.

Peng *et al*[94] showed that the deletion of TLR4 attenuated liver injury in AP. AP was induced in mice by choline-deficient ethionine diet. Besides the expected augmentation of TLR4 mRNA in mice liver, an increment in protein kinase C-zeta (PKCζ) was detected. However, induced TLR4$^{-/-}$ mice showed less apoptosis in hepatic cells and the hepatic PKCζmRNA expression was clearly reduced. PKCζ activates NFκB, which is essential for the production of cytokines in Kupffer cells[95]. Consequently, TLR4-deficiency protects the liver in AP through down-regulation of PKCζ, resulting in less inflammation and hepatic cell apoptosis.

Sawa *et al*[96] showed that in SAP, TLR4 expression is not only increased in the liver, but also in the kidneys and small intestine. Closed duodenal loop operation was performed in mice. The increased expression of TLR4 occurred 4 h after the ligation and returned to baseline after 12 h. Curiously, TLR4-deficient mice showed the same tendency and histological analyses of the liver and kidney did not show any differences between the different groups. However, apoptosis was seen in the liver and kidney of ligated TLR4-deficient, but not in wild type, mice. Additionally, Gram-negative bacterial translocation into the pancreas occurred in higher rates in TLR4-deficient animals. The translocation ensued 12 h after induction, but not before. Even Gram-positive bacterial translocation was registered, but the difference between the groups was not significant. Bacterial translocation highly correlated to fluctuations in TLR4 expression. According to the authors, as MODS develops in the early or the late phase of SAP, the early inhibition and late stimulation of TLR4 could result in a milder clinical course, since it could prevent MODS and bacterial translocation. Yet, results from another experiment in mice challenges this hypothesis[97]. van Westerloo *et al* showed that the immune response against Escherichia coli in AP-induced TLR4$^{-/-}$ mice was not different from that observed in controls. Nevertheless, there is a chance that mice developed the compensatory anti-inflammatory response syndrome (CARS), which is generally (but not exclusively) related to SIRS and sepsis[98]. CARS is a systemic deactivation of the immune system, that can ensue after SIRS and sepsis in order to restore homeostasis[99]. Thus, CARS could explain why LPS-mediated TLR4-activation was not observed in TLR4$^{+/+}$ mice after bacterial challenge in AP.

TLR4 and AP in humans

Despite controversy, there is an increasing amount of data suggesting that TLR4 plays a role in experimental AP in rodents. However, in humans, the role of TLR4 in AP patients has been investigated mainly indirectly *via* DNA analysis or immune cells taken from blood.

In a Chinese study 310 patients were diagnosed with AP according to the Atlanta severity classification[100,101]. Pancreatic necrosis was recognized in 115 patients and in 37 of those, TLR4 mutation (*896G allele*) was identified. When compared to AP patients without TLR4 mutation (*896A allele*), patients with mutated TLR4 had an increased morbidity following Gram-negative infection. When compared to healthy volunteers (n = 80), TLR4 mutation frequency was significantly higher in patients with pancreatic necrotic infection. Thus, according to this study, TLR4 *Asp299Gly* polymorphism appears to be associated with an increased risk for pancreatic necrotic infection in AP. However, this study may have limited value as all patients were recruited from one hospital located in southwestern China, thus questioning its representative value for the whole Chinese population. In a later study, Zhang *et al*[102] could not find any significant difference in the occurrence of *Asp299Gly* polymorphism between 238 Chinese AP patients and 121 healthy volunteers.

DNA samples were harvested from 92 AP patients in a Hungarian medical centre[103]. Not only TLR4 *Asp299Gly* polymorphism was considered, but also as *Thr399Ile* polymorphism was taken into account. No significant differences were detected between AP (n = 42) and SAP patients (n = 50) in any polymorphism analysed. Likewise, no differences were found between the 92 patients and healthy controls (n = 200). Perhaps, the strongest data against the involvement of TLR4 mutations in AP comes from an intercontinental study reported by Guenther *et al*[104]. No significant differences could be found between 521 AP patients (343 from Germany and 178 from United States) and healthy controls (128 Germans and. 265 Americans, respectively) in the incidence of *Asp299Gly* and/or *Thr399Ile* polymorphism. Thus, current knowledge indicates that the investigated TLR4 polymorphisms are not important for the development and clinical course of AP, even if these mutation have been linked to impairment of LPS-induced TLR4-mediated immune response in humans[105].

In vitro acute alcohol stimulation seems to inhibit TLR4 expression in human monocytes[57]. When LPS was added, a decreased secretion of pro-inflammatory cytokines was observed. Intriguingly, the effect was abolished if LPS and TLR2 ligands were added at the same time to the cells. Li *et al*[106] showed that the expression of TLR4 in human peripheral blood mononuclear cells in mild AP, raises in the beginning of the disease to return to baseline levels after a week, when the patients recovered. As TNF-α and IL-6 showed the same pattern, the authors concluded that TLR4 might play an important role in the pathogenesis of AP.

In summary, there is strong data indicating that TLR4 plays an important role in experimental AP in rodents. Nevertheless, contrary results have been published. While most studies emphasize the role of TLR4 in the pancreas in AP, its role in AP-associated ALI is controversial. There is some evidence linking TLR4 levels and tissue

damage in the liver in AP. Likewise, the general opinion is that TLR4 is very important in the development of endotoxemia in AP.

In humans, DNA mutations in *TLR4* genes do not seem to be of importance for the development or the clinical course of AP, but TLR4 expression changes in monocytes and macrophages may be of significance. Unfortunately, the latter is only based on a very limited number of studies. There are some promising reports about the use of herbs from traditional Chinese medicine in AP that may act through TLR4 inhibition[107-109]. *Salvia miltiorrhizae* (also known as danshen) appears to inhibit the binding of LPS to TLR4 in the rat liver in SAP, which may reduce bacterial translocation and liver injury. Moreover, treatment with *emodin* and/or *baicalin* reduced serum levels of amylase, IL-6 and TNF-α in AP-induced rats. Pancreatic damage and ALI were also ameliorated. The effect of *emodin* and *baicalin* appears to be mediated by TLR4, since decreased TLR4mRNA expression and protein levels were found in the pancreas and lungs in treated animals. Its implication in experimental AP in rodents makes TLR4 a potentially very promising therapeutic target in AP, its utility though to be demonstrated in humans in future studies.

TLR9-UNEXPLORED IMPLICATIONS

As for TLR2 and TLR4, TLR9 is expressed intracellularly (endosomes) in several immune cells, including B cells and dendritic cells[110]. TLR9 recognises unmethylated *CpG* dinucleotides found in *bacteria* and *virus*[111,112]. *CpG* motifs are rare in vertebrate DNA (less 1% in human genome), but they are common in bacterial DNA. Besides, if present in vertebrate DNA, *CpG* motifs use to be methylated. *CpG* DNA directly stimulates B cells, macrophages and dendritic cells to secrete cytokines[113]. TLR9 can also recognize haemozoin, which is a disposal product formed from the digestion of erythrocytes by some parasites (*e.g.*, *Plasmodium spp.*)[114].

Upon activation, TLR9 signals through a MyD88-dependent pathway, leading to the production of pro-inflammatory cytokines (see previous sections). This pathway is mainly observed in macrophages, B cells, conventional dendritic cells and plasmacytoid dendritic cells. However, in plasmacytoid dendritic cells, TLR9 can induce the production of type I IFN through a different pathway. After the recruitment of Myd88 and IRAK-4, these interact with TRAF6, TRAF3, IRAK-1, IKKα and osteopontin. IRAK-1 and IKKα phosphorylate and activate IRF7, culminating in the production of type I IFN (Figure 2B)[26]. Apart from its role in bacterial, viral or malaria infection; TLR9 has been associated with SLE and cancer[115,116].

TLR9 and AP

To date, there are only two publications in which the role of TLR9 in AP has been investigated. Zeng *et al*[117] reported that TLR9 was expressed in rat pancreas in cerulein-induced AP. TLR9 staining was detected both in the pancreas from AP-induced rats, as in controls. The epithelium of the pancreatic duct and pancreatic microcirculation were the main sites for TLR9 staining in AP-induced animals. Controls showed staining in the vasculature, but not in the pancreatic duct. Moreover, no staining was detected in pancreatic acinar cells in either group. Interestingly, a similar pattern of staining has been reported for TLR4 in AP[64]. TLR9mRNA expression was increased after 30 min, peaked at 1 h, and remained high for the first eight hours after cerulein challenge.

In a more extensive study, Hoque *et al*[118] found that TLR9 is involved in pancreatic acinar cell death in AP-induced mice. After cerulein-administration, $TLR9^{-/-}$ mice had less oedema, leukocyte infiltration and IL-1βmRNA expression in the pancreas. Even if several cell types express TLR9 in the pancreas, bone marrow-derived $CD45^{+}$ cells (mainly macrophages) had the highest expression level. Furthermore, the action of a TLR9 antagonist (IRS954) was evaluated. $TLR9^{+/+}$ animals had IRS954 administered 1 h before inducing AP by cerulein. Pancreatic oedema, leukocyte infiltration and pancreatic cell apoptosis were ameliorated. Moreover, pancreatic pro-IL-1β elevation was also reduced, as serum amylase levels. These results were observed at 1 h after AP-induction.

The authors speculated if IRS954 might have a therapeutic value. Interestingly, the administration of IRS954 after cerulein challenge reduced pancreatic oedema, leukocyte infiltration and pancreatic cell apoptosis. Similar results were observed when another model for AP was used. Pre-treatment with IRS954 at 1 h after AP induction through taurolithocholic acid 3-sulphate challenge in $TLR9^{+/+}$, reduced serum amylase elevation, pancreatic necrosis and inflammatory cell infiltration in mice lungs. Additionally, *in vitro* experiments were performed. When isolated peritoneal macrophages were exposed to pancreatic homogenate and DNA, significant NFκB activation was observed. Interestingly, pre-treatment with IRS954 reduced NFκB activation to baseline levels.

IRS954 appears to be a good candidate for further investigation. Like TLR2 and TLR4, TLR9 may be important when AP is aggravated by sepsis. Reports indicate that during sepsis, TLR9 is expressed both in murine and human adrenal glands and its stimulation leads to corticosterone release and inflammatory response[119]. Macrophages and NK-cells in the liver mediates liver toxicity and express high levels of TLR9 in murine peritonitis[120]. Chloroquine inhibits TLR9 and may prevent sepsis-induced acute kidney injury in mice[121]. Additionally, $TLR9^{-/-}$ mice have reduced mortality in polymicrobial sepsis[122].

Still, the number of studies is very limited. Hence, it is impossible to conclude if TLR9 plays an important role in AP with a clinical course complicated with our without sepsis.

Closing remarks

An increasing number of publications suggest that TLRs

Table 5 Toll-like receptors and acute pancreatitis

	Observed change	Tissue/cell	Ref.
TLR2	Increased mRNA expression	Pancreas	[35]
		Lungs	[40]
		Liver	[48,49]
	Increased protein levels	Pancreas	[35]
		Liver	[48]
	Decreased mRNA expression	Pulmonary macrophages	[43]
TLR4	Increased mRNA expression	Pancreas	[35,64,73,92]
		Lungs	[40,88]
		Liver	[48,94,96]
		Kidney	[96]
	Increased protein levels	Small intestine	[96]
		Pancreas	[35,92]
		Lungs	[88]
		Liver	[48,49]
		Intestine	[65]
		Blood monocytes	[106]
	Decreased mRNA expression	Pulmonary macrophages	[43]
TLR9	Increased mRNA expression	Pancreas	[117,118]
	Increased protein levels	Pancreas	[118]

TLR: Toll-like receptor.

Table 6 Toll-like receptor intervention in acute pancreatitis

	Substance	Ref.
TLR2	Chloroquine	[40,49]
	L-Arg	[40,49]
	WY14643	[35]

	Salvia miltiorrhizae	[108,109]
TLR9	IRS954	[118]

TLR: Toll-like receptor; MIF: Migration inhibitory protein.

are involved in the pathophysiology of several important medical conditions. In acute pancreatitis, TLRs appear to play a role, but a general consensus has not been achieved, since contradictory results have been presented.

The main candidate for targeting seems to be TLR4, which recognizes numerous DAMPs associated to AP[123,124]. TLR2 has also been linked to AP, but there are few studies that exclusively has studied its role in AP. There is data suggesting that TLR9 also can play a role in AP. The associations found between TLRs and AP, as possible novel types of therapy are presented (Tables 5 and 6). There is also some evidence indicating that TLR4 and TLR3 may be involved in chronic pancreatitis[125,126]. This is of particular importance since chronic pancreatitis may develop following repeated AP episodes, as chronic pancreatitis is to some extent a risk factor for pancreatic cancer[127].

CONCLUSION

To our knowledge, this is the first time the current understanding of the role of TLRs in acute pancreatitis is summarized. Of course, further research and elucidation of involved mechanisms is warranted, hopefully stimulated by the present review giving an update and state-of-the-art concerning the role of TLRs in acute pancreatitis and its potential future clinical implications.

Abstract

One unresolved issue of endoscopic retrograde cholangiopancreatography (ERCP) is post-ERCP pancreatitis (PEP), which occurs in up to 40% of patients. Identification of risk factors for PEP is especially important in the field of ERCP practice because it may assist physicians in taking protective measures in situations with high risk. A decade ago, Freeman *et al* meticulously evaluated a large number of potentially relevant risk factors for PEP, which can be divided into patient-related and procedure-related issues. In this commentary, we summarize this classic article and reevaluate the risk factors for PEP from the current point of view. This is followed by assessment of strategies for prevention of PEP that can be divided into mechanical and pharmacologic methods.

COMMENTARY ON HOT TOPICS

One unresolved issue of endoscopic retrograde cholangiopancreatography (ERCP) is post-ERCP pancreatitis (PEP), which occurs after 1% to 40% of procedures[1-4]. This variable frequency of PEP is due to a number of factors, including the definition used, the patient population, the type of maneuvers, the type and duration of patient follow-up, and the personnel performing the ERCP[2,3,5]. Postulated mechanisms for pancreatitis after ERCP include mechanical, chemical, hydrostatic, enzymatic, microbiologic, and thermal disruptions[1,2]. A widely used consensus definition for PEP is: (1) new or worsened abdominal pain; (2) new or prolongation of hospitalization for at least 2 d; and (3) serum amylase three-fold or more above the upper limit of normal, measured more than 24 h after the procedure[6,7].

Prediction of PEP is of utmost importance in the field of ERCP practice. Although PEP is sometimes inevitable and can occur in the best of hands, identification of its risk factors may assist physicians in taking protective measures in situations with high a priori risk[8,9]. This article is intended as a commentary on the classic article "Risk factors for post-ERCP pancreatitis: a prospective, multicenter study" by Freeman *et al*[1] published in *Gastro-*

intestinal Endoscopy, a landmark study in the field of PEP, and it also provides strategies for the prevention of PEP.

In the classic article[1], comprehensive evaluation of the risk factors for PEP were performed by 26 endoscopists from 11 centers in the United States (6 private practices and 5 university-affiliated teaching hospitals), who collaborated in a painstaking prospective study of almost 2000 procedures[10]. The authors of the classic article meticulously determined eye-opening numbers (n = 32) of potentially relevant risk factors for PEP and provided vigilant analysis.

Risk factors for PEP

In the classic article[1], the authors classified risk factors into clearly demarcated patient-related and procedure-related factors. This allowed them to demonstrate that the risk of PEP is determined as much by patient characteristics as by endoscopic technique or maneuvers. Stratification of patients into low-risk or high-risk categories for PEP is important in order to ensure that gastroenterologists remove borderline indications of ERCP in high-risk patients and that adequate pre-procedure information is provided to the patient[5].

Patient-related risk factors: Of the 16 patient-related risk factors identified, in the classic article, 5 variables were statistically significant by multivariate analysis: history of PEP, suspected sphincter of Oddi dysfunction, female gender, normal serum bilirubin, and absence of chronic pancreatitis. Although a few other factors, such as young age and absence of common bile duct stones, were only significant in univariate analysis, subsequent multivariate studies by other groups or further meta-analysis showed that young age, non-dilated extrahepatic ducts, and absence of common bile duct stones are factors that may increase the risk for PEP (Table 1)[3,5,6,11,12]. A recent multivariate study, published in abstract form, suggested that obesity and hyperlipidemia were independent risk factors for PEP based on a nationwide database analysis[13]. Interestingly, some of the patient-related risk factors, such as normal serum bilirubin, non-dilated extrahepatic ducts, and absence of common bile duct stones, are poor indicators of ERCP. This may attest to the statement by Cotton[10,14] that "ERCP is most dangerous for those who need it least".

Procedure-related risk factors: Of the 16 procedure-related risk factors identified, in the classic article, 4 variables were significant by multivariate analysis: biliary balloon sphincter dilation, moderate-to-difficult cannulation, pancreatic sphincterotomy, and pancreatic contrast injections. Subsequent multivariate studies by other groups or further meta-analysis showed that precut sphincterotomy, ampullectomy, pancreatic brush cytology, failure to clear bile duct stones, and involvement of trainees are all factors that may increase the risk for PEP (Table 2)[3,5,6,11,12].

Although pancreatic stent placement was associated with risk of pancreatitis by univariate analysis, no independent contribution of pancreatic stent placement was evident in the multivariate analysis because pancreatic stents were primarily placed in patients with multiple other independent risk factors for PEP. Actually, pancreatic stent placement can reduce the risk of PEP in a number of settings, so that prophylactic pancreatic stent placement has become a standard of care for reducing PEP in high-risk cases[15-17].

The classic article also indicated the importance of the general similarity of the overall risk of pancreatitis for diagnostic and therapeutic ERCP and showed that the performance of biliary sphincterotomy did not appear to add significant independent risk of pancreatitis to ERCP[1]. The article emphasized that these observations point not to the safety of sphincterotomy, but rather to the risk of diagnostic ERCP[1]. Despite the general similarity of the overall risk of PEP for diagnostic and therapeutic ERCP, certain high risk procedures such as pancreatic sphincterotomy, pancreatic brush cytology, and ampullectomy may increase the risk for PEP. Therefore, we should pay attention to the type and complexity of maneuvers when comparing the incidence of PEP between studies.

Interactive effect of patient-related and procedure-related risk factors: The striking message of the classic article was that patient-related and procedure-related risk factors are cumulative and perhaps even synergistic[1,10]. Subsequent studies confirmed that patients with multiple factors had an extremely high chance (up to 40%) of developing PEP[5,17-20]. The typical very high risk patient is a young to middle-aged woman with recurrent abdominal pain, normal serum bilirubin, no biliary obstruction, and difficult cannulation. The combinations of patient-related and procedure-related risk factors allow reliable prediction of the possibility that an individual patient will develop PEP[17]. Furthermore, this cumulative effect may influence the severity as well as the incidence of PEP. According to the literature[1,21-23], nearly all patients who developed severe or fatal pancreatitis after ERCP had multiple risk factors. Gastroenterologists are now more able to predict PEP.

Field of vision after a decade from the classic article: Even from the current point of view, the classic article investigated most of the potentially relevant risk factors for PEP, dividing these into patient-related and procedure-related issues. Over the past decade, subsequent studies have usually confirmed or just slightly altered the significance of these risk factors. The confirmation of the risk of diagnostic ERCP has focused the role of ERCP into an exclusively therapeutic modality with the advent of other diagnostic modalities[22]. Confirmed risk factors for PEP have also enabled the conception of several strategies for the prevention of PEP in actual practice[3,5,17,22,24,25].

Strategy for prevention of PEP

The most important goal of recognizing the risk factors for PEP is the development of a strategy for prevention

Table 1 Comparison of patient-related risk factors for post-endoscopic retrograde cholangiopancreatography pancreatitis by multivariate analysis in the classic article and current knowledge by meta-analysis or multivariate studies

Risk factors in the classic article	Current knowledge[1]
Significant in multivariate analysis	High risk factors
Suspected sphincter of Oddi dysfunction	Suspected sphincter of Oddi dysfunction
Female gender	Female gender
History of post-ERCP pancreatitis	Previous pancreatitis
Normal serum bilirubin	Normal serum bilirubin
Absence of chronic pancreatitis	Young age
Significant only in univariate analysis	Possible risk factors
Pancreas divisum	Non-dilated extrahepatic ducts
Recurrent abdominal pain	Absence of chronic pancreatitis
History of acute pancreatitis of any etiology	Absence of definite common bile duct stone
Cholangiogram normal	Obesity[2]
Pancreatogram normal	
Age < 55 yr	
Prior cholecystectomy	
Absence of definite common bile duct stone	
Not significant	Not related
Previous sphincterotomy	Pancreas divisum
Distal common bile duct diameter ⩽ 5 mm	Allergy to contrast media
Prior failed ERCP	Prior failed ERCP

[1]Current knowledge is based on recent guidelines by American Society for Gastrointestinal Endoscopy[6] and European Society of Gastrointestinal Endoscopy[5], and relevant articles[3,22]; [2]Based on recent multivariate analysis in abstract form[13]. ERCP: Endoscopic retrograde cholangiopancreatography.

Table 2 Comparison of procedure-related risk factors for post-endoscopic retrograde cholangiopancreatography pancreatitis by multivariate analysis in the classic article and current knowledge by meta-analysis or multivariate studies

Risk factors in the classic article	Current knowledge[1]
Significant in multivariate analysis	High risk factors
Difficult cannulation	Difficult or failed cannulation
Balloon dilation of biliary sphincter	Balloon dilation of biliary sphincter
Pancreatic sphincterotomy	Pancreatic sphincterotomy
⩾ 1 pancreatic contrast injections	Pancreatic duct injection
	Precut sphincterotomy
	Failed attempts at placing pancreatic duct stent
Significant only in univariate analysis	Possible risk factors
Sphincter of Oddi manometry	Ampullectomy
Pancreatic stent placement	Pancreatic acinarization
Minor papilla cannulation	Pancreatic brush cytology
Precut (access) papillotomy	Failure to clear bile duct stones
⩾ 1 pancreatic deep wire pass/cannulation	Involvement of trainee during ERCP
Endoscopist performing > 2 ERCP/wk	
Not significant	Not related
Acinarization of pancreas	Sphincter of Oddi manometry (using aspirated catheter)
Biliary sphincterotomy	Biliary sphincterotomy
Intramural contrast injection	Intramural contrast injection
Pancreatic stricture dilation by any method	Prior failed ERCP
Pancreatic duct tissue sampling by any method	Therapeutic *vs* diagnostic
Training fellow involved	

[1]Current knowledge is based on recent guidelines by American Society for Gastrointestinal Endoscopy[6] and European Society of Gastrointestinal Endoscopy[5], and relevant articles[3,22]. ERCP: Endoscopic retrograde cholangiopancreatography.

of PEP. A practical strategy appears to be the combination of careful patient selection - which means avoiding inappropriate ERCP in high-risk patients - and selection of appropriate preventive measures (Table 3)[2,6].

Patient selection: Gastroenterologists should take much more care in the selection of patients for ERCP. The clinical role of ERCP has diminished substantially with the advance of relevant diagnostic and therapeutic modalities[6,9,26,27]. For diagnostic purposes, a plethora of relevant diagnostic procedures now are available, such as magnetic resonance cholangiopancreatography and endoscopic ultrasonography (EUS), which may obviate the need for ERCP or better focus its application[9]. For therapeutic purposes, minimally invasive surgeries now show considerable improvements in safety and outcomes[9]. Thus, balancing the benefit with risk is a prerequisite for determining the indication for ERCP. If the potential risk

Table 3 Clinical pearls to help avoid post-endoscopic retrograde cholangiopancreatography pancreatitis

Remember that ERCP is the most dangerous endoscopic procedure that can be associated with bad outcomes
Instead of diagnostic ERCP, use alternative imaging techniques such as magnetic resonance cholangiopancreatography or EUS, especially in high-risk patients
Rectal NSAIDs before or after ERCP procedure can be a simple measure to prevent PEP
Tailor a variety of cannulation techniques to the individual risk profile and the papillary anatomy of the patient
In cases of difficult cannulation, early precut or fistulotomy technique with a pancreatic stent (performed by an expert endoscopist) can decrease the risk of PEP
Quit the ERCP procedure earlier in high-risk patients if success is not achieved quickly. After a failed ERCP, alternative therapeutic methods such as percutaneous or EUS-guided approaches can be considered
In high risk patients, make sure that a prophylactic pancreatic stent is placed. In cases with equivocal risk at the end of the procedure, a prophylactic pancreatic stent can eliminate the fear of PEP

ERCP: Endoscopic retrograde cholangiopancreatography; PEP: Post-endoscopic retrograde cholangiopancreatography pancreatitis; EUS: Endoscopic ultrasonography; NSAIDs: Non-steroidal anti-inflammatory drugs.

is much greater than the possible benefit, gastroenterologists should seek other diagnostic and/or therapeutic modalities or refer their high-risk patients to tertiary centers that have more experience and other tools.

Once a decision for ERCP is made, the gastroenterologist should reassess the risk profile of the patient and apply several mechanical and pharmacological interventions in order to reduce the likelihood of PEP[2]. In addition, an adequate consent process is very important to ensure that patients and their relatives understand that ERCP is potentially dangerous[14].

Mechanical prevention: Careful endoscopic techniques in cannulation and therapy are naturally important, but these are not sufficient to prevent PEP in high-risk patients[17]. Several modifications in endoscopic technique have been identified that can reduce the risk of PEP. (1) Prophylactic placement of pancreatic duct stents**:** The prophylactic placement of pancreatic duct stents improves the drainage of the manipulated pancreatic duct. Otherwise, this might be impaired by mechanical injury to the pancreatic sphincter from catheter and guidewire manipulation, and from thermal injury caused by biliary and pancreatic sphincterotomy[17]. The general consensus in the literature is that prophylactic pancreatic stents can reduce the risk of PEP in high-risk populations, such as those undergoing ampullectomy, pancreatic sphincterotomy, sphincter of Oddi manometry, precut sphincterotomy, pancreatic brush cytology, difficult cannulation, and pancreatic duct injection[3,8,17,28,29]. Recent meta-analyses of high-risk populations demonstrated that prophylactic pancreatic stents reduced the incidence of PEP from 18.6% to 5.6%[28,29]. An elegant cost-effectiveness analysis also suggested that prophylactic pancreatic stents in high-risk patients were a cost-effective strategy[30]. Actually, the routine use of pancreatic stents in high-risk cases has reduced the incidence and severity of PEP to a more acceptable level in advanced centers, allaying the fear of ERCP in high risk settings[17,31]; (2) Wire-guided cannulation: Compared with conventional use of contrast injection, wire-guided cannulation may avoid inadvertent injection of contrast into the pancreatic duct and decrease the risk of PEP[3,8]. Several meta-analyses have demonstrated a greater success of biliary cannulation and a lowered risk of PEP[21,32], but recent studies have shown that guidewire manipulation of the pancreatic duct for guidewire biliary cannulation is an another independent risk factor for PEP[33-35]. Prophylactic pancreatic stents might be recommended after pancreatic-guidewire assisted biliary cannulation to reduce the incidence of PEP[33]; and (3) Early precut biliary sphincterotomy and fistulotomy in cases of difficult cannulation: Although precut biliary sphincterotomy is an independent risk factor for PEP, prolonged cannulation attempts using standard techniques may also impart a higher risk for PEP than does the precut biliary sphincterotomy itself[5,36-39]. Early precut technique can be considered in cases of difficult biliary cannulation by advanced endoscopists with expertise in various cannulation techniques[5]. Fistulotomy is a variation of the precut needle-knife techniques that creates a direct bilio-enteric fistula by making an incision at the upper end of the ampullary region of the major papilla[40,41]. This technique has a potential advantage in that it evades the pancreatic orifice, which is the probable site of initiation of the cascade of PEP. Several studies have reported a lower incidence of PEP (up to 0%) in patients who underwent fistulotomy, with or without the prophylactic pancreatic stent[40-43]. Fistulotomy, however, may be more feasible in patients with bulging papillae and clear landmarks than in patients with tiny or diminutive papillae[40, 44]. For sparing the pancreatic orifice, reported investigational techniques include suprapapillary puncture with a needle-tip catheter, blunt dissection using a cotton swab, and EUS-guided suprapapillary puncture[39,45-47].

Pharmacologic prevention: Numerous trials have been attempted with many kinds of pharmacologic agents in order to reduce the risk of PEP. Pharmacologic agents, based on various theoretical benefits, have included nitroglycerin, ceftazidime, somatostatin, octreotide, gabexate, ulinastatin, nafamostat, antioxidants, allopurinol, glucocorticoid, non-steroidal anti-inflammatory drugs (NSAIDs), and *etc.*[5,24,48-52]. Early studies suggested that protease inhibitors such as gabexate or nafamostat may decrease the incidence of PEP[53,54]. At present, the dismally universal finding is that a strategy of pharmacologic prevention that proves effective in a few trials ultimately yields largely disappointing results over the long term

Table 4 Unresolved issues with prevention of post-endoscopic retrograde cholangiopancreatography pancreatitis

The ideal design of a prophylactic pancreatic stent
Cannulation technique to lower incidence of PEP, tailored to the shape of the major papilla
The ideal pharmacologic agent
Comparison of rectal NSAIDs *vs* pancreatic stent placement *vs* combination in high risk patients
The route (rectal or intravenous) and the timing (before or after ERCP) of NSAIDs administration

ERCP: Endoscopic retrograde cholangiopancreatography; PEP: Post-ERCP pancreatitis; NSAIDs: Non-steroidal anti-inflammatory drugs.

when adopted in routine clinical practice[55,56]. Endoscopists in the ERCP field appear to believe that mechanical techniques such as pancreatic stents, much more than pharmacologic prophylaxis, play a key role in the prevention of PEP[55].

Despite a current climate of skepticism regarding the efficacy of any prophylactic medication for PEP, evidence for the efficacy of rectal NSAIDs in reducing PEP continues to accumulate[15,57-60]. Rectal NSAIDs are particularly attractive because of their low cost, easy administration, and known favorable risk profiles.[15] In addition to several meta-analyses[15,58,59], a recent well-designed randomized controlled trial beautifully showed the effect of rectal indomethacin in preventing PEP in 602 high risk patients (9.2% in the indomethacin group *vs* 16.9% in the placebo group, $P = 0.005$)[57]. However, only time will tell whether rectal NSAIDs can significantly reduce PEP.

Selection of preventive measures: According to the European Society of Gastrointestinal Endoscopy guidelines, periprocedural rectal administration of NSAIDs is recommended for low-risk ERCPs, whereas prophylactic pancreatic stent placement should be strongly considered for high-risk ERCPs[5]. However, the combined use of NSAIDs and prophylactic pancreatic stent placement might further reduce the rate of PEP in high-risk patients[61]. Therefore, rectal administration of NSAIDs for all ERCPs and prophylactic pancreatic stent placement for high-risk ERCPs might be more practical. A further practical strategy might be rectal administration of NSAIDs for patient-related high risk and prophylactic pancreatic stent placement for procedure-related high risk. However, the possibility remains that rectal NSAIDs may obviate the need for prophylactic pancreatic stent placement[61]. Studies to compare the effectiveness of rectal NSAIDs and pancreatic stent placement in high risk patients are warranted.

Future prospects for research

Although PEP has benefited from evolved understanding, there is still room for continuing research. In the future, the individual incidence of PEP should be accurately calculated according to the previously listed patient-related and procedure-related risk factors for PEP. In addition, the complexity of ERCP procedures[62,63] should be incorporated into the calculation of the individual incidence of PEP. Regarding the prevention of PEP, many issues still remain to be resolved (Table 4).

In conclusion, more than a decade has passed since the publication of the classic article that revealed the risk factors for PEP. Subsequent multivariate analyses have confirmed a number of risk factors for PEP that can be divided into patient-related and procedure-related issues. Prophylactic pancreatic stent placement has become a standard of care in high-risk patients and rectal NSAIDs have become a potential candidate as an ideal pharmacologic agent for preventing PEP. However, PEP is still the most frequent and most feared complication of ERCP. In the past decade, indications of ERCP have become more stringent owing to the development of other diagnostic and therapeutic modalities. To minimize PEP and maximize benefits[9], ERCP should be done for the best indications, while recognizing accurate risks to the individual and using meticulous endoscopic techniques with optimal preventive measures.

Abstract

Although the association between alcohol and pancreatic diseases has been recognized for a long time, the impact of alcohol consumption on pancreatitis and pancreatic cancer (PC) remains poorly defined. Nowadays there is not consensus about the epidemiology and the beverage type, dose and duration of alcohol consumption causing these diseases. The objective of this study was to review the epidemiology described in the literature for pancreatic diseases as a consequence of alcoholic behavior trying to understand the association between dose, type and frequency of alcohol consumption and risk of pancreatitis and PC. The majority of the studies conclude that high alcohol intake was associated with a higher risk of pancreatitis (around 2.5%-3% between heavy drinkers and 1.3% between non drinkers). About 70% of pancreatitis are due to chronic heavy alcohol consumption. Although this incidence rate differs between countries, it is clear that the risk of developing pancreatitis increases with increasing doses of alcohol and the average of alcohol consumption vary since 80 to 150 g/d for 10-15 years. With regard to PC, the role of alcohol consumption remains less clear, and low to moderate alcohol consumption do not appear to be associated with PC risk, and only chronic heavy drinking increase the risk compared with lightly drinkers. In a population of 10%-15% of heavy drinkers, 2%-5% of all PC cases could be attributed to alcohol consumption. However, as only a minority (less than 10% for pancreatitis and 5% for PC) of heavily drinkers develops these pancreatic diseases, there are other predisposing factors besides alcohol involved. Genetic variability and environmental exposures such as smoking and diet modify the risk and should be considered for further investigations.

INTRODUCTION

Alcohol causes different diseases and they are considered an important medical and social burden on society. Alcohol has been identified as a leading risk factor for death and disability globally, accounting for 3.8% of death and 4.6% of disability adjusted life years lost in 2004[1].

Pancreas is one of the most important organs adversely affected by alcohol consumption. An association between alcohol abuse and pancreatic injury was reported by Friedreich[2] as early as 1878. Freidreich recognized an

association of alcohol abuse with chronic pancreatic injure.

Since Friedreich's initial observation, many studies have confirmed that excessive alcohol intake is associated with pancreatic damage. Nowadays it is widely recognized that pancreatic injure due to alcohol consumption ranges from isolated episodes of acute pancreatitis (AP) to chronic manifestations that with time could move to pancreatic cancer (PC). However, there is not a consensus in the epidemiology and it is no clear how different drinks or dose of alcohol affect to the development of pancreatic diseases and finally, how drinking trigger pancreatic injury only in a minority of alcoholics.

Here, we review different studies and meta-analysis that have been published in the last years relating alcohol and pancreatic diseases as AP, chronic pancreatitis (CP) and PC. We summarize the effects of alcohol consumption in these diseases and at the end we present the possible mechanisms that have been proposed as a cause of this pancreatic pathogenesis.

Alcohol consumption measures

The incidence and prevalence of alcoholic pancreatic diseases are difficult to ascertain with precision, in part because of the variable considerations of drinking behavior and alcohol intakes measures.

Most of the studies in cohorts measures alcohol intake from wine, beer, and spirits separately. The final value of the daily alcohol intake is expressed in grams for each beverage based on the frequency of consumption, the alcohol content of the beverage, and the average quantity consumed. The United States Department of Agriculture established that alcoholic beverages are 12.8 g for 335 mL of alcohol for a bottle of beer (12-oz, 5% alcohol), 11.0 g for 118 mL (4-oz, 12% alcohol) glass of wine, and 14.0 g for 44 mL (1.5 oz, 40% alcohol) of 80-proof liquor.

The definition of a "standard drinker" differs between countries[3,4]: in United States it is 14 to 15 g, in Great Britain is 8 g and 19.75 g of alcohol in Japan. In addition to the amount to alcohol in one drink, the cut points to define "moderate" and "heavy" drinking also vary. In general, and to simplify a "standard drink" can be considered equal to 10 g of alcohol. A glass of wine, beer or half a glass of liquor would equivalente a beverage. For example in United States the standards are as following: moderate drinking is for women less than 2 drinks per day and less than 3 drinks for men; Heavy drinking is more than 7 drinks per week or 3 per occasion and more than 14 drinks per week or 4 per occasion; Bingo drinkers is 4 or more drinks in a row for women and more than 5 for men[5].

PANCREATITIS

Alcoholic pancreatitis is a potentially fatal illness that may be short term (*i.e.*, acute) or long term (*i.e.*, chronic). The relationship between acute and CP is complex. Symptoms are shared by acute and CP and include abdominal pain and interference with normal pancreatic functions. Although the prevalence of alcoholic pancreatitis in the population is unknown, clinicians usually agree that both acute and chronic alcoholic pancreatitis are responsible for a significant amount of illness and death in the world. However, the proportion of cases of pancreatitis attributed to alcohol varies widely among countries and even among different studies in the same country.

There are not universally accepted criteria to assign alcohol as an etiology of patient's pancreatitis but experts defines that varying from consumption of over 50 to 80 g (4-7 drinks/d) with or without a minimum drinking duration[6-9]. An international consensus defined alcoholic CP based on typical clinical history, threshold alcohol consumption (80 g or more of alcohol for a few years in males and less in females) and morphological evidence of CP on imaging studies or histology[10].

Besides the alcohol intake, other list of etiologies have been described as factors that could increase the risk for pancreatitis as gallstones, cystic fibrosis, hyperlipidemia, hyperparathyroidism, pancreas divisum or traumas, infections, genetic factors and autoimmune disease[11,12].

There is only a few numbers of epidemiological studies on the quantitative aspects of risk estimations for pancreatitis in relation to alcohol. In 2004, Corrao *et al*[13] conducted a meta-analysis of case-control and cohort studies published between 1966 and 1995 that assessed the association between alcohol consumption and CP. Then, Irving *et al*[14] in a review and meta-analysis published in 2009 analyzed studies published between 1980 and 2008 and assessed the association between alcohol consumption and the risk of pancreatitis. They concluded that the threshold between alcohol consumption and pancreatitis is 4 drinks daily.

However, about 70% of pancreatitis cases are believed to be attributable to chronic, heavy alcohol consumption but this percentage differs between countries[13,15,16]. Autopsies done on alcohol abusers have shown that up to 75% of them present CP[17]. On another hand, as less than 10% of consumers of alcohol in excess develop CP, other factors modify ethanol toxicity *in vivo*[16].

ACUTE PANCREATITIS

Historically it has been well-known that the risk of developing AP increases with increasing doses of alcohol[18] and with the duration of alcohol abuse[19], although epidemiological studies have shown that only a minority of heavy drinkers develop evident pancreatitis episodes[20,21]. This correlation shows again that besides of alcohol effects, additional factors are involved in AP develop.

Alcohol is the second most common cause of AC after gallstones[22]. The clinical features at the time of initial presentation are abdominal pain, jaundice, distal common bile duct obstruction and exocrine or endocrine insufficiency. Generally, the onset of alcoholic pancreatitis occurs in the 4th decade of males with an average of alcohol consumption around 150 g/d for a period of

Table 1 Alcoholic pancreatitis epidemiology in the different countries

Frulloni *et al*[37]	Italy	79%
Lankisch *et al*[9]	Germany	78%
Nøjgaard *et al*[29]	Denmark	44%
Díte *et al*[33]	Czech Republic	60%
Ammann *et al*[38]	Switzerland	71%
Robles-Díaz *et al*[39]	Mexico	68%
Dani *et al*[40]	Brazil	90%
Marks *et al*[41]	South Africa	80%
Balakrishnan *et al*[42]	India	33%

10-15 years[23]. Initially patients present acute abdominal pain, elevated serum levels of pancreatic enzymes and evidence of pancreatic damage in imaging studies.

These acute toxic effects of alcohol on the pancreas are considered AP but the progression of acute episodes (potentially reversible) leads to chronic disease with irreversible changes in the pancreas.

Traditionally, AP has been classed as fundamentally different from CP as the first one is characterized by restoration of normal pancreatic histology after full clinical recovery[24]. However, acute, recurrent acute and CP are now regarded as a disease continuum[25,26]. For this reason, the majority of the epidemiologic studies of alcoholic pancreatitis are referred to CP.

There is no data in the literature showing whether the heavy alcohol intake (> 80 g/d) in abstainers or moderately drinkers is a risk factor for AP. Also it is unknown whether this risk would be the same for all alcoholic beverages (wine, beer or spirits).

CHRONIC PANCREATITIS

CP is an inflammatory disorder of the pancreas typically associated with heavy alcohol consumption. Clinical features of CP consist of abdominal pain, recurrent attacks of clinical AP, and exocrine and/or endocrine insufficiency[27].

Alcohol is the most common cause for CP[22]. Clinical and experimental studies analyzing alcoholic CP development have concluded that alcoholic pancreatitis begins as a acute process that progresses to chronic irreversible pancreatic damage as a consequence of repeated acute attacks[23,28].

The overall survival in patients with alcoholic pancreatitis is significantly lower compared with the background population, but most of the patients die from causes unrelated to pancreatitis[29,30].

Dufour *et al*[16] concluded that CP development is proportional to the dose and duration of alcohol consumption (minimum, 6-12 years of approximately 80 g of alcohol per day).

The incidence rates of CP and the proportion of cases attributed directly to alcohol etiology differ based on geographic distribution (see Table 1).

In United States alcohol etiology accounts around 50%-55% depending on the study. Layer *et al*[7] published a study with patients obtained since 1976 to 1982 and they found that 56% were heavy drinkers (> 50 g/d) and present alcoholic etiology. Coté *et al*[31] published their results from a multicenter study (2000-2006) in 2010 concluding that alcohol contributes to CP in 45% of the patients. In 2011, Yadav *et al*[32] published a population-based study with patients from Mayo Clinic in Olmsted County, MN concluding that 51% presented alcoholic CP. In these studies patients with alcohol consumption of > 50 g/d were defined as alcoholic CP.

In general this percentage is lower than Europeans series[6,9,33,34] or other regions[35] (67%-89%) but similar to those from Japan (56%)[36].

In European series there is some variability between countries. For example in Italy the described percentage was 43%-79%[6,37], Germany 78%[9], Denmark 44%[29], Czech Republic 60%[33] and Switzerland 71%[38].

The series published in Mexico show 68%[39] of patients with alcoholic etiology, while alcohol is the responsible factor in 90%[40] of patients in Brazil, 80%[41] in South Africa and 33%[42] in India.

Taken together the data presented above, independently of the region it has been shown that 50% or more of AP or CP are associated with alcohol consumption.

Besides of the geographic distribution, CP due to alcohol consumption could be different based on the race but not on the sex. Lowenfels *et al*[43] determined that at equal levels of consumption the rates of alcoholic pancreatitis are similar for males and females although patients with alcoholic pancreatitis are more likely males. This is due to the overrepresentation of males among patients with alcoholic pancreatitis, showing a higher prevalence of alcohol consumption than sex-based differences in susceptibility.

Also, regardless to the race it was initially described by Lowenfels *et al*[30] and then confirmed by other authors[44-46] that blacks have two to three folds higher rates of alcoholic pancreatitis. Other authors have described that polymorphisms associated to specific populations and races are associated with functional differences in alcohol metabolizing enzymes leading to variation in pancreas damage[47].

However, detailed reasons for geographic or racial differences in susceptibility to alcoholic pancreatitis are still unknown and most likely are because differences in alcohol intake influenced by habits and genetic susceptibility. Further investigations are needed to confirm that or look in detail for cofactors associated to alcohol consumption.

Based on alcohol consumption, Kristiansen *et al*[48] estimated that the risk of any pancreatitis among non drinkers (abstainers) is 1.33% while it is among 2.5% (1.6% acute and 1.6% chronic) in heavy drinkers (> 35 drinks/wk or > 5 drinks/d). Lowenfels *et al*[30] concluded that the risk of pancreatitis among heavy drinkers (> 5

drinks/d) is about 2%-3%.

Also, some studies have been made to evaluate whether the type of beverage (beer, wine or spirits) or the frequency of drinking (daily, almost daily, weekly or monthly) is associate with the risk of pancreatitis[48]. This study concluded that consumption (> 14 drinks/wk) of beer but not wine or spirits increase the risk of pancreatitis. However this analysis was limited by the number of cases at high levels of consumption. These authors did not find an independent association between the frequency of consumption and risk. In addition some experimental studies carried out in animals conclude that prolonged ethanol feeding does not induce CP although causes little histological changes and variation in pancreatic enzymes[49,50].

Although it has been well established that pancreatic inflammation appears to increase the risk of PC[51] and it could be that alcoholic pancreatitis could leads also to PC, future epidemiological studies are needed to analyze this correlation in population.

Some studies have indicated that CP can result in type 2 diabetes, and with a time (up to 20 years) 2%-4% of these pancreatitis cases will develop PC[52]. Also, long-standing type 2 diabetes is a risk factor for PC[53]

Even in heavy alcoholics, CP and alcoholic cirrhosis seldom occur together in the same patient[54,55], despite a few contradictory reports. The mechanisms or factors determining this dichotomy of some alcoholics developing pancreatitis and others developing liver cirrhosis have not been adequately explained. Whether this can be explained by the quantity, duration, and pattern of drinking, or by other cofactors, tobacco smoking, genetic predispositions or dietary factors is debatable.

Veena *et al*[56] showed that a longer duration of use and bigger amounts of alcohol consumption are necessary before cirrhosis disease compared with CP.

PANCREATIC CANCER

Looking at the risk factors of PC, cigarette smoking represent one of the most important contributing lifestyle risk factor accounting around 20% of the patients. Other factors include CP, diabetes, *Helicobacter pilory* infection, obesity, family history of PC and also heavy alcohol consumption[57].

While the association between alcohol abuse and pancreatitis is well established the association between alcohol consumption and PC is less clear and remains controversial.

Historical studies in different cohorts have shown that patients with CP have an increased risk of PC; the excess risk was observed in men and women[52].

Epidemiological data on alcohol and PC are difficult to interpret due to several reasons as: the small sample size (and limited power to detect a possible weak effect of a rare exposure), variability in dose and time of alcohol exposure and other causes influencing (genetic or environmental).

Since 2009 three pooled data analysis and one meta-analysis have been performed. The first pooled study published in 2009 was adjusted for age, smoking status, diabetes, weight, food intake and time of exposure. The control group was no drinkers (0 g ethanol/d). The authors showed a moderate effect of heavy drinking (> 30 g ethanol/d or approximately more than 2-3 alcoholic beverages/d) in women but not in men although the difference in the results by gender was not statistically significant. No associations were observed for the different types of beverage (beer, wine or liquor). This finding is consistent with a modest increase in risk of PC for alcohol intakes of at least 30 g/d[58].

The second pooled analysis[59] was performed using PanScan study. Analysis was adjusted for age, study, race, smoking status, diabetes and body mass index. The control group was a very light drinkers (> 0-4.99 g ethanol/d) for the total alcohol intake and non-drinkers (0 ethanol/d) for the beverage type group. The author concluded that heavily consumption of alcohol from liquor (> 45 g ethanol/d) was associated with PC in men but not in women and not in men and women combined.

The third pooled analysis[60] included a big number of PC cases. Analysis was adjusted for age, sex, race, area, smoking status, education, body mass index and diabetes. The study concluded that heavy drinkers (> 9 drinks/d) have a moderately increased risk of PC compared with lightly drinkers (< 1 drink/d).

The meta-analysis of alcohol consumption and PC includes 21 case-control studies and 11 cohort studies published since 2009[61]. The results obtained indicate that heavy drinkers (> 3 drinks/d) but not moderate or low drinkers, have an increased risk of PC. This result is valid for both men and women.

In summary, these analysis and meta-analysis suggest that heavy drinkers (>30-40 g ethanol/day or > 3 drinks/d) can result in an increased risk of PC. The authors conclude that in a population of 10%-15% of heavy drinkers, 2%-5% of all PC cases could be attributed to alcohol consumption.

Most of the data published in the literature indicate that alcohol drinking at the levels typically consumed by the general population is probably not a risk factor for PC, however heavy alcohol drinking may be related to PC risk[62]. As an extreme case, Gupta *et al*[63] conclude that men binge drinkers (> 5 drinks/episode or > 70g ethanol/episode) leads to a 3.5-fold increased risk of PC and this risk is higher with the numbers of drinks per binge episode. This effect is greater in current smokers than in former or never smokers.

In contrast, most previous epidemiological studies could not demonstrate an excess risk for PC associated with moderate alcohol intake. Velema *et al*[64] did not find sufficient evidence for a causal relationship. Ye *et al*[65] concluded that the excess risk for PC among alcoholics was small, and may be totally attributable to a mix of causes, for example also increased by smoking.

Some of these studies demonstrated no significant

elevation in risk of PC was observed among alcohol consumers less than 55 years old; however, no similar elevation in risk was observed among those 55 or more years old[66].

In conclusion, there is several difficulties to evaluate the association between alcohol and PC and in epidemiological studies the small sample size has probably contributed to the problem of limited power to detect a possible weak effect of a rare exposure (*i.e.*, chronic heavy alcohol drinking). Also causes like exposure measurement error, limited number of cases under study and competing causes have made difficult study the potential effects of alcohol consumption on the risk of PC[67].

Compared with the general population, alcoholic drinkers without alcoholic CP or alcoholic liver cirrhosis have a modest 40% excess risk to develop PC. Even patients diagnosed with alcoholic CP or liver cirrhosis, have only two folds risk for PC. In addition, it has been shown that non-alcoholic CP patients have a markedly greater excess risk for PC, and this risk is higher than that among alcoholic CP patients[65]. These data suggest that in some circumstances, pancreatitis may be an early manifestation of an as yet undiagnosed PC. Also Kudo *et al*[68] concluded that alcohol drinking was not significant risk factor for developing PC in CP patients. So far, no studies have demonstrated that alcoholic pancreatitis leads to an increased risk of PC compared with non-alcoholic pancreatitis.

Taking these data together, although the role of alcohol consumption in PC remains unclear, it appears that low to moderate alcohol consumption is not associated with PC risk, but chronic heavy drinking (and perhaps prolonged bingering, although available data are confusing) may increase risk of PC[58,59,61,63]. Heavy alcohol consumption may increase PC risk by potentiating the effects of other risk factors such as tobacco smoking, poor nutrition, and inflammatory pathways related to CP, but also may have independent genetic and epigenetic effects.

Overall alcohol intake is only one dimension of drinking behavior. Other considerations such as spacing of drinking occasions, quantity of alcohol consumed, type of alcoholic beverages, ways in which beverages are mixed and commodities consumed in conjunction with alcoholic beverages as salt[69], coffee or tobacco or food[70] are important of pancreatic disease and were described many years ago.

POTENTIAL MECHANISMS OF ALCOHOL CONSUMPTION AND PANCREATIC DISEASES

Over the last decades there have been numerous efforts to elucidate the mechanisms by which alcohol damages the pancreas.

The injurious effects of ethanol on the pancreas are mediated through different mechanisms[71] as (1) sensitization of acinar cells to cholecystokinin (CCK) inducing premature activation of zymogens[72]; (2) potentiation of the effect of CCK on the activation of transcription factors, nuclear factor-κB and activating protein-1[73,74]; (3) generation of toxic metabolites such as acetaldehyde and fatty acid ethyl esters; (4) sensitization of the pancreas to the toxic effects of coxsackievirus B3[75]; and (5) activation of pancreatic stellate cells by acetaldehyde and oxidative stress and subsequent increased production of collagen and other matrix proteins[76].

Chronic alcohol exposure leads to impaired exocytosis mediated by acetaldehyde-induced microtubular dysfunction and apical cytoskeleton reorganization in acinar cells, with a subsequent accumulation of intracellular enzymes[77]. In addition, alcohol decreases the stability of zymogen and lysosomal membranes and enhancers acinar cell sensibility to CCK further increasing susceptibility to pathological enzyme activation[78,79]. Some theories also show that physiologically ethanol leads to the formation of protein secretory plugs that obstruct pancreatic ducts, spam of the sphincter of Oddi or decreased tone of the sphincter causing reflux[80-82].

Ethanol and its major metabolite, acetaldehyde, are classified by the International Agency for Research on Cancer as group 1 carcinogens[83].

Alcohol metabolism depends on enzymes that transform ethanol. Genes for these modifying enzymes have specific polymorphisms that differ between subjects and races leading to differences in susceptibility to alcohol effects and alcohol dependence[47].

Although the liver is the major ethanol-metabolizing organ in the body, the pancreas can metabolize alcohol both via oxidative and non-oxidative pathways.

The oxidative pathway is catalyzed by the enzyme alcohol dehydrogenase (ADH) and the cytochrome P450 and produces the metabolite acetaldehyde. Finally, the oxidative alcohol metabolism results in the generation of oxygen species (ROS)[84] and a depletion of the ROS scavenger glutathione[85]. The increased ROS production (which damage DNA and proteins) and a reduction of proteins that eliminate this ROS (glutathione and enzymes related) lead to oxidant stress and resultant damage in tissue. This stress could be responsible for induce alcoholic pancreatitis as has been demonstrated by several models[86-88].

But in pancreas, the non-oxidative pathways may be more important than oxidative metabolism, generating fatty acid ethyl esters (FAEE) by fatty acid ethyl ester synthases (FAEE synthases)[89]. It has been shown that pancreas exhibits higher FAEE synthase activity than liver[90] and FAEEs accumulation have been observed in human and rat pancreas after alcohol intake[91-93].

The products of alcohol oxidation (acetaldehyde and ROS) and of non-oxidative metabolism have been reported to cause acinar cell injury. Acetaldehyde cause morphological changes in rat and dog's pancreas[94] and it has been showed that inhibits CKK-simululated cinar cell secretion[95]. Also, several studies have demonstrated that alcohol intake causes oxidant stress within the pan-

creas[86-88] which may play a role in the alcohol-induced destabilization of zymogen granules and lysosomes. In addition, alcohol oxidation contributes to acinar damage altering the intracellular redox state (a reduced NAD/NADH ratio and increased lactate/piruvate ratio). Other results obtained in isolated mouse pancreatic acinar cells suggest that FAEEs leads to mitochondrial damage, loss of ATP and rise in cytosolic free calcium, which leads to acinar cell toxicity[96]. Other authors have shown that acute application of ethanol at clinically relevant concentrations (1-50 nmol/L) of isolated acinar cells resulted in calcium influx due to the production of oxidative metabolites of alcohol[97]. Together, these data show that the role of alcohol metabolites in acinar cell damage could be due to aberrant calcium signals[98]. FAEEs can elevate Calcium greater that ethanol alone. In addition, FAEEs and their products, fatty acids induces necrosis in acinar cells and this process could be avoided by calcium chelation[99].

These physiological changes leads to the pathobiology found in alcoholic pancreatitis including acute and chronic inflammation, elimination of parenchymal cells of the pancreas by a deregulation of apoptosis/necrosis and/or modification in cell proliferation[49]. The hypothesis called "necrosis-fibrosis sequence" shows these pathological changes where in the early episodes of pancreatitis, patients present focal necrosis and mild fibrosis while patients evaluated years later of the onset of symptoms presents fibrosis and calcifications but not necrosis[100].

But the fact that only a minority of heavily drinkers develops pancreatitis or PC indicates that other susceptibility factors as lipid tolerance, smoking or hereditary factors play an important role. In the last decades, genetic susceptibility has been considered between the factors that contribute mainly to the development to alcoholic pancreatic diseases.

One study showed an association between a polymorphism of the gene for one FAEE synthase enzymes, carboxylester lipase and risk of developing alcoholic pancreatitis[101].

In addition, the G191R variant in the anionic trypsinogen gene *PRSS2*, has been shown to result in a form of trypsin that is easily degraded, is more infrequent in alcoholic pancreatitis patients compared with healthy controls[102].

Other studies have demonstrated that mutation N34S in *SPINK1* gene is found in 5%-5.8% of patients with pancreatitis compared with 1% in healthy controls[103,104]. But still the functional consequences of this mutation are unknown.

One of the enzymes that have been also related to alcoholism and drug dependence for decades is ADH. Li *et al*[105] performed a recent meta-analyses and confirmed strong associations of the *ADH1B* and *ALDH2* genes with alcoholism and alcohol-related medical diseases[106]. Recently, Celorrio *et al*[107] demonstrated that some specific polymorphism in the genes *TH*, *ADH1B* increase the risk to develop diseases a consequence of excessive consumption of alcohol.

Although it is clear that alcohol consumption is genetically influenced, but characterized by incomplete penetrance, phenocopies, heterogeneity, and polygenic inheritance.

In conclusion, nowadays it appears clear that alcohol consumption is the first or second most common cause of pancreatitis. Based on the different epidemiology studies published in the literature the percentage of pancreatitis cases attributable to alcohol abuse vary since 30% to 90% between countries. A statistical association has been shown with a threshold of $\geqslant$ 5 drinks per day with a dose of alcohol $\geqslant$ 50 g/d.

But despite that excessive alcohol consumption is primarily responsible for most cases of pancreatitis, alcohol intake alone is not sufficient to lead to this disease, as less than 10% of heavily drinkers develop pancreatitis.

Regarding to PC, the role of alcohol consumption remains less clear, and low to moderate alcohol consumption do not appear to be associated with PC risk, but only chronic heavy drinking increase the risk compared with lightly drinkers.

Genetic variability and environmental exposures such as smoking and diet could act synergistically with regard to pancreatitis and PC and should be considered for further investigations. Probably heavy alcohol consumption may increase pancreatic disease risk most likely potentiating the effects of these other risk factors, but also may have independent genetic and epigenetic effects.

Abstract

Many data coming from animal models and clinical observations support an involvement of intestinal microbiota in the pathogenesis of Crohn's disease (CD). It is hypothesized in fact, that the development of chronic intestinal inflammation is caused by an abnormal immune response to normal flora in genetically susceptible hosts. The involvement of bacteria in CD inflammation has provided the rationale for including antibiotics in the therapeutic armamentarium. However, randomized controlled trials have failed to demonstrate an efficacy of these drugs in patients with active uncomplicated CD, even if a subgroup of patients with colonic location seems to get benefit from antibiotics. Nitroimidazole compounds have been shown to be efficacious in decreasing CD recurrence rates in operated patients, and the use of metronidazole and ciprofloxacin is recommended in perianal disease. However, the appearance of systemic side effects limits antibiotic long-term employment necessary for treating a chronic relapsing disease. Rifaximin, characterized by an excellent safety profile, has provided promising results in inducing remission of CD.

ROLE OF GUT MICROBIOTA IN CROHN'S DISEASE

Crohn's disease (CD) is a chronic inflammatory bowel disease characterized by an altered composition of the intestinal commensal bacteria (dysbiosis)[1,2]. Dysbiosis is considered to have a preeminent role in CD pathogenesis by inducing an abnormal immune response in genetically susceptible individuals[3-7].

Intestinal sites commonly affected by CD lesion, in fact, are those with the highest bacterial concentration, such as colon, terminal ileum, especially after the loss of the ileocecal valve, and upstream from strictures. The luminal content is necessary for causing intestinal inflammation, and CD lesions do not appear when it is diverted from the gut, whereas restoration of bowel continuity or infusion of faecal material into the bypassed intestine rapidly results in recurrence of the disease[8-10]. In genetically engineered rodent models susceptible to spontaneous colitis, inflammation does not occur when the animals are raised in germ-free conditions[11]. Patients with CD have an altered composition of gut microbiota with increased concentrations of invasive bacteria, especially *Escherichia coli* (*E. coli*) and a decreased number of protective bifidobacteria, lactobacilli and the more recently studied *Faecalibacterium prausnitzii,* that has been shown to have anti-inflammatory properties[12-15]. Genetic susceptibly in a subgroup of patients with CD is related to polymorphisms in the *NOD2/CARD15* gene, suggesting that individuals with mutations in *NOD2* present defective intestinal immune responses to gut microbiota[16-20]. About 20% of CD patients are homozygous for *NOD2* variants and they may have an increased susceptibility to CD localized at the ileum[21].

Moreover, a loss of immunologic tolerance to the

commensal flora has been observed in patients with active IBD[22].

Experimental studies in animal models have shown that broad-spectrum antibiotics are efficacious in almost all models of acute and chronic colitis and ileitis[23]. However, they have only a transient benefit in HLA-B27 transgenic rats[24]. Broad-spectrum antibiotics can both prevent and treat experimental colitis of rodent models, while metronidazole and ciprofloxacin can only prevent the onset of colitis, but not reverse the established disease[25,26].

ANTIBIOTIC TREATMENT IN CROHN'S DISEASE

These and other data, confirming the role of the gut microbiota in the pathogenesis of CD, provide the rationale for a therapeutic manipulation of the intestinal flora through the use of antibiotics and probiotics[27-30].

Some of the suggested mechanisms of action for antibiotics in CD are the ability to reduce luminal and mucosa adherent bacteria concentrations, to eliminate in a selective way aggressive bacterial species, to decrease bacterial tissue invasion and translocation. Additionally, some antibiotics also exert a potential immunosuppressive action.

The role of antibiotics as primary or adjunctive treatment of active, uncomplicated CD has not been clearly demonstrated and their use is controversial. A recent meta-analysis suggests that antibiotics may be effective as primary therapy of CD[31], but guidelines do not recommend their use except for the treatment of septic complications of CD, symptoms attributable to bacterial overgrowth, or perianal disease[32].

ANTIBIOTICS FOR INDUCTION AND MAINTENANCE OF DISEASE REMISSION

The similarity of CD to tuberculous enteritis and Johne's disease of ruminants, caused by *Mycobacterium Avium* subspecies *Paratuberculosis* (MAP), and the isolation of atypical Mycobacteria from blood and tissue of CD subjects, have lead to evaluate the efficacy of anti-mycobacterial drugs in these patients[33-37]. However, the results of the randomized controlled trials performed with antibiotics active against atypical Mycobacteria for obtaining and maintaining CD remission have been conflicting.

A meta-analysis that considered eight trials employing different associations of anti-mycobacterial drugs showed that these drugs seem to be ineffective for inducing remission without a course of steroid therapy[38].

In the largest study 213 Australian patients were randomized to receive a combination of clarithromycin plus rifabutin and clofazimine, antibiotics active against MAP, or placebo for up 2 years, in addition to a 16-week course of corticosteroids[39]. The results showed a significant benefit only at 16 wk, when the antibiotic combination was added to steroids, confirming the data founded by the meta-analysis, and suggesting that the short-term advantage could be related to a generic antibacterial effect. Therefore, this study does not support a significant role for MAP in CD pathogenesis, although several objections to this conclusion have been raised[40-44]. At the present time the mycobacterial hypothesis cannot be completely ruled out, and it continues to be plausible that an infectious agent could start the inflammatory process[45].

Pathogenic adherent and invasive *E. coli* have been detected in Crohn's ileal and colonic tissue[46-49]. This bacterium can invade and replicate within macrophages, inducing the secretion of large quantities of tumor necrosis factor[50]. Clarithromycin is a broad spectrum macrolide antibiotic that can penetrate into macrophages, and may therefore be effective in eradicating the bacteria. However, a study comparing clarithromycin 1 gr to placebo for 3 mo in patients with active CD, was stopped because of poor efficacy[51].

Metronidazole, which is active against anaerobic bacteria and some parasites, and ciprofloxacin, particularly active against *E. coli* and *Enterobacteriacee*, are the most frequent studied and used antibiotics. Several randomized clinical trials have been performed employing metronidazole and/or ciprofloxacin for induction of CD remission.

The results of the trials have indicated that metronidazole is efficacious in active Crohn's colitis and ileo-colitis, but not in small bowel location[52-55]. Five randomized controlled studies evaluating the efficacy of ciprofloxacin, alone or in association with metronidazole, in patients with active CD, have shown uncertain results[56-60].

Patients with colonic involvement get more benefit from antibiotics, probably because of the high concentration of bacteria in the colon.

The efficacy of antibiotics in CD seems to be related to a prolonged therapy, that is frequently burdened by an elevated number of systemic adverse events (AEs). In particular, there is concern about the *Clostridium difficile* infection caused by antibiotics, especially fluoroquinolones such as ciprofloxacin[61]. *Clostridium difficile* infection can induce CD relapse and gastroenterologists in charge of CD patients must be aware of this serious complication. In 2007 two retrospective studies demonstrated a dramatically increased incidence of *Clostridium difficile* infection in patients with IBD, who appeared to be more susceptible to this infection than non IBD-patients[61,62].

The minimally absorbed antibiotic rifaximin, which is active against gram-positive and gram-negative bacteria, has been shown to be effective in active CD patients. In an exploratory study, a gastro resistant formulation of rifaximin [extended intestinal release (EIR)] (rifaximin-EIR) at a dose of 800 mg twice daily for 12 wk reported significantly higher rates of remission and response compared to placebo, in a subgroup of patients with mild to moderate CD and an elevated value of C-reactive protein[63].

In a recent, larger study 402 patients with moderately active CD were randomized to receive rifaximin-EIR 400, 800, 1200 mg or placebo twice daily for 12 wk[64]. The

results showed that rifaximin-EIR 800 mg twice daily was significantly superior to placebo in inducing remission, defined as a Crohn's Disease Activity Index (CDAI) score < 150, after 12 wk of therapy (62 % *vs* 43%). The effect was maintained throughout a subsequent 12-wk follow-up period in 65% of patients. Remission rates in patients treated with 400 and 1200 mg twice daily (54 % and 47 %, respectively) showed a trend towards but without reaching the statistical significance in comparison with placebo. The lack of a dose-response relationship was probably caused by the higher percentage of subjects who discontinued the treatment due to AEs in the 1200 mg twice daily group. Median CRP values over time showed no statistically significant differences between treatment groups. The most frequent AEs were of gastrointestinal origin, either determined by an underlying disease, with consequent CDAI score increase and treatment failure, or to rifaximin related side effects. Also in this study colonic location appeared to be associated with a higher response to the antibiotic therapy. Overall, the safety profile of rifaximin-EIR was good, indicating that rifaximin could be administered for a long period of time. However, *Clostridium difficile* infection was reported in a single patient with rifaximin 800 mg twice daily 20 d after the end of the treatment period. Rifaximin has been successfully employed for the treatment of CDI in metronidazole resistant patients[65], however it is probable that rare clones of rifaximin-unresponsive *Clostridium* can develop[66].

ANTIBIOTICS FOR PREVENTION OF POSTOPERATIVE RECURRENCE

Prevention of recurrence after intestinal resection is one of the major aims in the treatment of CD, and antibiotics have been used in this setting in 3 randomized placebo-controlled studies. The rationale for the employment of antibiotics is that bacteria are strongly suspected to be the main reason for the recurrence of lesions. In the first trial, metronidazole, at a dosage of 20 mg/kg per day for a 3-mo period, significantly decreased the incidence of early severe endoscopic recurrence, and also seemed to delay the symptomatic recurrence at 1 year, but it was associated with a high percentage of side effects[67]. The same authors have later performed a 12 mo placebo-controlled trial employing ornidazole, which has the same bacterial spectrum with a better safety profile. Ornidazole at a dose of 1 g/d proved significantly to reduce the clinical recurrence rate at 1 year, but more than 30% of patients in the antibiotic group discontinued the therapy because of side effects[68]. More recently, D' Haens *et al*[69]compared metronidazole (250 mg 3 times per day) given for 3 mo plus azathioprine for 12 mo to metronidazole alone in 81 operated CD patients at high risk of recurrence. This drug combination uses metronidazole as bridge therapy, given the slowness of azathioprine activity. At 3 mo after surgery severe endoscopic recurrence occurred in 34.3% of patients in the metronidazole/azathioprine group and in 52.6% of patients in the metronidazole/placebo group (P = 0.11). At month 12, severe endoscopic recurrence was observed in 43.7% of patients in the metronidazole/azathioprine group and in 69.0% of patients in the metronidazole/placebo group (P = 0.048). The study treatment was well tolerated and only 3 patients discontinued the therapy in the first 3 mo because of side effects, probably ascribable to metronidazole. The authors concluded that the combined treatment seems to be recommendable to CD patients with an elevated risk for postoperative recurrence. Recurrence prevention requires a long-term treatment, and this is burdened by a high number of AEs. Given its high safety profile, rifaximin, provided that its efficacy is completely demonstrated, should be employed for long term recurrence prevention.

ANTIBIOTICS FOR TREATMENT OF PERIANAL DISEASE

Antibiotics are widely employed for treatment of perianal CD, alone or as adjuvant therapy, and, despite the lack of controlled trials, European Crohn's and Colitis Organisation consensus statements recommend them in simple and complex fistulising perianal disease[70].

Most of the studies of perianal disease treated with antibiotics are, in fact, uncontrolled with a small sample size. In these studies, metronidazole and ciprofloxacin used alone or in combination have proved to induce a decrease of fistula drainage, but rarely induce closure. Moreover, symptoms tend to recur after suspending the treatment[71-73]. AEs resulting from prolonged use of antibiotics may, however, limit their use.

Recently, a randomized, placebo-controlled pilot study evaluating ciprofloxacin or metronidazole for the treatment of perianal fistulas in 25 CD patients failed to demonstrate a significant benefit of either antibiotic treatment over placebo in the cessation of drainage[74]. However the study was probably too small to permit detecting differences between treatment arms.

In conclusion, the different antibiotic regimens evaluated in the randomized controlled studies, the limited number of patient enrolled, the heterogeneity between the trials, and the uncertain results have led to the conclusion that antibiotics cannot be recommended for treatment of active CD, except for septic complications, symptoms attributable to bacterial overgrowth, or perianal disease. In addition, their efficacy could be limited by the prolonged therapy usually required for treating CD. However, there seems to be a subgroup of patients with colonic disease who can respond to these medications, likely due to the differences in gut microbiota between ileal and colonic location. Nitroimidazole antibiotics seem to be effective in decreasing both endoscopic and clinical recurrence rates after surgery, but their long-term use is complicated by an elevated number of AEs.

Treatment of patients with mild and moderate CD with rifaximin seems promising, but further larger studies are needed.

Abstract

Chronic infection by either hepatitis B virus (HBV) or hepatitis C virus (HCV) share epidemiological characteristics with risks for development of severe complications such as liver cirrhosis and hepatocellular carcinoma. HBV and HCV also share a high genetic variability. Among highly variable regions, viral genes encoding surface proteins (hepatitis B surface antigen, E1/E2 HCV glycoproteins) play key roles in the stimulation of the host-related immune response and viral entry into hepatocytes. Specific segments of HBV envelope proteins (preS1, "a" determinant) are crucial in the entry process into permissive cells. HCV entry is a complex multistep process involving multiple cell cofactors (glycosaminoglycans, low density lipoprotein receptor, SR-B1, CD81, claudin-1, occludin, EGFR, EphA2) in the interaction with HCV E1/E2 envelope glycoproteins. *In vitro* both viruses can be controlled by antibody-mediated neutralization targeting viral envelope, also essential in preventing HBV infection *in vivo* as observed through successful vaccination using HBs antigen. But preventive vaccination and/or therapeutic pressure can influence HBV and HCV variability. For HBV, the patterns of antiviral drug resistance in chronic hepatitis are complex and the original *pol*/*S* gene overlap has to be taken into account. Treatment-induced HBV mutations in pol could indeed generate S mutants with subsequent modified antigenicity or increased cancer induction. Variability of HBV and HCV envelope proteins combining high exposure to selective pressures and crucial functional roles require investigation in the context of diagnostic, vaccination and treatment tools. In this editorial a synthesis is performed of HBV and HCV envelope properties at the entry step and as antigenic proteins, and the subsequent clinical impact.

INTRODUCTION

Approximately 400 million people are currently living with chronic infection due to hepatitis B virus (HBV) and the number is approaching 160 million for chronic hepatitis C virus (HCV)-related infection[1]. Besides sharing many epidemiological features, HBV and HCV can both provoke chronic infections after an acute phase, due to a failure of humoral and cellular immune host responses[2-5].

HBV and HCV also share some biological similarities, especially the high frequency of mutations occuring dur-

ing viral replication. As a result both viruses can develop mutations leading to drug failure, especially for drugs with low potency and a low genetic barrier to resistance such as with anti-HBV lamivudine monotherapy. It is expected this will be less likely during treatment by entecavir or tenofovir which exhibit potent anti-HBV activity and high genetic barriers to resistance.

Viral dynamics are rapid with daily production of $10^{12\text{-}13}$ virions for HBV and 10^{12} for HCV. The half-life of free viral particles is short, less than 4 h for HBV[6,7] and 2-3 h for HCV[8]. Although both HBV and HCV can produce consistently high levels of virus in serum, they do so using viral templates with very different life-spans. The template for HBV replication, covalently closed circular DNA (cccDNA), resides in the nucleus of infected hepatocytes and is very stable in chronic infection, likely persisting for months[9], if not longer. On the other hand the intracytoplasmic minus strand RNA HCV template only persists for a few hours. Correspondingly HBV eradication is more difficult and only occurs after several years of viral suppression by therapy. Another characteristic of HBV is that its genome consists of overlapping reading frames: as a consequence, mutation rates to functional virus are lower for HBV compared to HCV which does not contain any overlapping gene. The counterpart of this molecular HBV characteristic is that changes at one position may affect the structure and function of more than one viral protein: the polymerase gene overlaps with the envelope gene, and consequently mutations have yet been published in polymerase gene under treatment pressure can produce mutations in the envelope *S* gene[10].

Despite the availability of an effective vaccine against HBV, new infections are still highly frequent worldwide. Hence, a careful examination of circulating viral strains must be considered in order to possibly adapt the antigenic vaccine content. To date however no effective vaccine is available against HCV. For both viruses, surface envelope glycoproteins are the external antigens first encountered by host-related immune responses during primary infection. These proteins contain both highly variable and conserved regions, the latter providing possible targets for preventive immunization and/or complementary therapeutic approaches.

The aim of this editorial is to give an overview of the current knowledge on hepatitis B and hepatitis C envelope glycoproteins, however with a particular emphasis on HBV. Structural and functional data will be described on the role of these proteins in the viral entry step into hepatocytes and in the stimulation of host-related responses and clinical impacts for HBV will also be described.

GENERAL PRESENTATION OF HBV ENVELOPE GLYCOPROTEINS AND ANIMAL/CELL CULTURES SYSTEMS SUITABLE FOR THEIR INVESTIGATION

For more than 20 years, primary human hepatocytes (PHH) from surgically excised liver specimens have been the only available *in vitro* HBV infection model. The transfection of hepatocyte-related cells (based on primary hepatocytes or hepatic cell lines which are easier to handle) with replication-competent HBV genomes allowed the production of secreted infectious virions. Regardless of the difficulty in maintaining these *in vitro* models, PHH cultures have for a long time been the only way to study viral infectivity. Due to poor efficiency of HBV infection in this model, virus amplification required the use of dimethylsulfoxide (DMSO) and of 4% polyethylene glycol during cultivation and infection, respectively. Primary hepatocyte cultures from *Tupaia belangeri* can also be infected with HBV, as efficiently as PHH cultures, but with fewer restrictions. Among human hepatic cell lines, the optimal system for various experiments was shown to be HepaRG cells, recently established from a liver tumor, and which become susceptible to HBV upon treatment with DMSO and hydrocortisone[11,12] (Table 1).

Many discoveries about the viral replication cycle, persistence and clearance have been obtained using animal models such as chimpanzee, gibbon or tupaia infected with HBV[13,14]. Moreover, humanized uPA/SCID mice have been recently used to study HBV/hepatitis D virus coinfection and represent an interesting model allowing us to investigate new antiviral drugs[15]. Experimental systems have also been provided by other *Hepadnaviridae* such as the duck HBV transmissible to many duck species or the woodchuck hepatitis virus, restricted to the North-Eastern American woodchuck[13].

Hepadnaviruses are characterized by specific liver tropism and high species specificity, restricting *in vivo* infection to their natural host or closely related species and contributing to the difficulty in developing suitable models of HBV infection[11].

HBV envelope glycoproteins are key viral elements in the viral cycle and in the stimulation of host-related immunity. Within virions, HBV surface envelope antigen (HBsAg) includes three viral surface glycoproteins, named large, medium, and small proteins (LHBs, MHBs and SHBs). They exhibit various distributions either in virions or in subviral particles. Their expression is directed by one stop codon and three start codons in a single open reading frame for translation into preS1, preS2 and S proteins[16]. The preS1 protein [108 or 119 amino acids (aa) depending on the genotype] is present only in LHBs; the preS2 protein (55 aa) is present in LHBs and MHBs; and the S protein (226 aa) is shared by LHBs, MHBs and SHBs[11] (Figure 1).

The three HBV surface preS1, preS2 and S proteins have different functions. Within the preS1 domain, amino acids 3-77 of the Large protein are essential for infectivity as is the myristoylation of glycine at position 2. The preS2-domain is present in both M- and L-proteins but because of the cytosolic orientation of the preS1-domain in the L-protein, it is N-glycosylated only in the M-protein. Although antibodies against the N-terminal part of preS2 can inhibit HBV infection *in vitro*, the Medium protein of HBV is believed to play an accessory

Table 1 Cell culture systems and *in vitro* models developed to study hepatitis B virus and hepatitis C virus envelope glycoproteins

	In vitro model/cell culture system	Step of the viral cycle	Benefits and major findings	Drawbacks
HBV	Primary hepatocyte cultures PHH PTH	Replication	No need for DMSO and hydrocortisone for PTH system	Not easy to handle Cells cannot be propagated *in vitro* Addition of growth factors
	Hepatic cell lines HepG2 HepaRG	Binding and infection (HBV and HDV)	Specific binding and uptake Cellular determinants of hepatocyte differentiation and their influence on HBV infection	No productive infection Addition of DMSO and hydrocortisone
HCV	Recombinant E2 glycoprotein: Truncated soluble form of recombinant E2 glycoprotein	Entry process	Identification of two major receptors CD81 and SR-BI Interaction with heparan sulfate proteoglycans	Different behavior from E1 E2 heterodimers Binding to various cell lines different from hepatocytes
	VLPs: Self assembly of HCV structural proteins produced in insect or mammalian cells using a recombinant virus	Entry process	E1–E2 heterodimers at virion surface Cell attachment Attractive vaccine candidate	Difference in glycosylation status Difficult to prepare Non replicative
	HCVpp: Unmodified HCV envelope glycoproteins assembled onto retroviral or lentiviral core particles	Entry process	Study of infectivity and neutralization	Only the very early steps of viral cycle No association with lipoproteins No budding at the ER
	HCVcc: Transfection of one HCV strain sequence (JFH1) from a Japanese patient with fulminant hepatitis, in Huh 7 cell line.	Entire life cycle	Entry process +++ Replication Virus production Screening of antiviral molecules	Restricted to Huh-7 cell line Restricted to JFH1 non structural proteins sequence

role in infectivity. While the preS-domains form linear epitopes, the S-domain forms multiprotein complexes using inter- and intramolecular disulfide bonds with the eight Cys residues within the antigenic loop. A crucial function of the S-domain is viral morphogenesis, but the first transmembrane sequence also plays a role in viral entry into hepatocytes[11]. Moreover, two different transmembrane topologies have been described for the L surface protein: L chains with an internal N-terminal preS1 part are required in virion morphogenesis, whereas the L molecules which expose their preS1 domain on the viral particle surface probably link to a putative virus receptor and could determine the species specificity and viral tropism[16]. In addition to the preS1 domain, a second infectivity determinant, located in the antigenic loop of the S domain, is also required for infectivity[17].

HBsAg plays a central role in stimulating and, because of its variability, also oppositely thwarting the host-related immune response. The main antigenic part of HBsAg, namely the "a" determinant which is the core part of the major hydrophilic region (amino acid residues 99-169 of HBsAg), is a target of neutralizing antibodies. Immunogenic T cell epitopes are also present in the HBs Ag : P1 (aa 16-33) and P4 (aa 213-226) are the dominant epitopes in vaccine immunization[18].

INTERACTION WITH PUTATIVE CELLULAR RECEPTOR(S)

HBV envelope glycoproteins are the key components contributing to the attachment to the hepatocyte plasma membrane, thus defining organ and species specificity of HBV. Viral tropism is essentially restricted to the liver[14]. Although there is considerable evidence that a HBV receptor exists on hepatocyte membranes, it still remains to be identified. Convergent data place the receptor-binding site in the preS1 segment of HBV envelope proteins that play a key role at the early entry step for further viral infectivity, as described above. The preS1 (21-47) region of the envelope protein was demonstrated to be the dominant binding site to hepatoblastoma cell line (HepG2). More recently, the region consisting of amino acids 9-18 of the preS1 domain was identified as a conserved crucial attachment site while amino acids 28-48 as an accessory binding site[19]. The receptor for the preS1 peptide seems to be a single major peptide of molecular weight 31 kD[20]. The asialoglycoprotein receptor was described as playing a role in the attachment process[21], and numerous other cellular partners have been suggested to also contribute, such as heparin or annexin V, earlier referred to as Endonexin Ⅱ[22-26]. Interestingly, heparan sulfate proteoglycans emerged as potential major components in the HBV entry step[27]. However HBV entry and different steps of this process are not characterized in detail, while it is substantially known for HCV.

HOST-RELATED IMMUNE RESPONSES

During viral infection, immunological reactivity usually begins with an innate response in infected cells, where viral replication induces activation of intracellular an-

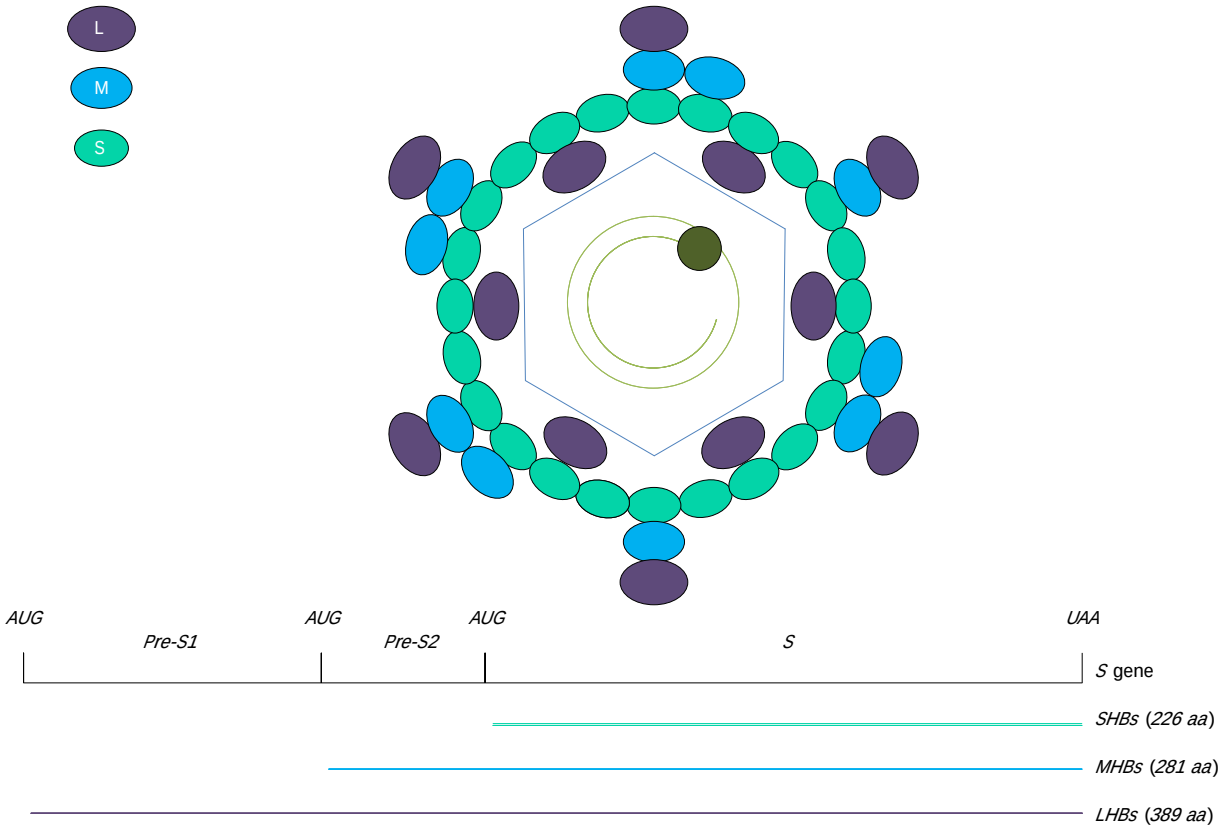

Figure 1 Schematic representation of hepatitis B virus envelope proteins and genome. Hepatitis B virus (HBV) surface envelope antigen includes three viral surface glycoproteins, named large, medium, and small proteins (LHBs, MHBs and SHBs). Their expression is directed by the *S* gene including three start codons and one stop codon in a single open reading frame.

tiviral mechanisms through transcription of interferon (IFN) inducible genes. However, in acutely HBV infected chimpanzees no specific pattern of cellular genes expression was observed during widespread expansion of HBV in the liver, revealing an absence of innate response by infected cells[28]. Interestingly, this could be thwarted by using IFN-α which has been described to inhibit HBV transcription and replication in cell culture and in humanized mice by targeting the nuclear cccDNA[29]. The adaptive immune response is responsible for viral clearance as well as HBV-related diseases pathogenesis. In patients with acute hepatitis, the T cell response is vigorous and multispecific. The CD8+ T cell response, under the control of CD4+ T cells, acts on viral clearance by triggering direct hepatocyte apoptosis and by secreting IFN-γ which inhibits HBV replication. In chronically infected patients, a weak and focused T cell response is observed (Figure 2). This seems less related to sufficient numbers of CD8+ T cells, but more to their functional alteration[30]. Human leukocyte antigen (HLA) class I and HLA class Ⅱ restricted T-cell epitopes have been recently reviewed in Desmond 2008[31]. Several HBV epitopes recognized by CD4+ T cells were described in the surface protein, including $S2_{109-134}$, $S_{200-214}$ and $S_{337-357}$, with $S_{179-194}$, considered as an immunodominant HLA-DR1-restricted epitope[32].

Regulatory T (Treg) lymphocytes, known to suppress the activation, differentiation and proliferation of immune cells, could be major actors in the inadequate immune responses observed during chronic HBV infection. The Treg response protects the host by limiting liver immunopathology while at the same time favouring the virus by inhibiting a protective T-cell response. The timing of the Treg response is vital; it needs to be not too late otherwise resulting in the excessive destruction of hepatocytes by effector T-cells, and not too early which would favour the establishment of chronic infection by blocking antiviral T-cell activity[33]. As suggested by Manigold *et al*[33], a higher frequency of Treg cells has been described in patients with chronic infection and correlated with greater HBV DNA concentration in serum.

The humoral immune response is based on anti-envelope protective antibodies. On the one hand, antibodies complex with free particles, removing them from circulation and on the other hand they prevent HBV attachment to hepatocytes, thus playing a critical role in viral clearance. Both viral and host factors can delay or inhibit antibody-mediated neutralization of HBV. As it will be further described, viral variability contributes to the failure of the humoral response. Other factors such as HIV coinfection[34] or immunosuppression from a variety of causes can also negatively modulate humoral reactivity[35]. Additionally, the development of an immune response, usually characterized by the strong appearance

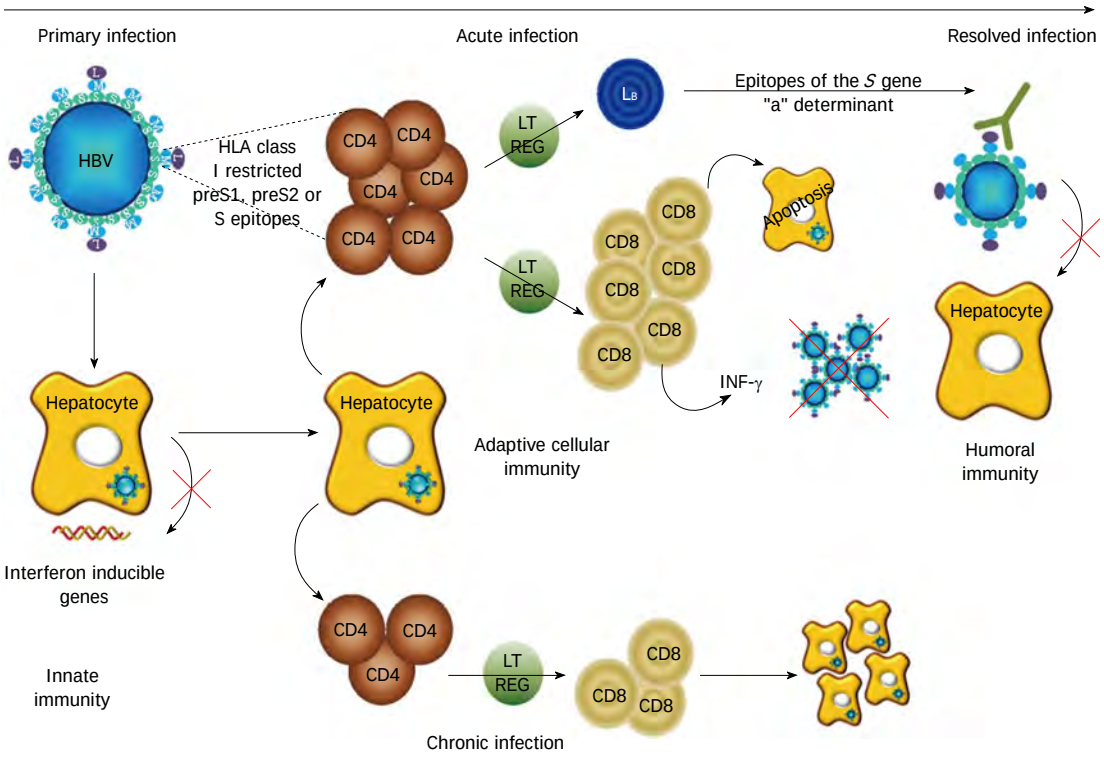

Figure 2 Role of the hepatitis B surface protein in the immune response to hepatitis B infection. Hepatitis B virus (HBV) primary infection does not induce activation of intracellular antiviral mechanisms through transcription of interferon inducible genes. After acute infection, the evolution to resolved hepatitis B is promoted by a vigorous and multispecific T cell response (CD4+ and CD8+ T cell) through hepatocyte apoptosis and interferon (IFN)-γ secretion, while evolution to chronicity is characterized by a weak and focused T cell response. Regulatory T cells (Treg) cells (LT REG) limit the function of effector T cells preventing excessive auto-destructive disease. A protective immunity is due in part to humoral and cellular anti-envelope response, preventing HBV attachment to hepatocytes, thus playing a critical role in prevention of infection after classical vaccination and in viral clearance in resolved hepatitis. HLA: Human leukocyte antigen.

of anti-HBs antibodies, may be delayed by social stress, as identified during HBV vaccination of students under exam stress[36].

GENERAL PRESENTATION OF HCV ENVELOPE GLYCOPROTEINS AND RELEVANT ANIMAL/CELL CULTURE MODELS

HCV envelope glycoprotein E1 and E2 represent crucial elements in the viral life cycle. Indeed, they are involved in virus cellular entry and are also targeted by host immune components. Thus characterization of these two proteins is essential to better understand virus-host interactions.

E1 and E2 are transmembrane glycoproteins containing an important N terminal ectodomain and a C terminal hydrophobic anchor domain. The E2 protein displays an amphipathic helix that forms a stem region, linking the ectodomain and the transmembrane region. The two glycoproteins form a non-covalent heterodimer at the viral particle surface, interacting with each other during virus entry into target cells. E1 and E2 are both stabilized by numerous disulfide bonds. Krey *et al*[37] described the connectivity of the E2 disulfide bonds and suggested that E2 could display a tertiary structure similar to that of class Ⅱ fusion proteins, and containing three domains termed DI, DII and DIII. Their model reveals the distribution of E2 amino acids among the different domains. E1 and E2 are highly glycosylated proteins and glycosylation is needed for correct glycoprotein processing, folding and/or cellular entry.

The E2 glycoprotein contains three hypervariable regions, termed hypervariable region (HVR) 1, HVR2 and HVR3 and conformational binding sites to certain cellular co-receptors (CD81 binding site as an example). E1 and E2 glycoproteins are targets of both humoral and cellular immune responses generated during HCV infection and several specific epitopes have been described in E1 and E2.

Our knowledge of the HCV viral cycle and of the structural and functional characteristics of envelope glycoproteins has been hampered by the lack of reliable *in vivo* and *in vitro* models. Chimpanzee infection has long been the only available animal model, but with many limitations including ethical considerations, high cost, and clinical differences with human HCV infection. Other small animal models, such as humanized mice, are in development to overcome these problems.

Some *in vitro* models, such as soluble glycoproteins, virus like particles, and HCV pseudoparticles, have been developed that allow investigation of the viral entry process. Despite their ability to duplicate the early steps

of HCV entry, none of these models support the entire HCV replication cycle or efficient production of infectious particles. In this regard an important breakthrough was achieved with the cell culture system HCVcc, which is capable of producing infectious particles. The most useful *in vitro* models that allow the study of HCV glycoproteins are detailed in Table 1.

INTERACTIONS OF HCV ENVELOPE GLYCOPROTEINS WITH CELLULAR RECEPTORS

The main target cells of HCV are hepatocytes. HCV enters into target cells in a complex multistep process involving the following entry host factors: tetraspanin CD81, scavenger receptor class B member I (SR-BI), Heparan Sulfate and the tight junction proteins Claudin-1 and Occludin. Other partners in HCV entry were recently characterized, such as EGFR and EphA2[38].

Highly sulfated heparan sulfate structures are cell surface factors mediating initial virus attachment prior to virus interaction with CD81 and SR-BI, which directly interact with HCV envelope glycoproteins. SR-BI may define the attachment of the virion in the form of virolipoparticles to the cell surface and that then favours particle interactions with CD81 and Claudin coreceptors with a role of EGFR and EphA2 activated kinases in the CD81-Claudin binary complex. CD81 and Claudin-1 are essential for the clathrin dependant particle internalization, and the engagement of CD81 promotes internalization. CD81 associates with HCV and mediates entry *via* Claudin-1 and occludin complexes. Claudin-1/CD81 complexes seem to localize at the basolateral surface of polarized hepatoma cells. After uncoating and internalization by clathrin-dependent endocytosis, the viral genome is released into the cytoplasm leading to its translation and replication.

INTERPLAY BETWEEN HCV ENVELOPE GLYCOPROTEINS AND THE HOST IMMUNE RESPONSE

Persistent viral infection can be explained by the fact that HCV escapes both innate and adaptative immune responses or interferes with host defense mechanisms. Despite broadly reactive neutralizing and multispecific T cell responses generated during chronic infection, in most cases viral clearance is not achieved.

HCV RNA can be detected in patient serum between one and two weeks following infection whereas the appearance of HCV specific T-lymphocytes and antibodies is delayed up to several weeks after infection. In the early phase of infection neutralizing antibodies are rapidly induced by patients who subsequently clear the virus or control viral infection whereas they are absent or of low quantity in patients who progress to chronic HCV infection[39]. Both cellular and humoral responses fail to control HCV infection during the very early phase of infection. If viral clearance is characterized by a broad vigorous and persistent T cell response, cellular immunity is weak, narrow and transient in patients chronically infected (Figure 3). Some mutations occurring in epitopes targeted by CD4+ or CD8+ T lymphocytes can show a strong inhibition of immune reactivity, such as HCV E1 226-240 and HCV E2 436-450[3]. Patients who do not clear the virus present high quantity and even cross-neutralizing antibodies during the chronic phase, but these antibodies are unable to control HCV infection.

The failure of the humoral response is mainly due to the rapid onset of mutations in HVR1 of E2 and in other epitopes of the E1 and E2 proteins. However, HVR1, the most variable region of the HCV genome, is one of the targets of the neutralizing immune response. HVR1 may function as an "immunological decoy", stimulating an ineffective immune response for viral clearance but inducing selection of viral variants[40].

The E2-CD81 interaction has been shown to modulate B and T cell function. During HCV infection, the E2-CD81 interaction induces hypermutation of the heavy chain immunoglobulin in B cells. Hypermutation may lower the affinity and specificity of HCV-specific antibodies, enabling HCV to escape immune surveillance. Additionally, engagement of CD81 on natural killer cells by the E2 protein has been shown to inhibit the antiviral function of NK cells early in the infection process.

GENES AND PROTEINS VARIABILITY, ESPECIALLY IN VIRAL ENVELOPE GLYCOPROTEINS

Despite the compact arrangement of its DNA genome and the overlapping open reading frames that limit genomic plasticity, HBV is evidently diverse on a global scale as indicated by the eight referenced genotypes (A-H). HCV is also characterized by high genetic variability given that six (and probably a seventh) major genotypes have been described, each including several subtypes. Intragenomic variability of HBV and HCV is further reflected in the quasispecies distribution defined by the genetic heterogeneity of the viral pool found in any infected subject at a given time point[41,42]. For both viruses, this genetic variability is a consequence firstly of the high spontaneous error rate associated with the lack of a proofreading mechanism of viral polymerases, and secondly of the structural and/or functional constraints exerted on the virus by host immunity, immunoprophylaxis or antiviral therapy pressure.

Due to the structural constraints of its genomic organization, the emergence of HBV mutants occurs more slowly than for HCV. Since the preS1 and preS2 domains overlap with the region of the polymerase gene encoding for the spacer domain, deletions in preS can occur without affecting the enzymatic properties of HBV

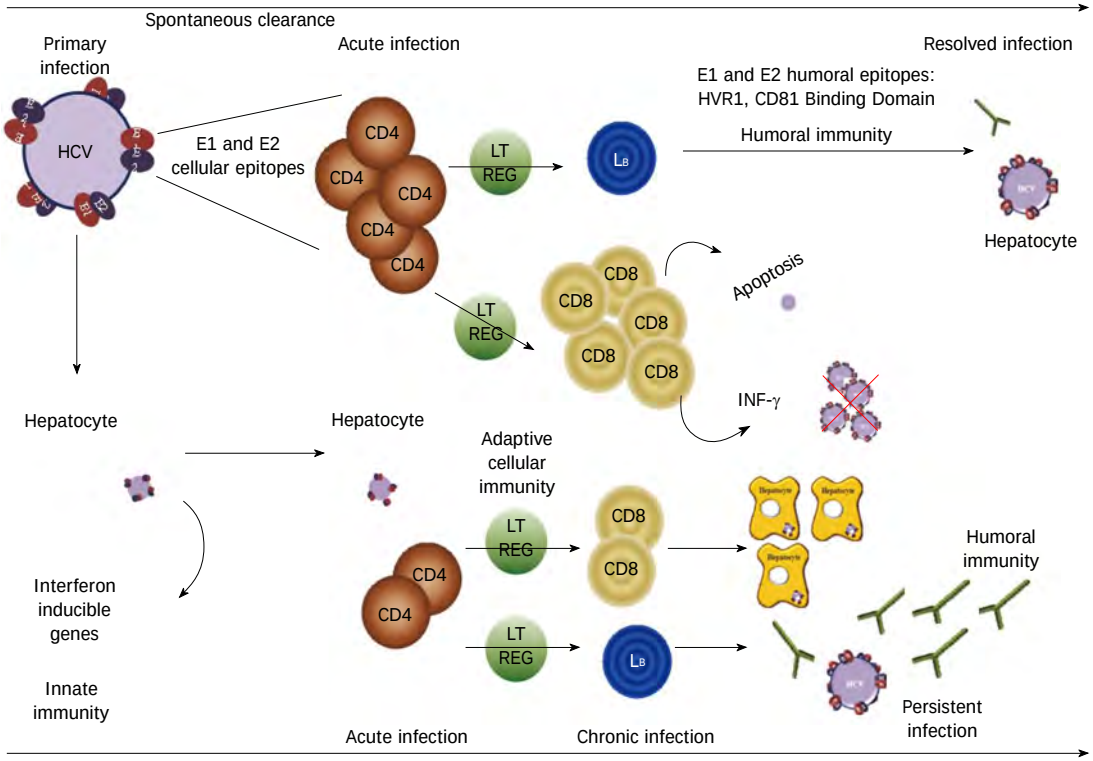

Figure 3 Role of hepatitis C glycoproteins in the immune response to hepatitis C infection. Following hepatitis C virus (HCV) infection, innate host response is initiated by hepatocytes producing an antiviral state by stimulating interferon inducible genes expression. In case of spontaneous clearance or resolved infection, a strong cellular response, due to CD4+ and CD8+ T lymphocytes (denoted as CD4 and CD8 in the figure), is observed in the early phase of infection. Moreover Regulatory T cells (Treg) cells (LT REG) limit the function of effector T cells. Then neutralizing antibodies are rapidly expressed. In most cases, the host adaptative immunity is unable to control HCV infection evolving to a chronic phase. The cellular response (CD4+ and CD8+ T lymphocytes and B lymphocytes, mentioned as L_B in the figure) is weak and transient. The appearance of neutralizing antibodies is delayed and the humoral response not efficient. IFN: Interferon.

polymerase. However, although preS1 deleted mutants are able to replicate they usually need a helper virus to infect new hepatocytes[43]. The surface S gene seems to vary less than the preS1 and preS2 regions[44]. Functional mutations that have been described in the HBV envelope genome consist of preS1 and preS2 deletions, preS2 start codon mutations, and C-terminally truncated or "a" determinant mutated S proteins. These viral variants exhibit modified replication capacities and antigenic characteristics; on the other hand they may be resistant to antiviral therapies and/or contribute to escape from host-related immune surveillance. They can also alter the sensitivity of diagnostic immunoassays. In HepG2 cells, replication of preS/S variants leads to decreased HBsAg secretion, retention of envelope proteins in the endoplasmic reticulum, less efficient virion secretion and higher amounts of cccDNA in the nucleus. In patients with HBV-related chronic liver disease, the emergence of preS/S variants appears to provoke the loss of correlation between HBV DNA replication and HBsAg synthesis/secretion[45].

Briefly for HCV, the HCV genome contains both highly conserved and highly variable regions. The most variable regions are located in NS5A and in parts of the E2 glycoprotein (HVR)[46,47]. Some mutations have been described in E2 showing an impact on HCV infectivity and/or its accessibility to antibodies or cellular response mediated by CD4+ and CD8+ T cells[3,48-51].

PREVENTIVE OPTIONS AND THE RISK OF ESCAPE MUTANTS

Vaccination using a recombinant HBV surface antigen is the most important prophylactic measure available for the prevention of new HBV infections. Immunoprophylaxis with vaccine or immunoglobulins is also recommended after exposure to blood from HBV-infected patients, in new born children from HBV-infected mothers, and to prevent recurrent HBV infection in patients receiving liver transplants for end-stage hepatitis B liver disease.

HBV surface gene variants can be selected under immune pressure after preventive immunization. This is illustrated by report of several surveys in Taiwan describing an increase in the prevalence of *S* gene "a" determinant mutants during a vaccination campaign[52]. In HBV DNA positive children from four sequential surveys in Taiwan, the prevalence of hepatitis B surface gene "a" determinant mutants increased from 7.8% before the vaccination program, to 19.6%, 28.1% and 23.1% at five, 10 and 15 years after the immunization period. However, lower infectivity of the G145R mutant virus, the use of a recombinant vaccine, and mutant loss with older age seem to decrease the "a" mutant prevalence in an immunized population over time[53]. In Europe and North America, mutations in the HBV *S* gene are mostly observed in infants born from HBV-infected mothers,

in a small proportion of occult HBV infections, and in liver transplant recipients[54]. Among variants which were described, the Arg-145 and Arg-129 mutants show the lowest binding ability to monoclonal antibodies. In addition, variants epitopes in HBs antigen induced decreased or a lack of T-cell reactivity[18]. As an illustration, HBV replication was detected in vaccinated chimpanzees challenged with an HBV strain containing polymerase/envelope overlapping mutations[55].

The considerable global diversity of HCV has hampered the development of any successful vaccine. Consequently, neither vaccine, nor specific immunoglobulins are currently available for clinical practice. Current HCV vaccine research therefore follows two main pathways: (1) prophylactic; and (2) therapeutic to increase virological response to antiviral treatment and to reduce the duration of therapy. Although numerous approaches have been developed only a few of these have progressed to human trials, especially for potential therapeutic vaccines. HCV envelope proteins that induce antibodies against conserved domain involved in cell binding are considered as a promising target for vaccine research[56]. However, several mechanisms make antibody-mediated neutralization difficult: interference by interfering antibodies, glycans or lipids, the quasispecies distribution of HCV, and difficult to access cell-to-cell transfer[57].

TREATMENT AND RISK OF ESCAPE MUTANTS

The treatment of chronic hepatitis B aims to reduce liver cell inflammation, prevent the progression to cirrhosis and hepatocellular carcinoma through the suppression of viral replication, and ultimately to clear the infection. HBV treatments use the immunomodulatory agents IFN-α or its pegylated form as well as direct-acting antiviral molecules. IFN-α binding to type 1 IFN receptors activates an anti-viral state in cells by inducing stimulation of *IFN* genes. IFN also stimulates the cellular immune response and production of IFN-γ by CD4+ and CD8+ T cells[58]. On the other hand, nucleos(t)ide analogues block HBV polymerase functions[59]. A sustained virological response to antiviral therapy is defined by plasma HBV DNA < 2000 IU/mL six months after discontinuation of therapy, while a complete response is defined by the disappearance of both HBV DNA and HBsAg with or without appearance of anti-HBs antibodies[58]. During treatment various escape mutants can be detected. Well-characterized mutations in the reverse transcriptase (rt) gene have been described (*e.g.*, rtM204V for lamivudine and rtN236T for adefovir). HBV resistance can develop after a single mutation with some agents or only after multiple mutations for others. Entecavir exhibits low rates of resistance, with fewer than 1% of patients on monotherapy developing resistant mutants after 5 years of treatment[59], if patients strictly respect treatment recommendations. Similarly tenofovir has a very high genetic barrier. Due to the structure of the HBV genome, mutations in the rt domains can affect the amino acid sequence of other HBV proteins, as demonstrated for the rtM204V + rtV173L + rtL180M mutations that lead to envelope changes behaving as mutants escaping vaccination *in vitro*[59]. In addition, studies analyzing HBV quasispecies demonstrated that resistance mutations to nucleos(t)ide analogues can cause amino acid changes within epitopes of the HBV preS/S or core antigen leading to changes in HBV immunogenicity[60].

Treatment of HCV chronic infection consists of a combination of pegylated IFN-α and ribavirin, and this combination remains the basis of gold standard treatments including the use of anti-protease molecules. The rate of sustained virological response (undetectable HCV viral load six months after the end of the therapy, detection threshold at 12-15 IU/mL) depends on the genotype of HCV with lower rates for genotype 1 and is correlated to pre-treatment HCV load and several host-related factors. Both IFN and ribavirin have broad spectrum non specific antiviral activity without direct action on viral genomes[46]. IFN produce an antiviral state by the up-regulation of IFN stimulated genes, leading to the expression of several antiviral proteins including 2', 5' oligoadenylate synthase, and the Mx protein. Four putative mechanisms of action have been proposed to explain the effect of ribavirin on HCV infection: modulation of the host adaptive antiviral response, HCV RNA mutagenesis, action on the intracellular GTP pool necessary for RNA synthesis and inhibition of HCV polymerase. Thus resistance to treatment is a complex mechanism involving host- and virus-related features.

Several HCV proteins (E2, core, NS5A, NS5B) are suspected to be linked with resistance mechanisms to antiviral therapy[46,61,62]. In relation to HCV envelope glycoproteins, treatment outcome can be influenced by amino acid substitutions within CD81 binding sites and HVR2 of E2[63] as well as theoretically through mutations in the PKR/eIF-2α phosphorylation homology domain of E2[61]. A lower HVR1 heterogeneity among viral variants in an individual before antiviral therapy seems to be associated with higher rates of virological response to IFN-based treatment[46,64]. HCV genetic variability in regions such as E2 HVR1 has been associated with antiviral treatment failure[46,65]. In a clinical context, Aurora *et al*[66] described frequent covarying amino acids positions, most often located in E1 and E2, that linked to response to treatment.

CONCLUSION

For both HBV and HCV, viral envelope glycoproteins play a key role in viral entry into hepatocytes and are exposed to host-related immune responses. Even though data that fully elucidates HBV entry into permissive cells are still lacking, specific segments of HBV envelope proteins (preS1, "a" determinant) are instrumental in the process. For HCV, numerous experimental results have recently demonstrated that viral entry is a com-

plex multistep process involving multiple cell cofactors (glycosaminoglycans, low density lipoprotein receptor, SR-B1, CD81, claudin-1, occludin, EGFR, EphA2) in the interaction with HCV E1/E2 envelope glycoproteins. *In vitro* both viruses can be controlled by antibody-mediated neutralization targeting viral envelope. Neutralizing antibodies are also essential in preventing HBV infection *in vivo* as is well characterized through successful vaccination using HBs antigen.

Several factors, such as preventive vaccination and/or therapeutic pressure, can influence HBV and HCV variability. Moreover, for HBV, the patterns of antiviral drug resistance in chronic hepatitis are complex and the original pol/S gene overlap has to be taken into account in the analysis of public health significance of emerging genomic mutations in infected populations. Treatment-induced HBV mutations in pol could indeed generate S mutants with subsequent modified antigenicity or pathogenesis such as increased cancer induction[10].

Variability of HBV and HCV envelope proteins combining high exposure to selective pressures and crucial functional roles require investigation for the adaptation of diagnostic, vaccination and treatment tools. In this context, improved therapy for chronic HCV infection has emerged from a better understanding of the viral replication cycle, with HCV entry providing a large number of therapeutic targets[67,68]. Besides IFN-α and nucleos(t)idic analogues, complementary therapies for chronic HBV infection are desperately needed and the HBV entry process, when better characterized, can offer potential therapeutic opportunities.

Abstract

Burning mouth syndrome is a debilitating medical condition affecting nearly 1.3 million of Americans. Its common features include a burning painful sensation in the mouth, often associated with dysgeusia and xerostomia, despite normal salivation. Classically, symptoms are better in the morning, worsen during the day and typically subside at night. Its etiology is largely multifactorial, and associated medical conditions may include gastrointestinal, urogenital, psychiatric, neurologic and metabolic disorders, as well as drug reactions. BMS has clear predisposition to peri-/post menopausal females. Its pathophysiology has not been fully elucidated and involves peripheral and central neuropathic pathways. Clinical diagnosis relies on careful history taking, physical examination and laboratory analysis. Treatment is often tedious and is aimed at correction of underlying medical conditions, supportive therapy, and behavioral feedback. Drug therapy with alpha lipoic acid, clonazepam, capsaicin, and antidepressants may provide symptom relief. Psychotherapy may be helpful. Short term follow up data is promising, however, long term prognosis with treatment is lacking. BMS remains an important medical condition which often places a recognizable burden on the patient and health care system and requires appropriate recognition and treatment.

INTRODUCTION

Burning mouth syndrome (BMS) is a chronic pain disorder characterized by burning, stinging, and/or itching of the oral cavity in the absence of any organic disease. It lasts at least 4 to 6 mo and most often involves the tongue with or without extension to the lips and oral mucosa[1,2]. BMS can be accompanied by dysgeusia (distortion in sense of taste) and subjective xerostomia (dry mouth). Its onset is spontaneous and the syndrome has a clear predisposition to peri-/postmenopausal women. Its secondary form has been associated with a variety of conditions including thyroid disease, psychiatric illnesses, oral infections, drug use, dental treatment, vitamin/mineral deficiencies, and others[3,4].

First described in mid nineteenth century, this condition was further characterized in the early twentieth century by Butlin and Oppenheim as glossodynia[5]. Over the ensuing years, BMS has been referred to as glossopyrosis, oral dysesthesia, sore tongue, stomatodynia, and stomatopyrosis[6]. It was first categorized as a distinct disease in 2004 by the International Headache Society, which defined primary BMS as "an intraoral burning sensation for which no medical or dental cause can be found." Current diagnostic criteria consist of daily persistent pain in the mouth with normal oral mucosa after exclusion of local and systemic diseases[7]. Its etiology is thought to be multifactorial, involving various local, sys-

temic, and/or psychogenic causes. Female gender, perimenopause, depression and anxiety, Parkinson's disease, and chronic medical conditions including gastrointestinal and urogenital diseases are risk factors for developing BMS[1,8-11].

BMS is an important clinical condition with aggravating symptoms, directly and indirectly impacting the quality of life, which often places a recognizable burden on the patient and health care system. Clinical consultations with a practicing gastroenterologist are common practice in today's medicine for the patients with BMS. This review focuses on various aspects of BMS, including its epidemiology, pathophysiology, etiology, clinical presentation, differential diagnosis, classification, clinical diagnosis, current treatment, and general prognosis.

EPIDEMIOLOGY

The estimated prevalence of BMS in the general population varies widely in the literature. Tammiala-Salonen *et al*[12] reported a rate of 15% of burning mouth symptoms in Finnish adult population, though half of the patients had visible oral mucosal lesions. In a cross-sectional analysis of over 1000 randomly selected Swedish patients from Public Dental Health Service registers, 3.7% of subjects were diagnosed with BMS after reporting burning mouth symptoms and undergoing a subsequent physical examination[8]. In contrast, Lipton *et al*[13] reported a prevalence of 0.7% based solely on self-reported symptoms from over 45 000 American households. Haberland *et al*[14] noted that 10% of new patients observed in his practice were diagnosed with BMS. Most recently, a large retrospective study of over 3000 Brazilian patients referred to an oral pathology service reported a prevalence of about 1%[1]. These highly variable rates are attributed to the wide age disparities of the examined population (typically, prevalence of BMS dramatically increases with age) as well as previous lack of universally accepted diagnostic criteria for BMS. Although further studies are needed with satisfactory criteria to determine the true prevalence of BMS, this data illustrates that the disease is an important medical condition that may be often encountered in the clinical practice.

BMS has a clear predisposition to gender and age. Women are 2.5 to 7 times more commonly affected than men[1,8,10]. Furthermore, up to 90% of female patients with BMS are perimenopausal women with typical onset from 3 prior- to 12 years post- the beginning of menopause[9]. BMS may affect any age group, with patients age ranging from 27 to 87 years of age, and a reported mean age of 61 years. Recent analysis by the same group showed an increased likelihood of gastrointestinal and urogenital disease in patients with BMS, with estimated odds ratio of 3.5 and 2.9, respectively, compared to control subjects. Patients with BMS had a statistically higher intake of medications for gastric disease compared to control group as well[1].

ANATOMY

The oral cavity is primary responsible for the ingestion and mastication of food. Its anatomical boundaries include the lips anteriorly, the cheeks laterally, the oropharynx posteriorly, the palate superiorly, and the floor of the mouth inferiorly[15]. The oral cavity contains several structures, including upper and lower dentition, the tongue, salivary glands, and mucosal glands[16]. It is lined by non-keratinized stratified squamous epithelium, which is moistened by secretions from various salivary glands[17].

The neuroanatomy of the oral cavity, particularly somatosensory innervation, has been implicated in the pathophysiology of BMS. The maxillary (V2) and mandibular (V3) branches of the trigeminal nerve supply most of the somatosensory innervation in the oral cavity, with some contribution from the glossopharyngeal nerve (cranial nerve Ⅸ). In regards to the tongue, the most commonly affected area in BMS, the lingual branch of V3 innervates the anterior two-thirds of the tongue while the glossopharyngeal nerve innervates the posterior third of the tongue. Together, they innervate the receptors on the papillae of the tongue, which are sensitive to mechanical, thermal, and tactile stimuli[17].

Alterations in taste and quantity of salivation are commonly reported in BMS. The chorda tympani branch of the facial nerve (Ⅶ) supplies chemoreceptors for taste in the anterior two-thirds of the tongue. The glossopharyngeal nerve (Ⅸ) provides taste sensation for the posterior third of the tongue. There are also taste receptors on the soft palate supplied by the greater superficial petrosal nerve branch of Ⅶ and on the larynx from the superior laryngeal nerve of the vagus nerve (Ⅹ). The salivary reflex begins with afferent inputs from taste and mechanoreceptors in the mouth that reach the brainstem salivatory centers. Parasympathetic and sympathetic fibers then supply the efferent fibers that act on the salivary glands[15].

PATHOPHYSIOLOGY

The pathophysiology of BMS has not been fully elucidated. Various studies have shown significant differences in thermal and nociception thresholds of patient with BMS compared to control subjects[18,19]. Thus, a neuropathic mechanism for BMS is currently favored. However, controversy remains over whether a peripheral or central dysfunction is responsible for BMS.

Evidence in the literature links BMS to a peripheral neuropathy. Superficial biopsies of the anterolateral tongue from BMS patients showed a significantly lower density of epithelial and subpapillary nerve fibers than controls. Morphologic changes were consistent with axonal degeneration. This supports a trigeminal small-fiber sensory neuropathy or axonopathy[20]. Moreover, Borelli *et al*[21] found increased levels of nerve growth factor, a neuropeptide vital to nociceptive function in adults, in the saliva of BMS subjects. Other histopathologic studies of patients with BMS have shown increased density

of TRPV1 ion channels and $P2X_3$ receptors on scattered nerve fibers, a finding previously linked to hypersensitivity and neuropathic pain symptoms in various models of human pain conditions[22]. Additionally, dysfunction of the chorda tympani branch of the facial nerve may be involved in the pathogenesis of BMS. Patients with BMS will report improved symptoms with eating, suggesting that stimulation of the gustatory system decreases pain sensation. Finally, increased excitability or inhibition of the trigeminal system has been implicated as patients with BMS have greater alterations in blink reflexes compared to normal subjects[23-28].

However, recent evidence indicates that dysfunction in the central nervous system can also cause BMS. Albuquerque *et al*[29] showed that BMS patients process thermal and pain stimulation in the brain differently than pain-free individuals as demonstrated by functional magnetic resonance imaging of the thalamus. Additionally, the dysregulation of the nigrostriatal dopaminergic system has been implicated in BMS[30]. Patients with Parkinson's disease are reportedly five times more likely to have BMS than the general population[31]. Finally, hospital anxiety and depression scores were significantly higher in the patients with central BMS[22].

As evident from these studies, the pathophysiology of BMS is highly complex, likely involving neural pathways at different levels of neuraxis. A recent double blind, randomized cross-over study of postmenopausal women showed heterogeneity of the response of BMS symptoms to lingual nerve block with lidocaine. If fact, it may lead to an effective increase, decrease, or an unchanged burning pain in patients, an effect attributed to variation in central, peripheral, or combined neurological pathways in pathogenesis of BMS[32]. The symptoms of BMS can result from subclinical insults at various points in the nervous system, presenting with instant or gradual bilateral distribution. Recent classification suggests a possible overlap of three distinct subclasses in BMS: a peripheral oral small fiber neuropathy (50%-60% of cases), subclinical major trigeminal neuropathy (20%-25%), and central deficiency in dopaminergic top-down inhibition (20%-40%)[23].

ETIOLOGY

The exact etiology of BMS remains imprecise and is likely multifactorial, including neuropsychiatric, endocrine, immunologic, nutritional, infectious, and iatrogenic causes. The disorder has been associated with several psychiatric diseases[9,33-35]. Depression or anxiety occurs in more than 50% of BMS patients, with depression predominating[34]. Personality disorders are also linked to BMS, affecting 86% of sufferers compared to 24% of normal individuals, with significant predilection to Cluster A disorders[36]. Most recently, a cross-sectional controlled study showed that BMS patients have a significantly higher frequency of past or present major depressive disorder, general anxiety disorder, hypochondria, and cancerophobia[37]. Although psychiatric disease was initially considered as a primary cause of BMS, it is now considered a concurrent or secondary factor as there is no definite correlation between the onset of BMS and stressful events and many other causes of BMS have been identified[9,33,35,38,39].

As described previously, BMS most commonly affects perimenopausal women, a finding that is attributed to dryness of mucosal membranes from age-related reduction in estrogen and progesterone levels and increased frequency of psychological disorders in middle-aged and elderly women[40]. Woda *et al*[41] has suggested that the fall in neuroprotective gonadal and adrenal steroids during menopause leads to a concomitant decrease in neuroactive steroids, leading to degeneration of oral mucosal small nerve fibers and brain areas involved in oral somatic sensations. These changes can become irreversible, resulting in burning pain and associated symptoms. Gao *et al*[42] showed that peri-/post-menopausal patients suffering from BMS may have lower levels of estradiol and increased levels of follicle stimulating hormone compared to healthy controls. Other endocrine conditions implicated in BMS may include diabetes mellitus and hypothyroidism[8].

Evidence also exists for an immunologic etiology. Allergic reactions have been demonstrated in BMS patients to dietary antigens. These include sorbic acid, cinnamon, nicotinic acid, propylene glycol, and benzoic acid[43,44]. Other allergens identified by patch testing are dental metals such as zinc, cobalt, mercury, gold, and palladium[45]. Sodium lauryl sulfate, a detergent in toothpaste known to cause dry mouth, may also be involved in the development of BMS[46]. Finally, autoimmune connective tissue disorders such as Sjogren's syndrome and systemic lupus erythematosus, are also associated with BMS[47].

BMS has also been linked to nutritional deficiencies including vitamins B1, B2, B6 and B12 as well as folic acid[2]. Most recently, zinc deficiency was shown to be a possible cause of BMS, with patients reporting improved symptoms after zinc replacement therapy[48].

A potential relationship between smoking and development of BMS has been described, with an estimated odd ratio of 12.6 in a recent study[43].

Certain oral infections have been implicated in BMS, particularly candidiasis. Patients with BMS have a higher intraoral prevalence of *Candida* species and coliforms like *Enterobacter* and *Klebsiella*[49,50]. Although this finding may be related to xerostomia and prosthetic dental wearing, a possible infectious origin of BMS is suggested by reports of remission after oral antifungal therapy[18].

Drug-associated BMS has also been reported in the literature. ACE inhibitors and angiotensin receptor blockers may trigger development of BMS, possibly due to increased levels of kallikrein in the saliva of BMS patients leading to increased inflammation in the oral cavity[9,51-53]. Nevirapine and efavirenz have been reported to cause BMS *via* an unknown mechanism[54,55]. Levodopa may play a role in the development of BMS in patients with Parkinson disease[31]. Finally, a case report of topiramate causing burning mouth-like symptoms has been de-

scribed, with symptom resolution upon discontinuation of the medication[56].

CLINICAL PRESENTATION

A typical patient with BMS is a peri- or post-menopausal woman with various medical comorbidities who complains of the classic triad of unremitting oral mucosal burning pain associated with dysgeusia and xerostomia in nearly two thirds of the cases with no visible disease in the oral mucosa for 4-6 mo duration. Clinical presentations may vary as some patients can be oligosymptomatic (pain and dysgeusia or xerostomia) or monosymptomatic (pain only)[10]. In general, 63% of patients report accompanying dry mouth, 60% bitter/metallic taste, and 35% altered taste perception[9]. The pain is described as burning, scalding, tingling, or numbness. It is of moderate to severe intensity and can decrease during eating. It is commonly bilateral and most often involves the tongue followed by the palate and lower lip. In contrast, the buccal mucosa and floor of the mouth are rarely affected[9]. The onset is spontaneous, though some BMS patients report antecedent dental procedures, initiation of medications, or other illnesses[10,57]. Xerostomia may be subjective however some patients have demonstrated alterations in saliva quantity and quality[10]. Vertical visual analogue scale (VAS, 0-10 cm)[58] is commonly used to describe pain intensity in BMS.

Review of systems may be remarkable for headache, chronic fatigue, gastrointestinal and urogenital symptoms, insomnia, mood changes, irritability, anxiety, and depression[4,57]. Other observed clinical conditions may include gastroesophageal reflux disease, hypertension, hematological disorders, nutritional deficiencies, diabetes mellitus, thyroid disorders, Parkinson's disease, Sjogren's syndrome and other autoimmune diseases[51,59]. Finally, parafunctional habits such as lip and cheek biting, bruxism, tooth grinding and clenching, tongue thrusting, and lip licking are observed with BMS[10].

Physical examination and laboratory analysis are classically unremarkable in primary BMS. However, they can be abnormal in secondary BMS. Oral findings potentially include areas of erythema, geographic tongue, candidiasis, atrophic glossitis, lichen planus, and xerostomia. Laboratory evaluation may reveal positive fungal oral cultures, elevated fasting blood sugar, decreased levels of vitamin B1, B2, B6, B12, folate, iron, and zinc, abnormal thyroid function studies, and positive serum autoantibodies[4,49].

MIMICKERS OF BMS

BMS presents with a main complaint of an intraoral sensation of burning, tingling, or stinging and sometimes accompanied by taste disturbances or dry mouth. The mimickers of BMS may include stomatitis, atypical facial pain, atypical odontalgia, idiopathic facial arthromyalgia, pemphigoid, pemphigus, neoplastic lesions in the oral cavity, acoustic neuroma, denture design or tooth restoration failures, herpes simplex or herpes zoster, trauma to lingual or mandibular nerves after dental surgery[10,57]. Detailed history and physical exam is crucial to differentiate above medical conditions.

CLASSIFICATION

Two classification schemes have been proposed based on either etiology or clinical symptoms. When classifying by etiology, primary BMS is the idiopathic form for which organic causes cannot be identified while secondary BMS results from local or systemic pathological conditions[10]. The other scheme divides BMS cases into three types based on diurnal fluctuations of symptoms. Patients with type 1 BMS (35%) are symptom-free upon awakening with worsening symptoms throughout the day and variable symptoms at night. Type 2 BMS (55%) is defined by continuous symptoms in the day but none at night. Patients with type 3 BMS (10%) have intermittent symptoms interspersed with symptom-free days[34,60]. Type 1 BMS is linked to nutritional deficiencies and diabetes, type 2 to chronic anxiety, and type 3 to dietary or prosthetic allergies[2,18,44,61].

CLINICAL DIAGNOSIS

The diagnosis of BMS remains challenging as diagnostic criteria are not sufficiently defined or universally accepted, several confounding diagnoses exist, and the clinical picture is often variable. Scala *et al*[10] proposed the following fundamental criteria: (1) daily and deep bilateral burning sensation of the oral mucosa; (2) burning sensation for at least 4 to 6 mo; (3) constant intensity, or increasing intensity during the day; (4) no worsening but possible improvement on eating or drinking; and (5) no interference with sleep. Additional supportive criteria are, (1) dysgeusia and/or xerostomia; (2) sensory or chemosensory alterations; and (3) mood changes or psychopathological alterations.

Since primary BMS is a diagnosis of exclusion, thorough investigation for local and systemic factors associated with secondary BMS is essential. Careful review of recent mood disturbances, dietary habits, history of dental procedures, use of dental prosthetics, nutritional deficiencies, and changes in medication is necessary in the evaluation of BMS. Physical examination primarily consists of detailed study of the oral cavity, including dental inspection. Laboratory analyses must include hematological assessment of nutritional deficiencies, blood glucose levels, autoimmune markers, estrogen and progesterone concentrations, patch testing for specific allergies[10]. Measurement of salivary flow rates should be employed[62].

Additional studies may warrant oral cultures and scrapings to evaluate for a bacterial or fungal origin of symptoms. Tongue biopsy is not required if the tongue appears normal on clinical exam and is only indicated when a particular lesion is visualized. In general, the diagnosis of BMS remains a major challenge, requiring extensive clinical and laboratory evaluation with a particular atten-

tion to details of patient's history and physical exam.

TREATMENT

The first step in management is contingent on the specific type of BMS, primary versus secondary. The goal of therapy for secondary BMS should initially be directed at treating the causative local or systemic disease and withdrawing offending medications (such as ACE inhibitors). This etiology-directed therapy typically yields a good response. The cure for primary BMS, however, remains elusive despite attempts with different classes of medication. The variable response rate to medical therapy is likely due to the multifactorial pathophysiology of idiopathic BMS, including irreversible processes. Treatment is aimed at management this disease as a type of chronic neuropathy. Investigated strategies include benzodiazepines, antidepressants, topical capsaicin, alpha-lipoic acid, hormone replacement therapy, anticonvulsants, biofeedback technique to modify parafunctional habits, and psychosocial therapies.

Early studies by Italian researchers supported the use of alpha lipoic acid (ALA, a potent antioxidant) in 600 mg daily dose over two months in patients with BMS[63]. This data was not replicated by subsequent analysis in Brazilian patients[64], possibly due to the multivitamin compound of the ALA supplements or longer duration of the original therapy. Interestingly, same group suggested added benefit of ALA in patients with thyroid disease[65].

Recent randomized double blind placebo controlled trial showed that use of gabapentin alone (300 mg daily) or in combination with ALA (600 mg daily) was beneficial in reducing symptoms in 50% and 70% of patients with BMS, respectively, compared to placebo (15%)[66]. In line with the observed predisposition of BMS to peri-/post- menopausal women, a hormone replacement therapy may be intuitive, but short of initial promise with local oral administration, it is largely not effective when given systemically[67] possibly due to the irreversible nature of the neuropathic changes.

Clonazepam lozenges (oral dissolution of 1-mg tablets for 3 min with subsequent expectoration three times a day) are beneficial in patients with predominantly peripheral BMS. A double blind, randomized controlled study of topical clonazepam reported a reduction in pain intensity in 66% of patients after 2 wk and 29% after 6 mo[68]. Similar clinical benefit was replicated in follow up studies[33].

Short term use of oral Chlordiazepoxide (5-10 mg three times a day) to treat BMS has been reported, however, its long term effects were not significant[69].

Efficacy of capsaicin, a desensitizer of receptors for neurogenic inflammation, has been evaluated in several studies. Systemic capsaicin 0.25% capsules three times daily showed dramatic improvement (93%) in patients with severe BMS (VAS scale 8-10) at 1 mo[70]. Side effects including gastric pains in 32% of the patients were cumulative, and may preclude long term use of this medication. Local capsaicin rinse may be beneficial in treating BMS, with reported improvement of symptoms in over 75% of the patients after 8 wk of therapy without significant side effects[71].

Use of proton pump inhibitors (PPI), although clearly increased in the patients with BMS[1], may not necessarily be of benefit. Recent study measuring oropharyngeal pH found no significant correlation between laryngopharyngeal reflux and intraoral burning sensation in the examined population[72]. Anecdotal evidence exists in case reports of symptom relief with twice daily omeprazole in patients with endoscopy proven gastroesophageal reflux disease[73]. Whether there is a casual relationship between use of PPI and clinical primary BMS, an observation phenomenon, a true response, or simply a failed therapy remains to be established. Treatment of secondary BMS in the setting of gastroesophageal reflux disease is, however, warranted. Larger studies are needed to address potential benefit (or lack of it) of PPI in treatment of BMS.

Medical management of BMS may also include antidepressants and antipsychotics. In a prospective, open-label, noncomparative study of selective serotonin reuptake inhibitor (SSRI) paroxetine, 80% of patients experienced overall pain reduction including 36% of patients who reported complete remission after 12 wk of incremental treatment. Both treatment effects and adverse events were found to be dose dependent[74]. However, prophylactic use of domperidone for nausea in selected study patients may have had a potential confounding effect on the results. Another single-blinded non-placebo controlled study comparing paroxetine (20 mg daily), sertraline (50 mg daily), and an atypical antipsychotic amisulpride (50 mg daily) demonstrated a nearly 70% improvement in VAS score after 8 wk of therapy in each of the three groups[75]. A group from Spain reported complete remission in all female patients after 8 wk of amisulpride use, an effect lasting up to 24 wk with continuous administration of the medication[76].

Additionally, modifications of parafunctional habits may offer some symptom relief. Tongue protectors (worn 15 min three times a day) were shown to significantly improve pain scales in BMS patients after two months of treatment, however sample sizes were small and placebo effect could have been introduced[77].

Finally, psychiatric interventions show great promise in treating patients with BMS. Weekly one-hour sessions of cognitive behavioral therapy lasting for 12-15 wk significantly reduced BMS symptoms in all study patients compared to placebo control group, with an estimated 27% of patients remaining symptom-free at 6 mo follow up (none in placebo group)[78]. Weekly group psychotherapy administered for three consecutive months achieved symptom improvement in 70% of the patients[52]. Femiano *et al*[79] noted a statistically significant symptom improvement with cognitive psychotherapy (40%), alpha lipoic acid (81%), combination therapy (90%) compared to pill placebo control group (13%) of patients with BMS.

Anecdotal use of diphenhydramine/pectin swish and spit elixir[18] as well as oral pramipexole in BMS patients with Parkinson's disease have been reported[57].

Perceived variation in the results of the published data may stem from lack of effective differentiation between predominantly peripheral and predominantly central pathways in the pathogenesis of BMS. Therefore, improvement in future clinical diagnosis and discrimination between such groups of patients may improve clinical response rate to targeted local and systemic therapies.

For now, BMS remains a challenging medical condition to treat, and further research is required to determine the true efficacy of current management strategies for patients with this disorder. Future blinded randomized control trials with large sample size are necessary to provide new insight for use of various treatment modalities in BMS.

PROGNOSIS

Although the short term follow up studies may show potential symptomatic improvement with treatment in patients with BMS, the long-term outcomes for BMS remain unclear. Early observational report by Gilpin[5] in 1936 may provide a closer look at the natural history of the disease that follows a "rule of 3's": up to one third of cases would enter spontaneous remission, another third would show moderate improvement, and finally the last third would show no improvement or even worsening of the symptoms. Prospective clinical and pharmaceutical advances may have significantly changed the landscape of BMS, as recent study showed nearly 10% of spontaneous remission, 26% of moderate improvement, 37% of no significant change, and finally 26% of worsening of symptoms in patients receiving no therapy with an estimated follow up of at least 18 mo. Therapy may be effective in 29% of the patients, with 56% reporting no changes, and 15% admitting worsening of the pain[62]. In perspective, complete understanding of the etiology and pathogenesis is imperative to the development of novel and efficacious therapeutic strategies, and will guide overall prognosis of the disease in the future.

CONCLUSION

BMS is a relatively common chronic intraoral pain disorder classically characterized by intractable burning that may be associated with dysgeusia and xerostomia. Its pathogenesis relates to complex interlay of central and/or peripheral neural pain pathways. Etiology of BMS is multifactorial and a secondary form of BMS should be diligently sought for and treated. Multidisciplinary approach, including medical and psychosocial therapy may be effective in symptom relief in patients with BMS, however, further studies are necessary to establish long term prognosis. BMS remains an important medical condition which often places a significant burden on the patient and health care system, and requires diligent recognition and treatment.

Abstract

AIM: To evaluate whether desferrioxamine decreases ischemia and perfusion injury aggravated by cold storage (CS) in a rat liver perfusion model.

METHODS: Isolated rat livers were kept in CS in University of Wisconsin Solution for 20 h at 4 ℃, then exposed to 25 min of warm ischemia (WI) at 37 ℃ followed by 2 h of warm perfusion (WP) at 37 ℃ with oxygenated (95% oxygen and 5% carbon dioxide) Krebs-Henseleit buffer. Desferrioxamine (DFO), an iron chelator, was added at different stages of storage, ischemia and perfusion: in CS only, in WI only, in WP only, in WI and perfusion, or in all stages. Effluent samples were collected after CS and after WI. Perfusate samples and bile were collected every 30 min (0, 0.5, 1, 1.5 and 2 h) during liver perfusion. Cellular injury was assessed by the determination of lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) in the effluent and perfusate samples. Total iron was analysed in the perfusate samples. After WP, the liver was collected for the determination of liver swelling (wet to dry ratio) and liver morphological examination (hematoxylin and eosin staining).

RESULTS: Increased CS time caused increased liver dysfunction during WP. After 2 h of WP, liver injury was indicated by increased release of AST (0.5 h CS: 9.4 ± 2.2 U/g liver *vs* 20 h CS: 45.9 ± 10.8 U/g liver, $P < 0.05$) and LDH (0.5 h CS: 59 ± 14 U/g liver *vs* 20 h CS: 297 ± 71 U/g liver, $P < 0.05$). There was an associated increase in iron release into the perfusate (0.5 h CS: 0.11 ± 0.03 μmoL/g liver *vs* 20 h CS: 0.58 ± 0.10 μmoL/g liver, $P < 0.05$) and reduction in bile flow (0.5 h CS: 194 ± 12 μL/g *vs* 20 h CS: 71 ± 8 μL/g liver, $P < 0.05$). When DFO was added during WI and WP following 20 h of CS, release of iron into the perfusate was decreased (DFO absent 0.58 ± 0.10 μmoL/g liver *vs* DFO present 0.31 ± 0.06 μmoL/g liver, $P < 0.05$), and liver function substantially improved with decreased release of AST (DFO absent 45.9 ± 10.8 U/g liver *vs* DFO present 8.1 ± 0.9 U/g liver, $P < 0.05$) and LDH (DFO absent 297 ± 71 U/g liver *vs* DFO present 56 ± 7 U/g liver, $P < 0.05$), and increased bile flow (DFO absent 71 ± 8 μL/g liver *vs* DFO present 237 ± 36 μL/g liver, $P < 0.05$). DFO was also shown to improve liver morphology after WP. Cellular injury (the release of LDH and AST) was significantly reduced with the addition of

DFO in CS medium but to a lesser extent compared to the addition of DFO in WP or WI and perfusion. There was no effect on liver swelling or bile flow when DFO was only added to the CS medium.

CONCLUSION: DFO added during WI and perfusion decreased liver perfusion injury aggravated by extended CS.

INTRODUCTION

Hypothermia is used extensively to preserve many types of donor organs for transplantation and protects organs, in part, by reduced requirements for metabolic energy[1]. Donor livers are flushed and then stored at 4 ℃ in specialized storage solutions (*e.g.*, University Wisconsin solution). However, preservation injury can cause primary graft dysfunction and increased morbidity and mortality in liver transplant recipients[2]. When cold storage (CS) time is extended beyond 10 h, there is a significant increase in primary graft dysfunction and long term biliary complications following liver transplantation[3-6].

The mechanisms responsible for donor liver dysfunction after preservation are not fully understood but one important potential contributor to liver damage is redox active iron. Redox active iron has been identified as a contributor to isolated hepatocyte death and liver damage during hypothermia[7-10]. Redox active iron can react with hydrogen peroxide and initiate radical reactions which damage cellular macromolecules, such as DNA, proteins and membrane lipids. Chelation of iron by specialised proteins usually prevents the generation of radical species *in vivo*. However, when cells[7,9,11] or organs[12-14] are cooled there is an increase in redox active iron and this increase has been linked to cell death during hypothermia[7,9,10].

One approach to abrogating the activity of redox active iron is to chelate free iron with iron chelators such as desferrioxamine (DFO)[7,9,15]. When DFO was added to CS media there was reduced hepatocyte and endothelial cell death during CS, and liver damage on re-perfusion[7,11,14,16]. However, it is unlikely that DFO is taken up intracellularly by liver cells during storage at 4 ℃[7,17,18], so intracellular redox active iron has the potential to predispose the donor liver to injury during implantation [warm ischemia (WI)] and subsequent re-perfusion[14]. DFO enters tissue by endocytosis at 37 ℃ and therefore the presence of DFO during WI and re-perfusion may offer additional protection from CS injury. To test this hypothesis, isolated rat livers were perfused after CS, with DFO added to the preservation media during CS, WI and WP. This strategy significantly protected livers from CS damage.

MATERIALS AND METHODS

Materials

Krebs-Henseleit buffer (KHB), DFO and reduced glutathione were purchased from SIGMA and Aldrich, Sydney, Australia. Hartmann's solution was obtained from Baxter Health Care Pty Ltd, Old Toongabbie, Australia, University of Wisconsin solution (UWS) from Bristol-Myers Squibb Company, New York, United States, gentamicin from Pfizer, West Ryde, Australia and Actrapid human insulin from Novo Nordisk Pharmaceuticals Pty Ltd, Baulkham Hills, Australia. Dexamethasone sodium phosphate was from DBL, Rowville, Australia.

Liver isolation, CS and WI

The use of animals was approved by the Animal Ethics Committee of the University of Western Australia. All animals received food and water before graft retrieval. Adult male rats (Strain PVG, average weight 272 ± 5 g, n = 35) were anesthetized with halothane. The gastroduodenal vein, splenic vein, right renal artery, right and left adrenal veins were ligated and the bile duct was cannulated. The liver was flushed with 20 mL of cold Hartmann's solution (control) or UWS with supplements (reduced glutathione, dexamethasone, insulin and gentamicin, pH 7.35-7.4 on ice) and heparin (5 U/mL) *via* the aorta. The liver was excised and placed in UWS with supplements for 20 h at 2-4 ℃. After CS the suprahepatic vena cava (outlet) and portal vein (inlet) were cannulated, and the liver was connected to a rat liver perfusion system while it was in the CS medium. In the control group, after the liver was excised, the liver was connected to a rat liver perfusion system while it was in cold saline for up to 0.5 h (CS0.5 h). The liver was then transferred to the perfusion chamber (37 ℃) and flushed with 20 mL of Hartmann's solution and heparin (5 U/mL). The first 6.5 mL of effluent and the CS medium were collected. To simulate WI during liver implantation, the liver was covered with damp gauze and left at 37 ℃ chamber for 25 min.

Liver WP

After WI, the liver was perfused using a water-jacketed perfusion system (Radnoti Glass Technology, Inc., Monrovia, United States) with oxygenated (95% oxygen and 5% carbon dioxide) KHB at 20 mL/min at 37 ℃ and the first 6.5 mL of perfusate was collected. After 7.5 min of perfusion, the perfusate was re-circulated and filtered through a pre-filter and filter (0.8 μm/0.2 μm, 32 mm OD, Pall Life Sciences, Australia) and the liver was then perfused for 2 h. During liver perfusion, perfusate (1.5 mL) and bile were collected at 0, 0.5, 1, 1.5 and 2 h and

Table 1 Details of experimental groups

Experimental group	Number per group	CS time (h) in UWS	Addition of DFO		
			CS	WI	WP
CS0.5 h	5	-	-	-	-
CS20 h	5	20	-	-	-
DFO (CS)	5	20	DFO	-	-
DFO (WI)	5	20	-	DFO	-
DFO (WP)	5	20	-	-	DFO
DFO (WIP)	5	20	-	DFO	DFO
DFO (CS WIP)	5	20	DFO	DFO	DFO

DFO: Desferrioxamine; CS: Cold storage; UWS: University of Wisconsin solution; WI: Warm ischemia; WP: Warm perfusion; WIP: Warm ischemia and perfusion.

kept on ice. Perfusates were centrifuged at 10 000 *g* for 10 min at 4 ℃ and the supernatant was analysed for lactate dehydrogenase (LDH), aspartate aminotransferase (AST) and total iron.

After 2 h of perfusion, the liver was pat-dried and weighed. Tissue (approximately 0.5 g) was dried at 80 ℃ for 72 h for the calculation of wet to dry ratio and a portion of tissue was snap frozen in liquid nitrogen for subsequent analysis. The remaining liver was fixed in 10% formaldehyde for histopathological examination.

Assays

Perfusate LDH levels were measured by the method of Passonneau[19]. AST enzyme activity was measured by automated biochemical analyser (Hitachi 917, Roche Diagnostics). Total iron levels were measured by Inductively Coupled Plasma-Mass Spectrometry (Varian 820, California, United States) with aqueous standards used for the calibration curve. LDH, AST and total iron were expressed relative to dry liver weight.

Liver histopathology

Liver sections were stained with hematoxylin and eosin and then examined independently by a pathologist (B DeBoer) and a hepatologist (GP Jeffrey). A scale for morphological classification of hepatic injury was used as previously described[20]. The 9 point scale was: (1) normal rectangular structure; (2) round hepatocytes with an increase of sinusoidal spaces; (3) vacuolization in zone 3; (4) vacuolization in zone 2; (5) vacuolization in zone 1; (6) vacuolization and nuclear pyknosis in zone 3; (7) vacuolization and nuclear pyknosis in zone 2; (8) vacuolization and nuclear pyknosis in zone 1; and (9) necrosis.

DFO addition to media

There were seven experimental groups and each group consisted of 5 rats. DFO (1 mmol/L) was tested in five experimental groups with different combinations of DFO during CS, WI, WP and perfusion (WIP), or CS, WI and perfusion (CS WIP) (Table 1). The required amount of DFO was weighed and added to the media prior to use and the concentration (1 mmol/L) was based on our previous isolated rat hepatocyte study[7].

Statistical analysis

All analyses were carried out using R 2.10.1[21], using the package base and agricolae[22]. A one-way between ANOVA was used to compare the outcome of each measurement (the levels of LDH, AST, liver wet to dry ratio and bile flow) and treatment condition (Table 1). Least Square Difference (LSD) was used for Post Hoc testing. Differences are considered to be significant if $P < 0.05$. Data is reported as mean ± SE.

RESULTS

Effect of extended CS

The degree to which liver damage occurred during CS, WI and WP was measured by the release of LDH and AST. Liver damage was evident immediately after extended CS. The LDH level was 7.9 ± 0.6 U/g liver and the AST level was 1.9 ± 0.1 U/g liver after 20 h of CS compared to 0.7 ± 0.1 U/g liver and 0.1 ± 0.0 U/g liver in the controls (CS0.5 in Figure 1). Increased damage was also evident after WI, with 9 fold higher LDH and 8 fold higher AST release in extended CS, relative to the controls (CS0.5 in Figure 1). The bulk (more than 95%) of LDH and AST release occurred during WP of livers subjected to extended CS (Figure 1). After 2 h of perfusion, LDH levels were 297 ± 71 U/g liver and AST levels were 45.9 ± 10.8 U/g liver in livers subjected to 20 h of CS compared to 59 ± 14 U/g liver and 9.4 ± 2.2 U/g liver respectively in livers of the control group. Twenty hours of CS resulted in a 14% increase in liver swelling and a 63% decrease in bile flow (Figure 1). Taken together, these data indicate that 20 h of CS caused a detrimental effect on liver function during subsequent WI and WP.

Protective effect of DFO

DFO was first added to CS medium only. There was no significant improvement in LDH levels or AST levels during WI. However during WP there was a 40% reduction of LDH and AST levels after 2 h of perfusion compared to livers that had not been exposed to DFO during CS (Figure 2). There was no effect on liver swelling or bile flow (Figure 2).

To test if either redox active iron was not completely chelated by DFO during CS, or additional redox active iron release occurred during WI and WP, DFO was added to solutions during all stages of the experiment. This resulted in a significant reduction of AST levels from 6.7 ± 1.3 U/g liver to 3.4 ± 0.5 U/g liver compared with no DFO during WI ($P < 0.05$). LDH levels were not significantly affected (DFO absent 39.9 ± 7.9 U/g liver *vs* DFO present 24.4 ± 2.5 U/g liver). In contrast, after 2 h of WP there was a large reduction of AST levels and LDH levels from 45.9 ± 10.8 U/g liver to 8.1 ± 0.9 U/g liver and 297 ± 71 U/g liver to 56 ± 7 U/g liver respectively when compared to no DFO (Figure 2). These levels were similar to the controls (CS0.5 in Figure 1). Consistent DFO effects were observed with improved liver swelling, decreased from 4.01 ± 0.17 to 3.37 ± 0.05 (wet weight to dry weight ratio) and bile flow increased from 71 ± 8

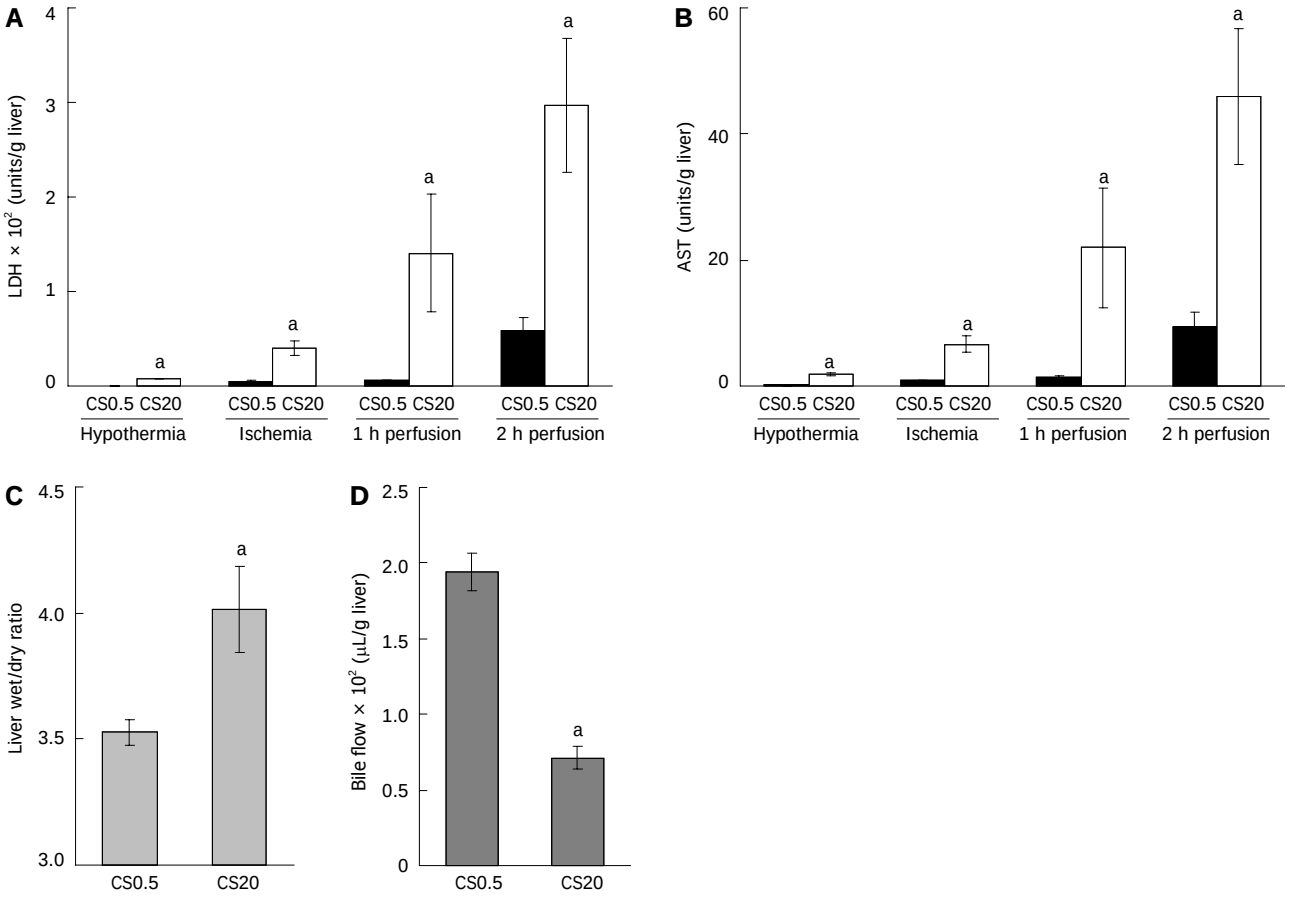

Figure 1 Liver function following cold storage, warm ischemia and perfusion. A, B: Liver damage was assessed by measuring lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) in media from control livers after 0.5 h of cold storage (CS0.5) and from the livers after 20 h of extended cold storage (CS20). LDH and AST were measured in media flushed from livers following cold storage, in media flushed from livers following 25 min of warm ischemia and in media at 1 and 2 h of warm perfusion; C, D: Liver health was assessed by liver swelling (liver wet to dry ratio) after 2 h of perfusion and bile flow over 2 h of perfusion. Significantly different from the controls (mean ± SE, $n = 5$, $^{a}P < 0.05$).

μL/g liver to 237 ± 36 μL/g liver (Figure 2).

To test the possibility that DFO had its predominant protective effect during WI and/or WP, DFO was added to either WI or WP media alone. DFO had no effect when added during WI alone, however there was a protective effect when it was added to perfusion medium alone (Figure 2). There was a reduction of LDH from 297 ± 71 U/g liver to 72 ± 15 U/g liver and AST from 45.9 ± 10.8 U/g liver to 13.4 ± 2.2 U/g liver compared to livers not treated with DFO (Figure 2). Furthermore, liver swelling was prevented and bile flow was maintained (Figure 2). Of note, the protective effect was comparable to that observed when DFO was present during all three stages of the experiment and this is consistent with the concept that redox active iron continued to be a major cause of liver damage during WI and WP following extended CS.

To further assess the protective effect of DFO, liver morphology was examined following 2 h of WP and assessed using a nine point scale ranging from 1 (normal structure) to 9 (necrosis) (Figure 3). Relative to the controls (CS0.5 h, morphological classification of 3.0 ± 0.1, mean ± SE, $n = 4$), extended CS resulted in extensive vacuolization and marked pyknosis (morphological classification of 5.5 ± 0.9, mean ± SE, $n = 4$, $P < 0.05$). DFO was largely effective in preventing changes to liver morphology (morphological classification of 3.0 ± 0.4, mean ± SE, $n = 4$, $P < 0.05$ relative to no DFO).

Iron release during CS and perfusion

The effectiveness of DFO in preventing liver damage indicated redox active iron was likely a major contributor to liver damage. To further investigate this, iron release was measured following WI and during perfusion. Following WI and 20 h of CS there was 0.15 ± 0.02 μmoL iron/g liver compared with 0.02 ± 0.01 μmoL iron/g liver in the controls (CS0.5 in Figure 4, $P < 0.05$). After 2 h of WP, iron release after 20 h of CS was 0.58 ± 0.10 μmoL iron/g liver which was significantly higher than 0.11 ± 0.03 μmoL/g liver in the controls (CS0.5 in Figure 4, $P < 0.05$). Iron concentrations were significantly correlated with LDH release and AST release during WI (Figure 5). During WP, the concentration of iron was also correlated with LDH release and AST release (Figure 5). The significant correlation between iron and the damage markers LDH and AST was consistent with the hypothesis that redox active iron was causing liver damage.

The presence of DFO altered iron concentrations in

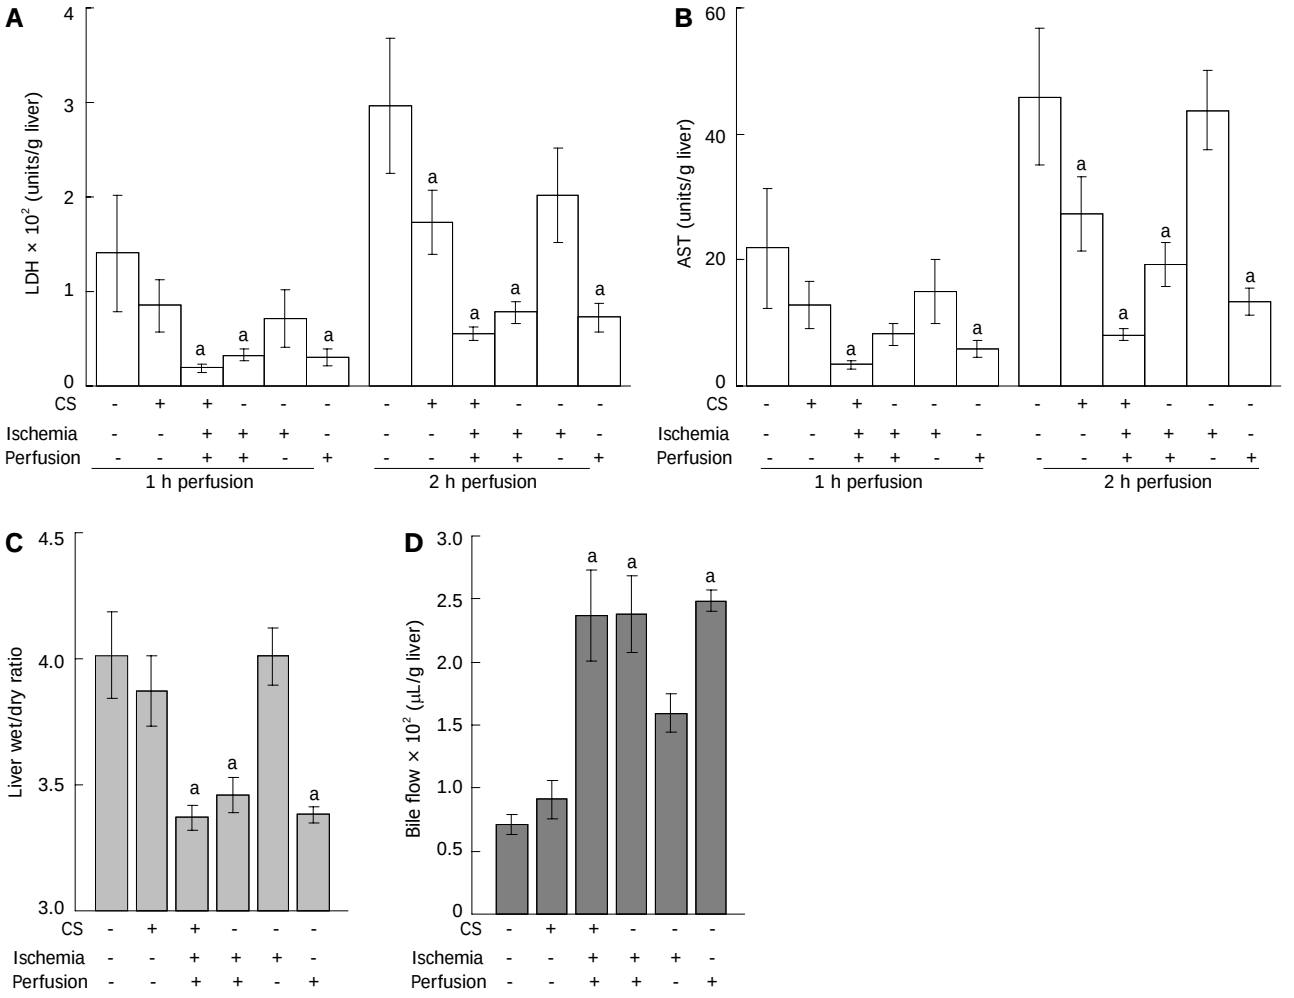

Figure 2 The effect of desferrioxamine added during cold storage, warm ischemia and/or perfusion on liver function following 20 h of cold storage. A,B: Desferrioxamine was added (indicated by +) to cold storage (CS), warm ischemia and perfusion media. Liver damage was assessed by measuring lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) in media from livers during perfusion at 1 and 2 h; C, D: Liver health was assessed by liver swelling (liver wet to dry ratio) after 2 h of perfusion and bile flow over 2 h of perfusion. Data for extended (20 h) CS are shown. Significantly different from 20 h of CS (mean ± SE, $n = 5$, $^{a}P < 0.05$).

WP media. When DFO was added during CS, WI and perfusion, iron concentrations were significantly decreased from 0.58 ± 0.10 μmoL/g liver (no DFO) to 0.31 ± 0.06 μmoL/g liver (with DFO, $P < 0.05$) (Figure 4). There was also a significant relationship between the concentration of iron and liver damage during both WI and WP (Figure 5). However, the slope of the line describing the relationship was significantly lower in the presence of DFO compared to the absence of DFO during WP (Figure 5). Consequently, for the same concentration of iron, there was less damage in the presence of DFO relative to absence of DFO. One explanation for this observation may be that by chelating iron during WI or perfusion, DFO prevented ongoing liver damage caused by redox active iron.

DISCUSSION

It is well established that extended CS causes increased liver damage and that the presence of iron chelators in storage media can substantially protect hepatocytes and livers from damage during cold incubation or storage[9,14,23,24]. In this study, extended CS also aggravated liver damage during the simulated transplantation protocol involving WI (mimicking implantation) and WP. The presence of DFO during CS only partial decreased the subsequent vulnerability of livers to the simulated transplantation protocol. The novel finding of this study was that the presence of DFO during WI and WP could substantially decrease the vulnerability of livers to extended CS.

Liver damage during WP was related to events occurring during CS, such that extended CS sensitised the liver to subsequent WI and perfusion injury. Redox active iron has been identified as a contributor to hepatocyte death[10] and liver damage during CS[7,9,10]. Data from this study provided evidence that redox active iron was involved in sensitising the liver during extended CS, as the presence of DFO during CS did partially protect against subsequent liver damage. There is evidence that DFO is not able to cross membranes during incubation at 4 ℃[7,18], so by what mechanism did DFO partially protect the liver in this present model? Iron is present in UWS solu-

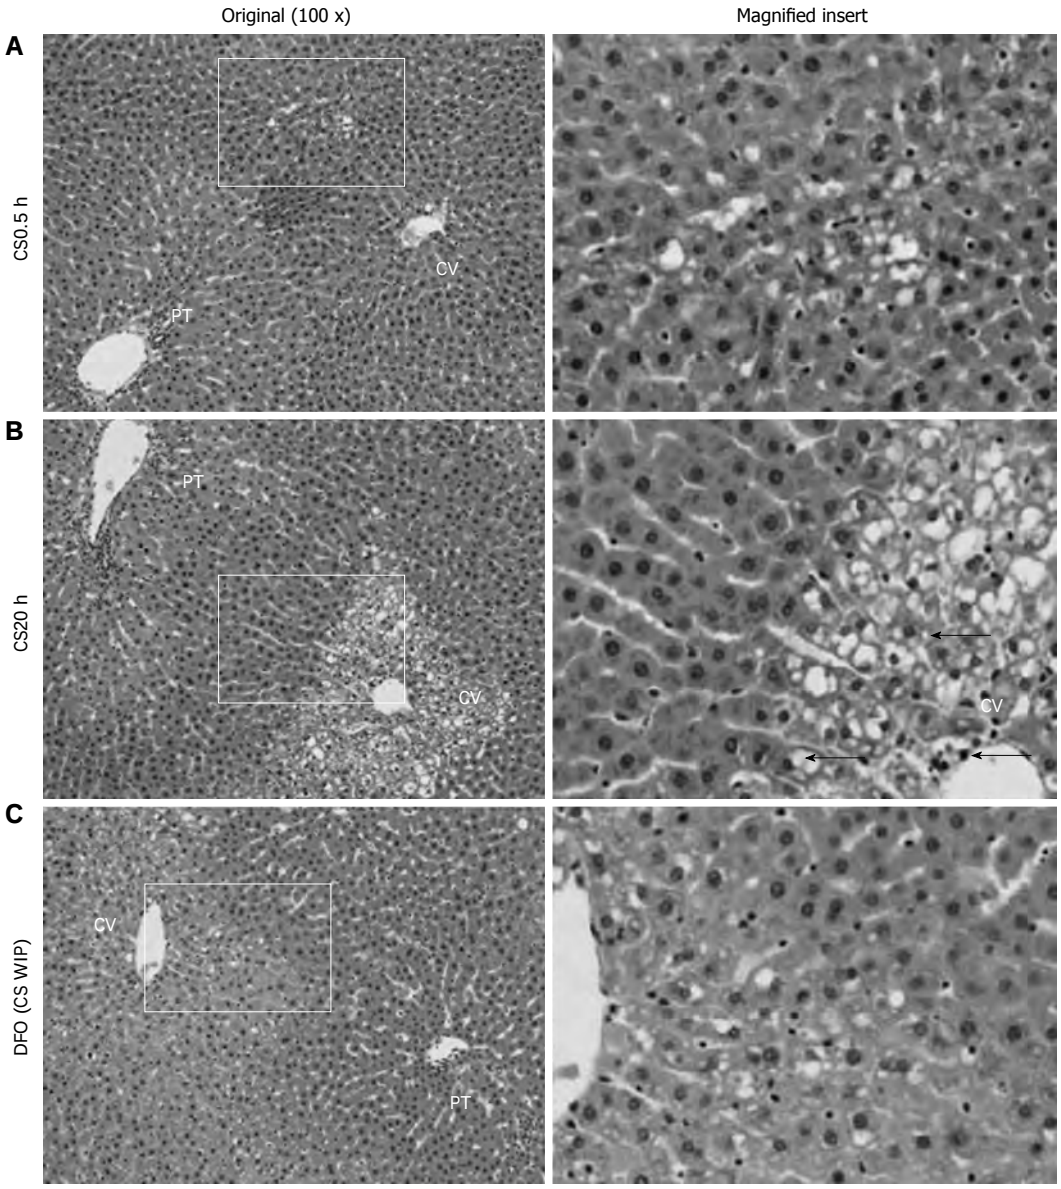

Figure 3 Histopathological appearance of livers following cold storage, warm ischemia and perfusion and the effect of desferrioxamine. A: The control liver shows some early vacuolization in zone 2 following 0.5 h of cold storage (CS0.5) (magnified insert); B: Following 20 h of cold storage (CS20), the liver shows marked vacuolization and nuclear pyknosis in zones 3 as indicated by arrows (←, magnified insert); C: Following 20 h of CS with desferrioxamine (DFO) in CS, warm ischemia and perfusion media (CS WIP), the liver shows mild vacuolization in zone 3 (magnified insert). tion as measured in our laboratory (4.43 ± 0.05 μmoL/L, n = 4) and in another study[25], so the protective effect of DFO added during CS could be a result of chelation of extracellular iron. It has also been suggested that DFO is able to reduce intracellular iron by draining cytosolic iron to the extracellular medium[26]. Consistent with this concept, we have previously shown that chelation of extracellular iron protects hepatocytes during cold incubation[7]. Therefore, during extended CS, extracellular iron could have contributed to the sensitisation of livers to subsequent WI and perfusion injury.

Intracellular redox active iron could have also contributed to the sensitization of livers to subsequent WI and perfusion injury. Intracellular redox active iron has been shown to increase during cold incubation/storage in isolated hepatocytes[9,11] and whole liver[14]. Additionally, we have linked increased intracellular redox active iron to hepatocyte cell death during extended cold incubation[7]. In previous experiments not involving CS, redox active iron has been implicated in renal ischemia and perfusion injury[12,27] and ischemia and perfusion injury in livers[28]. Therefore, an increase in the concentration of intracellular redox active iron caused by the extended CS would exacerbate an ongoing cycle of redox active iron release during WI and WP. This explanation would account for the added effectiveness of DFO during WI and WP.

The findings of this study have implications for liver transplantation. There has been a focus on protecting livers during CS by developing various cryoprotective media or improving liver function prior to transplant us-

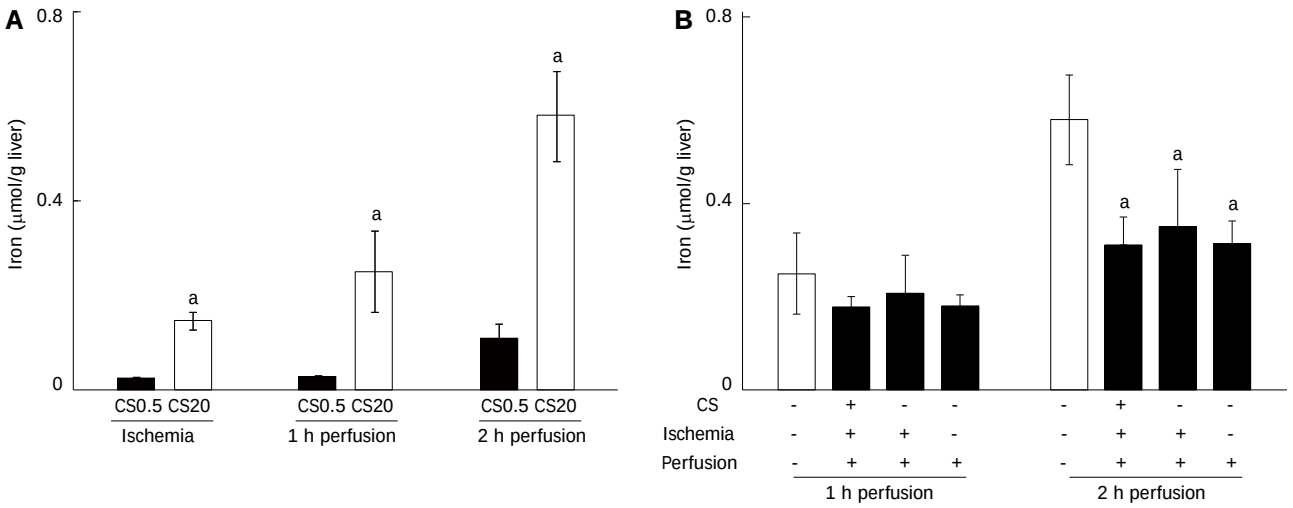

Figure 4 Iron release during warm ischemia and perfusion and effect of desferrioxamine on iron release. A: Iron release was measured in media after warm ischemia (WI) and at 1 and 2 h of perfusion from the control livers after 0.5 h of cold storage (CS0.5) and from the livers after 20 h of extended cold storage (CS20). Significantly different from the controls (mean ± SE, $n = 5$, $^{a}P < 0.05$); B: Iron release was measured in media at 1 and 2 h of perfusion from livers following 20 h of cold storage (CS). Addition of desferrioxamine (DFO) to CS, WI and perfusion media is indicated by (+). Significantly different from 20 h of CS with no DFO (mean ± SE, $n = 5$, $^{a}P < 0.05$).

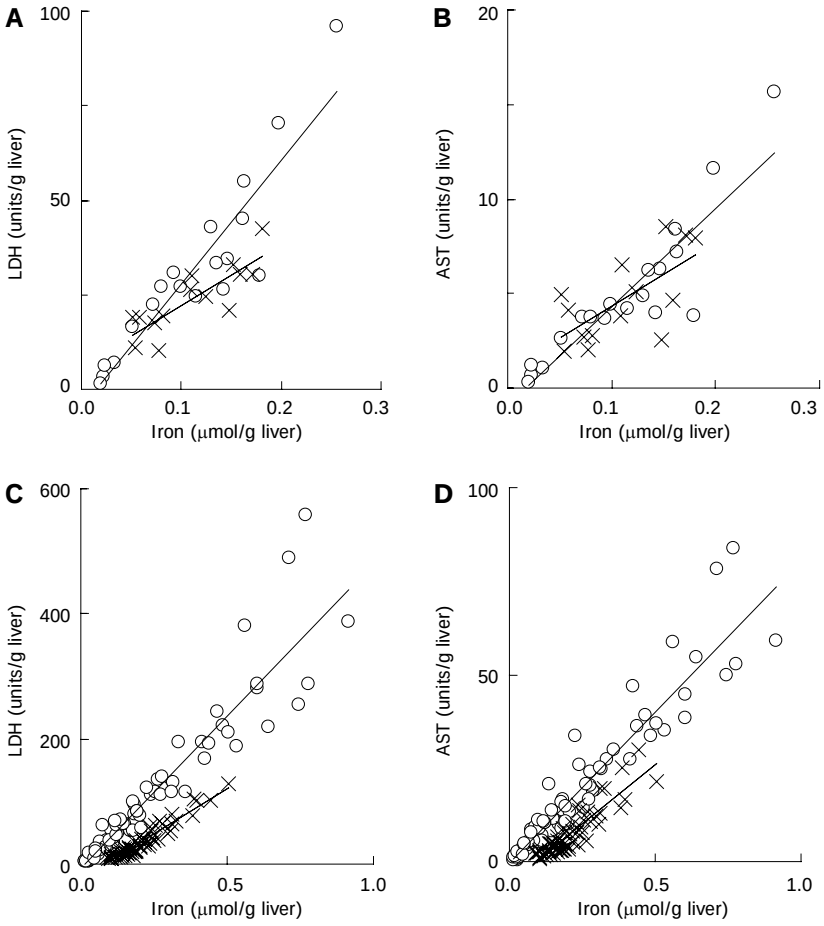

Figure 5 Relationship between presence of iron and liver damage. Following ischemia: A: The relationships between lactate dehydrogenase (LDH) and iron in the absence of desferrioxamine (DFO) (circles) and the presence of DFO (crosses) were described by y = 327x - 5 ($n = 19$, $r^2 = 0.84$) and y = 162x + 6 ($n = 14$, $r^2 = 0.69$) respectively; B: The relationships between aspartate aminotransferase (AST) and iron in the absence of DFO (circles) and the presence of DFO (crosses) were described by y = 52x - 0.9 ($n = 19$, $r^2 = 0.81$) and y = 33x + 1 ($n = 14$, $r^2 = 0.44$); C: During perfusion, samples collected at 0.5 h, 1 h, 1.5 h and 2 h were analysed. The relationships between LDH and iron in the absence of DFO (circles) and the presence of DFO (crosses) were described by y = 487x - 8.1 ($n = 76$, $r^2 = 0.88$) and y = 291x - 24.4 ($n = 56$, $r^2 = 0.91$) respectively; D: The relationships between AST and iron in the absence of DFO (circles) and the presence of DFO (crosses) were described by y = 81x - 0.5 ($n = 76$, $r^2 = 0.90$) and y = 62x - 5.6 ($n = 56$, $r^2 = 0.80$) respectively. All correlation coefficients were significant ($P < 0.05$), and all slopes for media containing iron were significantly different ($P < 0.05$) from the equivalent treatment without DFO.

ing perfusion systems. This data indicates there may be a further opportunity to enhance liver preservation during transplantation and following transplantation by chelating redox active iron. This concept will need further testing in liver transplant models as the *in vitro* model used in this study does not fully encapsulate the complexity of the recipients' response to the transplant procedure and drug intervention. From a clinical application perspective it is worth noting that DFO is already approved for a variety of clinical applications such as treating iron overload patients[29,30].

COMMENTS

Background

Cold donor organ preservation techniques were developed to reduce cellular metabolic activity and maintain cellular viability in donor organs. However, livers stored beyond about 12 h are generally considered to be unsuitable for transplantation.

Research frontiers

Extending the time of cold storage (CS) increases the susceptibility of livers to ischemia and reperfusion injury during transplantation. Preventing ischemia and reperfusion injury would permit extended times of CS.

Innovations and breakthroughs

Desferrioxamine (DFO), an iron chelator, is often included in CS media to prevent oxidative stress caused by redox active iron. The novel finding of this study was that including DFO during warm ischemia and warm perfusion could substantially decrease the vulnerability of rat livers to an extended time (20 h) of CS.

Applications

This study shows that it is possible to extend the time in which livers can be kept in CS. Extended CS times would improve the numbers of livers available for transplant.

Abstract

AIM: To investigate the role of interleukin (IL)-17 in small bowel allograft rejection.

METHODS: We detected the expression of helper T cell 17 (Th17) cells in biopsy specimens from 3 cases of living small bowel transplantation in our department through immunofluorescence stain. We then established a rat heterotopic small bowel transplantation model. The rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after small bowel transplantation. The degrees of transplantation rejection in rat intestine graft were examined through hematoxylin eosin (HE) stain, and the expression of Th17 cells in rat intestine graft were detected through immunofluorescence stain. In addition, the recipient rats undergoing intestinal transplantation were administrated with mouse-anti-rat IL-17 monoclonal antibody (mAb), and the survival of rats was analyzed. The recipient rats which received mouse-anti-rat IL-17 mAb treatment were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after small bowel transplantation. The degrees of transplantation rejection and the expression of Th17 cells in rat intestine graft were detected through HE and immunofluorescence stain. The expression of IL-17, IL-1β, tumor necroses factor receptor-α (TNF-α), IL-6, and IL-8 in the intestine graft or serum were also detected.

RESULTS: The expressions of Th17 cells ran parallel with the degree of acute rejection in human intestine grafts. The intestine graft rejection of rats was aggravated with prolonged duration after intestinal transplantation, and the expressions of Th17 cells were also correlated with the degree of acute rejection in rat intestine grafts. Administration of mouse-anti-rat IL-17 mAb prolonged the survival of rats after small bowel transplantation ($P < 0.001$). Furthermore, we found that the administration of mouse-anti-rat IL-17 mAb significantly decreased the intensity of $CD4^+IL\text{-}17^+$ Th17 cells in intestine grafts on the 2nd, 3rd, 5th, and the 7th d (97.22 ± 4.05 *vs* 12.45 ± 2.02 on the 7th d, $P < 0.0001$), and suppressed the severity of acute rejection. The expression of IL-17 in the intestine graft declined after mouse-anti-rat IL-17 mAb administration on the 2nd, 3rd,

5th, and the 7th d (0.88 ± 0.03 *vs* 0.35 ± 0.02 on the 7th d, $P < 0.0001$). We also detected the IL-17 serum level and found that the IL-17 level reduced from the 1st d to the 7th d (6.52 ± 0.18 ng/mL *vs* 2.04 ± 0.15 ng/mL on the 7th d, $P < 0.0001$). No significant difference in the level of IL-17 mRNA in the intestine graft was identified between the two groups. The levels of IL-1β, TNF-α, IL-6, and IL-8 mRNA in the intestine graft after the administration of mouse-anti-rat IL-17 mAb were also tested. We found that on the 3rd, 5th, and 7th d after intestinal transplantation, administration of mouse-anti-rat IL-17 mAb significantly inhibited the levels of IL-1β (12.11 ± 1.16 *vs* 1.27 ± 0.15 on the 7th d, $P < 0.001$), TNF-α (27.37 ± 2.60 *vs* 1.06 ± 0.26 on the 7th d, $P < 0.001$), IL-6 (21.43 ± 1.79 *vs* 1.90 ± 0.32 on the 7th d, $P < 0.001$), and IL-8 (20.44 ± 1.44 *vs* 1.34 ± 0.20 on the 7th d, $P < 0.001$) mRNA in the intestine graft.

CONCLUSION: IL-17 may act as a promising and potent target for inhibiting acute rejection after small bowel transplantation.

Interleukin-17 plays a critical role in the acute rejection of intestinal transplantation. *World J Gastroenterol* 2013; 19(5): 682-691 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/682.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.682

INTRODUCTION

Small bowel transplantation is a prevailing therapy for short bowel syndrome[1-3]. However, compared with liver[4,5], kidney[6,7], and heart transplantation[8,9], small bowel transplantation has less satisfying effects. The small bowel and mesentery involve redundant lymphoid tissue, which are organs with high immunogenicity prone to inducing severe transplantation rejection. FK506 (Tacrolimus) may inhibit the activation of T cells through suppressing the production of rejection related cytokines, calcium-dependent phosphatase calcineurin, and JNK/p38 pathways[10,11]. FK506 can prevent the aggregation of lymphocytes in the early rejection and chemotaxis of inflammatory cells. But the usage of FK506 after clinical small bowel transplantation may result in severe side effects, such as renal toxicity and neurotoxicity[12].

Recently, the helper T cell (Th)1/Th2 paradigm has been expanded, following the discovery of a third subset of effecter T helper cells that produce interleukin (IL)-17 (Th17) and exhibit effecter functions[13-15]. On the basis of these studies, investigators proposed that IL-17-producing T cells serve as a distinct T helper cell subset, which are called Th17 cells[16-18]. The primary function of Th17 cells appears to be the clearance of pathogens that are not adequately handled by Th1 or Th2 cells[19]. Th17 cells, as potent inducers of tissue inflammation, have a proven association with the pathogenesis of many experimental autoimmune diseases and human inflammatory conditions[20,21].

In the present study, we reveal that Th17 cells and IL-17 cytokine are expressed in the intestine graft after small bowel transplantation. Furthermore, we found that the level of Th17 cells ran parallel with the degree of rejection. The data clearly indicates that Th17 cells and IL-17 cytokine may play an important role in transplant rejection.

MATERIALS AND METHODS

Patients and specimens

This study was approved by the Ethics Committee of the Fourth Military Medical University. Biopsy specimens embedded in paraffin from 3 cases of living-related small bowel transplantation were collected from Xijing Hospital of Digestive Diseases, Fourth Military Medical University (FMMU) from 1999 to 2003. All clinical information was available. The sections were stained for pathological examination. The brief clinical characteristics of these patients are listed as follows: Patient No. 1 was an 18-year-old boy with a 40 cm intestine who received a 150 cm segment of distal ileum from his father; Patient No. 2 was a 17-year-old boy with a 8 cm intestine who received a 170-cm graft of distal ileum from his father and; Patient No. 3 was a 15-year-old boy with a 10 cm intestine who received a 160-cm graft of distal ileum from his mother. All the recipients underwent different degrees of graft rejection after operation. The first two patients survived, while the third died from acute graft rejection and severe infection.

Mice

Forty inbred male F344/NCrl BR and forty LEW/Crl rats (age: 8 to 12 wk old, weight: 180 to 230 g) were purchased from Vital River Lab Animal Technology Co., Ltd (Beijing, China). Animals were maintained in specific pathogen-free conditions. All animal experiments were approved by the Animal Experiment Administration Commission of FMMU.

Small bowel transplantation

Donors and recipients were intraperitoneally anesthetized with pentobarbital (5 g/L). The small intestine 5 cm distal to the ligament of Treitz was harvested from the donor rats and 20 cm of isolated jejunum, along with mesenteric blood vessels, was prepared for transplantation. The left kidney of each recipient was removed and the infrarenal abdominal aorta isolated. An end-to-side vascular anastomosis was performed between the recipient and donor's abdominal aortae. The cuffed portal vein was inserted into the left renal vein. The two ends of the small bowel graft were constructed as separate stomas through the left abdominal wall. Detailed procedures were followed as previously

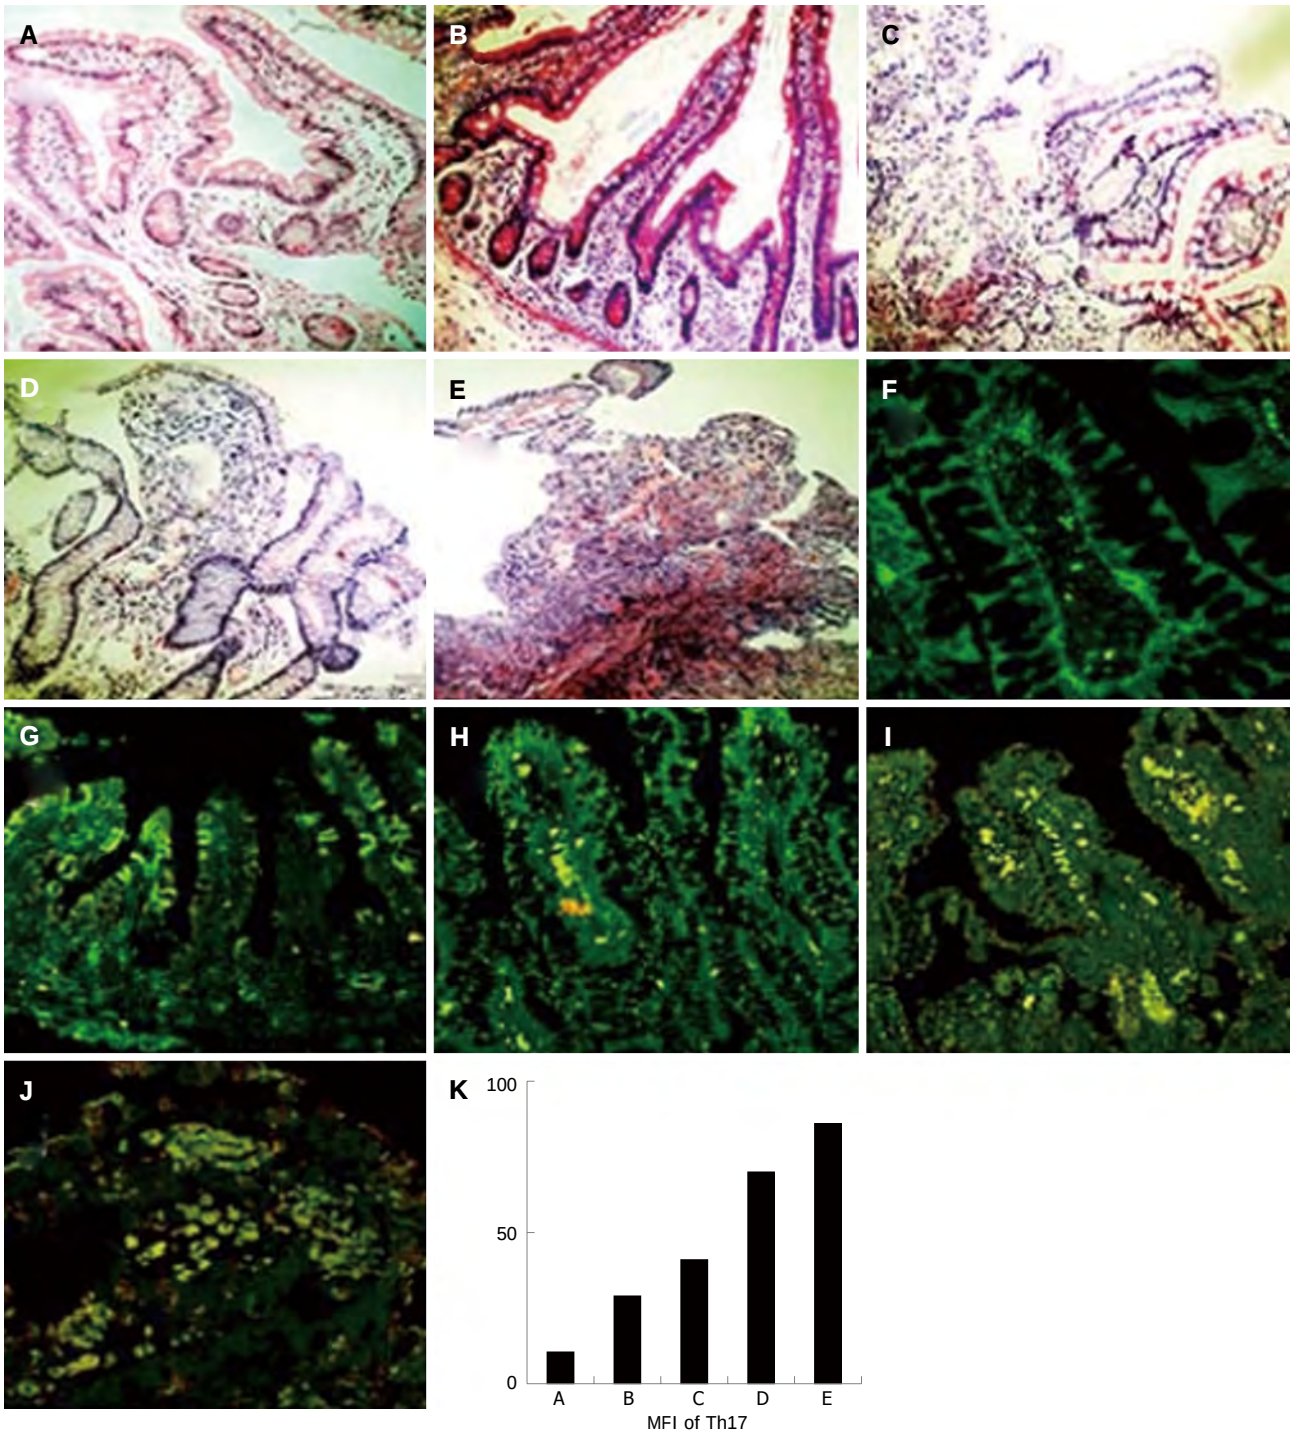

Figure 1 Expression levels of helper T cell 17 cells in intestine grafts paralleled with the degree of rejection in human recipients. The paraffin-embedded human intestine tissues after small bowel transplantation were sectioned and stained with hematoxylin eosin (HE), anti-rat-interleukin-17, and anti-rat-CD4 fluorescence antibodies (× 400). described[22]. In treatment experiments, the recipient rats in the control group were administrated with mouse-immunoglobulin G (IgG), while the recipient rats in the anti-IL-17 monoclonal antibody (mAb) group were administrated intravenously with 200 μg mouse-anti-rat IL-17 mAb[23] daily during the operation, and on the 1st, 2nd, 3rd, 5th, and 7th d afterwards.

Histology

Specimens were fixed in 4% paraformaldehyde, embedded in paraffin, sectioned at 4 μm thickness, and stained with hematoxylin and eosin, following standard methods

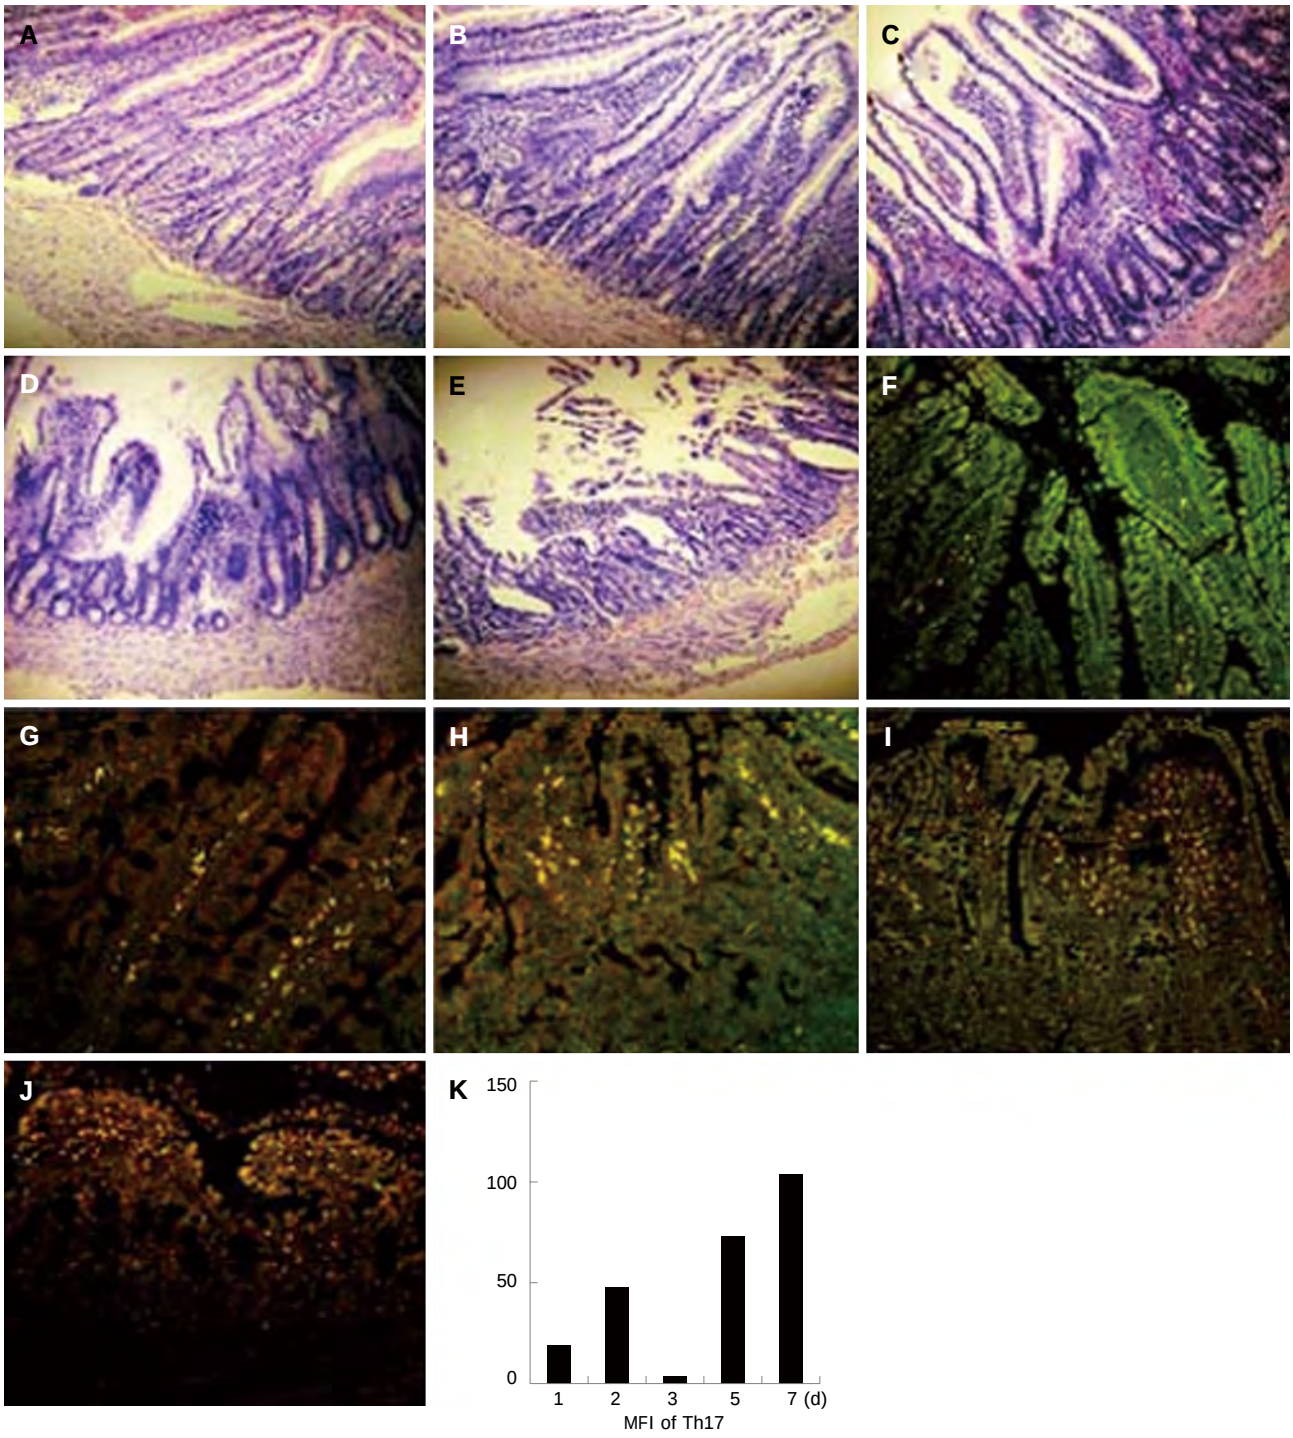

Figure 2 Expression levels of helper T cell 17 cells in intestine grafts paralleled with the degree of rejection in rat recipients. The intestines from inbred F344 were transplanted to LEW rats. The recipient rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation. The grafts were removed, fixed, and embedded. The sections were stained with hematoxylin eosin (HE), anti-rat-interleukin-17, and anti-rat-CD4 fluorescence antibodies (× 400). for routine morphological analysis.

Diagnostic criteria for transplant rejection of human and rat small bowel transplantation

The biopsy specimens of human and rat intestine grafts were stained with hematoxylin eosin (HE), and analyzed by two independent pathologists. The histological degrees for acute intestine graft rejection were divided into four grades: indeterminate for acute rejection, mild acute rejection, moderate acute rejection, and severe acute rejection. The details of the diagnostic criteria for acute intestine graft rejection have been described previously[24].

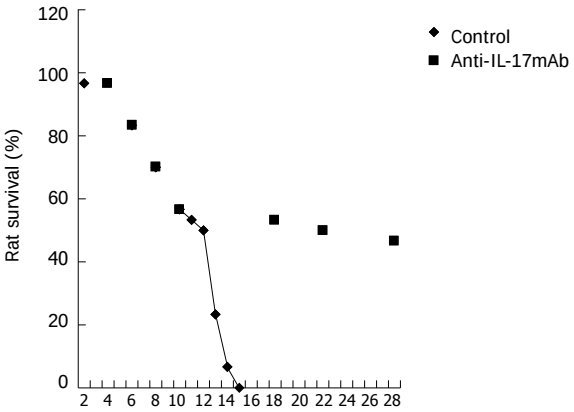

Figure 3 Administration of anti-interleukin-17 monoclonal antibody prolonged the survival of rats after small bowel transplantation. The intestines from inbred F344 were transplanted to LEW rats. The recipient rats were randomly divided into control and anti-interleukin (IL)-17 monoclonal antibody (mAb) treated groups. The survival of recipient rats was analyzed.

Immunofluorescence

The paraffin-embedded human intestine mucosa specimens were sectioned at 4 μm thickness. Immunofluorescence was performed by standard procedures, with rabbit-anti-human IL-17 polyclonal antibody (1:50 dilution; Santa Cruz Biotechnology) and mouse-anti-human CD4 mAb (1:100 dilution; Santa Cruz Biotechnology) as the primary antibodies. Goat-anti-rabbit IgG-TR (1:50 dilution; Santa Cruz Biotechnology) and goat-anti-mouse IgG-FITC (1:50 dilution; Santa Cruz Biotechnology) were taken as secondary antibodies. We did not compare the staining for IL-17 before and after transplantation, but only selected the paraffin-embedded human intestine mucosa specimens at different transplantation rejection degrees in order to detect the expressions of Th17 cells.

The negative control sections were used in our immunofluorescence method. We took phosphate buffered solution (PBS) instead of the primary antibodies as a negative control, and adopted rat cardiac allograft specimen sections as a positive control (data not shown). The methods of the immunofluorescence stain of Th17 in our present study were in accordance with our previous report[25].

Western blotting

The total proteins of the intestine graft were extracted and determined according to the manufacturer's manuals. Proteins were electrophoresed in 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and blotted on a nitrocellulose membrane. The membrane was incubated with rabbit anti-rat IL-17 polyclonal antibody (1:500 dilutions). After three washes for 15 min in PBS-T, the membrane was incubated with the HRP-conjugated goat-anti-rabbit IgG antibody (1:2000 dilutions). Blots were developed by using an enhanced chemiluminescence system (ECL, Amersham, Little Chalfort, United Kingdom). β-actin was considered as an internal control.

Enzyme-linked immunosorbent assay

Blood from the heart was extracted when the rat was sacrificed. Serum was collected and adopted in order to detect the level of IL-17 with a rat IL-17 enzyme-linked immunosorbent assay kit (ELISA) (Rapidbio, America) by standard procedures. $A_{450\ nm}$ was recorded by a spectrophotometer, and was compared between groups.

Quantitative real time polymerase chain reaction

Total RNA was extracted from rat intestine grafts with a homogenizer by using TRIzol reagent (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. Complementary DNA was prepared with a reverse-transcription kit from TOYOBO (Osaka, Japan). Real-time reverse-transcription polymerase chain reaction (RT-PCR) was performed by using a kit (SYBR Premix EX Taq, Takara) and the ABI PRISM 7500 real-time PCR system, with β-actin as an internal control. Primers used in real-time PCR were as follows, β-actin, forward: CATCCGTAAAGACCTCTATG CCAAC, reverse: ATGGAGCCACCGATCCACA; IL-17, forward: GGGAAGTTGGACCACCACAT, reverse: TTCTCCACCCGGAAAGTGAA; IL-1β, forward: CTTCAAATCTCACAGCAGCATCTCG, reverse: TCCACGGGCAAGACATAGGTAGC, tumor necroses factor receptor-α (TNF-α), forward: CTGTGCC TCAGCCTCTTCTCATTC, reverse: TTGGGA ACTTCTCCTCCTTGTTGG; IL-6, forward: GACTGATGTTGTTGACAGCCACTGC, reverse: TAGCCACTCCTTCTGT GACTCTAACT, IL-8, forward: GCCAACAC AGAAATTATTGTAAAGCTT, reverse: CCTCTGCACCCAGT TTTCCTT.

Statistical analysis

Statistical analysis was performed with the SPSS 16.0 program. Results were expressed as means ± SD. Comparisons between groups were made by the unpaired Student's *t*-test. For survival studies, Kaplan-Meier survival curves were generated and a statistical analysis was performed via the log-rank test. $P < 0.05$ was considered statistically significant.

RESULTS

Expression levels of Th17 cells in intestine graft ran parallel with the degree of rejection.

To examine the expression of Th17 cells on a human intestine graft, biopsy specimens embedded in paraffin from 4 cases of living small bowel transplantation in our department were collected and stained with HE (Figure 1A-E) and antibodies against IL-17 and CD4 (Figure 1F-J). The density of IL-17$^+$CD4$^+$ Th17 cells was calculated and analyzed by Image-Pro-Plus 5.1 software. As shown in Figure 1K, the density of IL-17$^+$CD4$^+$ Th17 cells increased when the rejection degrees aggravated.

In order to investigate whether Th17 cells exist in rat intestine grafts after transplantation, intestines from F344/NCrl BR were grafted to LEW/Crl rats; the recipi-

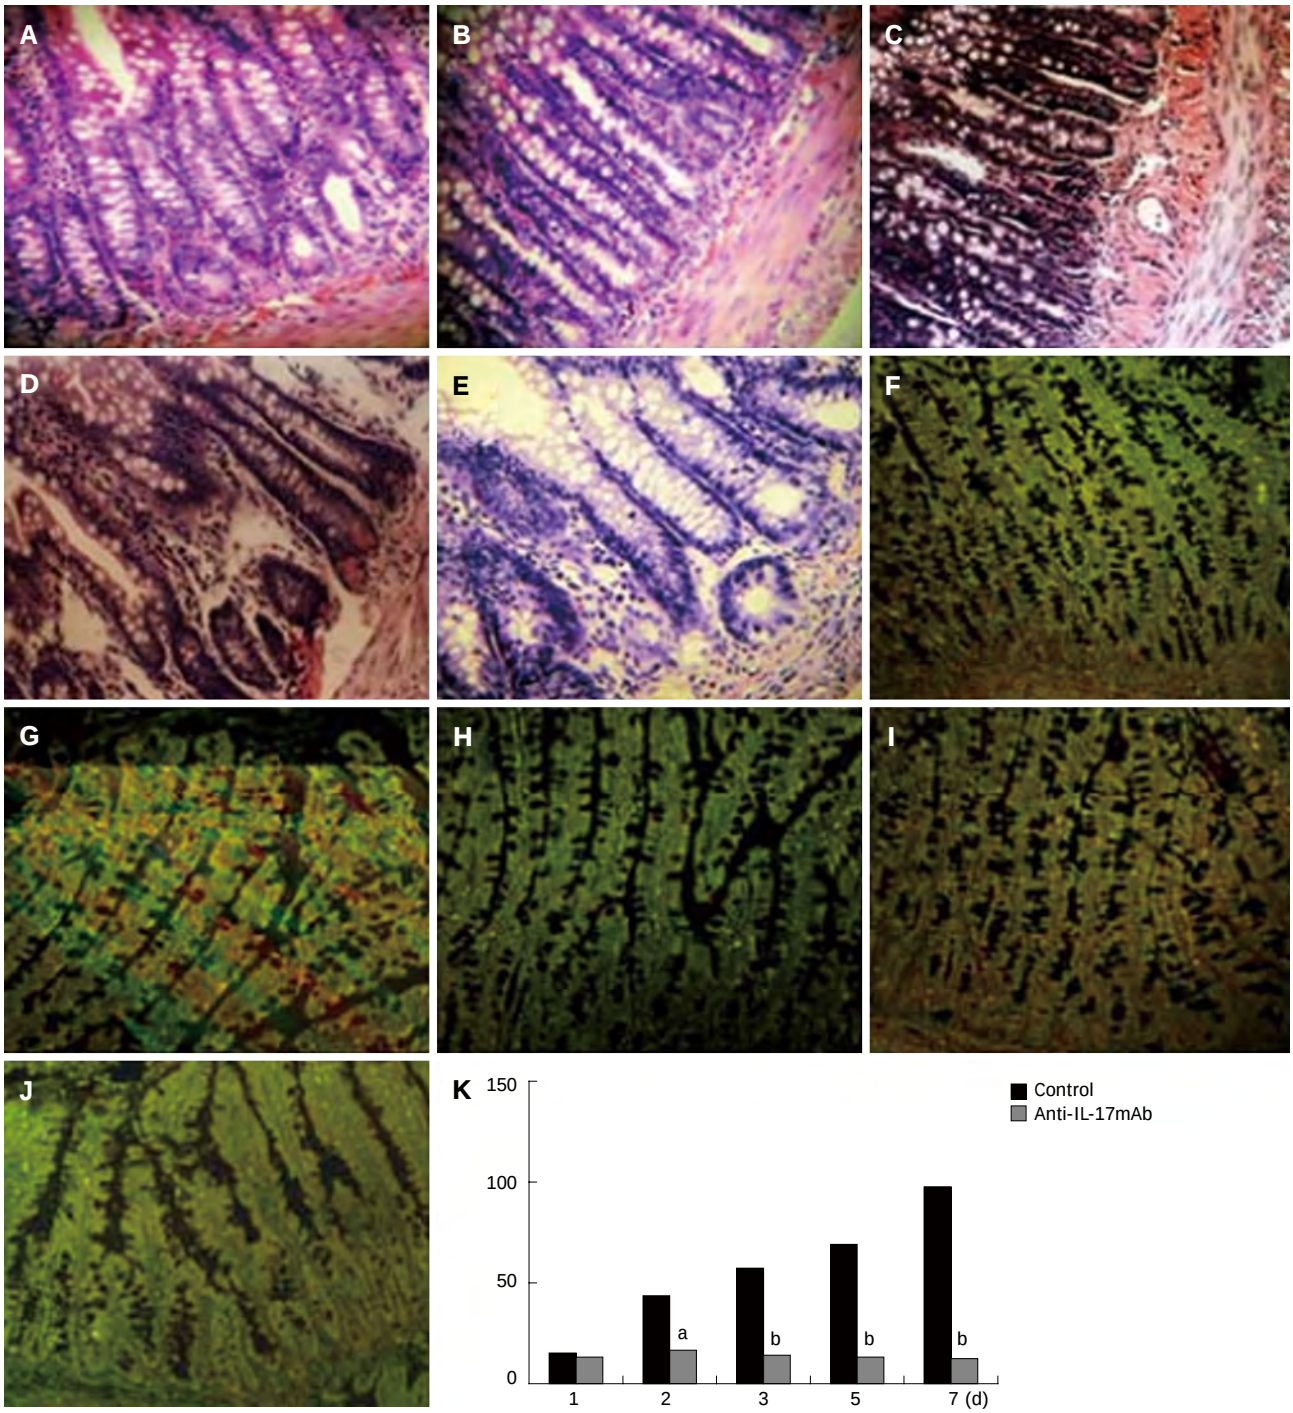

Figure 4 Administration of anti-interleukin-17 monoclonal antibody decreased the expression levels of helper T cell 17 cells in intestine grafts in rat recipients. The intestines from inbred F344 were transplanted to LEW rats. The recipient rats were randomly divided into control and anti-interleukin (IL)-17 monoclonal antibody (mAb) treated groups. The rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation. The grafts were removed, fixed, and embedded. The sections were stained with hematoxylin eosin (HE), anti-rat-IL-17, and anti-rat-CD4 fluorescence antibodies (× 400). A-E: HE staining of intestine graft; F-J: Helper T cell (Th) 17 immunofluorescence staining of intestine graft; A, F: 1 d after transplantation; B, G: 2 d after transplantation; C, H: 3 d after transplantation; D, I: 5 d after transplantation; E, J: 7 d after transplantation; K: Mean fluorescence intensity of Th17 expression of intestine graft. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control group.

ent rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation, and the expression of Th17 cells in rat intestine grafts were analyzed (Figure 2A-J). In accordance with the findings in human intestine grafts, we found that Th17 cells were located in rat intestine grafts and the degree of Th17 cells corresponded to the severity of transplant rejection (Figure 2K). Taken together, Th17 cells did exist in intestine grafts, and the levels of Th17 cells might relate to the transplant rejection degrees in both human and rat recipients.

Administration of anti-IL-17 mAb prolonged the survival of rat post-transplantation

Since IL-17 may play a role in small bowel transplantation rejections, we hypothesized that IL-17 could be considered as a potential target for the treatment of graft rejec-

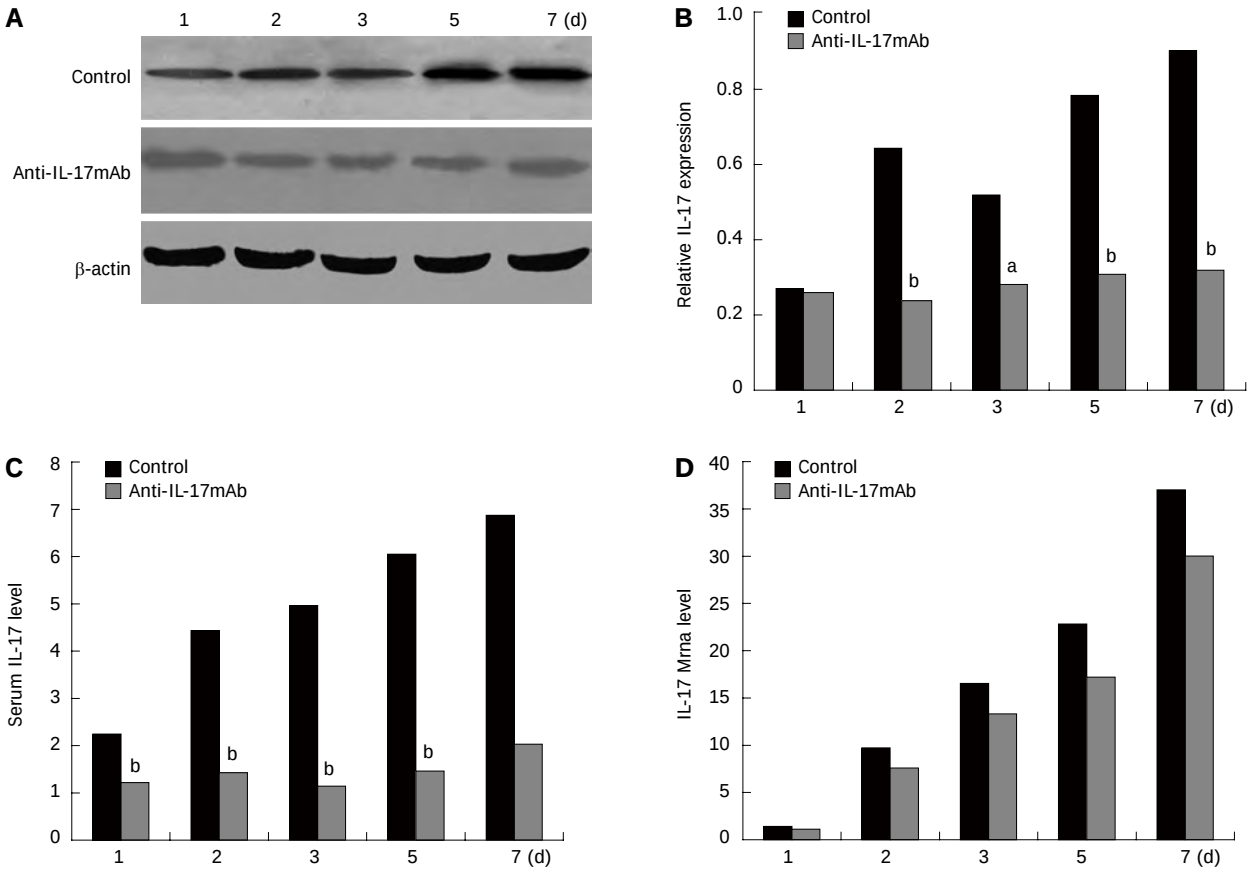

Figure 5 Expression of interleukin-17 in rat intestine and serum after transplantation. The intestines from inbred F344 were transplanted to LEW rats. The recipient rats were randomly divided into control and anti-interleukin (IL)-17 monoclonal antibody (mAb) treated groups. The rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation. A: Western blot analysis of graft proteins of different groups. β-actin were considered as an internal control; B: The bands were scanned and the protein expressions were analyzed with Band Scan software; C: Blood from the heart was extracted and the serum IL-17 levels was detected by enzyme-linked immunosorbent assay; D: The mRNA of IL-17 was detected by quantitative reverse transcriptase polymerase chain reaction. β-actin was considered as an internal control. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control group.

tion. In order to further demonstrate our hypothesis, the recipients were administrated with mouse-anti-rat IL-17 monoclonal antibody intravenously during, and after, small bowel transplantation, and the survival of recipients were analyzed. We found that administration of anti-IL-17 mAb could significantly prolong the survival of rats after small bowel transplantation (Figure 3).

Anti-IL-17 mAb administration inhibited transplant rejection of intestine graft

We further analyzed the effect of anti-IL-17 administration on graft rejections. The administration of anti-IL-17 mAb was proved to effectively inhibit transplant rejection of intestinal grafts in rats post-transplantation by HE staining (Figure 4A-E). Furthermore, we found that the expression of Th17 cells in intestine grafts also dramatically declined (Figure 4F-K), indicating that anti-IL-17 mAb could possibly prolong the survival of recipient rats by inhibiting transplant rejection.

Anti-IL-17 mAb administration decreased IL-17 expressions in rat

During and after allotransplantation, recipient rats were administrated with anti-IL-17 mAb. The recipient rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation. The expressions of IL-17 in intestine grafts and serums were further detected by western blot and ELISA (Figure 5). In the control group which only received saline administration, the levels of IL-17 protein in the intestine graft and serum were found to have increased post-allotransplantation and run parallel with transplant rejection degrees. In the anti-IL-17 mAb administration group, the expression of IL-17 could also be detected, but the degrees were remarkably lower than the control group. The levels of IL-17 mRNA in the intestine graft in two groups were not significantly different. Therefore, the administration of anti-IL-17 mAb could decrease the IL-17 level in intestine grafts and serum.

Anti-IL-17 mAb administration decreased expressions of related cytokines

As shown in Figure 6, the expressions of IL-1β, IL-6, IL-8, and TNF-α mRNA of intestine grafts in the control group were found to increase post-allotransplantation and correlate to transplant rejection degrees. Administration of anti-IL-17 mAb could dramatically decrease the expression of mRNA levels of these cytokines in intestine grafts, compared with the control group.

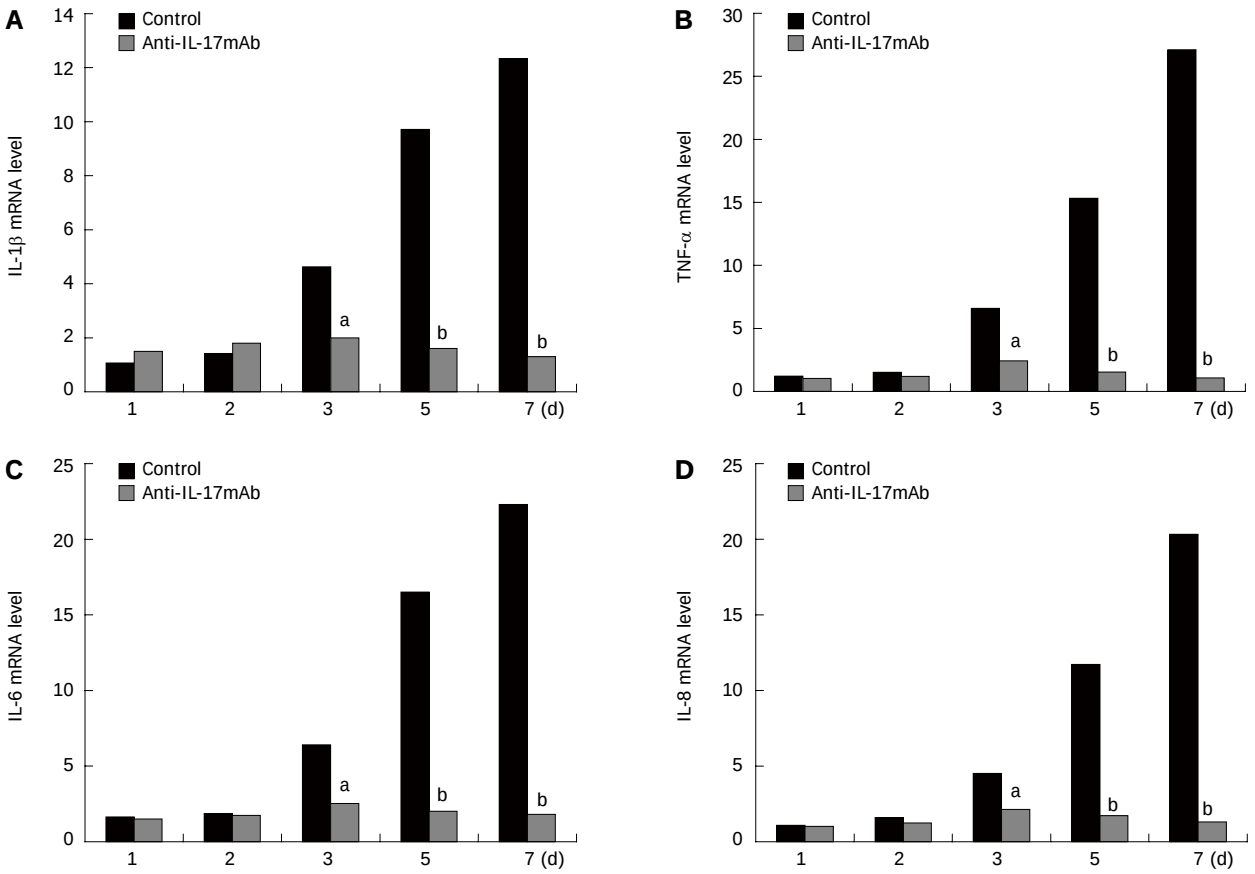

Figure 6 mRNA level of interleukin-1β (A), tumor necrosis factor-α (B), interleukin-6 (C), and interleukin-8 (D) were analyzed by reverse transcriptase polymerase chain reaction. The intestines from inbred F344 were transplanted to LEW rats. The recipient rats were randomly divided into control and anti-interleukin (IL)-17 mAb treated groups. The rats were sacrificed on the 1st, 2nd, 3rd, 5th, and 7th d after transplantation. The mRNA was extracted and quantitative reverse transcriptase polymerase chain reaction was performed. β-actin was considered as an internal control. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control group.

DISCUSSION

Th17, known as a distinct lineage of helper T cells from Th1 and Th2, has both a defense role against microbe infection and a pathogenic role in several autoimmune diseases[26]. Th17 cells have been shown to be implicated in allograft rejection of solid organs, such as lung and cardiac transplantation[25,27,28]. Vanaudenaerde *et al*[27] observed that IL-17 expression increased in bronchoalveolar lavages in patients with acute lung transplantation rejection. The disease-promoting role of Th17 in cardiac allograft rejection was also confirmed, especially in the absence of a Th1 response[25]. Th17 cells not only function in host-versus-graft disease, but also participate in graft-versus-host disease[29-31]. So far, the relationship between Th17 cells and small bowel transplantation has been unclear. In this study, we demonstrated that Th17 cells participated in the development of human and rat small bowel transplantation rejection.

Here we found that Th17 cells existed in intestine grafts with different degrees of acute rejection. Furthermore, we indicated that the density of Th17 cells increased when the rejection degree aggravated, suggesting that it might be related to the transplant rejection degrees in human recipients. Th17 cells were also found to be located in rat intestine grafts, and the degree of Th17 cells correlated with transplant rejection degrees, which was in accordance with the findings in human intestine grafts. These demonstrate that Th17/IL-17 may participate and play a critical role in the graft rejections of small bowel transplantation.

IL-17, secreted by Th17 cells, is a highly inflammatory cytokine with robust effects on stromal cells in many tissues[32,33]. Hsieh *et al*[34] reported that IL-17 could serve as a predictive parameter for borderline subclinical renal allograft rejection in the future. Itoh *et al*[35] found that IL-17-deficient recipient mice had decreased allograft inflammatory cell recruitment, and demonstrated that IL-17 contributed to the pathogenesis of chronic allograft rejection. In order to demonstrate the key role of IL-17 in the graft rejection of small bowel transplantation, we utilized mouse-anti-rat IL-17 mAb to treat recipient rats undergoing small bowel transplantation for the first time. Surprisingly, after administration of anti-IL-17 mAb, the acute rejection degrees of recipient rats significantly decreased compared to the control group. The levels of Th17 cells that had infiltrated the intestine graft during anti-IL-17 mAb administration also fell greatly. Administration with anti-IL-17 mAb could extend the survival time of rats undergoing small bowel transplantation. To sum up, IL-17 cytokine could probably be taken as a potent target to treat acute rejection in small bowel

transplantation.

The differentiation factors (transforming growth factor beta plus IL-6 or IL-21), the growth and stabilization factor (IL-23), and the transcription factors (signal transducer and activator of transcription 3, related orphan receptor-γt (RORγt), and RORα) were involved in the development of Th17 cells. Mice reconstituted with the bone marrow of RORγt deficient mice showed an impaired Th17 differentiation. The combinations of IL-1β plus IL-6[36] or IL-1β plus IL-23[37] were proposed to be the differentiation factors for human Th17 cells. We found that the expression of IL-1β and IL-6 was significantly decreased after anti-IL-17 mAb administration. Therefore, anti-IL-17 mAb might suppress the expression of IL-1β and IL-6 in rat intestine grafts, and then inhibit the development and activation of Th17 cells. TNF is also induced by IL-17 cytokine. Its expression was found to be reduced after anti-IL-17 mAb administration. The migration and infiltration of inflammatory cells into intestine grafts requires the expression of chemokines. Chemokine (C-X-C motif) ligand 8 (IL-8), a target of IL-17, is involved in transplant rejections. Compared to the control group, the expression of IL-8 was found to be obviously decreased in intestine grafts treated with anti-IL-17 mAb. This suggests that anti-IL-17 mAb administration might suppress the migration and infiltration of Th17 cells into intestine grafts by decreasing the expression of chemokines.

In conclusion, we have illustrated that Th17 cells might play an important role in human and rat small bowel acute transplantation rejection. The administration of anti-IL-17 mAb could significantly suppress the acute rejection degree of rat intestine grafts and prolong the survival time of recipient rats. IL-17 could be considered a promising and potent target for inhibiting acute rejection after small bowel transplantation.

COMMENTS

Background

Small bowel transplantation is a widespread therapy for short bowel syndrome. However, the efficacy of small bowel transplantation is not satisfactory due to severe transplantation rejection. Although administration of FK506 may inhibit the activation of T cells, prevent the aggregation of lymphocytes in early rejection, and restrain the chemotaxis of inflammatory cells, its administration after human small bowel transplantation may cause severe side effects such as renal toxicity and neurotoxicity.

Research frontiers

The helper T cell (Th) 17 cell, as a distinct lineage of helper T cells from Th1 and Th2, has a proven implication in the allograft rejection of solid organs, such as lung and cardiac transplantation. Interleukin (IL)-17 expression was increased in bronchoalveolar lavages in patients with acute lung transplantation rejection. The disease-promoting role of Th17 in cardiac allograft rejection was also confirmed. Th17 cells are involved not only in host-versus-graft disease, but graft-versus-host disease as well.

Innovations and breakthroughs

So far, the relationship between Th17 cells and small bowel transplantation has been unclear. Authors demonstrated the presence of Th17 cells in the intestine grafts of humans and rats, and further found that the expression levels of Th17 cells in intestine grafts correlated with the degree of rejection. The authors hypothesized that Th17/IL-17 might play a critical role in small bowel transplantation rejection and could be regarded as a potential target for the treatment of graft rejection. They then treated recipient rats with mouse-anti-rat IL-17 monoclonal antibody (mAb) and found that its administration could significantly prolong the survival of rats after small bowel transplantation. Furthermore, the authors found that the expression of Th17 cells in intestine grafts also dramatically declined, indicating that mouse-anti-rat IL-17 mAb may prolong the survival of recipient rats by inhibiting transplant rejections. In the present study, the authors demonstrated that Th17 cells participated in the development of human and rat small bowel transplantation rejection.

Applications

The administration of mouse-anti-rat IL-17 mAb could significantly suppress the acute rejection degree of rat intestine grafts and prolong the survival time of recipient rats. IL-17 could be considered as a promising and potent target for inhibiting acute rejection after small bowel transplantation.

Terminology

Small bowel transplantation: an operation to replace a diseased or shortened small bowel with a healthy bowel from a donor and a valuable therapy for short bowel syndrome. Transplant rejection: immune system attacks between the transplant recipient and the transplanted organ or tissue, which include host-versus-graft disease and graft-versus-host disease. Th17 cell: known as a distinct lineage of helper T cells from Th1 and Th2 that has both a defense role against microbe infection and a pathogenic role in several autoimmune diseases.

Peer review

This is an investigation of the role of IL-17 in acute intestinal transplantation rejection and the administration of anti-IL-17 monoclonal antibodies for the suppression of IL-17 production by Th17 cells in the intestine graft and, as a result, suppression of acute rejection of the intestine graft in both human and rat models. It is a very good work and I hope it is applicable in human subjects undergoing intestinal transplantation.

Abstract

AIM: To investigate different methods of creating incomplete intestinal obstruction in a rat model and to compare their electrophysiologic, morphologic and histologic characteristics.

METHODS: Rat ileum was partially obstructed by the respective application of: braided silk (penetrated the mesentery and surrounded intestine); half ligation (penetrated directly and ligated 1/2 cross-section of the intestine); wide pipe (6 mm in width, surrounded the intestine); narrow pipe (2 mm in width, surrounded the intestine). A control was also included (no obstruction). Various behavioral and electrophysiologic variables, as well as morphologic and immunohistochemical observations were recorded by blinded investigators at different time points (12, 24, 48, 72 h), including daily general condition, ileal wet weight and circumference, macromorphous and micromorphous intestine, bowel movement capability *in vivo* and *in vitro*, slow wave and neural electrical activity, and the number of c-Kit positive interstitial cells of Cajal (ICC).

RESULTS: Despite being of a similar general condition, these methods resulted in different levels of obstruction in each group compared with the control at different time points (12, 24, 48, 72 h). However, these fields of the wide pipe rat showed significantly differences when compared with the other three obstructed groups at 12 to 72 h, including macroscopic and histological presentation, intestinal transit ratio and contractility, circumference and wet weight, amplitude and frequency of nerve electrical discharge and slow wave, and ICC numbers (all $P < 0.01$).

CONCLUSION: The wide pipe rat method is significantly more reliable and stable than the other methods of obstruction, demonstrating that use of the wide pipe method can be a useful model of incomplete intestinal obstruction.

INTRODUCTION

Intestinal obstruction (IO) is one of the most common diseases in abdominal surgery. It can slowly lead to changes in intestinal structure and function, and in extreme cases it can be life-threatening[1,2]. Incomplete intestinal obstruction is the initial phase of intestinal obstruction and is the clinical pathological basis for other types of intestinal obstruction. In addition, when considering the impairment associated with incomplete intestinal obstruction, exploring its diagnosis and treatment has important clinical significance.

Animal models of incomplete intestinal obstruction are important in the investigation of the pathogenic mechanisms involved in human intestinal obstruction, and play an important role in identifying and testing novel interventions. To date, animal models of incomplete intestinal obstruction have included mice, rats, rabbits, pigs and approximately six other types of animals[3-5]. No particular model parallels the complex nature of human intestinal obstruction. The drawback of using animal models is that the basis for the high rate of incomplete intestinal obstruction is not known.

Therefore, it is necessary to establish a reliable animal model to study the pathogenesis of intestinal obstruction, and to have a good experimental model to allow the exploration, research and ultimate treatment of intestinal obstruction. Different types of materials to induce obstruction are currently available. The prosthetic valve has been used since 1996[5]. This was followed by half ligation using braided silk, which was developed in 2004 and has been available since 2008. One report describes the changes elicited by ligating the intestines outside the body[4]. A 24-Fr latex T-tube, cut to form a pipe, was used in China to establish a model of intestinal obstruction[6].

With regard to species selection, the anatomy and physiology of primates are similar to humans, but due to ethical and economic limitations this model is not widely used. Whichever method or species is selected, the ideal animal model should be similar and comparable to the human disease, demonstrate repeatability, be economic and easy to use[7]. In this study, rats were selected and three different materials were used to establish intestinal obstruction.

Based on the above factors, the purpose of the present experimental study was to compare the characteristics of four methods of incomplete intestinal obstruction in the rat model. In addition, we also obtained electrophysiologic, morphologic and histologic information on each method which may have clinical relevance.

MATERIALS AND METHODS

Animals

Healthy adult female and male Sprague-Dawley rats, weighing between 180 and 280 g, were provided by the Laboratory Animal Center [Licence No. SCXK (CHUAN) 2006-10; Sichuan University, Chengdu, China], and were individually housed at 22 ℃ in a 12-h light/dark cycle, with free access to tap water and a standard pellet diet (Laboratory Animal Center, Sichuan University, Chengdu, China) for at least 1 wk before the start of the experiments.

Surgical procedure

One hundred and fifty rats were randomly divided into five groups of thirty in each group. 12 h prior to each study, the animals were fasted but had free access to water, and were anesthetized with 1.5% pentobarbital sodium (30 mg/kg body weight, intraperitoneal; Beijing Chemical Reagent, batch number, 090205; Beijing, China). In this study, a loop of intestine was exposed, and partially obstructed using the respective material. Three different materials were used to obstruct the intestine. A round needle with braided silk No. 0 (Pudong Jinhuan Medical Products, batch number, 11L02028; Shanghai, China) penetrated the mesentery, a polyethylene pipe (2 mm exterior diameter) was placed at the side of the intestine and a ligature was formed with the braided silk, the pipe was then pulled out smoothly from the ligation. This group was known as the braided silk group. Braided silk No. 3-0 (Pudong Jinhuan Medical Products, batch number, 11L02028; Shanghai, China) was used to directly penetrated the intestine and ligate 1/2 cross-section of the intestine. This group was known as the half ligation group. A 24-Fr latex T-tube (Nantong Angel Medical Instruments, batch number, 20110304; Jiangsu, China) was cut to form a pipe 10 mm in length and 6 mm in width which surrounded the intestine. This group was known as the wide pipe group. In another group of rats, a narrow pipe 10 mm in length and 2 mm in width was used to obstruct the intestine. This group was known as the narrow pipe group. The rings were located in the ileum 20 mm oral to the ileocecal sphincter, and this was followed by closure of the abdomen. All materials were placed with the cut side between the lateral extensions of the mesenteric vascular bed to avoid vascular injury[3]. The control group underwent a similar procedure, but the rings used in these animals were 10 mm in length and did not result in occlusion of the ileum.

Postoperative care

After surgery, the animals were treated with an intraperitoneal injection of a 2 mL mixture of glucose (9 mg/mL; Shuanghe Pharmaceutical Industry, batch number,

Table 1 Criteria for scoring macromorphous intestinal damage

Feature	Description	Score
Adhesions	None	0
	Slight, ileum can be separated from other tissues with little effort	1
	Involved in a number of intestinal loops	2
Stenosis	None	0
	Slight	2
	Severe, proximal intestinal distention	3
Ulceration	None	0
	Damage extended to < 1 cm along the length at one site	1
	Damage extended to < 1 cm along the length at two sites	2
	Damage extended to > 1 cm along the length at one siteor multiple lesions	3
Bowel wall thickness	< 1 mm	0
	1-3 mm	1
	> 3 mm	2
Total score		10

Table 2 Criteria for scoring micromorphous intestinal damage

Feature	Description	Score
Ulceration	None	0
	Ulceration < 3 mm, no hyperemia or focal hyperemia, no ulceration	1
	Ulceration < 3 mm, with focal hyperemia or ulceration > 3 mm, without hyperemia	2
	Ulceration > 3 mm or hyperemia	3
Inflammation	None	0
	Slight	1
	Moderate	2
	Severe	3
Fibrogenesis	None	0
	Slight	1
	Severe	2
Extent of involved bowel wall	None	0
	Submucosa	1
	Muscular layer and even serosa	2
Total score		10

100829 6K; Anhui, China) and sodium chloride (50 mg/mL; Shuanghe Pharmaceutical Industry, batch number, 100825 1E; Anhui, China) in a ratio of 1:1 (vol/vol), and 0.1 mL potassium chloride (100 mg/mL; Jiaozuo Pharmaceutical Industry, batch number, 11031641; Tianjin, China). The animals were then allowed to recover on a heated blanket. The rats were allowed to fast 2 h before the last administration, and were rapidly euthanized with pentobarbital sodium at 12, 24, 48, and 72 h, respectively. The abdomen was then cut open and the test was started.

Daily general condition

After surgery, the rats were housed in individual cages. Each day at approximately 9 AM, body weight and food intake were recorded, and feces were collected from each cage. The number of feces pellets was counted and color was observed. Feces from each rat were then lyophilized and weighed to determine fecal dry weight. The total number and dry weight of the fecal pellets were calculated. The mental status and death of rats were recorded.

Measurement of ileum circumference and wet weight

Following sacrifice of the rats, a 3 cm fresh intestinal segment was obtained, the intestinal contents were removed using Tyrode's solution, the segment was then dried with filter paper, and ileal weight was recorded. The ileal wet weight index was calculated using the fasting body weight (kg) divided by the weight (g) of the 3 cm intestinal segment. A bowel segment (10 cm) cut longitudinally along the opposite side of the mesenteric edge was obtained, and its circumference was measured at three sites, and the average was recorded.

Morphological studies

The ileum was opened by an incision along the mesenteric border and laid flat. Tissue damage was assessed and was scored on the 3 cm intestinal segment which was taken 5 cm oral to the ileus, using the criteria outlined in Tables 1 and 2 adapted from Butzner *et al*[8]. Each section was then graded by two blinded observers. Scoring was based on a number of features which were scored from 0 to 10 depending on the presence and severity of visible ileal damage, which consisted of the extent and severity of adhesions, stenosis, ulceration, and bowel wall thickness. A score of 0 to 10 was used to describe the total scores of ulceration, inflammation, fibrogenesis and extent of bowel wall involved. Finally, the extent of histological intestinal mucosal damage was evaluated according to the grading system of Chiu *et al*[9].

Hematoxylin and eosin staining

Histological analysis of intestinal damage was carried out on pieces of muscle taken the same distance from the site of occlusion adjacent to the tissue regions used for electrophysiology. The intestinal tissues in Tyrode's solution were pinned. Connective tissues were removed, cut and pinned into a rectangular shape (1 cm × 2 cm, width and length). The ileal tissues were then fixed in 4% paraformaldehyde for 6 h at room temperature (RT). Two longitudinal sections, 1 cm in length and 2 mm thick, were taken from each fixed tissue segment. These sections were rinsed for 2 h in running water, dehydrated through a graded series of alcohols and embedded in paraffin using the Intelligent Program-controlled Automatic Hydroextractor of Biological Organization (Xiaogan Taiwei Science and Technology Industry, Hubei, China) and a tissue embedding console system (Jinhua Kedi Instrumental Equipment, Zhejiang, China). All paraffin-embedded tissue blocks were sectioned at 5 μm thickness using a microtome (Microsystems Nussloch; Leica Instruments, Shanghai, China), and slides were then prepared. The paraffin was removed from the slides by treatment with xylene. Sections were rehydrated with an ethanol series and stained with hematoxylin and eosin

and examined by light microscopy.

Bowel movement capability analysis

After the rats had fasted for 4 h, all groups received 3% activated charcoal suspension (Sigma, Aldrich, United States) in saline (1.5 mL/rat, *po*) as a charcoal meal. One hour after administration of the marker, the animals were anesthetized with an intraperitoneal injection (2 mL/kg) of pentobarbital sodium, and the small intestine from the pylorus sphincter to the ileocecal sphincter was removed. The intestinal transit ratio was calculated using the percentage of the small intestine length divided by the length the charcoal had travelled.

After the animals had been killed, the small intestine was exposed by a mid-line abdominal incision, and a 3 cm tubular segment of intestine was obtained 1 cm oral to the ileus. The bowel was opened along the mesenteric border and the intestinal contents were rinsed with Tyrode's solution. Segments from a 2 cm piece of bowel were cut and the mucosa was removed by sharp dissection. Strips of muscle (20 mm × 5 mm) were pinned to the hook and contractions were measured isometrically under a resting tension of 0.5-1 g in a 20 mL tissue chamber (Chengdu Technology and Market, Sichuan, China) containing Tyrode's solution for at least 30 min. A force transducer coupled to the BL-420F Biological Function Experimental System (Chengdu Technology and Market, Sichuan, China) was used to record the contractility of the ileum. The settings for the tension pattern was: scanning speed, 2.56 s/div, power gain, 2000, time constant, 5 s, and high-frequency filtering, 3 Hz. The sustained record time was up to 30 min, followed by 30 s of recorded data. Frequency and amplitude were recorded and calculated.

Measurement of neural electrical activity

Along the central line of the neck, a longitudinal cut open to the skin, layer by layer separating the muscles, fascia, and exposing the carotid sheath was made. After separating the vagus nerve, the nerve was immersed in 37 ℃ warm paraffin (Jiangcheng Lipid Chemical Industry, batch number, 100101; Jilin, China) and insulated with the surrounding tissue to prevent the nerve drying during recording. The recording electrodes were hooked to the vagus nerve, the reference electrode was placed on the skin fold, and the electrode input was connected to the BL-420F Biological Function Experimental System. The settings for the neural discharge pattern were: scanning speed, 80 ms/div, power gain, 10 000, time constant, 0.1 s, and high-frequency filtering, 1 KHz. As mentioned above, both frequency and amplitude were recorded.

Determination of slow wave

Ileal slow waves were measured using electrophysiology. A pair of self-made silver electrodes (5 mm in length, 0.1 mm in diameter) was implanted into the seromuscular layer of the intestine. The distance between the electrodes was about 5 mm and they were 10-20 mm away from the ring. The reference electrode was placed on the skin fold, the terminal was wired and connected to the BL-420F Biological Function Experimental System. A layer of paraffin gauze was used to cover the exposed ileum. The settings for the slow electrical signals pattern were: scanning speed, 1.28 s/div, power gain, 2000, time constant, 5 s, and high frequency filtering, 30 Hz. The sustained record time was up to 30 min, followed by 30 s of recorded data. Ten periods were then randomly intercepted using the modified Tomita method[10], and both frequency and amplitude were recorded, calculated and compared (as described earlier).

Immunohistochemistry

The expression of c-Kit in ileal tissue was assessed by immunohistochemistry. Specimens were fixed in 4% paraformaldehyde, dehydrated, and embedded in paraffin, as described previously. A mixed liquid suspension containing 5 mL garlic juice and fresh egg white was added to 100 mL glycerol, which was then used to coat a glass slide. The tissues were then deparaffinized in xylene and rehydrated in a descending ethanol series. After dewaxing and rehydration, antigen retrieval was performed using high pressure for 2 min, and then blocked by incubation in 3% H_2O_2 for 15 min at 37 ℃ to ablate endogenous peroxidase. The sections were washed in phosphate-buffered saline (PBS; 0.01 mol/L, pH 7.4), and then incubated with goat anti-c-Kit specific polyclonal antibody (sc-1494, 1:100, Santa Cruz, Biotechnology, United States) for 1 h at 37 ℃ in a wormwall incubator (Huyueming Instrument, Guangzhou, China). The slides were washed in PBS (5 × 3 min), and then incubated with a horseradish-peroxidase-conjugated rabbit anti-goat IgG(H+L) (Zhongshan Golden Bridge Biotechnology, Beijing, China) for 40 min at 37 ℃, rinsed (5 × 3 min) in PBS, and the sections were colored with 3,3-diaminobenzidine, kept at RT in the dark for 30 s. Following that, the slides were counterstained with hematoxylin, differentiated with 5 g/L hydrochloric ethanol, 1:400 ammonia recurrented blue, sequential ethanol dehydration, and then clearing and mounting with neutral resin. In the negative control the same steps as previously described were carried out, but the primary antibody was replaced by PBS. The positive expression of c-Kit in interstitial cells of Cajal (ICC) was shown by dotted dark brown cells with a nucleus or individual processes of dark brown rods.

Statistical analysis

All data were presented as means ± SE. P values < 0.01 were considered statistically significant. Each intestinal segment was taken from individual animals. The electrical parameters of each segment were analyzed: (1) frequency; (2) amplitude; and (3) contraction capability (contraction frequency multiplied by amplitude). A one-way ANOVA

test was used to compare parameters and the Kruskal Wallis test was used to compare parameters displaying abnormal distribution among the groups. Tukey's Honestly Significant Difference (HSD) test was used to detect the group causing variation when comparing qualitative data, and the Mann Whitney *U* test was used to detect the group causing variation. χ^2 or Fisher's exact test was used to compare qualitative data. All analyses were performed using SPSS 13.0 for Windows (SPSS Inc, United States). Adobe Photoshop 8.0 (Adobe, Mountain View, CA, United States) was used to construct and display the figures made from digital photos.

RESULTS

Clinical

Body weight, food intake, feces, mental status as well as mortality were recorded every 12 h. Of the average values in the control group, body weight, food intake, feces, mental status and death showed a wider band change from 12 to 24 h, this index showed a narrower band change from 24 to 72 h. Mean body weight, food intake, feces, mental status and death in the four different obstructed groups showed significant changes with persistent loss or gain ($P < 0.01$). The general condition of the rats is shown in Table 3.

Macroscopic and histological evaluation

The rings were placed on the ileum 20 mm oral to the ileocecal sphincter, which resulted in visible intestinal damage 12 to 72 h after surgery. In the control rats, no marked gross morphological changes in the intestine were observed (Figure 1A). However, morphological observation of the intestines revealed adhesions, stenosis, ulceration and bowel wall thickness of the rings to varying degrees in the rats with obstruction. In addition, flushing, tumefaction of intestinal mucosa, hyperemia and hemorrhage of bowel wall and stasis of bowel contents from the proximal region to the site of the ring were noted (Figure 1B-E). Figure 1F shows analytical data of the total scores of intestinal damage following macroscopic evaluation in obstructed and control rats.

The histological findings in ileal tissues are presented in Figure 2. No marked changes were observed in the control rats (Figure 2A). Histological observation of the intestines showed some features (including ulceration, inflammation, fibrogenesis and extent of involved bowel wall) of obstruction to varying degrees. As shown in Figure 2B-E, ulceration in the mucosa and submucosa, mucosal edema and inflammation, vascular congestion with focal hemorrhage from the mucosa to the muscular layer and even the serosa, occasional fibrogenesis, and infiltration of polymorphonuclear cells, plasma cells and neutrophils were observed. Figure 2F shows analytical data of the total scores of intestinal damage following histological evaluation and the scores of histological mucosal damage in obstructed and control rats. In the obstructed intestine, there was a marked increase in the thickness of the muscle layers. However, no apparent inflammatory changes, such as marked leucocyte infiltration of the tunica muscularis, were observed.

Circumference and wet weight of the intestine

After removing the intestine, 3 cm dilated intestinal segments were blotted with filter paper and weighed on an analytical balance. The sections were cut longitudinally and the circumference was measured at three sites. The average values for the ileal wet weight (Figure 3A) and ileal circumference (Figure 3B) in the dilated portion of the obstruction rat tissue were significantly larger ($P < 0.01$) than those in the corresponding portion of the controls.

Ileal contractility

We examined the contractile response of the obstructed and control rats, and the study was evaluated in terms of absolute force (mN per mg tissue wet weight). We also examined spontaneous contractile activity of the intestinal segments using isometric force measurements. Figure 4A-B shows the typical spontaneous contractile activity of the dilated intestine isolated from obstructed and control rats, which demonstrated that the slow form of the intestinal segments from control rats was regular; in contrast, the slow form of the intestinal segments from the obstructed rats at 12 to 72 h was attenuated and irregular to varying degrees. Analytical data of the intestinal transit ratio were obtained at four different time points and are shown in Figure 4C.

Autonomic nerve electrical discharge

Typical autonomic electrical activity of the vagus nerve was determined in obstructed and control rats *in vivo*, which indicated that the slow form of the vagus nerve autonomic electrical discharge in control rats was normal (Figure 5A); however, the slow form in obstructed rats at 12 to 72 h was attenuated and irregular to varying degrees (Figure 5B-C). At various time points, the obstructed group showed significant differences in nerve electrical discharge frequency and amplitude compared with the control group ($P < 0.01$). When the four groups were compared, the differences in the wide pipe group appeared to be most obvious, followed by the braided silk group, the half ligation and the narrow pipe group.

Ileum myoelectricity

The myoelectric changes in the ileum of each rat were determined (Figure 6A). The intestinal segments from the control rats did not show significant differences at the various time points, and the slow form was regular. In contrast, the obstructed rats showed significant reductions in vagus nerve electrical discharge frequency and amplitude ($P < 0.01$), the reduction in the wide pipe group was most obvious, followed by the braided silk group, the half ligation and the narrow pipe group. The

waveform of the dilated intestinal segment at 12 to 72 h was irregular to varying degrees and the appearance of a notching wave resembled a sine curve. The amplitude of the slow waves in the different groups was compared and is shown in Figure 6C. Amplitude and frequency values of the slow waves were significantly different in the obstructed group compared with the control group (both $P < 0.01$). Slow-wave amplitude was significantly reduced ($P < 0.01$) at all sites tested after surgery compared with the control rats. Frequency was reduced only at 72 h at the obstructed sites (Figure 6B).

ICC networks in the intestine

ICC networks are widely distributed within the submucosal (ICC-SM), intramuscular (ICC-IM, ICC-DMP) and inter-muscular layers (ICC-MY)[11,12]. Interestingly, the ICC-MY play an important role in the myenteric plexus and are characteristic of intestinal ICC. The control rats exhibited a dense network in the ICC-MY region of intestinal tissue from 12 to 72 h (Figure 7A), whereas the ICC-MY appeared to be greatly disrupted or absent in the obstructed rat tissue (Figure 7B-E). Analysis of c-Kit-like immunopositive cells in the obstructed rats showed that the immunopositive cells were significantly decreased compared with control animals.

DISCUSSION

An animal model is a reliable method of studying disease mechanisms and to test the effectiveness of a variety of therapeutic measures. Although the pathogenesis of intestinal obstruction is known, complete simulation of the pathology to establish an animal model of incomplete intestinal obstruction is difficult. In recent years, a number of studies have been published, such as that conducted by Chang *et al*[3], where the authors established incomplete intestinal obstruction in a mouse model by placing a polyethylene clip onto the intestine. The morphological and electrophysiological changes which occurred proximal to the site of the clip were investigated. Won *et al*[13] used a silicon tube to partially obstruct the ileum, and observed changes in intestinal contractility associated with the immunologically activated components.

In the present study, all rings were successfully placed to produce incomplete obstruction of the ileum. 12 to 72 h after obstruction, daily behavior did not significantly change in the control group, however, different daily behaviors were seen in the rats with intestinal obstruction (Table 3). In the obstructed rats, a significant reduction in body weight was observed ($P < 0.01$), which was most obvious in the narrow pipe group followed by the

(scale bar: 20 μm).

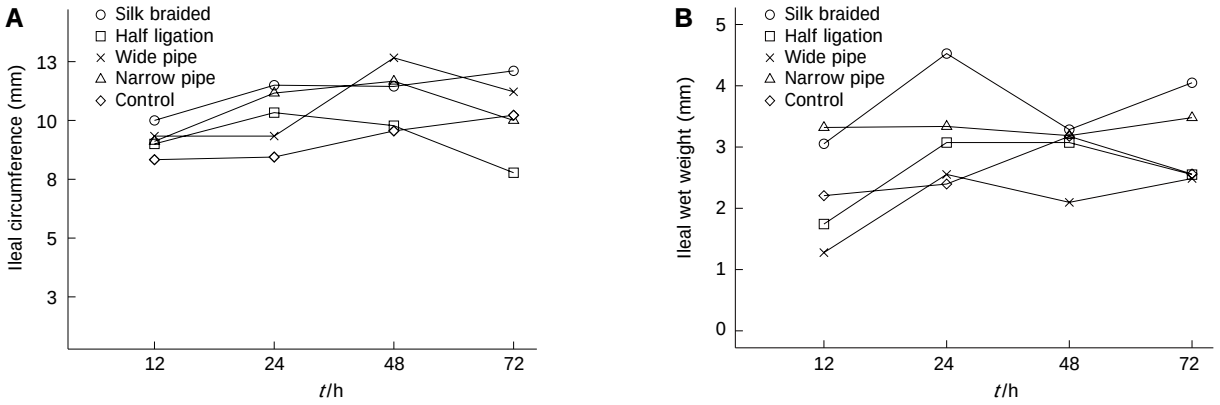

Figure 3 Average ileal wet weight and circumference in the obstructed and control rats. A: The average values for the ileal circumference in the dilated portion of the obstruction rat tissue were significantly larger than those in the corresponding portion of the controls ($P < 0.01$); B: In the obstructed intestine, there was a marked increase in the wet weight due to thickening of the muscle layers. When the groups were compared, these increases were most obvious in the braided silk group, followed by the wide pipe, the narrow pipe group and the half ligation group.

half ligation group, the braided silk group and then the wide pipe group which showed a slight decrease at 12 h, but gradually increased from 24 to 72 h. With regard to food intake and feces, these increased in the narrow pipe and half ligation groups compared with the controls. In contrast, the braided silk and wide pipe groups showed significant changes with varying degrees of weight loss or gain ($P < 0.01$). The mental status of the controls, narrow pipe and half ligation groups was good or moderate, however, the braided silk and wide pipe groups displayed the opposite status. Although not statistically significant, the number of deaths was lowest in the control rats. Deaths due to obstruction were higher in the controls, followed by the narrow pipe group the braided silk group, the half ligation group and the wide pipe group. These findings show that the braided silk and wide pipe established the incomplete intestinal obstruction model more successfully, with fewer deaths, than the other models.

Consistent with the findings in other reports[3-6,13-15], the changes in the extent and severity of adhesions, stenosis, ulceration and bowel wall thickness in the obstructed and control rats were assessed using the total scores of intestinal damage following macroscopic evaluation (Figure 1F). The controls (Figure 1A) showed slight intestinal wall thickness and no evidence of intestinal damage. In contrast, obstructed rats showed flushing, tumefaction of intestinal mucosa, hyperemia and hemorrhage of bowel wall and stasis of bowel contents to varying degrees from the proximal region to the site of the ring compared with control rats (Figure 1B-E). Statistically significant differences in the scores of intestinal damage were observed in obstructed rats compared with the controls ($P < 0.01$). Intestinal damage due to the braided silk and narrow pipe was serious as time passed, especially stenosis and ulceration. The half ligation and wide pipe groups showed medium damage at 12 to 72 h.

Some studies reported that intestinal wet weight and circumference were able to reflect the degree of dilation and increased weight of the intestine[15-16], therefore, we

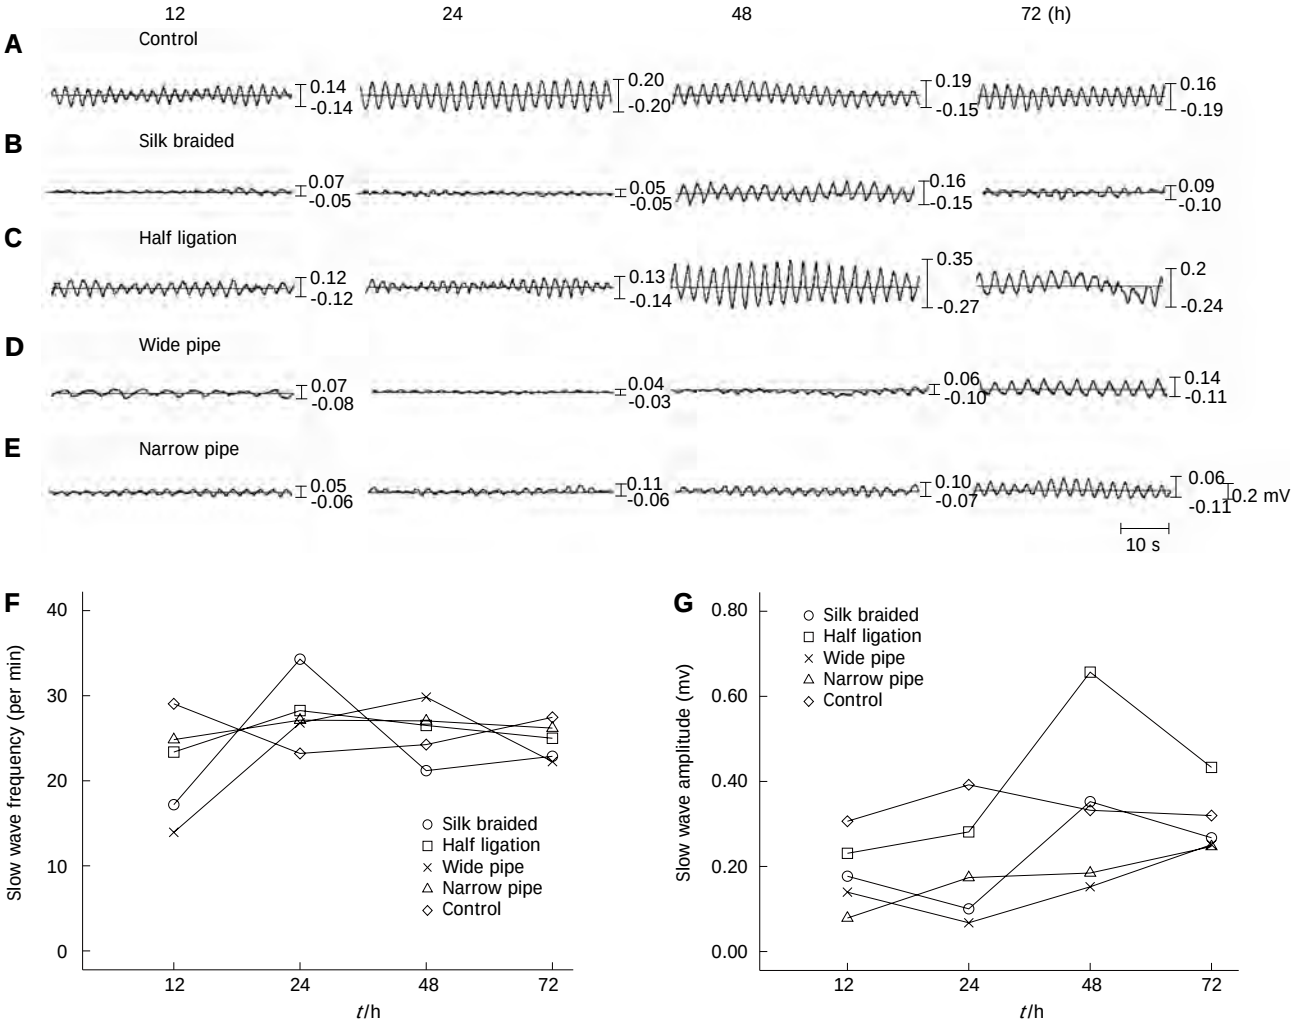

Figure 6 Change in pacemaker activity in the ileum. Typical intracellular electrical activity (slow waves) recorded in the small intestine of control rats and at 12-72 h at the site of intestinal obstruction. A: Control; B: Braided silk; C: Half ligation; D: Wide pipe; E: Narrow pipe; F: Data on slow wave frequency in normal functioning tissue away from the obstruction site; G: Slow-wave amplitude was markedly reduced near the site of obstruction and increased in amplitude in normal functioning tissue away from the obstruction site.

measured the wet weight and circumference of ileum 3 cm distal to the obstruction. In the *in vivo* study, ileal wet weights of the braided silk tissue in the dilated portion were significantly greater ($P < 0.01$) when compared with the controls (Figure 3B). The magnitude of this increase was reduced in the narrow pipe group. In contrast, other obstructed rats showed a decrease compared with those in the corresponding portion of the controls. The ileal circumference showed a negligible increase in both the obstructed and control groups (Figure 3A).

In accordance with the above findings, we speculated that the braided silk and wide pipe models would be useful in the clinic. Therefore, we evaluated the photomicrographs of tissues stained with hematoxylin and eosin (Figure 2), and found that all rats with intestinal obstruction showed ulceration of the mucosa and submucosa, and vascular congestion with focal hemorrhage in the entire tissue layer. In addition, mucosal edema and inflammation were found in the wide pipe and narrow pipe groups, and occasional fibrogenesis in the half ligation, wide pipe and narrow pipe groups at later time periods. Compared with the control rats (Figure 2A), the dilated intestinal region of obstructed rats (Figure 2B-E) showed infiltration of polymorphonuclear cells, plasma cells and neutrophils. A comparison of these scores in the obstructed rats showed that they were significantly different from each other ($P < 0.01$), and the scores were increased in obstructed rats compared with control rats (Figure 2F). Therefore, the braided silk and wide pipe models may better simulate intestinal obstruction found in the clinic.

In the *in vitro* experiments, the braided silk and wide pipe groups demonstrated reduced ileal contractility compared with the controls, the narrow pipe group demonstrated a moderate reduction, and the half ligation group demonstrated an increase in ileal contractility (Figure 4A-B). We observed that the basic spontaneous mechanical contraction activities of dilated intestine *in vivo* and *in vitro* were significantly reduced ($P < 0.01$). The transit ratio in obstructed rats was less than that in con-

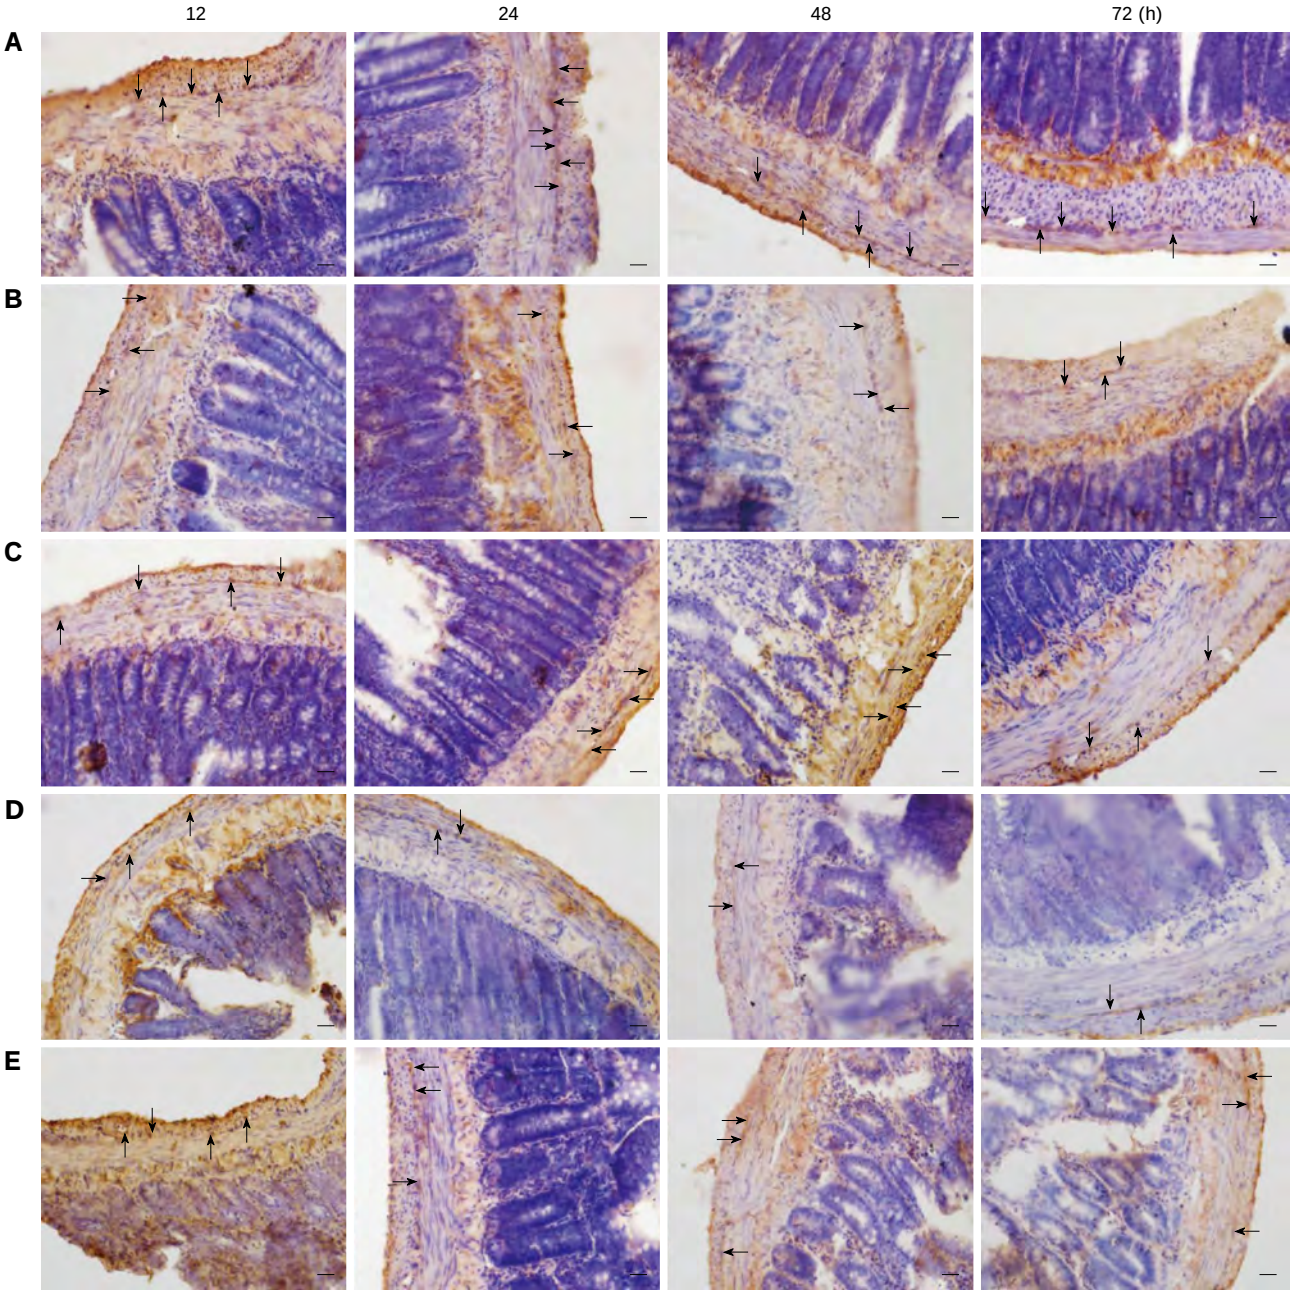

Figure 7 Immunohistochemistry of c-Kit positive interstitial cells of Cajal (arrow) in whole mount preparations of ileum in the obstructed and control rats. Each panel shows c-Kit positive interstitial cells of Cajal at different times (scale bar: 20 μm).

trols, especially in the braided silk group, and the other obstructed groups showed a smaller reduction in the transit ratio. In contrast to the *in vitro* approach, these *in vivo* studies showed that the incomplete intestinal obstruction models using braided silk and wide pipe were better than the other models, particularly with regard to influence on intestinal movement capability (Figure 4C). These findings are similar to those of Huizinga *et al*[17] who demonstrated that there was a close relationship between intestinal transit and myogenic mechanisms, and indicated that electrical and mechanical activities can influence each other.

Cheng *et al*[18] reported that intestinal motility is an autonomic rhythmic activity under normal circumstances, which is regulated by nerves, hormones and other factors. The autonomic nervous system plays an important role in the regulation of intestinal motility rhythm. External innervation of the intestinal tract is mainly by the vagus nerve, and the sympathetic nerves play a role in balance and coordination[19,20]. In the present study, we compared nerve electrophysiological activity in different models of intestinal obstruction in rats (Figure 5A), to determine the vagus nerve autonomic electrical discharge which represents changes in the complex enteric nervous system. The frequency and amplitude of vagus nerve autonomic electrical discharge in control rats were

normal and rhythmic. Those in the wide pipe group were irregular, moderate in the braided silk group, and were normal at each time point in the half ligation and narrow pipe groups (Figure 5B-C). These results demonstrated that the wide pipe can be used successfully to establish a model of incomplete intestinal obstruction in rats.

Considering the possible link between spontaneous mechanical contraction activities and the slow wave of dilated intestine *in vivo* and *in vitro*[17,21], we investigated the waveform and reflected frequency and amplitude of the slow wave in different rats (Figure 6A). We found that the waveform in the wide pipe group resembled a sine curve and showed a notching wave which was irregular at 12 to 72 h. The half ligation group showed no obvious change in the waveform compared with the controls. Peak amplitudes in the braided silk and narrow pipe groups demonstrated different degrees of weakening. In this study, we also found a close relationship between frequency (Figure 6B) and peak amplitudes (Figure 6C) in the vagus nerve electrical discharge at baseline and intestinal motility. This suggested that the wide pipe model may be similar to human incomplete intestinal obstruction.

It is well known that slow waves are relatively regular periodic electrical activities and the basis of intestinal smooth muscle action potentials. In earlier research, we found that the frequency and amplitude of slow wave propagation were reduced in ileac muscles[6]. Other studies[3,22] showed that myoelectrical rhythm is irregular and the slow waves decrease. In this study, the waveform and reflected frequency and amplitude of the slow wave in control rats were normal. Those in the wide pipe group were irregular, were moderate in the braided silk group, and were normal in the half ligation and narrow pipe groups at 12 to 72 h (Figure 6). These results suggest that slow wave abnormalities are responsible for intestinal motility dysfunction.

In our previous intestinal studies, we observed that the enteric nervous system (ENS) - ICC - smooth muscle cell (SMC) network constitute the basic functional unit of gastrointestinal motility and has an important relationship with spontaneous rhythmic activity[12,14,17-18,23]. We supposed that the wide pipe group abolished the propulsive peristaltic waves in the dilated intestine compared with the other obstructed groups, which caused a significant disturbance in spontaneous rhythmic contractions of intestinal smooth muscle. In smooth muscle, there are several factors which increase the frequency of contraction, such as increased pacemaker activity and shortened action potential[24].

It has been previously shown that ICC are regarded as the pacemaker cells of the gastrointestinal (GI) tract[25-28], which suggests that ICC may play a role in GI motility. In order to compare the differences in obstructed rats, and to identify the mutual influence between the ENS-ICC-SMC networks, we investigated the distribution of ICC in intestinal tissue using light microscopy.

Another interesting observation from this study was that, in the wide pipe group the increase in intestinal contractility was closely related to a reduction in the number of ICC and slow wave, which was different in the other obstructed groups. In addition, it was reported that a reduction in the frequency of rhythmic contractions was connected to the disruption of ICC in the dilated intestine of obstructed rats[29]. These findings confirmed those in our study (Figure 7). Therefore, it is likely that ICC lost their original cell phenotype, resulting in an increase in the number of smooth muscle cell-like cells, thereby improving contractility of the ileum. At the present time, we do not know the precise mechanisms underlying such alterations. Further study will be needed to clarify this point.

In conclusion, the results of the present study suggest that there are significant differences *in vivo* and *in vitro* among the four animal models of incomplete intestinal obstruction. The pathogenic mechanism and clinical features in the different models have essential distinctions. Despite being of a similar general condition, the rats in each group showed differences including macroscopic and histological presentation, intestinal transit ratio and contractility, circumference and wet

weight, amplitude and frequency of nerve electrical discharge and slow wave, and ICC numbers. These findings may allow use of the wide pipe to establish a model that is approximate to human incomplete intestinal obstruction. However, a detailed analysis of this is necessary based on the characteristics of the different models used in this study which can be used as a reference.

ACKNOWLEDGMENTS

We greatly thank Zhang Xiao of our department for their technical assistance with the present study.

COMMENTS

Background

Considering the impairment associated with incomplete intestinal obstruction, the use of animal models is now a focus in this research field, however, to date, no particular model parallels the complex nature of human intestinal obstruction.

Research frontiers

Animal have been used to establish incomplete intestinal obstruction models. However, animal models are not been widely used and research comparing the characteristics in different rat models is rare. In this study, the authors successfully established a reliable animal model and demonstrated that the wide pipe rat model is similar to human incomplete intestinal obstruction.

Innovations and breakthroughs

Recent reports have highlighted the need to establish a reliable animal model of intestinal obstruction. Different types of materials are currently available. This is the first experimental study to compare rat models of incomplete intestinal obstruction. Furthermore, the authors obtained electrophysiologic, morphologic and histologic information which may have some clinical relevance.

Applications

These findings may provide a valuable theoretical basis for selecting incomplete intestinal obstruction models with better feasibility and reproducibility.

Peer review

This is an animal model study which comprehensively demonstrates the results. Overall, it is suitable for publication.

Abstract

AIM: To compare the efficacy of modified percutaneous transhepatic variceal embolization (PTVE) with 2-octyl-cyanoacrylate (2-OCA) and endoscopic variceal obturation (EVO) with an injection of 2-OCA for prophylaxis of gastric variceal rebleeding.

METHODS: In this retrospective study, the medical records of liver cirrhosis patients with gastric variceal bleeding who underwent either endoscopic 2-OCA (EVO) or modified PTVE using 2-OCA at Shandong Provincial Hospital from January 2006 to December 2008 were reviewed. Patient demographics, rebleeding rate, survival rate, and complications were compared between the two groups (PTVE and EVO). All results were expressed as mean ± SD, or as a percentage. Quantitative variables were compared by two sample Student *t* tests, and qualitative variables were compared by the Fisher exact test or the χ^2 test (with Yates correction) where appropriate. A *P* value less than 0.05 was considered significant. Statistical computation was performed using SPSS 13.0 software.

RESULTS: A total of 77 patients were included; 45 patients who underwent EVO and 32 patients who received PTVE. During the follow-up (19.78 ± 7.70 mo in the EVO group, *vs* 21.53 ± 8.56 mo in the PTVE group) rebleeding occurred in 17 patients in the EVO group and in 4 patients in the PTVE group (37.78% *vs* 12.5%, *P* = 0.028). The cumulative rebleeding-free rate was 75%, 59%, and 49% in 1, 2, and 3 years respectively for EVO, and 93%, 84%, and 84% for PTVE (*P* = 0.011). Cox analysis was used to identify independent factors that predicted rebleeding after treatment. Variables including age, gender, cause, Child-Pugh classification, size of gastric varices (GV), location of GV, and treatment methods were analyzed. It was revealed that Child-Pugh classification [risk ratio (RR) 2.10, 95%CI: 1.03-4.28, *P* = 0.040], choice of treatment (RR 0.25, 95%CI: 0.08-0.80, *P* = 0.019), and size of GV (RR 2.14, 95%CI: 1.07-4.28, *P* = 0.032) were the independent factors for predicting rebleeding. Follow-up computed tomography revealed that cyanoacrylate was retained in the varices and in the feeding veins of PTVE patients. During the follow-up, eight patients in the EVO group and four patients in the PTVE group died. The cumulative survival rates at 1, 2, and 3 years were 93%, 84%, and 67% respectively in the EVO group, and 97%, 88%, and 74% respectively in the PTVE group. The survival rates were not significantly different between the two groups (*P* = 0.432). Cox analysis showed that the Child-Pugh classification was the most significant prognostic factor of survival (RR 2.77, 95%CI: 1.12-6.80, *P* = 0.027). The incidence of complications was similar in both groups.

CONCLUSION: With extensive and permanent obliteration of gastric varices and its feeding veins, PTVE with 2-OCA is superior to endoscopic 2-OCA injection for preventing gastric variceal rebleeding.

INTRODUCTION

Although the incidence of bleeding from gastric varices (GV) is lower than from esophageal varices (EV), once it occurs the outcome is worse, and with higher mortality[1-3]. After an episode of acute variceal bleeding, patients are at high risk for recurrent bleeding and death. Thus, prevention of recurrent bleeding is essential[4,5]. However, rupture from gastric varices, especially varices located in the gastric fundus, poses particular therapeutic challenges because of the location and rapid blood flow. The current treatment methods for gastric varices are far from ideal.

Endoscopic variceal obturation (EVO) with the injection of cyanoacrylate has been widely adopted and proved to be effective in the emergency hemostasis of bleeding from gastric varices since it was proposed in 1986[6]. At present, this method is the first-line treatment for gastric variceal bleeding recommended by Baveno IV consensus and AASLD guidelines[7,8]. However, the long-term rebleeding rate after endoscopic cyanoacrylate injection is still high[9-12]. Additionally, there is also a potential risk of systemic embolism in patients with underlying gastrorenal shunts, and other serious complications such as sepsis, fistula, and pericarditis[13-16].

Balloon-occluded retrograde transvenous obliteration (BRTO) has become the standard treatment for gastric varices in Japan. However, patients without catheterizable gastrorenal shunts cannot be treated by BRTO[17,18]. Therefore for these patients, percutaneous transhepatic variceal embolization (PTVE) with N-butyl-2-cyanoacrylate was introduced and showed satisfactory results[19,20] in a small series of patients.

Based on our previous reports of modified PTVE with 2-octyl cyanoacrylate (2-OCA) for bleeding EV[21,22], we have performed modified PTVE with 2-OCA to prevent gastric variceal rebleeding in recent years.

In this retrospective study, 77 patients with prior bleeding from gastric varices who underwent EVO or modified PTVE for prevention of rebleeding were analyzed. Rebleeding rate, survival, and complications were compared between these two procedures. To our knowledge, at the time of writing, no other report in the literature has compared these two procedures in the prevention of gastric variceal rebleeding.

MATERIALS AND METHODS

Patients

The medical records of liver cirrhosis patients with gastric variceal bleeding who underwent either endoscopic 2-OCA injection or modified PTVE using 2-OCA in our hospital from January 2006 to December 2008 were reviewed. Local ethics committee approval was obtained for the chart review.

The inclusion criteria: (1) diagnosis of liver cirrhosis by biopsy or clinical examination and imaging, including ultrasound, computed tomography (CT), or magnetic resonance imaging; (2) patient suffered bleeding within 6 mo before being admitted or acute bleeding with achieved hemostasis by pharmacological treatment; (3) endoscopically-confirmed bleeding from gastric varices: active spurting or oozing of blood from gastric varices during endoscopy, blood clot coating on gastric varices or the presence of erosive spots on gastric varices, with no other potential source of bleeding; and (4) patient aged between 20-65 years.

Exclusion criteria: (1) hepatocellular carcinoma or other malignancies; (2) a history of transjugular intrahepatic portosystemic shunt (TIPS), surgery, or endoscopic therapy for esophagogastric variceal bleeding; (3) portal vein thrombosis; or (4) infection.

Choice of treatment method was based on the patients' intentions after being given a sufficient explanation of the two treatment methods. Informed written consent was obtained from each patient.

Endoscopic injection procedure

Endoscopic intra variceal injection of 2-octyl cyanoacrylate (Baiyun Medical Adhesive Corporation, Guangzhou, China) was performed using a video endoscope (XQ230, Olympus Optical, Tokyo, Japan) and a 23-gauge disposable injection needle (Medwork Medical Products and Services GmbH). Each injection contained a 0.5-2.0 mL mixture of 2-OCA and Lipiodol (1:1). The injection was aimed at the varices that were either bleeding, possessed red color signs, or were the most prominent. Obliteration was assessed by blunt palpation with a catheter, and presence of hardness indicated a complete obliteration. If the varices remained soft, additional injections were done until all gastric varices became hardened. If necessary, additional injections of cyanoacrylate were performed 2-3 wk after the initial session.

PTVE procedure

PTVE was performed alone, or combined with left renal vein obstruction with a balloon catheter if a large gastrorenal shunt was present (Figure 1). Shortly after a percutaneous transhepatic puncture of the intrahepatic branch of the portal vein, a 5F cobra catheter (Cook,

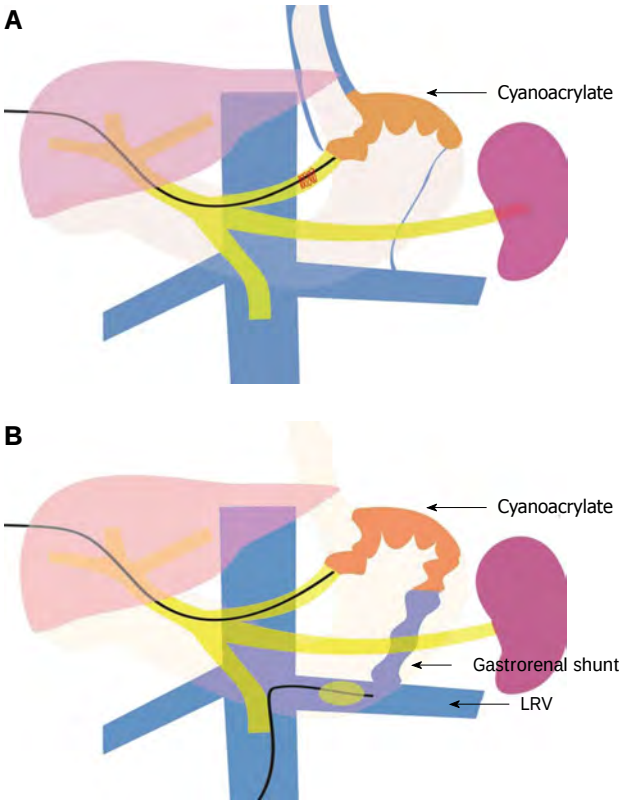

Figure 1 Illustrations of the two types of percutaneous transhepatic variceal embolization. A: Cyanoacrylate was directly injected into the gastric varices by percutaneous transhepatic variceal embolization (PTVE) alone in patients without large gastrorenal shunts; B: Cyanoacrylate injection with PTVE combined with a balloon catheter inserted into the left renal vein (LRV) in patients with large gastrorenal shunt.

Bloomington, IN) was inserted into the splenic vein and a splenoportography was performed to evaluate the gastric varices, the feeding veins, and draining veins. The main gastric feeding vein (*e.g.*, the left gastric vein, short gastric vein, or posterior gastric vein) was then selected with the 5F catheter, and a venography was performed to assess blood flow velocity and the size of varices (the gastrorenal shunt's size being of particular interest).

Based on these data, the embolization of 2-OCA was carried out in the following ways: (1) PTVE alone: In patients without large gastrorenal shunts, the blood flow in gastric varices was slow, and the contrast material could stay in the varices for more than 5 s after injection. In these patients, the cyanoacrylate was directly injected into the gastric varices; and (2) PTVE combined with left renal vein obstruction with a balloon catheter: In patients with large gastrorenal shunts, there was rapid blood flow in the varices and the contrast material disappeared within 3-5 s after injection. For these patients, a 6F balloon catheter (Cook, Bloomington, IN) with a diameter of 15 to 20 mm was inserted into the left renal vein via the right femoral vein to reduce the blood flow of the gastrorenal shunt and varices, and then the cyanoacrylate was injected. In these two ways, the cyanoacrylate could obliterate the entire varices and feeding veins, while cyanoacrylate migration to the systemic circulation could be avoided.

When the cyanoacrylate was flowing into all the gastric varices, the catheter was immediately withdrawn. Splenoportography was again performed to assess the obliteration of the varices. If other feeding veins (such as the short or posterior gastric veins) were present, the procedure would be repeated until the gastric varices and feeding veins were completely filled with cyanoacrylate. Finally, the 5F sheath system was withdrawn, and the puncture tract was embolized with microcoils. Low molecular heparin (100 IU/kg body weight, daily) was subcutaneously administered 24 h after the procedure for 5 to 7 d to prevent portal venous thrombosis.

Follow-up

Follow-up endoscopy was performed for the two groups at intervals of 1, 3, and 6 mo after the procedures, and then every 6-12 mo or when it was considered clinically necessary. In patients with rebleeding, endoscopy was performed to identify the cause of the bleeding. Portal venography was performed at 1 mo after the procedure, and every 6 mo thereafter with 3-dimensional multidetector row CT (GE Medical systems, Milwaukee, WI) to observe the formation of portal vein thrombosis, the location and extent of cyanoacrylate glue, variceal recanalization, and the occurrence of collateral vessels. Rebleeding, survival, and complications were recorded.

Recurrent bleeding was defined as the presence of hematemesis or melena, with the bleeding source being endoscopically proven to originate from gastric or EV, or other resources after the index treatment. Bleeding from gastric varices was distinguished from that of EV on the basis of whether active bleeding or erosive spots were present on the gastric varices themselves.

Complications were defined as any untoward events that required active treatment or prolonged hospitalization.

Statistical analysis

All results were expressed as mean ± SD, or as a percentage. Quantitative variables were compared by two sample Student *t* tests, and qualitative variables were compared by the Fisher exact test or the chi-squared test (with Yates correction) where appropriate. The Kaplan-Meier estimation was used to examine recurrence and rebleeding of gastric varices and rate of survival. Comparisons were performed using the log-rank test. A Cox's analysis was performed to detect possible independent predictors for variceal rebleeding and death. A P value less than 0.05 was considered significant. Statistical computation was performed using SPSS 13.0 software.

RESULTS

Demographic characteristics of patients

From January 2006 to December 2008, EVO or PTVE was performed in a total of 92 cirrhotic patients with a history of gastric variceal bleeding in Shandong Pro-

vincial Hospital. Of the 92 patients, six had hepatocellular carcinoma, and nine had previously received TIPS or shunt surgery; these 15 patients were excluded. Of the remaining 77 patients, EVO was performed in 45, and PTVE was performed in 32 (Figure 2). The clinical characteristics of the 77 patients in the two groups were retrospectively reviewed from a computerized database of our hospital. Gastric varices were subdivided by Sarin classification[4], the form of gastric varices was classified according to Hashizume classification[23], and liver function was estimated based on the Child-Pugh classification[24]. The follow-up records were carefully reviewed. The median follow-up period was 19.78 ± 7.70 mo (range, 3 to 41 mo) in the EVO group and 21.53 ± 8.56 mo (range, 6 to 44 mo) in the PTVE group (P = 0.350). Table 1 shows the patient characteristics in the two groups, for which there was no significant difference.

Technique outcomes

The outcomes of the procedures are shown in Table 2. In the EVO group, 35 patients (77.78%) achieved complete obliteration of gastric varices. Of the 35 patients, one session of EVO was needed to achieve complete obliteration in 23 patients, and two or three sessions were required in 12 patients. The total volume of cyanoacrylate used in the initial session of each EVO group patient was 3.03 ± 1.04 mL (range, 1.5-5.5 mL). In the PTVE group, 18 patients underwent gastric variceal embolization by PTVE alone, while the other 14 patients underwent combined PTVE with left renal vein balloon obstruction. Thirty patients (93.75%) achieved complete obliteration, which was confirmed by a splenoportography after the PTVE procedure. The volume of cyanoacrylate used in

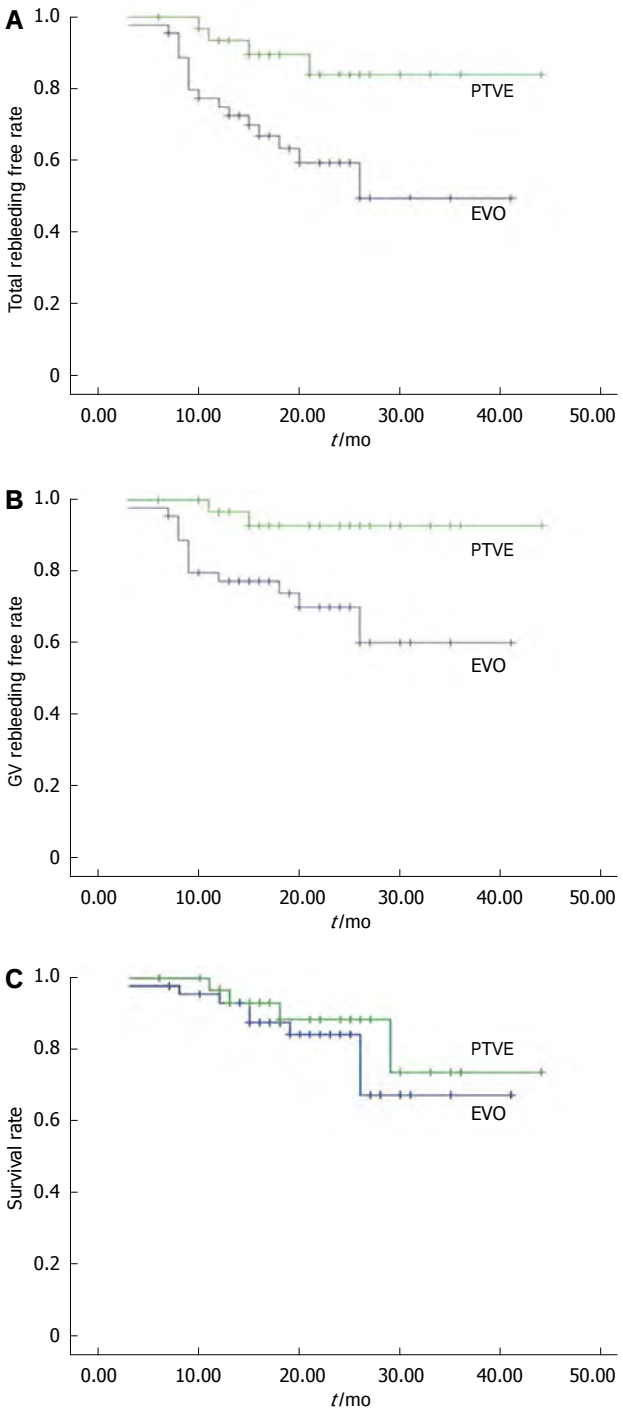

Figure 3 Cumulative survival. A: The cumulative rebleeding free rate was higher in the percutaneous transhepatic variceal embolization (PTVE) group than in the endoscopic variceal obturation (EVO) group, $P = 0.011$, log-rank test; B: The cumulative free gastric varix (GV) rebleeding rate was higher in the PTVE group than in the EVO group, $P = 0.012$, log-rank test; C: The cumulative survival rate was not different between the two groups. $P = 0.432$, Log-rank test.

the PTVE group was 6.69 ± 2.92 mL (range, 3-16 mL); more than in the EVO group ($P = 0.000$).

Endoscopic surveillance

An endoscopic follow-up was performed in all patients in both groups. Generally, 1-3 mo after the injection, the cyanoacrylate plug began to slough off the submucosa in some patients, and the varices disappeared or collapsed after complete or partial expulsion of the glue within one year in the PTVE group. In patients who underwent EVO, the endoscopic findings were similar to that in the PTVE group. During the endoscopic follow-up, the gastric varices disappeared in 16 patients or shrunk in 12 patients in the PTVE group, and disappeared in 17 patients or shrunk in 16 patient in the EVO group ($P = 0.290$).

CT and portal venography follow-up

Twenty patients in the EVO group and fifteen patients in the PTVE group underwent contrast-enhanced CT and portal venography during follow-up. In the PTVE group, it was confirmed that the gastric varices, the perforating veins in the fundus, the perifundus veins, and all the feeding veins were filled with cyanoacrylate 1 mo after the procedure. 3-6 mo after PTVE, the amount of cyanoacrylate in the submucosal varices was reduced compared to previously. Twelve months later, the cyanoacrylate in the submucosal varices almost completely gone, but the cyanoacrylate in the perifundus varices and feeding veins remained the same as at the start. Portal venography showed that there was no blood flow in the eradicated varices with sufficient amount of cyanoacrylate after one year. In the EVO group, CT revealed that the cyanoacrylate was only scattered in the gastric varices and the perifundus varices, which was not as extensive and complete as in the PTVE group.

Rebleeding

During the follow-up, rebleeding occurred in 17 patients (37.78%) in the EVO group and four patients (12.5%) in the PTVE group. The rebleeding rate was significantly lower in the PTVE group compared to the EVO group ($P = 0.028$). The cumulative rebleeding-free rate was 75%, 59%, and 49% in 1, 2, and 3 years respectively for the EVO group, and 93%, 84%, and 84% for the PTVE group ($P = 0.011$, Figure 3A).

The causes of rebleeding included: gastric variceal rebleeding (13 in EVO and 2 in PTVE), aggravated esophageal variceal bleeding (2 in EVO and 1 in PTVE), portal hypertensive gastropathy (1 in EVO and 1 in PTVE), and unknown reasons (1 in EVO and nil in PTVE). The cumulative rate free of GV rebleeding at 1, 2, and 3 years was 77%, 70%, and 60% respectively for the EVO group, and 97%, 93%, and 93% for the PTVE group ($P = 0.012$, Figure 3B). Of the 15 patients with rebleeding from GV, three died of uncontrolled bleeding, four received repeated EVO, three received TIPS, and five received surgery. No patient died of bleeding from EV or other sources.

Cox analysis was used to identify the independent factors that predicted rebleeding after treatment. Variables including age, gender, cause, Child-Pugh classification, size of GV, location of GV, and treatment methods were analyzed. It was revealed that the Child-Pugh classification (RR 2.10, 95%CI: 1.03-4.28, $P = 0.040$), choice of treatment (RR 0.25, 95%CI: 0.08-0.80, $P = 0.019$), and size of GV (RR 2.14, 95%CI: 1.07-4.28, $P = 0.032$) were

the independent predicting factors for rebleeding.

Survival

During the follow-up, eight patients in the EVO group and four patients in the PTVE group died. The cumulative survival rates at 1, 2, and 3 years were 93%, 84%, and 67% respectively in the EVO group, and 97%, 88%, and 74% respectively in the PTVE group. The survival rates were not significantly different between the two groups (P = 0.432, Figure 3C). In the EVO group, five patients died of progression of hepatic failure, compared with three patients in the PTVE group. Two patients in the EVO group and one in the PTVE group died of uncontrolled rebleeding. The remaining patient in the EVO group died of hepatocellular carcinoma, which occurred after the procedure.

Seven variables (sex, age, the Child Pugh classification, etiology, choice of modality, form of GV, and location of GV) were taken into consideration in the multivariate analysis using the Cox regression model. Based on the Cox analysis, the Child-Pugh classification was the most significant prognostic factor of survival (RR 2.77, 95%CI: 1.12-6.80, P = 0.027).

Complications

Complications of the procedures are shown in Table 3. Twenty-nine patients experienced complications in the EVO group, compared to twenty-two patients in the PTVE group (P = 0.881). There was no significant difference between the groups. The common complications after treatment were fever and abdominal pain. 19 patients in the EVO group and 12 patients in the PTVE group suffered from fever (P = 0.857). Abdominal pain was encountered in 12 patients in the EVO group and 15 patients in the PTVE group (P = 0.112). The patients were treated with conventional medicinal therapy, with fever and abdominal pain usually being alleviated within 1-2 wk. One patient in the EVO group encountered pulmonary embolism, while no patient encountered systemic embolization in the modified PTVE group (P=1.000). Mild to moderate ascites appeared in 3 patients in the EVO group and 6 in the PTVE group (P = 0.152), and all of them were controlled by medication. Partial portal vein thrombosis appeared in two patients in the PTVE group, but the portal vein was patent under Doppler ultrasound. No patient died of complications in either group.

DISCUSSION

Although gastric varices tend to bleed less than EV, the mortality associated with gastric variceal hemorrhage is substantial[1-3] (Kim, 1997 #5; Sarin, 1992 #4; Ryan, 2004 #6) (Kim, 1997 #5; Sarin, 1992 #4; Ryan, 2004 #6). Furthermore, with the successful management of bleeding EV, as well as successful prophylaxis of first bleeding from EV, "secondary" gastric varices develop in 9% to 15% of patients, which have a higher frequency of bleeding compared with primary gastric varices[1,23]. Unlike EV, gastric varices pose particular therapeutic challenges because of their size and location. Standard endoscopic therapies used for EV, such as sclerotherapy and band ligation, are less effective for gastric varices and have been shown to be associated with high complication rates[6,7]. This leads to the need for more aggressive and costly interventions, such as TIPS and BRTO, however each has its limitations. The current methods for the treatment of gastric varices are far from ideal.

EVO with the injection of agents such as N-buyt1-2-cyanoacrylate for the treatment of GV has been widely adopted, and both the immediate and long-term efficacies have been confirmed in the treatment of GV[25-28]. However, the long-term rebleeding rate after EVO was still high[9-12]. Incomplete obliteration and recurrence of varices are considered to be important causes of rebleeding[29]. However, the unobliterated components of the GV are sometimes small, and a further intraluminal injection might be difficult due to the previously injected polymers. In such circumstances, GV obliteration might not be complete. Over time, the residual GV can become larger, and rebleeding can occur. Incomplete obliteration and recurrence of varices are considered to be important causes of rebleeding[9]. Additionally, although rare, fatal complications do occur[13-16].

PTVE with cyanoacrylate is a modified procedure of the classical percutaneous transhepatic obliteration[30-32]. Though this novel technique was used only in a small number of patients with gastric varices and without gastrorenal shunts who were not candidate for BRTO[19,20], it started a new treatment method for gastric varices. In recent years, based on the good results of modified PTVE with 2-OCA in the treatment of EV reported in our previous study[21,22], we introduced 2-OCA in modified PTVE to treat gastric varices. In this retrospective study, we compared modified PTVE with an endoscopic injection using 2-OCA in the management of gastric varices. Despite the retrospective nature of the study, there were no significant differences in age, sex, cause of disease, or severity of liver disease between the studied patients.

In our study, the rebleeding rate of EVO was 37.8%, while it was only 12.5% in patients who underwent

PTVE with cyanoacrylate. This showed that PTVE with 2-OCA was superior to endoscopic 2-OCA injection with respect to preventing rebleeding. Regarding the risk factors of variceal rebleeding, it was revealed that liver function, size of GV, and treatment methods were independent factors that predicted the rebleeding risk of GV. Although the rebleeding rate of GV was lower in patients who underwent PTVE, this did not yield a decreased mortality compared with patients in the EVO group. Cox analysis showed the liver function in the Child-Pugh classification was the most significant factor.

There are two technical superiorities of PTVE over EVO, which may contribute to the lower variceal rebleeding rate of PTVE. The first is that PTVE can achieve a more extensive obliteration area than EVO. In the present study, with regards to the PTVE procedure, 2-OCA was injected into entire gastric varices, perforating veins in the fundus and perigastric veins, including all the feeding veins in most of the patients (30/32, 93.75%). In the EVO procedure, although we tried to achieve complete obliteration in one session, some patients needed repeated injections, and even then, the obliteration rate was only 77.7%. Contrast CT follow-up showed that the PTVE could obliterate all collaterals in the vicinity of the gastric fundus over a wider area and in deeper layers compared with EVO. Adequate 2-OCA injection is important for complete variceal obliteration. In our study, more cyanoacrylate was used in the PTVE procedure than in EVO, which also indicates a wider obliteration range in the PTVE group. The second technical superiority of PTVE over EVO is that 2-OCA can be permanently embolized in perforating veins in the fundus and perigastric veins, including all its feeding veins. In our study, follow-up endoscopy and CT scans showed that the cyanoacrylate in the submucosa could be released with time, and lead to the eradication of the varices after PTVE. However, CT scans revealed that the 2-OCA still stayed in the perifundus varices and perforating veins in the gastric fundus and all the afferent veins during follow-up. This might explain why PTVE achieved long-term obliteration, and prevented recanalization and rebleeding of gastric varices.

Complications were similar in patients who underwent EVO or modified PTVE. Fever and abdominal pain were the two common complications in both groups. They were given conventional treatment and the fever and abdominal pain were usually alleviated within 1-2 wk. Six patients in the PTVE group and three in the EVO group experienced mild to moderate ascites. They were given diuretics and or albumin transfusion, and no patients experienced refractory ascites. Partial portal vein thrombosis presented in two patients in PTVE group, but the portal vein was patent under Doppler ultrasound without serious consequences. In the present study, one patient in the EVO group encountered pulmonary embolism. However, no patient encountered systemic embolization in the modified PTVE group. The modification of PTVE contributed to this satisfactory result. Firstly, in patients without a large gastrorenal shunt, the blood flow in the gastric varices was slow, so there was enough time for 2-OCA to obliterate the varices, and it was unlikely that the tissue glue would migrate into the systemic circulation. Therefore, the 2-OCA could be injected into the gastric varices with percutaneous transhepatic variceal embolization alone. Secondly, in patients with a large gastrorenal shunt and rapid blood flow in the gastric varices, percutaneous transhepatic embolization combined with left renal vein balloon catheter obstruction was performed to prevent systemic embolization.

Some authors tried to obliterate the afferent vein of the gastric varices using TIPS combined with embolotherapy[33]. However, TIPS for gastric varices is not as effective as that for EV; moreover, stent failure and hepatic encephalopathy also limit its application[34-36]. BRTO embolized the gastric varices through the outflow vein (the gastrorenal shunt), and it is recognized as a safe and effective treatment for gastric varices with a gastrorenal shunt. However, patients without a catheterizable gastrorenal shunt are not suitable for BRTO. In our study, even in patients with a large gastrorenal shunt, the embolization was still performed by PTVE, in which the gastric varices were embolized through the inflow veins, such as the left gastric vein, short gastric vein and/or posterior gastric vein. We suppose that PTVE could achieve a more extensive obliteration range than BRTO. As antegrade transcatheter embolization, PTVE with 2-OCA could embolized the entire gastric varices and all its inflow veins (left gastric vein, short gastric vein and/or posterior gastric vein). But BRTO variceal embolization is performed by gastrorenal shunt (outflow vein), in which the inflow veins perhaps could not be completely embolized.

In conclusion, with extensive and permanent obliteration of both gastric varices and its feeding veins, PTVE with 2-OCA is a prospective modality for the treatment of gastric varices. It is superior to endoscopic 2-OCA injection in terms of preventing rebleeding. However, our study is a retrospective single-center study. A future prospective, randomized, and controlled trial is required.

COMMENTS

Background

Although gastric varices tend to bleed less than esophageal varices (EV), the mortality associated with gastric variceal hemorrhage is substantial. Unlike EV, gastric varices pose particular therapeutic challenges because of their size and location. The current methods for the treatment of gastric varices are far from ideal.

Research frontiers

At present, endoscopic variceal obturation with the injection of agents such as N-butyl-2-cyanoacrylate is the first-line treatment for gastric variceal bleeding. However, the unobliterated components of the gastric varices (GV) are sometimes small, and a further intraluminal injection might be difficult due to the previously injected polymers. In such circumstances, GV obliteration might

not be complete. Over time, the residual GV can become larger, and rebleeding can occur. Incomplete obliteration and recurrence of varices are considered to be important causes of rebleeding.

Innovations and breakthroughs

Percutaneous transhepatic variceal embolization (PTVE) with cyanoacrylate is a modified procedure of the classical percutaneous transhepatic obliteration. With GV, the perifundus veins and all the feeding veins in the vicinity of the gastric fundus are sufficiently obliterated with cyanoacrylate. PTVE with 2-octyl-cyanoacrylate (2-OCA) can improve long-term efficacy by preventing gastric varices rebleeding. In this retrospective study, the authors compared modified PTVE with endoscopic injection using 2-OCA in the management of gastric varices.

Applications

With extensive and permanent obliteration of both GV and its feeding veins, PTVE with 2-OCA is a prospective modality for the treatment of GV. It is superior to endoscopic 2-OCA injection in terms of preventing rebleeding.

Peer review

The authors report their results of a retrospective control study: modified PTVE with 2-OCA and endoscopic variceal obturation with the injection of 2-OCA for prophylaxis of gastric variceal rebleeding. Important data including the rebleeding rate, survival rate, complications, and prognostic predictors were reported. This study indicates that PTVE with 2-OCA can be a better option for secondary prophylaxis of the gastric variceal hemorrhage. However, given the small sample size and retrospective nature of this study, their results may not be representative of the broader population of patients with gastric variceal and a future prospective, randomized, and controlled trial is required.

Abstract

AIM: This study analyzed clinical long-term outcomes after endoscopic therapy, including the incidence and treatment of relapse.

METHODS: This study included 19 consecutive patients (12 male, 7 female, median age 54 years) with obstructive chronic pancreatitis who were admitted to the 2nd Medical Department of the Technical University of Munich. All patients presented severe chronic pancreatitis (stage Ⅲ°) according to the Cambridge classification. The majority of the patients suffered intermittent pain attacks. 6 of 19 patients had strictures of the pancreatic duct; 13 of 19 patients had strictures and stones. The first endoscopic retrograde pancreatography (ERP) included an endoscopic sphincterotomy, dilatation of the pancreatic duct, and stent placement. The first control ERP was performed 4 wk after the initial intervention, and the subsequent control ERP was performed after 3 mo to re-evaluate the clinical and morphological conditions. Clinical follow-up was performed annually to document the course of pain and the management of relapse. The course of pain was assessed by a pain scale from 0 to 10. The date and choice of the therapeutic procedure were documented in case of relapse.

RESULTS: Initial endoscopic intervention was successfully completed in 17 of 19 patients. All 17 patients reported partial or complete pain relief after endoscopic intervention. Endoscopic therapy failed in 2 patients. Both patients were excluded from further analysis. One failed patient underwent surgery, and the other patient was treated conservatively with pain medication. Seventeen of 19 patients were followed after the successful completion of endoscopic stent therapy. Three of 17 patients were lost to follow-up. One patient was not available for interviews after the 1st year of follow-up. Two patients died during the 3rd year of follow-up. In both patients chronic pancreatitis was excluded as the cause of death. One patient died of myocardial infarction, and one patient succumbed to pneumonia. All three patients were excluded from follow-up analysis. Follow-up was successfully completed in 14 of 17 patients. 4 patients at time point 3, 2 patients at time point 4, 3 patients at time point 5 and 2 patients at time point 6 and time point 7 used continuous pain medication after endoscopic therapy. No relapse occurred in 57% (8/14) of patients. All 8 patients exhibited significantly reduced or no pain complaints during the 5-year follow-up. Seven of 8 patients were completely pain free 5 years after endoscopic therapy. Only 1 patient reported continuous moderate pain. In contrast, 7 relapses occurred in 6 of the 14 patients. Two relapses were observed during the 1st year, 2 relapses occurred during the 2nd year, one relapse was observed during the 3rd year, one relapse occurred during the 4th year, and one relapse occurred during the 5th follow-up year. Four of these six patients

received conservative treatment with endoscopic therapy or analgesics. Relapse was conservatively treated using repeated stent therapy in 2 patients. Analgesic treatment was successful in the other 2 patients.

CONCLUSION: 57% of patients exhibited long-term benefits after endoscopic therapy. Therefore, endoscopic therapy should be the treatment of choice in patients being inoperable or refusing surgical treatment.

Weber A, Schneider J, Neu B, Meining A, Born P, von Delius S, Bajbouj M, Schmid RM, Algül H, Prinz C. Endoscopic stent therapy in patients with chronic pancreatitis: A 5-year follow-up study. *World J Gastroenterol* 2013; 19(5): 715-720 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/715.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.715

INTRODUCTION

The optimal treatment for chronic pancreatitis is controversial among surgeons and endoscopists. Endoscopic drainage procedures include optional sphincterotomy, stricture dilation, stone removal, and the insertion of a plastic stent. The surgical approaches are classified as drainage and resective procedures. Resective procedures, such as the duodenum-preserving head resections of Beger and Frey, provide good pain control and preserve pancreatic function[1]. Drainage procedures, such as the pancreaticojejunostomy, are comparable to endoscopic treatments because both of these procedures are based on the same pathophysiological idea. The primary goal is to restore pancreatic drainage to lower the pressure within the pancreatic duct and relieve pain[2-4]. Cahen *et al*[5] compared the clinical outcome of patients with endoscopic treatment and patients undergoing pancreaticojejunostomy in a prospective randomized trial. The authors concluded that surgical drainage of the pancreatic duct was more effective than endoscopic treatment. However, some patients are inoperable or refuse surgical treatment. Endoscopic therapy offers as an alternative approach for these patients. We reported previously that endoscopic therapy provided good immediate and short-term benefits to patients with obstructive chronic pancreatitis[6]. The current manuscript provides additional data from a 5-year follow-up to analyze clinical long-term outcomes after the successful completion of endoscopic therapy, including the incidence and treatment of relapse.

MATERIALS AND METHODS

Patients

This section is similar to our previously published 2-year follow-up study[6]. All patients presented severe chronic pancreatitis (stage Ⅲ°) according to the Cambridge classification[7] at the time of sphincterotomy and the majority of the patients (11/19) suffered intermittent pain attacks according to the Amman Score[8]. About 6 of 19 patients had strictures of the pancreatic duct; 13 of 19 patients had strictures and stones.

Methods

The first control endoscopic retrograde pancreatography (ERP) was performed 4 wk after stenting, and the subsequent control ERP was performed after 3 mo to re-evaluate the clinical and morphological conditions. Either a new stent was inserted, or stent therapy was terminated depending on the clinical and morphological conditions.

The long-term effects of stent therapy were analyzed after the successful completion of stent therapy. A short overview of the study protocol is illustrated in Figure 1. Follow-up analyses were conducted from 2004 to 2009. The ethical committee stated that the patient's choice of treatment was protected. Clinical parameters, such as pain and the intake of pain medication, were documented: (1) Prior to endoscopic therapy (time point 1); (2) During endoscopic therapy (time point 2); and (3) Annually during the 5-year follow-up period (time points 3, 4, 5, 6 and 7).

Interviews: The first interview was a two-part session that was conducted during stent therapy. This interview analyzed the technical success of ERP and compared the pain situation prior to and after initial stent therapy (Figure 1). The first session was conducted prior to the first stent implantation (time point 1), and the second session was conducted after the initial stent implantation (time point 2). All 17 patients were interviewed annually during the follow-up period. The interviews primarily evaluated the course of pain. The patients graded their pain on a pain scale from 0 to 10: 0 was no pain, 1-2 slight pain, 3-4 moderate pain, 5-6 strong pain, 7-8 very strong pain, and 9-10 extreme pain. The date and choice of the therapeutic procedure (*e.g.*, conservative pain management, endoscopic or surgical treatment) were documented for instances of relapse.

Statistical analysis

Statistical analysis was not performed. The evaluation of pain was carried out using a pain score in absolute numbers.

RESULTS

Primary outcome, duration and complication rate of stent therapy

This section is similar to our previously published 2-year follow-up study[6].

Long-term follow-up

Nineteen patients with chronic obstructive pancreatitis

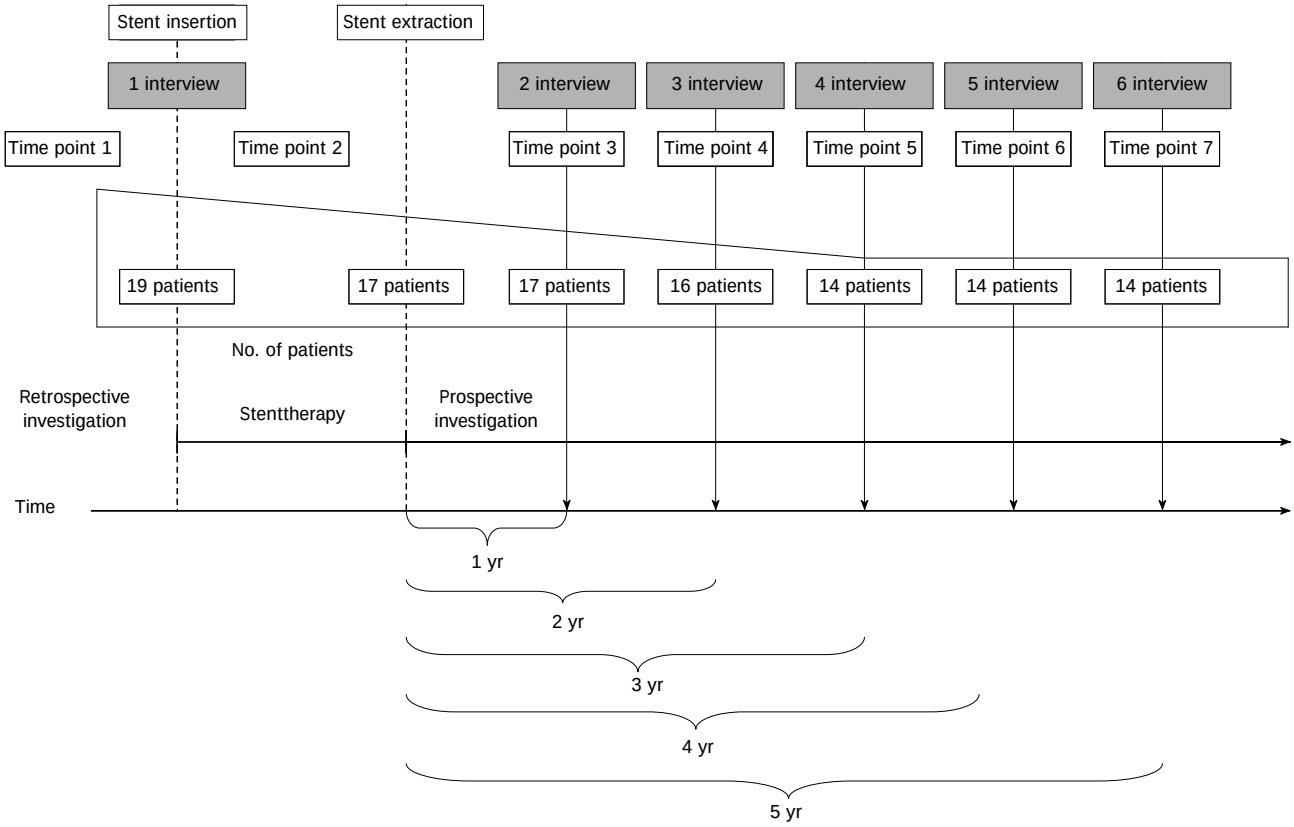

Figure 1 Protocol of the current study, time points of investigation and examination. Nineteen patients with chronic obstructive pancreatitis underwent endoscopic stent therapy. Endoscopic therapy failed in 2 patients. Seventeen of 19 patients showed clinical benefit and were included to follow-up analysis after completion of stent therapy. During the follow-up, patients were interviewed yearly. Three patients were lost to follow-up. One patient was not available any longer and two patients died.

underwent endoscopic stent therapy. Figure 2 is an illustration of a representative ERP procedure. ERP failed in 2 patients in which cannulation or permanent stent therapy was not achieved. One failed patient underwent surgery, and the other patient was treated conservatively with pain medication. We excluded these 2 patients from follow-up analyses. Endoscopic stent therapy was successfully completed in 17 of 19 patients. All 17 patients reported partial or complete pain relief.

The clinical courses of 17 patients were evaluated after the successful completion of stent therapy. Three of the 17 patients were lost during follow-up. One patient was not available for interviews after the 1st year of follow-up (Figure 1). Two patients died during the 3rd year of follow-up, and chronic pancreatitis was excluded as the cause of death. One patient died of myocardial infarction, and one patient succumbed to pneumonia.

Patients consumed the following pain medications during the 5-year follow-up period: paracetamol (500-1000 mg/d), diclofenac (50-100 mg/d), metamizol (500-1000 mg/d) and/or tramadol (100-300 mg/d). 4 patients at time point 3, 2 patients at time point 4, 3 patients at time point 5 and 2 patients at time point 6 and time point 7 used continuous pain medication after endoscopic therapy.

Seven relapses occurred in 6 of the 14 patients (43%). One patient developed 2 relapses during the 1st and 3rd follow-up years. Two relapses were observed during the 1st year, 2 relapses occurred during the 2nd year, one relapse was observed during the 3rd year, one relapse occurred during the 4th year, and one relapse occurred during the 5th follow-up year.

Four of these six patients received conservative treatment with endoscopic therapy or analgesics. Two patients were successfully treated with endoscopic therapy. Two patients achieved pain improvement with analgesic therapy. Only 2 of the 6 patients required surgery.

In contrast, 57% (8/14) of the patients without relapse reported significantly reduced pain or no complaints 5 years after stent extraction. Seven of these patients were completely pain free. Only 1 patient reported continuous moderate pain.

DISCUSSION

Several reviews[9-14] suggest that the majority of physicians consider pancreatic duct stenting a safe and effective therapy for patients with chronic abdominal pain due to chronic pancreatitis. The primary goal of endoscopic therapy is pain relief. Approximately half of the patients in the current study exhibited clinical long-term benefits. Most patients (57%, 8/14) exhibited significantly reduced pain or no pain complaints 5 years after stent extraction. Endoscopic treatment was an effective alternative

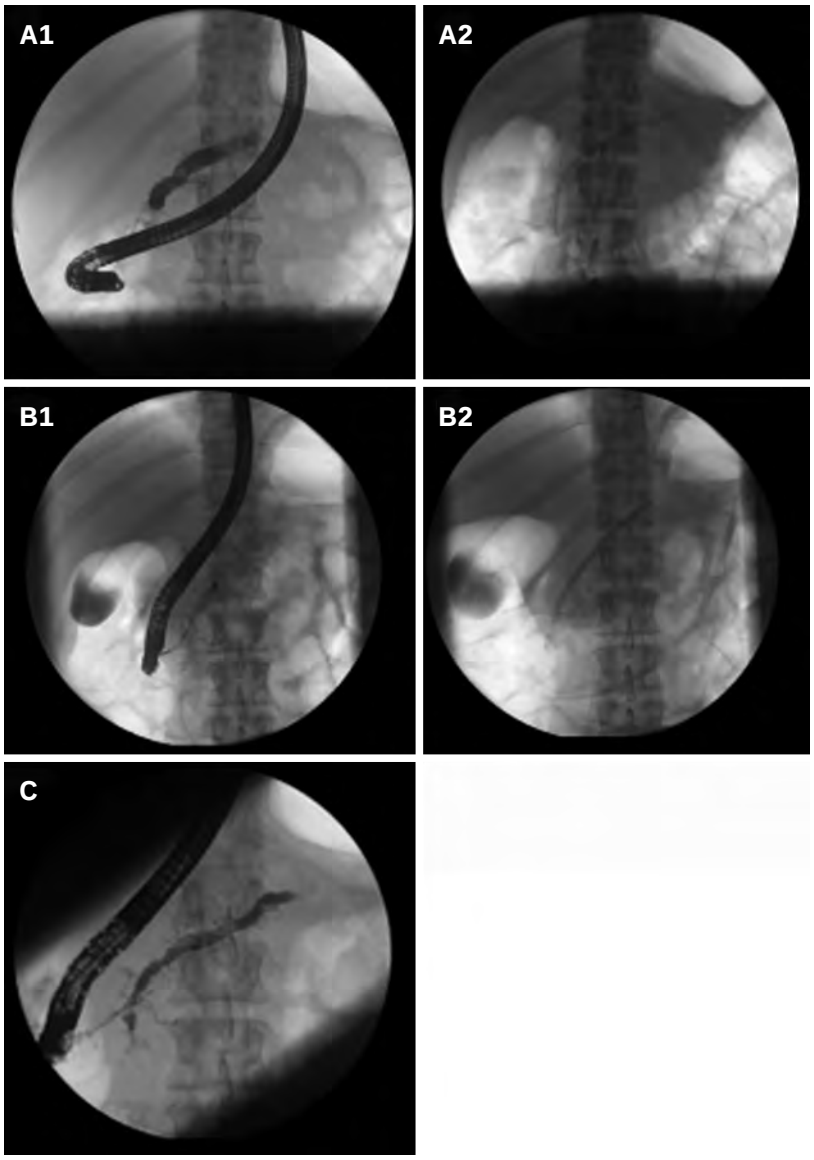

Figure 2 Illustration of a representative endoscopic retrograde pancreatography procedure. A: A dilated pancreatic duct due to a stenosis in the head and several stones in the main duct (A1). The stenosis was passed through with a 5 F catheter followed by a 8.5 F Sohendra Bougie. Subsequently, a 7 F stent was inserted (A2). After initial endoscopic intervention the patient was completely pain free; B: Four weeks later, the patient was readmitted for control endoscopic retrograde pancreatography (ERP). Stones were partially extracted by a dormia basket (B1), and the 7 F stent was replaced by a 10 F stent (B2); C: Three months later, the patient was still free of complaints. ERP revealed a slightly dilated duct with typical stone formations in the corpus and tail of the pancreas. Stones were extracted.

to surgery in instances of relapse. Four of six re-treated patients received conservative treatment with endoscopic or analgesic therapy. Only two of these patients required surgery.

The impact of smoking and alcohol on pain development was not evaluated in this study. However, smoking and alcohol are associated with more a progressive disease course[15-20]. Therefore, the cessation of smoking and alcohol consumption was recommended to all patients in the study. No relationship between the duration of stenting and the occurrence of relapse was observed. However, the small number of patients in this study prohibits valid conclusions. Further studies with a larger number of patients are required.

Surgical procedures seem to be superior to endoscopic therapy. Díte *et al*[21] compared the clinical benefit of endoscopic and surgical therapies in a randomized prospective study. The study included 140 patients with chronic pancreatitis. Endoscopic therapy was performed in 64 patients, and 76 patients underwent surgery. Both therapeutic approaches produced excellent results in initial pain relief (92.1% and 92.2%, respectively). The number of patients with partial or complete pain relief at the 5-year follow-up in the stent group decreased from 92.2% to 65.1%, but 86.2% of patients with surgical procedures reported reduced or no pain. These authors concluded that surgery was superior to endoscopic therapy for long-term pain reduction in patients with painful obstructive chronic pancreatitis. However, 80% of the surgeries were resection procedures. Resection procedures are based on a different pathophysiological concept than endoscopic or surgical drainage. Therefore, these procedures are only

comparable to a limited degree. The prospective randomized study of Cahen *et al*[5] analyzed the clinical benefit of surgical drainage versus endoscopic drainage, which is more suitable for this type of comparison. Nineteen patients underwent endoscopic drainage, and 20 patients received surgical drainage. Two years after intervention, 75% patients with pancreaticojejunostomy were partially or completely pain-free, but complete or partial pain relief was achieved in only 32% of patients with endoscopic therapy. Cahen *et al*[5] concluded that the surgical drainage of pancreatic duct was more effective than endoscopic treatment in patients with obstruction of pancreatic duct due to chronic pancreatitis. In contrast, the data of our current series demonstrated that ERP failed in only 2 of 19 patients. Complete or partial pain relief was achieved in 17 of 19 patients after initial stent insertion. Approximately half of the patients benefited from endoscopic stent therapy 5 years after endoscopic intervention. The less effective outcome of endoscopic stent therapy in the Cahen study may result from the difficulty of managing the endoscopic group. The complication rate of the endoscopic group (58%) was approximately 4 times higher in their study compared to the average results of other studies[22,23].

Many patients present contraindications or refuse to undergo surgery due to the invasiveness of surgical procedures. Consequently, patients who were American Society of Anesthesiologists class Ⅳ, presented with portal vein thrombosis or declined to participate were excluded from the Cahen study[5]. Approximately 12% of patients with chronic pancreatitis exhibit portal hypertension[24]. Izbicki *et al*[25] evaluated the impact of concomitant nonhepatic portal hypertension in chronic pancreatitis on the outcomes after major pancreatic surgery. Patients with portal hypertension required significantly more blood transfusions and longer operative times than their nonhypertensive counterparts. The overall postoperative complication rate was significantly higher in this subgroup. Izbicki concluded that concomitant extrahepatic portal hypertension is a substantial risk in pancreatic surgery for chronic pancreatitis.

The major limitations of this study are the small number of patients, its single-center character and its nonrandomized design. Therefore, randomized long-term follow-up studies with a larger number of patients are required.

In conclusion, endoscopic therapy proved to be a safe and effective alternative to surgery, and endoscopic therapy did not adversely affect the outcome of subsequent surgeries[26]. Our current data demonstrate that endoscopic therapy provided long-term benefits in more than half of the patients (57%) with chronic obstructive pancreatitis. The management of obstructive chronic pancreatitis should be individual. Patients with multiple morbidities profit from low invasive endoscopic therapy. Therefore, endoscopic stent therapy is the treatment of choice in inoperable patients or patients who refuse surgical treatment.

COMMENTS

Background

Obstruction of the pancreatic duct is a common feature of chronic pancreatitis, and it often requires interventional therapy. The optimal treatment for chronic pancreatitis is controversial among surgeons and endoscopists. The primary goal of both surgical and endoscopic drainage procedures is the restoration of pancreatic drainage to lower the pressure within the pancreatic duct and relieve pain.

Research frontiers

This is the first prospective 5-year follow-up assessment of the incidence and treatment of relapse in patients with chronic obstructive pancreatitis after the successful completion of endoscopic stent therapy.

Innovations and breakthroughs

The current data demonstrate that endoscopic therapy provided long-term benefits in more than half of chronic obstructive pancreatitis patients. Most (57 %) of the patients remained free of relapse 5 years after endoscopic treatment. Endoscopic treatment was an effective alternative to surgery in cases of relapse.

Applications

These data suggest that endoscopic therapy is a safe, minimally invasive, and effective procedure in patients who experience pain attacks during chronic pancreatitis. Multimorbid patients benefit from the low invasiveness of endoscopic therapy. Therefore, endoscopic stent therapy should be the treatment of choice in patients who are inoperable or refuse surgical treatment.

Terminology

Chronic pancreatitis is a continuous inflammation of the pancreas that produces morphological changes, such as calcifications, irregularities of the pancreas duct and the formation of pancreatic stones. The pathogenesis of pain in chronic pancreatitis is controversial. Interstitial hypertension, ongoing pancreatic ischemia, neuronal inflammation, and extrapancreatic complications may contribute to the pathogenesis of pain.

Peer review

The current study provides interesting and clinically relevant data. The observed patient group was small, but the differences were obvious. The data support the benefit of long-term endoscopic therapy in a subgroup of patients.

Abstract

AIM: To evaluate the long-term treatment outcomes of entecavir monotherapy in treatment naive patients in an Australian tertiary care setting.

METHODS: A retrospective analysis of treatment naive patients receiving entecavir monotherapy through Westmead Hospital was performed. Patients were excluded if they had received previous treatment with another nucleoside or nucleotide analogue, were pregnant or less than 18 years old.

RESULTS: Out of 336 patients, 163 patients fulfilled the selection criteria. Range of follow up was 3-46 mo (mean 26 mo). 134 patients (82.2%) had pre-treatment biopsies, with 26 patients (16.0 %) demonstrating F3-4 fibrosis. In total, 153 patients (93.9%) achieved at least Partial Virological Suppression (PVS), with 134 patients (82.2%) achieving complete virological suppression. The cumulative CVS and PVS rates at 36 mo were 82.1% and 96.4%, respectively. 3 patients (1.8%) failed to achieve PVS, while 5 patients (3.0%) developed virological rebound. 128 patients (78.5%) maintained CVS throughout follow up. Predictors of CVS included lower baseline DNA level (P = 0.001), hepatitis B virus e antigen negative status (P = 0.001) and increasing age at treatment (log rank 0.001). No significant adverse effects were reported necessitating cessation of entecavir.

CONCLUSION: Entecavir monotherapy is efficacious and safe in an Australian tertiary care setting. Resistance and rebound rates are very low. This is similar to data from controlled and uncontrolled trials around the world.

Fahrtash-Bahin F, Kariyawasam VC, Gray T, Byth K, George J, Douglas MW. Australian tertiary care outcomes of entecavir monotherapy in treatment naive patients with chronic hepatitis B. *World J Gastroenterol* 2013; 19(5): 721-726 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/721.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.721

INTRODUCTION

An estimated 350 to 400 million people worldwide have chronic hepatitis B virus (HBV) infection, a leading cause of morbidity and mortality. Australia has an ethnically diverse population, with many migrants from the Asia-Pacific region, where the majority of hepatitis B related deaths occur[1].

The number of people living with chronic hepatitis B in Australia is estimated to be between 153 000 and 175 000, a prevalence of 0.7% to 0.8%[2,3]. In 2010, 228 incident cases of hepatitis B and 6878 notifications of hepatitis B were reported to the Australian government's National Notifiable Diseases Surveillance System[4]. This reflects the major burden of disease in people with childhood acquired chronic hepatitis B.

In chronic HBV infection the goals of antiviral therapy are to suppress HBV DNA and reduce hepatic inflammation [alanine aminotransferase (ALT)], with the aim of preventing progression of liver fibrosis and achieving immune control [hepatitis B e antigen (HBeAg) and/or hepatitis B surface antigen (HBsAg) loss/conversion]. This reduces mortality due to cirrhosis, liver failure and HCC. Antiviral agents available include pegylated interferon, lamivudine, adefovir, entacavir, telbivudine and tenofovir.

Entecavir is an oral deoxyguanosine analog with potent activity against HBV[5]. In multiple clinical trials, entacavir has been found to be highly efficacious in treating nucleoside naive and lamividine refractory patients[6-8]. Emergence of drug resistance during antiviral therapy is well described for HBV, particularly with lamivudine, with resistance appearing in 20% of patients after 1 year and 70% after 5 years[9]. Entecavir has a higher genetic barrier to resistance than lamivudine, with quoted resistance rates of only 1%-2% in treatment naive patients after 5 years[10]. However, cross-resistance with lamivudine is a problem, and in patients who have failed lamivudine, entecavir resistance appears in up to 8% after 5 years[10,11].

The rates of entecavir response and resistance in Australia are unknown. Most published data are from large clinical trials, which do not necessarily reflect the rates seen in "real world" clinical practice. These trials were almost exclusively performed in the Northern Hemisphere, and do not reflect the unique, diverse migrant population seen in Australia. Furthermore, much of this data is based on a 1 mg dose of entecavir, rather than 0.5 mg now recommended for treatment naive patients.

The aim of this study was to evaluate the efficacy, rates of viral resistance and treatment outcomes of entacavir monotherapy in an Australian tertiary referral centre, outside of a clinical trial environment.

MATERIALS AND METHODS

Data collection and clinical setting

Data was entered retrospectively into a database incorporating all patients receiving entecavir through the Westmead Hospital pharmacy (Sydney, Australia) between 1 November 2006 and 31 July 2010.

Selection criteria

All patients receiving entecavir through the Westmead Hospital pharmacy were considered for analysis. Patients were included if they met the following criteria: (1) eligible for entecavir 0.5 mg daily according to AASLD guidelines; (2) HBV infection for greater than 6 mo based on serology; and (3) deranged liver function tests or at least mild fibrosis on liver biopsy (> F2 on Scheuer classification).

Exclusion criteria were: (1) previous treatment with other nucleoside analogues, nucleotide analogues or trial medication (except for interferon); (2) pregnancy; (3) age less than 18 years; (4) hepatitis delta co-infection; and (5) Prophylactic entecavir during immunosuppression (*e.g.*, chemotherapy).

Definitions

Viral load was measured in international units/mL, using the Cobas Taqman assay (12 IU/mL) (Roche Diagnostics, Branchburg, NJ).

Complete and Partial Virologic Suppression were defined as HBV DNA < 12 IU/mL and 12-2000 IU/mL, respectively. Virologic rebound was defined as an increase in viral load > 1 $\log_{10}$ from the previous value, in a patient with initial virologic suppression[12]. Cumulative rates of suppression were calculated by the formula P = 1 - (1 - n1/N1) (1- n2/N2). . .(1 - nx/Nx), where P is the cumulative probability that the event will occur, nx is the number of cases at year x, and Nx is the number of patients still followed up at year x[13].

The Scheuer classification system for grading and staging of chronic hepatitis was used for patients that underwent liver biopsy.

Statistical analysis and ethical consideration

All statistical analyses were performed using SPSS (version 16, Chicago IL). The study was approved by the Westmead Hospital Human Research Ethics Committee.

RESULTS

A total of 336 patients were included in the database, which collected data from 2006 to 2010. 89 patients were excluded due to past or current treatment with another agent. A further 83 patients were excluded as they received treatment for less than 3 mo, were less than 18 years old, received prophylactic entecavir, had hepatitis delta co-infection or were pregnant. Thus, 163 patients were included for analysis. The patient demographics are summarised in Table 1.

Treatment setting

All patients were reviewed at least four-monthly by one of six hepatologists at Westmead Hospital Liver Clinic, with assessment of HBV DNA, viral serology, liver function tests and routine haematological and renal laboratory evaluation. Relevant 6-monthly HCC surveillance was also performed, with serum alpha-fetoprotein and hepatic ultrasound.

The mean and median duration of follow up were 26 and 23 mo, respectively. The range of follow up was 3-46 mo, with 50% of patients followed for greater than 24 mo.

Response to treatment

The response to entecavir treatment over time is detailed in Table 2, with a graphical summary of virological suppression in Figure 1. In total, 153 patients (93.9%) achieved partial virological suppression (PVS), with 134 patients (82.2%) achieving complete virological suppression (CVS). The cumulative CVS and PVS rates at 36 mo were 82.1% and 96.4%, respectively. Three patients (1.84%) failed to achieve partial or complete suppression (mean duration of therapy 8 mo). Five patients (3.01%) developed virological rebound (mean duration of therapy 29 mo, 3 females, 4 eAg negative, median fibrosis score 1 (biopsies in 4 patients), mean baseline DNA 9.71×10^6 IU/mL). Four of the 5 patients that developed virological rebound had achieved CVS. Reasons for rebound included non-compliance in 4 patients and suspected entecavir resistance in 1 patient. Specific viral resistance testing was not performed. Four patients (2.45%) were changed to another agent due to failed virologic suppression or virologic rebound. Of these, 3 patients (1.84%) were changed to tenofovir and 1 patient (0.61%) to adefovir, with CVS and PVS achieved in 2 patients each, respectively.

One hundred and twenty eight patients (78.53%) maintained CVS throughout follow up. One hundred and twenty nine patients (79.14%) achieved PVS at 12 mo. The annual HBeAg positive to negative seroconversion rate was 14.3%. One patient (HBeAg negative) had loss of surface antigen, resulting in an annual surface antigen loss rate of 0.3% for HBeAg negative patients and 0.2% for all patients, respectively.

Predictors of virological response

The time to achieve CVS was related to baseline DNA levels ($P = 0.001$) and HBeAg status at baseline ($P = 0.001$) (Figure 2).

The mean and median times to CVS were 11.4 (9.77-13.09) and 6 (5.32-6.69) mo, respectively. For HBeAg negative patients the mean time was 6 mo (5.35-6.65), while for HBeAg positive patients it was 12 mo (3.42-20.58) (log rank < 0.001).

There was a statistically significant difference in median time taken to achieve CVS based on age and HBeAg status (Table 3). There was no significant difference in loss of HBeAg based on age (log rank 0.559).

There was no significant effect of duration of therapy, fibrosis score or gender on time to CVS, HBeAg conversion or ALT normalisation. There was a trend towards faster ALT normalisation based on increased age (log rank 0.053).

HCC

Among the 163 patients in the study, 4 patients (2.45%) developed HCC (mean time to development 19.9 mo), while in 6 (3.68%) cases the diagnosis preceded commencement of therapy. Two patients with HCC had a pre-treatment biopsy which did not show cirrhosis (F2 and F3, respectively).

Treatment discontinuation and safety

Twenty one patients (12.88%) failed to follow up in clinic during the study period and thus did not receive ongoing entecavir through the hospital pharmacy. There were no reports of entecavir being ceased due to adverse effects.

DISCUSSION

This study gives an important insight into outcomes of entecavir monotherapy for treatment naive patients with chronic hepatitis B in an Australian tertiary referral setting, with up to 3.5 years follow-up. To our knowledge it is the first study to describe the efficacy, tolerability and resistance rates of entecavir in treatment naive patients in the Australian tertiary care setting. Daily monotherapy with 0.5 mg entecavir was efficacious, with 94% of patients achieving at least partial suppression, and 82% achieving undetectable HBV DNA levels. Only 2% of patients failed to reach any significant reduction in viral load, while 3% developed virologic rebound. Viral resistance testing was not performed. No significant adverse events were reported, and treatment discontinuation was not due to adverse events.

Table 2 Follow up of DNA values and cumulative rates of complete and partial virological suppression *n* (%)

Month	0	6	12	18	24	30	36	42
Patients with DNA	163 (100)	158 (96.9)	141 (86.5)	121 (74.2)	105 (64.4)	76 (46.6)	56 (34.4)	24 (14.7)
Complete virological suppression	0/169 (0)	104/158 (65.8)	117/141 (83.0)	96/121 (74.4)	94/105 (89.5)	65/76 (85.5)	46/56 (82.1)	19/24 (79.2)
Cumulative CVS	0%	66.7%	88.8%	85.1%	94.8%	93.2%	92.2%	91.6%
Partial virological suppression	22/163 (13.5)	141/158 (89.2)	133/141 (94.3)	117/121 (90.7)	100/105 (95.2)	75/76 (98.7)	54/56 (96.4)	23/24 (95.8)
Cumulative PVS	13.5%	89.2%	94.9%	92.1%	96.3%	99.0%	97.3%	96.6%

CVS: Complete virological suppression; PVS: Partial virological suppression.

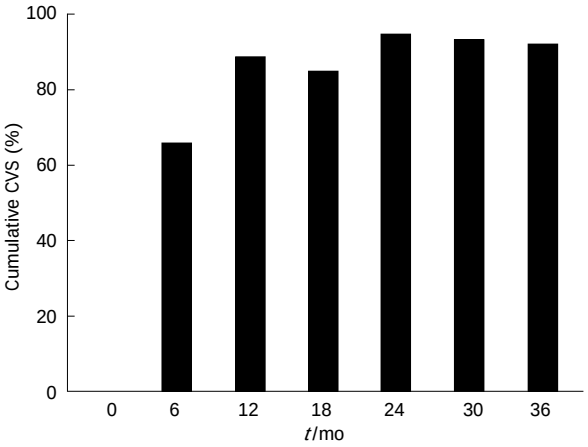

Figure 1 Total cumulative virologic suppression. CVS: Complete virological suppression.

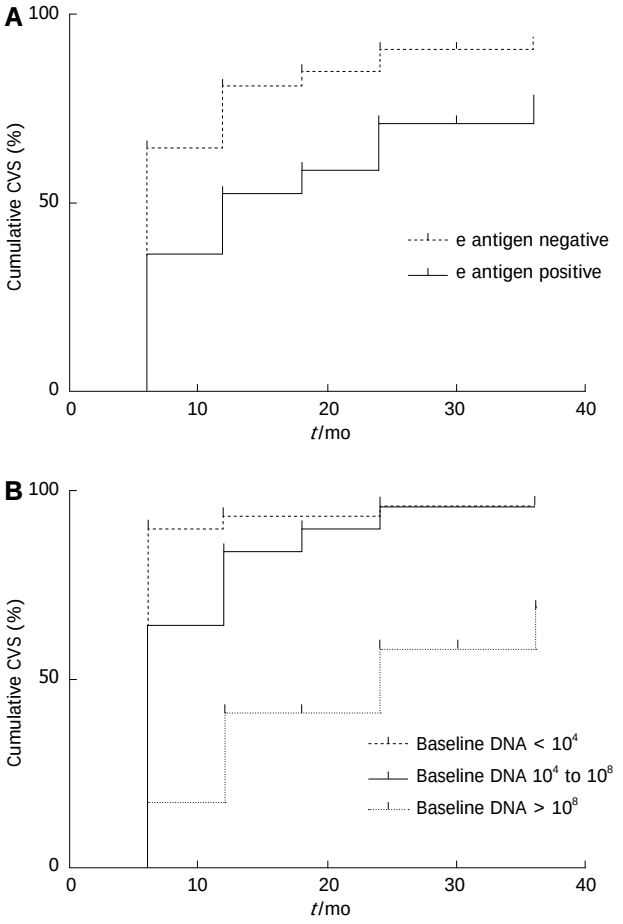

Figure 2 Predictors of complete virological suppression. A: Hepatitis B e antigen status; B: Baseline hepatitis B virus DNA. CVS: Complete virological suppression.

These results are consistent with earlier registration trials, which demonstrated suppression of HBV-DNA to undetectable levels in 67% of HBeAg-positive patients after 12 mo, and in 90% of HBeAg-negative patients[7,8]. Subsequent studies confirmed durable and increasing viral suppression on entecavir, with undetectable HBV DNA achieved by 94% of HBeAg-positive patients over 5 years of treatment, and in 95% of HBeAg-negative patients over 3 years of treatment[14,15]. Clinical trials have also demonstrated minimal emergence of viral resistance (1.2%), after up to 6 years of entecavir treatment[10,16].

Pol *et al*[17] analysed the efficacy and tolerability of entecavir in routine clinical practice settings, by comparing data from 5 international cohorts. In these studies CVS was achieved in 76%-96% of patients, with virologic rebound in 0.6%-4%, and excellent overall tolerability and safety. Therefore the findings from our study are consistent with international data from other "real life" clinical settings, as well as earlier registration trials, which applied more stringent selection criteria.

As has been shown in previous studies, we found that the likelihood of achieving CVS was increased in patients with lower baseline DNA levels and e antigen negative status[18,19]. Amongst patients with baseline HBV DNA $> 10^8$ the CVS was only 67.5% compared to 92% for patients with baseline HBV DNA $< 10^4$. This is most likely explained by the high proportion of eAg positive cases (82%) in the high baseline DNA group compared to the low baseline DNA group (10.5%). The time to achieve CVS was also significantly related to these factors. An interesting and novel finding was that the time taken to achieve CVS was significantly related to age. In patients older than 40 years old the median time to achieve CVS was 6 mo, whereas in patients younger than 40 years old it was 12 mo. This relationship was maintained following HBeAg status stratification, and may reflect better compliance in the older population groups.

A strength of this study is the high proportion of patients in whom pre-treatment liver biopsies were performed (82%). For the duration of this study, liver biopsy

Table 3 Complete virological suppression based on age and HBeAg status

< 40 yr-	40-55 yr-	> 55 yr-
36 mo (20.55-51.45)	30 mo (18.46-41.54)	6 mo (9.8-32.2)

was a requirement under the Australian Pharmaceutical Benefit Scheme to access subsidised entacavir treatment. Somewhat surprisingly the degree of fibrosis was not significantly associated with patients achieving CVS, or the time to achieve CVS.

Although there was an association between DNA suppression and ALT normalisation, our study did not take into account other variables that could influence transaminase changes, including anthropomorphic measurements, alcohol intake and intercurrent illness.

The study is limited by its retrospective analysis of medical records and the lack of sufficient follow up data for 13% of patients in the pharmacy registry. Furthermore only a minority of the patients included in the analysis (15%) had completed more than 36 mo of therapy. Finally, viral resistance testing was not performed for patients that failed to achieve PVS or had virologic rebound, as it was not routinely available in our clinic during the study period. The wide range in follow up is mainly due to late commencement in the study period with less time for follow up, drop out of patients and limited treatment duration.

In conclusion, entecavir monotherapy is efficacious and well tolerated for the treatment of patients with chronic hepatitis B infection in Australia. In our cohort baseline HBV DNA levels and HBeAg status influenced time to complete virologic suppression, consistent with previous studies. These factors are not independent, however, as HBeAg negative status most likely correlates with lower baseline HBV DNA levels. There was a very low incidence of failure to suppress DNA, and no apparent emergence of viral resistance on therapy. Our study supports the recommendations that 0.5 mg daily entecavir monotherapy is an appropriate first line agent for patients with treatment naive chronic hepatitis B in Australia.

COMMENTS

Background

An estimated 350 to 400 million people worldwide have chronic hepatitis B virus (HBV) infection, a leading cause of morbidity and mortality. Australia has an ethnically diverse population, with many migrants from the Asia-Pacific region, where the majority of hepatitis B related deaths occur.

Research frontiers

Entecavir is an oral antiviral agent with potent activity against HBV. The rates of entecavir response and resistance in Australia are unknown. Most published data are from large clinical trials, which do not necessarily reflect the rates seen in "real world" clinical practice.

Innovations and breakthroughs

Out of 163 patients, 153 patients (93.9%) achieved at least partial suppression of HBV DNA, with 134 patients (82.2%) achieving complete suppression. Predictors of complete suppression included lower baseline DNA level, HBV e antigen negative status and increasing age at treatment. No significant adverse effects were reported necessitating cessation of entecavir.

Applications

The study results suggest that entecavir monotherapy is efficacious and safe in an Australian tertiary care setting. Resistance and rebound rates are very low. This is similar to data from controlled and uncontrolled trials around the world.

Terminology

Hepatitis B is a viral infection that can lead to persistent inflammation and scarring of the liver. This has significant adverse outcomes including cirrhosis of the liver and liver cancer. Entecavir is a antiviral agent that prevents proliferation of the hepatitis B virus.

Peer review

Well described cohort of entecavir treated patients in clinical practice from Australia; This is an interesting retrospective study from Australia confirms the efficacy and safety of entecavir in clinical practice.

Abstract

AIM: To evaluate the possibility of reducing the volume of polyethylene glycol (PEG)-electrolyte solution using adjunctive mosapride citrate for colonoscopy preparation.

METHODS: This was a single-center, prospective, randomized, investigator-blinded, non-inferiority study involving 252 patients of both sexes, aged from 20 to 80 years, scheduled for screening or diagnostic colonoscopy in our department. A total of 126 patients was randomized to receive 1.5 L PEG-electrolyte solution plus 15 mg of mosapride (1.5 L group), and 126 received 2 L PEG-electrolyte solution plus 15 mg of mosapride (2 L group). Patients completed a questionnaire on the acceptability and tolerability of the bowel preparation process. The efficacy of bowel preparation was assessed using a 5-point scale based on the Aronchick scale. The primary end point was adequate bowel preparation rates (score of excellent/good/fair) *vs* (poor/inadequate). Acceptability and tolerability, as well as disease detection, were secondary end points.

RESULTS: A total of 244 patients was included in the analysis. There were no significant differences between the 2 L and 1.5 L groups in age, sex, body mass index, number of previous colonoscopies, and the preparation method used previously. The adequate bowel preparation rates were 88.5% in the 2 L group and 82.8% in the 1.5 L group [95% lower confidence limit (LCL) for the difference = -14.5%, non-inferiority P = 0.019] in the right colon. In the left colon, the adequate bowel preparation rates were 89.3% in the 2 L group and 81.1% in the 1.5 L group (95% LCL = -17.0%, non-inferiority P = 0.066). Compliance, defined as complete (100%) intake of the PEG solution, was significantly higher in the 1.5 L group than in the 2 L group (96.8% *vs* 85.7%, P = 0.002). The proportion of abdominal distension (none/mild/moderate/severe) was significantly lower in the 1.5 L group than in the 2 L group (36/65/22/3 *vs* 58/48/18/2, P = 0.040). Within the subgroup who had undergone colonoscopy previously, a significantly higher number of patients in the 1.5 L group than in the 2 L group felt that the current preparation was easier than the previous one (54.1% *vs* 28.0%, P = 0.001). The disease detection rate was not significantly different between the two groups.

CONCLUSION: Although the 1.5 L group had better acceptability and tolerability, 15 mg of mosapride may be insufficient to compensate for a 0.5-L reduction of PEG solution.

Tajika M, Niwa Y, Bhatia V, Kondo S, Tanaka T, Mizuno N, Hara K, Hijioka S, Imaoka H, Komori K, Yamao K. Can mosapride citrate reduce the volume of lavage solution for colonoscopy preparation? *World J Gastroenterol* 2013; 19(5): 727-735 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/727.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.727

INTRODUCTION

Polyethylene glycol (PEG)-electrolyte solution is widely used worldwide for bowel cleansing. By consensus of the American Society for Gastrointestinal Endoscopy, the American Society of Colon and Rectal Surgeons, and the Society of American Gastrointestinal and Endoscopic Surgeons, PEG-electrolyte solution is the gold standard for colonoscopic bowel preparation (Grade I A), and aqueous sodium phosphate (NaP) is an alternative regimen to PEG-electrolyte solutions (Grade I A)[1]. Several meta-analyses on the available bowel preparations have favored NaP, concluding that it was effective and better tolerated by patients than PEG-electrolyte solution[2-4]. However, the disadvantages of NaP are its associated side effects. Significant changes in serum electrolyte levels[5], even in patients without renal failure, have prompted recommendations for serum electrolyte evaluation prior to the administration of NaP[6,7].

On the other hand, osmotically balanced electrolyte lavage solutions offer safe and effective cleansing, but volume-related discomfort and adverse experiences have decreased the percentage of patients completing the pre-examination preparation[1,8,9]. This is mainly due to the large volumes of fluid required for bowel preparation, the unpleasant taste, and an increase in the incidence of side effects[10]. Although 3-4 L of this solution is used in Western countries, approximately 2 L of this solution, along with a laxative, is usually considered adequate for bowel preparation in Japan. Despite the lower volume in Japan, the need to drink such large volumes of liquid with an unpalatable taste has a negative impact on patient compliance[11]. Therefore, more effective bowel preparation regimens for colonoscopy are required to improve the acceptability and tolerability of the procedure.

Mosapride citrate (mosapride) is a selective 5-hydroxytryptamine 4 (5-HT4) receptor agonist. Mosapride enhances gastric emptying and motility by facilitating acetylcholine release from the enteric cholinergic neurons, without blocking the dopaminergic D2 receptors[12]. It is known to be effective in gastroesophageal reflux disease[13], functional gastrointestinal disorders, such as functional dyspepsia[14], chronic gastritis with delayed gastric emptying, and diabetic gastroparesis[15]. Since 5-HT4 receptors are also located in the human colon and rectum[16,17], mosapride is also expected to have a prokinetic effect on the colo-rectum. A few clinical studies have reported that mosapride in combination with PEG-electrolyte solution may enhance bowel cleansing and improve patient acceptability and tolerability[18,19]. Furthermore, we previously conducted a randomized, double-blind, placebo-controlled study with mosapride in addition to PEG-electrolyte solution and demonstrated that co-administration of mosapride with PEG-electrolyte solution improved the quality of bowel preparation for colonoscopy, especially in patients without severe constipation[20]. Among the subgroup that had undergone previous colonoscopy, a significantly higher number of mosapride-group patients than placebo-group patients felt that the current preparation was easier. However, mosapride could not improve symptoms such as nausea, abdominal distension, abdominal pain, and willingness to repeat the same regimen compared with placebo. In short, mosapride did not sufficiently improve patient acceptability and tolerability. Therefore, it appears that it is necessary to reduce the volume of PEG-electrolyte solution to improve patient acceptability and tolerability.

The aim of this study was to evaluate the reduction of PEG-electrolyte solution volume when combined with mosapride citrate for colonoscopy preparation.

MATERIALS AND METHODS

This was a prospective, randomized, investigator-blinded study, comparing 1.5 L PEG plus mosapride (1.5 L group), with 2 L PEG-electrolyte solution plus mosapride (2 L group) dosing for patients who underwent colonoscopy. All patients provided written, informed consent prior to entering the study. The study was conducted at Aichi Cancer Center Hospital (ACCH), Nagoya, from January 2010 to June 2010, and was reviewed and approved by the ethics committee of ACCH. This trial was registered in an international clinical trial registry (UMIN000001556).

Study population

All consecutive outpatients of both sexes, aged 20 to 80 years, who were scheduled for screening or diagnostic colonoscopy at ACCH were evaluated for inclusion in the study. Patients with the following clinical features were excluded: significant cardiac, renal, hepatic, or metabolic co-morbidities, ascites, severe constipation (< 2 bowel movements a week), known allergy to PEG-electrolyte solution, history of gastric stapling or bypass procedure, or a history of prior colonic or rectal surgery. Patients were excluded if there was a suspected diagnosis of intestinal obstruction because of advanced colorectal cancer.

Randomization and blinding

Patients were randomly allocated to receive one of two different bowel preparation regimens using a computer-generated random-number list. Patients were randomized in block sizes of two, with serially numbered, sealed, opaque envelopes. Concealed allocation was accom-

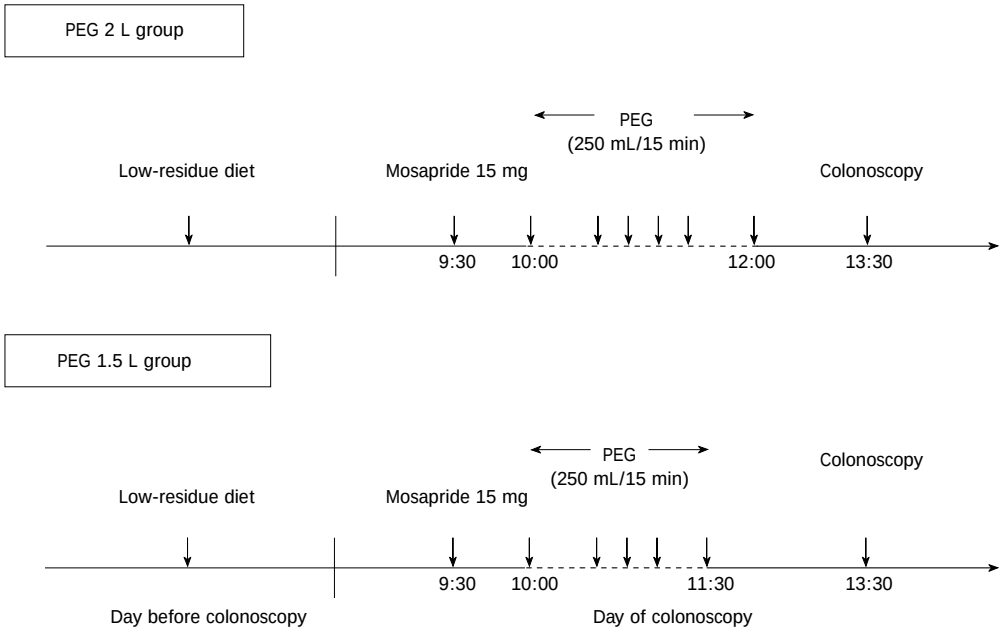

Figure 1 Steps in preparation for colonoscopy. PEG: Polyethylene glycol.

plished through non-research personnel who were not involved in this study. Patients were instructed not to discuss their bowel preparation with anyone other than the unblinded research assistant. With the exceptions of the patient and the unblinded research assistant, all other individuals participating in this study, including the endoscopists and endoscopy nurses, were blinded to the allocated treatment group. Comparisons between the 1.5 L group and the 2 L group were made in an investigator-blind fashion.

Bowel preparation methods

The day before colonoscopy, all patients were instructed to eat a pre-packaged, low residue diet (Enimaclin CS; Horii Pharmaceutical Ind., Ltd., Osaka, Japan) that consisted of a lunch, snack, and dinner, and asked to drink more than 2 liters of clear liquid. On the day of the colonoscopy, all participants reported to the endoscopy room at 9:00 am and received in-hospital bowel preparation. In-hospital preparation was important to ensure uniformity and remove any confounding caused by poor patient adherence. More than 10 toilet facilities were made available in the endoscopy unit for patient comfort. Six mosapride tablets (15 mg) (Gasmotin; Dainippon Sumitomo Pharma Co., Ltd. Osaka, Japan) were administered orally with water at half past nine. After 30 min, both groups were instructed to drink 0.25 L of PEG-electrolyte solution (Niflec; Ajinomoto Pharmaceuticals Co., Ltd. Tokyo, Japan) every 15 min (Figure 1). Colonoscopies were performed from half past thirteen, and the start times were recorded for each patient.

Evaluation of bowel preparation

The efficacy of bowel preparation was assessed using the Aronchick scale[21]. Participating endoscopists were trained to use the Aronchick scale to achieve a good level of agreement. Investigators performed calibration exercises involving more than 20 colonoscopies prior to study commencement, based on their interpretation of scale anchors, to ensure that their findings agreed. The final assessment of bowel preparation was divided into two categories, adequate and failure. Bowel preparation rated as fair, good, or excellent, based on the Aronchick scale, was considered adequate; poor or inadequate ratings were considered failure. After colonoscopy, two observers, one who was the operator and the other who was a fellow in the procedure room, decided the score by mutual agreement. They scored the quality of the preparation on the right side (proximal to splenic flexure) colon and on the left side (distal to splenic flexure) colon and rectum separately. If the decision was discordant, a third expert reviewer graded and scored the recorded images later, and this evaluation was used in the final analysis. Twelve experienced colonoscopists carried out all colonoscopy procedures, each of whom had performed more than 1000 colonoscopies.

During or immediately following the colonoscopy, the investigator completed a physician questionnaire regarding assessment of bowel preparation, amount of irrigation fluid used, time needed to reach the cecum, and ease of insertion to the cecum and difficulty in observing the lumen of the colo-rectum because of peristalsis.

Patient tolerance and other measurements

The nursing staff recorded the time required to drink the indicated volume of lavage solution. They also recorded the time and number of bowel movements from the start of ingestion to the appearance of clear excretion. Until one hour after finishing the PEG-electrolyte solution plus mosapride, the nursing staff checked patients' excretions.

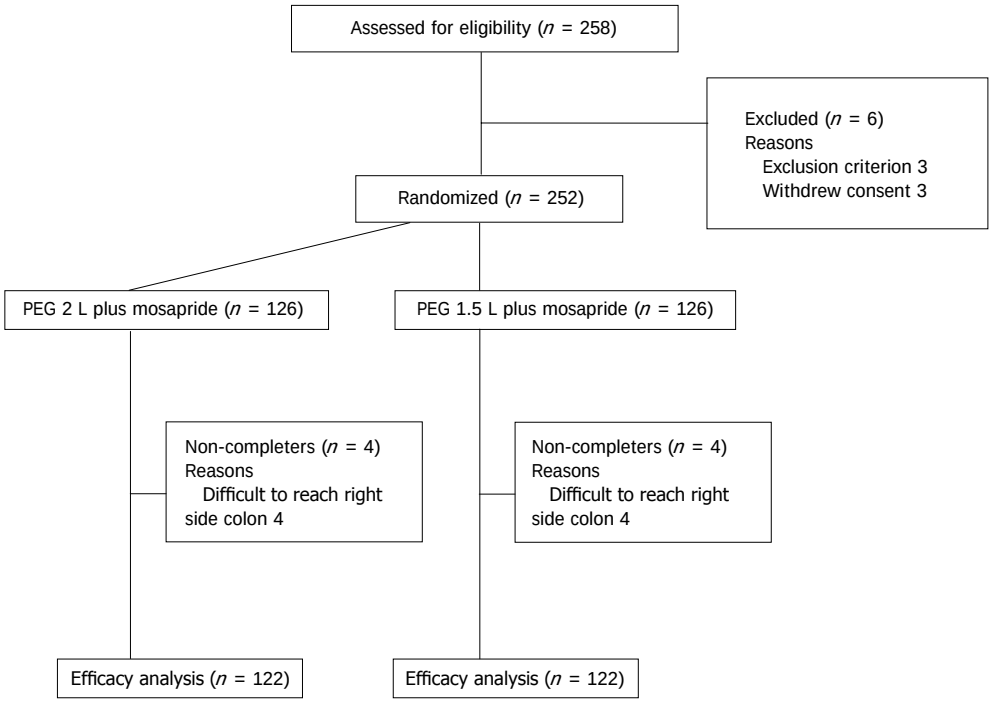

Figure 2 Patient disposition flow chart. PEG: Polyethylene glycol.

If there was a solid stool with muddy excretions or no excretion at that time, the patient was given an additional preparation, such as additional PEG-electrolyte solution or enemas. The patients who received an additional preparation were defined by the Aronchick scale as inadequate. The patient questionnaire consisted of 20 questions[20]. The adverse events were scored using a 4-point scale, where 1 = none, 2 = mild, 3 = moderate, and 4 = severe. The patients completed the questionnaire form before undergoing colonoscopy and submitted it to the nursing staff.

End points

The primary end point was the difference in the rate of adequate colon cleansing between the 1.5 L PEG-electrolyte solution plus 15 mg of mosapride (1.5 L group) and the 2 L PEG-electrolyte solution plus 15 mg of mosapride (2 L group). Secondary end points included differences in patients' acceptability and tolerance of solutions, time to first defecation, frequency of defecation, complete time for colonic preparation, time needed to reach the cecum, amount of irrigation fluid used, subjective difficulty in colonoscopy insertion to the cecum and in observing the lumen of the colo-rectum because of peristalsis, and disease detection rates.

Statistical analysis

Based on a previous study[20], the adequate bowel preparation rate for the PEG-electrolyte solution plus mosapride was expected to be less than 80%. It was expected that about 80% of the 1.5 L group would be judged adequate, and the non-inferiority margin was set at -15%. This study was designed to have 80% power to establish non-inferiority (using a one-sided significance level of 0.025 and a target sample size of 250).

The primary efficacy analysis was based on an intent-to-treat analysis and included patients who were randomized and received any treatment. In patients in this group, the preparation was classified as adequate or inadequate based on the colonoscopists' score of cleansing. Patients who did not undergo colonoscopy because of preparation-related adverse events, or preparation failure, or in whom the right colon could not be reached because of bowel obstruction or technical reasons were excluded. The rates of adequate preparation were compared between the groups by χ^2 test or Fisher's exact test for categorical variables.

For the secondary end points, the Mann-Whitney *U* test was used to compare continuous variables. Categorical variables were tested using the corrected χ^2 test or 2-sided Fisher's exact tests as appropriate. The criterion for significance was $P < 0.05$.

All statistical analyses were performed using Statistical Analysis Software (SAS Ver. 9.2 for the PC, SAS Institute Inc., Cary, NC, United States).

RESULTS

Patients' characteristics

A total of 252 patients was randomized into two groups (Figure 2). Although 252 patients were analyzed, colonoscope insertion to the right colon failed in 4 patients in each group (advanced stenosing cancer in two, and patient refusal in six because of pain). These eight patients were excluded from the efficacy analysis. The baseline characteristics of the patients are shown in Table

1. There was no significant difference in age, sex, body mass index, number of previous colonoscopies, and the preparation method used previously between the 2.0 L and 1.5 L groups.

Bowel cleansing efficacy

The efficacy of bowel preparation is shown in Table 2. The adequate bowel preparation rates were 88.5% in the 2 L group and 82.8% in the 1.5 L group (95% lower confidence limit, lower confidence limit (LCL), for the difference = -14.5%, non-inferiority $P = 0.019$) in the right side colon. In the left colon, the adequate bowel preparation rates were 89.3% in the 2 L group and 81.1% in the 1.5 L group (95% LCL = -17.0%, non-inferiority $P = 0.066$). In the right side colon, there were significant differences in the proportion of the overall colon-cleansing score between the two groups ($P = 0.006$). Eleven patients (8.7%) required additional preparation in the 2 L group. On the other hand, 18 patients (14.3%) required additional preparation in the 1.5 L group. However, there was no significant difference in required additional preparation between the two groups.

As shown in Table 3, there were no differences in frequency of defecation, time needed to reach the cecum, elapsed time from last fluid intake to colonoscopy, amount of irrigation fluid used, and subjective difficulties in insertion to the cecum and in observing the lumen of the colo-rectum between the two groups.

Patient acceptability, tolerability, and safety

There was no significant difference in compliance as defined by > 80% intake of the prescribed PEG-electrolyte solution volume. However, complete (100%) intake of the PEG solution was significantly higher in the 1.5 L group than in the 2 L group ($P = 0.002$) (Table 3). The proportion of abdominal distension was significantly less in the 1.5 L group than in the 2 L group ($P = 0.040$), but symptoms such as nausea, vomiting, abdominal pain, and circulatory reactions were similar in both groups. The proportion of patients willing to repeat the same preparation regimen was significantly higher in the 1.5 L group ($P = 0.034$). Furthermore, among the subgroup of patients who had undergone colonoscopy more than twice previously, a significantly higher number of patients in the 1.5 L group than in the 2 L group felt that the current preparation was easier than in the past ($P = 0.001$).

Disease detection rate

In this study, 11 colorectal cancers were detected in 11 patients (4.4%), 4 (3.2%) in the 2 L group and 7 (5.6%) in the 1.5 L group (Table 4). A total of 177 polyps was detected in 74 patients (58.7%) in the 2 L group, and 187 polyps were detected in 73 patients (57.9%) in the 1.5 L group. The proportions of polyps by size and location were similar in the two groups.

DISCUSSION

In this study, 1.5 L PEG-electrolyte solution plus mosapride was found to be non-inferior to 2 L PEG-electrolyte solution plus mosapride with respect to adequate bowel preparation rates only in the right colon, not in the entire colo-rectum. On the other hand, patient tolerability, especially abdominal distension, and acceptability were superior in the 1.5 L group compared to the 2 L group.

This is the first study, to the best of our knowledge, that has evaluated the effect of mosapride when used in conjunction with reduced dose, 1.5 L PEG-electrolyte solution for colonoscopy preparation. We previously conducted a randomized, double-blind, placebo-controlled study with mosapride in addition to PEG-electrolyte solution and demonstrated that co-administration of mosapride with PEG-electrolyte solution improved the quality of bowel preparation for colonoscopy, especially in patients without severe constipation[20]. On the other hand, the beneficial effect of mosapride on gastric emptying[22] was expected to ameliorate nausea, vomiting, and fullness of the abdomen during bowel preparation. Mishima *et al*[19] showed that administration of mosapride prior to PEG-electrolyte solution significantly decreased the incidence of uncomfortable abdominal symptoms. However, there were no significant differences in the

frequencies of these symptoms between the mosapride group and the placebo group in the previous study[20]. Therefore, we think that there is a need to reduce the volume of PEG-electrolyte solution to improve patients' acceptability and tolerability. In the present study, it was assumed that 2 L PEG-electrolyte solution plus mosapride was the standard regimen for bowel preparation based on the results of the previous study. Thus, the study was designed to compare a 1.5 L PEG group with a 2 L PEG group.

In the present study, the patients' acceptability and tolerability were superior in the 1.5 L group. The 0.5 L reduction of PEG-electrolyte solution significantly improved patients' acceptability and tolerability; 100% intake of PEG-electrolyte solution was significantly higher in the 1.5 L group than in the 2 L group. For Japanese patients with relatively smaller physiques than Western patients, 2 L PEG-electrolyte solution may be too much to drink. With respect to adverse events, abdominal distension was more common than nausea, vomiting, and abdominal pain. The proportion of abdominal distension was significantly improved in the 1.5 L group compared with the 2 L group. This may be the reason why willingness to repeat the same preparation regimen was significantly higher in the 1.5 L group, and a significantly higher number of patients in the 1.5 L group than in the 2 L group felt that the current preparation was easier.

Although 0.5-L volume reduction improved patient acceptability and tolerability, it would not make sense to decrease the volume of solution if the adequate bowel

preparation rates were worse, and it prolonged the time to preparation. In the present study, 1.5 L PEG was non-inferior to 2 L PEG with respect to adequate bowel preparation rates in the right colon, but the proportion for the overall colon-cleansing score was significantly higher in the 2 L PEG group than in the 1.5 L PEG group. Furthermore, although there was no significant difference between the two groups, 18 patients required additional preparation in the 1.5 L group compared with 11 patients in the 2 L group. One of the reasons why the times to preparation were similar in the two groups is that it took longer for the patients who required additional preparation in the 1.5 L group compared with the 2 L group. From these results, we cannot help but recognize that the dose of 15 mg may be insufficient to compensate for the 0.5-L reduction in PEG solution with respect to cleansing efficacy. In the present study, 15 mg of mosapride was given for colonoscopy preparation. The dose of 15 mg per day is the recommended usual dosage of mosapride citrate for adult patients with chronic gastritis. Since the effects of mosapride are reported to be dose-dependent[23], additional studies that address the optimal dosage are required to clarify the best bowel preparation method for colonoscopy.

Over the years, many researchers have investigated several different combinations and dosages of prokinetic agent or laxatives in search of acceptable, tolerable, and efficacious low-volume bowel preparation that may lead to a better experience for the patient and a more thorough colonoscopic examination[24-26]. Cisapride has been used as a prokinetic agent along with lavage solution for bowel preparation and has been demonstrated to shorten the required time period for precolonoscopic bowel preparation and to decrease the lavage solution volume[27,28], although these results have been difficult to reproduce[29]. However, cisapride was withdrawn from the market because of severe cardiac effects[30]. Other prokinetic agents, including metoclopramide and tegaserod, have been co-administered with oral lavage solution in an attempt to improve the quality of bowel preparation and patient tolerance to lavage solution through increasing the amplitude of gastric contraction and peristalsis of small intestine, and shortening transit time[31,32]. However, the effect of these agents had not yet been clearly established, and the results of studies that have evaluated these agents have thus far been contradictory[33]. The effects of prokinetic agents with the reported timings and doses may not be enough to compensate for the large volume of PEG solution.

Stimulant laxatives such as bisacodyl and magnesium citrate have been used as adjuncts to low-volume PEG-electrolyte solution, achieving results similar to those with full-volume PEG-electrolyte solution[8,34]. Recently, Cohen *et al*[35] compared a reduced-dose 2 L PEG formulation plus ascorbic acid with 2 L PEG formulation plus bisacodyl. The authors found that the use of PEG plus ascorbic acid resulted in better colon cleansing and higher adenoma detection rates than PEG plus bisacodyl. Moreover, Repici *et al*[36] compared a new iso-osmotic sulphate-free formulation (2 L formulation of PEG-citrate-simethicone) in combination with bisacodyl with 2 L formulation PEG plus ascorbic acid. The authors reported that low-volume PEG-citrate-simethicone with bisacodyl provided better bowel cleansing and similar tolerability and acceptance compared with PEG plus ascorbic acid. Unfortunately, these low-volume formulations are currently not available in Japan. In the previous study[20], we selected mosapride from among several prokinetic agents because it is a highly selective agonist for 5-HT4 receptors and does not affect other receptors, including dopamine D2 receptors. However, the results of this study did not demonstrate the efficacy of mosapride in reducing lavage solution volume. A combination with some laxatives may improve the cleansing efficacy of our low-volume 1.5 L PEG formulation plus mosapride.

Few studies designed to assess the quality of bowel preparation for colonoscopy have also examined the disease detection rates, including adenoma detection rates[37-39]. Previous studies demonstrated that a better bowel preparation led to a higher rate of colon lesion detection, enhancing the ability to discern smaller lesions and thus improving the thoroughness of colonoscopy[37,38]. In the present study, there were no differences between the two groups in the polyp detection rate, the proportion of the size of polyps, total polyps per study arm, and polyps per patient. These findings may lead to the conclusion that the efficacy of bowel preparation with 1.5 L PEG is non-inferior to 2 L PEG with respect to bowel cleansing. However, polyp detection rates are indeed affected by several variables, such as patients' background, colonoscopy indication, and endoscopist technique, as well as endoscopy technology, that would introduce uncertainly into the results of this study. Additional studies are necessary to demonstrate the relationship between bowel preparation and the adenoma detection rate.

There are several limitations to consider in interpreting the present results. First, the study was conducted in a single hospital with a small number of patients. Although we hypothesized that the non-inferiority margin was -15%, that margin might be inappropriate. The sample size may have been too small to elucidate the non-inferiority of 1.5 L PEG, which may explain why non-inferiority in only a limited part of colon could be demonstrated. Second, for the evaluation of bowel preparation, the Aronchick scale was used. The merit of the Aronchick scale is that in cases in which additional bowel preparation was needed, such cases could be defined as "inadequate" using the Aronchick scale. However, the Aronchick scale was designed to assess bowel preparation of the entire colon. In the present study, it was scored separately on the right side colon and left side colon; a different scoring system, such as the Ottawa scale[40] and the Boston scale[41], that evaluates different colon segments individually and generates a summary score may have been more appropriate. Finally, biochemical parameters were not evaluated in the two groups. However, co-administration of mosapride at a dose of 40 mg and

PEG-electrolyte solution is already approved in Japan for barium enema examination preparation[42], based on its excellent safety profile.

In conclusion, co-administration of mosapride with 1.5 L PEG-electrolyte solution was non-inferior to mosapride with 2.0 L PEG-electrolyte solution for adequate bowel preparation rates only in the right colon, although better acceptability and tolerability compared to the larger PEG-electrolyte solution volumes were found. A mosapride dose of 15 mg may provide insufficient cleansing efficacy to compensate for a 0.5-L reduction in PEG-electrolyte solution.

COMMENTS

Background

Although polyethylene glycol (PEG) electrolyte solution has been used for colonoscopy preparation since 1980, the need to drink large volumes is a limiting factor that affects patient tolerance. Low-volume bowel preparation regimens for colonoscopy are reported to improve patients' acceptance and compliance.

Research frontiers

Mosapride citrate (mosapride) is a selective 5-hydroxytryptamine 4 (5-HT4) receptor agonist. Mosapride enhances gastric emptying and motility by facilitating acetylcholine release from enteric cholinergic neurons, without blocking the dopaminergic D2 receptors. Since 5-HT4 receptors are also located in the human colon and rectum, mosapride is also expected to have a prokinetic effect on the colo-rectum.

Innovations and breakthroughs

The present randomized trial compared 1.5 L PEG plus mosapride with 2 L PEG plus mosapride dosing for patients who underwent colonoscopy in terms of cleansing effectiveness, patient compliance, tolerability, and disease detection rates.

Applications

The low-volume preparation (1.5 L PEG) represents a valid alternative to high-volume preparations (2 L PEG) with regard to patient compliance and tolerability. However, optimal visualization of colonic wall seems to be one of the primary advantages of high-volume preparations. A mosapride dose of 15 mg may provide insufficient cleansing efficacy to compensate for a 0.5-L reduction in PEG solution.

Terminology

PEG-electrolyte solution: PEG-electrolyte solution is used worldwide for bowel cleansing. Approximately 2 L of this oral solution with some laxatives are usually required for adequate bowel preparation in Japan.

Peer review

This randomized trial compared 1.5 L PEG plus mosapride with 2 L PEG plus mosapride in terms of cleansing effectiveness, patient acceptability, physical tolerability, and endoscopic findings. This is an interesting and well written study. The conclusion sounds good and useful for the general practice.

Abstract

AIM: To investigate the outcome and effectiveness of two screening programs, National Cancer Screening Program (NCSP) and opportunistic screening (OS), for the detection of gastric cancer.

METHODS: A total of 45 654 subjects underwent upper endoscopy as part of the NCSP or OS at the Chung-Ang University Healthcare System in Korea between January 2007 and December 2010. The study population was comprised of subjects over the age of 40 years. More specifically, subjects who took part in the NCSP were Medicaid recipients and beneficiaries of the National Health Insurance Corporation. Still photographs from the endoscopies diagnosed as gastric cancer were reviewed by two experienced endoscopists.

RESULTS: The mean age of the screened subjects was 55 years for men and 54 years for women. A total of 126 cases (0.28%) of gastric cancer were detected from both screening programs; 100 cases (0.3%) from NCSP and in 26 cases (0.2%) from OS. The proportion of early gastric cancer (EGC) detected in NCSP was higher than that in OS (74.0% *vs* 53.8%, $P = 0.046$). Among the 34 416 screenees in NCSP, 6585 (19.1%) underwent upper endoscopy every other year as scheduled. Among the 11 238 screenees in OS, 3050 (27.1%) underwent upper endoscopy at least once every two years during the study period. The detection rate of gastric cancer was found to be significantly higher during irregular follow-up than during regular follow-up in both screening programs (0.3% *vs* 0.2%, $P = 0.036$). A higher incidence of EGC than advanced gastric cancer was observed during regular follow-up compared with irregular follow-up.

CONCLUSION: Compliance to the screening program is more important than the type of screening system used.

Effectiveness of gastric cancer screening programs in South Korea: Organized *vs* opportunistic models. *World J Gastroenterol* 2013; 19(5): 736-741 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/736.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.736

INTRODUCTION

Gastric cancer is the second most common cause of cancer death worldwide, and East Asian countries, such

as China and Japan, have high incidence rates of gastric cancer[1,2]. Although the incidence has declined in recent decades, gastric cancer remains the most frequently diagnosed form of cancer in South Korea[3-6]. The symptoms of gastric cancer appear quite late; in fact, a large number of advanced gastric cancer cases, as well as most early gastric cancer (EGC) cases, show no symptoms. Thus, gastric cancer screening is extremely important for the early detection of gastric cancer.

Screening can be defined as the systematic application of a test or inquiry to identify individuals at sufficient risk of a specific disorder who will benefit from further investigation or direct preventive action, among those who have not sought medical attention[7]. Some countries, such as Japan and South Korea, provide gastric cancer screening to populations with an average risk to reduce the disease burden.

Cancer screening may be offered in an organized or opportunistic model[8]. An organized model is primarily distinguished from opportunistic screening (OS) in that invitations to screening are issued from population registers[9]. Organized screening programs have nationally implemented guidelines defining who should be invited, how frequently they should be screened, and how any abnormalities detected on screening should be followed up and treated[8,10]. In South Korea, a nationwide gastric cancer screening program began in 1999 as part of the National Cancer Screening Program (NCSP). NCSP provides screening services free of charge for Medicaid enrollees and people with National Health Insurance with a premium below 50%. The NCSP recommends biennial upper endoscopy or upper gastrointestinal series for men and women aged $\geqslant$ 40 years.

In addition to the organized screening program, OS is also widely available in South Korea. OS programs involve various options in terms of the items screened, intervals between screening, and costs, depending on the preference by the individual, but these services are entirely paid by the users[11]. OS has been highly implemented owing to the low cost and easy accessibility of endoscopy. However, OS involves fewer formal decisions on whether to screen, whom to screen, and at what intervals the screening should be done. Moreover, the evidence and efficiency of this examination tend to be underestimated.

Although screening programs are conducted widely in South Korea, the utilization of such screening programs, including both organized and opportunistic programs, is still unclear[11]. Even though there have been some studies carried out on the characteristics of gastric cancer detected by mass screening, there is neither a study evaluating the efficiency of gastric cancer screening programs or comparison between organized and OS. Therefore, in this study, we investigated the current features of gastric cancer screening programs in South Korea, in terms of the outcome and effectiveness of NCSP and OS conducted at a single center.

MATERIALS AND METHODS

Subjects

The present study was conducted by reviewing medical records. A total of 45 991 subjects underwent upper endoscopy as part of the NCSP or OS at the Chung-Ang University Healthcare System in South Korea between January 2007 and December 2010. The study population was comprised of subjects over the age of 40 years. More specifically, subjects who took part in the NCSP were Medicaid recipients and beneficiaries of the National Health Insurance Corporation. Still photographs from the endoscopies diagnosed as gastric cancer were reviewed by two experienced endoscopists. The gross shape of the lesion was determined as either EGC or advanced gastric cancer (AGC). If there was a discrepancy between the two endoscopists' findings, a final decision was made after further discussion.

Statistical analysis

Statistical analyses in this study were conducted using the SPSS version 12.0 software package (SPSS, Chicago, IL, United States). Categorical data analysis was conducted using the χ^2 test or Fisher's exact test. Continuous data were analyzed using Student's *t*-test. Continuous variables measured in this study are expressed as mean ± SD. All *P* values were 2-tailed. *P* values of less than 0.05 were considered statistically significant. The study was approved by the Institutional Review Board of the Chung-Ang University Medical Center in South Korea.

RESULTS

Demographics of the subjects

A total of 45 991 subjects were screened for gastric cancer during the study period. Of these, 34 481 subjects were included in NCSP and 11 238 subjects in OS. In NCSP, 275 subjects were excluded due to previous gastric surgery (n = 233) and endoscopic resection (n = 42). In OS, 62 subjects were excluded due to previous gastric surgery (n = 45) and endoscopic resection (n = 17). A total of 45 654 subjects (34 416 in NCSP and 11 238 in OS) were subsequently enrolled in this study. The mean age of the screened subjects was 55.1 years for men and 54.4 years for women. The male to female ratio of the screened subjects was 0.7:1. The mean age of the subjects was 56.2 ± 9.2 years in NCSP and 50.0 ± 8.0 years in OS, respectively. In addition, the male to female ratio was 0.5 in NCSP and 1.4 in OS, respectively. The demographics of the subjects are shown in Table 1.

Participation rate of the subjects

In NCSP, a total of 6585 subjects (19.1%) underwent upper endoscopy every other year as scheduled. Their mean age was 58.7 ± 8.3 years, and the male to female ratio was 0.5:1. In contrast, in OS, a total of 3050 subjects (27.1%) underwent upper endoscopy at least once

Endoscopic feature			0.942
EGC	12 (70.6)	76 (69.7)	
AGC	5 (29.4)	33 (30.3)	

EGC: Early gastric cancer; AGC: Advanced gastric cancer.

every two years during the study period. Their mean age was 49.4 ± 7.1 years, and the male to female ratio was 1.3:1. Among these subjects, 140 subjects (0.6%) had undertaken upper endoscopy every year during the study period.

Gastric cancer detection rate

As shown in Table 1, gastric cancer was diagnosed in 126 (0.28%) of 45 654 subjects (87 men and 39 women). Their mean age was 60.3 ± 9.5 years. Of these, 88 subjects (0.19%) were endoscopically diagnosed with EGC and 38 subjects (0.08%) with AGC. The proportion of EGCs among the total cases of gastric cancer was 69.8%. Figure 1 shows the annual EGC/AGC ratio in each system.

A total of 100 cases of gastric cancer found in NCSP included 74 cases of EGC (74%) and 26 cases of AGC (26%). The EGC/AGC ratio was 2.9. On the other hand, 14 cases of EGC (53.8%) and 12 cases of AGC (46.2%) were found in OS. The EGC/AGC ratio was 1.2. Hence, the detection rate of EGC in NCSP was significantly higher than that in OS ($P = 0.046$).

Outcomes according to compliance

In this study, we defined regular follow-up as satisfying the biennial checks in NCSP and a check-up at least once every two years during the period in OS. Table 2 shows the outcomes according to compliance to the systems. As a result, their detection rates in regular follow-up were 0.12% for EGC and 0.05% for AGC, respectively. With regard to compliance to the system, EGC was found more than AGC during regular follow-up compared with irregular follow-up in both NCSP and OS.

Among the 100 cases of gastric cancer in NCSP, 10 cases (83.3%) of EGC and 2 cases (16.7%) of AGC were found during regular follow-up. On the other hand, 64 cases (72.7%) of EGC and 24 cases (27.3%) of AGC were found during irregular follow-up. As for OS, 2 cases (40%) of EGC and 3 cases (60%) of AGC were found during regular follow-up, whereas 12 cases (57.1%) of EGC and 9 cases (42.9%) of AGC were found during irregular follow-up. Annual follow-up revealed no cases of gastric cancer among the 140 subjects.

DISCUSSION

In this study, we measured the effectiveness of gastric cancer screening between NCSP and OS. The results showed no significant difference in the gastric cancer detection rate between NCSP and OS. However, the proportion of EGC was higher in NCSP than in OS. In addition, regular check-ups were important regardless of the screening system.

Screening has become an important component in health promotion programs along with the progress of diagnostic technology aimed at early detection of diseases[7]. Screening has the potential to produce benefits in preventing morbidity and mortality as long as the screening program fulfills certain conditions.

The epidemiology and natural history of the disease, including development from the latent to declared disease, should be adequately understood; and there should be a detectable risk factor, disease marker, latent period, or early symptomatic stage. All cost-effective primary prevention interventions should have been implemented as far as practicable. Therefore, many countries have developed a variety of screening programs as part of their preventive health services according to the recommendations of specialized committees[7]. For example, national cancer control programs should be organized to ensure that a large proportion of the target group is screened and that those individuals in whom abnormalities are observed receive appropriate diagnosis and therapy. Agreement should be reached on the guidelines for proper application of national cancer control programs. The purpose of gastric cancer screening is to reduce the cancer-related mortality, and the effect of gastric cancer screening should be evaluated on the basis of this purpose. From the perspective of the South Korean public

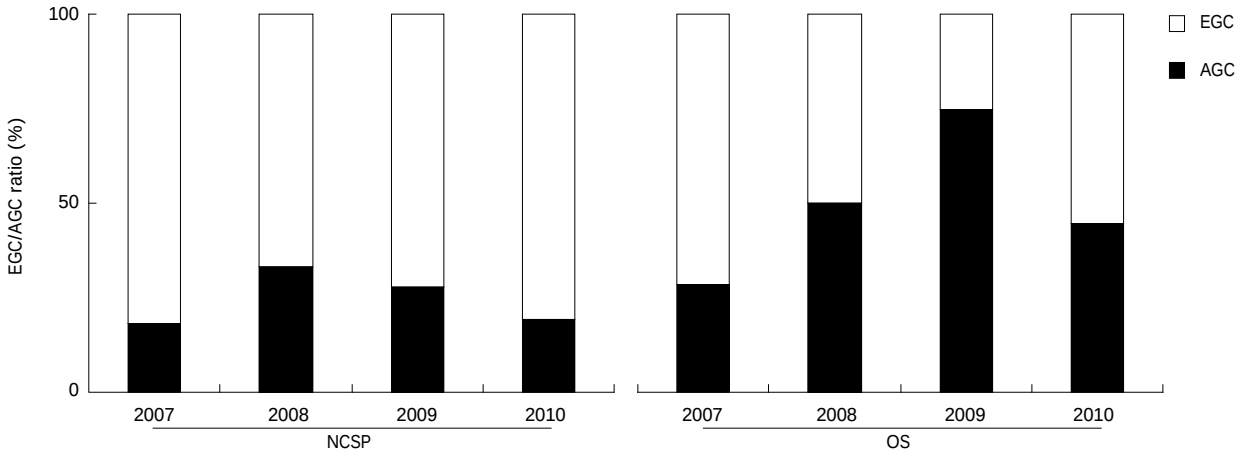

Figure 1 Annual early gastric cancer/advanced gastric cancer ratio in National Cancer Screening Program and opportunistic screening. The proportion of early gastric cancers (EGCs) among a total of 126 gastric cancers was 69.8%. The EGC/advanced gastric cancer (AGC) ratio in National Cancer Screening Program (NCSP) was 2.9, while the EGC/AGC ratio in opportunistic screening (OS) was 1.2. The detection rate of EGC in NCSP was significantly higher than that in OS (P = 0.046).

health care system, reducing the gastric cancer-related mortality rate appears to have the utmost importance[12].

Recently, endoscopy has replaced photofluorography as the initial mass screening method in South Korea. This method has become increasingly useful for gastric cancer screening owing to its high detection rate[13]. Considering the circumstances in South Korea that the cost of endoscopy is as low as that of photofluorography and the incidence of gastric cancer is still high, endoscopy is regarded as the most cost-effective screening method in South Korea. However, gastric cancer screening using endoscopy as a mass screening method has not yet been reported.

NCSP in South Korea has been available for several years, and has played a role in the early detection of gastric cancer. Apart from NCSP, OS has also contributed to screening gastric cancer in South Korea. Although the contents and process of the screening program are similar to those of the NCSP, there are some distinctive features in OS[7]. For this reason, some criticize that this unestablished guideline may drive the population into unnecessary socioeconomic consumption. Our hospital has run both NSCP and OS in the same healthcare system, which is rare in South Korea. A total of 8 well-trained gastroenterologists with at least 5 year of endoscopy experience performed upper endoscopy using a flexible endoscope (Q260 or Q240, Olympus Optical Co., Tokyo, Japan) in our healthcare system (NCSP and OS). They rotated between NCSP and OS as scheduled. Hence, there was little qualitative difference between NCSP and OS. Thus, this study could be regarded as a community-based study conducted for the local population.

So far, numerous studies on gastric cancer screening have focused on either OS or NCSP. Therefore, to our knowledge, this is the first study to compare the efficiency of two gastric cancer screening programs, NCSP and OS, in South Korea.

In this study, a total of 126 cases (0.28%) of gastric cancer were detected from both screening programs; 100 cases (0.3%) from NCSP and in 26 cases (0.2%) from OS during the study period. Screening for gastric cancer revealed that the proportion of EGC detected in NCSP was higher than that in OS (74.0% *vs* 53.8%, P = 0.046).

Kim *et al*[12] reported a significant relationship between the history of gastric examination and severity of gastric cancer. This suggests that gastric cancer screening is effective in detecting early stage gastric cancer. Unfortunately, an appropriate interval for screening gastric cancer has not been determined[14,15]. Despite the lack of evidence, screening for gastric cancer is conducted every other year in South Korea. Therefore, we compared the gastric cancer detection rates between NCSP and OS according to the frequency of check-ups.

We classified the subjects in each system according to the number of tests performed during the study period. This implies compliance to their target screening program. Regular follow-up was defined as satisfying the biennial check-ups in NCSP and a check-up at least once every two years during the period in OS. As a result, only 21.1% of subjects underwent endoscopy.

In this study, compliance to gastric cancer screening programs was determined to be as low as 19.1% in NCSP and 27.1% in OS, respectively. Hence, OS seems to be more effective regarding the examination interval. However, the detection rate of gastric cancer was significantly higher during irregular follow-up than during regular follow-up, regardless of the type of system (0.3% *vs* 0.2%, P = 0.036). While gastric cancer detected during the screening appears to have a good prognosis, several biases should be carefully assessed. Generally, individuals taking part in screening programs are healthier than those who do not. Selection bias has been discussed as a major limitation of case-control studies in which infor-

mation on confounding factors were not obtained[16,17]. Ideally, the effectiveness of a screening program is evaluated by an interventional study in which subjects are randomly allocated to screened and unscreened groups[18]. Due to the wide implementation of gastric cancer screening, however, no such interventional study has been carried out.

The present study had some limitations. First, this study had little information on risk factors. Second, gastric cancer was classified as EGC and AGC based on endoscopic findings, instead of surgical findings. Finally, this study did not cover the clinical course after diagnosis, including stage work-up, treatment, and prognosis, including survival. However, the present study reflects the features of presently available gastric cancer screening programs and may have an influence on future plans for cancer control.

In conclusion, this study demonstrated that NCSP was an effective screening system comparable to OS in the early detection of gastric cancer. The results suggest that compliance to the screening program is more important than the type of screening system itself. However, further studies on the efficiency and analysis of cost-effectiveness will be needed for successful progression of both systems. Furthermore, more comprehensive analyses with extensive nationwide data are warranted.

COMMENTS

Background

Gastric cancer remains one of the leading causes of cancer-related death worldwide. Currently, screening is performed in countries where gastric cancer is highly prevalent such as South Korea and Japan. In South Korea, cancer screening is widely available in two systems; organized cancer screening program, *e.g.*, National Cancer Screening Program (NCSP) and opportunistic screening (OS). However, there are no comparative studies on the effectiveness and outcomes of these two systems.

Research frontiers

Apart from government-led mass screening programs, OS programs by individual needs using an endoscopic examination have become common. However, OS has not been estimated in terms of clinical usefulness as well as cost-effectiveness. This study evaluated the effectiveness of screening systems with regard to early detection of gastric cancer and compliance to the system.

Innovations and breakthroughs

So far, most epidemiologic studies on gastric cancer screening have dealt with screening tools, screening interval and the cost-effectiveness of mass screening. However, little attention has been paid to the differences between two screening systems, *e.g.*, organized and opportunistic models. The authors made a comparison between these two systems and suggest that regular check-up is essential in the early detection of gastric cancer regardless of the screening system used.

Applications

The authors demonstrated that regular check-up is more important than the screening system in the early detection of gastric cancer. This work is interesting and will help health professionals establish a practical program for gastric cancer screening. Furthermore, it will contribute to the exploration of future strategies for gastric cancer prevention and control.

Terminology

NCSP is a cancer screening program which has been conducted by the South Korean government since 1999. OS is a screening program which depends on requests from individuals and has no guidelines.

Peer review

The authors have compared the effectiveness of NCSP and OS for gastric cancer screening. This paper has some valuable information and is worthy of publication.

Abstract

AIM: To investigate the effect of probiotics on regulating T regulatory cells and reducing the severity of experimental colitis in mice.

METHODS: Forty C57/BL mice were randomly divided into four groups. Colitis was induced in the mice using 2,4,6-trinitrobenzene sulfonic acid (TNBS). After 10-d treatment with Bifico capsules (combined bifidobacterium, lactobacillus and enterococcus), body weight, colonic weight, colonic weight index, length of colon, and histological scores were evaluated. $CD4^+CD25^+Foxp3^+T$ cell in mesenteric lymph nodes were measured by flow cytometry, and cytokines in colonic tissue homogenates were analyzed by a cytometric bead array.

RESULTS: The colonic weight index and the colonic weight of colitis mice treated with Bifico were lower than that of TNBS-induced mice without treatment. However, colonic length and percent of body weight amplification were higher than in TNBS-induced mice without treatment. Compared with TNBS-induced mice without treatment, the level of $CD4^+CD25^+Foxp3^+T$ cells in mesenteric lymph nodes, the expression of interleukin (IL)-2, IL-4 and IL-10 in colonic tissues from colitis mice treated with Bifico were upregulated, and tumor necrosis factor-α and interferon-γ were downregulated.

CONCLUSION: Probiotics effectively treat experimental colitis by increasing $CD4^+CD25^+Foxp3^+T$ cell and regulating the balance of Th1 and Th2 cytokines in the colonic mucosa.

Probiotics increase T regulatory cells and reduce severity of experimental colitis in mice. *World J Gastroenterol* 2013; 19(5): 742-749 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/742.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.742

INTRODUCTION

Ulcerative colitis (UC) belongs to the inflammatory bowel disease (IBD) group, which are chronic, relapsing-remitting gastrointestinal diseases of unknown etiology[1,2]. The primary treatments of UC (san azosulfamide, immunodepressants and surgery) are usually not well tolerated,

have side effects and show a high relapse rate[3,4]. Many reports have indicated that the non-specific inflammation of UC is associated with bacterial overgrowth and dysbiosis[5,6]. As live microbial feed supplements, probiotics can beneficially affect the host by improving the balance of the intestinal microbial flora to effectively and securely treat UC in human and murids[1,7,8]. A pivotal event in the development of UC is that high sensitivity to intestinal symbiotic microbial flora induces serious autoimmunity enteritis, which inhibits the function or lowers the level of $CD4^+CD25^+$T cells. Re-import of $CD4^+CD25^+$T cells may prevent the occurrence or aggravation of IBD[9]. This could be accomplished by secreting suppressor cytokines to recovering immunological tolerance and maintain the stability of internal environment in the intestines[10,11].

To explore the effects of probiotics on regular intestinal mucosal internal environment, we observed the level of $CD4^+CD25^+$T cells in mesenteric lymph nodes and the expression of related cytokines in colonic mucosa from mice with colitis induced by 2,4,6-trinitrobenzene sulfonic acid (TNBS).

MATERIALS AND METHODS

Reagents

TNBS (batch number: 2508-19-2) was purchased from Sigma (St. Louis, MO, United States). Bifico Capsules (batch number: 20101002), which combine bifidobacterium, lactobacillus and enterococcus, was purchased from Bifico Pharma (Shanghai, China). Mesalazine (batch number: 110201) was purchased from Sunflower Pharma (Jiamusi, China). The mouse regulatory T cell staining kit (batch number: 88-8111-40) was purchased from eBioscience CO (San Diego, CA, United States). The BD cytometric bead array (CBA) and mouse Th1/Th2/Th17 Cytokine Kit (batch number: 23-12380-00) was from BD Biosciences (San Jose, CA, United States).

Experimental design

Forty C57/BL mice (half male and half female, weighing 22-26 g, the animal certificate number was SCXK 2009-0004) were provided from Sino-British Sippr/BK Lab Animal Co. Ltd. (Changsha, China), and randomly divided into four groups of ten animals each: the normal group (mice were challenged and administrated with physiological saline), the model group (mice were induced by TNBS without treatment), the Bifico group (mice were induced by TNBS and treated with 345 mg/kg Bifico capsules), the Mesalazine group (mice were induced by TNBS and treated with 300 mg/kg mesalazine). All animals were housed at 20 ± 1 ℃ with a humidity of 50% ± 5% in a 12 h light/dark cycle and fed *ad libitum* with standard mouse feed and water throughout the experiments. The experimental protocols were performed according to the Guidelines of the Jiangxi University of Traditional Chinese Medicine Animal Research Committee.

Experimental colitis in mice was induced with TNBS Solution (100 mg·kg^{-1} body TNBS dissolved in 0.15 mL 30% ethanol) by enema[12]. The mice were maintained in a head-down position for 1 min. After 24 h, mice in the treated groups were administrated Bifico capsules (345 mg/kg) or mesalazine (300 mg/kg) by lavage for 10 d, while mice in the normal and model group received the equivalent volume of physiological saline.

To evaluate the therapeutic effect of probiotics treatment on experimented colitis, body weight, colonic weigh index [colonic weigh index (%) = colonic weigh/body weigh × 100%], colonic length and histological score were analyzed. The histological scoring was performed by Professor Chun Xiao of the pathological department from Jiangxi University of Traditional Chinese Medicine, and was a total score of inflammatory cell infiltration and tissue damage, according to the study of Schmidt and his colleagues[13]. Infiltration scores were as follows: 0, no infiltration; 1, increased number of inflammatory cells in the lamina propia; 2, inflammatory cells extending into the submucosa; 3, transmural inflammatory infiltrates; and for tissue damage: 0, no mucosal damage; 1, discrete epithelial lesions; 2, erosions or focal ulcerations; 3, severe mucosal damage with extensive ulceration extending into the bowel wall[13].

On day 11, mice were euthanized, and mesenteric lymph nodes were separated and triturated with cold physiological saline in a mortar into a cell suspension. The cell suspension was filtered through a 300-micron screen mesh to measure $CD4^+CD25^+Foxp3^+$T cells. The colon from the ileocecal junction to the anus was excised, its length was measured, and then it was cut open longitudinally at the mesenteric attachment, washed with 5 mL of 0.01 mol/L phosphate buffered solution (PBS) (pH 7.4) to remove the fecal remnants and weighted to compute the colonic weigh index. Partial colons were fixed in PBS-buffered 4% paraformaldehyde, and then processed for paraffin embedding and cut into 5-μm thick sections. The sections were stained with hematoxylin and eosin. Other colons were made into tissue homogenates to analyze the expressions of the cytokines.

Assay of $CD4^+CD25^+Foxp3^+$T cells in mesenteric lymph nodes

Cells from mesenteric lymph nodes were resuspended in eFluor® NC Flow Cytometry Staining Buffer at a final cell concentration of 2×10^7/mL. fluorescein isothiocyanate anti-mouse $CD4^+$Ab (RM4-5, 0.125 μg/sample; eBioscience) and APC anti-mouse $CD25^+$Ab (PC61.5, 0.25ug/sample; eBioscience) were added to the cell suspension. Cells were centrifuged at 300 × *g* at 4 ℃ for 5 min, fixed using Fix/Perm Buffer (eBioscience) for at least 12 h at 4 ℃, and then incubated with PE-anti-mouse $Foxp3^+$Ab (FJK-16s, 0.5 μg/sample; eBioscience) for 30 min in the dark at 4 ℃. Cells labeled with PE rat IgG2a were used as the isotype negative control. Fluorescence-activated cell sorting analysis was performed on a FACSCalibur (BD Biosciences)[14].

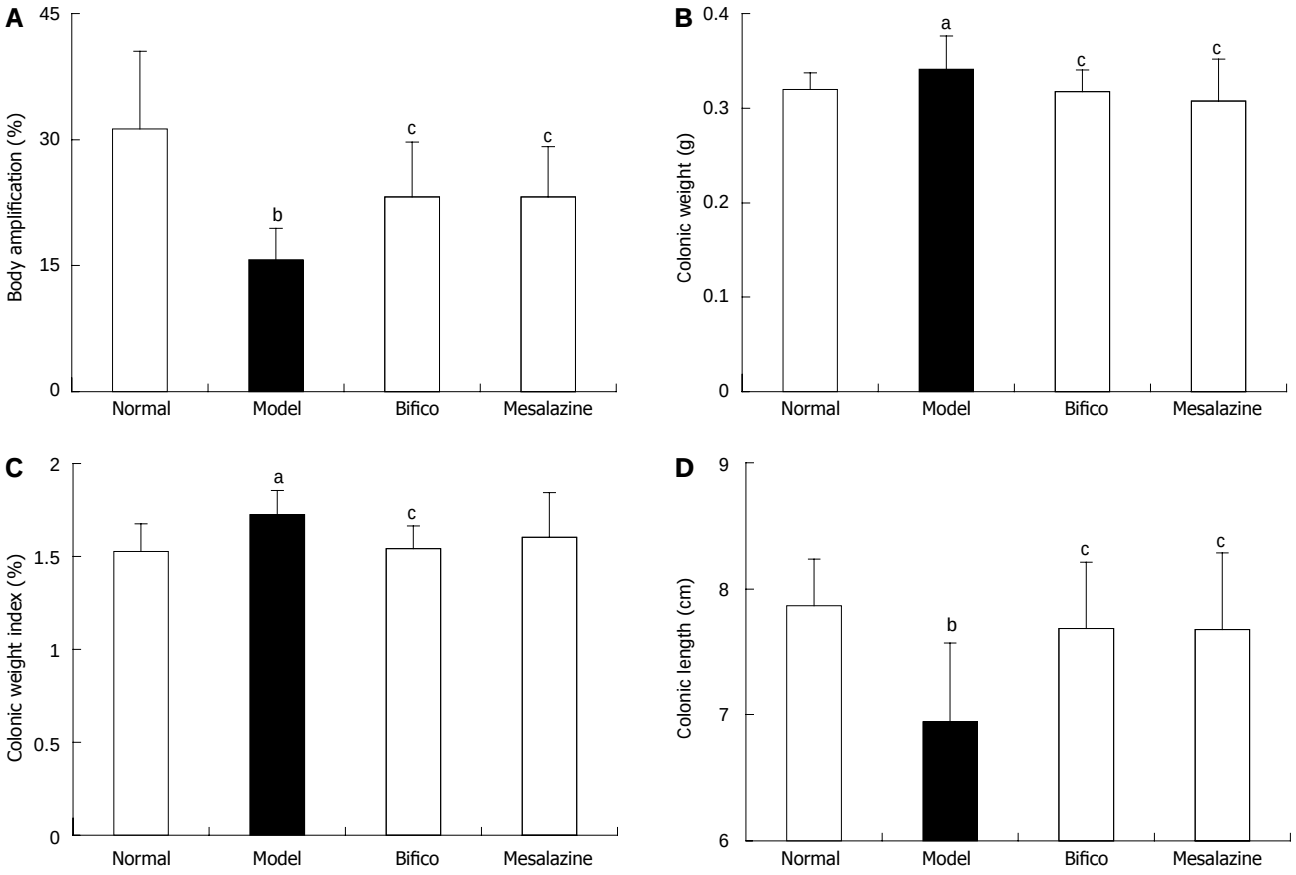

Figure 1 Change of body weight amplification, colonic weight index, colonic weight and colonic length. A: Percent of body weight amplification; B: Colonic weight; C: Colonic weight index; D: Colonic length. Normal: In the normal group, the animals were administrated with physiological saline; Model: In the model group, the animals were challenged with 2,4,6-trinitrobenzene sulfonic acid (TNBS) without treatment; Bifico: In the Bifico group, the animals were challenged by TNBS and treated with Bifico at 345 mg/kg; Mesalazine: In the Mesalazine group, the animals were challenged by TNBS and treated with 300 mg/kg Mesalazine. Data are means ± SE (n = 10). [a]$P < 0.05$, [b]$P < 0.01$ *vs* the normal group; [c]$P < 0.05$ *vs* the model group.

Determination of cytokines in colonic tissue homogenates

The concentrations of cytokines in colonic tissue homogenates were measured using a BD CBA Mouse Th1/Th2/Th17 Cytokine Kit according to the manufacturer's protocol. Fifty microliters of homogenates or standards were incubated with 50 μL of capture beads for 1h at room temperature, and then mixed with 50 μL of phycoerythrobilin (PE)-labeled tumor necrosis factor (TNF)-α, interleukin (IL)-4, interferon (IFN)-γ, IL-10, IL-6, IL-17 and IL-2 detection antibodies and incubated for 2 h at room temperature to form a sandwich complex. Following incubation, 1 mL of washing buffer (BD Biosciences Pharmingen, United States) was added to each tube, and the mean fluorescence intensity was detected using flow cytometry (FACSCalibur, B. D. Co, United States). Data were analyzed using BD Cytometric BeadArray analysis software[15].

Statistical analysis

Statistical analyses were performed using SPSS for Windows, version 15.0. Data were presented as means ± SD. Statistical analysis was performed using ANOVA and the F-test. $P < 0.05$ or $P < 0.01$ were considered significant.

RESULTS

Probiotics relieved macroscopic severity of TNBS-induced colitis in mice

Body weight amplifications of mice in the normal, Bifico and mesalazine groups were higher than that of the model group (31.28 ± 9.23, 23.20 ± 6.51, 23.17 ± 6.05, *vs* 15.73 ± 3.73, $P < 0.05$) (Figure 1A); however, the colonic weight index (CWI) and colonic weight (CW) in the Bifico group decreased compared with the model group (CWI: 1.53 ± 0.15, 1.54 ± 0.12 *vs* 1.72 ± 0.13, $P < 0.05$; CW: 0.32 ± 0.02, 0.32 ± 0.02 *vs* 0.36 ± 0.03, $P < 0.05$) (Figure 1B and C). The colonic lengths of mice in the normal, Bifico and mesalazine groups were significantly higher compared with those in the model group (7.86 ± 0.37, 7.68 ± 0.53, 7.68 ± 0.61, *vs* 6.94 ± 0.63, $P < 0.05$) (Figure 1D).

Probiotics attenuated histological severity of TNBS-induced colitis in mice

As shown in Figure 2A, integral colonic epithelium and no inflammatory cell infiltration were observed in the slice from the normal mice. However, ulceration, colonic epithelium loss, incrassate intestinal wall and abundant

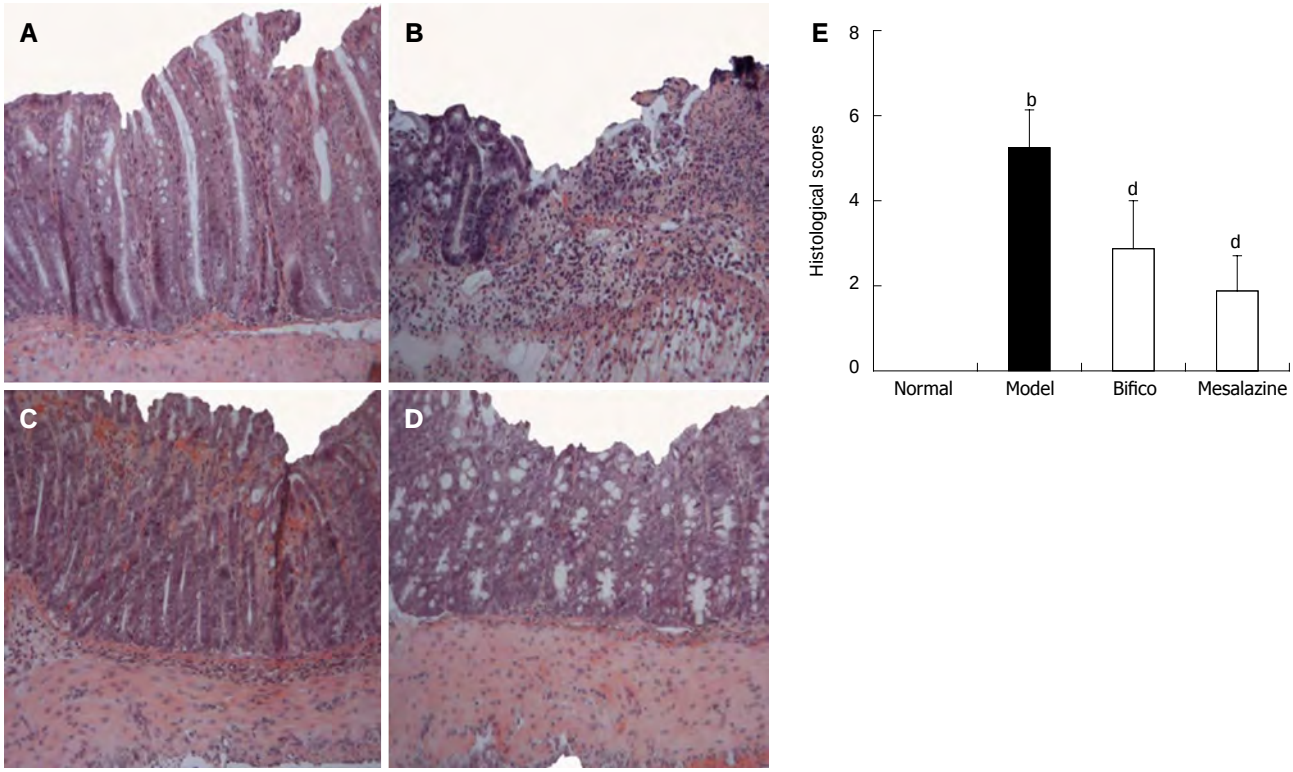

Figure 2 Representative histological images and scores of mice. A: The normal group; B: The model group; C: The bifico group; D: The mesalazine group; E: Histological images and scores (hematoxylin and eosin, light microscope, × 100). Normal: In the normal group, the animals were administrated with physiological saline; Model: In the model group, the animals were challenged with 2,4,6-trinitrobenzene sulfonic acid (TNBS) without treatment; Bifico: In the Bifico group, the animals were challenged by TNBS and treated with Bifico at 345 mg/kg; Mesalazine: In the Mesalazine group, the animals were challenged by TNBS and treated with 300 mg/kg mesalazine. Data are means ± SE (n = 10). $^{b}P < 0.01$ *vs* the normal group; $^{d}P < 0.01$ *vs* the model group.

inflammatory cell infiltration were observed in the colon of mice in the model group (Figure 2B). Meanwhile, the above histological symptoms were remarkably relieved with fewer infiltrated inflammatory cell and restored epithelium in slices from colitis mice treated with Bifico and mesalazine (Figure 2C and D). Compared with the model group, the histological score in the Bifico and mesalazine groups decreased statistically significantly (2.88 ± 1.33, 1.88 ± 0.83 *vs* 5.25 ± 0.89, $P < 0.01$) (Figure 2E). The results indicated that Bifico effectively restrained colonic injury of experimented colitis mice.

Probiotics improved the level of $CD4^+CD25^+Foxp3^+$T cells in mesenteric lymph nodes

To identify the developmental capacity of $CD4^+CD25^+$T regulatory cells, the level of $CD4^+CD25^+Foxp3^+$T cells in mesenteric lymph nodes was analyzed by flow cytometry. As shown in Figure 3, the level of $CD4^+CD25^+Foxp3^+$T cells in the model group was decreased compared with the normal group (29.70 ± 1.87 *vs* 34.73 ± 4.04, $P < 0.05$). But in the Bifico and mesalazine groups, the levels of $CD4^+CD25^+Foxp3^+$T cells were higher than in the model group (34.46 ± 4.11, 32.18 ± 1.44 *vs* 29.70 ± 1.87, $P < 0.05$).

Probiotics regulated the expression of cytokines in colonic tissues

Compared with the normal group, the expressions of TNF-α and IFN-γ in colonic tissues from mice in the model group were significantly increased (TNF-α: 32.67 ± 7.12 *vs* 18.33 ± 4.55, $P < 0.01$; IFN-γ: 28.90 ± 6.13 *vs* 10.24 ± 3.74, $P < 0.01$) (Figure 4A and B), and they were significantly decreased in the Bifico and mesalazine groups compared with the model (TNF-α: 16.87 ± 2.70, 16.96 ± 1.72 *vs* 32.67 ± 7.12, $P < 0.05$; IFN-γ: 10.46 ± 5.44, 5.20 ± 2.10 *vs* 28.90 ± 6.13, $P < 0.01$) (Figure 4A and B). Meanwhile, the expressions of IL-2, IL-4 and IL-10 in the model group were lower than in the normal group (IL-2: 2.00 ± 0.17 *vs* 2.40 ± 0.34, $P < 0.05$; IL-4: 1.58 ± 0.16 *vs* 1.84 ± 0.24, $P < 0.05$; IL-10: 7.50 ± 2.96 *vs* 13.35 ± 2.89, $P < 0.05$) (Figure 4C-E). Compared with the model group, the three cytokines were upregulated in the Bifico and mesalazine groups (IL-2: 2.52 ± 0.40, 2.32 ± 0.11 *vs* 2.00 ± 0.17, $P < 0.05$; IL-4: 1.92 ± 0.34, 1.82 ± 0.20 *vs* 1.58 ± 0.16, $P < 0.05$; IL-10: 14.19 ± 4.14, 12.25 ± 3.41 *vs* 7.50 ± 2.96, $P < 0.05$) (Figure 4C-E). The expressions of IL-6 and IL-17 in colonic tissues from colitis mice without treatment were higher than in the normal group (IL-6: 4.69 ± 1.47 *vs* 2.35 ± 0.19, $P < 0.01$; IL-17: 5.94 ± 1.54 *vs* 3.37 ± 0.96, $P < 0.01$); however, in the two treated groups, they were no different compared with the model.

DISCUSSION

In the present study, the curative effect of probiotics treatment on experimental colitis was demonstrated by

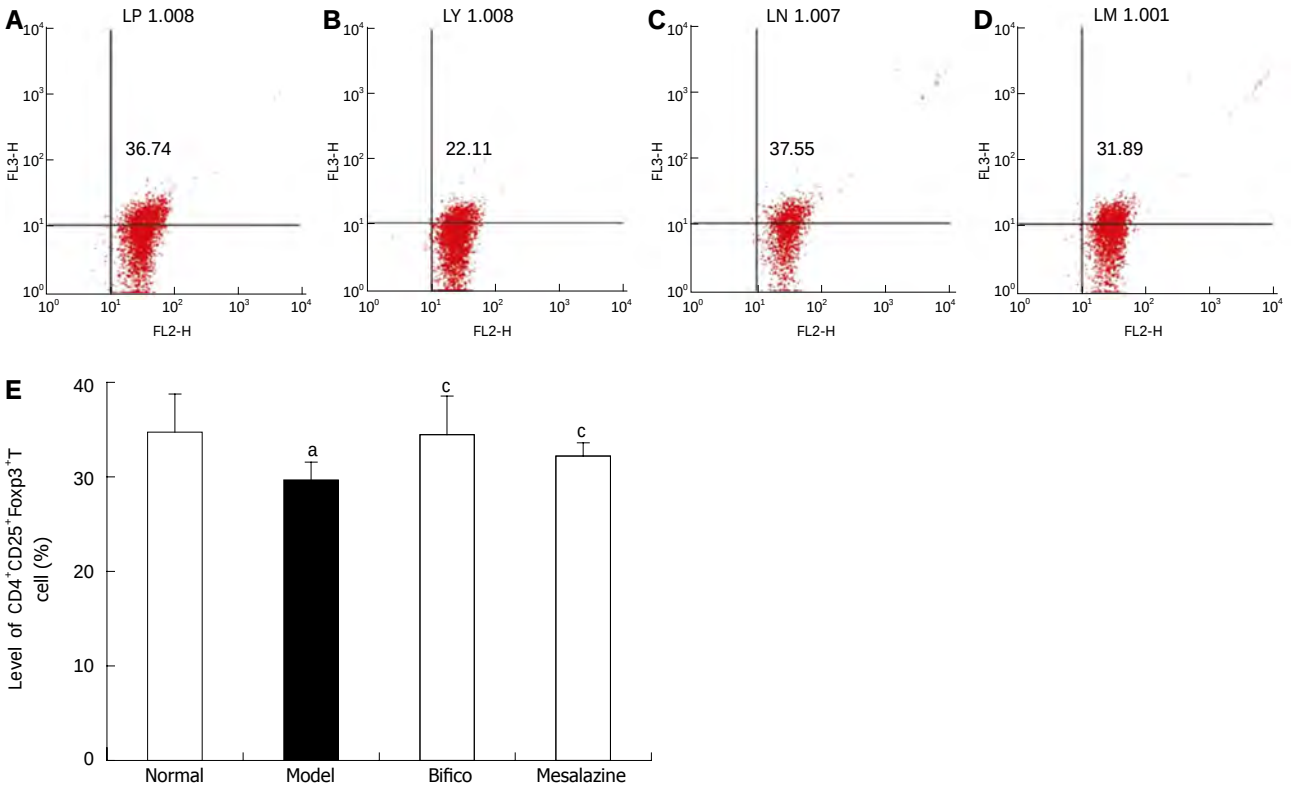

Figure 3 Representative flow plots and level of $CD4^+CD25^+Foxp3^+$T cell. A: The normal group; B: The model group; C: The bifico group; D: The mesalazine group; E: The level of $CD4^+CD25^+Foxp3^+$T. Normal: In the normal group, the animals were administrated with physiological saline; Model: In the model group, the animals were challenged with 2,4,6-trinitrobenzene sulfonic acid (TNBS) without treatment; Bifico: In the Bifico group, the animals were challenged by TNBS and treated with Bifico at 345 mg/kg; Mesalazine: In the Mesalazine group, the animals were challenged by TNBS and treated with 300 mg/kg Mesalazine. Data are means ± SE (n = 10). $^aP < 0.05$ *vs* the normal group; $^cP < 0.05$ *vs* the model group.

the increased body weight, the increased length of the colon, and decreasing histological scores followed by restored pathological characters. Probiotics treatment for 10 d inhibited the tendency to decrease $CD4^+CD25^+$T cells in mesenteric lymph nodes, downregulated the expression of TNF-α and IFN-γ, and upregulated the products of IL-2, IL-4 and IL-10 in colonic mucosa from TNBS-induced colitis mice.

Many studies have indicated that dysregulation of intestinal microflora plays an important role in initiating and perpetuating colonic inflammation in the development of human UC[16-18]. Findings from animal dextran sulfate sodium (DSS)- or TNBS-colitis models suggest that the intestinal microflora plays a key role in the abnormal immune response leading to mucosal injury in experimental colitis, because germ-free animals do not mount an intestinal inflammatory response[1,19-20]. Recently, probiotic therapy has been recognized as a safe and effective treatment for patients with UC. Lin-Lin Chen and their colleagues demonstrated that every strain of three probiotics in Bifico Capsules (combined bifidobacterium, lactobacillus and enterococcus) had a beneficial effect on DSS-induced experimental colitis in mice[21].

$CD4^+CD25^+$T regulatory (Treg) cells are critical for maintaining immune homeostasis and establishing tolerance to foreign, non-pathogenic antigens, including commensal bacteria and food, and are identified by their constitutive expression of Foxp3. $CD4^+CD25^+$T cell secretes suppressive cytokines, such as IL-2, IL-10 and TGF-β, to regulate the balance of Th1/Th2 cells and maintain mucosal immunity in the intestine[22-24]. Evidence has shown that non-functional, absent Tregs or genetic mutations in Foxp3 induces hypersensitivity to bacterial antigens[10,11], and destroys the balance of intestinal mucosal immunity to inflammatory injury followed by lymphocytic infiltration of the intestinal mucosa[25,26]. $CD4^+CD25^+Foxp3^+$ T cells increased in the colon of paracmasis patients with UC[22]. These data indicated that Tregs would be a promising target for treating UC, because increasing the activity of appropriate Tregs in the gut should help to restore inflamed colonic tissues[27].

In the present study, we found that the level of $CD4^+CD25^+Foxp3^+$ T cells was downregulated in mesocolic lymph nodes from experimented colitis mice without treatment, while IL-2, IL-10 and IL-4 were hypo-expressed in colonic tissues in the model group. The results showed that the suppressed function of $CD4^+CD25^+Foxp3^+$T cell induced disturbance of Th1/Th2 cytokines in the colonic mucosa, which leads to increased susceptibility to symbiotic bacteria, overexpression of proinflammatory factors (IL-1, TNF-α, IFN-γ), finally resulting in inflammatory injury and ulceration. After 10-d of treatment by probiotics, impaired colonic mucosa was restored with epithelial

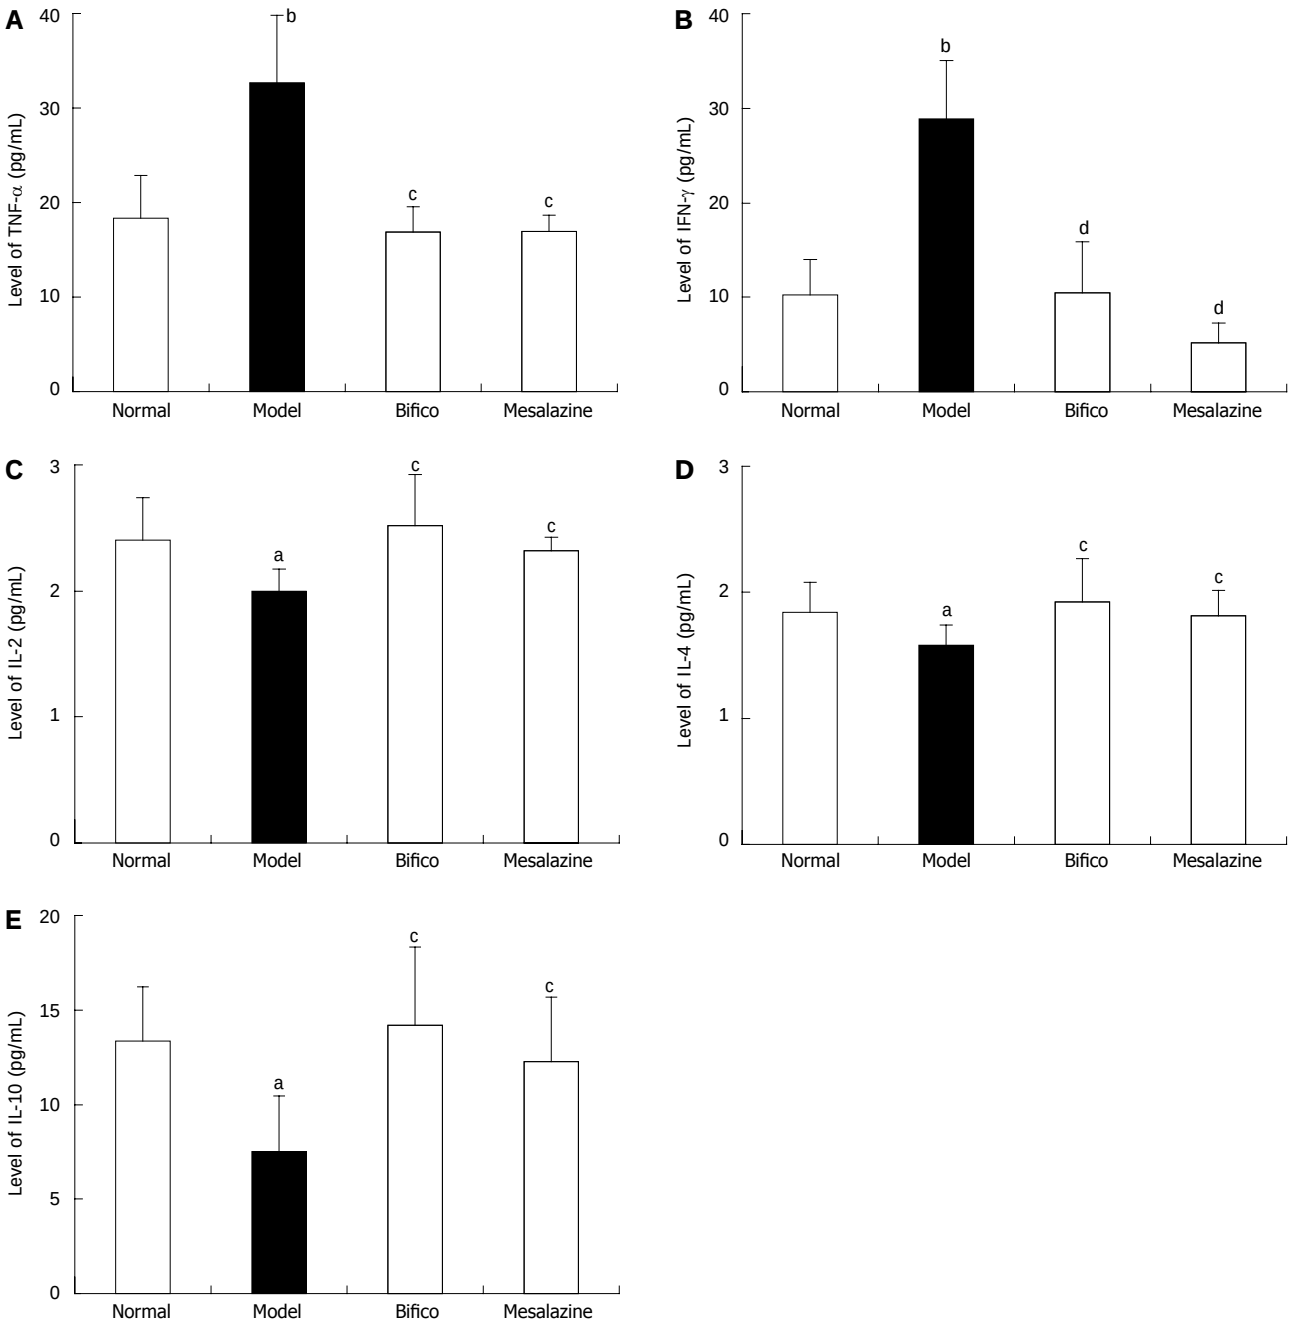

Figure 4 Expression of cytokines in colonic mucosa. A: Level of tumor necrosis factor (TNF)-α; B: Level of interferon (IFN)-γ; C: Level of interleukin (IL)-2; D: Level of IL-4; E: Level of IL-10. hyperplasia, intact colonic epithelia and fewer infiltrating inflammatory cells infiltration. Probiotics effectively treated mice with colitis. $CD4^{+}CD25^{+}Foxp3^{+}T$ cells were upregulated, with high expression of IL-10, IL-4 and IL-2, and TNF-α and IFN-γ were decreased in colonic mucosa from colitis mice treated by probiotics. In the study, probiotics improved the quantity of $CD4^{+}CD25^{+}Foxp3^{+}T$ cells, and restored the suppressed function of $CD4^{+}CD25^{+}Foxp3^{+}T$ cells. The Treg cells secreted more IL-10 and IL-4, competitively bound with IL-2, and enhanced the immune tolerance of intestinal mucosa to resist bacterial antigens and decreased the activity of proinflammatory factors (as TNF-α and IFN-γ), thereby renewing the immunological barrier of the colonic mucosa. Probiotics alleviated colonic inflammatory injury of colitis mice by alleviating the suppression of or increasing the quantity of $CD4^{+}CD25^{+}Foxp3^{+}T$ cell.

In summary, Probiotics effectively treated experimental colitis by improving $CD4^{+}CD25^{+}Foxp3^{+}T$ cell and regulating the balance of Th1/Th2 cytokines in the co-

lonic mucosa.

COMMENTS

Background

Ulcerative colitis (UC) is a chronic, inflammatory disease of the colonic mucosa, characterized by a relapsing-remitting course; however, the cause is largely unknown. Dysregulation of intestinal microflora and hypofrontality of T regulatory cell play important roles in pathogenicity of UC.

Research frontiers

The barrier of intestinal mucosal immunity may become damaged, which may be primarily caused by decreased inhibition of T regulatory cell by bacterial antigens. This suggested that regulating the function of T regulatory cells and/or the balance of intestinal microflora could potentially be used to treat UC.

Innovations and breakthroughs

Previous studies have highlighted that re-imported T regulatory cells may prevent occurrence or aggravation of UC. In the present study, probiotics (Bifico) inhibited the decreased tendency of $CD4^+CD25^+Foxp3^+$T cell induced by 2,4,6-trinitrobenzene sulfonic acid to effectively treat experimental colitis, followed by regulation of the balance of Th1/Th2 cytokines in the colonic mucosa.

Applications

By understanding the effects of probiotics in the treatment experimental colitis, which was mediated by inhibiting the decreased level of T regulatory cell and regulating the balance of Th1/Th2 cytokines, the study provided some evidence of the effect of probiotics on maintaining stable intestinal mucosal immunity in the treatment of UC.

Peer review

The authors investigated the effects of probiotics on treating experimental colitis and explored its potential mechanism by observing the level of T regulatory cell and expression of Th1/Th2 cytokines in colonic mucosa. It has revealed that probiotics effectively treated experimental colitis, which was accomplished by improving $CD4^+CD25^+Foxp3^+$T cell and regulating balance Th1 and Th2 cytokines in colonic mucosa. The results are valuable for exploring the mechanism of treating UC with probiotics.

Abstract

AIM: To introduce transvaginal or transanal specimen extraction in laparoscopic total mesorectal excision surgery to avoid an abdominal incision.

METHODS: Between January 2009 and December 2011, 21 patients with rectal cancer underwent laparoscopic radical resection and the specimen was retrieved by two different ways: transvaginal or transanal rectal removal. Transvaginal specimen extraction approach was strictly limited to elderly post-menopausal women who need hysterectomy. Patients aged between 30 and 80 years, with a body mass index of less than 30 kg/m^2, underwent elective surgery. The surgical technique and the outcomes related to the specimen extraction, such as duration of surgery, length of hospital stay, and the complications were retrospectively reviewed.

RESULTS: Laparoscopic resection using a natural orifice removal approach was successful in all of the 21 patients. Median operating time was 185 min (range, 122-260 min) and the estimated blood loss was 48 mL. The mean length of hospital stay was 7.5 d (range, 2-11 d). One patient developed postoperative ileus and had an extended hospital stay. The patient complained of minimal pain. There were no postoperative complications or surgery-associated death. The mean size of the lesion was 2.8 cm (range, 1.8-6.0 cm), and the mean number of lymph nodes harvested was 18.7 (range, 8-27). At a mean follow-up of 20.6 mo (range, 10-37 mo), there were no functional disorders associated with the transvaginal and transanal specimen extraction.

CONCLUSION: Transvaginal or transanal extraction in L-TME is a safe and effective procedure. Natural orifice specimen extraction can avoid the abdominal wall incision and its potential complications.

INTRODUCTION

A number of single and multicenter randomized trials and meta-analysis have demonstrated that the laparoscopic total mesorectal excision (L-TME) was superior to the open approach. Laparoscopic surgery resulted in faster postoperative recovery and fewer long-term complications than open surgery without apparently compromising the long-term oncologic outcomes[1-3]. However, this typically requires an abdominal incision for specimen

removal, which is commonly associated with postoperative pain. Surgical wound complications, mainly infection and postoperative hernia, continue to be major problems after both open and laparoscopic colorectal surgery, and the mini-laparotomy is often the most important source of postoperative pain after L-TME. Avoidance of the abdominal wall extraction site may be desirable to improve the short-term outcome of L-TME and limit the high cost of wound complication management[4-6].

The concept of natural orifice transluminal endoscopic surgery (NOTES) has gained interest in the surgical and gastrointestinal community as a technique to potentially reduce the surgical wound complications and trauma associated with conventional surgery[7,8]. However, NOTES has been limited because of lack of suitable instruments and platforms to facilitate a safe performance of such complex procedures. The combination of standard laparoscopy and specimen extraction through a natural orifice has the potential to reduce wound-related complications[9,10]. Natural orifice specimen extraction (NOSE) using either the anus or vagina as a route eliminates the need for abdominal wall incision for specimen extraction and anastomosis construction[11]. The NOSE concept is appealing as it maximizes the benefits of laparoscopic surgery while reducing potential wound complications and provides experience for cautious progression toward less incision surgery[12].

In this report, we adopted the technique of L-TME and transvaginal or transanal extraction in a series of 21 rectal cancer patients who required anterior rectal resection. Technique, results, morbidity, and mortality were described.

MATERIALS AND METHODS

Study participants

All consecutive patients operated on for rectal cancer using laparoscopic TME anterior rectal resection approach and transanal or transvaginal extraction of the specimen from January 2009 to December 2011 at First Hospital of Jilin University were enrolled in the study. Patients were aged between 30 and 80 years, had a body mass index of less than 30 kg/m^2, and underwent elective surgery. Patients operated on in an emergency setting and those who underwent Hartmann or abdominal perineal resection procedures were excluded. Written informed consent was obtained from all subjects and the study protocol was approved by the Ethics Committee of the First Hospital, Jilin University. The procedures were performed by a team consisting of experienced laparoscopic general surgeon and gynecologist. All patients underwent an oral magnesium citrate bowel preparation the day before surgery.

In this study, inclusion criteria for transvaginal specimen extraction were as follows: It is suitable for elderly post-menopausal women who need hysterectomy; female patients who were diagnosed with uterine myoma along with irregular vaginal bleeding, hematochezia, and receive

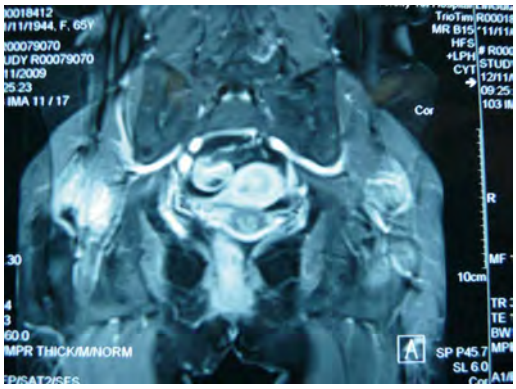

Figure 1 Computed tomography scan showed a rectal tumor combined with uterine myoma in a female patient.

L-TME combined with uterine myomectomy (Figure 1). All patients received preoperative gynecologic examination to rule out vaginal stenosis and congenital abnormalities. Women with a history of endometriosis, narrow vagina, virgins, extensive pelvic adhesions, and lesions > 6 cm, and refusal of the procedure were not considered candidates for the transvaginal removal route. All of the decision was made after consulting with gynecologist.

Transvaginal method

The patients were placed in the supine split leg or modified lithotomy position to allow for vaginal access. Abdominal and vaginal preparations were performed. After vascular control, mesocolic dissection, mobilization of tumor was performed, and the rectum distal to tumor was transected using stapler laparoscopically leaving the proximal rectum in the abdominal cavity. Then, with the assistance of gynecologist, laparoscopic hysterectomy was performed. Next, the specimens were placed in the specimen bag, which is then closed. The proximal rectum with tumor and uterus were delivered transvaginally and the rectum tumor was resected proximally outside body (Figure 2A). The anvil of the circular stapler was then inserted into the proximal colon and closed using purse string suture. The proximal colon was then returned into abdomen with the anvil transvaginally. Bowel anastomosis was completed by inserting the circular stapler via anal canal. Posterior fornix of the vagina was sutured. Final laparoscopic visualization was carried out to ensure hemostasis in the mesentery and inspect the anastomosis site.

Transanal method

The patients were placed in the lithotomy position. Briefly, a three-trocar laparoscopic approach was generally employed for mesenteric dissection and sigmoid colon and rectum mobilization. (1) Laparoscopically TME dissection was done and the upper and lower margins of the tumor determined and rectum was transected by endocutter stapler. Then, the anus was dilated, rectal stump was washed out with a 500 mL povidone-iodine normal saline solution; (2) After transanal lavage was performed,

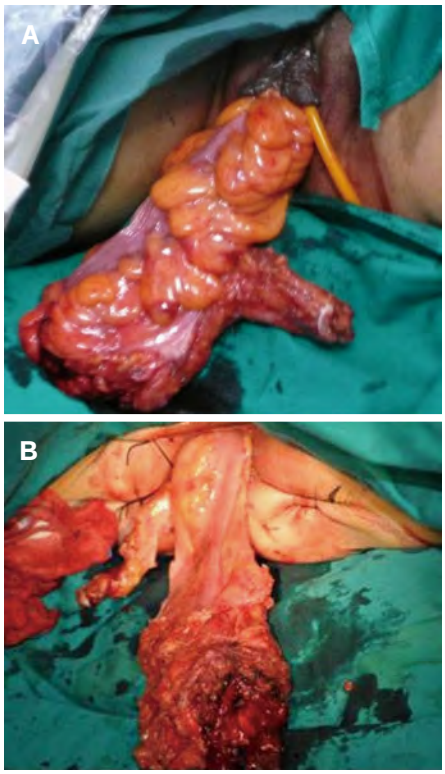

Figure 2 Natural orifice specimen extraction in laparoscopic total mesorectal excision surgery. A: Transvaginal; B: Transana specimen extraction.

the end of distal rectum was opened by ultrasonic scalpel and the specimen was extracted transanally with the specimen bag; (3) The anvil of circular end-to-end anastomosis stapler was introduced to peritoneal cavity transrectally and simultaneously put purse string suture by 2-0 prolene in the proximal colon stump; and (4) Finally, the head of the circular stapler was passed per anal, and a circular anastomosis was created (Figure 2B).

RESULTS

Within a 3-year time period, all 21 laparoscopic resections were performed successfully using a natural orifice removal approach. None of the patients were converted to open operation. The median age was 62 years (range, 50-80 years). Two of 14 patients (14%) had undergone abdominal surgery previously. The mean body mass index was 23.6 kg/m^2 (range, 18-30 kg/m^2). Median operating time was 185 min (range, 122-260 min) and the estimated blood loss was 48 mL. All patients underwent a same postoperative protocol: patient-controlled analgesia for the first 24 to 48 h. The diet was started as tolerated. The mean length of hospital stay was 7.5 d (range, 2-11 d). One patient developed postoperative ileus and had an extended hospital stay. The patient complained of minimal pain. There were no postoperative complications like rupture of the rectus, bleeding or leakage of the anastomosis, anastomosis stenosis or surgery-associated death. All margins in the resected specimens were macroscopically and microscopically free of any tumor. The mean size of the lesion was 2.8 cm (range, 1.8-6.0 cm), and the mean number of lymph nodes harvested was 18.7 (range, 8-27). Patients' demographics and pathologic details are shown in Table 1. At a mean follow-up of 20.6 mo (range, 10-37 mo), no patient experienced pain, drainage from the vaginal extraction site, and dyspareunia, and there was no incisional hernia (Figure 3).

DISCUSSION

At present, despite the advantages of laparoscopic colorectal surgery, during the specimen retrieval through substantial incisions, there is an increased postoperative pain, wound infections, and incisional hernias. Along with the development of the minimally invasive surgery, abdominal wall scarless surgery becomes the new goal for people who pursue laparoscopic surgery[13,14]. In order to leave no scar on the abdominal wall, to achieve fast recovery from surgery using a more minimally invasive technique, and better cosmetic appearance, the idea of the scarless surgery started from NOTES[15,16]. In the era of NOTES, incisionless transrectal or transvaginal approaches for colorectal resections have been investigated with promising results. Transanal retrieval of specimen in laparoscopic TME has been described but not widely adopted[17-21].

Because the NOTES requires advanced technique and equipment, and requests the surgeon to have a higher strain capacity of the anatomy and the techniques. So, at present, it is still at the initial step in many countries. Recently, we have performed fast track rehabilitation in laparoscopic colorectal resection for elderly patients[22].

Figure 3 Postoperative scars.

In this article, we described two different ways to retrieve the specimen based on the technique of the traditional laparoscopic radical surgery for rectal cancer, and experienced no additional difficulty during surgery, no needs of specific equipment.

Some additional hints which are helpful during above procedures as follows: First, if the tumor is a medium-lower rectal cancer, large in size or in the fat patient, mesocolon is generally fleshy and contracted, making it shorter and difficult when transanal retrieval of specimen is done. Secondly, before transanal retrieval of specimen, when the upper and lower margin tie off, it is very important to repeat transanal irrigation by povidone iodine solution and saline. This can reduce the chances of infection and tumor cell implantation in the pelvis. Finally, it is important to put the sample in the plastic bag in the abdominal cavity, which will reduce the chances of infection and helps in smooth extraction of specimens[23,24].

In conclusion, the present study showed that NOSE is safe and feasible to perform L-TME for rectal cancer and extract the specimen without scar on abdominal wall. NOSE is an applicable option for patients requiring L-TME and appears to be associated with little incisional pain and rapid recovery. Future randomized controlled trials are necessary to show the superiority of this approach with regard to postoperative pain and morbidity, hospital stay, recovery, function and cosmesis. NOSE constitutes a stepping stone in the transition to future incisionless NOTES colectomy[25,26].

COMMENTS

Background

Despite the advantages of laparoscopic total mesorectal excision rectal surgery, the need for an incision in the abdominal wall to remove the surgical specimen is a morbid factor.

Research frontiers

The development of natural orifice translumenal endoscopic surgery and natural orifice specimen extraction (NOSE) appears to be the next major frontier in minimally invasive surgery.

Innovations and breakthroughs

Present research showed that laparoscopic total mesorectal excision (L-TME) with transvaginal or transanal extraction is a safe and effective procedure. This technique is feasible and simple to perform, avoids the abdominal wall incision and its potential complications.

Applications

Natural orifice specimen extraction may provide both an attractive way to reduce abdominal wall morbidity and a bridge to pure natural orifice transluminal endoscopic surgery for rectal surgery.

Terminology

NOSE in colorectal surgery prevents the need for an enlarged port site or minilaparotomy to extract the surgical specimen. The current trend to develop less invasive laparoscopic techniques by reducing the number and size of abdominal incisions has spurred new interest in practice.

Peer review

The authors performed laparoscopic total mesorectal excision with NOSE, which is associated with rapid recovery. They conclude that NOSE is technically feasible for L-TME. It could be better if the authors could provide data from prospective control study showing that the recovery parameters of this approach is superior to those of L-TME with trans-abdominal incision.

Abstract

AIM: To investigate the feasibility of laparoscopy-assisted total gastrectomy (LATG) using trans-orally inserted anvil (OrVil™) in terms of operative characteristics and short term outcomes.

RESULTS: Characteristics of 27 patients with gastric cancer who underwent LATG from October 2009 to October 2012 in the Foshan Affiliated Hospital of South Medical University were retrospectively reviewed. Among these patients, six were reconstructed by mini-laparotomy and 21 by OrVil™. The clinicopathological characteristics, total operation time, total blood loss, abdominal incision and complications of anastomosis including stenosis and leakage, were compared between the groups undergoing LATG with OrVil™ and the group undergoing mini-laparotomy.

RESULTS: The operations were successfully performed on all the patients without intraoperative complications or conversion to open surgery. Two (10%) patients received palliative procedure under laparoscope who were prepared for LATG preoperatively. One case had hepatic metastatic carcinoma and 1 case had tumor recurrence near the anastomosis 8 mo after surgery. The mean follow-up duration was 10 mo (range, 2-24 mo). Operation time was significantly reduced by the use of OrVil™ (198.42 ± 30.28 min *vs* 240.83 ± 8.23 min). The postoperative course with regard to occurrence of stenosis and leakage was not different between the two groups. There were no significant differences in estimated blood loss. The upper abdominal incision was smaller in OrVil™ group than in mini-laparotomy group (4.31 ± 0.45 cm *vs* 6.43 ± 0.38 cm).

CONCLUSION: LATG using OrVil™ is a technically feasible surgical procedure with sufficient lymph node dissection, less operation time and acceptable morbidity.

Laparoscopy-assisted total gastrectomy with trans-orally inserted anvil (OrVil™): A single institution experience. *World J Gastroenterol* 2013; 19(5): 755-760 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/755.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.755

INTRODUCTION

Laparoscopic gastrectomy (LG) including laparoscopy-assisted gastrectomy (LAG) and totally LG with regional lymph node dissection as an alternative surgical treatment for gastric cancer has become increasingly common worldwide, especially in Asia[1-3]. However, laparoscopy-assisted total gastrectomy (LATG) has not been

accepted as widely as other LGs because of the low incidence of gastric cancer requiring LATG and because it is particularly difficult even for some experienced surgeons to perform[4,5]. Nevertheless, comparing with the conventional open total gastrectomy, laparoscopic surgery as an advanced procedure offers the advantages of less invasiveness and the same curability if surgeons are adroit at performing LATG[6,7].

Since 2009, our institution has adopted laparoscopic modalities for both the early and advanced stage gastric cancer patients, including 27 cases of LATG. Herein, we review our experience with LATG and analyze the results of LATG in terms of operative characteristics and short-term outcomes.

MATERIALS AND METHODS

Patients

We retrospectively reviewed a series of 27 patients who underwent LATG between October 2009 and October 2012. Twenty-one of them were reconstructed by transorally inserted anvil (OrVil™) and six by mini-laparotomy. The mini-laparotomy was performed in relatively early period and set for the comparisons of short-term outcomes.

Preoperative tumor node metastasis (TNM) stage was determined in all the patients according to the International Union Against Cancer (UICC, 7th edition) and based on endoscopic biopsy and abdominal computed tomography. The indication for LATG in gastric cancer was limited to preoperative stage $T_{1-4}N_{0-3}M_0$. Patients whose NRS 2002 score was more than 4 received more than 1-wk nutrition therapy before operation. Patients suitable for endoscopic submucosal dissection or had surgical contraindications were excluded. Written informed consent was signed by each patient who agreed to undergo LATG.

Surgical procedure

All patients were placed in relaxed dorsal lithotomy position. The surgeon usually stood on the left side of the patient, the first assistant surgeon on the right, and the second assistant surgeon holding the camera stood between the patient's legs. At the beginning, five trocars were introduced into the right upper quadrant (5 mm), right middle quadrant (5 mm), subumbilical (10 mm; camera port), left middle quadrant (5 mm), and left upper quadrant (12 mm) regions of the abdomen. The intraperitoneal pressure was maintained as 12 mmHg with carbon dioxide.

Total gastrectomy with complete omentectomy and extended lymphadenectomy (D2) was performed in all the patients. After sufficient mobilization of the duodenum near the pylorus ring and abdominal esophagus, the duodenum and esophagus were transected using EndoGIA™ Universal stapler (60 mm; Covidien). The stomach was bagged in an isolation pocket and pulled out extracorporeally through a 4-6 cm upper midline incision. In the next step, the gastrointestinal continuity was restored in a Roux-en-Y mode extracorporeally through the incision.

The OrVil™ orogastric tube was transorally introduced into the esophagus. The orogastric tube was then used to make a small hole on the middle of the abdominal esophageal stump. The tube was pulled out into the abdominal cavity through the hole until the anvil reached the esophageal stump. The orogastric tube was disconnected from the anvil and taken out of the esophagus. Subsequently, intracorporeal stapling esophagojejunostomy was performed and the jejunal stump was intracorporeally sutured with EndoGIA™ Universal (Figure 1). The intraperitoneal chemohyperthermia was performed and two drains were placed around the esophagojejunal anastomosis and pelvic cavity, respectively.

Postoperative course

The theory of fast track surgery is prevalent in our institution, but we adopt a conservative approach for the LATG patients postoperatively. The preoperatively inserted nasogastric tube for air decompression was removed at the end of surgery. A soft diet commenced orally on postoperative day (POD) 4, and abdominal drain tube was removed after 1 or 2 d when the drainage was less than 30 mL per 24 h. After a meglumine diatrizoate meal examination of esophago-intestinal tract was performed to evaluate anastomotic leakage and stenosis on PODs 8 to 10, patients were discharged on PODs 10 to 13.

Statistical analysis

Data were analyzed by the SPSS statistical software (SPSS 13.0). Quantitative variables were compared using the Student's *t* test and were expressed as means ± SD. *P* values were considered to be statistically significant at 0.05.

RESULTS

Patient characteristics

Patient characteristics including age, gender, body mass index (kg/m^2), history of abdominal surgery, NRS 2002 score and comorbidities are listed in Table 1. The operations were successfully performed in all the patients, without intraoperative complications or conversion to open surgery. Two (10%) cases received palliative procedure under laparoscope who were prepared for LATG preoperatively. One case developed hepatic metastatic carcinoma and 1 case had tumor recurrence near the anastomosis 8 mo after surgery. Mean follow-up duration was 10 mo (range, 2-24 mo).

Surgical procedure

Table 2 shows the surgical outcomes and postoperative complications. All patients underwent LATG with antecolic type Roux-en-Y esophagojejunostomy and D2

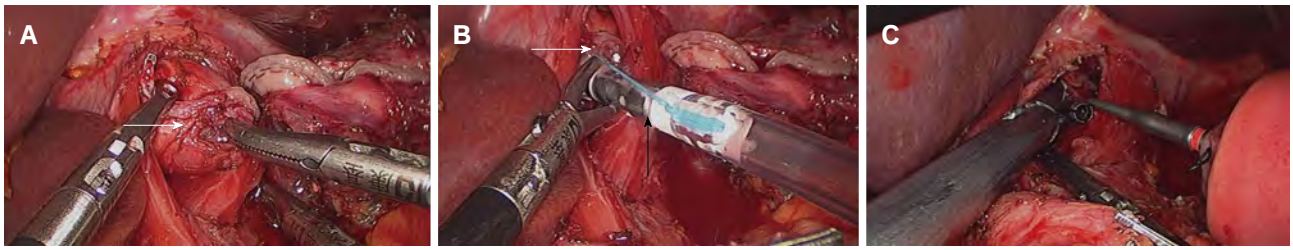

Figure 1 Esophagojejunostomy with trans-orally inserted anvil. A: The trans-orally inserted anvil orogastric tube was transorally introduced into the esophagus (white arrow); B: The tube was pulled out into the abdominal cavity through the hole. The black arrow shows the place to be separated; C: The orogastric tube was disconnected from the anvil and intracorporeal stapling esophagojejunostomy was performed.

Table 1 Characteristics of patients

Case	Gender	Age (yr)	NRS score	BMI	Previous abdominal operation	Comorbidity
1	Female	46	5	27.2	No	Urinary lithiasis
2	Male	77	7	24.1	No	No
3	Male	65	8	21.4	Appendectomy	No
4	Male	61	4	26.4	No	No
5	Male	62	5	22.1	Cholecystotomy	No
6	Female	71	8	20.9	No	Gout; high blood pressure
7	Male	48	5	24.4	No	No
9	Male	62	5	23.7	Cesarean section	Hepatic cyst; high blood pressure; cholecystolithiasis
10	Male	60	2	23.8	No	No
11	Female	55	2	23.2	No	No
12	Female	52	8	17.4	Cesarean section	No
13	Male	70	2	21.5	No	No
14	Male	54	3	20.5	No	Urinary lithiasis; urinary infection
15	Male	42	7	18.8	Gastrectomy	
16	Male	72	3	24.8	No	
17	Male	61	6	22.1	No	High blood pressure
18	Female	63	2	20.8	Appendectomy	
19	Male	66	5	19.2	No	
mean	NA				NA	NA

BMI: Body mass index; NRS: Nutritional risk screening (2002); NA: Not available.

lymph node dissection. One case received combined spleen and pancreatic tail resection. Operation time was significantly reduced by the use of OrVil™ (198.42 ± 30.28 min *vs* 240.83 ± 8.23 min, $P < 0.05$). The postoperative course with regard to stenosis and leakage did not differ between the two groups. There were no significant differences in estimated blood loss (130.57 ± 65.17 mL *vs* 140.83 ± 78.41 mL, $P > 0.05$). The upper abdominal incision was smaller in OrVil™ group than in mini-laparoscopy group (4.31 ± 0.45 cm *vs* 6.43b ± 0.38 cm, $P < 0.05$).

Postoperative course

The mean time to first oral intake and postoperative hospital stay were 3.2 d (range, 2-5 d) and 12.5 d (range, 10-19 d). Anastomotic stenosis and major leakage occurred in one case, respectively. All the patients were evaluated at over stage I and received adjuvant chemotherapy.

Tumor characteristics

Histologically, 13 patients had poorly differentiated carcinoma and 3 patients had signet ring cell carcinoma. The mean tumor size was 4.5 cm (range, 3.2-7 cm). The location of the tumor was the upper body in 7 patients and the mid body in 11 patients. Esophageal invasion was detected in 1 patient and double lesions were detected in 1 patient who had a mid-body cancer. The mean length of proximal resection margin was 4.7 cm (range, 2.2-6.1 cm) and the distal one was 6.2 cm (range, 3.1-9 cm). TNM staging according to the 7th UICC identified stage ⅡA in 2, stage ⅡB in 7, stage ⅢA in 6, stage ⅢB in 5 and stage ⅢC in 1 patient. The mean number of retrieved lymph nodes was 22.4 (range, 16-42). Multiple lymph node metastases were detected, 1-2 lymph nodes in 2 patients, 3-6 in 8 patients and more than 7 in 11 patients.

DISCUSSION

Since the first report of LG in 1992[8], LAG has been carried out not only in distal and proximal gastrectomy, but also in total gastrectomy which was more often used in advanced gastric cancer[9-11]. Although performance of LATG for gastric cancer has been increasing worldwide, especially in Asia, it remains controversial if laparoscopic

Table 2 Comparisons of characteristics between trans-orally inserted anvil group and mini-laparotomy group

	OrVil™ group (n = 21)	Mini-laparotomy group (n = 6)	P value
Total operation time (min)	198 (180-320)	240 (230-290)	0.018
Total blood loss (mL)	130 (100-400)	140 (100-300)	0.211
Abdominal incision (cm)	4.3 (4-6)	6.4 (5.5-7.0)	0.022
Complications of anastomosis	2	0	1.000
Stenosis	1	0	1.000
Leakage	1	0	1.000

In square brackets: Range. OrVil™: Trans-orally inserted anvil.

D2 dissection is equivalent to open surgery for advanced gastric cancer (AGC). In our cases, the dissection of more than 15 lymph nodes was performed and the final cutting edge negative rate was 100%. Some recent studies focus on the outcome of D2 lymph node dissection in LAG and open surgery for gastric cancer[11-13]. Du *et al*[11] evaluated 82 patients with AGC who underwent LATG with D2 dissection compared with 94 patients who received open surgery; a similar number of harvested lymph nodes (HLNs) was obtained in both groups. Cui *et al*[13] retrospectively analyzed 131 cases including a single LATG group, and found that laparoscopic D2 dissection is equivalent to open gastrectomy in the number of HLNs, regardless of tumor location.

The mean operation time for LATG with OrVil™ was 198 min, which was significantly shortened compared with the traditional mini-laparotomy group (240 min), and the mean operation time for LATG was also significantly shorter than for mini-laparotomy (180 min *vs* 406 min) in the previous studies[9,10,13]. It takes a longer time to perform esophagojejunal anastomosis through a narrow mini-laparotomy in LATG, which can be avoided by the use of OrVil™. The same conclusion is confirmed by other operative team and with OrVil™ their mean operation time was 152-243 min which mainly affected by tumor stage[3,5,9,14].

The incidence of postoperative complications in patients who underwent LATG has been reported to be 9.4%-39.4%, and common complications include anastomotic leakage, anastomotic stenosis, and pancreatic fistula[9,2,14,15]. Some studies revealed that the incidence of complications in the LATG group was similar to that in the open total gastrectomy group; however, other studies showed a lower or higher rate of complications in the LATG group[15-17]. In this study, 1 case developed anastomotic leakage and 1 case had anastomotic stenosis. The complication rate was 27%, being slightly lower compared with those from previous studies[15,18,19]. The high frequency of anastomotic complications in patients who underwent LATG might result from the excessive traction of the distal esophagus and the extensive mobilization of the jejunal limb. In our series, the rates of complications associated with anastomosis were not statitistically different between the LATG with OrVil™ and traditional mini-laparoscopy groups. However, it should be mentioned that the number of the mini-laparotomy group was small which may produce statistics bias. The same procedure was performed postoperatively in these two groups, so the comparison of mean time to first oral intake and postoperative hospital stays was meaningless.

There are some reconstructive methods used after LATG, such as Roux-en-Y esophagojejunostomy, and extracorporeal or intracorporeal anastomosis using a hand-sewn, circular stapler, or side-to-side linear stapler[1,9,20,21]. Roux-en-Y esophagojejunostomy by extracorporeal anastomosis through a small skin incision is the most common approach. However, it is difficult to perform through a mini-laparotomy, particularly on obese patients, and too larger laparotomy makes it similar to conventional open surgery[22]. OrVil™ as an intracorporeal circular stapling esophagojejunostomy can simplify the reconstruction procedure after total gastrectomy[23]. This device requires no purse-string sutures and offers wide intracorporeal operating views[24,25]. In this study, compared with control group, the smaller body incision and less operation time were observed. Moreover, two respective studies concluded that this technique was simple, safe, and efficient for performing gastrojejunostomy, and additionally less expensive and accelerated the surgical learning curve[23,26,27]. However, the earlier studies reported postoperative infection and recommended oral gargling with hexamidine solution and abdominal irrigation after anvil insertion[9,28]. No postoperative abdominal infection occurred in our series.

There were some limitations in this study. First, this retrospective analysis might have selection bias as a result of comparison of these nonrandomized groups with a retrospective profile. Second, there was no survival data. Thus, long-term oncological outcomes of LATG with OrVil™ need to be evaluated by future studies. Third, the sample size of the mini-laparotomy group is small and the operation was performed in relatively early period which cause the learning curve effect.

In conclusion, LATG using OrVil™ for gastric cancer may be a technically feasible surgical procedure with advantages of sufficient lymph node dissection, less operation time and acceptable morbidity. However, the number of patients is small in this study. It will be necessary to confirm these results by a large cohort study in the validity of LATG with OrVil™.

COMMENTS

Background

Laparoscopic gastrectomy (LG) including laparoscopy-assisted gastrectomy (LAG) and totally LG with regional lymph node dissection as an alternative surgical treatment for gastric cancer has become increasingly common worldwide, especially in Asia.

Research frontiers

Since the first report of LG in 1992, laparoscopy-assisted gastrectomy has been carried out not only in distal and proximal gastrectomy, but also in total gastrectomy which was more often used in advanced gastric cancer. Although performance of laparoscopy-assisted total gastrectomy for gastric cancer has

been increasing worldwide, especially in Asia, it remains controversial if laparoscopic D2 dissection is equivalent to open surgery for advanced gastric cancer.

Innovations and breakthroughs

LATG using orally inserted anvil (OrVil™) for gastric cancer may be a technically feasible surgical procedure with advantages of sufficient lymph node dissection, less operation time and acceptable morbidity. However, the number of patients is small in this study. It will be necessary to confirm these results by a large cohort study in the validity of LATG with OrVil™.

Peer review

This is an interesting manuscript on LG with trans-orally anastomosis. Since little is known about this technique, many readers would be interested to learn this experience.

Abstract

AIM: To assess the impact of preoperative neoadjuvant bevacizumab (Bev) on the outcome of patients undergoing resection for colorectal liver metastases (CLM).

METHODS: Eligible trials were identified from Medline, Embase, Ovid, and the Cochrane database. The data were analyzed with fixed-effects or random-effects models using Review Manager version 5.0.

RESULTS: Thirteen nonrandomized studies with a total of 1431 participants were suitable for meta-analysis. There was no difference in overall morbidity and severe complications between the Bev + group and Bev - group (43.3% *vs* 36.8%, P = 0.06; 17.1% *vs* 11.4%, P = 0.07, respectively). Bev-related complications including wound and thromboembolic/bleeding events were also similar in the Bev + and Bev - groups (14.4% *vs* 8.1%, P = 0.21; 4.1% *vs* 3.8%, P = 0.98, respectively). The incidence and severity of sinusoidal dilation were lower in patients treated with Bev than in patients treated without Bev (43.3% *vs* 63.7%, P < 0.001; 16.8% *vs* 46.5%, P < 0.00, respectively).

CONCLUSION: Bev can be safely administered before hepatic resection in patients with CLM, and has a protective effect against hepatic injury in patients treated with oxaliplatin chemotherapy.

Preoperative administration of bevacizumab is safe for patients with colorectal liver metastases. *World J Gastroenterol* 2013; 19(5): 761-768 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/761.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.761

INTRODUCTION

The liver is the most common metastatic site of colorectal cancer (CC). Approximately 50% of CC patients develop colorectal liver metastases (CLM) over the course of the disease[1]. Hepatectomy is the most important modality in the treatment of CLM, offering a 5-year survival rate of approximately 30%-65%[2]. However, the long-term survival of CLM patients remains poor due to the high rate of recurrence and metastases after surgery. It is reported that neoadjuvant chemotherapy before hepa-

tectomy is associated with improved survival of CLM patients[3,4].

Bevacizumab (Bev) is a monoclonal antibody against vascular endothelial growth factor (VEGF) and can inhibit the growth of human tumor xenografts. In addition to inhibiting the antiangiogenic effect, Bev may also improve the delivery of chemotherapy by altering the tumor vasculature and decreasing the elevated interstitial pressure in tumors[5]. Randomized clinical trials[6,7] have demonstrated that the addition of Bev to fluorouracil-based combination chemotherapy can improve overall survival, the response rate and duration of response, and prolong time to disease progression in CLM patients with metastatic colorectal cancer. For this reason, some researchers advocate the use of Bev in the neoadjuvant setting before surgery for resectable CLM[8-11]. However, Bev is known to be associated with bleeding, thrombosis, gastrointestinal perforation, impaired wound healing and liver regeneration[8], thus alerts surgeons to the safe use of Bev at the time of hepatic surgery.

Chemotherapy-specific liver injuries have been more frequently reported as a disadvantage with the use of oxaliplatin in particular, because it is associated with the occurrence of sinusoidal dilation, a distinctive type of hepatic and vascular injury characteristic of hepatic veno-occlusive disease[12]. Nakano *et al*[13] reported that such injury was associated with increased morbidity and mortality after hepatectomy in CLM patients. Although the etiology of sinusoidal dilation remains unclear, it has been documented that VEGF is one of the causative cytokines for the development of sinusoidal dilation in patients undergoing bone marrow transplantation[14]. VEGF blockade by Bev may therefore attenuate sinusoidal injury[15].

Although several recent studies[8-10,15-24] have commented on the impact of preoperative Bev administration on the safety and/or oxaliplatin-associated liver injury after CLM resection, none of these studies were randomized controlled trials. A meta-analysis is therefore required to provide an improved level of evidence on this subject.

MATERIALS AND METHODS

Study selection

A Medline, Embase, Ovid and Cochrane database search was performed to identify all studies published up to March 2012 that assessed the influence of preoperative Bev administration on the outcome after CLM resection. The following Mesh search headings were used: "colorectal cancer", "liver metastases", "bevacizumab", "hepatic resection", "hepatectomy" and "neoadjuvant chemotherapy". A manual search of the reference lists of relevant papers was also carried out to identify additional trials.

Data extraction

Two reviewers (Li B and Wu LP) independently appraised each article and extracted the following parameters: first author, year of publication, study population characteristics, study design, number of patients in each arm, sex, age, inclusion and exclusion criteria, and outcomes of interest. All relevant text, tables and figures were reviewed for data extraction. Discrepancies between the reviewers were resolved through discussion and consensus.

Morbidity and mortality were defined as those events occurring within 30 or 90 d after surgery. Severe complications were defined as events requiring intensive care management or surgical, endoscopic, or radiologic interventions[25].

Criteria for inclusion and exclusion

Only trials that compared postoperative outcomes after hepatectomy between CLM patients treated with neoadjuvant chemotherapy with and without Bev administration before surgery were included. Abstracts, letters, proceedings from scientific meetings, editorials and expert opinions, reviews without original data, case reports, studies lacking control groups, repetitive data, non-English language papers and animal studies were excluded. To avoid drug interactions, studies involving other targeted molecular therapies were also excluded.

Statistical analysis

The meta-analysis was performed using the Review Manager (RevMan) software version 5.0 (The Cochrane Collaboration, Software Update, Oxford, United Kingdom). The Mantel-Haenszel method was used to combine odds ratio with 95%CI for the outcomes of interest, including overall morbidity, major complications, Bev-related complications, general complications, mortality, and incidence and severity of sinusoidal dilation. Heterogeneity between trials was assessed by calculating the Q and I^2 statistic. If $I^2 > 10\%$, a random-effects approach instead of a fixed-effects analysis was undertaken. Publication bias was assessed visually using a funnel plot. Statistical significance was defined as $P < 0.05$.

RESULTS

Eligible studies

Thirteen nonrandomized studies published between 2007 and 2012 met the inclusion criteria and were suitable for meta-analysis[8-10,15-24]. The characteristics of the included studies are summarized in Table 1. Sample size ranged from 31 to 274, with a total of 1431 participants.

Meta-analysis

Results from overall meta-analysis are outlined in Table 2.

Postoperative morbidity

Ten studies reported on overall morbidity, which was found to be comparable in the Bev + group and Bev - group (43.3% *vs* 36.8%, $P = 0.06$) (Figure 1A). Similarly,

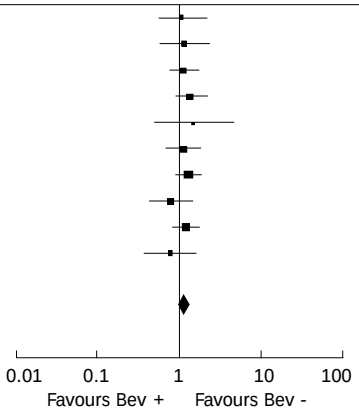
Outcome of interest	No. of studies	No. of patients	OR	95%CI	*P*-value	I^2 (%)
Overall morbidity	10[8-10,16-18,20,22-24]	Bev + = 452, Bev - = 494	1.17	1.00, 1.37	0.06	0
Severe complication	8[8-10,16,17,20,22,23]	Bev + = 390, Bev - = 421	1.57	0.97, 2.53	0.07	18
Wound complication	6[8-10,16,22,23]	Bev + = 269, Bev - = 296	1.43	0.82, 2.50	0.21	0
Bleeding/thromboembolic complication	5[8-10,23,24]	Bev + = 218, Bev - = 284	0.99	0.41, 2.38	0.98	0
Cardiovascular complication	2[16,23]	Bev + = 148, Bev - = 141	1.14	0.23, 5.56	0.88	0
Pulmonary complication	6[8,16,18,20,23,24]	Bev + = 247, Bev - = 267	1.10	0.60, 2.02	0.77	0
Renal or urinary complication	6[8,16,18,20,23,24]	Bev + = 247, Bev - = 267	0.73	0.24, 2.23	0.58	0
Hepatic dysfunction	5[16-18,20,23]	Bev + = 223, Bev - = 219	0.48	0.22, 1.05	0.07	0
Mortality	10[8-10,16-18,20,22-24]	Bev + = 452, Bev - = 494	0.63	0.16, 2.56	0.52	0
Overall sinusoidal dilation	6[15,19-21,23,24]	Bev + = 265, Bev - = 395	0.53	0.38, 0.75	< 0.001	0
Moderate or severe sinusoidal dilation	6[15,18-21,24]	Bev + = 267,Bev - = 387	0.34	0.19,0.64	< 0.001	46

OR: Odds ratio; Bev: Bevacizumab.

there was no significant difference in severe complications between the Bev + and Bev - groups (17.1% *vs* 11.4%, $P = 0.07$) (Figure 1B). Nor was there a significant difference in cardiovascular, pulmonary and renal or urinary complications between the Bev + and Bev - groups (2.7% *vs* 2.1%, $P = 0.88$; 10.1% *vs* 9.3%, $P = 0.67$; 1.2% *vs* 2.2%, $P = 0.58$, respectively).



Bev-related complications including wound and thromboembolic/bleeding events were also similar in the Bev + and Bev - groups (14.4% *vs* 8.1%, $P = 0.21$; 4.1% *vs* 3.8%, $P = 0.98$, respectively). Four studies reported other types of Bev-related complications[16,22-24]. Kesmodel *et al*[16] reported hypertension in nine patients and proteinuria in two patients. van der Pool *et al*[24] reported hypertension in one patient. In one study, mild arterial hypertension occurred before surgery in one patient, necessitating dose reduction and treatment with beta-blocker therapy. No bowel perforations occurred in 13 patients with primary colorectal tumor *in situ* who received Bev. Anastomotic leakage with localized peritonitis occurred in one of seven patients who underwent synchronous colorectal and hepatic resections[23]. In another report by Tamandl *et al*[22], one patient developed anastomotic dehiscence after combined hepatic surgery and right colectomy.

Five studies reported on hepatic dysfunction, which was nonsignificantly less frequent in the Bev + group as compared with the Bev - group (5.3% *vs* 9.5%, $P = 0.07$).

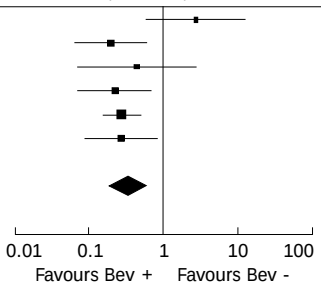

Figure 1 Forest plot. A: Overall morbidity; B: Severe complications; C: Overall sinusoidal dilation; D: Moderate or severe sinusoidal dilation. Bev: Bevacizumab.

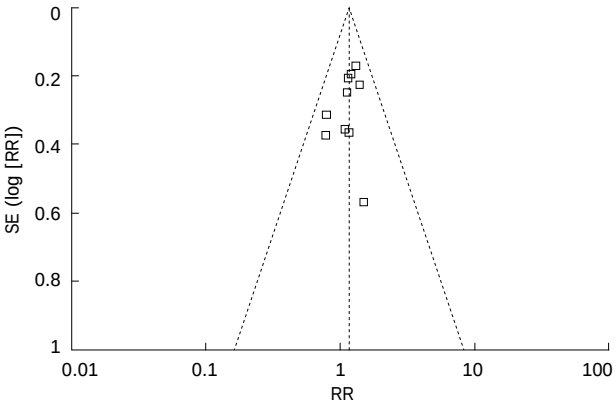

Figure 2 Funnel plot of the results obtained from studies comparing overall morbidity. RR: Risk ratio.

Postoperative mortality

Ten studies reported on postoperative mortality. There were 3 (0.6%) deaths in the Bev + group, which was similar to that in the Bev - group (5 deaths, 1.0%).

Nontumorous liver histology

Seven studies evaluated the effect of Bev for CLM on nontumorous liver histology, and one study reported a significant difference in neoadjuvant treatment regimens between patient groups. To ensure homogeneity within groups, only patients treated with oxaliplatin were included for analysis[23]. Pooled analysis showed that Bev significantly reduced the incidence (Bev + 43.3% *vs* Bev - 63.7%, $P < 0.001$) and severity (Bev + 16.8% *vs* Bev - 46.5%, $P < 0.001$) of sinusoidal dilation (Figure 1C, D).

Publication bias

A funnel plot of the studies included in the meta-analysis reporting on overall morbidity is shown in Figure 2. None of the studies lay outside the limits of the 95%CI, and there was no evidence of publication bias.

DISCUSSION

Liver regeneration is an important component of the recovery process that occurs after various forms of hepatic injury, including partial hepatectomy (PH)[26]. Angiogenesis, the formation of new blood vessels, is a fundamental process in liver regeneration and repair. VEGF is considered a key regulator of normal and pathological angiogenesis. VEGF increases vascular dilatation and permeability, and induces the migration and proliferation of endothelial cells. These activities are mediated *via* two receptors for VEGF: kinase insert domain-containing receptor, and fms-like tyrosine kinase-1 receptor[27,28]. Endogenous expression of VEGF in hepatocytes and its receptors in endothelial cells has been shown to increase after PH[26].VEGF treatment protected the liver against chemically induced cytotoxicity, associated with a marked increase in the proliferation of hepatocytes and sinusoidal endothelial cells (SEC)[28,29]. In addition, exogenous VEGF administration promoted the increase of vessel density, vessel diameter, intrasinusoidal space, liver body weight ratio and hepatocyte proliferation after PH in the rat model. Conversely, these effects were completely suppressed by anti-VEGF treatment[30]. These results suggest that VEGF plays an important role in liver regeneration. Therefore, the safety of VEGF inhibitor administration at the time of hepatic surgery needs to be addressed.

The present meta-analysis shows that both overall and severe complications were not significantly different between the Bev + and Bev - groups. In addition, Bev treatment did not seem to increase the risk of Bev-related complications (wound and bleeding/thromboembolic events), hepatic dysfunction, and postoperative deaths. On the other hand, Wicherts *et al*[23] reported that liver functional recovery parameters including prothrombin time and serum total bilirubin level were equivalent between the Bev + and Bev - groups in the postoperative period, suggesting that Bev administration should be safe before hepatic resection.

To increase the safety of surgery, preoperative portal vein embolization (PVE) has been used for major hepatic resection in CLM patients, because PVE can induce homolateral atrophy and contralateral compensatory hypertrophy of the remnant liver, thus decreasing the risk of postoperative liver failure[31]. In a relatively large cohort study of 100 patients, Covey *et al*[32] found that the mean growth of non-embolized hemiliver was comparable in patients treated with and without neoadjuvant chemotherapy (22% ± 3% *vs* 26% ± 3%) with a similar number of patients with less than 5% growth of liver (4 *vs* 6) after PVE. Similar findings were also reported by other authors[33,34]. Zorzi *et al*[17] found that chemotherapy with Bev did not alter non-embolized liver hypertrophy. In contrast, a study conducted by Aussilhou *et al*[18] demonstrated that the hypertrophy of the future liver remnant after PVE was impaired in patients treated with Bev. These inconsistent results may be attributed to different durations of chemotherapy used in the two studies. It was reported that postoperative morbidity was correlated with the number of cycles of chemotherapy before surgery. Karoui *et al*[35] reported that morbidity in patients who received six or more cycles of chemotherapy was significantly higher that that in patients who received less than six cycles (54% *vs* 19%, $P = 0.047$). Indeed, almost 80% of the patients in the series by Aussilhou *et al*[18] received six or more cycles of chemotherapy compared with 53% in the study by Zorzi *et al*[17].

Although oxaliplatin is often utilized as a chemotherapeutic agent in the treatment of CLM, it can exert adverse effects on the liver. Oxaliplatin-based chemotherapy has been shown to cause hepatic sinusoidal dilation[12]. Our study has shown that Bev can significantly reduce the incidence and severity of sinusoidal dilation,

thus supporting the use of Bev for CLM. An explanation for the above protective effect remains unclear. Increased expression of matrix metalloproteinase (MMP)-9 and MMP-2 by SEC was found to play an important role in sinusoidal dilation development in the monocrotaline-induced rat model[36]. An *in vitro* study[37] suggested that VEGF could up-regulate MMP-9 expression. It is postulated that VEGF blockade by Bev may attenuate sinusoidal injury by down-regulating MMP-9[15].

There is no consensus on the optimal time interval between discontinuation of Bev and hepatic surgery. D' Angelica *et al*[8] found that postoperative complications were more common in patients who received Bev within 8 wk. Similarly, Reddy *et al*[9] noted that patients who underwent hepatectomy within 8 wk of Bev treatment may be at a higher risk of overall, severe and hepatic complications after surgery. Whereas Kesmodel *et al*[16] failed to confirm that the time interval from discontinuation of Bev ($\geq$ 60 *vs* < 60 d) to surgery was associated with an increased likelihood of developing complications. In addition, a subgroup analysis of patients who received Bev also demonstrated that there was no significant difference in complication rates between patients who received Bev 31-45 d, 46-60 d and greater than 60 d before surgery (P = 0.21). In another report, Mahfud *et al*[10] showed that the occurrence of postoperative complications was similar in patients who had received Bev for < 6 wk and in those who had taken Bev $\geq$ 6 wk before liver resection. Based on the evidence that the median half-life of Bev in humans is approximately 21 d (range 11-50 d), some authors recommend waiting at least 6-8 wk from discontinuation of Bev to surgery[8,9,16].

The main limitation of this meta-analysis was that all evidence came from nonrandomized trials which could introduce potential bias in data collection and analysis. However, there is evidence that nonrandomized studies may generally give valid results[38].

In conclusion, our meta-analysis has shown that Bev can be safely administered before hepatic resection in CLM patients, knowing that it has a protective effect against oxaliplatin-related liver injury. The issue of optimal timing of hepatectomy in patients treated with Bev should be addressed in future prospective multicenter trials.

COMMENTS

Background

Bevacizumab (Bev), a monoclonal antibody that targets vascular endothelial growth factor (VEGF) A, has recently been added to standard neoadjuvant chemotherapy in patients with colorectal liver metastases (CLM). However, Bev is reportedly associated with bleeding, thrombosis, gastrointestinal perforation, impaired wound healing and liver regeneration. Therefore, the safety of Bev at the time of hepatic surgery needs to be addressed.

Research frontiers

The study evaluated the impact of preoperative administration of neoadjuvant Bev on the outcome of patients undergoing resection for CLM using a meta-analysis of all relevant studies.

Innovations and breakthroughs

Findings from this meta-analysis suggest that preoperative Bev does not seem to increase postoperative morbidity after hepatic surgery of CLM and has a protective effect against hepatic injury in patients treated with oxaliplatin chemotherapy.

Applications

Bev can be safely administered in CLM patients before hepatic resection.

Terminology

Bev, a monoclonal antibody against VEFG, can inhibit the growth of human tumor xenografts.

Peer review

The topic is interesting and the methodology of the meta-analysis is appropriate.

Abstract

Recently, follicle stimulating hormone receptor was found to be selectively expressed by endothelial cells on tumor-associated blood vessels in a wide range of human cancers. In this context, we hypothesized that degarelix, a new gonadotropin-releasing hormone receptor antagonist developed for patients with prostate cancer, may have antiangiogenic effects *via* its capacity to block follicle stimulating hormone (FSH) production. We report the case of a patient with metastatic colon cancer exhibiting tumor progression after failure of all conventional chemotherapeutic regimens. The addition of degarelix to the last chemotherapeutic regimen was proposed as compassionate treatment. Degarelix induced a rapid decrease in FSH level. This treatment induced radiological stabilization and carcinoembryonic antigen stabilization during 1 year. Contrast-enhanced ultrasonography demonstrated reduction of tumor vasculature. This case represents the first report of an antitumoral effect of degarelix in metastatic colon cancer and suggests an antiangiogenic property of this drug.

INTRODUCTION

In adult humans, the follicle stimulating hormone receptor (FSHR) is expressed only in the testicular sertoli cells and the ovarian granulosa cells. Recently, FSHR was also found to be selectively expressed by endothelial cells on tumor-associated blood vessels in a wide range of human cancers, compared to blood vessels from normal tissue[1]. This leads to the hypothesis that follicle stimulating hormone (FSH) and FSHR could be involved in endothelial cell survival or proliferation, especially during tumor-associated angiogenesis. Thus, the FSH pathway could be a new target for cancer therapy, notably in cancer types in which tumor angiogenesis is critical for cancer progression. Degarelix is a new gonadotropin-releasing hormone (GnRH) receptor antagonist, developed for patients with prostate cancer requiring androgen-deprivation therapy. Degarelix blocks the GnRH receptors in the anterior pituitary gland, resulting in a rapid decrease in the secretion of both luteinising hormone (LH) and FSH[2]. In this context, we hypothesized that degarelix may have antiangiogenic effects *via* its capacity to block FSH production, thereby interrupting the FSH-FSHR pathway on tumor-associated blood vessels.

We report here on a patient with metastatic colon cancer exhibiting tumor progression after failure of all conventional chemotherapeutic regimens, and who ex-

perienced long term disease stabilization associated with tumor devascularization under degarelix treatment.

CASE REPORT

A 69 year-old woman was referred to our center for sideropenic anemia in March 2008. A tumor of the cecum was discovered and the patient underwent right colectomy. The tumor was staged T3 N2, and non-resectable peritoneal carcinomatosis was discovered. The tumor had a K-RAS mutation status. The patient was initially treated starting in July 2008 by FOLFIRI + bevacizumab, and subsequently by LV5FU2 + bevacizumab because of hematological toxicity and grade 3 diarrhea. During treatment, the tumor marker carcinoembryonic antigen (CEA) decreased from 15 ng/mL, to 6 ng/mL in July 2009. Disease progression occurred in December 2009, with a CEA level of 14 ng/mL. The patient received FOLFOX + bevacizumab from December 2009 to September 2010, at which time CEA level increased to 42 ng/mL, and the patient presented an occlusive syndrome with abdominal pain requiring morphine treatment. On compassionate grounds, we proposed the addition of degarelix to LV5FU2 + bevacizumab. Degarelix was initiated subcutaneously at 240 mg for 1 mo, followed by monthly maintenance doses of 80 mg. FSH level was 42.5 IU/L before the first injection. A peritoneal nodule of 135 mm was selected as a target lesion for radiological evaluation by computed tomography (CT) scan and contrast-enhanced ultrasonography. Fifteen days after the first injection, the FSH serum level was < 2 IU/L (Figure 1A), and remained at this level during the entire treatment period. Contrast-enhanced ultrasonography was performed on day 0 and day 15. Radiological evaluation was performed by the same 2 independent radiologists, who were blinded to the patient's clinical, biological and treatment data. A single target tumor was studied and selected on the basis of size (> 2 cm), and site (tumors with a good acoustic window that enabled data acquisition for longer than 3 min). A dynamic study was conducted after a single intravenous bolus injection of 4.8 mL of a contrast agent consisting of sulfur hexafluoride-filled microbubbles (SonoVue; Bracco, Milan, Italy). The investigation recordings and timing were triggered as soon as the contrast agent was injected. A total of 720 images were acquired during each 3-min investigative examination. Three semi-quantitative perfusion parameters were extracted from the time-intensity curves, namely peak intensity, time to peak intensity, total area under the time-intensity curve (AUC)[3]. Before degarelix initiation, AUC of the peritoneal nodule was 1650 mm^2. Fifteen days after treatment initiation, a dramatic reduction of almost 80% in the vascularized surface was observed, at 351 mm^2 (Figure 1B, C) (The area of interest is marked by a dotted white line). Moreover, resolution of the occlusive syndrome was achieved 5 wk after degarelix initiation, and morphine treatment was stopped without residual abdominal pain. Tolerance was excellent, without side effects using NCI-CTCAE v3 grade. Patient was previously treated by amlodipine for bevacizumab related and blood pressure was not modified by degarelix. The patient was menopause at the beginning of the treatment with degarelix so no side affect related to gonad suppression were observed. CT scans performed 2 mo after the beginning of the treatment showed stable disease according to the RECIST criteria with a stable target lesion and a regression of small none target lesion of peritoneal carcinomatosis. Successive CT scans performed between September 2010 and August 2011 confirmed stable disease according to the RECIST criteria (version 1.1) (target lesion evaluated between 137 and 138 mm). CEA levels remained stable during this period (Figure 1A). Unfortunately, occlusive syndrome re-appeared in October 2011. CT scan showed peritoneal progression, and only best supportive care was maintained. The patient died 6 wk later.

DISCUSSION

To the best of our knowledge, this case represents the first report of an antitumoral effect of degarelix in metastatic colon cancer.

The FSH receptor was recently recognized as a specific marker of endothelial cells in blood vessels from different tumor types[1]. Biological data have shown that the binding of FSH to FSH receptor in granulosa cells induces increased production of the hypoxia-inducible factor 1α[4]. This transcriptional factor is commonly induced by hypoxic conditions and drives the up-regulation of vascular endothelial growth factor (VEGF), one of the most important pro-angiogenic factors secreted during cancer growth. Thus, we hypothesized that triggering the FSH-receptor could induce VEGF production and thereby promote tumor angiogenesis. FSH signaling is also known to generate activated Gq protein[5]. Gq protein has been shown to induce VEGFR-2 signaling in human endothelial cells, even in the absence of VEGF[6]. This effect may enhance the proliferation and migration of endothelial cells in cancer, independently of VEGF availability. Thus, blocking FSH-receptor signaling may represent a new antiangiogenic strategy. In this report, we present the first clinical observation that degarelix, a GnRH antagonist used for the treatment of castrate-sensitive prostate cancer, could considerably decrease FSH production in a post-menopausal cancer-bearing woman. Contrast-enhanced ultrasonography seemed to indicate that this period of 12 mo with disease stabilization in a previously chemorefractory patient could be related to an antiangiogenic effect of degarelix, suggesting that this treatment could overcome resistance to anti-VEGF therapies, such as bevacizumab. However, we cannot provide specific immunohistochemical analysis of FSHR expression on tumor-associated blood vessels from the patient's peritoneal tumors. This constitutes a

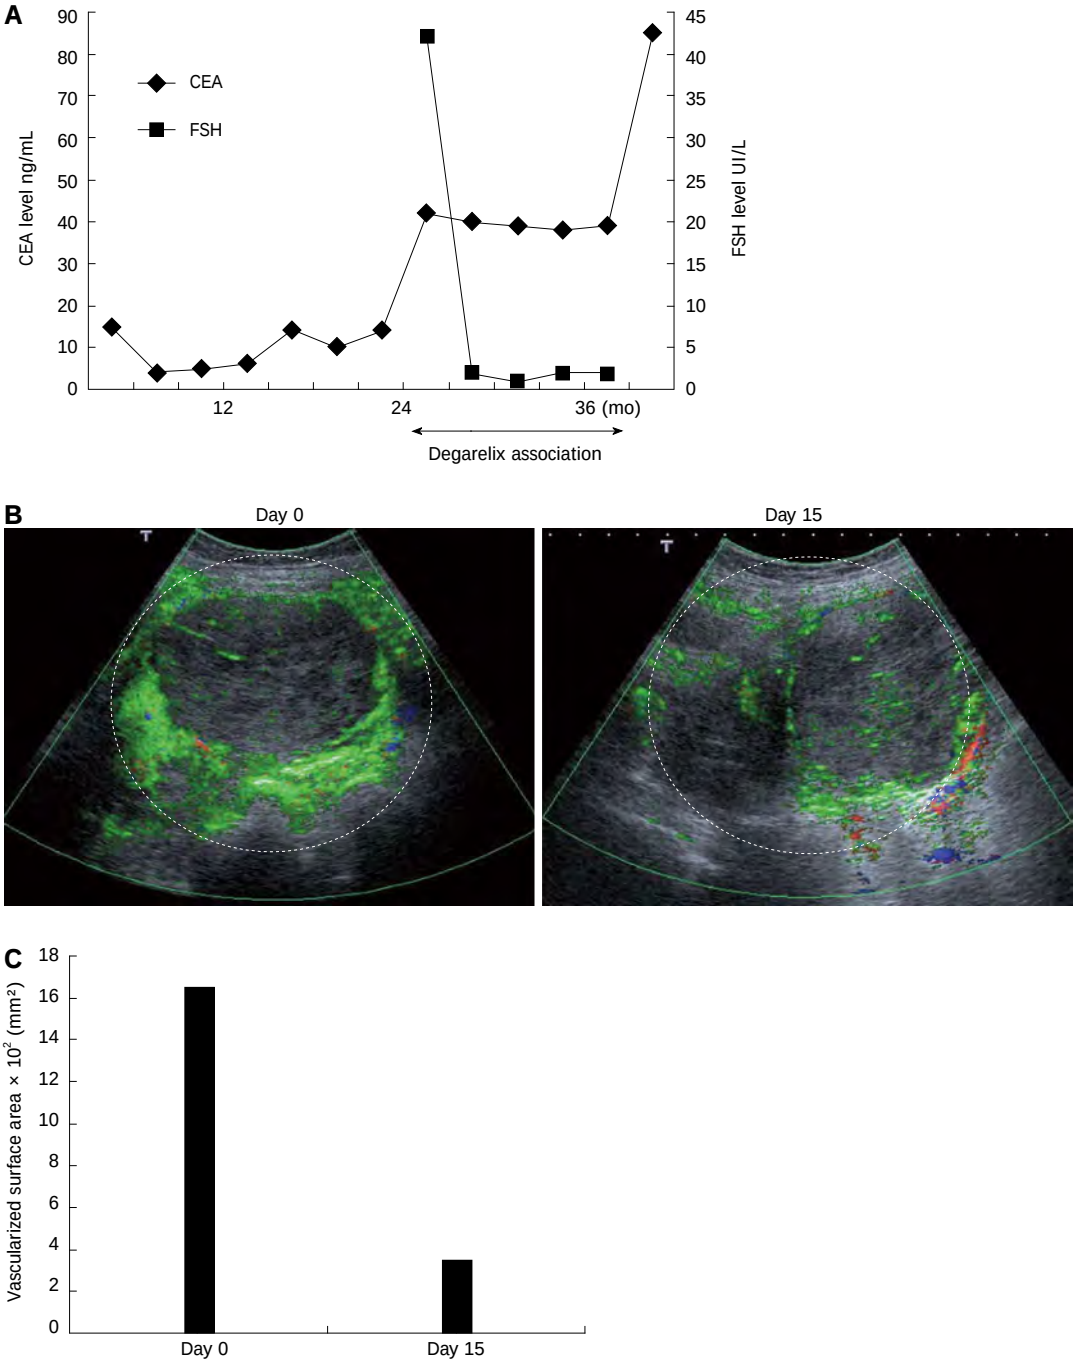

Figure 1 A tumor of the cecum. A: Kinetic of carcinoembryonic antigen (CEA) and follicle stimulating hormone (FSH) serum level; B: Representative images of contrast-enhanced ultrasonography performed before (left panel) and 15 d after (right panel) the beginning of the treatment by degarelix; C: Evaluation of vascularized surface area on contrast-enhanced ultrasonography performed before and 15 d after the beginning of the treatment by degarelix.

limitation of this report, but it should be noted that in the initial report by Radu *et al*[1], consistent expression of FSHR by endothelial cells was detected in all the colorectal cancers analyzed. As we do not test the efficacy of degarelix monotherapy was could not determine if only combination of 5 FU/leucovorin bevacizumab and degarelix or degarelix monotherapy alone could be proposed in further clinical trial. Nonetheless, further clinical trials guided by FSHR expression on tumor vasculature are warranted to investigate the antiangiogenic effect of degarelix in cancer patients.

Abstract

Increased ischemic stroke risk is observed in patients with inflammatory bowel disease (IBD). Causes and physiopathological aspects of cerebral infarct, in this specific population, are less often described. There is little information to provide guidelines for the best curative and preventive treatment. We report 2 cases of ischemic strokes due to internal carotid thrombus in patients during active phase of IBD. Ulceration of early atherosclerotic plaques activated by a hypercoagulation state may cause a thrombus. A combined therapy with heparin and corticosteroids was used for both our patients. Lysis of the thrombus was obtained after several days without surgical treatment and shown by ultrasonography. These cases highlight an aetiology of stroke in patients with IBD and use of a synergic treatment to respond to hypercoagulability in link with IBD. Benefits and safety of this therapy should be confirmed with clinical studies.

INTRODUCTION

Patients with inflammatory bowel diseases (IBD) have a higher risk of arterial cerebral infarction even if they are young with few cardio-vascular risk factors[1]. Causes and physiopathological aspects are less known. We describe 2 cases of IBD patients who presented ischemic strokes due to homolateral internal carotid thrombus.

CASE REPORT

Case report 1

A 32 year-old man, with Crohn's disease (CD) without immunosuppressive treatment for several years, was admitted for sudden right hemiplegia. He was a light smoker without any other vascular risk factor like hypertension, dyslipidemia, diabetes, and had no family history of vascular disease. At admission the National Institute of Health Stroke Scale (NIHSS) was 13, and blood pressure was 110/70 mm Hg. Brain magnetic resonance imaging (MRI) revealed ischemic stroke with thrombosis of the initial part of the left middle cerebral artery (MCA). Intravenous thrombolysis with plasminogen tissue activator was administered. Cervical ultrasonography (US) revealed occlusion of the left internal carotid artery (Figure

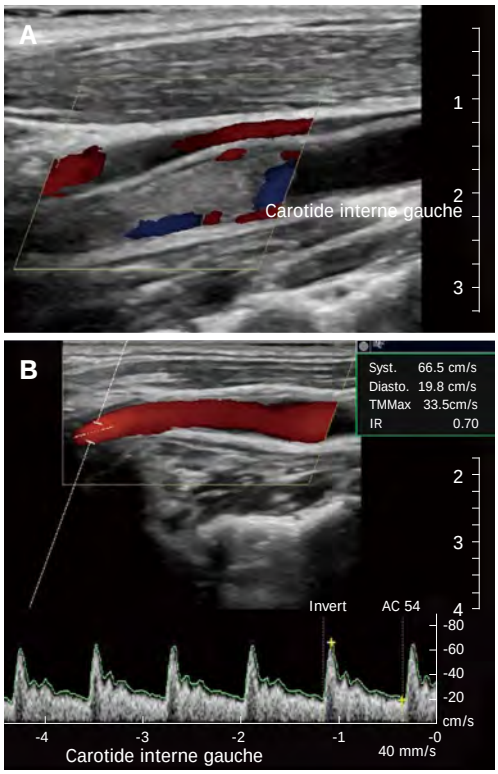

Figure 1 Cervical ultrasonographies in case 1, showing occlusion of the left internal carotid (A), due to a thrombus, and repermeabilization of the vessel with tiny plaque (B) after 15 d of treatment.

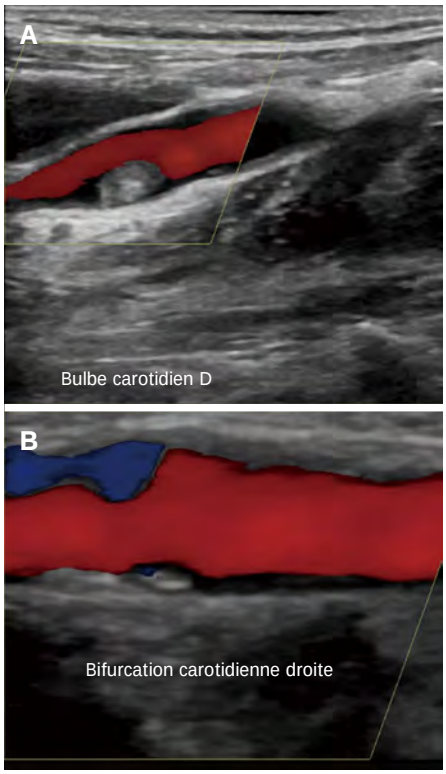

Figure 2 Cervical ultrasonographies in case 2, showing thrombus in the right internal carotid (A) and resorption of this with tiny plaque (B) after 1 wk of treatment.

1A), due to a thrombus, confirmed by computed tomography (CT) angiography. Blood tests were performed: the platelet count was 342 G/L, hyperhomocysteinemia 137 μmol/L; C-reactive protein (CRP) 15.4 mg/L; low-density lipoprotein (LDL)-cholesterol 0.87g/L; preprandial blood glucose level 1.01g/L, and the erythrocyte sedimentation rate (ESR) was elevated at 40 mm. Digestive endoscopy found signs of active CD. Unfractionated heparin and corticosteroid treatment (prednisolone 0.5 mg/kg per day) were initiated and 15 d later, there was total resorption of the thrombus, apart from a tiny plaque as controlled by cervical US (Figure 1B) and CT angiography. One month later, the NIHSS was 6, an overlap treatment of vitamin K antagonist was initiated and the patient was transferred to a rehabilitation center with a daily dose of prednisolone and folic acid. Proctectomy with terminal ileostomy was performed 4 mo later.

Case report 2
